As in allergic inflammation, the precise role of eosinophils in the immunopathologic changes associated with helminth infections remains ill understood and rather controversial. Increases in the number of tissue and peripheral blood eosinophils, together with elevations in the levels of total and parasitic-specific IgE and mastocytosis, have been considered for a long time to be hallmarks of infection with parasitic worms ([4]), especially during their tissue migratory phases. Much has been published about the inimical role this cell may play in protection against helminths, but there is equally important evidence to suggest that their presence may be a reflection of their participation in the pathology of the disease rather than immunity to the parasitic metazoa ([267]). The original observation of Basten and Beeson ([7]) that helminth-associated eosinophilia is T-cell–dependent was an important turning point in our current understanding of eosinophil-mediated inflammation in worm infections. The identification and subsequent cloning of GM-CSF, IL-3, and, particularly, IL-5 helped to explain the T-cell control of eosinophilic response, both in terms of eosinophilopoiesis and differentiation as well as priming and activation of the mature cell. The question, however, remains as to why there is a selective increase of eosinophils and what their function is, both locally and systematically, in infected subjects.

***IN VITRO* AND MURINE PARASITIC HELMINTH STUDIES** Much has been published on the helminthicidal effects of human, primate, and rodent eosinophils against metazoan targets coated with IgG, IgA, IgE, or complement components. In this context, a number of parasitic targets have been studied including schistosomula of *Schistosoma mansoni*, newborn larvae of *Trichinella spiralis*, larvae of *Nippostrongylus brasiliensis*, *Fasciola hepatica*, and others ([133], [268]). Eosinophils adhere readily to appropriately coated larvae and undergo exocytosis, which results in the deposition of the basic and cytotoxic granule-associated proteins. On their own, these preformed products of eosinophils (including MBP, ECP, and EPO) have potent helminthicidal properties at low molar concentrations ([133]). The exogenous addition of a number of chemotactic agents, such as LTB_4, PAF, fMLP ([269], [270]), and cytokines, such as GM-CSF, IL-3, TNF-a, and IL-5 ([271]), to eosinophil preparations enhances their cytotoxic capacity against parasitic larvae. In addition to killing worm larvae, eosinophils that adhere to schistosomula via IgG, IgE, or complement generate substantial amounts of membrane phospholipid–derived mediators, especially LTC_4 ([272]). More recent studies have shown that in IL-5 $^{-/-}$ mice, skin implants containing parasites did not eliminate larval forms of the organisms ([273]). The mechanism underlying larval expulsion was shown to be dependent on eosinophils as well as IgM, and the results suggested that the function of eosinophil granule proteins might be associated with disrupting parasitic larvae to allow processing by antigen-presenting cells, including the eosinophil itself.
HELMINTHIASES IN HUMANS AND NONHUMAN PRIMATES The precise regulatory and functional roles of eosinophils in human helminthiases during the well-documented inflammatory reaction require urgent and extensive attention. In general, no clear evidence exists of direct contact between eosinophils and adult worms, although accumulation of eosinophils about helminthic parasites has been described. Eosinophil-rich granulomas surrounding dead fragments of skin-invading larvae of the skin-invading nematode *Strongyloides ratti* have been described in hyperimmune rats after challenge ([274]). Eosinophils were also found in close contact with the surface tegument of schistosomula of *Schistosoma haematobium* in the cutaneous tissue of immune monkeys, associated with the presence of large number of dead larvae in eosinophil-rich sites ([269]). Similar observations were made in other host-parasite systems ([133]). Using appropriate antibodies, eosinophil-derived toxic proteins such as MBP have been identified on filarial worm targets *in vivo* ([270]), and levels of blood ECP are elevated in patients with filariasis, which may suggest the activation and degranulation of eosinophils ([271]).

CONCLUSIONS

The eosinophil is an enigmatic and fascinating cell that has intrigued biomedical scientists for more than a century. The precise function of this cell in allergic inflammation and asthma remains a matter of debate and requires further study in appropriately designed research projects. However, it is important to recognize that no single cell type, whether the eosinophil, T cell, mast cell, neutrophil, or other lung cell, is on its own responsible for all aspects of the immunopathology and clinical sequelae of airway inflammation in asthma and related diseases. In recognition of this fact, the attention currently focused on the eosinophil is warranted and timely. This relates partially to the overwhelming evidence in favor of a potential effector role of the eosinophil in parasitic helminthic and allergic diseases, including asthma. Although the mechanisms of eosinophilia in association with allergic disease are not yet fully understood, they seem likely to be controlled at the level of the T-cell response to antigen and the subsequent elaboration of cytokines, which exert both direct and indirect effect on these inflammatory cells. The profile of cytokines generated in allergic reactions, such as the allergen-induced late-phase response in the skin, nose, and lungs, appears to conform to a Th2 profile because mRNA expression of IL-4 and IL-5, but not IFN-? or IL-2, are expressed or up-regulated during these reactions. The release of IL-5 by Th2-type T cells after stimulation with allergen may, therefore, be responsible for the eosinophilia of allergic disease. Thus, a complex network of T cells, eosinophils, and other inflammatory cells as well as their cytokine products may participate in a cascade of events that leads to specific accumulation of eosinophils in sites of allergic inflammation and asthma. Whether tissue damage, a feature of these disease conditions, is the consequence of the activation and exocytosis of these infiltrating cytotoxic cells and the release of their highly basic protein products is yet to be demonstrated unequivocally.

Basophilic Leukocytes: Mast Cells and Basophils

In his 1965 tome, Hans Selye ([1]) reviewed the literature on two populations of basophilic leucocytes, namely, mast cells and basophils. These cells have many similarities, but also exhibit several intriguing differences. Despite an ever-expanding scientific literature, we do not understand the precise nature of their relationship or the integration of factors that determine if one, the other, or both are present and active in inflammatory disorders such as allergic inflammation. More recently, there have been several reviews that document advances made in our understanding of these cells, their development, contents, biosynthetic activities, activation, and functions ([2], [3], [4], [5], [6], [7], [8], [9], [10], [11] and [12]).

Mast cells and basophils contain electron-dense cytoplasmic granules and stain metachromatically with selected basic dyes. They produce numerous inflammatory mediators, many, such as histamine, that are common to both cells, and others that are cell-specific. Both cells express a tetrameric isoform of the high affinity receptor for immunoglobulin (Ig) E with one a-, one ß- and two ?-chains (aß?2), whereas human monocytes, dendritic cells, and Langerhans cells express a trimeric isoform (a?2) of the receptor ([13]). When this high-affinity IgE receptor is cross-linked by sensitizing allergen or by anti-IgE antibodies, both mast cells and basophils can be activated, mediator synthesis and secretion induced, and their gene expression altered. Through such mechanisms, mast cells and basophils are prominent players in allergic inflammation and other immune and inflammatory events.

In a thoughtful review, Galli et al. ([2]) provided concise descriptions for mast cells and basophils. Basophils (Fig. 12.1A) ([14]) are

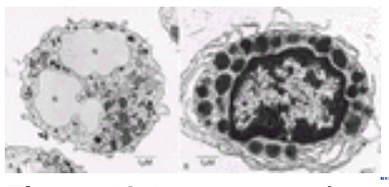

Figure 12.1. A: Human basophils are round and have irregular, short surface projections, cytoplasmic secretory granules, and aggregates of cytoplasmic glycogen. N, nucleus. (Reproduced from Dvorak AM, Warner JA, Fox P, et al. Recovery of human basophils after FMLP-stimulated secretion. Clin Exp Allergy 1996;26:281–294, with permission.) **B:** Human skin mast cell with monolobed nucleus with partially condensed chromatin, numerous cytoplasmic granules containing crystalline structures, and regularly distributed, narrow, thin surface projections. (Reproduced from Dvorak AM. Human mast cells. In: Beck F, Hild W, Kriz W, et al., eds. Advances in anatomy, embryology and cell biology. Leicester: Springer-Verlag, 1989, with permission.)

> cells with the kinetics and natural history of granulocytes that mature in bone marrow, circulate in the blood, and retain certain characteristic ultrastructural features, even after migrating into the tissues during inflammatory or immunologic processes. The ultrastructure of mature basophils varies according to species but generally includes electron-dense cytoplasmic granules, prominent aggregates of cytoplasmic glycogen, and short, blunt, irregularly distributed plasma membrane processes. There is no convincing evidence that mature basophils, whether in the circulation or in the tissues, retain mitotic capability, or that basophils metamorphose into mast cells upon entering the tissues.

Mast cells (Fig. 12.1B) ([15]):

> ordinarily mature outside of the bone marrow or circulation, generally in the connective tissues or serous cavities. Cells in this lineage(s), wherever distributed, apparently retain at least limited or latent proliferative capacity…. immature and mature granules of mast cells and basophils differ distinctively in ultrastructure. Mast cells also differ from basophils in lacking electron-dense aggregates of cytoplasmic glycogen, and in having a plasma membrane surface with uniformly distributed, thin, elongate folds and processes. Mast cell nuclei may appear bilobed in an individual photomicrograph, but they generally lack the pattern of peripherally condensed nuclear chromatin characteristic of basophils and other granulocytes.

These descriptions have withstood the test of time well and represent our current understanding of basophils and mast cells. In many ways, the original statement by Ehrlich in 1879 ([1]) that basophils were “blood mast cells,” and the corollary, that mast cells are tissue basophils, while incorrect from a developmental standpoint, is still of some value in thinking about the nature of these two cells types. The striking inverse relationship between the numbers of circulating basophils and the numbers of tissue mast cells has been used for decades to infer similarities in function ([1]).

In this chapter, we provide an overview of the developmental biology of the two cell types, including knowledge about their progenitors and growth factors involved in lineage commitment, differentiation, and maturation. Programmed cell death and factors influencing survival have been increasingly well recognized as important components in the regulation of inflammation and myeloproliferative disorders. Mature basophils and mast cells differ markedly in their surface phenotype, stored mediators, and in the synthesis of new mediators after activation. Factors that activate and regulate the functions of mast cells and basophils also show fascinating similarities and differences. Last, from this background, we provide a conceptual overview of the functions of mast cells and basophils in allergic disease and in other inflammatory and noninflammatory clinical settings. There is much to be learned about the developmental biology and cellular and molecular controls of their phenotypes and functions. As we progress early in the 21st century and in exciting new developments in biology and medicine, we are optimistic that our exponential learning curve for basophils and mast cells will continue and lead to effective strategies to manipulate the complexities of these cells for the betterment of those suffering from allergic and other diseases.

GENERAL MORPHOLOGY, DEGRANULATION, AND RECOVERY

Histochemical staining of blood smears or cytocentrifuge preparations of enriched basophils or mast cells with Wright-Giemsa or May-Grünwald stains, shows many similarities in these cell types (Fig. 12.2). The cytoplasm of the cells is generally pink, the nucleus is purplish or blue, and the cytoplasmic granules are dark blue to

purple or even blackish. Basophils in peripheral blood or tissues range in size from 10 to 15 µm, whereas mast cells in tissue sites may appear irregular in shape and up to 20 µm in a long dimension. Dvorak has published extensively on the morphology of normal mast cells and basophils, as well as on the changes associated with degranulation and recovery of these cells following their activation by different stimuli. The reader is encouraged to review her work, which is only briefly summarized here ([16], [17]).

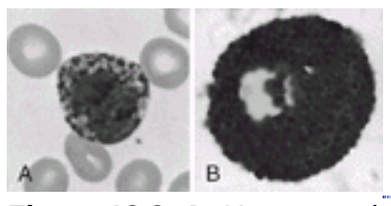

Figure 12.2. A: Human peripheral blood basophil stained with Wright. (From Lee G, Bithell T, Foerster J, et al., eds. Wintrobe's clinical hematology, 9th ed. Philadelphia: Lea & Febiger, 1993, with permission.) **B:** Rat peritoneal mast cell stained with May-Grunwald Giemsa. See Color Plate.

Ultrastructural analyses demonstrate many similarities between mast cells and basophils, but also identify some differences (Fig. 12.1A and Fig. 12.1B). In the blood, basophils are round, whereas in the tissues they can appear in various shapes. Mast cells can appear to be round, oval, or elongate-spindle shaped in the tissues. The surface of basophils exhibits blunt processes of variable shape and size, whereas mast cells often possess long, fingerlike processes that extend from the surface. The nucleus of mast cells can be round or lobed, whereas that of the basophil is generally multilobed. Nucleoli are often not apparent or are absent from normal mast cells and basophils. Basophils have an abundance of condensed chromatin positioned at the periphery of the nucleus, whereas mast cells have little condensed chromatin.

The cytoplasm of normal mature mast cells has few mitochondria and a relatively inconspicuous Golgi apparatus; ribosomes, rough endoplasmic reticulum, and aggregates of glycogen are rare. In normal basophils, mitochondria and aggregates of glycogen are more abundant than in mast cells, but as with mast cells, Golgi apparatus, ribosomes, and rough endoplasmic reticulum are rare in normal basophils. The most prominent cytoplasmic elements in both cell types are the membrane-bound, electron-dense granules.

Basophils generally possess fewer granules than mast cells, and the granules exhibit a more homogeneous morphology than those of mast cells. Basophil granules are often homogeneously electron-dense, although dense particles may be interspersed with membrane aggregates and whorls. Charcot-Leyden crystals can be formed in basophils as well. Mast cell granules may be homogeneously electron-dense, or may exhibit electron-dense particles, membrane or complex scroll-like patterns, highly organized crystalline structures, or combinations of these. The relationship of these different granule patterns to the tissue site, phase in development, or mediator content is not clear, although it has been proposed that major histocompatibility complex class II–positive vesicles of 60 to 80 nm, called *exosomes*, released by mast cells after activation arise from these structures within the granules ([18]). Interestingly, Dvorak has reported that mast cell granules, in addition to storing mediators, are also sites of RNA metabolism and protein synthetic activity ([19]). Additionally, basophils contain numerous electron-lucent vesicles of 50 to 70 nm that often contain contents similar to granules. These may be associated with a form of mediator exocytosis (see Degranulation).

In addition to these membrane-bound granules, mast cells and basophils also contain rounded, non–membrane-bound, electron-dense structures called *lipid bodies*, rich stores of arachidonic acid. Lipid bodies appear to increase in number associated with cell activation and are thought to be derived from membrane catabolism and the rapid synthesis of lipid mediators, such as the cyclooxygenase and lipoxygenase derivatives of arachidonic acid.

Degranulation

Mast cells and basophils appear to undergo distinct types of mediator secretion from granule stores, depending on the stimuli involved in their activation ([16], [17]). Anaphylactic degranulation occurs after stimulation through the IgE receptor or after other stimuli, such as fragments of the complement cascade. Anaphylactic degranulation can be extensive, involving the majority of the granules, or it can be more restricted. The numbers of granules involved appears to correlate with the proportion of the total cellular histamine that is released. By contrast, in numerous inflammatory reactions where mast cell and basophil infiltration can occur, such as in cutaneous delayed hypersensitivity, a less explosive form of mediator secretion, called piecemeal degranulation or secretion can occur.

In anaphylactic degranulation in mast cells, the granules rapidly exhibit signs of swelling, then demonstrate membrane fusion with adjacent granules, interconnecting chains and channels form that ultimately fuse with the plasma membrane, creating pores or larger openings where granule contents or larger granule structures can be seen outside the cell. Prominent cytoplasmic filaments can be seen close to the granules, and actin complexes can be seen outside the cell in association with granules or their contents. The process is generally similar for basophils. Electron-dense granules appear to evolve into electron-lucent vacuoles, many of which communicate to other vacuoles and to the cell surface through pores within 5 to 10 minutes. In addition, apparently intact granules can be seen outside the cell. This anaphylactic degranulation does not lead to major cell death, but as outlined later in the chapter, the cells can recover and be able to degranulate again.

Piecemeal secretion also occurs in mast cells, basophils, and eosinophils ([20]) and is the most prevalent morphologic expression of mast cell and basophil secretion in nonallergy inflammatory conditions in human biopsy material. This form of mediator secretion can also demonstrate a continuum in its extent, presumably depending on the magnitude or nature of the activation stimulus. It is postulated that exocytotic vesicles containing granule contents bud off the granules, move to the cell surface, fuse with the plasma membrane, and discharge their contents to the extracellular space. This form of mediator secretion is believed to be associated with secretion of only selected mediators, not the entire contents of the granules, and there is increasing evidence for such selectivity. As with anaphylactic degranulation, piecemeal secretion is associated with the ability of mast cells to recover and to function again.

Recovery

Dvorak ([16]) has summarized the evidence for the ability of mast cells and basophils to recover and regranulate after activation. In the process of recovery, mast cells and basophils appear to be able to conserve membrane and other components and exhibit several morphologic changes that demonstrate the cells can resynthesize granule and other components, for example, extensive rough endoplasmic reticulum, elaborate Golgi apparatus, microtubules, and new granules. This recovery appears to occur within 1 to 2 days, but may involve longer times. Whether death by necrosis or apoptosis is a feature of mast cell or basophil activation in some conditions remains to be carefully evaluated.

ONTOGENY AND DEVELOPMENTAL BIOLOGY OF MAST CELLS AND BASOPHILS

The tissue mast cell and the blood basophil are probably not, under normal conditions, derived directly from a common progenitor in any species. However, recent evidence from a variety of observations of leukemic cell lines and clinical conditions has revived the notion of lineage pathways that may be shared by basophils and mast cells, basophils and eosinophils, and basophils and megakaryocytes ([21], [22] and [23]). Phylogenetically, there appears to be an inverse relationship between the presence of basophils and mast cells ([1]). Whereas mast cell growth and differentiation has, until now, been relatively better understood in rodents than in human systems and basophil production more fully worked out in the human, major advances in understanding human mast cell growth and differentiation have come about by application of knowledge from rodent models. An exponential growth in knowledge of human basophil and mast cell ontogeny has ensued, including identification and the developmental biology of the specific mast cell hemopoietin, stem cell factor (SCF), and its receptor, *c-kit.* Using definition by flow cytometry and culture with recombinant cytokines, the lineage pathways of basophils and mast cells have been investigated, including analysis of signal transduction and specific transcriptional regulation of basophil and mast cell differentiation in hemopoietic stem cells.

Mast Cell Growth and Differentiation

In rodents and humans, mast cells can be grown *in vitro* from lineage-committed, unipotent, or multipotent progenitors. Although interleukin-3 (IL-3) is known to contribute to murine mast cell and basophil development ([24]), it is unable to induce human mast cell differentiation from cultures of human cord blood or fetal liver; however, IL-3 can promote human basophil development ([25]). A “novel” growth factor was thus postulated for human mast cells, shown to be fibroblast-derived, and identified in both rodents and primates as SCF or c-kit ligand ([26], [27] and [28]). In general, human mast cell differentiation *invitro* is not influenced directly by cytokines

that promote mast cell development in rodents, such as IL-4, IL-9, IL-10, or eotaxin ([29]), but almost uniquely by SCF ([25], [27]), with cofactor effects by IL-3 ([26], [27]), IL-6 ([30]), thrombopoietin ([31], [32]), and nerve growth factor (NGF) ([33], [34]). SCF is produced by murine and human fibroblasts, epithelial cells, endothelial cells, and tumor cell lines ([35]), and must bind to an intact c-kit receptor to effect differentiation. Mutations in c-kit can result in mast cell deficiency *in vivo* and *in vitro* (loss-of-function) or, alternately, in autonomous mast cell growth (gain-of-function) ([35], [36], [37] and [38]). IL-3 by itself, in addition to rodent mast cell differentiation–inducing activity, is a differentiation and activation factor for human and primate basophils ([39], [40] and [41]). Because it does not bind to human mast cells, its supportive role in human mast cell differentiation may be due to its ability to induce SCF-responsive progenitors into cycle ([42]). Table 12.1 lists cytokines, growth factors, transcription factors, and signaling molecules that regulate primate/human and rodent mast cell differentiation ([43], [44], [45], [46], [47], [48], [49], [50] and [51]).

TABLE 12.1. Regulation of Mast Cell Growth and Differentiation

Rodent (reference)	Primate/Human (reference)

[a] Role in phenotype switching.

Mast Cell Progenitors

Studies of protease content of human mast cells, identifying tryptase-containing (MC_T) and tryptase/chymase-containing mast cells (MC_{TC}) subpopulations (see below) have been used to infer lineage commitments of mast cell subtypes: for example, studies of bowel biopsies from patients with T-cell or combined immunodeficiency ([52]) and *in vitro* examination of fetal liver-derived MC_T and MC_{TC} ([26]). In rodents and humans, mast cell differentiation proceeds from an immature $CD34^+$, $CD38^+$, $CD13^+$, c-kit^+, $FceRI^-$, Fc?RII/III $^+$ progenitor into mucosal or serosal phenotypes, as characterized by serine protease content primarily under the stimulation of SCF and other cytokines ([27], [53], [54], [55], [56] and [57]) (Fig. 12.3). In human SCF-stimulated cord blood of fetal liver cultures, both MC_T and MC_{TC} phenotypes are found; likewise, various phenotypes of murine mast cells, characterized according to serine protease content, are present in IL-3 and SCF-stimulated bone marrow cultures. Various cytokines can regulate these phenotypic changes, which may not necessarily occur in any linear order, but rather exhibit switching and “trans-differentiation” ([58], [59] and [60]), reflecting stochastic processes in progenitor differentiation. Primitive cord blood $CD34^+$, c-kit^- progenitors may respond quite differently to hemopoietic cytokines than more mature $FceRI^+$, c-kit^+ cells ([61], [62]). Thus, tissue-dependent stages of progenitor commitment may ultimately predict, in the presence of SCF, differences in mast cell differentiation and phenotype *in vitro* ([27]). Mast cell progenitors can be identified in blood, bone marrow, and tissues, especially in relation to mast cell-inducing stimuli, such as viruses or nematodes ([52], [56], [57], [63], [64] and [65]).

Figure 12.3. Mast cell (MC) and basophil (B) ontogeny. An orderly sequence of differentiation is depicted, beginning with a primitive $CD34^+$, $FceRI^-$, c-kit^- hemopoietic stem cell (HSC), and proceeding through various stages of commitment to either mast cell or basophil/eosinophil (E) lineages. In reality, the differentiation process is stochastic, and multiple cytokines binding to their receptors permit specific, end-stage differentiation to proceed. GM-CSFR, granulocyte-macrophage colony-stimulating factor receptor; IL, interleukin; Meg, megakaryocyte.

Leukemic cell lines with basophilic phenotype have also been used to study basophil and mast cell progenitors and immunophenotypic markers of lineage commitment ([65], [66], [67], [68], [69], [70] and [71]). These are reviewed later in the chapter for mature basophils and mast cells. A model of HL-60 basophilic differentiation ([66]), for example, has identified unexpected phenotypic profiles of maturing basophils and possibly mast cells, including CD15 (Lewis X) down-regulation, CD35 (CR1) up-regulation and transient expression of c-kit. Similar concepts of combined basophil/mast cell commitment in leukemic cells have been raised from studies of KU812, HMC-1 and other cell lines ([67], [71], [72] and [73]). Although these findings may represent aberrant pathways activated during malignant transformation, the recent identification of a novel antigenic marker of mast cells, basophils, and their progenitors ([21], [74]), and the presence in peripheral blood of basophilic cells, which express mast cell proteases ([23]), has revived earlier postulates ([75], [76]) that these two cell types indeed share some lineage characteristics in humans.

Basophil Growth and Differentiation

Most of what is known of basophilopoiesis is derived from human systems, because basophils are readily identifiable in the circulation in humans. In addition, pure or mixed basophil colonies in semisolid cultures can be identified ([75], [77], [78]), thus defining a basophil (-eosinophil) progenitor (termed *colony forming unit–basophil* or *colony forming unit -basophil/eosinophil*). These colony forming unit–basophils can be derived from normal, atopic ([77], [79]), or leukemic human specimens ([76], [77], [79], [80]), the latter including blood of patients with chronic myeloid leukemia (CML) or related myeloproliferative disorders, acute myeloid leukemia, and systemic mastocytosis. The phenotype and lineage commitment of the basophil progenitor, including more recent notions of lineage sharing with mast cells and/or megakaryocytes ([21], [22]), is depicted in Figure 12.3.

Basophil Differentiation-Inducing Cytokines

Although no single cytokine has been shown to be a specific basophilopoietin, IL-3 is the main cytokine involved in human basophil growth and differentiation ([39]); granulocyte macrophage-colony stimulating factor (GM-CSF) ([66], [75], [77], [78]), IL-4 ([14], [81]), IL-5 ([14], [80]), and SCF ([35], [53]) may also play roles. IL-5, interestingly, promotes both eosinophil and basophil differentiation ([14], [80]), because it acts on a common basophil-eosinophil progenitor (Fig. 12.3) ([81]). Retinoic acid (RA) may influence granulocyte progenitors to a neutrophilic as opposed to basophilic-eosinophilic pathway, as well as down-regulate human mast cell differentiation ([82]); conversely, a mutation in the RA receptor allows for expression of basophil differentiation ([83]). Studies on basophil crisis in CML and the *in vitro* suppressive effects of RA on basophil-eosinophil differentiation in these and normal cultures support this notion ([69], [84]).

Other factors that modulate basophil-eosinophil or mast cell differentiation include tumor growth factor-ß (TGF-ß) ([85]), which can suppress eosinophil and enhance basophil differentiation in the presence of IL-3; the bcr-abl gene, which presents in CML as the Philadelphia chromosome or t(9;22) translocation ([86]); NGF, which can induce basophil colony growth in humans and mast cell phenotype switch in rodents ([34]); the oncogene v-erb, which in the rodent is associated with the development of lethal mastocytosis as a result of co-stimulation of mast cell growth by epidermal growth factors and SCF ([87], [88]); and platelet-activating factor (PAF), which may synergize with other cytokines to induce basophil and eosinophil differentiation ([89]). *In vivo* in primates, parenteral IL-3 and GM-CSF administration leads to basophilia and eosinophilia, along with an egress from the marrow of granulocyte, and specifically, basophil/eosinophil progenitors ([40]); this is in contrast to SCF-induction of mastocytosis *in vivo* in human skin ([90]).

Table 12.2 lists the cytokines involved in basophil growth and differentiation ([81]). Although IL-3 and SCF represent the primary mast cell growth factors in mouse and rat ([35], [91]), IL-3 is a basophil, but not a mast cell; differentiation factor in the human and SCF has little known effect on basophil differentiation ([35], [39]). Together with GM-CSF, NGF can co-stimulate human basophil differentiation ([34]). IL-4 has minimal activity on human basophil differentiation ([25], [81]) even though IL-4 can down-regulate c-kit expression ([35]). GM-CSF and IL-5 are prominent basophilopoietins, as well as basophil-activation factors, both *in vitro* and *in vivo* in several species ([25], [66], [75], [77], [79], [81], [92], [93]). Microenvironmental stimuli, including various cytokines such as IL-3, IL-6, SCF, GM-CSF, TGF-ß, and tumor necrosis factor (TNF), may regulate the ultimate phenotypic direction and lineage commitment of human basophils and mast cell subtypes ([81], [94]); these include negative regulatory effects documented for TGF-ß ([85], [95]), IL-4 ([96]), interferon-? (IFN-?) ([85], [97]), and GM-CSF ([47]). Contrasts between the murine and human systems, in terms of which factors stimulate basophil or mast cell growth and differentiation or regulate phenotypic switching, must be recognized in any analysis of basophil and mast cell lineages.

TABLE 12.2. Cytokines and Other Factors Involved in Basophil Growth and Differentiation

Cytokine	Effect
Granulocyte-macrophage colony-stimulating factor	Basophil growth and differentiation; promotes *in vivo* basophilia and increases in circulating colony-forming unit–basophil/eosinophil (primates); basophil activation/survival; down-regulates human mast cell differentiation
IL-3	Human basophil growth and differentiation; basophil activation/survival; promotes *in vivo* basophilia (in primates); mast cell differentiating activity in rodents
IL-5	Primarily eosinophil, but also basophil growth and differentiation; basophil and eosinophil activation/survival
Tumor growth factor-ß	Suppresses human eosinophil and enhances basophil differentiation in the presence of IL-3; suppresses rodent IL-3–dependent mast cell proliferation
bcr-abl	Involved in basophil/mast cell/megakaryocytic lineage expression in human myeloid leukemias
Nerve growth factor	Induces mast cell hyperplasia (rodents), human mast cell line (HMC-1) and basophil-eosinophil differentiation *in vitro*

IL, interleukin.

Clinical Relevance of Basophil and Mast Cell Differentiation

ALLERGY AND ALLERGIC DISEASE The clinical relevance of basophil-eosinophil or basophil-mast or mast cell progenitor fluctuations in the blood of patients with a variety of allergic disorders, especially those with allergic rhinitis, nasal polyposis, and asthma, but also in subjects with atopic dermatitis and drug allergies, has been documented ([31], [98], [99] and [100]). The numbers of these progenitors in the peripheral blood are higher out of allergy season, and decreased during seasonal allergen exposure ([100], [101] and [102]), with recovery towards normal after the season. Likewise, selective increases occur in circulating basophil progenitors in patients with allergic asthma in response to allergen inhalation challenge ([100], [103]), including up-regulation of cytokine (IL-3, IL-5, and GM-CSF) as well as chemokine (CCR1, –CCR3 and CXCR4) receptors on $CD34^+$ cells from bone marrow ([104], [105]). In transient leukemias occurring in Down syndrome (trisomy 21), as well as in related megakaryoblastic leukemia, there is basophilic differentiation (which could include mast cells) from leukemic cell progenitors ([106]). Because there are increased numbers of mast cells as well as basophils in various hematologic malignancies ([107]), the relationship between leukemic processes and basophil or mast cell lineage commitment is underscored. One of the reasons for this may be aberrant stimulation of basophil or mast cell lineage development by certain transcription factors that also regulate erythroid and megakaryocytic lineages; these include GATA-1 through 3 ([108], [109] and [110]), with GATA-2 having been shown, using knockout mice and transfection to be primarily involved in basophil/mast cell lineage commitment ([111], [112]), and GATA-3 in Th2 cell switching, the latter supportive of basophil, eosinophil, and mast cell differentiation. Embryonic stem cells or $CD34^+$ progenitors transfected with GATA genes express varying degrees of erythroid/megakaryocytic and basophil/mast cell commitment ([108], [109] and [110]). Factors such as Gab-2, an adaptor protein ([45]); the signaling molecule Lyn ([46]); or the flt3 ligand for tyrosine kinase receptor appear to play secondary roles to c-kit and its ligand in signal transduction and subsequent transcription factor regulation of basophil and mast cell differentiation ([113]). Several other hemopoietic malignancies also exhibit basophil and mast cell lineage dysregulation, including CML/myeloproliferative disorders and systemic mastocytosis. In mast cell proliferative diseases (systemic mastocytosis and urticaria pigmentosa), proliferation of tissue mast cells is common; although mature mast cells appear only rarely in the blood (termed *mast cell leukemia*), higher numbers of both basophil and mast cell progenitors can be documented ([56], [75], [114]). These observations emphasize the atypicality of hemopoietic malignancies with regard to clear-cut distinctions between basophil and mast cell lineages ([68]). Gain-of-function mutations in both juxtamembrane and intracellular domains of c-kit provide an explanation for many adult mast cell proliferative diseases (either associated with hemopoietic malignancy or not), though such mutations are rarely found in the pediatric form of limited, skin-associated mastocytosis termed *urticaria pigmentosa* ([37], [38], [43], [44]). The presence of basophilia or basophil crisis heralding terminal blast crisis in CML has long been known ([114]) and bcr-abl (see above) may play a role in basophil/mast cell lineage expression during this phase ([69]). Hyperhistaminemia in CML and myeloproliferative disorders is related to increased numbers of turnover of basophils (and, possibly, mast cells) ([65], [76]); indeed, blood basophilia and basophil progenitor increases are poor prognostic indicators in CML ([76], [114]). Such phenomena may relate to specific chromosomal abnormalities in atypical forms of leukemia associated with basophilia or eosinophilia ([68], [69], [115], [116] and [117]), for example, inversion of chromosome 16 (inv 16) associated with atypical eosinophils with basophilic granulation ([115]); t(6;9) chromosomal translocation associated with basophilia and leukemia ([116]); trisomy 21 ([106]); and, in several translocations associated with increased numbers of basophils in patients with acute promyelocytic and other leukemias, such as t(15;17), del(5)(q31q35) and t(9;14) ([116], [118]). Basophils and/or mast cells, sometimes concurrently, can be derived from leukemic clones ([119]); analysis of leukemic cell lines derived from such patients reveals cells of mixed basophil–mast cell lineage ([30], [65], [71], [72], [76], [120]). However, the precise relationship between specific chromosomal aberrations and basophil or mast cell differentiation *in vivo* has not yet been clarified. The biologic significance of increased numbers of mast cells in a variety of hemopoietic and lymphatic malignancies, as well as in refractory anemias ([107]), may be related to acquisition in the leukemic clone of concomitant c-kit mutations ([43]); see above. Apart from c-kit/SCF, whether other cytokines are involved in malignant basophil or mast cell proliferation *in vivo* is not known; for example, whether dysregulated cytokine genes such as IL-3, IL-4, IL-5, and GM-CSF in 5q leukemias ([121], [122]) are responsible for CML basophil crisis is unclear. Overproduction of a cytokine at local tissue sites may induce cell proliferation; this is supported by recent experiments on SCF-induced mast cell and melanocyte hyperplasia *in vivo* in humans ([90], [123]), and in studies on the mast cell–promoting effects of basic fibroblast growth factor ([44]).

CHARACTERISTICS OF MAST CELLS AND BASOPHILS

Surface Phenotype

With the widespread use of monoclonal antibodies to identify surface markers on cells, a wealth of information is available about the surface phenotype of mast cells and basophils. This includes information about Ig receptors, complement components, cytokine receptors, adhesion molecules, and other molecules with or without CD nomenclature. Many authors have contributed to a comprehensive characterization of these markers on human mast cells and basophils and the mast cell and basophil-like cell lines, HMC-1 and KU812 respectively ([124], [125], [126] and [127]). One prominent difference is that mature mast cells express CD117 or c-kit, the receptor for SCF (Table 12.3), whereas mature basophils do not. As outlined above, SCF is an important factor in mast cell development and given that in addition to mast cell progenitors, mature mast cells also express its receptor, CD117, it is not surprising that SCF affects the activation of mediator secretion by mature mast cells.

TABLE 12.3. Selected Surface Phenotypic Markers of Human Mast Cells and Basophils

Marker	Cell Type	
	Mast Cells	Basophils
Fc receptors		
FceRI (aß?2)	+	+
FceRII (CD23)	–	–
Fc?RI (CD64)	+	–
Fc?RII (CD32)		
A	+	+
B	+	+
Fc?RIII (CD16)	+	–
Integrins		
CD11a/18 (aLß2)	–	+
CD11b/18 (aMß2)	–	+
CD11c/18 (aXß2)	–	+
Cytokine receptors		
IL-2R (CD25)	–	+
c-kit (CD117)	–	–
IL-3Ra (CD123)	±	+
IL-3/5/GMRß	–	+
Other		
2D7 antigen	–	+
HLA-DR	+	Inducible

IL, interleukin; +, yes; ±, some mast cell populations respond, some do not; –, no.

Another potentially important difference between mast cells and basophils is in their expression of Fc receptors. Mast cells and basophils both express high-affinity receptors for IgE ([13]), but to date, the only receptor for IgG that has been identified on basophils is Fc?RII (CD32), whereas mast cells can express CD16, CD32, and CD64 ([127]). Further investigation of Fc? receptors on human mast cells and basophils will be important, because different receptors such as Fc?RIIA and B and Fc?RIII have been shown to play distinct roles in mediator secretion and phagocytosis or endocytosis ([128]). Mice deficient in Fc?RII are highly sensitive to IgG-triggered mast cell degranulation through Fc?RIII and exhibit enhanced passive cutaneous anaphylaxis and elevated Ig levels in response to both thymus-dependent and thymus-independent antigens ([129]). It has been postulated that Fc?RIIB down-regulates FceRI signaling and is important in the regulation of mast cell and basophil activities ([7], [10], [130]).

Another intriguing difference between mast cells and basophils lies in their expression of selected integrin molecules (Table 12.3). Human basophils, but not mast cells, express CD11a/18, CD11b/18 and CD11c/18, which have as their complementary ligands ICAM-1/2, C3bi, and fibrinogen respectively. The latter are expressed on endothelial cells and appear to be involved in the migration of basophils into the tissues during inflammation. By contrast, mature mast cells and basophils express a repertoire of adhesion molecules designed to interact with the extracellular matrix components. The ligation of these surface molecules plays a significant role in cell recruitment and activation, and in the future these interactions may be targets for strategies to modulate allergic or other diseases ([131]).

Mediators

Mast cells and basophils are storehouses of inflammatory mediators that can be released by IgE-mediated and other stimuli (Table 12.4). Mediators such as histamine, PAF, and arachidonic acid metabolites have been extensively studied and are considered to be important in the pathogenesis of inflammatory diseases such as asthma ([132]). A major distinction between the two cell types (i.e., mast cells and basophils) lies in the proteinases that are abundant in mast cells in humans ([133]) or other species ([134], [135] and [136]). Proteinases are excellent markers of mast cell heterogeneity. In humans, two major populations have been identified based on their proteinase content, namely, MC_T and MC_{TC}.

TABLE 12.4. Selected Mediators of Human Mast Cells and Basophils

Marker	Cell Type	
	Mast Cells	Basophils
Histamine	+	+
Platelet activating factor	+	+
Nitric oxide	+	Not known
Proteoglycans	Heparin, chondroitin sulfates	Chondroitin sulfates
Arachidonic acid metabolites	LTB_4, LTC_4, PGD_2, PGE_2, thromboxane A_2	LTB_4, LTC_4
Proteinases	Tryptase, chymase, carboxypeptidase A, cathepsin G-like	
Cytokines	IL-1, -2, -3, -4, -5, -6, -8, -10, -11, -13, -16, TNF, LT, NGF, TGFß, GM-CSF, RANTES, MCP1 I-309, MIP-1a, -1ß, FGF, lymphotactin, PDGF-AB, VEGF, BDNF	IL-4, IL-13, MIP-1a

FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LT, leukotriene; MCP, macrophage chemotactic protein; MIP, macrophage inflammatory protein; NGF, nerve growth factor; PDGF, platelet-derived growth factor; PGD_2, prostaglandin D_2, PGE_2, prostaglandin E_2; RANTES, regulated upon activation, normal T-cell expressed and secreted; TGF, tumor growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.
NOTE: Mediators selected from more comprehensive lists published by others and recent updates (e.g., 4,6,12,132,137–141).

Perhaps the most exciting research on the mediators of mast cells and basophils has focused on the cytokines that these cells produce (Table 12.4) ([4], [6], [137], [137], [138], [139], [140], [141], [142] and [143]). Since initial observations in the late 1980s, research in this field has expanded rapidly and one must be careful in making generalizations. There is literature on cytokine expression in cells freshly isolated from *in vivo* sites, but many studies have used primary cell cultures or long-term cell lines, and the relevance of this work to cytokine expression *in vivo* must be viewed cautiously. Additionally, several species have been studied, and often the cytokines have only been identified by the expression of mRNA as assessed by the sensitive technique of reverse transcriptase-polymerase chain reaction. However, cytokine protein levels have been defined in numerous studies as well, and the amounts secreted by mast cells and/or basophils range from small to relatively large quantities. For example, basophils produce large quantities of IL-4 and IL-13 (100s of pg/10 ^{6} cells). The cytokine repertoire of mast cells includes a broad spectrum representing those associated with both Th1 and Th2 phenotypes. It may be that in a given population of mast cells, cytokines are differentially expressed in individual cells or at different times, or that individual mast cells truly express several functionally distinct cytokines. In the latter case, one would speculate that there are rigorous control mechanisms regulating production, secretion, and functions of individual cytokines.

Activation of Mast Cells and Basophils

Much has been written about factors that activate basophils and mast cells, and it is clear that for many of the stimuli that have been studied, it is difficult to make generalizations. Much of the literature involves cells from rodents or guinea pigs and not all the factors that activate mast cells or basophils from these species also activate human cells ([144]). Furthermore, in addition to species differences, marked heterogeneity exists among mast cell populations from different tissue sites within a single species ([4], [12], [145]). Another important consideration is that there are stimulus-specific differences in the mediators released when basophils or mast cells are activated, that is, activation is not an all-or-none phenomenon.

Human basophils and mast cells can be activated by cross-linkage of Fc receptors for IgE or IgG with sensitizing allergens or with antibodies to the receptors or to their Ig ligands (Table 12.5). Such cross-linkage initiates a complex cascade of biochemical signaling events in the cells ([6], [7], [11]) and results in the release of several stored and newly synthesized mediators. A number of other stimuli, including anaphylatoxins C3a and C5a, certain lectins, and the bacterial product formyl methionyl leucyl phenylalanine activate basophils and/or mast cells. Interestingly, with the unexplained exceptions of polyarginine, polycationic substances such as compound 48/80 and numerous basic polypeptides, including a spectrum of neuropeptides, activate human skin mast cells, but not human mast cells from other sites or human basophils ([144]).

TABLE 12.5. Factors That Activate Mediator Secretion from Human Basophils and Mast Cells

Stimulation	Mast Cells	Basophils
FceR and Fc?R cross-linkage	+	+
Compound 48/80	SMC only	–
Basic polypeptides [a] (includes several neuropeptides)	SMC only	–
Polyarginine	±	+
Anaphylatoxins (C3a, C5a)	+	+
FMLP	–	+
Lectins (e.g., Concanavalin A)	+	+
Interleukins/chemokines (CC)/Histamine releasing factors (HRF)	MIP-1a, IL-1, SCF	IL-1 and -3, GM-CSF, MCP-1 and -3, MIP-1a, RANTES, CCL-7, IL-8, HrHRF, CTAPIII/NAP-2

CTAP, connective tissue activating peptide; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin, MCP, macrophage chemotactic protein; MIP, macrophage inflammatory protein; NAP, neutrophil activating peptide; RANTES, regulated upon activation, normal T-cell expressed and secreted; SCF, stem cell factor; SMC, human skin mast cells; +, yes; ±, some mast cell populations respond, some do not; –, no.

[a] Includes adrenocorticotropic hormone, melitin, substance P, vasoactive intestinal polypeptide, neurotensin, bradykinin, etc.

Presently, the working model to explain these observations ([144]) proposes that human skin and rat peritoneal mast cells possess a nonspecific binding site for these polycationic secretagogues, including neuropeptides such as substance P, that involves the direct activation of Gi-like G-protein, initiating cell activation. Neurogenic vasodilatation produced by an axonal reflex in human skin appears to involve mast cell activation by neuropeptides released from primary afferent nerves ([144]). Similar mast cell–dependent neurogenic inflammation has been described in other sites, such as the respiratory ([146]) and gastrointestinal tract ([147]), and appears to be important in at least some inflammatory and infectious diseases. Most recently, Janiszewski et al. ([148]) provided strong evidence that this neurogenic mast cell activation can occur at physiologic doses of substance P, rather than only at pharmacologic doses as has been shown previously for mast cell activation *in vitro* ([149]).

In recent years, there has been great interest in observations that basophils and mast cells can be activated by several interleukins, chemokines, and histamine releasing factors (Table 12.5) ([4], [6], [150], [151]). However, the significance of these pathways of basophil and mast cell activation *in vivo* in health or disease is becoming increasingly clear, particularly in chronic allergic diseases. The CC chemokines appear to be important in basophil, but there is less information about mast cell activation, whereas SCF is a specific stimulus for mast cells, acting through the receptor CD117 ([25], [35]). Most recently, Redegeld and colleagues made the intriguing observation that highly purified Ig light chain can sensitize mast cells for antigen-specific activation ([152]), providing a molecular mechanism for earlier observations of antigen-specific, but nonantibody-mediated, mast cell activation ([153]). Currently, it is not clear how a light chain confers antigen specificity, although the authors reported light chain binding to the mast cell surface. Additional research on the role of such stimuli for mast cells and/or basophils will shed light on the pathogenesis of inflammatory diseases.

Inhibition of Basophil and Mast Cell Activation

Several antiallergic and antiinflammatory drugs inhibit the release of histamine from human basophils and/or mast cells (Table 12.6) ([154], [155] and [156]). Although such drugs are valuable in the treatment of a variety of inflammatory diseases, their actions are multiple and varied, and it is impossible to define precisely their mode of action. In turn, it is difficult to attribute to one cell type or another an unequivocal role in these inflammatory diseases. Furthermore, given the heterogeneity of mast cells in different tissue sites, and perhaps even at different times during the evolution of an inflammatory insult, (e.g., initial injury, repair phase, chronicity, or remodeling phase), different agents may vary in the nature or extent of their modulatory effects on basophils and mast cells.

TABLE 12.6. Inhibition of Histamine Secretion from Human Basophils and Mast Cells

Drug	Basophils	Mast Cells
Sodium cromoglycate/nedocromil sodium	–	? (lung); – (skin)
ß $_{2}$ agonists	?	?
Methylxanthines	?	?
Cetirizine (H $_{1}$ antagonist)	?	?
Sulfasalazine or metabolites	?	?
Corticosteroids	?	– (short term); ? (long term)
Cyclosporine A/FK506	?	?

?, decreased; –, negative.

Given the plethora of functions of cytokines in immune and inflammatory responses, it is not surprising that they have become a focal point to study the modulation of allergic and other inflammatory events. Furthermore, despite some notable exceptions, the postulate that distinct profiles of cytokines (Th1 and Th2) orchestrate these responses ([157]) has stimulated a flurry of studies of cytokine regulation of mast cell functions. Selected cytokines modulate mast cell activation and mediator secretion (Table 12.7) and as would be predicted, the Th1-associated cytokine IFN-? and the related IFN-a/ß, inhibit histamine, serotonin, and TNF secretion by mast cells ([158] , [159] and [160]). Interestingly, the effects of IFN-? on mast cell mediator secretion are dependent on exogenous or endogenous nitric oxide ([161] , [162]). TGF-ß $_1$ also inhibits histamine and TNF production by rat mast cells ([163]). Furthermore, IL-10, often associated with Th2 responses, inhibits TNF and IL-6 production by mast cells ([164] , [165] and [166]), but enhances their antigen-induced secretion of histamine ([166]). This information, taken together with evidence that histamine, serotonin, and prostaglandin E $_2$ ([167] , [168] , [169] and [170]) also modulate mediator secretion, suggests that several basophil and mast cell mediators may have autocrine regulatory roles in inflammation.

TABLE 12.7. Inhibition of Basophil and Mast Cell Activation by Cytokines and Other Factors

Factor	Basophils	Mast Cells
Cytokines		
IFN-?, -a/ß	? Histamine	? TNF, serotonin, histamine, adhesion
IL-10	? Histamine	? TNF, IL-6, IFN-?
		–/? histamine
TGF-ß	?	?TNF, histamine
Histamine [H $_2$ and H $_3$ (mast cells) receptors]	? Histamine	? Histamine and TNF
Prostaglandin $_2$	?	? Histamine, platelet- activating factor, TNF
		? IL-6

IFN, interferon; IL, interleukin; TGF, tumor growth factor; TNF, tumor necrosis factor; ?, decreased; ?, increased.

BASOPHIL AND MAST CELL FUNCTIONS

Inflammatory Injury and Host Defenses

Investigations of the functions of basophils and mast cells have focused on their roles in allergic and other inflammatory disorders. The highly visible symptoms of IgE-mediated allergic reactions and life-threatening anaphylaxis have directed scientific priorities in studies of basophilic leucocytes. In turn, we have learned a great deal about some aspects of these cells, notably about their activation, inflammatory mediators, and regulation. Numerous drugs are available that inhibit many of their functions, and a wealth of novel approaches are on the horizon that will attempt to exploit endogenous pathways employed by cytokines to regulate allergic and other inflammatory responses ([163] , [164] , [165] and [166]). Nevertheless, several challenges remain, including perhaps the most obvious question, why do both basophils and mast cells exist, and what functions distinguish them?

Both basophils and mast cells are central players in allergic inflammation. They share high-affinity receptors for IgE and produce several mediators in common, each with a wealth of potential in the initiation of inflammatory cascades and in the complex cellular and molecular networks involved in injury and repair (Fig. 12.4). In the early phase of the allergic responses, it appears to be critically important that there is a pool of circulating mature basophils, and also a large tissue repository of mast cells. However, basophils and mast cells are not restricted to these sites, as under certain circumstances a large influx of basophils can occur into local tissues [e.g., cutaneous basophilic hypersensitivity ([171]) and asthma ([172] , [173])], and the numbers of mast cell progenitors in the circulation can be increased ([81]). Cutaneous basophilic hypersensitivity reactions can often be dissociated in time or in mediator content from allergic inflammation, and also from classic delayed type hypersensitivity; such reactions appear to involve both a T cell–dependent phase in basophil recruitment, as well as a phase that can involve IgE and IgG antibodies that interact with antigens to activate the cells in the tissues ([81]).

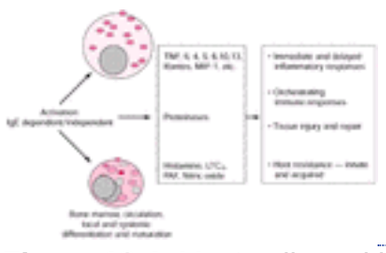

Figure 12.4. Mast cells and basophils in injury and host defense. Summary of the activation of mast cells and basophils, the mediators they produce, and the spectrum of their actions in host defenses and tissue injury. Ig, immunoglobin; IL, interleukin; LTC, leukotriene C; PAF, platelet-activating factor; TNF, tumor necrosis factor.

The roles of basophils and mast cells in allergic inflammation also differ by some of the stimuli that appear to be important for the activation of each cell type. Some mast cell populations respond to a number of basic secretagogues, including several neuropeptides. Moreover, given the close anatomic association between mast cells and nerves ([174]) and abundant evidence for their functional interdependence, it is likely that as a component of allergic and other inflammatory reactions, mast cell–dependent neurogenic pathways are important. There is much less evidence to suggest that neurogenic inflammation is a major pathway in basophil-mediated reactions. However, CC chemokines appear to be important in basophil activation (Table 12.5).

Because initial reports of the role of mast cells in innate antimicrobial immunity ([175] , [176]) and in the possible role of toll-like receptors, there has been great interest in expression and function of these receptors on mast cells ([9] , [177] , [178]) and basophils ([6] , [179]). The mechanisms by which engagement of such receptors on mast cells and/or basophils induce cell activation and mediator secretion will be particularly enlightening with regard to their functions. Undoubtedly, the spectrum of mediators produced by these pathways of mast cell and basophil activation will differ from that following IgE-mediated activation in allergic reactions, and will help elucidate the different roles of these two cell types in host defenses and homeostasis.

The mediators that are produced by the two types of basophilic leucocytes are another obvious source of similarities and distinctions in their functions. Several mediators are shared (e.g., histamine, LTC4, PAF, and others), whereas the cytokine and proteinase profiles of the two cells types are distinct. Although the differences in proteinase content likely hold clues to the functional distinctions between the cell types, we are just beginning to identify some of the substrate specificities of mast cell proteinases or of their functions ([180] , [181]). It is intriguing that an inhibitor of mast cell–specific tryptase has promising bronchodilatory and antiinflammatory effects in a model of allergic asthma ([182] , [183]). Perhaps such drugs will help distinguish between the roles of mast cells and basophils in allergic inflammation. Differences in the cytokine profiles of mast cells and basophils, for example, TNF in mast cells and IL-4 and IL-13 in basophils, may help uncover the unique aspects of the functions of these two cells. These functions could include alterations in the cytokine profiles in the microenvironment that influence the development of particular local immune and inflammatory responses ([184]).

Containment of Injury, Initiation of Repair, Remodeling, and Normal Function

After the initial insult and injury, the inflammatory response elaborates mediators and pathways that minimize the extent of the tissue damage and begin repair processes. Mast cell and basophil mediators are involved in these phases of the response (Fig. 12.5). Histamine, arachidonic acid metabolites, and several cytokines, particularly IL-1, IL-6, IL-10, TNF, and TGF-ß have several effects on endothelial, epithelial, mesenchymal, and inflammatory cells. Such effects include influences on epithelial integrity and function, regulation of blood flow and vascular permeability, tissue edema, fibroblast proliferation, and biochemical phenotype, etc. Unfortunately, these aspects of the functions of basophils and mast cells are poorly known. The relationship between mast cell activation and fibroblasts and angiogenesis in models of tissue repair and remodeling has been studied ([185], [186]), and it is obvious that the pathways involved are multifactorial. As experimental models are developed to address these questions, we will begin to understand the role of mast cells and basophils in this “containment and repair phase” of inflammatory injury.

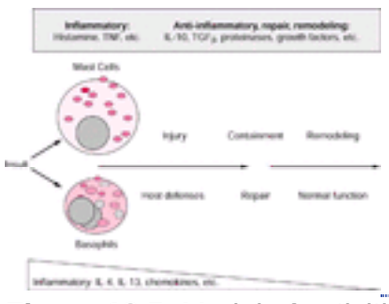

Figure 12.5. Model of activities of mast cells and basophils in the sequential responses of tissue injury, containment, repair, and remodeling. IL, interleukin; TGFß, tumor growth factor-ß; TNF, tumor necrosis factor.

Once the site of injury is contained and repair processes have begun, mast cells and perhaps basophils are likely to be involved in the remodeling of the tissues and the return to normal function. The numerous proteinases of mast cells have distinct substrate specificities and among their functions must be restructuring of the connective tissue, extracellular matrix in the local environment ([187], [188]). Cytokines, such as TGF-ß, IL-1, and IL-6, that influence the activities of fibroblasts are likely to be important candidates for this remodeling phase in the responses to injury. Given the lifespan and normal distribution of mast cells and basophils, an attractive hypothesis is that in this simplified model of tissue injury, containment, and remodeling, basophils play a particularly important role in the injury phase, but that their importance in the latter phases is minimal. By contrast, mast cells are undoubtedly important in the injury phase, but also in the containment and remodeling phases. Given the plasticity of mast cell phenotype, it may be that there is a general pattern of expression of functionally linked clusters of mast cell genes that in a carefully orchestrated manner facilitate the evolving roles of local mast cell populations in the phases of injury, containment, and repair.

Dynamic Equilibrium and Homeostasis

In addition to the evolving mast cell phenotype in the sequence of injury, repair, and remodeling, some phenotypes of mast cells are involved in normal tissue homeostasis. Neurogenic and endocrine activation of mast cells occurs at subtle physiologic, rather than pharmacologic, levels of activity ([189], [190]). This aspect of mast cell function is not well understood, but there is a wide and fascinating literature on these cells in such diverse processes as sexual behavior, implantation, parturition, neuroendocrine signaling (e.g., thyroid and adrenal function), hypothalamic-pituitary-adrenal axis, gastric acid secretion, metabolism of bone, central nervous system functions, and myelopoiesis. Furthermore, given the prominent anatomic association between mast cells and the vasculature, and the effects of mast cell products on blood flow, permeability, and leucocyte adhesion and diapedesis in inflammation ([191]), it is widely held that one normal physiologic role of mast cells is in the dynamic regulation of tissue perfusion and the chemical and cellular composition of extravascular spaces. To date, little direct evidence exists that basophils exhibit similar functions, although given that they produce several potent mediators known to have such effects, it is possible that they exhibit such effects outside of acute inflammatory injury. However, it is the mast cell literature that suggests these cells are prominent in these more physiologic activities, whereas the basophil appears to be a rapid, circulating response that can be recruited to sites of injury.

It is an exciting time to be involved in biomedical research on basophilic leucocytes. The tools available to ask critically important questions are constantly improving ([6], [132]) and as a result our conceptual overview of function is improving and our ability to use this knowledge to treat allergic and other inflammatory conditions or myeloproliferation disorders is improving. The next several years promise to hold exciting advances in the field.

Mononuclear Phagocytes

The *mononuclear phagocyte system*, also known as the *reticuloendothelial system*, is composed of monocytes, macrophages, and their precursor cells ([1]). The cells composing this system (Table 13.1) possess common origins, morphologies, and functions, and they arise in the bone marrow from progenitors committed to mononuclear phagocyte production. Monocytes are released into the blood and, after a short time in the circulation, migrate into different tissues, either randomly or specifically in response to chemotactic stimuli. In the tissues, they differentiate in response to soluble stimuli to become tissue macrophages with characteristic morphologic and functional qualities. This process of differentiation (the acquisition of different, more specialized functions) has been termed *activation*. Figure 13.1 depicts the bidirectional, factor-influenced modulation of function (“classic activation”) of a monocyte or macrophage.

TABLE 13.1. Cells of the Mononuclear Phagocyte System

Bone marrow
Monoblast
Promonocyte
Monocyte
Blood
Monocyte
Tissue
Bone macrophage (osteoclast)
Bowel macrophage
Brain macrophage (microglial cell)
Liver macrophage (Kupffer cell)
Lung macrophage (interstitial and alveolar)
Lymph node macrophage
Milk macrophage
Renal macrophage
Reproductive tract macrophage (testicular, ovarian, uterine, oviductal)
Serosal macrophage (peritoneal and pleural)
Skin macrophage (Langerhans cell)
Spleen macrophage

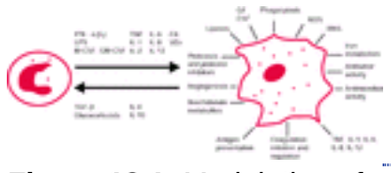

Figure 13.1. Modulation of mononuclear phagocyte function (“classic activation” of macrophages). Monocytes and macrophages can produce and elaborate many different bioactive products, and their function can be modulated by different substances. The figure depicts the reversible “activation” and “deactivation” mediated by these substances. CK, chemokine; CSF, colony-stimulating factor; GF, growth factor; GM-CSF, granulocyte macrophage CSF; IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; M-CSF, macrophage CSF; RNS, reactive nitrogen species; ROS, reactive oxygen species; TGF, tumor growth factor; TNF, tumor necrosis factor; VD_3, vitamin D_3.

Cells of the mononuclear phagocyte system are phylogenetically very primitive. No animals can live without them. They participate in a wide variety of important functions in the body, including removal of dead, senescent, foreign, or altered cells or foreign particles, regulation of the function of other cells, processing and presentation of antigens in immune reactions, participation in various inflammatory reactions, and destruction of microbes and tumor cells.

History

Ilya Metchnikov studied amoeboid cells of invertebrate animals. He believed that these mobile cells, which were capable of ingesting solid particles, could serve in the defense of the organism against “noxious intruders.” In an experiment using the transparent starfish larva, he observed the cells migrating to and aggregating around a rose thorn introduced into the tissue ([2], [3]). He coined the term *macrophage* for these phagocytic connective tissue cells (as opposed to the more common *granular leukocytes* or *microphages*). Based on his subsequent observations on phagocytosis in invertebrates and the prior observations of Cohnheim regarding the migration of leukocytes through vessel walls ([4]), he stated in 1882 that “Diapedesis and accumulation of white corpuscles in inflammatory diseases must be regarded as modes of defense of the organism against microorganisms, the leukocytes in this struggle devouring and destroying the parasites” ([5]).

In the late 1800s, Ehrlich introduced techniques for staining blood cells; these allowed a more exact identification of the white corpuscles. Using several different dyes, he divided the blood cells into lymphocytes, large mononuclear cells, large mononuclear cells with indented nuclei, and polymorphous nucleated cells with neutrophilic, acidophilic, or basophilic granules ([6]). The “large mononuclear cells with indented nuclei” were later called *monocytes* ([3]).

The term *reticuloendothelial system* was first used by Aschoff in 1924 to designate cells that have the ability to remove and store injected carbon particles or the dye neutral red from the blood and lymph ([7]). *Reticulo* refers to the property of forming reticular or lattice networks in various organs, and *endothelial* refers to the location of most of the phagocytic cells identified in these early studies. The microscopic techniques at that time could not discern that the vascular linings in organs such as the spleen, liver, and lymph nodes were composed of endothelial cells (essentially nonphagocytic cells) as well as phagocytic cells (macrophages). Modern methods permit the distinction to be made, and, thus, the term *reticuloendothelial system* for the body's system of monocytes and macrophages is a misnomer. During the early investigations, different components of the system were named descriptively, depending on their location, the nature of material engulfed by the cells, and the diseases affecting the cells, as well as their relationship to other structures. For example, macrophages of the tissues were called “histiocytes,” and the histiocytes of loose connective tissue were referred to as “resting wandering cells” or “amoeboid wandering cells” depending on their observed motility in the tissues, whereas the highly vacuolated histiocytes were called “rhagio-crine cells” because of their supposed secretory activity. The histiocytes of the omentum were named “clasmatocytes” because of the cytoplasmic budding, which was interpreted by Ranvier as an indication that the cells served a nutritive function. The “littoral cells” were those histiocytes adjacent to the bloodstream (e.g., the Kupffer cells of the liver or the splenic macrophages) ([8]). In the early 1900s, several investigators demonstrated that blood monocytes, after long-term culture *in vitro*, developed into cells that were similar in appearance to tissue macrophages, inflammatory epithelioid cells, and multinucleated giant cells ([9], [10] and [11]). Using meticulous observations with supravital dyes through the transparent rabbit ear, Ebert and Florey showed that blood monocytes emigrated into the tissue *in vivo* and changed into cells with the appearance of inflammatory tissue macrophages ([12]).

In the 1950s and 1960s, work by George Mackaness and colleagues helped define mechanisms by which macrophages become activated to control the growth of intracellular organisms ([13]). In the 1960s through the 1990s, Zanvil Cohn and co-workers defined many aspects of the cell biology of mononuclear phagocytes ([14]). John Hibbs, Carl Nathan, and colleagues in the 1970s through the 1990s further defined the processes of macrophage activation and the importance of nitric oxide (NO) as a macrophage effector molecule for antimicrobial and antitumor action ([15]). Studies beginning in the 1970s by Seymour Klebanoff, Bernard Babior, John Curnutte, and colleagues helped to clarify mechanisms of oxidative microbial killing and molecularly define the phagocyte oxidase ([16], [17] and [18]). Donald Metcalf, Richard Stanley, and co-workers in the 1970s through the 1990s did detailed studies of hematopoiesis and growth factors, demonstrating basic mechanisms of hematopoiesis/monocytopoiesis, the clinical uses of colony-stimulating factors (CSFs), and the actions of macrophage CSF (M-CSF) in monocytopoiesis and mononuclear phagocyte function and embryogenesis ([19], [20]). Molecular characterization of leukocyte receptors and ligands by a variety of investigators in the 1980s and 1990s gave new insights into mononuclear phagocyte interactions with other cells (e.g., lymphocytes and endothelium), microorganisms, and tumor cells ([21]). In the 1990s, gene transfer or gene disruption techniques ([22], [23]) provided new tools for the analysis of mononuclear phagocyte and cytokine biology. In the late 1990s and early 2000s, researchers identified mammalian analogs of the *Drosophila* Toll receptor, cloned the mammalian Toll-like receptor 4 (TLR4), identified TLR4 as the receptor for lipopolysaccharide (LPS) and the membrane transducer for LPS signaling in mononuclear phagocytes and other cells, and identified other TLRs as receptors for other microbial components ([24], [25]). The complex interplay of novel cytokines and receptors [osteoprotegerin (OPG), OPG ligand (OPGL), and receptor activator of nuclear factor-?B (NF-?B)] controlling osteoclast formation and differentiation was defined ([26]). Researchers further established the arginine/inducible NO synthase type 2 (NOS2)/arginase pathway as a regulator of cell growth and toxicity, apoptosis, inflammation, and host resistance to tumors and microbes ([27], [28], [29], [30], [31] and [32]). And finally, further particulars of the paths of macrophage activation (classic and alternative) are being dissected ([33], [34]).

Phylogeny and Ontogeny

Phylogenetically, mononuclear phagocytes are primitive cells. Invertebrates have phagocytic mononuclear cells that are known by various names (e.g., *coelomocytes*, *amoebocytes*, *hemocytes*) and are morphologically and functionally similar to the mononuclear phagocytes of mammals ([35]). These or comparable phagocytes are present in all the phyla of the animal kingdom (metazoan or higher). Whereas lymphocytes first appear in the cyclostome hagfish (vertebrate), immunoglobulins (Ig) and complement (C') appear still later in evolution. Amoebocytes serve various functions in these primitive animals. First, they are important in nutrition. Different particles and microbes are digested and transported by the amoebocytes, and the digested products are used by the host ([36]). Second, amoebocytes serve as scavengers by surrounding and ingesting/digesting apoptotic, dead, or dying tissue. This is especially important in the physiologic process of metamorphosis in insects and amphibians ([2], [35], [37]), as well as in encapsulating and walling off foreign material ([35], [38], [39] and [40]). Third, amoebocytes play an important role in protecting the animal against infections and, possibly, cancer. For example, cells of the earthworm, crayfish, starfish, oyster, cockroach, and sponge recognize bacteria as foreign and phagocytize and destroy them ([35], [40], [41]). Cells from crayfish also can kill mammalian tumor cells *in vitro* by a nonspecific, nonphagocytic process comparable to that of mammalian macrophages ([42]). Invertebrates have soluble “recognition factors” that function as primitive opsonins for particles ([35], [42]); these may have been forerunners of the Ig and C' systems. As in mammalian macrophages, products from bacteria appear to be specifically chemotactic for amoebocytes ([43]). Phagocytes mediate the rejection of foreign tissue grafts ([35], [44]). Thus, phagocytes from evolutionarily primitive animals function very effectively in protecting the host in the absence of B or T lymphocytes, Ig, or C'. With evolution and the acquisition of lymphocytes, Ig, and C', phagocytes developed receptors for these ligands, and their nutritive function decreased, but the important functions of phagocytosis, endocytosis, encapsulation, and recognition of foreign substances, remained.

During ontogeny, pluripotent hemopoietic stem cells sequentially occupy the embryonic yolk sac, fetal liver, spleen, and adult bone marrow. Hematopoietic stem cells are derived from ventral mesodermal tissue. Stem cells migrate from the yolk sac and colonize receptive intraembryonic hemopoietic organs, where they can then respond to stimuli for differentiation along certain cellular pathways ([45]). The embryonic macrophages play important roles in tissue metamorphosis by scavenging dying and dead cells and, possibly, by mediating the destruction of cells in areas of tissue remodeling ([2], [37]). Mononuclear phagocytes may also regulate embryonic

growth by the secretion of various mitogens or growth factors ([46], [47]).

Before day 9 in the mouse embryo, no cells identifiable as mononuclear phagocytes are seen anywhere (including the yolk sac), even though the yolk sac contains cells capable of forming macrophage colonies in appropriate assays ([48]). After day 10, glass-adherent macrophages with Fc receptors (FcRs) are seen in the yolk sac. After 12 days of gestation, mononuclear phagocytes are found in the liver and then in other tissues ([48]). In fetal rats, macrophages with phagocytic capability can be detected in inflammatory lesions as early as 16 days. Work in transparent zebrafish embryos has shown that macrophages appear as early as erythroid cells, originating from the ventrolateral mesoderm ([49]). The macrophages migrate to the yolk sac, differentiate, and then join the blood or invade the head region. These macrophages can phagocytose apoptotic cells and also ingest and kill injected bacteria. In zebrafish hematopoiesis, macrophages appear to use a rapid differentiation pathway that goes from early hematopoietic cells directly to relatively mature, functional macrophages without use of the monocyte as an intermediary cell ([49]).

The macrophage inflammatory response is seen at earlier times in gestation than the neutrophil response ([50]). Research in transparent zebrafish has shown that infection of the embryo with mycobacteria at a stage before lymphocyte development results in macrophage aggregates with hallmarks of granuloma ([51]). At birth, mononuclear phagocyte function is not fully developed. Neonates are highly susceptible to infections by viruses and intracellular pathogenic bacteria and have a poorly developed inflammatory response. Studies in mice show that the abnormalities relate to abnormal immune response–related antigen expression that results in poor antigen presentation, macrophage-mediated cytotoxicity, and interleukin (IL)-1 production. These defects can be bypassed by treatment of macrophages with lymphokines ([52], [53]). Prostaglandins of the E series and a-fetoprotein suppress the expression of major histocompatibility complex (MHC) class II antigen on macrophages; these substances may play a role in the low expression of MHC class II antigen in neonatal macrophages. The uptake and degradation of opsonized bacteria and the phagocytosis of C'-coated erythrocytes are normal in neonatal macrophages ([52], [53]).

MORPHOLOGY

Monoblasts

The monoblast normally is found only in the bone marrow. This cell is difficult to identify with certainty ([54]). However, the ability of single cells grown in agar culture to produce mixed granulocyte-macrophage or pure macrophage colonies suggests that there is a common precursor that develops into neutrophil (microphage) or macrophage cells ([55], [56]). The monoblast is defined by its ability to form mature colonies of mononuclear phagocytes in *in vitro* cultures. It is nonmotile, nonadherent to glass or plastic, and measures approximately 14 µm in diameter. It is characterized by deeply basophilic cytoplasm, a large nucleus with little indentation, fine stringy chromatin, and one or two large nucleoli. Numerous fine, spherical, or slender rodlike mitochondria can be seen in supravitally stained cells, but neutral red–containing vacuoles are absent or only a few very fine bodies are seen. These are presumably pinocytic vesicles. On electron microscopic examination, aggregated ribosomes and scattered strips of endoplasmic reticulum are seen in the cytoplasm, but the Golgi apparatus is small ([57]). Distinguishing the monoblast from the myeloblast on morphologic grounds is difficult and probably impossible even when using the electron microscope.

Promonocytes

The human promonocyte, essentially the earliest cell clearly recognizable morphologically in this lineage, is 11 to 13 µm in diameter and has a high nuclear to cytoplasmic ratio ([54], [58], [59]). The nucleus is indented with fine chromatin and may contain a nucleolus. The cytoplasm has considerable basophilia on Wright stain, and the cells stain for nonspecific esterase, peroxidase, and lysozyme (Table 13.2). These cells can phagocytize opsonized bacteria and IgG-coated erythrocytes but not IgM C'–coated erythrocytes. There is active pinocytosis as determined by uptake of dextran sulfate. A high proportion of these cells can incorporate tritiated thymidine, indicating that they are actively synthesizing DNA ([54], [60]). On electron microscopy, rough endoplasmic reticulum (RER) is well developed, and free polyribosomes are scattered throughout the cytoplasm ([61]) (Fig. 13.2). The Golgi apparatus is well developed, and granules of varying size and shape surround it, together with small vesicles that seem to arise from the Golgi cisternae. The RER, Golgi cisternae, and the early granules contain peroxidase, aryl sulfatase, and acid phosphatase ([62]). Numerous bundles of filaments are present in the cytoplasm around the nucleus, a feature of value in identifying these cells as monocytes ([61], [62], [63] and [64]). The cytoplasmic membrane of the promonocyte exhibits various processes and projections that presumably are related to its property of motility and active endocytosis ([61], [62]). The promonocyte is distinguishable from the promyelocyte by the fact that promonocytes contain fewer and smaller granules, and their granules lack crystalloids; the cytoplasm characteristically contains bundles of filaments, and the nuclei are quite irregular and deeply indented ([61], [62], [63] and [64]).

TABLE 13.2. Characteristics of Human Mononuclear Phagocytes

	Bone Marrow	Blood	Tissue

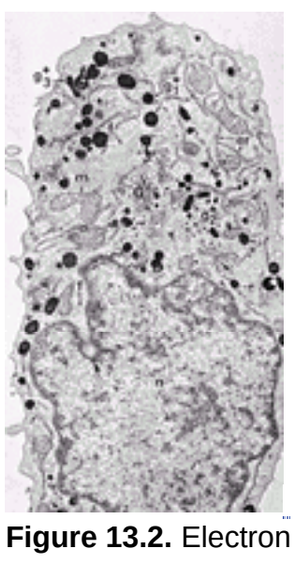

Figure 13.2. Electron micrograph of a promonocyte from human bone marrow stained for peroxidase. The nucleus (*n*), situated at one end of the cell, exhibits an

irregular outline and deep indentations. The cytoplasm contains a number of cytoplasmic organelles. Peroxidase reactivity is demonstrable throughout the rough endoplasmic reticulum (*er*), Golgi complex (*G*), and all cytoplasmic granules (*g + 1*, *g + 2*, *g + 3*). Apparently, all granules mature from the earliest forms, which are spherical and dense (*g +1*) with a homogeneous matrix, to more condensed and elongated forms (*g +2*) and then to dumbbell forms (*g +3*). The Golgi complex (*G*) is composed of several stacks of cisternae and occupies a large area adjacent to the nucleus. Bundles of filaments (*f*) are prominent in the cytoplasm and are believed to be useful in characterizing the cell as a monocyte form. Several mitochondria (*m*) are also seen. ×18,000. (From Nichols BA, Bainton DF. Differentiation of human monocytes in bone marrow and blood. Lab Invest 1973;29:27, with permission.)

Monocytes

Monocytes are 10 to 11 µm in diameter, being generally smaller than promonocytes but larger than other mature leukocytes. Monocytes seen in the bone marrow and the peripheral blood vary considerably in size and shape, but the “typical” monocyte is usually easily distinguishable from other leukocytes. The nucleus is large and oval or indented and centrally placed. By light microscopy, nucleoli usually are not seen. The nuclear chromatin is delicate, and the membrane is thin. The cytoplasm is abundant, gray or light blue-gray in Wright-stained preparations, and contains numerous fine, clear, or lilac vacuoles (Fig. 13.3). The granules resemble fine dust and give the bluish cytoplasm a ground-glass appearance. In certain circumstances (e.g., bacteremia) or with heavy staining, the granules appear more prominent. The delicate chromatin and the bluish color of the cytoplasm in the monocyte are most helpful in differentiating these cells from metamyelocytes or band forms of neutrophils. Granules in monocytes contain peroxidase but are much smaller than those found in neutrophils ([62], [64], [65]).

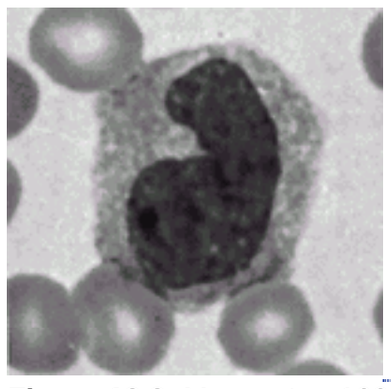

Figure 13.3. Monocyte ×1000 (approximately). Wright stain. See Color Plate.

The cells attach avidly to plastic (polystyrene) or glass, are motile in their adherent state, and spread and project thin processes within 1 to 3 hours ([9], [10] and [11], [66], [67]). On phase microscopy, phase-dense granules, which correspond to lysosomes, can be seen in the cytoplasm. The lysosomes are excluded from the actin-rich thin border area of cortical cytoplasm (hyaloplasm). Cell motion is ameboid in nature; large, filmy, irregular pseudopods extend slowly from the delicate cytoplasm as the cell moves randomly. In response to chemotactic signals, the movement is directed, and the cell assumes a delta shape with the slender, pointed edge trailing ([66]).

Electron microscopy shows that the mature monocyte contains a horseshoe-shaped nucleus, with dense, granular peripheral chromatin surrounding extensive, light-staining central nucleoplasm (Fig. 13.4). Nucleoli have been observed in as many as 50% of blood monocytes ([62], [64]). The mitochondria are spherical or elongated and are usually located in the periphery of the abundant cytoplasm. The Golgi apparatus is well developed, and small vesicles are especially numerous in this region but may be found throughout the cytoplasm.

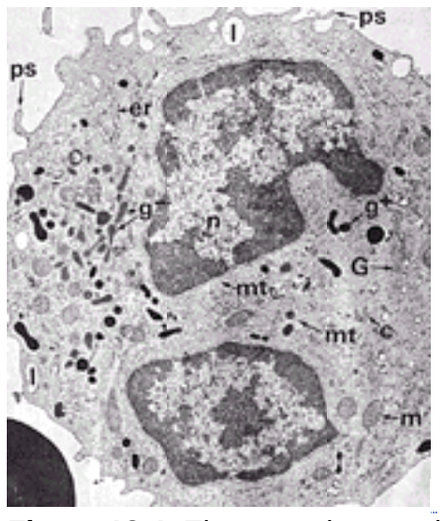

Figure 13.4. Electron micrograph of a normal human blood monocyte examined for peroxidase. In the nucleus (*n*), the chromatin is more condensed than in earlier forms, is mainly peripheral in distribution, and is interrupted at the nuclear pores. The voluminous cytoplasm (*c*) contains a full complement of organelles associated with protein synthesis and export of secretory granules. Peroxidase is present in only some of the granules (*g*+), but others (*g*–), as well as the endoplasmic reticulum (*er*) and Golgi complex (*G*), now lack the reaction product. At this stage, the two kinds of granules are approximately equal in number and similar in size and shape, ranging from 90 to 450 nm in length and from spherical or rodlike to dumbbell in shape. Microtubules (*mt*) radiate from the cell center, where a centriole can be seen adjacent to the Golgi complex (*G*). The moderately abundant endoplasmic reticulum has a more peripheral distribution than in the promonocyte, and modest numbers of mitochondria (*m*) are present. Numerous pseudopodia (*ps*) extend from the cell surface. The peripheral lacunae (*l*) represent tangential sectioning through surface irregularities. ×16,200. (From Nichols BA, Bainton DF. Differentiation of human monocytes in bone marrow and blood. Lab Invest 1973;29:27, with permission.)

At the monocyte stage, peroxidase production ceases, and the RER and Golgi complex no longer contain the enzyme, but peroxidase is present in storage granules ([63]). A second population of granules is produced that contains no peroxidase ([63], [64], [68]). In normal human monocytes, peroxidase activity can be detected in the Golgi area and in the RER after adherence to plastic or glass for 2 to 18 hours. Patients with hereditary deficiency of neutrophil peroxidase have monocytes that lack the enzyme in their storage granules ([68]); however, after adherence and *in vitro* culture, peroxidase activity appears as it does in normal monocytes, suggesting that the peroxidase stored in monocyte granules and the peroxidase that appears in the RER and Golgi after adherence are two distinct proteins ([68]). The peroxidase of the RER and Golgi is inhibited by aminotriazole and sodium azide, whereas that of the granules is not ([64]). Cytochemical staining at the light and electron microscope levels has demonstrated many other enzymes, including acid phosphatase, sodium fluoride–resistant nonspecific esterase (alpha naphthyl butyrate or acetate esterase), naphthylaminidase, lysozyme, beta glucuronidase, 5' nucleotidase, galactosidases, and numerous other hydrolases and proteases ([69], [70], [71], [72] and [73]).

Macrophages

Macrophages represent the tissue component of the mononuclear phagocyte system. This is a very heterogeneous group of cells with many different phenotypes. In general, they are believed to arise from emigrated blood monocytes and apparently differentiate in response to local conditions and factors ([1]). Macrophages are large, actively phagocytic cells measuring 15 to 80 µm in diameter. Their shape is irregular, and their motility comparable to that of blood monocytes. Bleblike and filiform pseudopods are seen frequently. The cytoplasm is abundant. The nucleus is egg-shaped or may be indented or elongated. When stained with Wright stain, the chromatin appears “spongy,” and the nuclear membrane is distinct. The cytoplasm is sky-blue and contains coarse, azure granules and vacuoles. Electron microscopy of macrophages shows a spectrum of cell types ranging from those comparable to monocytes to much larger cells with more cytoplasm and more vacuolization and granulation (Fig. 13.5). Peroxidase is seen in the RER and Golgi but, in contradistinction to monocytes, is absent in the granules ([64], [68]). Some “intermediate” cells are seen in which peroxidase is present in the RER, Golgi, and granules; these may be monocytes that have recently emigrated into the tissues (

74).

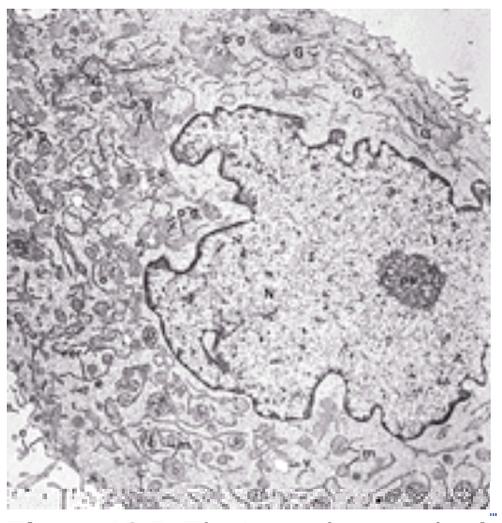

Figure 13.5. Electron micrograph of a peroxidase-negative human macrophage that developed after 14 days in liquid culture. The eccentric nucleus (*N*) contains a distinct nucleolus (*nu*) and the cytoplasm is filled with many organelles [i.e., mitochondria (*m*), rough endoplasmic reticulum (*rer*), a large Golgi complex (*G*), and numerous small vesicles of vacuoles (*v*)]. No peroxidase can be detected at this late stage of maturation. In addition to the occasional clear vacuoles (*v*) are many inclusions, which are peroxidase-negative granules (*p-g*). Their content is unknown. ×14,500. *e*, filipodium. (From Bainton D, Golde DW. Differentiation of macrophages from normal human bone marrow in liquid culture. J Clin Invest 1978;61:1555, with permission.)

MONONUCLEAR PHAGOCYTE PRODUCTION AND KINETICS

Bone Marrow Kinetics

The major site of production of mononuclear phagocytes is the bone marrow. Primitive stem cells become committed to the mononuclear phagocyte lineage in a stochastic fashion and then, under the influence of growth factors and cytokines, differentiate into monocytes. Myeloid cell growth is controlled by different glycoprotein growth factors that can cause the development *in vitro* of colonies composed of granulocytes only (G-CSF), macrophages only (M-CSF), both granulocytes and macrophages (GM-CSF), or granulocytes, macrophages, normoblasts, megakaryocytes, mast cells, and stem cells (MULTI-CSF or IL-3) (55 , 75). The macrophage growth factors cause both proliferation and differentiation of primitive hematopoietic cells to monoblasts, promonocytes, and mature monocytes. They work through specific, high-affinity cell-surface receptors that initiate the cell proliferation (55 , 76 , 77). Receptors for M-CSF are restricted to cells of the mononuclear phagocyte system and are species specific. Mouse mononuclear phagocytes bind M-CSF specifically with high affinity (saturation at >2 × 10^{10}/L) (77). Blood monocytes have approximately 3000 receptors per cell, and the larger alveolar macrophages have up to 16,000 receptors per cell. Of bone marrow cells, approximately 4.0% have receptors (determined by autoradiographic studies), whereas 2.0% of spleen cells, 8.0% of blood cells, 21.0% of peritoneal cells, 0.4% of lymph node cells, and 12.0% of alveolar cells can specifically bind the M-CSF and form macrophage colonies *in vitro* in response to M-CSF (77). The receptor for the mononuclear phagocyte growth factor, M-CSF, is closely related to the c- *fms* protooncogene product (78 , 79). The transcription factor PU.1 is necessary for the M-CSF–dependent proliferation of mononuclear phagocytes (80). Mononuclear phagocyte development during fetal and neonatal life is dependent on M-CSF (81). The critical importance of M-CSF in the development of mononuclear phagocytes is underscored by the absence of abnormalities in mononuclear phagocytes in mice lacking GM-CSF (those with targeted disruption of the GM-CSF gene) (82 , 83).

Studies of human mononuclear phagocytopoiesis have shown that 3% of bone marrow cells are promonocytes (84). When marrow cells were incubated *in vitro* with ^{3}HTdR, one group of investigators showed that approximately 79% of the promonocytes were labeled (65), whereas another group showed that 12% were labeled (84 , 85). Double-labeling studies (^{3}HTdR and ^{14}CTdR), as well as serial ^{3}HTdR injections, indicated a DNA synthesis time of approximately 10 hours and a generation time of 29 hours for promonocytes. When ^{3}HTdR was injected into normal subjects and the subsequent appearance of labeled monocytes in the blood was monitored, a lag period of only 5 to 7 hours was noted, thus demonstrating the absence of a significant storage compartment. Subsequently, several waves of labeled cells appeared, reflecting the flow into the blood of cells labeled during promonocyte proliferation in the marrow (85). From studies of the time course of labeled monocytes in the blood after the intravenous injection of ^{3}HTdR, the transit time through the marrow proliferation pool was estimated to be 54 hours (85). This is approximately twice the promonocyte generation time of 29 hours and suggests that there are, on the average, two catenated promonocyte generations in the bone marrow of normal humans (Fig. 13.6). The size of the marrow promonocyte pool in normal humans has been calculated from data on total marrow cellularity to be approximately 60 × 10^{6} cells per kg of body weight. From these data, the labeling index of 12%, and DNA synthesis time of 10 hours, a production rate of 7 × 10^{6} cells per kg per hour can be calculated (60 × 10^{6} × 0.12/10 hours) (85). Other workers have demonstrated comparable values using different techniques (54 , 65). Similar numbers of cells are turning over through the blood as determined from blood monocyte kinetic measurements (86).

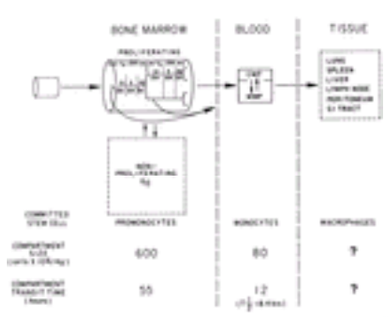

Figure 13.6. Model of the production and kinetics of the monocyte-macrophage system in humans. The marrow and blood compartments are drawn to show their relative sizes. The compartment transit times are derived from ^{3}HTdR and ^{3}H-DFP labeling studies. A small number of young cells may enter the blood from the G_1 phases of the promonocyte cell cycle (*curved arrows*). The box outlined by dashed lines indicates a large compartment of marrow promonocytes in the resting or G_0 stage (see text). G, cell generation time with the subcompartments G_1 (pre–DNA synthesis gap), S (DNA synthesis period), and G_2 (post–DNA synthesis gap); CMP, circulating monocyte pool; GI, gastrointestinal; MMP, marginal monocyte pool; $T_{1/2}$, half-life.

Monocyte Kinetics in Blood

Blood monocytes are a population of recently formed young cells on their way from the bone marrow to their ultimate sites of activity in the tissues; therefore, monocyte production can be calculated from the turnover of blood monocytes. Blood monocyte kinetics have been evaluated in humans by *in vivo* and *in vitro* labeling of autologous blood with tritiated diisopropyl fluorophosphate, reinjecting the labeled cells, and measuring the proportion of labeled cells present at later times by autoradiographic techniques (85 , 86). These studies have shown the marginal monocyte pool to be approximately three and one-half times the size of the circulating pool. Blood monocytes left the vascular system in an exponential manner with a half-life of 4.5 to 10.0 hours (mean of 8.4 hours) (85 , 86). This 8.4-hour half-life is shorter than the 71.0 hours calculated from experiments using *in vivo* labeling with ^{3}HTdR (87). From the blood pool size and the half-life value, the blood monocyte turnover rate was calculated to be approximately 7 × 10^{6}/kg/hour (85).

Alterations in monocyte kinetics have been measured after the acute or chronic administration of adrenal glucocorticoids to humans (88) and mice (89). Profound monocytopenia develops promptly in both species, and its duration and degree depend on the amount, solubility, and route of steroid administration. In humans, the

cellularity of induced exudates is decreased by steroid administration ([88]). In mice, the number of cells harvested from the peritoneum is only moderately decreased (approximately 30%), but the flow of ^{3}HTdR-labeled monocytes from the blood into the peritoneum in response to an inflammatory stimulus is markedly reduced. The mechanism of the sudden monocytopenia is not fully understood, nor is it clear whether the reduced cellularity at the site of inflammation merely reflects the monocytopenia, is the result of other steroid effects on the monocytes or the vascular wall, or is due to yet other factors. In septicemia, monocytopoiesis is enhanced in the marrow, and the blood monocyte turnover rate is increased in humans ([85]). Administration of recombinant G-CSF, GM-CSF, or IL-3 to humans amplified bone marrow production of mononuclear phagocytes and release of monocytic cells into the blood ([90]). The peripheral half-life of blood monocytes in subjects receiving the growth factors was reduced ([90]). G-CSF administration to normal people in preparation for blood stem cell harvesting caused an eightfold increase in neutrophil and monocyte counts and a slight decrease in platelet counts ([91]). The effects of recombinant growth factors on tissue macrophage numbers and function are not known.

Tissue Macrophage Kinetics

Tissue macrophages arise primarily from emigrated blood monocytes that differentiate into macrophages. Chimera studies in experimental animals have shown that marked donor marrow or blood monocytes (radioactive label, abnormal or opposite sex chromosome marker, unique enzyme, or distinctive morphologic marker) eventually are found in tissues as macrophages. This has been shown in the case of peritoneal macrophages ([92] , [93] , [94] and [95]), liver Kupffer cells ([96] , [97] and [98]), alveolar macrophages ([99] , [100] , [101] and [102]), osteoclasts ([103]), type-A synovial cells ([104]), and inflammatory tissue macrophages ([105]). Studies in humans after bone marrow or liver transplants from opposite sex donors have given evidence for the bone marrow or blood origin of liver Kupffer cells ([106]) and alveolar macrophages ([107]). Animals receiving total body irradiation with shielding of a small portion of bone marrow followed by *in vivo* ^{3}HTdR injection have near-normal levels of labeled (bone marrow–derived) peritoneal ([60]), Kupffer ([96]), and alveolar macrophages ([108]), suggesting that these tissue macrophages are derived from the bone marrow. Furthermore, glucocorticosteroids, which inhibit the egress of blood monocytes into tissues but not the ^{3}HTdR incorporation into mononuclear phagocyte precursors ([89]), decrease the labeling indices of peritoneal, Kupffer, and alveolar macrophages to near zero ([65] , [96] , [108]). However, most studies in experimental animals and in humans have shown a detectable, albeit small, ^{3}HTdR-labeling index in peritoneal, alveolar, Kupffer, and wound macrophages ([54] , [65] , [96] , [108] , [109] and [110]). Some have contended that local proliferation of tissue macrophages plays an important physiologic role in the maintenance of macrophage numbers there. For example, in mice made severely monocytopenic by the injection of strontium-89 (which localizes in bone marrow and dramatically reduces marrow mononuclear phagocyte production), the levels of peritoneal macrophages remain stable for months with ^{3}HTdR-labeling indices of 3 to 5% in the tissue macrophages ([110] , [111] and [112]). Local proliferation of tissue macrophages in physiologic conditions contributes to tissue macrophage renewal, but the precise extent of this is unknown.

Studies in mice have attempted to define the kinetics of tissue macrophages. Pulse labeling with ^{3}HTdR has given information on blood half-lives, the numbers of macrophages in the various compartments, and the number of monocytes that enter the tissues per unit of time for peritoneum, liver, and lung ([65] , [96] , [108]) (Fig. 13.7). Approximately 8% of the blood monocytes go to the peritoneal cavity, and there are approximately 1 to 3 × 10^{6} resident peritoneal macrophages per mouse. The turnover rate for peritoneal macrophages is low (approximately 0.1% per hour), giving a turnover time of approximately 41 days. There are approximately 0.9 × 10^{6} Kupffer cells per liver in the mouse ([96]), and the calculated mean turnover time is 21 days. Approximately one-half of the labeled blood monocytes migrate to the liver, where they reside as Kupffer cells. Approximately 15% of labeled blood monocytes migrate into the lung. The total mouse lung macrophage population is approximately 2 × 10^{6} ([108]); of these, 93% are in alveoli and 7% are found in the interstitium. The calculated mean turnover time for lung macrophages is approximately 27 days. Data for other tissue mononuclear phagocytes are not available.

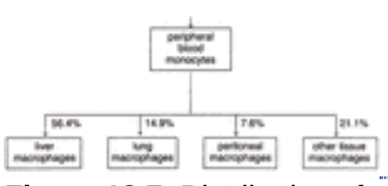

Figure 13.7. Distribution of mouse monocytes that leave the peripheral blood. In the various organs, the monocytes become macrophages. (From van Furth R, et al. Characteristics, origin, and kinetics of human and murine mononuclear phagocytes. In: van Furth R, ed. Mononuclear phagocytes. Functional aspects. The Hague: Martinus Nijhoff, 1980, with permission.)

To maintain a steady number of tissue macrophages in the face of the noted steady influx of monocytes into the tissues, the tissue macrophages must have a steady local death rate, a steady efflux from the tissues, or both. Some alveolar macrophages are removed by the mucociliary pathway and are expectorated or swallowed ([108] , [113] , [114]). There is evidence that interstitial lung macrophages migrate to lymph nodes via the lymphatics ([115] , [116]), where they may die. Macrophages from the small intestine and liver migrate to regional lymph nodes ([117] , [118]). Macrophages in granulomas (epithelioid cells and multinucleated giant cells) die *in situ* ([119]). There is no good evidence that tissue macrophages ever reenter the blood. However, when researchers injected fluorescent spheres into the subcutaneous tissue of mice, the spheres were phagocytized by exuded monocytes and then migrated to draining lymph nodes where they had characteristics of dendritic cells (DC) ([120]). In monocyte-deficient osteopetrotic mice, the appearance of the labeled cells in lymph nodes was reduced by more than 85%. These data indicate that tissue macrophages can leave one tissue (subcutaneous tissue) and enter another (lymph node), where they may differentiate into another cell type (DC) ([120]).

CHARACTERISTICS AND DISTRIBUTION OF TISSUE MACROPHAGES

Cells of the mononuclear phagocyte system are widely distributed throughout the body (Table 13.1). The cells in the various tissues are quite heterogeneous, differing in numerous parameters. Because of the broad distribution and the difficulty of isolating those deeply embedded in some tissues, it has been difficult to quantitate the numbers in different compartments and the total number in the body. Studies using a monoclonal antibody that recognizes a specific mononuclear phagocyte antigen (F4/80) have provided some data ([121]). The macrophage antigen was found in a wide variety of tissues; the organs with the highest total F4/80 antigen content were the bowel, liver, bone marrow, spleen, lymph nodes, and kidney ([121]). Although levels of F4/80 may vary with the “activation” state of macrophages, these studies are helpful in assessing macrophage content.

Lung Macrophages

The interstitial and alveolar macrophages constitute the lung macrophage pool, with approximately 7% being interstitial ([108]). Interstitial cells are likely the immediate antecedents of the free alveolar macrophages ([122] , [123]). Pulmonary macrophages are essential components of the respiratory defense system, and, because of their accessibility, alveolar macrophages have been studied most extensively. Alveolar macrophages are 15 to 50 µm in diameter. Their appearance and structure depend on the age of the cell and the nature and quantity of the material that has been endocytized. In Giemsa- or Wright-stained preparations, their cytoplasm is gray or light blue and contains numerous cytoplasmic granules. The nuclear to cytoplasmic ratio is approximately 1:3. Nucleoli are sometimes seen. There is abundant smooth endoplasmic reticulum and RER. A variable number are extremely vacuolated or “foamy.” Phagosomes may contain dust particles, bacteria, erythrocytes, and cellular debris. Some of the inclusions contain surfactant, the phospholipid synthesized by alveolar type II cells that is important in the maintenance of normal lung function. The normal alveolar macrophage removes and degrades surfactant material ([124]). It does not contain hemoglobin (Hb), and only trace amounts of iron are present. However, in situations of pulmonary hemorrhage (occult or overt), large quantities of Hb and iron in the form of hemosiderin can be found in the cells ([124]). They contain a-naphthyl butyrate esterase (nonspecific esterase), lysozyme, and acid phosphatase and stain positively with the periodic acid-Schiff (PAS) stain. There is little or no peroxidase activity in alveolar macrophages, but they do contain catalase. They have receptors for the Fc fragment of IgG and C' (C3b) ([125] , [126] and [127]). Ultrastructurally, the nuclei of alveolar macrophages are polymorphous and frequently have an eccentrically placed nucleus with a nucleolus ([124] , [128]). Multinucleated cells are rarely seen. There are numerous membrane-bound cytoplasmic vesicles or primary lysosomes that contain various enzymes typical of lysosomes, including cathepsins, lysozyme, ß-glucuronidase, aminopeptidase, ß-galactosidase, aryl sulfatase, acid ribonuclease, and phospholipases ([124] , [129] , [130]).

Alveolar macrophages exist at the tissue-air interphase, where they encounter inhaled pollutants and microorganisms. They exist in an environment with a high partial pressure of oxygen as compared to the other mononuclear phagocytes of the body. As a consequence, alveolar macrophages have metabolic properties different from macrophages in other sites. Their basal glucose consumption and respiratory rate are greater than those of all other phagocytes studied ([131]). However, unlike phagocytes from other sites, they have a poor respiratory burst and little increase in hexose monophosphate shunt activity in response to soluble stimuli or

phagocytosis ([131]). Rat alveolar macrophages have high levels of cytochrome oxidase and low levels of the glycolytic pathway enzymes pyruvate kinase and phosphofructokinase when compared to peritoneal macrophages. This particular enzyme phenotype in alveolar macrophages can be changed to that of peritoneal macrophages by incubating the cells in relatively anaerobic conditions *in vitro* ([132]).

Alveolar macrophages contain and secrete numerous enzymes typical of mononuclear phagocytes. Elastase and collagenase may have a role in the production of tissue destruction and the evolution of emphysema ([133]), especially in people with a ¡-antitrypsin (a ¡-antiprotease) deficiency. In addition to the various proteases, alveolar macrophages have been noted to contain the protease inhibitor a ¡-antiprotease ([134] , [135]). The elastolytic enzyme activity of alveolar macrophages (possibly a cathepsin B) is poorly inhibited by the natural protease inhibitors of serum, whereas that of neutrophils is well inhibited ([136]). This suggests that macrophages of the lung may be more important in elastin degradation than neutrophils.

Numerous environmental agents can alter alveolar macrophage function ([137]). Cigarette smoke is one of the most important toxins to which alveolar macrophages are exposed and contains many materials in the particulate and vapor phases. Smokers have increased numbers of alveolar macrophages ([124] , [138]), and cells from smokers show several abnormalities. They are slightly larger in diameter than those from nonsmokers and contain variable numbers of inclusions ([124] , [139]), such as electron dense areas, lipid vacuoles, and “needlelike” and “fiberlike” structures. The needlelike structures may represent ingested kaolinite or aluminum silicate from the cigarettes ([140]). Cells from smokers spread more on glass and have more lamellipodia and filipodia than those of nonsmokers ([124]). The smokers' cells contain higher levels of elastase and lysosomal enzymes, and these enzymes are released more completely from smokers' cells either spontaneously or in response to cigarette smoke ([124]). These enzymes are important in the pathogenesis of pulmonary emphysema. Alveolar macrophages from smokers also have impaired synthesis of RNA and protein ([141]), increased glucose utilization ([142]), increased hydrogen peroxide production, increased hexose monophosphate shunt activity, and reduced levels of glutathione peroxidase ([124]). *In vitro* cigarette smoke exposure in high amounts impairs various functions of macrophages ([124]). Also, alveolar macrophages contain the enzyme aryl hydrocarbon hydroxylase, and it is increased in macrophages from smokers ([125] , [143]). This enzyme transforms carcinogenic, polycyclic aromatic hydrocarbons into less dangerous hydrophilic compounds. There may be a relationship between the inducibility of this enzyme and the susceptibility to lung cancer ([144]).

Pulmonary macrophages are important in specific immunologic reactions because of their processing of inhaled antigens and interactions with lymphocytes ([124]). Alveolar macrophages can produce IL-1 ([145]), interferon (IFN)-a and -? ([146] , [147]), chemotactic substances ([148]), and CSFs ([149]). IL-1, with its multiple effects, may be important in many different physiologic and pathologic conditions in the lungs ([47]). IL-1 is a mitogen for fibroblasts. Alveolar macrophages interacting with silica or asbestos have been noted to contain or secrete a factor(s) that enhances fibroblast proliferation and collagen synthesis ([150] , [151] and [152]), suggesting that IL-1 may play a role in the fibrosis seen in humans with silicosis and asbestosis. Chemokines produced by macrophages may also be important in the pathogenesis of fibrotic lung disease ([153]).

Splenic Macrophages

Splenic macrophages are present both in the red and the white pulp ([121]). The red pulp is composed almost exclusively of macrophages involved in the phagocytosis and destruction of blood cells. Although the precise routes and dynamics of cellular movement within and through the spleen are not fully understood, red pulp macrophages apparently emigrate there through the fenestrations of the basement membranes of the splenic sinuses and, occasionally, can be seen extending their pseudopods through these fenestrations, possibly interacting with blood elements ([154]). The red pulp has the densest concentration of the macrophage antigen F4/80 found in the mouse ([155]). In the white pulp, the macrophages are much less frequent and are found in the germinal centers, where, occasionally, they are seen phagocytizing lymphocytes ([156]). White pulp macrophages are presumably involved in antigen processing and generation of the immune response. Splenic macrophages measure 17 to 50 µm in diameter and contain more RER and Golgi zone than blood monocytes ([156]). Red pulp macrophages contain numerous inclusions, including phagocytized erythrocytes, neutrophils, eosinophils, and platelets ([154] , [157]). In hemolytic anemias and immune thrombocytopenias, an increased amount of phagocytized debris is present; occasionally, the macrophages appear as “sea-blue histiocytes” with the endocytized cellular membranes converted to ceroid ([158]). Splenic macrophages have receptors for the Fc portion of IgG and for C' ([159] , [160]), express antigens typical of other mononuclear phagocytes at other sites ([155] , [160]), and contain ferritin and hemosiderin ([154]).

Bowel Macrophages

Using immunohistochemical techniques, researchers demonstrated numerous macrophages bearing the macrophage-specific antigen F4/80 in the lamina propria throughout the gastrointestinal tract ([161]). Many of the labeled cells are spread along the base of the epithelial cells, apparently underlying the basement membrane. In the small intestine, the macrophages extend to the epithelium of the crypts. Some of the macrophage antigen-positive cells are associated with capillaries or with numerous lymphocytes and plasma cells in the lamina propria ([161]). The cortical areas of the gut-associated lymphoid areas contain very few of the antigen-positive macrophages ([155]). There are very few of the macrophages in the Peyer patches, but there are macrophages in the dome epithelium of the Peyer patch ([155] , [162]).

In addition to immunohistochemical means of detection, bowel macrophages are recognizable by observing ingestion of carbon particles, PAS staining, and cytochemical stains for acid phosphatase. By electron microscopy, bowel macrophages are often located adjacent to blood vessels or in close association with plasma cells in the lamina propria. They have large lysosomes, phagosomes, and electron-dense inclusions ([163]). Mitoses are rarely seen ([162]).

The role of intestinal macrophages in physiologic and pathologic conditions is not fully understood. Gut-associated macrophages probably play a role in the development of an immune response to absorbed antigens, in suppressing immune responses, or in developing immune tolerance ([162]). The cells may be important in phagocytizing bacteria and cell debris. Sequestration of waste material in macrophages and then shedding these macrophages into the intestinal lumen may serve as a mechanism for eliminating accumulated or dead intestinal wall material ([162]). Likewise, iron-laden macrophages are shed from the villi into the gut lumen in patients with iron overload ([164] , [165]). In the obligate sanguivore vampire bat, the bowel apparently plays a large role in the elimination of excess body iron; iron-laden macrophages migrate there and desquamate into the stool ([166]). We do not know if this excretory system for iron is important in humans.

Intestinal macrophages are involved in diseases affecting the bowel. Various investigators have postulated that macrophage-secreted proteases [including acid hydrolases, elastases, and collagenases ([69] , [167])] may injure the bowel in conditions such as Crohn disease in humans and in experimentally induced cecal inflammation in guinea pigs ([162] , [168]). In inflammatory bowel disease, there is an increase in the mucosal macrophage population derived from circulating monocytes. These macrophages contribute to inflammation by secreting cytokines such as IL-1, IL-6, IL-8, IL-12, IL-18, and tumor necrosis factor (TNF) ([169]). They also generate reactive oxygen and nitrogen species, molecules with proinflammatory properties. Elevated bowel lumen NO and increased expression of NOS2 have been noted with various inflammatory bowel disorders ([170]). These include celiac disease ([171] , [172] and [173]), ulcerative colitis ([174]), and inflammatory bowel disease ([175]). IL-10 generally serves as a deactivator of macrophage function, and mice with genetically disrupted IL-10 gene have overactive bowel macrophages and an inflammation of the bowel comparable to that seen in humans with inflammatory bowel disease ([176]). Lysozyme, an enzyme found in highest concentrations in macrophages, is elevated in stool and intestinal mucus in humans with bowel inflammation ([177]). Serum lysozyme is elevated in patients with Crohn disease ([178]) and in other types of inflammatory bowel disease ([179]). Granulomas seen in Crohn disease and in intestinal tuberculosis are composed of monocytes/macrophages, together with lymphocytes and plasma cells ([180] , [181] and [182]). Fibrosis, which accompanies these disorders, may be caused, in part, by proliferation of local fibroblasts stimulated by macrophage-derived fibroblast growth factors, such as IL-1 ([47]).

Using epidemiologic and linkage studies, a susceptibility locus for inflammatory bowel disease has mapped to chromosome 16. Mutations in a gene at this location (Nod2) have been discovered in patients with Crohn disease. Nod2, a monocyte/macrophage-specific protein ([185]), is involved in activation of NF-?B and regulation of apoptosis. Subjects with variant Nod2 have a dramatically increased likelihood of developing Crohn disease (but not ulcerative colitis) ([183] , [184]).

Whipple disease, a multisystem disease caused by an infection with an unusual and fastidious microorganism, is characterized by an accumulation of epithelioid macrophages in various organs, prominently including the bowel wall ([186]). The macrophages contain PAS-positive material. The causative organism, *Tropheryma whippelii*, has been identified by polymerase chain reaction studies of nucleic acid from involved tissues ([187] , [188]). The organism is very difficult to culture *in vitro*, but by incubating blood mononuclear cells with the monocyte “deactivating” cytokine IL-4, researchers are able to grow *T. whippelii* in blood monocytes in tissue culture (

[189], [190]). The organism can also be grown *in vitro* in fibroblasts under certain conditions. Practical laboratory diagnosis is based on identifying typical PAS-positive macrophages in affected tissues and demonstration of *T. whippelii* nucleic acid in blood leukocytes or affected tissues using polymerase chain reaction amplification and possibly by use of specific tests using antiorganism antibody or *in situ* hybridization using specific nucleic acid probes ([190], [191]).

Skin Macrophages (Langerhans Cells)

The mononuclear phagocytes of the skin are called *Langerhans cells* ([192]). Not easily seen in routine stains, these cells must be stained with metal salts such as gold chloride, with cytochemical stains, or with immunohistochemical stains ([192], [193] and [194]). Langerhans cells have a relatively clear cytoplasm, a lobulated nucleus without organelles characteristic of keratinocytes and melanocytes, and a unique cytoplasmic granule, the *Birbeck granule* ([192], [195]) (Fig. 13.8). The tennis racket–shaped granules are seen only by electron microscopy and may measure 0.8 to 2.0 µm in length. The origin and function of these granules are unknown.

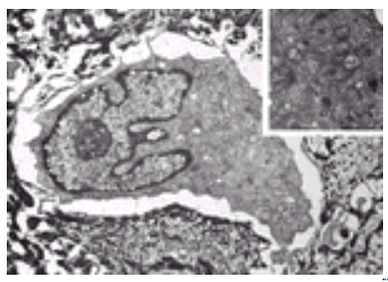

Figure 13.8. Electron micrograph of a Langerhans cell from the skin of a normal human. The cell displays a lobulated nucleus and numerous cytoplasmic Langerhans ("Birbeck") granules. The inset shows a higher power view of several of the granules. ×25,000. (Photograph courtesy of Dr. John Shelburne.)

Langerhans cells make up 3 to 8% of the epidermal cells ([196]). They are of bone marrow origin ([197]) but can proliferate locally as well ([198]). Reticular dysgenesis is a rare inherited immunodeficiency characterized by lack of blood monocytes and neutrophils and low lymphocyte numbers (despite normal erythrocyte and platelet counts). These patients have normal skin macrophages but absent Langerhans cells ([199]). After bone marrow transplant therapy, the Langerhans cells return. Langerhans cells have receptors for the Fc portion of IgG and for C3 ([200], [201]) and express the MHC class II antigens [immune-associated (Ia) in mice and HLA-DR in humans] ([192], [202]). The cells express a macrophage-related antigen recognized by monoclonal antibody F4/80 ([161]) and the CD1a antigen ([203]). CD1a is not expressed on normal blood monocytes, but it is found on intrathymic thymocytes. Langerhans cells contain no peroxidase, but adenosine triphosphatase activity is present. They adhere to glass and have some pinocytic and phagocytic activity but much less than macrophages from other areas ([192]).

The primary function of Langerhans cells is to serve as antigen-presenting cells ([204]). In this respect, they are closely related to the marginal zone macrophages, the follicular DC, the medullary macrophages, and interdigitating cells of the T-cell areas of lymph nodes ([192], [204]). There is a strong correlation between the expression of MHC class II antigen and the ability to serve as an accessory cell. Langerhans cells synthesize and express large amounts of MHC class II antigen and are seen in apposition to lymphocytes at sites of allergic contact dermatitis, suggesting an important role in contact (delayed) hypersensitivity ([205], [206]). Langerhans cells can also acquire antigen in the skin and carry it to regional lymph nodes, where they are sometimes seen as "veiled" cells ([192]). Langerhans cells are probably also involved in rejection of skin allografts, and there is some evidence that they aid in the differentiation (keratinization) of epidermal cells by an unknown mechanism ([207]).

Langerhans cells are involved in various disease states. As discussed above, they participate in allergic contact dermatitis reactions. In histiocytosis X (or so-called Langerhans cell granuloma), there is an accumulation of these cells in various areas of the body ([208]). Histologically, this does not appear to be a malignant condition ([209], [210]). The cells in this condition have the Birbeck granules, express Fc and C3 receptors, and have more phagocytic capability than normal Langerhans cells ([208]).

Liver Macrophages (Kupffer Cells)

A large portion of the body's mononuclear phagocytes resides in the liver ([96], [121]). Liver macrophages (or Kupffer cells) are the phagocytes of the liver sinusoidal walls ([211]). They lie on the endothelial cells or are embedded in the endothelial lining and may extend into the Disse space. Kupffer cells are also in close contact with other liver cells, including fat-storing cells and pit cells, as well as reticulin fibers. By scanning electron microscopy, they have microvilli and occasional lamellipodia. The cells have slightly irregular oval nuclei, small mitochondria, and numerous endocytic vacuoles. They contain "wormlike structures," apparently unique internal structures consisting of internalized membrane with a thick coat of membrane material ([212], [213]). By transmission electron microscopy, the external membrane has a thick, fuzzy coat. Kupffer cells contain peroxidase in the endoplasmic reticulum, whereas liver endothelial cells contain no peroxidase ([211]).

Kupffer cells play important roles in liver injury and in various disorders ([214]). In their critical position along the sinusoidal wall, they phagocytize different bloodborne particles. These include injected experimental particles such as carbon and latex, liposomes, bacteria ([215]), parasites ([216]), viruses ([217]), and altered or opsonized erythrocytes ([157], [218]). They efficiently remove portal blood bacteria that come from the gut ([215]). Furthermore, they are important in clearing endotoxin from the blood passing through the liver ([219]). Kupffer cells can produce IL-1, TNF, arachidonic acid catabolites, reactive oxygen species (ROS), and reactive nitrogen species and alter the functions of hepatocytes ([214], [220]). These alterations range from subtle Kupffer cell–mediated changes to marked hepatocyte injury. Kupffer cells can regulate hepatocyte general protein and fibrinogen synthesis ([221]) and cytochrome P-450 drug transformation reactions ([222]). Bacteria and endotoxin cause an increase in the membrane microvilli and an increase in the levels of certain lysosomal enzymes ([213]). Kupffer cells may play a role in eliminating fibrin and fibrin degradation products from blood; in disseminated intravascular coagulation, this capability is depressed ([223]).

Phagocytosis by the macrophages in the liver is mediated by Kupffer cell Fc or CRs ([159], [224], [225] and [226]). Antibody opsonization of various particles dramatically enhances their removal from the circulation by these liver cells ([211]). The Kupffer cells recognize erythrocytes that have been injured or aged *in vitro* ([218]) or that have been treated with neuraminidase ([227]). The cells have receptors for *N*-acetylglucosamine ([228]). Plasma fibronectin also acts as a particle opsonin recognized by Kupffer cells ([229]). Murine Kupffer cells synthesize and secrete fibronectin, C' factor B, and apolipoprotein E ([230]). They also display MHC class II antigen and the macrophage antigen F4/80, but they lack the Mac-1 antigen ([230]).

Kupffer cells can serve as accessory cells in presenting antigens to and stimulating DNA synthesis in T lymphocytes ([231], [232]). This interaction, like that involving macrophages from other sites, is genetically restricted ([232]). Kupffer cells from normal animals are cytostatic for tumor cells ([233]), and those from animals injected with *Corynebacterium parvum* are cytolytic for tumor cells ([234]). In mice, unlike peritoneal macrophages, Kupffer cells produce hydrogen peroxide very poorly in response to phagocytosis or soluble stimuli ([230]). IFN-?, which enhances capacity for peroxide production in peritoneal macrophages and blood monocytes, has no such effect on Kupffer cells ([230]). Kupffer cells are not very effective in *in vitro* killing of *Toxoplasma gondii* trophozoites and *Leishmania donovani* promastigotes and amastigotes, and IFN-? does not enhance this cytotoxicity ([230]). IFN-? does, however, increase the expression of MHC class II antigen in murine Kupffer cells. In experimental sublethal infection of mice with *Listeria monocytogenes*, there is an influx of immigrant macrophages into the liver ([230]). These newly immigrated liver macrophages, unlike the Kupffer cells, are able to produce substantial amounts of peroxide and display significant antimicrobial effect ([230]).

Kupffer cells, like hepatocytes, can produce large amounts of NO, and this can have profound effects on hepatocyte function and liver homeostasis in general ([220]). NO is responsible for many Kupffer cell–mediated effects on hepatocytes. These include alteration of hepatocyte total protein synthesis, decreased glycolysis, decreased glyceraldehyde-3-phosphate dehydrogenase activity, increased cellular cyclic guanosine monophosphate content, decreased cytochrome P-450 activity, decreased mitochondrial respiration, and tumor cell cytostasis. In microbial sepsis and endotoxemia, there is an increase in hepatic production of IL-1 and TNF, as well as an increase in NO production. Although the NO likely mediates the vasodilation and hypotension and has the potential for toxic effects on hepatocytes, experiments in sepsis models using mice have shown that inhibition of NO production by administration of L-arginine analogs causes an accentuation of hepatic necrosis ([220], [235]). Part of this accentuated toxicity may be caused by worsening of thrombosis and coagulative necrosis.

Brain Macrophages (Microglial Cells)

Investigators in the early 1900s noted special-appearing cells in brain prepared by silver impregnation staining methods ([236]). These cells have been called *microglial cells*, *gitter cells*, and *rod cells* ([237]). Although early workers postulated that these microglial cells were a type of brain macrophage ([236] , [237] and [238]), only recently have studies given unambiguous evidence of this ([239] , [240]). Using immunohistochemical techniques, researchers have shown that cells with the typical appearance of microglial cells display the macrophage-specific antigen F4/80, the FcR for IgG1/IgG2b, and the myelomonocytic antigen Mac-1 ([240]). In the adult mouse, there are two distinct populations of brain cells bearing the macrophage antigens. Round monocytelike cells with short processes associated with the choroid plexus, ventricles, and leptomeninges measure approximately 10 μm in diameter. More typical microglial cells have little cytoplasm but long processes. The body of the latter cell measures approximately 5 to 7 μm in diameter, and the processes extend up to 40 μm from the body ([240]). Most of the microglial cells are in the gray matter. By electron microscopy, the nucleus is irregularly shaped with unevenly distributed nuclear chromatin. The cytoplasm has elongated cisternae of endoplasmic reticulum, and the long processes themselves contain few organelles. Mitochondria are present in moderate numbers. Lysosomes, endocytic vacuoles, and internalized lipid material are seen in the cells. The cells can internalize erythrocytes and carbon particles, and they contain nonspecific esterase. With injury or inflammation, there is a dramatic increase in the number of microglial cells ([237] , [241]).

Information from experiments using chimera and labeled monocytes strongly suggests that microglial cells are derived from circulating blood monocytes ([237] , [242] , [243]). Dying neurons likely act as a chemotactic stimulus for monocytes to migrate into the area and differentiate into microglial cells ([239] , [240]). In developing mouse retina, degenerating neurons can be observed, and macrophages migrate from the blood vessels overlying the developing retina, phagocytize the dying neurons, and then develop into F4/80+ microglial cells ([239]). In the brain gray matter, the microglial cells are seen in highest concentrations around vessels and around degenerating, pyknotic cells ([237] , [240]). During development in the mouse, macrophages invade the brain and can be followed through a series of transitional forms as they differentiate to become microglial cells. Apparently, the programmed neuronal cell death that accompanies brain maturation acts as a stimulus to attract monocytes ([240]).

Brain macrophages are frequently infected with human immunodeficiency virus 1 (HIV-1) in subjects with HIV-1 infection or acquired immunodeficiency syndrome. Infected blood monocytes can emigrate into the brain carrying HIV-1 with them and then differentiate and reside in the central nervous system. This “Trojan horse” introduction of the virus is apparently the primary method of infection ([244]). Also, brain macrophages and microglial cells express the HIV-1 receptors/co-receptors CD4, chemokine receptor 3 (CCR3), CCR5, and CXCR4. Products of infected macrophages may directly injure and kill neurons; candidate neurotoxins from macrophages include NO, platelet-activating factor, kynurenine metabolites, and proinflammatory cytokines ([244]).

The function of brain mononuclear phagocytes is not fully known. They phagocytize dying neurons and their processes, debris, and foreign material ([237] , [238]). Although no experimental evidence has been presented, they probably also play a role in the induction of immune responses, in mediating antimicrobial and antitumor effects, and possibly in modulating neuronal cell function. Brain macrophages may function to prevent excessive inflammatory responses by controlling T-lymphocyte responses through the inhibition of T-lymphocyte proliferation and, in some cases, by inducing T-lymphocyte anergy ([245]).

Peritoneal Macrophages

Much of the work with mononuclear phagocytes in experimental animals has been done with peritoneal macrophages because they can be conveniently obtained in adequate numbers and cultured. Peritoneal macrophages differ morphologically from their precursor blood monocytes. They measure 15 to 45 μm in diameter, adhere avidly to glass or plastic substrates, and frequently manifest vacuolated cytoplasm. Human studies have primarily used cells from women undergoing elective laparoscopy or laparotomy ([246] , [247] , [248] , [249] and [250]), patients with indwelling catheters immediately after operative placement or patients undergoing chronic dialysis with indwelling peritoneal catheters ([251] , [252]), or patients with benign or malignant ascites ([251]). The cell population from normal women is composed of 85 to 95% macrophages; the remainder are lymphocytes ([246] , [247] and [248]). The macrophages are heterogeneous, with some resembling blood monocytes morphologically, but most looking more like tissue macrophages ([246]). There are approximately 2 to 5 × 10^{6} peritoneal macrophages in a normal woman ([247] , [248] and [249]). The number varies during the menstrual cycle, with the highest numbers near the time of menstruation; retrograde menstruation may cause this increase ([248]). Women with endometriosis have increased numbers of peritoneal macrophages ([247] , [248] and [249] , [253]). These peritoneal macrophages in endometriosis are activated as judged by a number of parameters, including increased expression of NOS2 and increased ability to produce NO ([254]).

Peritoneal macrophages are peroxidase negative, have Fc and C' receptors (CRs), and are heterogeneous with respect to cytochemistry and phagocytic ability ([247] , [250] , [252] , [255]). Hydrogen peroxide and superoxide production in response to phorbol myristate acetate is comparable to that of blood monocytes ([256]). Peritoneal macrophages are capable of killing tumor cells and bacteria ([251] , [252] , [256]), and, in general, are more effective in killing tumor cells than are blood monocytes ([256]). The number of peritoneal macrophages in patients with acute inflammatory peritonitis or with malignant ascites is elevated ([251]). However, the functional capabilities in comparison to resident normal peritoneal macrophages are not known.

Renal Macrophages

Although inconspicuous on routine hematoxylin- and eosin-stained sections, kidneys contain a large number of macrophages ([121] , [257]). They are of bone marrow origin, are phagocytic, bear Fc and CRs, express MHC class II antigen, stain positively for nonspecific esterase, and adhere to plastic or glass substrate. The highest concentration of macrophages is in the medullary interstitial cell population, where they cover much of the outer surfaces of the collecting tubules ([155]). Macrophages are also seen in close proximity to the macula densa and afferent and efferent arterioles of the glomerular capillary bed, as well as around Bowman capsule ([155]). The glomerular mesangium of normal animals usually does not contain cells typical of mononuclear phagocytes ([258] , [259]).

In conditions of glomerular injury, however, there is an influx of monocytes into the glomerulus. This is especially prominent in disorders characterized by crescent formation, in which macrophages constitute up to 50% of the cells in the crescent ([260]). IL-1, TNF, and IL-6 may contribute to the inflammation noted in glomerulonephritis ([260]). IL-1 secreted by the mononuclear phagocytes may play a role in the glomerular cell proliferation seen in these disorders ([47] , [261] , [262]). Mice that develop a spontaneous disease similar to human systemic lupus erythematosus overexpress NOS2 and overproduce NO. Blocking the NOS *in vivo* with an L-arginine analog prevents development of arthritis and nephritis ([263]). In humans with lupus nephritis or IgA nephropathy, there is an increased expression of NOS2 that correlates with the severity of disease ([264]).

Milk Macrophages

There are a large number of mononuclear phagocytes in human colostrum and milk, and these macrophages can be transferred from mother to nursing baby. There are from 0.2 to 21.0 × 10^{6} cells/ml milk ([265] , [266]). Approximately 40% of milk leukocytes are nonspecific esterase-positive macrophages capable of adhering to plastic or glass substrate ([265]). These cells have Fc and CRs, are able to mediate cytostasis and cytolysis of tumor cells ([265] , [266] and [267]), and can phagocytize and kill bacteria ([268]). They can also modulate the mitogenic activity of lymphocytes ([269]). Breast milk macrophages (unlike blood monocytes) spontaneously produce GM-CSF in *in vitro* culture and differentiate to DC after treatment with IL-4 alone ([270]). Milk macrophages express high levels of CD86, CD40, and HLA-DR, but they do not express CD1a, a molecule characteristic of DC. CD83, a molecule usually found in DC, is expressed by milk macrophages but not by blood monocytes ([270]). Also, unlike blood monocytes, milk macrophages express the molecule “DC–specific intracellular adhesion molecule-3–grabbing nonintegrin” (DC-SIGN). DC-SIGN is generally a DC–specific lectin that mediates interactions with a variety of particles, including HIV-1 ([270]). DC-SIGN expression in milk macrophages could be important in the vertical transmission of HIV-1.

Reproductive Tract Macrophages

The testis contains large numbers throughout the interstitium ([271] , [272]). The cells adhere to glass or plastic, bear Fc and CRs, and express MHC class II antigen and nonspecific esterase activity. Testicular macrophages display F4/80, CD11b, CD11c, CD13, CD14, and CD68. The cells can produce cytokines typical of mononuclear phagocytes (e.g., IL-1 and TNF). Also, they phagocytize sperm in the seminiferous tubules and vas def-erens ([273]) and are believed to be important in

eliminating unejaculated, dying sperm ([273] , [274]). They can phagocytize bacteria ([275]), participate in the destruction and elimination of invading organisms ([276]), and participate in the formation of “sperm granulomas” seen occasionally in men who have had vasectomies ([277]). Because of their location and the presence of MHC class II antigen on their surfaces, some have speculated that testicular macrophages are important in the induction of immunity against antigens (including sperm antigens) ([277]). In a group of men with infertility of various causes, testicular macrophages were more prominent in the tubular wall and tubular lumen (compared to those with other types of infertility and to fertile men), and in those with germ cell arrest and Sertoli only causation, the numbers of macrophages were increased in number by twofold ([278]). This suggests that the testicular macrophages may adversely affect fertility in certain situations. Macrophage function can be modified by sex hormones, and macrophages can modulate sex hormone production ([275] , [279] , [280]). Apparently, macrophages can synthesize testosterone ([280]). Testicular macrophages express the HIV-1 receptors CD4, CCR5, and CXCR4 (but not CCR3) ([281]). This indicates that these macrophages can be infected with HIV-1 and possibly play a role in HIV-1 transmission.

The ovary contains macrophages that phagocytize degenerating luteal cells during normal estrus, postpartum luteolysis, and follicle atresia ([271] , [282]). These mononuclear phagocytes have the usual characteristics of tissue macrophages—FcRs, ability to ingest latex spheres, tight adherence to plastic substrate, and nonspecific esterase activity ([282]). Macrophages isolated from mouse corpora lutea enhance progesterone production by ovarian cells. It is likely that intraovarian macrophages play a role in maintaining progesterone secretion by luteal cells *in vivo* ([282]).

The number of macrophages in the body of the uterus is increased immediately after insemination ([283]), in the presence of intrauterine contraceptive devices ([284] , [285] and [286]), and during pregnancy ([287] , [288]). Intrauterine devices are seen to be coated with macrophages, and these inflammatory macrophages may play a part in damaging the gametes or zygote and preventing implantation ([284] , [285] and [286]). Uterine macrophages are frequently seen phagocytizing sperm ([283]). In mice, macrophages constitute 10 and 22% of uterine cells from normal and pregnant mice, respectively ([288]). These macrophages represent a large part of the uterine decidua during pregnancy (up to 10 to 20% of the total number of uterine cells). A large proportion of uterine macrophages in pregnancy are MHC class II antigen– or CD54-positive, suggesting that they may be activated in some fashion ([288] , [289]). Uterine macrophages (many expressing NOS2) increase as pregnancy progresses, but there is a decline in endometrial macrophage numbers at least 1 day before onset of parturition ([289] , [290]). Because NOS2-derived NO exerts a relaxing effect on uterine smooth muscle and promotes uterine quiescence, some have suggested that the decrease in macrophages just before delivery results in a decrease in this general inhibitory effect on uterine contractility ([289]). Decidual macrophages produce NO; NO elaborated by activated decidual macrophages may be an effector molecule in mediating early embryo loss in spontaneous abortion ([291]).

Oviducts contain a few typical macrophages that, based on analysis of women with oviducts blocked either proximally or distally, arise from migration of peritoneal macrophages through the fimbrial openings ([292]). The number of macrophages in these sites reflects the number in the peritoneum. Oviductal macrophages may interfere with fertilization by injuring or phagocytizing normal or antibody-opsonized sperm ([249] , [292] , [293]).

Mice with a genetically disrupted M-CSF gene have reduced fertility ([294]). Homozygous M-CSF $^{-/-}$ mice have markedly reduced numbers of testicular and ovarian macrophages that accompany their reduced fertility. Males have reduced numbers of sperm and decreased libido, and females have extended estrous cycles and poor ovulation rates. However, the major reproduction defect appears to be a defective feedback regulation of the hypothalamic-pituitary-gonadal axis, suggesting that defects in brain macrophages (microglial cells) contribute to the problem. Also, it is likely that there is abnormal macrophage-influenced function of steroidogenic cells, such as Leydig cells in males and corpus luteal cells in females ([294]).

Bone Macrophages (Osteoclasts)

Osteoclasts are specialized multinucleated cells found in bone that mediate bone resorption ([295] , [296] and [297]). They form from circulating hematopoietic cells of bone marrow origin ([295] , [298]). Because of their morphologic similarity to inflammatory multinucleated giant cells, investigators have postulated that they are formed from emigrated blood monocytes ([103] , [295] , [296] , [298]). Blood monocytes and peritoneal macrophages can degrade bone *in vitro* ([299] , [300]). In murine systems, bone-degrading ability relates to the degree of macrophage multinuclearity ([299]). In osteopetrosis, there is an inability to produce M-CSF with a resultant defect in osteoclast function ([20] , [301] , [302] and [303]). Some studies have provided evidence that osteoclasts may be derived from a hematopoietic cell that is different from monocytes/macrophages ([304]). Osteoclasts, but not mononuclear phagocytes, respond to calcitonin ([305]), isolated osteoclasts do not express most antigens characteristic of mononuclear phagocytes ([306]), osteoclasts do not have the macrophage antigen F4/80 ([298]), and monoclonal antiosteoclast antibodies do not react with mononuclear phagocytes ([307]). Nevertheless, it is likely that the osteoclast represents a highly differentiated mononuclear phagocyte that simply differs in these respects.

Osteoclasts lack certain antigens usually noted on macrophages (e.g., Fc and C3 receptors), but they express high levels of tartrate-resistant acid phosphatase, the vitronectin receptor, and calcitonin receptors ([26]). Several factors have been discovered that enhance osteoclast formation *in vitro*. These include 1,25 dihydroxyvitamin D_3, prostaglandin E_2, IL-1, IL-11, TNF, and glucocorticoids. These factors work through induction of OPGL (identical to TNF-related activation-induced cytokine) in osteoblasts. OPGL, in turn, binds to the receptor activator of NF-?B on osteoclast precursors, and, in the presence of M-CSF, the osteoclast precursors develop into mature osteoclasts. OPG is a soluble decoy receptor for OGGL that serves to inhibit osteoclast formation and differentiation ([26] , [308]). Tumor growth factor (TGF)–ß increases the proportion of precursors that become osteoclasts, and it is an essential co-stimulator of osteoclast formation. Research using mice with disruption of various genes has been very helpful in understanding the control of osteoclast formation and function and bone resorption. Mice with disruptions of M-CSF, C-src, C-fos, NF-?B, OPGL, and receptor activator of NF-?B have osteopetrosis, whereas those with disrupted OPG have osteoporosis ([26]).

Granuloma Macrophages

A *granuloma* is defined as “…a compact, organized collection of mononuclear phagocytes (macrophages or epithelioid cells), which may or may not be accompanied by accessory features such as necrosis or the infiltration of other inflammatory leukocytes” ([309]). Granulomas are characteristic of host responses to many different living and nonliving agents ([119] , [310] , [311]). In general, they form as reactions to particulate or indigestible agents that persist in tissues for long periods of time. Cells of granulomas serve both protective and destructive functions for the host. They protect by killing microbial agents and, possibly, tumor cells, by processing antigen, and by interacting with lymphocytes. But they also cause destruction and fibrosis of adjacent normal tissues ([119] , [309] , [312]). Multinucleated giant macrophages are prominent features of these granulomas. Multinucleated macrophages form by a process of cellular fusion of uninuclear monocytes or macrophages ([119] , [311] , [313]). Cytokines, growth factors, and dihydroxyvitamin D_3, as well as fusion proteins of viruses (including HIV-1) are important in inducing this fusion process ([119] , [311] , [313] , [314]). IFN-?, IL-3, IL-4, and GM-CSF can induce the fusion of monocytes or macrophages to form cells *in vitro* resembling those seen in human granulomas ([313] , [315] , [316] , [317] , [318] and [319]). TNF may be important in these *in vitro* processes ([320]).

Granulomatous inflammation *in vivo* is characterized by heterogeneous responses controlled by inciting antigens and different cytokines, with Th1-type (e.g., IL-2 and IFN-?) or Th2-type cytokines (e.g., IL-4 and IL-10) influencing patterns of responses. The specific cytokines involved in granulomatous inflammation vary with the inciting organisms/antigens. IFN-?, IL-1, and TNF generally serve to enhance granulomatous inflammation associated with mycobacteria (Th1 type), whereas in those associated with schistosomiasis, IL-4 and IL-10 enhance granulomatous inflammation (Th2 type) ([320] , [321] , [322] and [323]). In studies of mice with either Th1- (induced with mycobacterial purified protein derivative on plastic beads) or Th2- (induced with Schistosoma mansoni egg antigens on plastic beads) antigens, there are differing patterns of chemokine responses ([324]). Of 24 different chemokines analyzed, there were characteristic profiles for Th1- and Th2-type responses that appeared to be controlled by certain cytokines. NOS2 is noted in induced granulomas, indicating that NO may play a role in the inflammation ([325] , [326]), and NOS2-derived NO regulates the size, quantity, and quality of granulomas in *Mycobacterium avium*–infected mice ([327]).

There is increased expression of osteopontin in granulomas, and osteopontin is absolutely required for granuloma formation ([328] , [329]). Osteopontin is a secreted soluble cytokine that influences migration of mononuclear phagocytes and T lymphocytes. Osteopontin deficiency in mice is associated with impaired resistance to herpes simplex virus, *Listeria monocyto-genes*, and mycobacterial infection ([328] , [329]), and relatively low-level osteopontin in tissues in humans is associated with poorly formed granulomas, lack of multinucleated giant cells in granuloma, and impaired resistance to infection with *Mycobacterium bovis* (bacillus Calmette-Guérin) ([329] , [330]). Secreted lymphotoxin (LT-a3; also known as *TNF*-ß) is also required for granuloma formation and for control of mycobacterial infection, whereas membrane-bound LT-ß does not ([331]). Although LT-ß is required for lymph node formation, absence of LT-ß does not in itself modify granuloma formation. Lung inflammatory lesions that develop in LT-a–deficient mice show absence of macrophages and multinucleated giant cells and increased numbers of neutrophils.

Generally, however, LT-a–deficient mice have normal T-cell and macrophage function ([331]). In transparent zebrafish, infection of the embryo with mycobacteria at a stage before lymphocyte development results in macrophage aggregates with hallmarks of granuloma ([51]). These studies indicate that granuloma formation is possible in the context of “innate” immunity.

The functions of multinucleated macrophages are not precisely known. They differ from mononuclear phagocytes in several ways—namely, diminished ability to phagocytize particles and to reduce nitroblue tetrazolium, diminished expression of 5' nucleotidase, and reduced expression of various mononuclear phagocyte antigens ([310] , [332]). Fusing macrophages express a unique surface molecule that may be involved in the fusion process ([333]). Multinucleated macrophages can also kill tumor cells ([334] , [335]). The lifespan of multinucleated macrophages is believed to be shorter than that of other tissue macrophages ([119]).

Synovial Macrophages

Synovial type A cells are macrophages. These cells are phagocytic, have FcRs, express MHC class II antigen and nonspecific esterase activity, are of bone marrow origin, and look like mononuclear phagocytes on light and electron microscopy ([104]). In inflammatory arthritides such as rheumatoid arthritis (RA), there are increased numbers of synovial tissue macrophages ([336]), and the numbers of synovial macrophages correlate well with the degree of articular destruction ([337]). Macrophages play a critical role in the initiation and propagation of arthritis; they participate in antigen presentation, regulation of T- and B-lymphocyte activity, secretion of proteases, production of proinflammatory cytokines and arachidonic acid derivatives, and generation of reactive oxygen and nitrogen species ([336]). Humans with RA have accelerated generation of mononuclear phagocytes by bone marrow cells ([338]). Elimination of macrophages in rat models of arthritis ameliorates the arthritis ([339]). Evidence points toward proteases ([336]), ROS ([340]), and reactive species such as NO and peroxynitrite ([263] , [341] , [342]) as the most important macrophage-derived effector molecules in arthritis.

MONONUCLEAR PHAGOCYTE ANTIGENS AND RECEPTORS

The plasma membrane is a dynamic structure in a constant state of change. The mouse macrophage, through endocytosis, completely internalizes the equivalent of its entire surface membrane area every 33 minutes ([343]). Accompanying this and other kinds of endocytosis, various surface membrane components are internalized and diminished in activity. These include 5' nucleotidase (CD73) ([344]) and the antigen F4/80 ([345]). This probably accounts for the reduced levels in activated macrophage cells that possess enhanced rates of endocytosis ([346]). The membrane lipids of macrophages influence membrane fluidity and can be altered by environmental conditions. For example, membrane cholesterol and phospholipids change after phagocytosis ([347]), and membrane fatty acid composition changes after incubation in medium with high levels of saturated fatty acids ([348]); these changes can alter the activities of the macrophages.

HLA

Several mononuclear phagocyte antigens have been identified with monoclonal antibodies ([349] , [350]). Antibodies against these antigens are of use in precisely identifying, separating, and isolating mononuclear phagocytes *in vitro*, in typing leukemias, and, potentially, in treating disorders such as transplant rejection, hemolytic anemias, immune thrombocytopenias, and malignancies of mononuclear phagocytes. Many of the antibodies recognize determinants expressed on other cell types, especially other myeloid cells, but some of the antibodies recognize antigens found only on mononuclear phagocytes. Many antigens on the surface of macrophages have been characterized. Antigens of the major histocompatibility complex are expressed by mononuclear phagocytes [class I or HLA-A, B, and C ([351]) as well as class II or HLA-D ([352] , [353])]. The expression of these antigens can be modulated by various factors, such as IFN-? ([352]). Some monoclonal antibodies discriminate between different classes of mononuclear phagocytes—for example, between normal mouse macrophages and those activated for tumor cell killing ([354] , [355]), between human mononuclear phagocytes isolated from different anatomic sites ([356] , [357] and [358]), between freshly isolated human blood monocytes and monocytes cultured for several days ([356] , [358]), and among different “subsets” of mononuclear phagocytes ([359]).

CD4 and Chemokine Receptors (Human Immunodeficiency Virus 1 “Receptors”)

The mononuclear phagocyte interacts with the environment through its receptors. Some ligands, such as glucocorticoids, diffuse through the membrane to interact with intracellular receptors, but most bind to plasma membrane receptors. Once a ligand binds to its receptor, the macrophage reacts in some way (e.g., by altering gene expression, inducing secretion, or changing shape). Table 13.3 lists some of the mononuclear phagocyte receptors. Although once believed to be exclusively a lymphocyte antigen, the CD4 (T4) molecule is also expressed on mononuclear phagocytes. CD4 is necessary for infection of these cells with HIV-1 ([360]). HIV-1 infection of lymphocytes leads to rapid death of the infected cells, but HIV-1–infected monocytes and macrophages persist in *in vitro* culture and *in vivo*, frequently forming multinucleated giant cells (syncytia) and serving as reservoirs for the virus ([360] , [361]). Different strains of HIV-1 preferentially infect different hematopoietic cells; these are broadly divided into *lymphocytotropic* (LCT) and *monocytotropic* (MCT) viruses. LCT strains infect normal T lymphocytes and T-cell line cells (but not mononuclear phagocytes), whereas MCT strains infect normal mononuclear phagocytes and normal T lymphocytes but not cell line cells ([361]). MCT strains are preferentially transmitted in new infections, despite an evolution of viruses to LCT from MCT strains over the course of infection in individuals ([362] , [363] and [364]). For LCT strains of HIV-1, the seven transmembrane–spanning receptor *fusin* is required (in addition to CD4) for fusion of bound virus and productive infection ([365]). For MCT strains (and primary HIV-1 isolates), a different seven transmembrane–spanning receptor, *CCR5*, serves as the major co-receptor for infection and cofactor for fusion ([366] , [367]). This molecule also serves as a receptor for regulated upon activation, normal T-cell expressed and secreted, macrophage inflammatory protein (MIP)-1a and MIP-1ß; these beta chemokines can inhibit HIV-1 infection of cells ([368]). Some people resist infection with HIV-1 despite repeated challenges. It appears that these individuals are resistant because they have a defect in CCR5 that renders their cells noninfectable by primary strains of HIV-1 ([369] , [370]). Furthermore, infected individuals who are heterozygotic for the mutant CCR5 have a slow progression of disease and prolonged life after infection ([371]). Approximately 1% and 10 to 15% of western Europeans are homozygotic and heterozygotic for the mutant gene, respectively, whereas very few (essentially zero) Africans have the mutation ([371]). DC, unique cells differentiated from monocytes, display the DC-SIGN (CD209) antigen. DC-SIGN, which can also be expressed by some macrophages, is a C-type lectin that serves as antigen receptor, recognizing pathogens through carbohydrates ([372]). It regulates DC trafficking, and it also binds HIV-1 and protects it in early endosomes, allowing HIV-1 transport by DC to lymphoid tissues where it enhances infection of permissive target cells ([372]). DC-SIGN also serves as the receptor for *Mycobacterium tuberculosis* on DC, using lipoarabinomannan as the ligand for binding ([373] , [374]).

TABLE 13.3. Mononuclear Phagocyte Receptors

Ig Fc receptors	IL, cytokine, and growth factor receptors
IgG receptor	IL-1 receptor (CD121)
Fc?RI receptor (CD64)	IL-3 receptor (CD123)
Fc?RII receptor (CD32)	IL-4 receptor (CD124)
Fc?RIIA receptor	IL-5 receptor (CD125)
Fc?RIIB receptor	IL-6 receptor a (CD126)
Fc?RIIC receptor	IL-10 receptor (CDw210)
Fc?RIII receptor (CD16)	IL-12 receptor (CD212)
Fc?RIIIA receptor (CD16a)	IL-13 receptor (CD213)
Fc?RIIIB receptor (CD16b)	Macrophage CSF receptor (CD115)
IgE receptor	
FceRI receptor	IFN-? receptor (CD119)
FceRII receptor (CD23)	IFN-a receptor (CD118)
FceRIIA receptor	TNFRs
FceRIIB receptor	p55 (TNFR1; CD120a)
IgA receptor	p75 (TNFR2; CD120b)
FcaR receptor (CD89)	Granulocyte CSF receptor (CD114)

CRs
CR1 (CD35)
CR3 (CD11b/CD18)
a $_2$-Macroglobulin receptor (CD91)
Mannose receptor (mannose-binding protein; CD206)

Dendritic cell–specific intercellular adhesion molecule-3–grabbing nonintegrin (CD209)

Transferrin receptor
Lactoferrin receptor
Urokinase plasminogen activator receptor (CD87)
Microbial component receptors
LPS/LPS-binding protein receptor (CD14)
TLRs
TLR2 (receptor for bacterial lipoprotein, peptidoglycan, lipoarabinomannan, zymosan)
TLR3 (receptor for double-stranded RNA and polyinosine/polycytosine)
TLR4 (receptor for bacterial LPS)
TLR5 (receptor for bacterial flagellin)
TLR6 (with TLR2, receptor for mycoplasma lipoprotein)
TLR9 (receptor for CpG-containing DNA)
Scavenger receptors (A–F)
Lipoprotein receptors
LDL-R
Modified LDL-R
“Remnant receptor”
Macrophage CSF receptor (CD115)
Granulocyte-macrophage CSF receptor (CD116)
Tumor growth factor–ß receptor (endoglin; CD105)
Chemotactic factor receptors
Chemotactic peptide receptor (e.g., formyl-methionine-leucine-phenyl-alanine)

Chemokine receptors (CXCR4, chemokine receptor 5)
C5a receptor (CD88)
Fibronectin receptors
Hormone receptors
1,25 dihydroxyvitamin D $_3$ receptor
Glucocorticoid receptor
Insulin receptor
Prostaglandin receptor

Glucagon receptor
Thyrotropin receptor
Somatomedin receptor
Testosterone receptor
Estrogen receptor
Nicotinic acetylcholine receptor
Poliovirus receptor (CD155)
Hyaluronan receptor (CD44)

CpG DNA, Microbial DNA with a large content of unmethylated cytosines adjacent to guanosines; CR, complement receptor; CSF, colony-stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LDL-R, low-density lipoprotein receptor; LPS, lipopolysaccharide; TLR, Toll-like receptor; TNFR, tumor necrosis factor receptor.

Fc Receptors

Mononuclear phagocytes react with Igs through the FcR. All FcRs are integral membrane proteins in the Ig superfamily, except for Fc?RIIIB, which is linked to the membrane by a gly-cosylphosphatidylinositol (GPI) anchor. The receptors interact with the Fc portions of Igs. Ig interaction with cells through FcRs results in many responses, ranging from effector functions such as antibody-dependent cytotoxicity, particle phagocytosis, enzyme secretion, and reactive oxygen and nitrogen species generation ([375], [376], [377] and [378]). The best-characterized FcRs are those for IgG and IgE (Fc?R and FceR, respectively). Fc?RI (CD64) is the high-affinity FcR for IgG; it is expressed on numerous leukocytes, including neutrophils, monocytes, and macrophages. IFN-? can enhance Fc?RI expression on mononuclear phagocytes by more than 20-fold. Fc?RII (CD32) is found on essentially all cells that bear Fc?Rs except natural killer cells. Fc?RII binds IgG with low affinity, and, unlike Fc?RI, it does not bind monomeric IgG. Fc?RII is encoded by a minimum of three related genes, and isoforms of Fc?RIIB are formed by alternative splicing. Fc?RIIB is expressed by mononuclear phagocytes, lymphocytes, and some primitive hematopoietic cells but not by natural killer cells or neutrophils. Fc?RIIA and IIC are preferentially expressed in neutrophils, and IIB is expressed in lymphocytes; monocytes express all three. Fc?RIII (CD16) is seen only in mononuclear phagocytes, natural killer cells, and myeloid precursor cells. Fc?RIIIB noted in neutrophils is not an integral membrane protein; it is linked by the GPI anchor and is absent in patients with paroxysmal nocturnal hemoglobinuria. Fc?R-IIIA is a conventional integral membrane protein with an intracytoplasmic tail. Fc?RIIIA is able to mediate antibody-dependent cell-mediated cytotoxicity and phagocytosis, whereas Fc?RIIIB is not.

FceRI, the high-affinity FcR for IgE, is present only on mast cells and basophils; it is involved in allergic reactions. FceRII (CD23), the low-affinity receptor, is present on B and T lymphocytes, mononuclear phagocytes, and eosinophils. This receptor does not belong to the Ig superfamily of receptors. It is somewhat homologous to the receptor for asialoglycoprotein. FceRIIA is found in resting B cells, whereas FceRIIB is noted in activated B cells, mononuclear phagocytes, and eosinophils, especially after stimulation with IL-4. Engaging FceRII on mononuclear phagocytes induces a variety of cellular changes, many of which relate to the induction of NO synthesis ([378]).

IgA receptors (FcaR; CD89) have been detected on monocytes, polymorphonuclear neutrophils, and eosinophils and on phagocytic cells at mucosal sites ([379]). These receptors bind both secretory and serum forms of IgA and require the Ca2 region of the IgA molecule for ligand recognition. Monocytes and polymorphonuclear neutrophils modulate their expression of the FcaR on treatment with cytokines, such as GM-CSF, and LPS. Purified FcaRs appear as heavily glycosylated molecules with an average molecular weight of 60 kd, dropping to 32 and 36 kd on treatment with *N*-glycanase. Ligation of FcaRs on phagocytic cells by multivalent IgA complexes induces a variety of responses, including superoxide generation, release of inflammatory mediators, phagocytosis, and killing of various pathogenic microorganisms. Thus, the apparent role of these receptors is to amplify the protective effects of the IgA antibody, a function of potential importance to mucosal defense ([379]).

Complement Receptors

Mononuclear phagocytes have different types of CRs ([380], [381]). *CR1* (CD35) binds C3b/C4b and is found primarily on erythrocytes but also on monocytes and neutrophils. The receptor is a 200-kd transmembrane glycoprotein. Expression of CR1 on human mononuclear phagocytes can be increased by treatment of the cells with agents such as chemotactic peptides, lymphokines, and fibronectin. *CR2* (CD21), the receptor for C3d, g and the Epstein-Barr virus, is not found on mononuclear phagocytes. *CR3* (CD11b/CD18, Mac-1) binds C3bi. It is found on mononuclear phagocytes as well as on neutrophils ([380], [381]). CR3 exists as a dimer (one a-chain CD18 and one ß-chain CD11b) in the membrane. The a-chains are shared by the antigens recognized by antibodies LFA-1, Mac-l/Mo1, and pl50,95, whereas the ß-chains are distinct for each antigen ([382]). CR3 appears to function as an adherence protein, and cells lacking these antigens (and CR3) show defective adherence, phagocytosis of C3bi-coated particles, and depressed production of ROS ([383], [384] and [385]). When normal human monocytes bind particles to their CR1 or CR3, these particles are generally not ingested. However, cultured blood monocytes as well as freshly isolated human peritoneal macrophages both bind and ingest these particles ([250], [380]). In addition to binding C3bi, CR3 also binds intercellular adhesion molecule-1 (ICAM-1, CD54). Certain patients with recurrent bacterial infections whose monocytes, granulocytes, and null cells lack these antigens have been described ([383], [384] and [385]). Cells from these patients manifest reduced phagocyte adherence to glass or plastic, phagocytosis of C3bi-coated particles, and reduced production of ROS with phagocytosis of zymosan.

C5a anaphylatoxin, the amino-terminal fragment of C5 produced after the enzymatic cleavage, causes a variety of effects on mononuclear phagocytes, most notably chemotaxis ([386]). C5a receptors (CD88) are members of the superfamily of G-protein–coupled receptors characterized by unique motifs, including seven membrane-spanning hydrophobic domains. These receptors are closely related to receptors for chemotactic (fMLP) peptides ([386], [387]). C5a and fMLP receptors are expressed on both neutrophils and mononuclear phagocytes.

a $_2$-Macroglobulin Receptors

Mononuclear phagocytes have specific receptors for a $_2$-macroglobulin (A$_2$M) (CD91) that has been modified by interacting with proteases or certain ligands ([388], [389]). A$_2$M is synthesized by many different cells, including mononuclear phagocytes, hepatocytes, and fibroblasts. A$_2$M serves not only as a broad-spectrum protease inhibitor, but it also binds numerous growth factors, cytokines, hormones, antigens, and microbial proteins, including IL-1, leukemia inhibitory factor, TNF, IL-6, TGF-ß, IFN-?, streptococcal cell wall proteins, and modified lipoproteins ([389], [390]). *Modified A2M* [A2M that has interacted with protease or ligand (A2M*)] binds to mononuclear phagocyte A2M* receptors and initiates cellular changes. Expression of the receptor can be modulated by several factors, including IFN-?, endotoxin, and M-CSF. A2M* binding is accompanied by receptor-mediated internalization and modulation of cell function ([388], [389]). Antigen bound to A2M is apparently targeted to mononuclear phagocytes for subsequent antigen presentation to lymphocytes and enhanced immune responses ([389]). A2M* may either antagonize or enhance cellular responses to bound growth factors and cytokines by blocking growth factor/cytokine receptor binding or by enhancing cellular uptake and processing of the ligand.

Glycoprotein Receptors

Macrophages also have specific receptors for glycoproteins with mannose, fucose, or *N*-acetylglucosamine terminal groups ([391]). These proteins are bound and internalized by the phagocytes, and the receptors are probably recycled to the surface. This system may represent a mechanism for clearing escaped or excess glycoprotein hydrolases in the macrophage's environment. Macrophages from mice with chronic infection with bacillus Calmette-Guérin (so-called activated macrophages) have reduced numbers of receptors for these glycoproteins, whereas receptors for other ligands such as A$_2$M are not altered ([392]). The mannose-binding protein (CD206) can serve as a primitive opsonin for various microbes ([33]).

Transferrin and Lactoferrin Receptors

The mononuclear phagocyte diferric transferrin receptor (TfR) (CD71) plays a role in the transport of iron into the cell ([393]). Diferric transferrin binds to a specific membrane receptor and is internalized from a coated pit into an acid uncoated vesicle; at the acid pH of the vesicle, iron dissociates from the transferrin protein. Then the apotransferrin dissociates from the receptor, and the receptor is available for another round of ligand binding ([394]). The number of TfRs per cell is reduced in mouse macrophages activated *in vivo* or *in vitro* ([395], [396]). Mononuclear phagocytes also have specific cellular receptors for lactoferrin ([397]). In episodes of acute endotoxemia or bacteremia, apolactoferrin is released from the specific granules by the action of IL-l. This apolactoferrin, after competing for and binding iron, is internalized by the mononuclear phagocyte receptors, thus possibly contributing to the hyposideremia seen in these conditions ([47], [397], [398]). Transferrin also binds to the low-density lipoprotein (LDL) receptor–related protein ([390]).

Lipoprotein Receptors

Mononuclear phagocyte lipoprotein receptors control the entry of these proteins and their associated lipids into the cells ([399]). Subendothelial vascular mononuclear phagocytes accumulate lipoproteins and cholesteryl esters and form “foam cells,” thus contributing to the generation of the atherosclerotic plaque ([400], [401]). Certain receptors for LDL and modified lipoproteins (“macrophage scavenger receptors” or MSR) are important in this accumulation ([390]). The LDL receptor recognizes apolipoproteins B-100 and E, which are constituents of LDL, very LDL, intermediate-density lipoprotein, and catabolized chylomicrons (chylomicron remnants). Mouse peritoneal macrophages have very few receptors for LDL, but they do have many MSR ([400], [402]). Human blood monocytes have both LDL receptor and MSR, and, in the course of *in vitro* culture of monocytes, there is a dramatic increase of MSR ([400], [402], [403], [404], [405] and [406]). Modified LDL with its cholesteryl esters binds to the MSR and is internalized into the lysosomal compartment where an acid lipase produces free cholesterol. This cholesterol is reesterified to cholesterol esters, which are stored in the cytoplasm as lipid droplets. Unlike the LDL receptor, the levels of acetyl-LDL receptors are not regulated by the cellular level of cholesterol or cholesteryl esters, so the process can proceed unchecked and result in engorgement of the macrophages with lipid ([400]). Patients with homozygous familial hypercholesterolemia who lack the receptors for LDL have normal numbers of acetyl-LDL receptors ([400]). Modified LDL can bind to a variety of mononuclear phagocyte receptors; these include (a) MSR (CD204), (b) Fc?RIIB2, (c) CD36 (thrombospondin), and (d) CD68 (macrosialin), a lysosomal-associated membrane protein (“lamp”) of macrophages ([390]).

Mononuclear phagocyte scavenger receptors (SRs) are a group of proteins that bind chemically or oxidatively modified lipoproteins, polyanions, and apoptotic cells ([407], [408]). There are at least six classes of SR (classes A through F). SR-AI and SR-AII bind acetylated and oxidized LDL, polyanions, and apoptotic cells. SR-B includes CD36 and SR-BI. CD36 binds acetylated and oxidized LDL, phosphatidyl serine, and apoptotic cells. CD36 interacts with the vitronectin receptor in binding apoptotic cells. CD36 is a phagocytic receptor. SR-BI is a receptor for high-density lipoprotein, the lipoprotein that can remove cholesterol from cells. SR-CI binds acetylated LDL and polyanions. The class D SR macrosialin (CD68) binds oxidized LDL, the class E SR LOX-1 binds oxidized LDL and polyanions, and the class F SR binds acetylated and oxidized LDL and polyanions. Humans with CD36 deficiency have reduced myocardial fatty uptake and an increased incidence of hypertrophic cardiomyopathy ([408]).

Expression of the SR can be regulated by various factors, including LPS, M-CSF, TGF-ß, IFN-?, retinoic acid, glucocorticoids, and vitamin D$_3$. M-CSF stimulates SR expression, and *in vivo* M-CSF lowers cholesterol levels. Based on the large variety of ligands for these receptors, SR appears to play a role in several physiologic and pathologic processes [e.g., atherosclerosis, cell adhesion, host defense and innate immunity, cell interactions involving adhesion molecules, inflammatory responses to microbes (namely, bacterial LPS and lipoteichoic acid), and inanimate particulates (i.e., asbestos)] ([390], [408], [409]).

Cholesteryl esters are removed from mononuclear phagocytes only after deesterification with the production of free cholesterol ([400]), which is then removed by a high-density lipoprotein. Mononuclear phagocytes produce and secrete apoprotein E in the form of phospholipid discs. These particles, along with cholesteryl ester formed by the action of lecithin-cholesterol acyl transferase, are assembled extracellularly into a large spherical particle containing a core of cholesteryl esters and a coat containing apoproteins A-I and E ([400], [403]). This particle may be high-density lipoprotein-c, which transports the cholesterol to the liver, where it is metabolized.

The LDL receptor–related protein (also called the *remnant receptor*) binds chylomicrons and very LDL that have been modified by hydrolases (e.g., lipoprotein lipase) and by association and disassociation with apolipoproteins ([390]). Receptors for these “remnants” are expressed on hepatocytes and Kupffer cells. LDL receptor–related protein has a *C*-terminal cytoplasmic portion, a single transmembrane domain, and an extracellular domain that is similar to that of the LDL receptor. The receptor mediates the endocytosis of apolipoprotein E–containing, remnantlike lipoproteins, lipoprotein lipase, chylomicron remnants, lactoferrin, A2M–ligand complexes, plasminogen activator–plasminogen activator inhibitor-1 complexes, and certain toxic ligands such as *Pseudomonas* exotoxin A and, possibly, bacterial LPS. LDL receptor–related protein expression is decreased by treatment of cells with IFN-?, LPS, or prostaglandin E$_2$, and is increased by M-CSF.

Cytokine, Interleukin, and Growth Factor Receptors

Mononuclear phagocytes express members of the TNF receptor (TNFR) family. This is a family of receptors that includes the p55 (TNFR1; CD120a) and p75 (TNFR2; CD120b) components of the TNFR, CD40, CD27, CD30, and CD95 (Fas) ([410]). These receptors are type I membrane proteins containing homologous extracellular domains, with cytoplasmic domains of variable length without significant sequence homology. Ligands for these proteins are all type II membrane molecules, with extracellular carboxy-terminal regions and intracellular amino-termini. Binding of ligand to receptor can induce cellular growth, differentiation, or apoptotic death. In the case of TNFR1 and Fas, engaging the receptor with TNF-a/ß or Fas ligand, respectively, induces apoptotic death of the cell by activating a complex pathway leading to fragmentation of DNA by endonucleases, nuclear dissolution, and nonnecrotic death ([411]). This apoptotic cell death occurs in a variety of cell types under physiologic (“programmed cell death”) and pathologic conditions. It serves as an important means of immunologic cell selection of lymphocytes during development (negative selection or clonal deletion of immature T cells), tissue remodeling during embryogenesis and inflammation, and cell-mediated cytotoxicity. MRL-*lpr/lpr* mice have no or very little Fas (CD95) due to a retrotransposon insertion in the gene, resulting in aberrant splicing and premature termination of transcription; they have defective apoptosis with consequent massive lymphadenopathy and autoimmune disease comparable to humans with RA and systemic lupus erythematosus. Mice with the *gld* defect have a point mutation in the gene for Fas-ligand, defective apoptosis, lymphadenopathy, and autoimmunity ([412], [413]). Humans with CD95 defects, impaired apoptosis, and aspects of autoimmunity have been identified ([414], [415]).

Mouse macrophages and human monocytes have high-affinity specific receptors for IFN-? (CD119) ([416], [417]). The effects of IFN-? in modulating the activities of mononuclear phagocytes apparently are mediated through these receptors. IFN-? serves as a “macrophage-activating factor” in mouse ([418]) and human ([313], [419], [420]

and [421]) mononuclear phagocytes. Individuals with mutations in IFN-? receptor chains are susceptible to severe infections with bacillus Calmette-Guérin, nontuberculous mycobacteria, *Listeria*, and *Salmonella* ([422], [423]). Monocytes also have receptors for IFN-a (CD118) ([424]). IFN-a administered *in vivo* or used *in vitro* with isolated cells can activate monocytes for expression of NOS2 and for NO production ([425]). Macrophages have IL-12 receptors (CD212), and genetic deficiencies of these receptors predispose to severe infections with poorly virulent mycobacteria and *Salmonella* ([426]).

Integrins

As noted earlier, mouse mononuclear phagocytes have receptors for M–CSF (CD115), the specific growth factor for the mononuclear phagocyte lineage ([55], [77], [427]). Mononuclear phagocytes also express integrin receptors. The integrins are a family of widely expressed cell-surface adhesion receptors. Integrins are aß heterodimers, including the leukocyte-specific ß2 integrin LFA-2 (CD11a/CD18), Mac-1 (CR3, CD11b/CD18), and p150, p95 (CD11c/CD18) ([428]). Ligands for the various integrins include collagen, laminin, fibronectin, vascular cell adhesion molecule-1, vitronectin, ICAM-1 and -2, fibrinogen, factor X, and C3bi. In addition to mediating adhesion, binding to integrins can cause transmission of signals into cells and modulate aspects of cellular function, including migration, proliferation, and differentiation ([428]).

Chemotactic Peptide Receptors

Mononuclear phagocytes have specific high-affinity receptors for synthetic chemotactic peptides ([429], [430]), such as *N*-formyl-norleucine-leucine-phenylalanine-norleucine-tyrosine-lysine and *N*-formyl-methionine-leucine-phenylalanine. The chemotactic peptide (“fMLP”) receptor is a member of the seven transmembrane–spanning, G-protein–linked receptor family ([387]). There is sequence and structural similarity of the fMLP receptor to the C5a receptor, and the responses of neutrophils and mononuclear phagocytes (the major cell types expressing these receptors) are likewise quite similar ([386], [387]). These peptides induce not only directed movement (chemotaxis) of the cells but also lysosomal enzyme release and ROS production.

Coagulation Factor Receptors

Mononuclear phagocytes are capable of synthesizing coagulation factors (see below), and they also display coagulation factor receptors ([431], [432]). Coagulation processes and activated coagulation factors are important mediators of blood coagulation and anticoagulation, and they also play roles in cell mito-genesis, inflammation, atherogenesis, tissue remodeling, cell adherence, and chemotaxis. Monocytes and macrophages have well-characterized receptors for factor VII/VIIa [tissue factor (TF)], fibrinogen (CD11b/CD18 and CD11c/CD18), factor X (CD11b/CD18), factor Xa (membrane-bound factor V and an “effector cell protease receptor type 1”), thrombin (the thrombin protease-activated receptor), and urokinase-type plasminogen activator (CD87). TF is a membrane lipoprotein that initiates the extrinsic pathway of coagulation on mononuclear phagocytes and endothelial cells ([433]). TF acts as a high-affinity receptor and cofactor for factor VII/VIIa. Monocyte expression of TF is increased by treatment with LPS, TNF, immune complexes, and lymphocyte products ([433], [434]). The thrombin receptor is G-protein–linked seven transmembrane segment receptor expressed on several cell types, including mononuclear phagocytes ([435]). Thrombin cleavage of the extracellular part of the receptor exposes a tethered ligand that mediates functional changes in the receptor-bearing cell. The urokinase-type plasminogen activator receptor (CD87) is identical to the monocyte differentiation antigen Mo3 ([436]). It localizes urokinase-type plasminogen activator on the membrane and contributes to cell-mediated fibrinolysis, plays a role in tissue remodeling and cell invasiveness through tissues, and modulates cell adhesiveness. The receptor is a GPI-linked membrane protein. Its expression is increased by treatment of cells with IFN-? and TNF.

Hormone Receptors

The effects of several different hormones (e.g., insulin, glucagon, thyrotropin, somatomedin, prostaglandins of the E series, dexamethasone, dihydroalprenolol, 1,25 dihydroxyvitamin D_3, and sex hormones) on mononuclear phagocytes are probably mediated by specific cellular receptors ([275], [279], [437], [438]). Monocytes and macrophages display receptors for a variety of other cytokines and growth factors, as noted in Table 13.3.

Microbial Component Receptors

Mononuclear phagocytes respond to picomolar to nanomolar amounts of microbial components in complex ways. TLRs are central to the mediation of these effects and key to the innate immune system in animals ([25], [439]). The Toll protein was originally identified in *Drosophila* (the fruit fly) as an essential determinant of dorsoventral polarity in embryogenesis, and it was subsequently shown that a family of Toll proteins and related proteins were important in antifungal and antimicrobial immunity in the flies ([25]). The cytoplasmic portion of the IL-1 receptor has homology to *Drosophila* Toll. In vertebrates, the TLRs are a family of proteins (TLR1 through TLR10) (Table 13.4). Members of the TLR family are involved in the recognition of pathogen-associated molecular patterns, with various TLRs binding recognized microbial components. TLR2 binds bacterial peptidoglycan, LPS-associated protein, and bacterial laminoarabinomannan. TLR2 also cooperates with TLR6 to bind and mediate the effects of *Mycoplasma* lipoprotein. Mice with disrupted TLR2 have impaired production of TNF, IL-6, and NO in response to several gram-positive cell walls (likely the peptidoglycan component). TLR2 may also interact with *Porphyromonas gingivalis* and *Leptospira interrogans*, two unique LPSs. TLR2 also reacts with the GPI membrane components of *Trypanosoma cruzi*.

TABLE 13.4. Toll-Like Receptors (TLRs)

TLR	Ligand
TLR2	Peptidoglycan, LPS-associated lipoprotein, laminoarabinomannan, zymosan, *Mycoplasma* lipoprotein (in association with TLR6)
TLR3	Double-stranded RNA, polyinosine/polycytosine
TLR4	LPS
TLR5	Flagellin
TLR6	*Mycoplasma* lipoprotein (in association with TLR2)
TLR9	CpG-DNA

CpG DNA, microbial DNA with a large content of unmethylated cytosines adjacent to guanosines; LPS, lipopolysaccharide.
Adapted from Takeuchi O, Akira S. Genetic approaches to the study of toll-like receptor function. Microbes Infect 2002;4:887; and Medzhitov R, Janeway CJ. Advances in immunology: innate immunity. N Engl J Med 2000;343:338.

Investigators noted in the mid-1900s that mice of the inbred strains C_3H/HeJ and C57Bl/10ScCr were unresponsive to LPS from gram-negative bacteria *in vivo*, and that LPS did not activate macrophages and B cells of these mice *in vitro*. Researchers cloned the mouse TLR4 gene and discovered that this LPS insensitivity is caused by mutations in the TLR4 gene in these strains—a point mutation in the cytoplasmic domain of TLR4 in C_3H/HeJ mice and a TLR4 null mutation in C57Bl/10ScCr mice ([24], [440], [441]). Subsequently, investigators have demonstrated TLR4 mutations in humans who were unresponsive to inhaled LPS ([442]). TLR4 is expressed by mononuclear phagocytes, cardiomyocytes, airway epithelium, endothelial cells, smooth muscle cells, and, to a small extent, in other cells. People with TLR4 mutations appear to be at increased risk for infection with gram-negative organisms and for septic shock ([443]), but they have decreased risk of atherosclerosis ([444]). This protection from atherosclerosis may be due to diminished inflammatory responses to certain microbes (e.g., *Chlamydia pneumoniae*) believed to be important in the pathogenesis of atherosclerosis ([444]). Levels of TLR4, MD2, and MyD88 are increased in human mononuclear phagocytes by IFN-? treatment, and these increases correlate with increased responsiveness to LPS ([445]).

TLR3 is the receptor for double-stranded RNA and polyinosine/polycytosine, and TLR5 serves as the receptor for flagellin, the major protein of bacterial flagella. Microbial DNA is a potent immunostimulant and inducer of inflammation, and it is a potent adjuvant in vaccines ([446], [447] and [448]). Microbial DNA (unlike DNA from vertebrates) has a large content of unmethylated cytosines adjacent to guanosines (CpG DNA). TLR9 is the receptor for CpG DNA, and it mediates the cellular effects

of this immunostimulant ([449], [450]). Mice with a disrupted gene for TLR9 have absent or diminished responses to CpG DNA.

Signaling through the TLR/IL-1R pathways proceeds through several common signaling pathways leading to the nuclear translocation of NF-?B and activation of various kinases. For example, LPS binds a plasma protein (LPS-binding protein), which, in turn, can bind in a specific manner with membrane or soluble CD14 ([451], [452]). Also, LPS alone (or the LPS/LPS-binding protein complex) binds to TLR4, which is complexed with protein MD2. Signal transduction starts with the adapter protein MyD88 interacting with the TLR/IL-1R cytoplasmic tail and recruitment of the IL-1R–associated kinase. Activated IL-1R–associated kinase then binds and activates TNFR-associated factor 6, which, in turn, stimulates the I?B kinase and MAP kinase. This leads to nuclear translocation of NF-?B and transcription of proinflammatory cytokines and growth factors ([25]). MyD88 is absolutely critical to this complex pathway that mediates responses through TLR2, TLR4, TLR9, and the IL-1R pathways ([25], [453]). MyD88-deficient mice lack cellular responses to LPS, peptidoglycan, CpG DNA, IL-1, and IL-18.

ENDOCYTOSIS/PHAGOCYTOSIS

Mononuclear phagocytes internalize substances by either *pinocytosis* (the uptake of solutes) or *phagocytosis* (the uptake of particulates). Pinocytosis can proceed by receptor-mediated processes (discussed above) or by receptor-independent processes. In general, most of the internalized vesicles fuse with lysosomes, and the contents of the vacuoles are processed in the lysosome ([454]). Parts of the lysosome/vesicle membrane bud off and return to the plasma membrane, thus recycling the originally internalized membrane and providing a mechanism for maintaining membrane surface area without requiring new membrane synthesis ([454], [455]).

Particles are phagocytized either through opsonins (e.g., Ig, C', or fibronectin) or by ill-defined, opsonin-independent mechanisms ([456]). Polystyrene (latex) spheres and aldehyde-fixed erythrocytes are examples of particles avidly phagocytized by mononuclear phagocytes without the need for opsonins. Surface hydrophobicity, charge, or both may be determinants of this nonspecific uptake, but the precise processes involved are not known. When particles such as erythrocytes are opsonized with IgG, mouse macrophages or human monocytes bind and phagocytize them, but if they are opsonized with C3b or C3bi, macrophages or monocytes bind the particles but do not internalize them ([380]). However, activated mouse macrophages, cultured human monocytes, or fresh human peritoneal macrophages can bind and internalize C'-coated particles ([250], [380]). For an IgG-opsonized particle to be phagocytized, it must have IgG ligands surrounding it circumferentially. Otherwise, the macrophage membrane extends only as far as the IgG without totally internalizing the particle. This “zipper” concept of opsonized particle phagocytosis requires that the opsonins be in continuous approximation in a density great enough to encircle the entire surface of the particle ([457], [458]).

CHEMOTAXIS

Mononuclear phagocytes, like neutrophils, exhibit general movement (chemokinesis) as well as directed movement (chemotaxis) in response to various factors ([66], [429], [459]). Movement of monocytes and macrophages to and within sites of inflammation and tissue injury is influenced by chemotactic factors. Substances derived from plasma, cells, bacteria, and connective tissue proteins can serve as chemotactic factors. These include C5a ([460]), fibronectin fragments ([461]), elastin fragments ([462]), collagen fragments ([463]), *N*-formylated oligopeptides ([429], [430]), the chemokines ([464], [465]), and a variety of proteins derived from normal and malignant cells ([459], [466], [467]). The mononuclear phagocyte recognizes the chemotactic factor through a receptor, senses the direction of the concentration gradient of the factor, and then transduces this information into the cell and regulates intracellular effector mechanisms. The transduction mechanism may involve protein kinase C and the phosphatidylinositol cycle with generation of the second messengers 1,2-diacylglycerol and inositol 1,4,5-triphosphate ([468], [469]). In addition to their chemotactic effects, many of the chemotactic factors cause mononuclear phagocyte membrane depolarization and ion flux, cellular aggregation, and lysosomal enzyme and ROS secretion ([429], [459]).

C5a is a potent chemotactic factor for mononuclear phagocytes ([459]). This C' fragment is released after C' activation by antigen–antibody complexes, endotoxin, or cell-derived proteases. Cell-derived chemotactic factors may play an important role *in vivo*. These can come, for example, from antigen-stimulated lymphocytes ([467]), platelets ([470]), or tumor cells ([466]). Neoplasms are also known to elaborate peptides that selectively inhibit mononuclear phagocyte chemotaxis *in vitro* and macrophage accumulation *in vivo* ([471]). This factor, derived from various murine and human cell tumor cell lines and human malignant effusions, is chemically and antigenically related to the immunosuppressive retroviral protein P15E ([472]).

The cytoskeletal apparatus of the mononuclear phagocyte is responsible for membrane ruffling, pseudopod formation, and cellular locomotion ([473]). Local intracellular variations of calcium concentration modulate the gel/sol states of the cytoskeletal filaments on which myosin contracts. Actin is the main constituent of microfilaments, and it is the most abundant protein of macrophages ([474]). Acumentin ([475]) and gelsolin ([476]) retard globular actin from polymerizing. But when intracellular calcium falls, globular actin is converted to filament actin. Filament actin is then strengthened by cross-linking by actin-binding protein ([477]). Macrophage myosin, a magnesium adenosine triphosphatase, serves to contract actin ([474]). Mononuclear phagocyte microtubule function is necessary for normal chemotaxis, but phagocytosis is altered little by microtubule-disrupting agents ([478]).

PRODUCTS OF MONONUCLEAR PHAGOCYTES

Mononuclear phagocytes are capable of producing many substances that can influence the host. Some of these substances are secreted constitutively, not requiring any particular stimulus to initiate the secretion. However, secretion of most macrophage products is influenced by stimuli acting on the cell. In general, the secretory capacity of macrophages parallels their state of activation and correlates well with their ability to mediate bactericidal and tumoricidal activities. Some of the products can act on the phagocytes themselves, thus providing the possibility for autoregulation of cell function. Table 13.5 lists some of the secretory products of mononuclear phagocytes.

TABLE 13.5. Products of Mononuclear Phagocytes

Enzymes	Angiogenesis factors
Acid hydrolases	Binding proteins
Angiotensin-converting enzyme	Transferrin
Arginase	Transcobalamin II
Catalase	Fibronectin
Heme oxygenase	Apolipoprotein E
Lipoprotein lipase	Bioactive lipids
Lysozyme	Arachidonate derivatives
Reduced nicotinamide adenine dinucleotide phosphate oxidase	Hydroxyeicosatetraenoic acids
Neutral proteases	Leukotrienes B, C, D, and E
Plasminogen activator	Prostacyclin
Elastase	Prostaglandin E_2
Collagenase	Prostaglandin F_{2a}
Nitric oxide synthase type 2	Thromboxane B_2
Nonspecific esterase	Platelet-activating factor
Peroxidase	Chemotactic factors
Phospholipase A_2	Cytokines/growth factors
Superoxide dismutase	Erythropoietin
Complement factors	Fibroblast growth factor
C1, C4, C2, C3, C5	IFN-a
Factors B, D, I, H	IFN-?

Properdin	IL-1
Coagulation factors	IL-3
XIII, X, IX, VII, V, II	IL-6
Thrombomodulin	IL-8
Thromboplastin (tissue factor)	IL-10
Reactive oxygen species	IL-12
Hydrogen peroxide	Macrophage colony-stimulating factor
Hydroxyl radical	Platelet-derived growth factor
Singlet oxygen	Tumor necrosis factor
Superoxide anion	
Reactive nitrogen species	
Nitric oxide	
Peroxynitrite	

IFN, interferon; IL, interleukin.

Enzymes

Lysozyme (also called *muramidase*) is a 14-kd protein secreted from mononuclear phagocytes in a steady, constitutive manner. It is a major secretory product, composing up to 2.5% of cellular protein produced per day ([479]). Mononuclear phagocytes contain and secrete more lysozyme than do neutrophils. This enzyme is able to lyse bacteria (especially gram-positive organisms) that contain a certain glucosidic linkage. Animals or patients with an increased mononuclear phagocyte mass or with monocytic or myelomonocytic leukemia have high levels of plasma, urine lysozyme, or both ([480]). This sometimes leads to tubular dysfunction, excess loss of potassium, and refractory hypokalemia ([481]).

The *neutral proteases*, including plasminogen activator, collagenase, and elastase, are enzymes that are active at neutral pH and can degrade connective tissue components. Plasminogen activator secretion from macrophages is enhanced if the cells have been activated to a certain state and if they are phagocytizing particles ([482]). However, endotoxin, a stimulus known to produce highly activated or tumoricidal macrophages, dramatically reduces plasminogen activator secretion ([483]). Plasminogen activator not only generates plasmin from plasminogen, but it also cleaves C1, C3, and activated Hageman factor. As noted earlier, elastase and collagenase secreted by alveolar macrophages may play a role in the genesis of emphysema ([133]). Elastase can degrade a large number of substrates other than elastin, including a $_1$-antiprotease ([484]), Ig ([485]), proteoglycans, fibronectin, fibrin, and fibrinogen ([486] , [487] and [488]). These neutral proteases may be used by the mononuclear phagocytes to degrade components of the extracellular matrix as they migrate through the tissues.

A large number of acid hydrolases are present in macrophage lysosomes. The content of these enzymes is increased as mononuclear phagocytes are stimulated by microbial products, lymphokines, phagocytosis, and *in vitro* culture ([69] , [72] , [489]). The secretion of these enzymes can be stimulated by phagocytosis, by engaging Fc or CRs, or after treatment with lymphokines ([489]). In certain instances of tissue inflammation with low tissue pH ([490]), the acid hydrolases may be able to act on tissue components. Potential substrates include basement membranes, cartilage, collagen, C' components, proteoglycans, and Ig ([489]).

Mononuclear phagocytes synthesize all of the C' factors of the classic and the alternative pathways except C6-9 ([489] , [491]). Some of these factors can be acted on by various proteases to form products that can alter the function of macrophages. These include Bb, C3b, and C3a ([491]). Factor Bb inhibits macrophage migration and promotes macrophage spreading ([492]). C3a and C3b modulate macrophage production of arachidonic acid metabolism ([493]). IFN-? increases factor B and C2 production and decreases C3 production, whereas IFN-a has little or no effect.

Mononuclear phagocytes produce several coagulation factors. These include those enhancing coagulation [the membrane-bound TF (procoagulant) activity that binds and activates factor VII ([433]), as well as factor XIII, which cross-links fibrin ([494] , [495])] and those inhibiting coagulation [plasminogen activator ([482] , [483]) and different protease inhibitors]. The procoagulant activity of macrophages and monocytes is dramatically enhanced by endotoxin or antigen–antibody complexes ([496] , [497]). Mononuclear phagocyte–associated procoagulant/anticoagulant activities are important in atherogenesis, inflammation, cellular growth control, tissue remodeling, cell migration, and invasiveness. Much of the fibrin deposition seen in delayed hypersensitivity reactions and in tumors likely results from mononuclear phagocyte–derived procoagulants ([498] , [499]). In inflammatory lesions such as those seen in RA, macrophages express a variety of procoagulant and anticoagulant molecules ([500] , [501]). Mononuclear phagocyte–associated procoagulants play important roles in the disseminated intravascular coagulation seen in malignancy and infection and in the prothrombotic state noted in association with malignancy ([502]).

Among the protease inhibitors, A2M is very important because it affects many of the proteases, including plasminogen activator, plasmin, elastase, kallikrein, and thrombin ([503]). Mononuclear phagocytes synthesize and secrete this protein ([487] , [504]), as well as a $_1$-antiprotease ([134] , [135] , [505]). As noted earlier, mononuclear phagocytes have receptors for A2M–protease complex, and this complex can modulate the function of these cells ([506] , [507] and [508]).

Reactive Oxygen Species

As mononuclear phagocytes ingest particles or as they are stimulated with certain surface active agents, they exhibit a respiratory burst, much like that seen in neutrophils ([18]). Oxygen is consumed at an increased rate, the hexose monophosphate shunt is stimulated, reduced glutathione and reduced nicotinamide adenine dinucleotide phosphate (NADPH) are generated, and oxygen is reduced to superoxide anion by an oxidase. This oxidase requires NADPH, a flavoprotein, cytochrome b245, and ubiquinone ([17]). The superoxide anion dismutates to hydrogen peroxide, and some hydroxyl radical may also form in the presence of iron ([509]). Some peroxide diffuses out of the cell, whereas some is changed to water and oxygen by the action of catalase. In addition to phagocytic stimuli and surface active agents (e.g., arachidonic acid or phorbol myristate acetate), antigen–antibody complexes, C5a, ionophores, fatty acids, and lectins can also trigger the mononuclear phagocyte respiratory burst ([510]). If mononuclear phagocytes have been activated by *in vivo* infection or by *in vitro* treatment with lymphokines such as IFN-?, their ability to secrete ROS is greatly enhanced ([313] , [420] , [421] , [510]). These oxygen species have the ability to lyse nucleated and nonnucleated cells, to inactivate certain enzymes, and to alter lipids, nucleic acids, and proteins ([511]). The reduced oxygen species are also important in the metabolism of arachidonic acid products.

The enzyme complex NADPH oxidase in neutrophils and mononuclear phagocytes consists of membrane components (cytochrome b558, p22-Phox, the guanosine triphosphate–binding protein Rac2, and flavin adenine dinucleotide) and cytoplasmic components (p47-Phox and gp91-Phox) ([16]). Humans with chronic granulomatous disease (CGD) have a defect in one of these subunits, rendering their phagocytes unable to generate ROS. Abnormalities in gp91-Phox are the most common. CGD from a gp91-Phox defect is an X-linked disease, with male hemizygotes expressing the full defect, whereas CGD patients with defects in the other subunits are autosomal recessive. Mouse models of CGD created by genetically disrupting expression of gp91-Phox ([512]) or p47-Phox ([513]) are useful in analyzing CGD and in developing new treatments for the disease. Hydrogen peroxide formed from O_2^- can be used by certain peroxidases or converted to oxygen and water by catalase. Superoxide and peroxide may be toxic in themselves, or they may interact with NO and metals to form more toxic species such as peroxynitrite or hydroxyl radicals (see below).

Reactive Nitrogen Species

The simple gas NO has multiple important physiologic and pathologic functions ([514] , [515]). These include roles in (to mention only a few) host resistance to tumors and microbes, regulation of blood pressure and vascular tone, neurotransmission, learning, neurotoxicity, carcinogenesis, and control of cellular growth and differentiation ([514] , [515] , [516] , [517] and [518]). In the presence of oxygen, NO rapidly (within seconds) is converted to nitrite and nitrate, substances that are generally not bioactive ([519]). NO binds with high affinity to iron in heme groups of proteins such as Hb, myoglobin, and guanylyl cyclase; Hb and myoglobin are very effective quenchers of NO action. NO also nitrosylates the Hb globin ß-chain cysteine at position 93 ([520]). This S-nitrosohemoglobin can subsequently release NO and participate in a cycle of

NO/oxygen loading/unloading that is somewhat comparable to that of oxygen/carbon dioxide in the respiratory cycle ([520], [521]).

NO also reacts with O_2^-, and superoxide dismutase prolongs NO life by eliminating O_2^-. On reacting with O_2^-, NO may generate peroxynitrite (OONO–), a very toxic/reactive molecule that is a very important final effector toxic molecule when one thinks of NO toxicity in oxygenated systems ([515]). Peroxynitrite reacts with protein and nonprotein sulfhydryls, DNA, and membrane phospholipids. Peroxynitrite also nitrates free and protein-associated tyrosines (and other phenolics) via the metal-catalyzed formation of the nitronium ion to form nitrotyrosine. Nitration of proteins modifies their functions, and nitrated proteins serve as relatively long-lived markers (a “track”) of NO and peroxynitrite action in tissues ([515], [522]). Tyrosine nitration has been associated with inflammatory disorders ([515], [522], [523]).

There are three forms of the enzyme NOS encoded by three different genes. Neural NOS (nNOS or NOS1) and endothelial cell NOS (eNOS or NOS3) are constitutive enzymes, demonstrating low level, constant transcription of messenger RNA (mRNA). The enzymatic expressions of NOS1 and NOS3 are modulated by regulation of cytoplasmic calcium levels, with agents inducing increases in calcium (e.g., calcium ionophores or ligands such as acetylcholine) with subsequent binding to calmodulin and activation of the enzyme. Inducible NOS (iNOS or NOS2) can be regulated at multiple levels, but induction of mRNA transcription by agents such as cytokines or LPS appears to be of major importance ([524]) (Fig. 13.9). Although NOS2 was described initially in mononuclear phagocytes, it is also found in synoviocytes, chondrocytes, endothelial cells, smooth muscle cells, hepatocytes, and others ([514], [518], [525], [526] and [527]). NOS3 is myristoylated and membrane-bound; although NOS1 and NOS2 are not myristoylated, they can exist in membrane-bound and cytoplasmic forms. In the mouse macrophage NOS2 promoter, there are two functionally important areas upstream of the 5' end of the gene, which contain consensus sequences for several known DNA-binding proteins ([524]). The human NOS2 promoter differs from that in the mouse, extending at least 26 kb upstream from the transcription start site ([528]).

Figure 13.9. Factors inhibiting or enhancing expression of nitric oxide (NO) synthase type 2 (iNOS or NOS2) and production of NO. The transcription of NOS2 messenger RNA (mRNA) can be enhanced (+) or diminished (–) by various cytokines/growth factors and bacterial products. The enzyme NOS converts L-arginine (l-arg) to nitric oxide and L-citrulline, and it requires reduced nicotinamide adenine dinucleotide phosphate (NADPH), biopterin, flavin mononucleotide (FMN), FAD, oxygen, and heme for activity. Depletion of L-arginine or biopterin diminishes activity. L-arginine analogs, such as Ng-mono-methyl-L-arginine, block enzyme activity. NO can inhibit NOS activity by oxidizing the enzyme's heme group. Superoxide and oxygen rapidly diminish NO activity by oxidizing it. Iron, heme, and cobalamins can blunt NO's activity by binding NO to their iron or cobalt. CaM, calmodulin; IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; TGF, tumor growth factor; TNF, tumor necrosis factor.

Regulation of NOS2 can occur at multiple steps ([524]), including mRNA transcription, mRNA stability, mRNA translation, and mRNA level (precise mechanisms not known). At the protein level, NOS may be regulated by calmodulin binding, dimer formation (the functional enzyme exists as a dimer), substrate (L-arginine) depletion, substrate recycling (L-citrulline to L-arginine), tetrahydrobiopterin availability, end product inhibition (NO interaction with NOS heme), phosphorylation, and subcellular localization. Important NOS cofactors include FAD, flavin mononucleotide, NADPH, tetrahydrobiopterin, and calmodulin-calcium. For NOS2, calmodulin is tightly bound to protein, making it relatively resistant to inhibition by calcium chelators. Activities of NOS can be influenced by tetrahydrobiopterin levels, and cytokines/LPS can enhance tetrahydrobiopterin production ([529], [530]). Heme is a critical component of NOS; NO can act as a feedback inhibitor of NOS activity by binding to the iron in heme ([531], [532]). At the protein level, NOS may be regulated in many ways: calmodulin binding, dimer formation (the functional enzyme exists as a dimer), substrate (L-arginine) depletion, substrate recycling (L-citrulline to L-arginine), tetrahydrobiopterin availability, end product inhibition (NO interaction with NOS heme), phosphorylation, and subcellular localization.

Although many have shown high-level NO production by murine macrophages, there has been some difficulty in showing that human mononuclear phagocytes produce NO *in vitro*. However, recent studies have clearly documented that human mononuclear phagocytes from patients with a variety of illnesses express high levels of NOS2 and produce NO *in vitro* and *in vivo* ([533], [534]). Some researchers have seen NOS2 antigen in human alveolar macrophages ([535], [536] and [537]). Cancer patients treated with IL-2 overproduce NO via an NOS mechanism ([538]). Blood mononuclear cells from RA patients express higher levels of NOS2 than do those from normal individuals, and the cells are more responsive to IFN-? and endotoxin stimulation for NO production *in vitro*, indicating that their cells are activated for NOS expression and NO production *in vivo* ([342]). Tanzanian children spontaneously express NOS2 antigen in their blood mononuclear cells, and this is increased in those with mild or asymptomatic malaria and markedly decreased in those with cerebral malaria ([539]). Patients with hepatitis C infection receiving IFN-a treatment *in vivo* have monocytes that express high levels of NOS2 mRNA and antigen and have high-level NOS enzyme activity ([425]). Also, IFN-a activates normal blood monocytes *in vitro* for NOS2 expression and NO production ([425]). Finally, as noted above, peritoneal macrophages from women with endometriosis and infertility spontaneously express NOS2 antigen and produce NO *in vivo* and *in vitro*, and they are more responsive to IFN-a or IFN-? and LPS *in vitro* ([254]).

NOS2 expression is controlled primarily by levels of mRNA transcription. Human NOS2 promoter polymorphisms have been identified that are associated with resistance to infection and NOS2 expression/NO production. The G-954C (a G to C change at 954 bases upstream from the transcription site) polymorphism is associated with protection from severe malaria in Gabonese children ([540]), and mononuclear cells from those with the G-954C genotype express more NOS activity and produce more NO *in vitro* ([541]). The polymorphic pentanucleotide repeat CCTTT (approximately 7 to 20 repeats) is at approximately position -2500 in the NOS2 promoter. Gambian children with high numbers of repeats were found to have more severe malaria and to be more likely to die from malaria ([542]). Other researchers discovered the C-1173T NOS2 promoter polymorphism, which was very significantly associated with protection from severe malaria in Tanzanian children (primarily cerebral malaria) and severe malaria in Kenyan children (primarily severe malaria anemia) ([543]). Those with the C-1173T polymorphism had increased levels of NO *in vivo*, suggesting that the polymorphism was functional. C-1173T was noted only in Africans, and its protective effects against malaria disease were independent of any other NOS2 polymorphism ([543]).

Bioactive Lipids

Bioactive lipids produced by mononuclear phagocytes are important in inflammatory processes. The secretion of these products can be triggered by engagement of the FcRs, phagocytosis of particles, and treatment with phorbol diesters or ionophores ([544]). Much of the macrophage fatty acid is arachidonic acid, and a great deal of this can be mobilized and used in the synthesis of both cyclooxygenase (COX) and lipoxygenase products. The ability of mononuclear phagocytes to produce these bioactive lipids is dramatically influenced by the activation state of the cells. Prostaglandins of the E series can depress the ability of mononuclear phagocytes to produce CSF ([544], [545]) and cause decay in the tumoricidal ability of macrophages ([546]). Leukotriene B, a potent chemotactic factor ([547]), and leukotriene C, an important mediator in anaphylaxis ([548]), are produced by mononuclear phagocytes. Human blood monocytes produce as much thromboxane and as many leukotrienes as platelets and more than neutrophils ([544], [549]). There is a complex interplay between NOS2 and COX2 and between NO and prostaglandin production ([550]). Macrophage-derived NO and prostaglandin E_2 may modulate the activities of COX2 and NOS2, respectively, and thus determine levels of prostaglandin and NO produced ([550]).

Peroxisome Proliferator-Activated Receptor–?

Cyclopentenone prostaglandins [e.g., 15-deoxy-? ^{12,14} PGJ_2 (15d-PGJ_2)] are metabolites of PGD_2; they act as physiologic agonist ligands for peroxisome proliferator-activated receptor–? (PPAR-?) ([551]). PPARs are members of the nuclear hormone receptor superfamily of ligand-activated transcriptional factors that includes receptors for steroids, thyroid hormone, vitamin D, and retinoic acid ([552]). PPAR binds to the peroxisome proliferator response element as a heterodimer with the retinoic acid receptor. PPAR-a is expressed in liver, heart, kidney, muscle, brown adipose tissue, and gut. PPAR-? is expressed widely, but its function is unknown. PPAR-? is expressed in adipose tissue and leukocytes.

PPAR-a and PPAR-? both play important roles in inflammation ([553], [554]). The natural prostaglandin 15d-PGJ $_2$ and the antidiabetic thiazolidinediones are ligands for PPAR-?, whereas hypolipidemic fibrates (e.g., clofibrate) and eicosanoids, such as leukotriene B $_4$ and 8 (S)-hydroxyeicosatetraenoic acid, are synthetic and natural ligands for PPAR-a. Leukotriene B $_4$ activates oxidative degradation of fatty acids and their derivatives and regulates the degradation of leukotriene B $_4$, and thus, perhaps, prolongs the duration of inflammation ([554]). Mice with PPAR-a gene disrup-tion have a prolonged response to inflammatory stimuli ([554]). PPAR-? with its ligands modulates transcription of genes that regulate lipid metabolism and expression of genes involved in inflammation ([551]). In leukocytes, PPAR-? is expressed mainly in mononuclear phagocytes. With activation, PPAR-? expression is increased ([551], [555], [556]). PPAR-? is highly expressed in thioglycollate-induced mouse peritoneal macrophages, in atheromatous plaque macrophages, and in macrophages treated with LPS, GM-CSF, M-CSF, or phorbol myristate acetate ([556], [557]). Natural ligands include 15d-PGJ $_2$ and components of oxidized LDLs (e.g., 13-hydroxyoctadecadienoic acid). The antidiabetic thiazolidinedione drugs and the nonsteroidal antiinflammatory drugs aspirin and indomethacin also serve as ligands ([558], [559]). In macrophages, the PPAR-?–ligand system increases CD36 expression but decreases expression of several factors including gelatinase-B, IL-1, IL-6, and TNF ([555], [556]). Treatment of macrophages with IL-4 enhances expression of 12/15-lipoxygenase, and its products 13-hydroxyoctadecadienoic acid and 15-hydroxyeicosatetraenoic acid act as ligands for PPAR-? ([560]). This system is involved in the IL-4–dependent transcription of the CD36 gene in mouse and human macrophages. Furthermore, activation of the PPAR-? pathway inhibits mouse and human osteoclast differentiation, blocking the effects of M-CSF- and OPGL-induced osteoclast formation and activity ([561]).

PPAR-? ligands reduce NOS2 expression; this has been shown in mononuclear phagocytes and mesangial cells. In mesangial cells from autoimmune MRL- *lpr/lpr* mice [animals in which spontaneous NOS2 overexpression and NO overproduction are critical for disease pathogenesis ([263])], there is a relative deficiency of 15d-PGJ $_2$ ([562]). Researchers postulated that this lack of a “deactivator” contributed to the heightened activation and increased NOS2. Others showed that PPAR-? agonists inhibited induction of NOS2 by cytokines that were accompanied by an increase in heme oxygenase-1 expression ([563]). Zinc deuteroprotoporphyrin, an inhibitor of heme oxygenase-1 expression, partially blunted the agonist-induced decrease in NOS2. They found no consistent effects of 15d-PGJ $_2$ on COX2. The agonist 15d-PGJ $_2$ reduces LPS-induced COX2 expression in human monocytelike U937 cells ([564]). It is possible that there is feedback control of COX2 expression through PPAR-?. The effects of PPAR-? agonists on COX2 expression have not been examined methodically in mononuclear phagocytes from normal humans or from those with inflammation (e.g., RA). Activation of PPAR-? by 15d-PGJ $_2$ or BRL49653 (and, to a lesser extent, by activation of PPAR-a by Wy13,643) induces apoptosis of human monocyte–derived macrophages *in vitro* ([565]). The apoptotic effects are greatest in cells treated with TNF/IFN-? and the PPAR-? agonists. Treatment with PPAR-? agonists is accompanied by inhibition of the transcriptional activity of the NF-?B p65/RelA subunit. Regulation of gene expression by PPAR-? is mediated, in part, by antagonizing the activities of activating protein-1, signal transducer and activator of transcription-1, and NF-?B ([555], [566]). Also, PPAR-? directly interacts with certain specific response elements as a heterodimer with retinoid X receptor ([552]).

The PPAR-? agonists 15d-PGJ $_2$ and troglitazone induce human RA synoviocyte apoptosis *in vitro* ([567]). In human RA synovium, there is increased PPAR-? expression, primarily in the synovial lining macrophages, with some expression in fibroblasts and endothelial cells. Intraperitoneal administration of 15d-PGJ $_2$ (and, to some extent, troglitazone) suppresses adjuvant-induced arthritis and pannus formation in rats ([567]).

Cytokines and Growth Factors

Mononuclear phagocytes secrete factors that promote cellular proliferation and regulate the activities of other cells. IL-1 is a mononuclear phagocyte product that has many different activities ([47]). It can stimulate proliferation of T and B lymphocytes; cause hyperthermia by action through hypothalamic cells; alter synovial cell synthesis of prostaglandins, collagenase, and plasminogen activator; enhance fibroblast proliferation; enhance catabolic activities in muscle; cause specific granule release from neutrophils; and cause hepatocyte synthesis of acute phase reactants ([47]).

Mononuclear phagocytes are important in angiogenesis ([568]). Macrophage-derived factors modify extracellular matrix by releasing degrading enzymes, by synthesizing extracellular matrix components, and by releasing monokines that influence the extracellular matrix. Mononuclear phagocytes also produce factors that induce proliferation of endothelial cells (basic fibroblast growth factor, G- and GM-CSF, TGF-a, insulinlike growth factor-I, platelet-derived growth factor, vascular endothelial growth factor, IL-8, and substance P). Furthermore, mononuclear phagocytes can produce substances that inhibit angiogenesis (e.g., monocyte-derived endothelial cell inhibitory factor, macrophage-derived endothelial cell inhibitor, thrombospondin 1, IFN-a, and IFN-?) ([568]). Mononuclear phagocytes produce M-CSF ([55]) and erythropoietin ([569]).

Macrophages, after stimulation with endotoxin, can secrete TNF (also called *cachectin*), a 17-kd protein that has multiple activities, including the stasis and lysis of various tumor cells, suppression of lipoprotein lipase, synthesis of lipogenic enzymes in fibroblasts/adipocytes, and the induction of insulin resistance in fibroblasts/adipocytes ([570], [571] and [572]). This factor may contribute to cachexia in animals with chronic infections and cancer and to death from endotoxin administration in mice ([573], [574], [575] and [576]). TNF and its close relative lymphotoxin-a are members of a family of ligands that bind to either a 55-kd or a 75-kd receptor ([573]). The 55-kd receptor generally mediates apoptosis of cells, whereas the 75-kd receptor mediates the proliferative and metabolic responses. Several factors are secreted by mononuclear phagocytes that inhibit the proliferation of normal and malignant cells. These include arginase ([577]), thymidine ([578]), IFN-a and IFN-? ([146], [147]), ROS, reactive nitrogen species, and TNF.

IMMUNOREGULATORY FUNCTIONS

Mononuclear phagocytes, and the morphologically similar but clearly distinct DC, act as antigen-presenting (“accessory”) cells working to promote B- and T-lymphocyte viability, proliferation, and lymphokine secretion ([351], [353]). As mentioned above, they secrete IL-1, which enhances T- and B-lymphocyte proliferation ([47], [204], [579]). Antigens are processed by mononuclear phagocytes before they are presented to T cells. Antigens are degraded to peptide fragments, which are then presented via either class I or class II MHC molecules, with class I molecules being involved with endogenously generated antigens and class II with exogenous antigens. Antigen peptides generated endogenously in the cytoplasm (e.g., those generated from an intracellular infection such as influenza virus) by the actions of the proteasome are actively transported across the RER and presented at the mononuclear phagocyte membrane in association with the class I MHC molecule. This antigen is then presented to CD4 T lymphocytes for the generation of sensitized, cytotoxic lymphocytes. Exogenous protein antigens presented at the membrane of mononuclear phagocytes are endocytosed and processed in a lysosomal compartment. Class II a- and ß-chains associate with invariant (Ii) chains and progress through the endoplasmic reticulum. Exogenous antigen peptide fragment then complexes with the aß-chains in an acidic endosome with dissociation of Ii from the complex. The antigen–class II aß complex is then transported to the cell membrane, where antigen can be presented to responding cells in the context of MHC class II molecule. Antigen-presenting cells must physically interact with responding lymphocytes. The process of MHC class I or II-associated–antigen presentation to the T-cell receptor complex is facilitated by certain receptor-ligand couplings between mononuclear phagocytes and responding T lymphocytes (Fig. 13.10). These pairs include CD2 with LFA-3, LFA-1 with ICAM-1 or -2, and CD28 with B7-1 (CD80) or B7-2 (CD86). Lymphokines and monokines elaborated by the interacting cells influence expression of these accessory molecules and act as co-stimulatory molecules for activation of lymphocytes. CD8 and CD4 have a low affinity for binding to MHC class I and II molecules, respectively, and they likely contribute to the interactions.

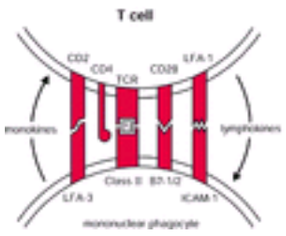

Figure 13.10. Mononuclear phagocyte antigen presentation enhancement by mononuclear phagocyte–lymphocyte interactions involving certain receptor-ligand pairings. The major histocompatibility complex class II antigen presentation to the lymphocyte T-cell receptor complex is facilitated by interactions of cell adhesion molecules with their respective receptors/ligands. Levels of expression of the receptors/ligands are modulated by monokines/lymphokines elaborated by the mononuclear phagocytes/lymphocytes. Ag, antigen; ICAM, intercellular adhesion molecule; LFA, lymphocyte function–associated; TCR, T-cell receptor complex.

ANTIMICROBIAL AND ANTITUMOR EFFECTS

Experimental animals that harbor chronic infections due to intracellular microorganisms have enhanced resistance to infection with antigenically unrelated microbes and parasites and to the growth of tumor cells. Mononuclear phagocytes mediate this resistance ([13], [580], [581] and [582]). Macrophages from these animals show enhanced ability to cause stasis and lysis of such microbes and tumor cells *in vitro* and are termed *activated macrophages*. Although activities for antimicrobial and antitumor effects generally parallel each other, these functions sometimes diverge ([583]). Mononuclear phagocytes in their unactivated state can serve as reservoirs for a latent, persistent infection with organisms such as mycobacteria, fungi, protozoa, viruses, and certain bacteria. However, once activated, macrophages inhibit replication and kill most of these organisms. These antimicrobial effects are believed to be mediated by NO and ROS ([15], [584], [585] and [586]). Lymphokines, especially IFN-?, enhance antimicrobial effects; these parallel the enhanced ability to produce NO and hydrogen peroxide. Differentiated macrophages do not possess appreciable peroxidase, with the result that the peroxidase/halide/peroxide complex [which is so potent in producing hypochlorous acid in neutrophils ([18])] is not always operative in mononuclear phagocytes. Oxygen-independent mechanisms, such as lysozyme, cationic proteins, defensins ([587]), lysosomal enzymes and acid pH, IFN, and iron sequestration, can play a role in mononuclear phagocyte–mediated antimicrobial effects ([511], [588], [589]). Monocytes and macrophages from patients with CGD are unable to produce superoxide and hydrogen peroxide, yet these cells have nearly normal antitumor effects ([590]). Microorganisms can evade the effects of mononuclear phagocytes by different mechanisms. Examples include the inhibition of phagosome-lysosome fusion by mycobacteria and *Chlamydia* ([591], [592]) and rupture of the phagosome membrane with spilling of *T. cruzi* into the cytoplasm ([593]).

Both NAPH oxidase–derived superoxide and NOS2-derived NO play critical roles in the antimicrobial activities *in vivo*. Using mice with disruptions of NOS2 or the gp91 subunit of NAPH oxidase (Phox) (either the respective single “knock-outs” or a double NOS2/Phox “knock-out”), investigators have determined that mice with disrupted NOS2 or Phox are highly susceptible to infection and death with *Salmonella typhimurium*, and those with the double disruption are more susceptible ([585], [586]). Despite impaired resistance in both NOS2- and Phox-disrupted mice, the kinetics of bacterial replication were markedly different in the two groups, with Phox-disrupted mice having dramatic proliferation of *S. typhimurium* in the first few hours, whereas NOS2-disrupted mice had a slower accumulation of the microbes. Thus, Phox (and superoxide, hydrogen peroxide, and, perhaps, peroxynitrite) appears to be most important in the first few hours of infection, whereas NOS2 (and NO and NO-related molecules) had a more sustained effect that lasted for several days ([585], [586]). Mice with NOS2 disruption are also extremely susceptible to infection and death from mycobacterial tuberculosis infection ([594]). Studying *L. donovani* in comparable mice, researchers noted that both mice with disruption of NOS2 and those with disrupted Phox have increased susceptibility to infection during the early stage of liver infection ([595]). After this early phase, infection was controlled in the Phox-disrupted mice, but it was unrestrained in mice with NOS2 disruption. Granulomas developed in both types of mice ([595]).

Genetic defects in Phox (CGD) have been noted in humans, but comparable human NOS2 mutants with associated immunodeficiency have not been noted. In addition to the direct antimicrobial effects of NO, NO can serve to dampen or prevent manifestations of disease in those infected with microbes. For example, children with the C-1173T NOS2 promoter polymorphism have increased NO production and are protected from severe disease and death from infection with *Plasmodium falciparum* ([543]). However, despite this protection, those with the polymorphism do not have reduced levels of malaria parasitemia ([543]). The “antidisease” effect of NO is likely related to an NO-mediated decrease in TNF production ([596]) and an NO-mediated decrease in endothelial cell adhesion molecule expression (and, thus, a decrease in adherence of parasitized erythrocytes to endothelium cells) ([597]).

The antitumor effects of mononuclear phagocytes are potent and complex. Macrophages activated for antitumor activity are immunologically nonspecific in that they act on tumor cells irrespective of species or antigenic makeup, but they are selective in that tumor cells are affected whereas normal cells are relatively spared ([581]). This cytotoxic activity generally requires macrophage–target cell contact, and supernatants do not mediate the damage. Tumor cell cytotoxicity consists of both cytostasis and cytolysis. It is unlikely that ROS are the primary mediators of tumor cell cytotoxicity. Spontaneous tumor cell killing by mouse or human mononuclear phagocytes is unaffected by anaerobiosis and quenchers or by scavengers of ROS ([590], [598]), and monocytes from patients with CGD (those unable to produce peroxide and superoxide) kill target cells normally ([590], [599]). The cytostatic effects are mediated, at least in part, by inhibition of mitochondrial respiration with resultant inhibition of DNA synthesis ([600], [601]). The cytotoxic effect is accompanied by a loss of tumor cell iron ([602]). Potential mediators of the cytotoxic effect include ROS ([603]), thymidine ([578]), arginase ([577]), a cytolytic protease ([604]), TNF ([573], [605]), and NO ([606]). Cytotoxic activated macrophages synthesize NO (frequently measured as its oxidation products nitrite and nitrate). NO is a mediator of activated macrophage–induced tumor cytotoxicity; it causes inhibition of tumor cell DNA synthesis, induction of iron release from tumor cells, inhibition of tumor cell mitochondrial respiration, inhibition of ribonucleotide reductase, and induction of apoptosis ([514], [601], [602], [606], [607], [608] and [609]).

The process of mononuclear phagocyte activation can result in cells with various phenotypes. For the sake of precision, most designate the function for which the cells are activated (e.g., “activated for increased ability to kill microbes” or “activated for increased expression of arginase”). Activation is generally a graded process in which cells can be modulated to different states in which they display different functional abilities ([33], [34], [581], [610], [611] and [612]). *Classic macrophage activation* was originally described as the process by which the cells are activated to a state of increased ability to inhibit the growth of or to kill microbes or tumor cells (Fig. 13.1). In animals with chronic infection, lymphocytes sensitized to microbial antigens secrete lymphokines that chronically act on mononuclear phagocytes ([13], [581]). *In vitro*, macrophages are activated by multiple signals in a sequential fashion. Cells are primed for function by the action of soluble activating factors. IFN-? serves as one of these potent factors ([416], [418], [419], [420] and [421]). Once primed in this manner, macrophages show several different functional and antigenic changes, but they are, in general, not tumoricidal. However, these macrophages can be triggered to kill by different bacterial products such as endotoxin, porin, and muramyl dipeptide in very low amounts ([581], [610], [612], [613] and [614]). This system of sequential, stepwise classic activation has been demonstrated with experimental animal and human cells ([581], [610], [613]). IFN-?, TNF, and LPS are prototype classic activators. Classicly activated macrophages generally have increased production of NO, superoxide, TNF, IL-1, IL-12, IL-6, MIP-1a, and macrophage chemotactic protein-1, and they display lower levels of the mannose receptor ([33], [34]) (Table 13.6). Classicly activated macrophages have markedly enhanced antimicrobial activity.

TABLE 13.6. Activated Macrophages

	Classic	Alternative	Type II
Activators	IFN-?, TNF, LPS	IL-4, IL-13, glucocorticoids	IFN-?, TNF, LPS with Fc receptor ligation
Markers	? MHC-II, CD86; ? mannose receptor	? Mannose receptor; ? scavenger receptor; ? FIZZ1, Ym1	? MHC-II, CD86
Cytokine production	? TNF, IL-12, IL-1, IL-6	? IL-1 receptor antagonist; ? IL-10, CD23	? IL-10, TNF, IL-6
Chemokine production	IP-10, macrophage inflammatory protein-1a, macrophage chemotactic protein-1	Alternative macrophage-activation-associated-1	—
NOS2/Nitric oxide	????	??? or none	??? or none
Arginase	None	????	—
Microbicidal activity	????	None	—

IFN, interferon; IL, interleukin; LPS, lipopolysaccharide; MHC-II, major histocompatibility complex class II antigen; TNF, tumor necrosis factor; ?, increased; ?, decreased.
Adapted from references 33, 34, 610, and 612.

IL-4, IL-13, and glucocorticoids are the prototype activators for the *alternative activation of macrophages* ([33], [34]). Alternatively activated macrophages produce high levels of arginase (and, thus, consume arginine and limit NO production because of substrate depletion) and high levels of IL-1 receptor antagonist and IL-10, display increased levels of the mannose receptor and the SR, and kill microbes poorly. They also display the unique transcription factors FIZZ1 and Ym1, whereas classicly activated macrophages do not ([615]). They have little or no increase in MHC class II antigen, and they are poor at presenting antigen to T cells. However, they have

increased fibronectin and extracellular matrix synthesis. Increased polyamine synthesis as a result of arginase activity leads to increased cell growth, collagen formation, and tissue repair.

Ligation of FcRs of macrophages (e.g., with IgG immune complexes) coupled with signaling through TLR (e.g., with LPS) or with CD40 or CD44 results in perhaps a third variety of activated cells, *type II activated macrophages* ([34]). These cells are similar to classicly activated macrophages but produce high levels of IL-10 and do not have high levels of arginase. In general, they inhibit inflammation, probably as a result of the high IL-10 production. Whereas classicly activated macrophages stimulate T cells to produce IFN-? (Th1 response, likely as a result of IL-12), type II activated macrophages induce T lymphocytes to produce IL-4 (Th2 response, likely in response to IL-10) and cause Ig class switching by B lymphocytes.

A variety of factors and actions can cause *macrophage deactivation*. It is important to define *activation* when assessing these processes. The cytokines IL-10 and TGF-ß "deactivate" macrophages by decreasing MHC II expression, NOS2 expression, NO production, COX2 expression, and prostaglandin production. As noted above, IL-4 diminishes NOS2 expression and NO production, but it also increases arginase expression, and IL-4–treated macrophages, although "deactivated" for some functions, are activated for others. Also, IL-4 increases macrophage CD23 (the low-affinity IgE receptor), and engagement of CD23 by IgE increases macrophage NOS2 expression and NO production ([378]). As noted above, PPAR-? agonists reduce monocyte and macrophage production of TNF and NO ([551]). Phagocytosis of apoptotic cells decreases activity of macrophages, generally by enhancing production of IL-10 and TGF-ß.

MONONUCLEAR PHAGOCYTES AND APOPTOSIS

Apoptosis (programmed cell death) is a natural, active process that can be envisioned as a way to rid the body of effete cells, excess cells, or cells that are potentially dangerous ([616]) (Fig. 13.11). The process can begin with either the cell death receptor pathway (initiated by a variety of ligands through TNF receptors and CD95) or the mitochondrial pathway [initiated by a variety of signals such as x-irradiation, ultraviolet irradiation, chemotherapy drugs, and p53 (DNA damage)] ([616]). Both paths lead to a cascadelike activation of a series of cysteine-aspartate proteases (caspases), with resultant apoptosis and cell death. In the cell death receptor pathway, for example, CD95 ligand binds to CD95 and induces receptor clustering. This clustering recruits, via the Fas-associated death domain protein, multiple procaspase 8 molecules, and the resulting high concentrations of the caspase zymogens causes caspase 8 activation. Caspase 8 then activates procaspase 3 to active caspase 3, the final common caspase in the cascade. The mitochondrial pathway is activated by exogenous insults, as noted above, and also by internal signals such as DNA damage. These signals cause release of mitochondrial cytochrome *c* and the adapter protein Apaf-1. These two molecules associate with procaspase 9 to form the apoptosome with activation of procaspase 9 and subsequently procaspase 3, with resultant active caspase 3 and apoptosis. Caspase substrates include procaspases but also an inhibitor of DNAse (ICAD), nuclear lamins, and a member of the p21-activated kinase family (PAK2). These caspase actions (and likely others) result in apoptosis and death of cells. The Bcl-2 family of proteins are important apoptosis regulators that act mainly at the mitochondrion membrane. Bcl-2 blocks apo-ptosis by inhibiting release of cytochrome *c* and Apaf-1 from the mitochondrion, whereas proapoptotic members of the Bcl-2 family (e.g., Bax) enhance release. Caspase 3 activity is inhibited by the inhibitor of apoptosis protein, and this, in turn, can be blocked by the second mitochondria–derived activator of caspases or the direct IAP-binding protein with low isoelectric point (DIABLO). The complexity and redundancy of the regulatory factors for this pathway underscore its importance and potency. In addition to protein inhibitors of caspases, NO inhibits all members of the caspase family by nitrosylating the active-site cysteine ([617] , [618]). Also, NO enhances Bcl-2 expression and, thus, reduces apoptosis ([619]). On the other hand, high levels of NO delivered exogenously to cells from NO donors or by adjacent NO-producing cells induce apoptosis and cell death ([620] , [621]).

Figure 13.11. Apoptosis pathways. Apoptosis (programmed cell death) can be initiated through the cell death receptor pathway [via ligands for tumor necrosis factor–related receptors (TNF-Rs)] or through the mitochondrion pathway (via exogenous insults such as chemotherapy drugs or irradiation). Both paths lead to activation of cysteine-aspartate proteinases (caspases) with resultant apoptosis and cell death. In the cell death receptor pathway, a TNF-R (e.g., CD95 or TNF-R1) is engaged by ligand; the receptors cluster and recruit numerous procaspase 8 molecules via the Fas-associated death domain (FADD) protein. Caspase (Casp) 8 is then generated, and this activates caspase 3 zymogen to active caspase 3. In the mitochondrion pathway, an external signal, such as a drug or irradiation, modifies the mitochondrion membrane's permeability, resulting in release of cytochrome *c* (Cyt C) and the apoptosis-activating factor-1 (Apaf-1). These two molecules associate with procaspase 9 to form the apoptosome with activation of procaspase 9 and then subsequently procaspase 3, with resultant active caspase 3 and apoptosis. Inhibitors of apoptosis include Bcl-2, which inhibits Cyt C release from mitochondria, inhibitor of apo-ptosis protein (IAP), which blocks caspase 3 activity, and nitric oxide (NO), which inhibits caspases by nitrosylating the active site cysteine. IAP activity can be blocked by the second-mitochondria–derived activator of caspases (Smac). NO synthase (NOS) inhibitors, which reduce NO production, or NO quenchers, which block biologic activity of NO, reduce the NO inhibition of caspases and eventually enhance apoptosis. NO can also enhance production of Bcl-2 (*dashed line*). L-arg, L-arginine; *uv*, ultraviolet irradiation; XRT, x-ray therapy.

Several microbes can cause apoptosis of macrophages ([622]), and macrophage-mediated cellular cytotoxicity for tumor target cells is mediated, at least in part, by apoptosis ([623]). As noted above, macrophages play a critical role in cell destruction and tissue remodeling in embryonic development and in physiologic destruction and elimination of effete cells ([624]). These processes are, in the main, apoptotic in nature. Macrophages are also critically important for the removal of apoptotic cells from tissues ([625] , [626]). This removal of apoptotic cells is apparently important to reduce the release of toxic cell debris in the local environment and to diminish any proinflammatory effects of the debris. In addition to this physical removal, phagocytosis of apoptotic cells by macrophages increases production of the antiinflammatory substances IL-10, TGF-ß, and prostaglandin E_2, and it decreases production of the proinflammatory substances TNF, IL-1, IL-8, GM-CSF, NO, leukotriene C_4, and thromboxane B_2, thus further diminishing inflammation ([625] , [626]). Phagocytosis of necrotic (as opposed to apoptotic) cells by macrophages generally results in production of proinflammatory mediators and a decrease in antiinflammatory mediators.

Phosphatidyl serine exposed on the outer leaflet of apoptotic cells is the primary recognition signal used by macrophages to initiate phagocytosis and other apoptotic surface molecules such as sugars on proteins and lipids, oxidized LDL-like proteins, ICAM-3, and a C1q-binding site ([625] , [626]). A macrophage phosphatidyl serine–receptor is central to the process, but other molecules also play important roles. These include certain lectins, the C1q-receptor, CR3, CR4, the vitronectin receptor, CD14, and SRs (SRA, CD36, CD68, and LOX-1) ([625] , [626]).

ERYTHROCYTE DESTRUCTION AND IRON METABOLISM

Mononuclear phagocytes in different sites (especially the spleen and liver) are important in removing altered or senescent cells such as erythrocytes ([157] , [627]), neutrophils ([628]), and platelets ([158] , [629]). The mechanism by which these senescent cells are recognized is poorly understood. It is possible that aged erythrocytes are opsonized by an Ig that reacts with band 3 of the erythrocyte membrane ([630]) or that desialyation that accompanies aging renders erythrocytes recognizable as altered ([227]). Macrophages process a large amount of erythrocytes and Hb daily. Once erythrocytes are internalized into macrophage phagosomes, their membrane is lysed, Hb is oxidized to methemoglobin, heme and globin dissociate, and globin is degraded to amino acids. The heme is degraded by the heme oxygenase complex to carbon monoxide, biliverdin, and iron. Ferrous iron is transported intracellularly by an iron-adenosine triphosphatase ([631]). Iron is transferred to the membrane, where ceruloplasmin oxidizes iron for transfer to transferrin. Ferroportin 1 may play an important role in exporting iron from mononuclear phagocytes in a fashion comparable to that in the placenta and in the enterocyte ([632]). Depending on iron needs, iron may be stored in ferritin within the mononuclear phagocyte ([633] , [634]). Ferritin (or hemosiderin) iron can be retrieved later through a "labile" iron pool to be made available to transferrin and used for Hb or heme protein synthesis. Mononuclear phagocytes normally serve as important storage sites for body iron. Their antimicrobial and antitumor effects can be inhibited by iron overload ([588] , [598]). SCLC11A1 (formerly called *natural resistance macrophage-associated protein 1*) is a divalent ion transporter that plays a role in macrophage iron transport and

sequestration. Defects in this gene determine susceptibility to infection with intracellular organisms in mice and humans ([635], [636] and [637]).

NO regulates the RNA-binding protein *iron response element–binding protein* (IRE-BP) ([638], [639]). IRE-BP is a cytoplasmic protein that binds to the 5' untranslated region of ferritin mRNA and erythroid aminolevulinic acid synthase mRNA and to the 3' untranslated region of the TfR mRNA. Binding to these respective regions decreases ferritin and aminolevulinic acid synthase mRNA translation (resulting in lower levels of ferritin and aminolevulinic acid synthase) and stabilizes TfR mRNA (resulting in higher levels of TfR). IRE-BP is cytoplasmic aconitase, an iron-sulfur cluster protein. NO reacts with the iron in aconitase and inhibits its enzymatic function. When NO reacts with IRE-BP, iron is displaced from the iron-sulfur cluster, decreasing aconitase enzyme activity and increasing IRE-BP binding to appropriate mRNAs. NO produced by mouse Mac can modify IRE-BP activity and influence ferritin synthesis ([640], [641]). An arginine analog that inhibits NO synthesis prevents IFN-?- and LPS-induced activation of IRE-BP and IRE-BP binding to the appropriate mRNAs. This is important as a clue to understanding certain abnormalities in iron metabolism noted in inflammatory states and in the anemia noted in patients with chronic inflammation (the “anemia of chronic disease”). NO produced in association with inflammation may modify iron metabolism and cause disorders in heme, TfR, ferritin synthesis, and erythrocyte production by mechanisms involving IRE-BP.

Phagocytosis

The discovery of phagocytosis by Elie Metchnikoff marks the birth of immunology ([1]). As with many other great ideas in the history of science, its origin and evolution can be traced to questions totally unrelated to the subsequent demonstration that phagocytosis plays a major role in defense against intruders in multicellular organisms. Metchnikoff was a zoologist with research in embryology. His early research was concerned with the identification of primordial embryologic structures and functions that could link them to the evolution of species; in other words, he was searching for a link between ontogeny and phylogeny. Digestion was considered one of the most ancient functions—it existed even in unicellular organisms and was also detected among cells of primitive embryologic layers.

These early investigations led to the observations that mobile cells of the primitive digestive tract of the starfish larvae were engulfing foreign material, such as carmine droplets, that Metchnikoff introduced into the larvae. Because carmine had no nutritive value, as he later described the moment, “a new thought suddenly flashed across my brain. It struck me that similar cells might serve in the defense of the organism against intruders.” The now famous Messina experiment provided proof for his new idea. He introduced thorns from his Christmas tangerine tree to starfish larvae, and, after anxiously waiting all night for his results, he observed the next morning that several mobile cells surrounded the thorns. This experiment was followed by observations that, if the spores of the *Monospora bicuspidata* that had entered the body of *Daphnia* were quickly engulfed by wandering cells, *Daphnia* survived; otherwise, the organism died. These results led him to believe that the function of the ameboid cells was important in the defense against infection. The word *phagocytosis* was suggested to him by Dr. Claus, a professor of zoology at Vienna, defining the function of “devouring cells” (from the Greek *phago*, eat).

In multicellular organisms, the cells that are involved in phagocytosis have been called *professional phagocytes* by Rabinovitch. Most widely recognized phagocytes, are the polymorphonuclear leukocytes and the mononuclear phagocytes (monocytes and macrophages). A number of mechanisms have been identified by which extracellular material gains entry into the cell ([2]). The term *endocytosis* is used to characterize the uptake of macromolecules in solution, and it can be subdivided into *clathrin-mediated endocytosis*, *non–clathrin-mediated endocytosis*, and *macropinocytosis* ([3]). Clathrin-mediated endocytosis is the best characterized ([4]). Clathrin consists of three heavy and three light chains (triskelions) forming lattices of hexagons and pentagons. In addition to clathrin, the endocytic vesicles are also coated with adaptors such as adaptor protein 2, can assemble into empty coats or cages, and produce lattice-coated vesicles. The formation of the endocytic vesicle is regulated by a guanosine triphosphatase (GTPase), dynamin. Clathrin-mediated endocytosis is used by certain macromolecules with well-defined receptors present in the clathrin-coated pit or vesicle in the cell membrane, such as receptors for transferrin, low-density lipoprotein, and epidermal growth factor. Non–clathrin-mediated endocytosis is carried out by caveolae and non–clathrin-coated vesicles. Macropinocytosis is a form of endocytosis that results in the formation of large vesicles, usually at the leading edge of the cell membrane where ruffling occurs. It is used by antigen-presenting cells to capture antigen for presentation in the context of major histocompatibility molecules. These various forms of endocytosis involve uptake of fluids, a process that was known as *pinocytosis* (from the Greek *pino*, drink). Phagocytosis is endocytosis of large particles (<1 μm). Phagocytosis differs from pinocytosis not only in terms of the size of the material to be ingested but also in its temperature dependence (it does not occur below 18°C) and its requirement of an intact cytoskeletal system.

It is helpful to consider the morphologic aspects of phagocytosis in three stages: (a) attachment and opsonization, (b) ingestion, and (c) digestion.

ATTACHMENT: ROLE OF OPSONINS

Attachment of foreign particles on the phagocytic surface is facilitated greatly by substances known as *opsonins*, discovered by Almroth Wright and immortalized in *The Doctor's Dilemma* by George Bernard Shaw. The best-known opsonins are immunoglobulin (Ig) G antibodies, complement components (or their activation products), and certain oligosaccharides terminating in mannose or galactose.

The various opsonins bind to the surface of the phagocyte by specific receptors: Fc receptors (FcRs) for the IgG (Fc?R), complement receptors (CRs) for complement components, and the mannose receptor for the mannose-terminating oligosaccharides.

Fc? Receptors

There are three Fc?Rs: Fc?RI (CD64), Fc?RII (CD32), and Fc?RIII (CD16). Their genes have been mapped on chromosome 1 at q21-23. Many isoforms exist; some are encoded by distinct genes, whereas others are generated as a result of alternative splicing ([5], [6] and [7]). Eight genes have been identified so far, three for Fc?RI (A, B, and C), three for Fc?RII (A, B, and C), and two for Fc?RIII (A and B). All FcRs have a ligand-binding polypeptide chain known as a *-chain*, and, in some, the a-chain is associated with homodimers of the ?-chain or heterodimers of the ?- and ?-chains (discussed later). The a-chain belongs to the Ig superfamily with conserved extracellular regions, which contain two (Fc?RII and Fc?RIII) or three (Fc?RI) Ig domains. Their cytoplasmic regions are distinct, suggesting that they may be involved in different functions.

One important characteristic feature of their cytoplasmic region is the presence of conserved tyrosine (Y)–containing sequences YXXL (where X is any amino acid and L is leucine) known as *ITAM* (immunoreceptor tyrosine-based activation motif), which is found in components of B-cell and T-cell receptors. The ITAM motif consists of two YXXL sequences separated by nonconserved amino acids and, in its full-length form, contains up to 25 residues ([8]). This sequence plays a central role in signal transduction of several receptors of the cells of the immune system.

Understanding the role of Fc?R in phagocytosis became possible with transfection of the appropriate gene in a cell line (COS-1) from monkey kidney, which lacks

Fc?Rs but has the intracellular machinery required for phagocytosis ([9]).

The Fc?RI (CD64) is found on monocytes and macrophages and binds monomeric IgG with high affinity (Ka = 5 × 10^{8} mol/L). When present alone, it does not mediate phagocytosis, although it binds IgG-coated sheep erythrocytes. The binding site of the IgG is located in the NH_2 terminal region of the CH_2 domain of the IgG. IgG1 and IgG3 subclasses bind with higher affinity than IgG4 and IgG2. The a-chain of Fc?RI lacks the ITAM motif and can mediate phagocytosis even when it totally lacks its cytoplasmic region, provided that it is associated with the ?-chain that contains ITAM motifs ([10]). On monocyte and macrophage cell lines, the Fc?RI is associated with the ?-chain ([11] , [12]).

The Fc?RII (CD32) is a low-affinity receptor and does not bind monomeric IgG. Its expression on neutrophils is low (10,000 to 40,000 per cell) and shows subclass specificity for IgG dimers (IgG3 > IgG1 = IgG2 ≫ IgG4). The CH_2 and CH_3 domains of the IgG may be involved in the binding. Fc?RIIA is expressed on neutrophils, monocytes, and macrophages, whereas the Fc?RIIB is expressed only on B lymphocytes ([13] , [14]). The Fc?RIIA isoform contains two YXXL sequences (i.e., one complete ITAM) and effectively induces phagocytosis, whereas the Fc?RIIB contains only a single cytoplasmic YXXL sequence and does not induce a phagocytic signal unless a second YXXL sequence is inserted by transfection ([15]). The position of the two sequences and the number of amino acids separating them play a role in phagocytosis.

The Fc?RIIIA (CD16) is also a low-affinity receptor and consists of an a-chain (the ligand binding) and a homodimer of ?-chains or a heterodimer of ? and ? subunits ([16] , [17]). The ? subunit is important not only for the induction of the phagocytic signal but also for the surface expression of Fc?RIII. The Fc?RIIIB is found on neutrophils and is anchored to the outer leaflet of the plasma membrane by a glycosylphosphatidylinositol group, whereas the Fc?RIIIA is a transmembrane protein with a cytoplasmic domain and is expressed on natural killer cells ([18]). The most critical difference between the two Fc?RIII proteins is located in amino acid 203, where a serine in Fc?RIIIB determines the glycosylphosphatidylinositol anchor, whereas a phenylalanine in the Fc?RIIIA directs for the transmembrane form.

The expression of Fc?R can be constitutive or inducible by cytokines. The resting neutrophils do not express Fc?RI but express between 10,000 and 40,000 copies of Fc?RII and 100,000 to 300,000 copies of Fc?RIII ([19]).

Soluble forms have been demonstrated for all three Fc?Rs, which are generated by several mechanisms. Serum contains high levels of Fc?RIIIB, probably released from polymorphonuclear cells by serine protease activity ([20]). Other mechanisms involve alternative splicing (Fc?RIIA) or stop codons (Fc?RI). It becomes apparent that FcRs in general exert a wide range of biologic functions within the network of immunologic regulation and function ([21] , [22]). The expression of the various forms of Fc?R and their functions are summarized in Table 14.1 and Table 14.2, respectively.

TABLE 14.1. Fc? Receptor (Fc?R) Expression

	Mf	Monocytes	Neutrophils	Natural Killer Cells	B Cells	T Cells
Fc?RI	+	+	+	–	–	–
Fc?RIIA	+	+	+	–	–	–
Fc?RIIB	+	+	–	–	+	–
Fc?RIIC	+	+	+	–	–	–
Fc?RIIIA	+	+	–	+	–	+
Fc?RIIIB	–	–	+	—	—	—

+, receptor expressed on cell; –, receptor is not expressed on cell.

TABLE 14.2. Fc? Receptor (Fc?R) Function

	Phagocytosis	O_2	ADCC	Tumor Necrosis Factor-a
Fc?RI	+	+	+	+
Fc?RII	+	+	+	+
Fc?RIIIA	+	+	+	+
Fc?RIIIB	–/+	–/+	–/+	?

ADCC, antibody-dependent cell cytotoxicity; +, receptor performs this function; -/+, receptor sometimes performs this function.

Complement Receptors

Certain complement components and their activation-induced fragments bind to receptors present on phagocytes and enhance phagocytosis. The best studied are the C3b receptor (CR1; CD35), the C3d receptor (CR2; CD21), and the receptor for the inactive fragments of C3b, that is, iC3b (CR3; CD11b and CR4; CD11c). Under certain conditions, some of them mediate ingestion of complement-coated particles. Opsonization by C3 is necessary for phagocytosis to occur, but C3 by itself does not induce ingestion. Marked synergy, however, exists between C3 and IgG in inducing phagocytosis. C3b- or C3d-coated red cells enhance phagocytosis of IgG-coated red cells by 20-fold ([23]). However, CRs can promote both attachment and ingestion in macrophages activated under the influence of T-cell–derived lymphokines ([24] , [25]), shown to be macrophage colony-stimulating factor and interleukin (IL)-4 ([26]). The ability of C3b receptors to promote phagocytosis relates to their capacity to be redistributed on the surface of the phagocyte, and lymphokines may do precisely this ([27]). This lateral mobility of the CRs may permit their engagement to the intracellular machinery that is involved in engulfment. Actually, this mobility of the FcR and CR on the cell membrane can be induced by soluble ([28]) or immobilized immune complexes ([29]), and, when it becomes extensive, it leads to impairment of the ability of phagocytes to ingest IgG-coated particles.

A receptor for C1q also mediates enhanced phagocytosis ([30]). Three cell-surface C1q-binding proteins have been identified. Two of them (60 kd and 126 kd) bind to the “collagenlike” region of C1q (cC1qR) and the third one (33 kd) binds to the globular heads of C1q (gC1qR). The 60-kd cC1qR is structurally related to the Ca-binding protein, calreticulin ([31]), and binds also to mannose-binding lectin and pulmonary surfactant protein A ([32]), all of which enhance phagocytosis ([33]). Mannose-binding lectin and pulmonary surfactant protein A have a primary structure similar to C1q. They have collagenous and globular domains.

The mannose-binding lectin, more commonly known as the *mannose receptor*, is a C-type lectin expressed by macrophages and dendritic cells ([34]) and is involved in uptake of mycobacteria and other pathogens as a result of binding to lipoglycan, lipoarabinomannan ([35] , [36]). Phagocytosed pathogens are directed to the endocytic pathway, and the lipoarabinomannan antigens associated with these pathogens are presented to T cells in the context of CD1b molecules ([37]) (see Chapter 2 and Chapter 18). This is a link between innate and adaptive immunity.

Macrophages also express high-affinity receptors for lipopolysaccharides, the lipopolysaccharide receptor (CD14) ([38]) (see Chapter 2). This receptor enhances ingestion of gram-negative bacteria ([39]) and triggers release of cytokines, especially tumor necrosis factor-a.

Opsonization of pathogens (coated with antibody or complement) markedly facilitates attachment and subsequent ingestion and is particularly important for encapsulated bacteria, such as pneumococci, that resist phagocytosis. Capsules are usually very hydrophilic and prevent the approach of the phagocyte. Opsonization with antibody and complement combined results in bacterial clearance by several logs more than without opsonization or opsonization with either opsonin alone. It is interesting that the subclasses of IgG that bind strongly to the Fc?R also fix complement well. Nonencapsulated bacteria can be ingested without

opsonization through receptors that bind latex particles, zymosan, and others.

INGESTION

After attachment, the phagocyte extends pseudopodia that encircle the particle and eventually enclose it within a vesicle known as a *phagosome*. Phagocytosis stimulated by one particle does not induce ingestion of other particles attached to the same phagocyte that by themselves would not be phagocytosed ([40]). In other words, the response of the membrane to the phagocytic stimulus is segmental, not generalized. This segmental response engages the receptors of the phagocyte with the respective ligand on the particle. Successive ligand-receptor engagements lead to the extension of broad lamellipodia of the phagocytic membrane over the particle, forming a phagocytic cup (Fig. 14.1). Eventually, the advancing ends of the lamellipodia fuse and enclose the particle within the phagosome. This sequential and circumferential ligand-receptor interaction has been called the *zipper hypothesis of phagocytosis* ([41]) (Fig. 14.2). The validity of the zipper mechanism is shown by the inability of macrophages to phagocytose lymphocytes when their surface Ig is capped by anti-Ig antibodies. Lymphocytes treated with anti-Ig antibodies can be phagocytosed if their entire surface is coated with the anti-Ig antibody ([42]) (Fig. 14.3). However, if capping of surface Ig is allowed to take place (i.e., the surface Ig and anti-Ig complexes have moved to one pole of the cell), the phagocyte is firmly attached to the cap, but pseudopodia do not extend to the remaining surface of the cell.

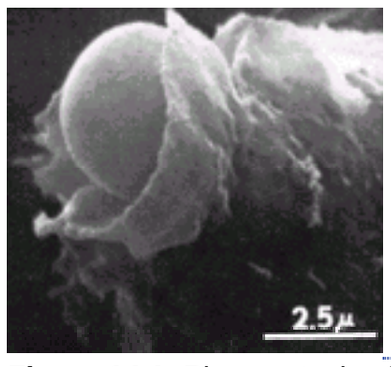

Figure 14.1. Phagocytosis of a red blood cell. Scanning electron micrograph of phagocytosis of an immunoglobulin G–coated red blood cell. Lamellipodia extending from the macrophage over the red cell form a “cup” that engulfs the red cell. (From Kay MM. Hodgkin's disease: a war between T-lymphocytes and transformed macrophages? Recent Results Cancer Res 1976;56:111–121, with permission.)

Figure 14.2. The “zipper” mechanism of phagocytosis. A phagocyte establishes contact with an immunoglobulin G (IgG)–opsonized particle through interaction of the Fc? receptor (FcR) of the phagocyte with the IgG opsonin. Signals generated by this interaction lead to actin polymerization and the formation of pseudopodia. New contacts between the Fc?R on the advancing pseudopodia and the IgG opsonin lead to further advancement of the pseudopodia and additional contacts resulting in progressive encircling of the opsonized particle and the formation of the phagosome. This stepwise binding of the ligands (opsonins) to their respective receptors is known as the *zipper mechanism of phagocytosis*. Partially opsonized particles are not ingested (see Fig. 14.3).

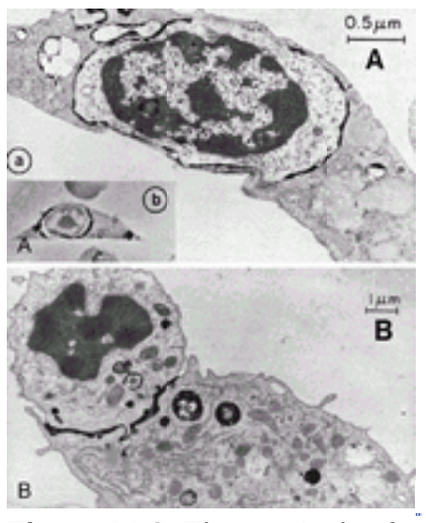

Figure 14.3. Phagocytosis of opsonized and partially opsonized lymphocytes. **A:** Mouse lymphocytes were treated with immunoglobulin (Ig) G rabbit anti-mouse Ig followed by sheep IgG anti-rabbit-F(ab')$_2$ antibody. The peroxidase reaction shows that these lymphocytes have surface Ig distributed around the entire surface of the cell. As shown by electron microscopy **(a)** and phase microscopy **(b)**, these lymphocytes are phagocytosed by the macrophages. **B:** Lymphocytes were first allowed to cap their surface Ig and then were treated with the sheep anti-rabbit-F(ab')$_2$ antibody. The macrophage is attached to the lymphocyte only in the area of the cap, whereas pseudopodia are unable to extend beyond the cap over the lymphocyte surface that has lost the Ig–anti-Ig complexes. Peroxidase-labeled antibodies are seen in vacuoles (*asterisks*) and tubular invaginations of the membrane (*arrows*). (From Griffin FM Jr, Griffin JA, Silverstein SC. Studies on the mechanism of phagocytosis. II. The interaction of macrophages with anti-immunoglobulin IgG-coated bone marrow-derived lymphocytes. J Exp Med 1976;144:788, with permission.)

Signal Transduction by Phagocytic Receptors

Six members of the Src family have been identified in phagocytes: Fgr, Fyn, Hck, Lyn, Ycs, and Src. Some of these are associated with specific receptors. These kinases are important for the early phosphorylation events after Fc?R engagement ([43]). There is a high degree of redundancy among these kinases because significant interference of phagocytosis requires inactivation of several members ([44]).

On stimulation with IgG-coated particles, these kinases are activated and are redistributed to actin-rich phagocytic caps (Fig. 14.4, part 1). The ITAMs of the FcRs are phosphorylated by Src kinases and become docking sites for Syk kinase, which has a critical role in phagocytosis because Syk$^{-/-}$ macrophages cannot internalize IgG-opsonized particles ([45]).

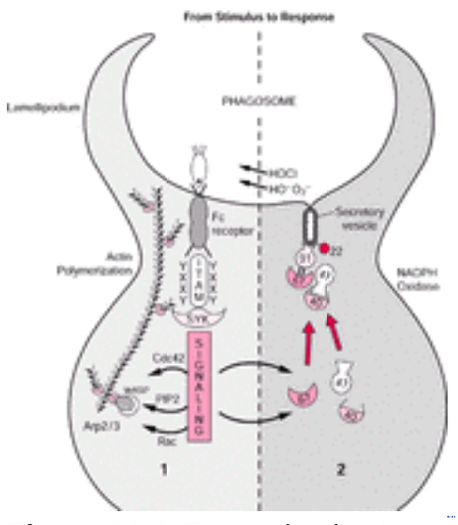

Figure 14.4. From stimulus to response: signaling pathways in phagocytosis. A particle opsonized by immunoglobulin G binds to Fc? receptor (stimulus). Two types of responses are triggered by the stimulus: response 1 (*1*), formation of the phagosome through actin polymerization and extension of pseudopodia, which ingest the particle; and response 2 (*2*), the respiratory burst through activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. Response 1 involves SYK and other kinases (phosphatidyl-inositol 3-kinase, and so forth), generating a second wave of downstream signaling molecules (e.g., phospho-inositides, activation of guanosine triphosphatases, and so forth), which focus on the Wiskott-Aldrich syndrome protein (WASP), a master activator that links the process to actin polymerization through Arp2/3 (see text for details). Response 2 consists of the assembly of the NADPH oxidase in the membrane of the forming phagosome from several individual proteins present in the membrane or translocated from the cytosol (see text for details). Response 1 will enclose the invader within the phagosome, to be killed by response 2 and eventually withdrawn in the interior of the cell to be disintegrated in the endosomes and lysosomes. Arp2/3, actin-related proteins 2 and 3; ITAM, immunoreceptor tyrosine-based activation motif; PIP2, phosphatidylinositol 4,5-bisphosphate.

Several molecules have been implicated in downstream signaling, such as protein kinase C (PKC), phospholipase A_2, phospholipase C, phosphatidyl-inositol 3-kinase (PI3K), GTPases of the Rho family, and so forth.

Ca^{2+} concentration increases around the phagocytic cup, but its role remains controversial. The increase seems to be due to Ca^{2+} release from the phagosome into the cytosol ([46]). Ca^{2+} is important for triggering actin depolymerization through gelsolin activation. Ca^{2+} mobilization is independent of inositol 1,4,5-triphosphate in neutrophils, indicating that the increase of Ca^{2+} around the forming phagosome does not come from intracellular stores.

Phospholipase C? ([47]) and PI3K ([48]) have also been shown to have a role in phagocytosis in different cells. The main role of PI3K in neutrophils and macrophages appears to be regulation of membrane extension during pseudopod formation, mediated by myosin X ([49]). PI3K acts both directly at the level of pseudopod extension and for extracellular signal-regulated kinase activation, which stimulates phospholipase A_2 for arachidonic acid release. Arachidonic acid acts as a second messenger to regulate phagocytosis.

Rac and Cdc42 regulate actin assembly and internalization of Fc?R-coated particles ([50], [51]). The Wiskott-Aldrich syndrome protein (WASP) directly binds Cdc42 and Rac and is recruited to the phagocytic cup ([52], [53]) (see below).

The signaling for inhibition of phagocytosis is regulated through inhibitory receptors, which express immunoreceptor tyrosine-based inhibitory motifs. Ligation of inhibitory receptors results in phosphorylation of the ITIMs by Src kinases, which become docking sites for protein tyrosine phosphatases SHP-1 and SHP-2. The phosphatases dephosphorylate activating receptors, blocking downstream signaling, and the activation is arrested ([54]). The inhibitory receptor, Fc?RIIB, recruits the inositol phosphatases SHIP-1 and SHIP-2, which act on $PI(3,4,5)P_3$ (PIP_3) and break it down to $PI(3,4)P_2$ (PIP_2), thus arresting the downstream signaling of PI3K. Recruitment of SHIP-phosphatases is determined by the amino acid in the Y+2 position within the immunoreceptor tyrosine-based inhibitory motifs ([55]) and by inadequate phosphorylation level ([56]). Overexpression of SHIP in macrophages results in inhibition of Fc?RIIB-mediated phagocytosis ([57]), and co-ligation of Fc?RIIA and Fc?RIIB reduces phagocytosis in monocytes ([58]).

Enclosure of the Phagocytic Vacuole

It is believed that the receptor interaction is solely sufficient to trigger phagocytosis. However, mechanical parameters of the target particle can affect the outcome. When presented with particles of identical chemical properties but of different rigidity, macrophages show a preference to engulf rigid objects ([59]). Constitutively active Rac1 stimulates phagocytosis of soft particles.

Internalization of the engulfed particle requires actin reorganization and membrane fusion. However, macrophages are able to ingest a number of particles with a total surface larger than the cell itself without net loss of surface, and even with surface gains ([60]). Phagocytes must, therefore, supply new membrane from sources within the cell to be able to meet the needs for the enclosure of the phagosome ([61]). Membranous pieces are supplied from an endosomal compartment recruited by phospholipase A_2 ([62]). Focal exocytosis at sites of phagocytosis is necessary along with actin rearrangements to induce proper pseudopodial extension. Focal addition of endomembranes is now considered a partner to cytoskeletal actin rearrangements for several cellular processes [i.e., phagocytosis (extension of lamellipodia), cell spreading, and chemotaxis] ([63]). Actin reorganization and membrane insertions by exocytosis are regulated by different mechanisms. Inhibition of PI3K plays no role in actin polymerization, yet it blocks completion of the phagosome, indicative of mechanisms other than rearrangements of actin cytoskeleton ([48], [64]). The detection of endosomal markers on the plasma membrane during phagocytosis is accepted as evidence of membrane insertions during phagosome formation ([65]).

Most intracellular fusion events are determined by a specific protein machinery, which includes soluble factors, such as the N-ethylmaleimide-sensitive factor (NSF) and the soluble NSF-attachment protein, SNAP, as well as membrane complexes such as SNAP-attachment protein receptor, SNARE. NSF is an adenosine triphosphatase (ATPase) important for SNARE function. The membranes to be fused need to bear specific SNAREs, known as *vesicle* or *v-SNAREs* and *target* or *t-SNAREs*. Particular v- and t-SNAREs dictate the specificity of intracellular molecular fusion events ([66]). Inactivation of two SNARE proteins, VAMP2 and VAMP3, reduces efficiency of phagocytosis. Exocytosis of endosomal membranes is a focal event and occurs at the sites of phagocytosis.

Another group of GTPases, the Rabs, contribute to vesicle exocytosis and interact with SNARE proteins ([67]).

Two other proteins, dynamin2 and amphiphysin IIm, which are associated with endocytic vesicles, also participate in phagocytosis ([68], [69]). Dynamin2 is a GTPase and, through its SH_3 (Src homology 3) domain, interacts with amphiphysin IIm recruited to clathrin-coated pits. It also contributes to pseudopod extension.

Once the phagosome is formed, it is pulled to the interior of the cell by actin filaments and myosins. There are several myosin isoforms ([70]), which are localized around phagosomes in macrophages, and their ATPase activity moves the phagosome along actin filaments. As the phagosome is internalized, it matures. Maturation implies changes of the composition of its membrane. During maturation, the phagosomes progressively acquire a variety of proteins that are characteristic of endosomes and lysosomes ([71], [72] and [73]), whereas other proteins acquired during invagination are recycled back to the plasma membrane.

Early in the maturation process, an ATPase acidifies the phagosomal vacuole. The exact mechanism of the maturation process is not clear. According to one view, the “kiss and run” model ([74]), phagosomes and endosomes do not coalesce, but membrane components and luminal contents are exchanged by momentary fusion followed by fission. Multiple fusion and fission events change the composition of their membrane and content. Others believe that early and late endosomes and lysosomes simply exchange components by means of carrier vesicles ([3]).

Phagosomes move toward the cell interior with the help of microtubules, and, during this journey, they have multiple contacts with endocytic organelles with which they fuse (Fig. 14.5). Eventually, their membrane is remodeled and comes to resemble a lysosomal membrane. This change is characterized by loss of small GTPases and acquisition of lamp proteins. The Rab family of proteins consists of ras-like GTP-binding proteins that serve as key regulators in endocytic trafficking. Rab proteins may, therefore, be used as markers for the endosomal vesicles. Rab5 is present on early endosome, whereas Rab7 is a late endosome–specific marker. The Rab5 member of the family, which is detected in the phagosome and normally regulates fusion of early endosomes, suggests that the phagosome fuses at an early stage with endocytic vesicles. The evidence is certainly more convincing that the phagosome fuses later with late endosomes and eventually transforms to terminal lysosomes.

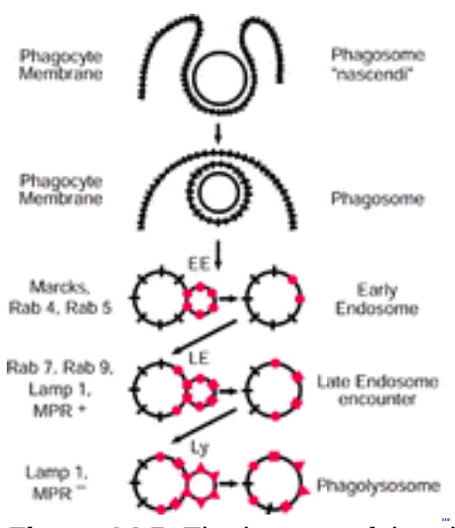

Figure 14.5. The journey of the phagosome along the endocytic pathway to the cell interior. The membrane of the phagosome in the process of being born (phagosome nascendi) has the same composition as the cell membrane and contains the phagocytosed particle. The intracellular movement of the phagosome and other endocytic vesicles involves the microtubules. During this journey, the membrane composition of the phagosome changes as it bounces and partially fuses with other endocytic vesicles such as the early (EE) and late (LE) endosomes. Eventually, the altered phagosome fuses with lysosomal vesicles, which are in a dynamic, continuous exchange cycle with the LEs. The fusion between endocytic vesicles is regulated by the Rab family of guanosine triphosphate–binding proteins. Some of them are highly restricted to a certain stage in the endosomal pathway, such as Rab 4 and Rab 5 in the EEs and Rab 7 and Rab 9 in the LEs. The Rab proteins are not present on the lysosome. At the stage of LE and later, other proteins, such as the lysosomal associated membrane proteins (Lamp), are characteristic markers of these vesicles. Marcks, myristoylated alanine-rich C-kinase substrate; MPR, mannose-6-phosphate receptor.

The relationship of late endosome to lysosome is dynamic. Molecules (i.e., receptors) that will be recycled are sorted out in the early endosome and are directed back to the membrane through the recycling vesicles, whereas other endocytosed material is delivered by carrier vesicles to late endosomes. The late endosomes are of lighter density than lysosomes, and although lysosomes eventually contain all internalized substances, they probably fuse with late endosomes on more than one occasion, indicating that an equilibrium likely exists between late endosomes and lysosomes.

Rab9 functions in the transport of mannose-6-phosphate receptors (MPRs) between late endosome and the trans-Golgi network. There are two distinct MPRs, one 275 kd and a second 46 kd. The former binds mannose independently of divalent cations and has been called *cation-independent MPR*. It also binds insulinlike growth factor II. The latter requires divalent cations for optimal ligand binding and is referred to as *cation-dependent MPR*. MPRs cycle between Golgi, endosomes, and plasma membranes. Cation-independent MPR is present in one or more endosomes but is undetectable in lysosomes. The cation-dependent MPR is also found in endosomes that contain the cation-independent MPR. This suggests that the lysosomal enzymes that are transported by the MPRs are delivered to the acidic endosomal compartment rather than to lysosomes, and the MPRs are then recycled back to the Golgi, plasma membrane, or both.

ACTIN AND PARTNERS: AN INCREDIBLE MACHINE

Extension of pseudopods and locomotion of cells is achieved by the assembly of actin filaments and their branching to form networks.

Actin is an ATP-binding protein that exists as a globular monomer (G-actin) and as polymerized filaments (F-actin). In electron micrographs, actin filaments have a characteristic arrowhead appearance with a pointed end and a barbed end. The barbed end has a higher affinity for actin monomers than the pointed end.

Each actin monomer has a bound ATP, which, after polymerization, is hydrolyzed to adenosine diphosphate (ADP), releasing inorganic phosphate. Monomers released from polymerized actin carry ADP, and, to polymerize again, ADP must be exchanged with ATP because ATP-actin has a higher affinity for the barbed ends of F-actin.

The assembly of actin filaments is a highly complex process and, at the beginning, must involve reactions between actin monomers *de novo*, but later, when a filament is formed, monomers are added to the filaments for extension or branching. This process is called *nucleation*, which refers to “initiation of new actin filaments by assembly from monomers” ([75]). *Elongation*, on the other hand, is the addition of new monomers to barbed ends of the filament (Fig. 14.4, part 1). Recently, the protein complex Arp2/3 has been shown to be the universal actin nucleation and organizer machine, conserved across the species ([76] , [77]). Arp2/3 consists of seven subunits, two actin-related proteins (Arp), Arp 2 and Arp 3, and five other proteins (ARPC1 through 5). The crystal structure of Arp2/3 has recently been solved ([78]). The Arp2/3 complex is a flat ellipsoid with dimensions 150 Å long, 140 Å wide, and 70 to 100 Å thick. The overall shape is in the form of a C-shaped clamp formed by the ARPC2 and ARPC4 subunits, while the Arp2 and Arp3 sit in the center. The other ARPC subunits reinforce and decorate the edges of the clamp. Activation of Arp2/3 complex by the WASP family of proteins brings Arp2 into proximity with Arp3 for nucleation (see below).

Purified Arp2/3 has little activity ([79]) and requires activation by nucleation-promoting factors. Nucleation-promoting factors are members of the WASP family of proteins. WASP has a modular structure consisting of several structurally and functionally distinct domains (Fig. 14.6). At the *C*-terminal of the protein is the VCA region, consisting of three domains: W or V (*v*erprolin homology), C (*c*ofilin homology or *c*entral or “ *c*onnecting”), and A (*a*cidic). *W* is also known as *WH* $_2$ (WASP homology 2 domain), and *VCA* is referred to as *WA*. WH $_2$ binds monomeric actin, competing with profilin and thymosin-ß $_4$.

Figure 14.6. The structure of the Wiskott-Aldrich syndrome protein (WASP) and its ligands. WASP consists of several domains that mediate different functions (see text for details). Arp2/3, actin-related proteins 2 and 3; BR, basic region; GBD, guanosine triphosphatase–binding domain; PIP2, phosphatidylinositol 4,5-bisphosphate; SH $_3$, Src homology 3; VCA, verpolin homology, cofilin homology, acidic domains; WH1, WASP homology domain 1; WH2, WASP homology domain 2; WIP, WASP-interacting protein.

The A and C domains bind to the Arp2/3 complex, whereas the N-terminal to WA (VCA) polyproline region (P), rich in ProXXPro motifs (X = any amino acid), binds SH $_3$ domain–containing proteins (i.e., Grb2, Fyn, BTK).

The P region also binds the actin-binding protein, profilin, and the Cdc-42–interacting protein-4, which may connect WASP with the microtubules.

Farther to the center of WASP is the GTPase-binding domain (GBD), target for the small GTPases, Cdc42 and Rac. It is followed by a short lysine-rich basic region,

which may be the actual binding site of PIP_2 ([80], [81]). The *N*-terminal domain, WH_1, binds WIP (WASP-interacting protein), a member of the proline-rich actin-binding family of proteins. WIP has been implicated in regulation of actin cytoskeleton. It contains a WH_2 actin monomer–binding domain, a profilin-binding domain, and a WASP-binding domain in its carboxy terminus. It regulates N-WASP–mediated polymerization and filopodium formation and stabilizes actin filaments. N-WASP has two WH_2 domains, and Scar (*s*uppressor of G-protein– *c*oupled cyclic *A*MP *r*eceptor), also known as *WAVE* (WASP family verpolin-homologous proteins), lacks GBD and WH_1 domains. In conclusion, the C and A domains contribute to the binding of the Arp2/3 complex but not the WH_2 domain. The binding sites for actin and for the Arp2/3 complex are close together or even overlap.

Activation of Arp2/3 by Wiskott-Aldrich Syndrome Protein

The crucial role of WASPs depends on their *C*-terminal WA (VCA) region, which binds and activates the Arp2/3 complex. WA binds simultaneously to G-actin and to Arp2/3 complex, with the actin filament enhancing the affinity of WASP for the Arp2/3 complex. The WASP dissociates rapidly from the complex after nucleation ([82]).

WASP mediates the “presentation” of G-actin to Arp2/3 followed by its activation. As shown by constructs containing individual domains of the VCA region, the A domain confers high-affinity binding to Arp2/3 but not activation, whereas the V domain is indispensable for activation and, at the same time, enhances G-actin binding ([83]). Thus, the V, C, and A domains act cooperatively in Arp2/3-mediated function for actin polymerization ([84], [85]).

The ARPC2 and ARPC1 subunits anchor the complex to the side of the “mother” filament at a 70-degree angle. WASPs stabilize the conformation by linking ARPC1 and ARPC3 subunits.

Activity of WASPs is markedly enhanced by GTP-Cdc42, PIP_2, and GRB2. Each of these factors individually has a weak effect, and it is likely that their action is additive or even synergistic ([86], [87]). For example, GTP-Cdc42 is unable to activate WASP by itself, but it augments PIP_2 stimulation. Electron micrographs show that the Arp2/3 complex contacts three successive subunits of the “mother” filament, and the Arp2/3 form the first two subunits of the branching or “daughter” filament ([88]).

Actin Polymerization in Phagocytosis

Nucleation could take place either on the side of a filament (“branching nucleation”) ([88], [89] and [90]) or at its barbed ends ([91]). Strong evidence by a variety of techniques ([92], [93] and [94]) shows that a complex network of F-actin grows like a tree, with branches always extending from the sides of a filament (Fig. 14.7). As shown in Figure 14.8, gold-labeled Arp2/3 binds to the side of a preexisting branch or mother filament ([88]). Elongation of the daughter filaments then takes place by the addition of new actin monomers with their pointed ends fitting to the barbed ends of the previous units (Fig. 14.7). Thus, the branches of the advancing actin network push forward by their free barbed ends. This model of actin polymerization is also supported by the fact that Arp2/3 initiates nucleation even from mother filaments that have their barbed ends capped ([95]). Finally, the protein cortactin, which binds only to the sides of the F-actin filaments, mediates nucleation by Arp2/3 complex ([96]). Cortactin has an *N*-terminal acidic domain and five to six repeats in the central part of the molecule, which have the F-actin binding site ([97]). Cortactin acts as a mediator between WASP and the Arp2/3 complex. They both bind simultaneously to the complex and synergistically contribute to Arp2/3 activation, despite the fact that they compete for a common binding site on Arp2/3 ([98]). Cortactin binds to the Arp3 subunit of the complex and mediates the binding of the complex to F-actin, whereas WASP activates the complex. Cortactin thus promotes and stabilizes the formation of new daughter actin filaments ([99]).

Figure 14.7. Organization of actin polymerization. Actin-branching polymerization by actin-related proteins 2 and 3 (Arp2/3). Arp2/3 binds to the sides of preexisting (“mother”) filaments and adds new G-actin monomers by side branching. The “push” of the actin filaments comes from the barbed ends of the new elongated “daughter” filaments.

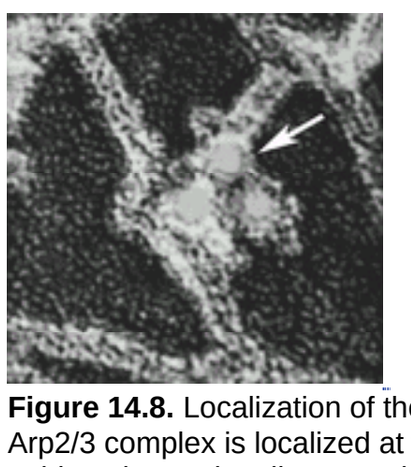

Figure 14.8. Localization of the actin-related proteins 2 and 3 (Arp2/3) complex at branching points of actin filaments. Electron micrographs of actin filaments. The Arp2/3 complex is localized at the branching points (arrow). The complex was identified by a specific antibody, the binding of which was detected by a secondary gold-conjugated antiimmunoglobulin antibody. (From Svitkina TM, Borisy GG. Arp2/3 complex and actin depolymerizing factor/cofilin in dendritic organization and treadmilling of actin filament array in lamellipodia. J Cell Biol 1999;145:1009–1026, with permission.)

WASP is subject to autoinhibition and exists in an inactive form. The “inactive conformation” results from an intramolecular interaction between the hydrophobic core of GBD and the *C*-terminal WA effector domain, which brings the occlusion of the WASP WA domain. Binding of GTP-Cdc42 to GBD disrupts the hydrophobic core, an action enhanced by PIP_2. Change in the conformation “opens” the *C*-terminal VCA domain for binding of the Arp2/3 complex ([86], [100]).

The leading edge of a moving phagocyte is known as the *lamellipodium*. It extends forward and seems to pull the rest of the cell body along with it. Pseudopodia project from the lamellipodium and attach closely to the particle to be ingested. The lamellipodium and pseudopodia contain no cytoplasmic organelles and, as a result, have a glassy appearance (Fig. 14.9). Both, however, are rich in actin filaments. Actin constitutes 10% of the total protein in macrophages and is present in two forms, G-actin (globular or monomeric) and F-actin (filamentous or polymeric).

Figure 14.9. Phagocytosis of yeast particles by polymorphonuclear leukocytes. A human neutrophil extends long pseudopodia that encircle two yeast particles. HE, hyaline ectoplasm. [From Stossel TP. Phagocytosis (second of three parts). N Engl J Med 1974;290:744, with permission.]

Actin polymerization during phagocytosis has been well documented ([101] , [102]), as has the role of the WASP family of proteins in the mechanism of polymerization through activation of the Arp2/3 complex ([103] , [104] and [105]). Monocytes and macrophages from patients with Wiskott-Aldrich syndrome (WAS) have reduced capacity for phagocytosis ([106]). WAS is a rare X-linked, recessive immunodeficiency disease. Patients suffer from recurrent pyogenic and opportunistic infections, eczema, and thrombocytopenia with small platelets. WAS is due to a wide spectrum of gene mutations that result in the expression of no WASP or a truncated protein lacking the crucial *C*-terminal VCA or WA region. In an X-linked thrombocytopenia form or attenuated WAS, the WASP gene has missense mutations in the *N*-terminal region ([107]). Finally, an X-linked neutropenia form or myelodysplasia has been detected as a result of mutations of part of the gene encoding the GBD domain. Mice with targeted disruption of the GBD domain share some of the features (i.e., lack of T-cell activation) but not others ([108]).

Fragments of Arp2/3 containing the WA domain almost completely inhibit phagocytosis, a finding emphasizing the importance of Arp2/3 in the process ([109]). The Arp2/3 complex, WASP, and N-WASP localize to the surface of phagosomes during Fc?R- and CR3-mediated phagocytosis ([106] , [109]).

An intriguing function of actin polymerization is related to the movement of various endosomal vesicles. Actin polymerization propels them to their destinations by a “rocketing” mechanism ([110]). The Arp2/3 complex and N-WASP are localized to the surface of moving endosomes and lysosomes and to the surface of motile macropinosomes ([111] , [112]). A similar function of actin polymerization has been demonstrated with the motility of intracellular pathogens ([113]). Such pathogens are associated with actin “comet tails,” which contain many of the components of lamellipodia. Structurally, however, the filaments in lamellipodia are branched as a result of dendritic nucleation, whereas the “comet tails” are short, randomly oriented filaments with some dendritic nucleation ([114]). Thus, it is evident that actin polymerization and dendritic nucleation with an expanding F-actin network provide all the mechanical force necessary for “pushing” lamellipodia around the particle and completing the enclosure of the phagosome ([115]).

Actin-Binding Proteins

PROFILIN AND COFILIN Profilin and thymosin-ß $_4$ bind monomeric actin and modify its properties for polymerization. Thymosin-b $_4$ is a peptide of 43 residues that competes with profilin (125 to 139 residues) for binding to actin ([116]). Thymosin-ß $_4$ binds more strongly to ATP-actin and is a sequestering protein. Profilin has a higher affinity for ATP-actin monomers than for the barbed ends of actin in filaments because its binding site is buried in the filament structure. As a result, profilin maintains a pool of free ATP-actin ready for filament elongation. In cells with both proteins, profilin serves as a carrier between the thymosin-b $_4$–actin pool and the barbed ends of actin filaments ([117]). At least two F-actin pools exist in vertebrate cells, one relatively stable, which is often associated with tropomyosin (an actin filament–binding protein with an a-helical coiled-coil structure), and one more dynamic, usually found in the leading edge of motile cells. Recently, it has been shown that the proteins that regulate the high turnover of F-actin filaments belong to the family of ADF-cofilin (ADF, *a*ctin *d*epolymerizing *f*actor; cofilin, forming *cofil*amentous structure with act *in*) ([118] , [119]). There are approximately 30 members in the family with conserved actin-binding regions. A second homologous region outside the actin-binding site suggests that they bind to another protein ([120]). ADF and cofilin are usually cytoplasmic proteins, but, under stress, they accumulate in the nucleus accompanied by actin, which forms actin rods ([118]). Nuclear localization, which is mediated by a specific sequence, has been detected in many types of cells as inclusion bodies that frequently have a fibrillar or lattice appearance. Actin and cofilin have been detected in these inclusions. The three-dimensional structure of yeast cofilin shows that it consists of a ß sheet with four strands surrounded by four a-helices. This structure has been called the *ADF-homology domain*. The ADF-homology domain shares similarities with the gelsolin family. Gelsolin has six repeats of this domain ([121]). Cofilin interacts with actin through its *N*-terminal region ([122]), an interaction inhibited by PIP $_2$. The structure of the cofilin–actin filament complex shows that cofilin makes contacts on the outside of the filament with both the pointed and barbed ends ([123]). In general, ADF/cofilin binds to the actin-ADP subunits of the F-actin filament, increasing the off-rate from the pointed end and thus depolymerizing F-actin and severing actin filaments ([118]); in doing so, it increases the number of barbed ends. When actin monomers dissociate from the pointed ends of the filament, they have ADP nucleotide, and, to be reused, ADP must be exchanged with ATP. However, ADP/cofilin prevents the exchange, limiting the reuse of actin monomers released from filaments ([124]). Profilin, on the other hand, strongly increases the nucleotide exchange, even in the presence of ADF/cofilin ([125]), and it appears that profilin and ADF/cofilin regulate recycling of actin-ADP and F-actin filament turnover based on their opposite effects on nucleotide exchange. Filament turnover is rapid during extension of pseudopods and cell movement. Lamellipodia move up to 1 µm per second (370 subunits per second). The mechanisms that regulate the high rate of depolymerization, and of severing when it is required, are not well understood. Polymerization or filament extension requires free barbed ends, which can be generated by various mechanisms such as uncapping and severing.

GELSOLIN Gelsolin is the most abundant protein that caps filament ends, and it regulates cytoskeleton remodeling in response to Ca^{2+} and PIP $_2$ binding ([126]). Severing is the breaking of noncovalent bonds between two actin molecules within a filament. After severing, gelsolin remains attached to the barbed ends of the filament as a cap (capping). Gelsolin is the most effective severing protein identified to date ([127]). Through actin cytoskeleton reorganization, it plays a role in cell motility, phagocytosis, chemotaxis, and wound healing ([128]). Animals of mixed-strain background that are deficient in gelsolin have no gross pathology, but inbred strains are not viable at perinatal stages ([129]). Gelsolin consists of six structurally similar domains (G $_1$ through G $_6$), evolved by gene duplications from one prototypical domain ([125]). Significant structural similarities exist between the domains in each triplex (G $_1$ through G $_3$ and G $_4$ through G $_6$). The actin-binding site is masked and is revealed in response to Ca^{2+} increase, which releases contacts between domains and exposes actin-binding sites in G $_2$, G $_1$, and G $_4$ domains. There are up to eight Ca^{2+}-binding sites of two types. Type 1 sites are shared between gelsolin and actin and govern the strength of interactions between them. Type 2 sites have the potential for causing movement between the domains. The structure of the gelsolin–F-actin complex has been solved and provides insights into the mechanism of severing ([130] , [131]). Ca^{2+} activation triggers binding of G $_2$ to F-actin, and this brings the G $_1$ into a position to disrupt actin-actin interaction. The second disruption needed to sever the monomer is contributed by G $_6$, which brings G $_4$ domain for a pincer action with G $_1$ to remove the actin monomer. There are at least two G-actin–binding sites in domains 1, 2, and 4 and one PIP $_2$-binding site in domain 2. Lowering Ca^{2+} concentration may not induce gelsolin uncapping after severing. PIP $_2$ is the only known agent that inhibits gelsolin severing and dissociates gelsolin from actin *in vitro* ([132]). In platelets, removal of gelsolin contributes to actin polymerization ([133]) and to filament growth. Severing is the major mechanism for generating free barbed ends in platelets ([134]), and the thrombin receptor–activating peptide stimulates Arp2/3 activation for all actin-dependent morphologic changes ([135]).

REGULATORY MECHANISMS: DOWNSTREAM PATHWAYS

Calcium

One of the first signals observed in response to Fc?R activation of phagocytosis is the increase of cytosolic Ca^{2+} ([136]). The role of Ca^{2+} in FcR-mediated phagocytosis remains controversial, but, for CR3-mediated phagocytosis in neutrophils, it plays no role. In macrophages, neither phagocytosis nor

phagosome-lysosome fusion is Ca^{2+}-dependent ([137]). Ca^{2+}, however, is important in some aspects of actin network reorganization and in the function of gelsolin.

Protein Kinase C Family

These serine/threonine kinases are activated by the phospholipase product diacylglycerol, as well as by Ca^{2+}. Members of the family have been identified in the phagosome (PKC-a, -ß, -?, and -?) during Fc?R-mediated phagocytosis, and pleckstrin, a major substrate for PKC phosphorylation, is recruited in macrophage phagosomes ([138]). Other substrates for PKC are the proteins MARCKS (*m*yristoylated *a*lanine- *r*ich *C*- *k*inase *s*ubstrate), which mediate cross-linking of actin filaments. In mice deficient in MARCKS, however, the Fc?R- and C3-mediated phagocytosis is normal ([139]), indicating that simple localization around the phagosome is not necessarily indicative of functional participation.

Phosphoinositide Kinases

Phosphoinositides bind to pleckstrin homology domains, which are detected in well over 100 different proteins. The majority of these proteins are found in membranes and have been implicated in a variety of membrane functions ([140], [141]).

Phosphoinositides are major regulators of various aspects of the phagocytic process ([142], [143]) and are produced from the function of PI3K. PI3K, however, is not localized in the phagosome ([144]) as a result of displacement by its own product, PIP_3 ([145]). PI3K is activated by Fc?Rs and is required for phagocytosis by macrophages—not in the initial stages of phagosome formation but mainly for its closure ([146]), when actin reorganization is important. Different sizes of particles seem to require different handling by the phagocytic machinery. Among the PI3K classes, PI3K class I is involved for phagocytosis of particles larger than 3 µm but not for their subsequent maturation ([147]). In contrast, PI3K class III (which forms PIP_3) is needed for phagosome maturation ([147], [148]). PIP_2 is an important regulator of WASPs and of gelsolin (see above).

Guanosine Triphosphatases

Small GTP-binding proteins are key regulators of actin cytoskeleton ([149], [150]). Assembly of actin beneath an opsonized particle requires the small GTPases, Cdc42, and Rac1, which control the cytoskeletal rearrangements during particle uptake ([102], [151], [152]). Cdc42 and Rac1 control different steps in the phagocytic process (i.e., pseudopod formation for Cdc42 and phagosome closure for Rac1) ([152]). In contrast, actin polymerization mediated by CR3 depends on the activity of Rho A, whereas Cdc42 and Rac1 are not involved ([153]). GTPases act on WASP family members, which activate the Arp2/3 complex ([154]). GTP-Cdc42 and PIP_2 act on the inactive form of WASP as a result of autoinhibition and restore its active conformation ([155], [156] and [157]). The transient PIP_2 accumulation at the phagocytic cups is part of the activation signal for WASP, together with Cdc42 recruitment. Rac1 stimulates gelsolin dissociation, thus preventing depolymerization of filaments and promoting the closure of the phagosome ([158]).

Ezrin, Radixin, and Moesin Family

The gap between cytoskeleton and membrane may be filled, in some systems, by a family of three proteins, ezrin, radixin, and moesin, known as the *ERM family* ([159]). These proteins act as linkers between plasma membrane and actin ([160]). Their *N*-terminal binds to some membrane proteins, such as CD44, and their *C*-terminal binds to actin. This intermolecular cross-linking requires activation, which is probably mediated by the Rho protein. Normally, the ERM proteins have a head-to-tail association that is released after activation ([161], [162]).

The cytoskeleton is linked to the extracellular matrix through integrins ([163]) and interacts with talin, which is a cytosolic protein recruited under the particle attachment at F-actin sites during FcR-mediated phagocytosis ([164]).

DIGESTION

Microbicidal Mechanisms

Microbicidal mechanisms used by the phagocytes can be divided into (a) oxygen-independent and (b) oxygen-dependent mechanisms. Oxygen-dependent mechanisms may be subdivided into (a) myeloperoxidase (MPO)-mediated (halide radicals–generated) and (b) MPO-independent.

OXYGEN-INDEPENDENT MECHANISMS Detailed description of neutrophil and macrophage granule content and their role in digestion of phagocytosed material is provided in Chapters 10 and 13, respectively. The neutrophil primary or azurophilic granules contain several bacteriocidal proteins (i.e., lysozyme, lactoferrin, cathepsin G, and elastase) and small peptides known as *defensins* ([165]). Defensins are peptides of 29 to 35 amino acids, including six invariant cysteines forming intramolecular disulfide bonds, which stabilize the cyclic structure of the peptide with a triple-stranded ß-sheet configuration. They kill microorganisms and mammalian cells, even those resistant to tumor necrosis factor-a, by inserting themselves into the cell membrane, which they permeabilize. The mechanism of insertion involves interaction with negatively charged molecules, probably membrane lipids. The secondary (or specific) granules contain lysozyme, collagenase, and so forth. Lysozyme is a cationic enzyme that hydrolyzes glycosidic bonds and has bactericidal properties for some bacteria.
OXYGEN-DEPENDENT MICROBICIDAL ACTIVITY During particle ingestion, phagocytes show a two- to threefold increase in O_2 consumption, which is insensitive to cyanide, a two- to tenfold increase of glucose oxidation via the hexose monophosphate shunt, and the generation of hydrogen peroxide. This combination of metabolic activities came to be known as *respiratory burst* ([166], [167]) (Fig. 14.4, part 2). Respiratory burst was actually discovered in 1933 ([168], [169]).
Myeloperoxidase-Independent Systems The burst of respiratory activity results from the activation of an enzyme known as *nicotinamide adenine dinucleotide phosphate (NADPH) oxidase*, a key enzyme present only in professional phagocytes and in much smaller quantities in B cells. When oxygen accepts one electron, it is reduced to superoxide anion, O_2^-, according to the reaction shown in Equation 1.

$$2O_2 + NADPH \rightarrow 2O_2^- + NADP^+ + H^+ \qquad [Eq.\ 1]$$

where $NADP^+$ is the oxidized form of nicotinamide adenine dinucleotide phosphate. H_2O_2 is produced by oxidation-reduction of two superoxide radicals (O_2^-), a reaction known as dismutation, catalyzed by the enzyme superoxide dismutase according to the reaction shown in Equation 2.

$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2 \qquad [Eq.\ 2]$$

Alternatively, H_2O_2 can be produced by reduction of O_2 by the transfer of two electrons catalyzed by the NADPH oxidase. It is possible, however, in conditions in which H_2O_2 is detected in the absence of detectable O_2^-, that the superoxide may not be diffusing out of the space of the enzyme ([169], [170] and [171]). Superoxide and H_2O_2 are not used by the phagocyte for bacterial killing because H_2O_2 is weakly microbicidal and superoxide is innocuous. They are, however, used as intermediates to produce oxidizing radicals or in reaction with halides to generate hypochlorous acid (HOCl) or hypochlorite mediated by MPO ([171]). Other O_2 radicals are generated by interaction of O_2^- and H_2O_2 such as the hydroxyl radical (OH ˙). This reaction is slow and may not take place directly but through the catalytic action of trace metals such as iron (Equation 3, known as the *Haber-Weiss reaction*).

$$H_2O_2 + O_2^- \rightarrow O_2 + OH- + OH^- \qquad [Eq.\ 3]$$

Singlet oxygen ($^1O_2$) is another O_2 intermediate that is generated as a result of the shifting of one of the two unpaired electrons to another orbit of energy and a change in its direction of spin. $^1O_2$ dissipates its excess energy quickly by thermal decay or light emission [like chemiluminescence (CL)], and it can be produced by a number of mechanisms such as spontaneous dismutation of two superoxide anions (Equation 4).

$$O_2^- + O_2^- + 2H^+ \rightarrow {}^1O_2 + H_2O_2 \qquad [Eq.\ 4]$$

Myeloperoxidase-Dependent Oxidants The MPO system produces potent antimicrobial reactive oxygen radicals effective against bacteria, fungi, viruses, and mycoplasma. MPOs are enzymes that catalyze the oxidation of a number of substances termed *hydrogen or electron donors*. The components of the system are MPO, H_2O_2, and halide. The products of the reactions are also toxic to tissues and cells of the host. H_2O_2 reacts with a halide, a reaction mediated by MPO that is present in the primary or azurophilic granules of the neutrophils and in the lysosomes of the juvenile monocytes but is not present in macrophages. This reaction generates hypochlorous acid as shown in Equation 5

$$Cl^- + H_2O_2 \rightarrow HOCl + H_2O \qquad \text{[Eq. 5]}$$

or hypochlorite (OCl^-) as shown in Equation 6.

$$Cl^- + H_2O_2 \rightarrow OCl^- + H_2O \qquad \text{[Eq. 6]}$$

HOCl attacks the phagocytosed microorganisms and causes damage to their cell membranes. Of the halides, chlorine is present in leukocytes at a high concentration, but iodine is considerably more effective on a molar basis. The halide oxidants are quickly detoxified by reacting with low-molecular-weight amines to yield chloramines (i.e., taurine), present in high concentrations in neutrophils. The acceleration of the hexose monophosphate shunt is a result of the production of $NADP^+$ and the regeneration of NADPH by the action of glucose-6-phosphate dehydrogenase (Fig. 14.10). However, $NADP^+$ increases also from the glutathione (GSH) peroxidase/GSH reductase system, which reduces H_2O_2 to H_2O (as shown in Equations 7 and 8).

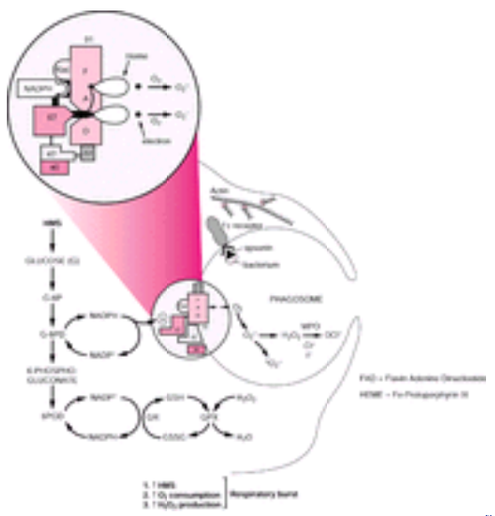

Figure 14.10. The production of oxygen radicals. The nicotinamide adenine dinucleotide phosphate reduced (NADPH) oxidase is assembled from five subunits (two localized on the membrane of a secretory vesicle and three residing within the cytoplasm). The assembly is powered by signals emanating from the triggering of the Fc receptor. Phosphorylation of $p47^{phox}$ in the cytoplasm may be an early event that triggers translocation of all three cytosolic subunits to join the other two on the membrane. The hexose monophosphate shunt (HMS) provides NADPH, which binds to $p67^{phox}$ associated with $p47^{phox}$ to the $gp91^{phox}$ of the membrane flavocytochrome b_{558}. Within $p67^{phox}$ is the "activation" domain of the oxidase, which mediates the transport of electrons to flavin adenine dinucleotide (FAD) of $gp91^{phox}$, then on to hemes (208 , 209 , 210 and 211), and finally to O_2 generating superoxide and H_2O_2. G6P, glucose-6-phosphate; G-6PD, glucose-6-phosphate dehydrogenase; GPX, glutathione peroxidase; GR, glutathione reductase; GSH, glutathione; GSSG, oxidized glutathione; Heme, Fe-protoporphyrin IX; MPO, myeloperoxidase; $NADP^+$, oxidized form of nicotinamide adenine dinucleotide phosphate; 6PGD, 6-phosphogluconate dehydrogenase.

$$2GSH + H_2O_2 \rightarrow GSSG + 2H_2O \qquad \text{[Eq. 7]}$$

$$GSSG + NADPH \rightarrow 2GSH + NADP^+ \qquad \text{[Eq. 8]}$$

where GSSG is oxidized GSH. NADPH is regenerated through the metabolism of the glucose (172). Not only microorganisms but also the phagocyte and surrounding tissues are susceptible to damage (173). Phagocytes apply different mechanisms to detoxify the oxidant radicals, such as the superoxide dismutase (converts O_2^- to H_2O_2), catalase (converts H_2O_2 to H_2O), GSH reductase (converts H_2O_2 to H_2O), amines (convert HOCl to chloramines), and so forth. The oxidants have been implicated in the pathogenesis of a number of clinical conditions such as chronic lung disease. The NADPH oxidase is the enzyme that catalyzes the generation of O_2-derived oxidants during phagocytosis or on stimulation by a variety of substances such as phorbol myristate acetate, N-formylated oligopeptides of bacterial origin that are secreted or released from dead organisms, complement-derived anaphylatoxin C5a, and IL-8. The activity of the enzyme depends on a number of components, which are brought together immediately after stimulation. The active enzyme is associated exclusively with the plasma membrane.

Nicotinamide Adenine Dinucleotide Phosphate Reduced Oxidase

NADPH oxidase is the enzyme that generates O_2 radicals from molecular O_2 (174). NADPH oxidase consists of five subunits that, in the resting state, are separated between the membrane (two) and the cytosol (three). The leukocyte oxidase is the prototype of oxidases found in a variety of cells. The neutrophil NADPH oxidase is also detected in B lymphocytes.

STRUCTURE

Membrane Components: Cytochrome b_{558} Two of the subunits of the oxidase, $gp91^{phox}$ and $p22^{phox}$ (phox: *ph*agocytic *ox*idase), are located in the membranes of secretory vesicles and specific granules and form a heterodimer known as *cytochrome* b_{558} (Fig. 14.10). The heterodimer contains two heme prosthetic "groups," both residing within the $gp91^{phox}$ (175) subunit, one of them within its hydrophobic NH_2 terminal region (176 , 177), coordinated by histidine residues (178). The carboxy terminal of $gp91^{phox}$ has flavin- and NADPH-binding sites, homologous to the ferredoxin-$NADPH^+$ reductase of the flavoenzyme family (179 , 180). In almost all patients with mutations in b_{558}, the neutrophils lack both subunits regardless of which subunit is affected by the mutation (181). Expression of one subunit affects the expression of the other. In patients deficient in $p22^{phox}$, the fully glycosylated $gp91^{phox}$ subunit is not detected, but only a partially processed precursor (65 kd) with high mannose carbohydrate side chains (182). Expression of the mature $gp91^{phox}$ polypeptide with fully processed oligosaccharide side chains was restored, however, by expression of a recombinant $p22^{phox}$. Inhibition of heme biosynthesis results in decrease of b_{558} expression with marked decrease of $p22^{phox}$ and of mature $gp91^{phox}$ (183), indicating that the heme prosthetic groups contribute to the assembly and stability of the heterodimer. The gene for $p22^{phox}$ (or a subunit) is located on chromosome 16q24. The protein has 195 amino acids with hydrophobic helices in the *N*-terminal half of the molecule that could serve as membrane-spanning regions (184). There are five potential glycosylation sites (185). The gene for $gp91^{phox}$ is located on chromosome X p21.1. The protein contains 570 amino acids with four or five transmembrane helices and five potential glycosylation sites in the *N*-terminal region. Mutations of this gene account for the most common forms of chronic granulomatous disease (CGD). There are three cytosolic components, $p67^{phox}$, $p47^{phox}$, and $p40^{phox}$. The gene for $p67^{phox}$ is located on chromosome 1q25. The protein has 526 amino acids and two SH_3 domains, which are present in Src tyrosine kinases and other signaling molecules. They mediate protein-protein interactions by binding to proline-rich sequences (186), which are detected in all cytosolic components. The $p47^{phox}$ has two SH_3 domains and three proline-rich sequences. In the resting state, the *C*-terminal proline-rich sequence interacts with one of its own SH_3 domains and the second from the N-terminus proline-rich sequence interacts with the SH_3 domain of $p40^{phox}$ (Fig. 14.11A). This interaction between its own domains is considered a possible reason for the inability of resting $p47^{phox}$ to bind cytochrome b_{558}. On activation, the *C*-terminal proline-rich sequence interacts with an SH_3 domain of $p67^{phox}$, which is important for their translocation to the membrane. The *C*-terminal region contains six to eight putative phosphorylation sites.

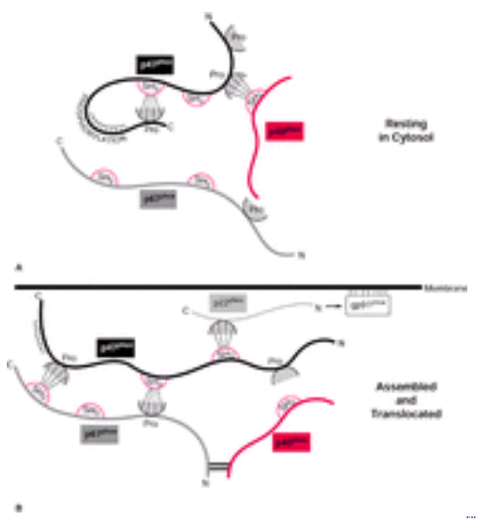

Figure 14.11. Interactions between the cytosolic components of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. All three components, p40 ^{phox}, p47 ^{phox}, and p67 ^{phox}, contain Src homology 3 (SH_3; found in signaling molecules), and p47 ^{phox} and p67 ^{phox}, in addition, have proline-rich sequences. These domains mediate protein-protein interactions involved in the association of the cytosolic components, which then are translocated to the membrane for the assembly of the NADPH oxidase.

Another domain recently discovered in NADPH oxidase subunits is called *phox homology domain* or *PX*. PX is a 125- to 140–amino acid module, which is found in proteins involved in membrane targeting and trafficking, cytoskeletal organization, and protein sorting ([187]). It is the hallmark domain of the members of the protein-sorting nexin family ([188]) but is also found in phospholipases D_1 and D_2 and the protein kinase CISK, implicated in IL-3–dependent cell survival. Localization on vesicular compartments is strictly PX-dependent. PX domain contains basic and hydrophobic residues and binds phosphoinositides. The p47 ^{phox} pleckstrin homology domain binds strongly PI(3,4)P_2 and weakly PI(3,5)P_2 and PI(3,4,5)P_3 ([189]). The binding site for phosphoinositides is contributed by ß-strands and a pair of a-helices linked by a loop. Basic clusters and hydrophobic residues contribute to the binding, and two of the basic residues crucial for binding are conserved. Mutation of one of them, Arg42Gln, results in an autosomal-recessive form of CGD. These findings provide a rational explanation for the impaired respiratory burst in mice deficient in the p110? (class IB PI3K), which are unable to produce phosphoinositides ([190]). The p40 ^{phox} subunit is a protein of 339 amino acids. It contains one SH_3 domain and one PX domain, which binds PI(3)P and targets localization of p40 ^{phox} on endosomal membranes. Localization is abolished as a result of inhibition of PI3K function on the mutation R57Q, which interferes with PI(3)P binding ([191]).

ASSEMBLY AND ACTIVATION OF NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE OXIDASE Multiple phosphorylations of p47 ^{phox} are critical for the assembly and translocation of the cytosolic subunits because they regulate a number of steps in the process. Phosphorylations are mediated by protein kinase *A* on *C*-terminal serines. Some of the serines, such as Ser379, are more important than others ([192]). Mutations Ser379Ala, Ser359Ala, and Ser370Ala result in loss of oxidase activity as well as block of phosphorylation of the remaining serines. Phosphorylation of Ser303/304 increases oxygen radical production, but the mechanism is not clear ([193]). In general, phosphorylation seems to increase binding of p67 ^{phox} to b_{558} ([194]). A very important consequence of p47 ^{phox} phosphorylations is the opening of the phosphoinositide-binding pocket on the PX domain ([195]). The PX domain has been shown to mediate targeting of p47 ^{phox} and p40 ^{phox} to endosomal membranes ([188] , [196] , [197] and [198]). However, the “pocket” that binds the phospholipids is “closed” as a result of intramolecular interactions ([195]). Phosphorylations (Ser303/304/328/359) seem to change the molecular conformation and “open” the pocket. One may envision the sequence of events regulated by phosphorylations of p47 ^{phox} as follows: conformational changes of p47 ^{phox}, “opening” of the pocket for phosphoinositide binding, targeting of the subunits to endosomes, facilitation of p67 ^{phox} binding to b_{558}, and increase of O_2 radical production. The assembly and translocation require interactions between all three cytosolic components. One interaction involves p47 ^{phox} (*C*-terminal proline-rich sequence) and p67 ^{phox} (*C*-terminal SH_3 domain) and a second interaction involves the SH_3 domain of p47 ^{phox} and proline sequences of p67 ^{phox} ([199] , [200] and [201]) (Fig. 14.11B). Deletion of both SH_3 domains of p67 ^{phox} abolishes its membrane binding. The adaptor protein p40 ^{phox} also participates in the assembly through direct binding to p67 ^{phox}, which is linked to p47 ^{phox} ([202]). p47 ^{phox} is critical for the translocation of the cytosolic subunits, whereas the other subunits follow as a result of their interactions with p47 ^{phox}. p47 ^{phox} binds to p22 ^{phox} through one of the two SH_3 domains, which are expressed in tandem in the middle of p40 ^{phox}. The *N*-terminal SH_3 domain binds to a proline-rich sequence in the C-terminus of p22 ^{phox} (Fig. 14.11B). This interaction is essential for oxidase activity. However, the SH_3 domain of p47 ^{phox} is masked in the resting state by an interaction with an Arg/Lys domain in the C-terminus. Phosphorylation of serines within the Arg/Lys domain unmasks the *N*-terminal SH_3 domain of p47 ^{phox} and allows binding to the *C*-terminal p22 ^{phox} proline-rich sequence ([203]). Another cytosolic component that regulates NADPH oxidase activity is Rac, which exists in two isoforms, Rac1 and Rac2. Both are low-molecular-weight GTP-binding proteins. On activation of neutrophils, Rac2 becomes associated with the cell membrane. The translocation is independent of the other cytosolic subunits. There are two functional regions in Rac: the “effector” region and the “insert” region ([204]). The C-terminus anchors Rac to the membrane, whereas the effector region binds to p67 ^{phox}, and the insert region binds to b_{558} ([205]). Rac2 regulates oxidase activity ([206]) as a result of interaction directly with b_{558} and participation in the electron transfer ([207]). The NADPH oxidase has an “activation domain,” which is localized on p67 ^{phox} ([208]) and is essential for the generation of superoxide ([209]). In the assembled NADPH oxidase on the membrane, the important component is b_{558}. Its p91 ^{phox} subunit is the catalytic moiety that transfers the electrons from NADPH to O_2, whereas the other components are regulatory. The pathway of electron flow consists of two steps, as shown in Equation 9 ([208]).

$$\text{NADPH} \rightarrow \text{flavin adenine dinucleotide} \rightarrow \text{heme A} \rightarrow \text{heme B} \rightarrow O_2 \qquad \text{[Eq. 9]}$$

The b_{558} shows no activity unless the cytosolic subunits and Rac assemble in the membrane in a 1:1:1 ratio with b_{558}. The p47 ^{phox} is essential for translocation and provides binding sites for the other components as well as enhancing p67 ^{phox} affinity ([210]). A protein complex constructed by genetically engineered fusion of p47 ^{phox} and p67 ^{phox} tested *in vitro* efficiently reconstituted the NADPH oxidase in terms of activity and stability ([211]). The fusion protein, tested in a cell-free system, had eightfold higher efficiency and produced a higher activity than the individual proteins. Rac binds to both b_{558} and p67 ^{phox} as an adaptor protein, but it is also required for electron transport. The activation domain of the NADPH oxidase is located within p67 ^{phox} (i.e., sequence 199 to 210, which mediates the electron transfer from NADPH to flavin adenine dinucleotide) ([208]). A single mutation of residue 204 completely eliminates NADPH oxidase activity without affecting the interactions of the components of the oxidase. The activation domain does not influence NADPH binding. In the second step, electrons are transferred to the hemes and then on to O_2 for superoxide formation. Rac is required for both steps of the electron transfer.

LOCALIZATION OF NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE OXIDASE The original assembly and activation of the NADPH oxidase are carried out within intracellular vesicles and not on the plasma membrane. Human neutrophils contain a unique population of slender, rod-shaped vesicles that contain alkaline phosphatase ([212]). Neutrophil stimulation up-regulates these vesicles, which fuse to form tubular structures and eventually reach the cell membrane. Flavoprotein b_{558} is associated with these vesicles, which are known as *secretory vesicles* ([213]). Using cytochemical markers for alkaline phosphatase to identify these vesicles and cationized native ferritin as a marker for plasma membrane, it was clearly shown that superoxide (identified by a diamino benzidine cytochemical reaction) was first released within the secretory vesicles of the neutrophil ([214]) (Fig. 14.12). In human neutrophils undergoing phagocytosis, most of the oxygen radicals are detected in these vesicles, which then, by a process of exocytosis, reach the plasma membrane. The plasma membrane remains devoid of free radical production. These findings provide an explanation for the lag period of the release of oxygen radicals after stimulation. Components of NADPH oxidase and Rac were detected by immunolabeling in punctate clusters of 0.03 to 0.10 µm ^{2} on the cytoplasmic side of the membrane on neutrophils attached on glass surfaces ([215]). However, the process of adherence may have altered the distribution of the oxidase components, whereas in the previous study ([214]), the neutrophils were in suspension.

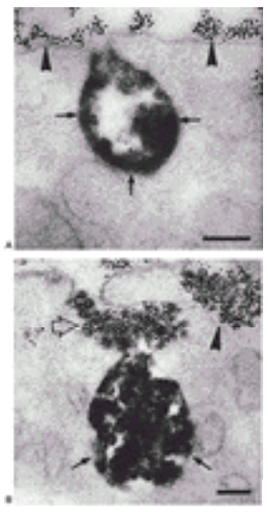

Figure 14.12. Localization of nicotinamide adenine dinucleotide phosphate oxidase. The NADPH oxidase is first assembled on the membrane of secretory vesicles of neutrophils, which then migrate and fuse with the cell membrane. **A:** The oxidant-positive vesicles (*arrows*) are separate from ferritin (*small dark dots*), identifying the cell surface (*arrowheads*). **B:** An oxidant-producing vesicle (*dark arrows*) opens to the cell surface (*arrowhead*) coated with cationic ferritin (*dots*, *wide arrow*). Defects of Oxidative Metabolism

CHRONIC GRANULOMATOUS DISEASE CGD is a rare inherited disorder caused by defective NADPH oxidase that affects approximately 1 in 500,000 individuals. The main manifestations of the disease consist of infections of the lungs, gastrointestinal tract, and skin. In the majority of cases, the manifestations of the disease appear during the first year of life. Infections are caused by a variety of microorganisms such as bacteria and fungi. Some of the main pathogens contain catalase, the enzyme that converts the H_2O_2 to H_2O, and, as a result, it cannot be used by the phagocytes for the formation of oxidants ([216]). Microbicidal mechanisms other than the oxidants (lysosomal enzymes and peptides) are not as effective, and, as a result, patients develop complications caused by chronic inflammatory stimulation, such as granulomatous obstruction of the esophagus and ileocolitis with diarrhea ([217], [218]). Early studies of the function of leukocytes *in vitro* from patients with CGD revealed that there is no respiratory burst on stimulation, suggesting that the defect is associated with the NADPH oxidase ([218], [219]). The breakthrough in our understanding of the genetics of inheritance of CGD and the nature of NADPH oxidase came with the development of a cell-free system for activating the oxidase ([220]). It was shown in this system that both the membranes and the cytosol are needed for oxidase activity ([221], [222]). With this system, it was found that some patients have a defect associated with the membranes, whereas others have a defect associated with the cytosol. Furthermore, it was established that patients with X-linked CGD were characterized by a membrane defect and absence of cytochrome b_{558}. Autosomal inheritance, on the other hand, was associated with normal levels of b_{558} and a defect in the cytosol, which later was shown to have absence of p47^{phox} or p67^{phox}. Analysis of a large number of patients and kindreds has shown that the majority of the patients (70%) have mutations affecting gp91^{phox} or p22^{phox} ([222], [223]). Those with mutations affecting gp91phox show X-linked inheritance, and those with mutations affecting p22phox show autosomal inheritance. A great variety of mutations have been identified with gp91^{phox}, including single nucleotide insertions or deletions, creating frameshifts or premature stop codons, and deletions of part or all of an exon ([224]). The X-linked CGD is highly heterogeneous. Mutations of the CYBB gene usually lead to lack of gp91^{phox} expression and absence of NADPH oxidase activity (known as *X91°CGD*). In others, the gp91^{phox} protein is normally expressed but totally lacks oxidase activity (known as *X91$^+$ CGD*), and, finally, in another group of patients, gp91^{phox} protein is decreased and oxidase activity is proportionally diminished (*X91–CGD*). An interesting X91$^+$ patient with an Arg54Ser mutation had a defect in the electron transport from flavin adenine dinucleotide to heme, but the translocation of p47^{phox} to p67^{phox} was normal ([225]). In another patient, neutrophils, monocytes, and B cells had no oxidase activity, but eosinophils had normal activity ([226]). This patient probably had a mutation in a regulatory element of the CYBB gene directing the transcription to various cells. These experiments of nature have provided us with considerable information about the structure, the assembly, and the function of this very important enzyme, the NADPH oxidase. A patient has been reported with a mutation of Rac2, having deficiency in phagocytosis. The mutation (Asp57Asn) was negative-dominant and was associated with reduced production of superoxide and decreased cell movement ([227]). The mutant protein was unable to bind GTP. Only a small number of mutations of p47^{phox} and p67^{phox} have been reported. Deficiency of p47^{phox} or p67^{phox} is seen in 33% and 5% of all CGD cases, respectively. Infections in patients with CGD are treated aggressively with antibiotics and, more recently, with interferon-?, which stimulates phagocyte activation ([228]).

DEFICIENCY OF GLUTATHIONE REDUCTASE AND GLUTATHIONE SYNTHETASE Deficiencies of GSH reductase and synthetase have been described. The patients have impaired neutrophil function but are not prone to bacterial infections. These enzymes are components of the GSH cycle, so that they convert H_2O_2 to H_2O in the presence of reduced GSH, which is converted to GSSG. The GSSG regenerates reduced GSH in the presence of NADPH.

DEFECTS IN GRANULE PROTEINS

Myeloperoxidase MPO is an important enzyme present in the azurophilic granules of neutrophils and in the lysosomes of monocytes. It generates oxidants from H_2O_2 and halides. The mature enzyme is a 150-kd heterodimer composed of two heavy and two light chains. It is synthesized primarily during the promyelocytic stage of myeloid differentiation. Hereditary MPO deficiency is a benign abnormality that does not result in clinical illness despite the fact that MPO-deficient neutrophils exhibit a delayed bacterial and fungal killing *in vitro* ([229]). MPO–messenger RNA transcripts are detected in neutrophils from patients, suggesting that deficiency of the enzyme is caused by some posttranslational defect. Because only neutrophils and monocytes have MPO, other cells (macrophages) may provide defense. It is also possible that the MPO-independent mechanisms are sufficient for protection ([230]).

Lactoferrin Lactoferrin is present in the specific or secondary granules and is a member of the transferrin gene family. It is found in secretions such as tears, milk, saliva, and pancreatic secretions. It has antimicrobial activity through iron chelation and regulates neutrophil adhesiveness. Some individuals have deficiency of the contents of specific granules. These patients are prone to recurrent bacterial and fungal infections of the skin and deep tissues. They are also deficient in defensins, a component of the primary granules.

PHAGOCYTOSIS OF APOPTOTIC CELLS

Macrophages discriminate between viable and apoptotic cells. Uptake of apoptotic cells is noninflammatory, although certain receptors recognizing apoptotic cells are critical for innate immunity. The same receptors engulfing microbial organisms, however, trigger an inflammatory response. Receptors contributing to uptake of apoptotic cells are scavenger receptors class A and class B, receptors for oxidized low-density lipoprotein, integrins, and so forth ([231], [232], [233] and [234]). Scavenger receptors class A and B are multiligand and multifunctional receptors. Class A scavenger receptors have been implicated for recognition of apoptotic thymocytes and activated platelets ([232]). The cells undergoing apoptosis lose phospholipid asymmetry and expose phosphatidyl serine (PS). This change is required for recognition and engulfment ([235]). Normally, phospholipid asymmetry is maintained by the activity of an amino phospholipid translocase, a Mg^{2+}-dependent ATPase. However, viable macrophages were shown to express PS constitutively on their surface. Annexin V, a PS-specific binding protein, inhibited phagocytosis of apoptotic cells but not of other particles ([236]). The antiinflammatory effect in the clearance of apoptotic cells is an active process due to the release of transforming growth factor-ß, IL-10, and prostaglandin E_2 ([233], [237]).

WASP is recruited to the phagocytic cup and plays an important and nonredundant role in clearance of apoptotic cells ([238]). Cdc42, which activates WASP, also contributes in this process ([239]). Defective clearance of apoptotic cells may explain the susceptibility of WAS patients to autoimmune disease because aggregation of lipids on apoptotic cell membranes and their inefficient removal have been linked to development of autoantibody production ([240]) and autoimmune disorders ([241]).

A flow cytometric method for measuring phagocytosis of apoptotic cells has been developed ([242]). It has the advantages of assessment of large numbers of cells and high sample throughput and can distinguish bound from internalized apop-totic cells. Apoptotic cells are labeled with 5-chloromethylfluorescein diacetate.

PHAGOCYTOSIS OF SENESCENT ERYTHROCYTES

Several processes have been implicated as causes of senescence of red blood cells (RBCs), such as loss of carbohydrates by desialylation, modification of natural components such as band 3, and glycophorin and phospholipid asymmetry with the appearance on the surface of PS ([243], [244] and [245]). There are several reports regarding the nature of the antigen that triggers removal of the RBC as it approaches the end of its lifespan. The nature of a senescent epitope is not yet clear, but all major classes of organic matter have been implicated for the primary signal (i.e., proteins, carbohydrates, and lipids). Senescence is considered by some to be the unmasking of amino acid sequences by proteolysis or rearrangement due to clustering or oligomerization of band-3 protein ([246], [247] and [248]). Others, however, have shown that the senescent antigen is not present on the polypeptide of band 3 but on a glycan ([249]). Strong evidence supports that ß-galactosyl residues stimulate IgG autoantibodies and phagocytosis of aging RBCs ([249]). Presence of PS on the cell surface directly correlates with the propensity of RBCs to bind to monocytes and be rapidly cleared in the spleen ([250], [251]).

A flow cytometric method has been developed for an accurate measurement of erythrophagocytosis ([252]).

ASSESSMENT OF PHAGOCYTIC FUNCTION

Nitroblue Tetrazolium

The standard method of laboratory testing for phagocytosis is the reduction of a colorless substance known as *nitroblue tetrazolium* to a blue-black formazan-insoluble deposit within the neutrophils. This indicates the presence of an activated respiratory burst oxidase. In normal persons, less than 10% of blood neutrophils are nitroblue tetrazolium–positive, whereas in patients with bacterial infections, more than 10% of neutrophils are nitroblue tetrazolium–positive.

Flow Cytometry

Phagocytic function can be assessed by flow cytometry, which has the advantage over other methods because of the smaller number of cells and fewer preparative procedures required. One useful method uses fluorescein heat-killed *Candida albicans*. After phagocytosis, ethidium bromide is added. Because the ethidium bromide (red color) does not penetrate viable cells, only the external organisms stain red, whereas those phagocytosed stain green (fluorescein) ([253]).

Flow cytometry can also be used to measure oxidative mechanisms. The most useful method is the measurement of intracellular H_2O_2 by the dichlorofluorescein (DCFH) diacetate probe ([254], [255]). The DCFH diacetate dye is incorporated into the lipid regions of the cell, where the acetate side chains are cleaved by hydrolytic enzymes to the nonfluorescence molecule, 2'-7', DCFH, which becomes trapped within the cell. On cell activation, the RBO generates superoxide anion, which is further reduced to H_2O_2. In the presence of H_2O_2, peroxidases oxidize the DCFH to 2'-7', dichlorofluorescein, which fluoresces at 530 nm (the same emission as fluorescein thioisocyanate). The green fluorescence produced is proportional to the amount of H_2O_2 generated. It is possible to determine the intracellular H_2O_2 produced ([254]).

Chemiluminescence

Some of the reactive oxygen intermediates generated during phagocytosis exist for a short period of time in a higher energy state but release this energy in the form of light known as *CL* ([256]), which can be quantified ([257]).

CL can be amplified by the use of bystander molecules called *chemiluminescent probes*, which react with the O_2 radicals to produce excited products in high yield. The intensity of CL is directly proportional to the functional capacity of the phagocytes. The two most commonly used probes are luminol (5-amino-2,3, dihydro-1,4, phthalazinedione) and lucigenin (10,10-dimethyl-9,9-biacridinium dinitrate), and the most commonly used stimulus is zymosan (yeast particles).

CL is proportional to phagocytic activity as long as the CL probes and the stimulus are not rate-limiting. Contamination by erythrocytes reduces CL because the extinction coefficient of hemoglobin is in the blue region of the visible region and light is absorbed.

Frixos Paraskevas

Lymphocytes and Lymphatic Organs

LYMPHOCYTES

In the early part of the twentieth century, the main debate about the nature and function of the lymphocyte centered around its relationship to cells of the connective tissue and other inflammatory exudate cells. Lymphocytes were considered capable of transforming into granulocytes, monocytes, macrophages, fibroblasts, and other cells. Marschalko ([1]), Downey ([2]), Maximow ([3]), and Bloom ([4]) all believed that lymphocytes also gave rise to plasma cells. Scientific evidence for these assumptions was lacking, however, and in 1936, Rich said, “the complete ignorance of the function of this cell is one of the most humiliating and disgraceful gaps in all medical knowledge” ([5]). The first conclusive evidence that antibodies were formed within lymph nodes (LNs) was presented in 1935 by McMaster and Hudack ([6]), but it took another decade to prove conclusively that lymphoid cells within LNs were the cells that contained antibody ([7], [8]). This discovery tipped the balance in favor of the lymphocytic theory of antibody production ([9]). In parallel with these studies, the classic work of Fagraeus ([10]) brought strong indirect evidence of the relationship of plasma cells to antibody production, and the conclusive demonstration by Coons et al. of the presence of antibodies within plasma cells by means of the new and powerful immunofluorescence technique is a landmark in the long debate on the origin of antibodies and the function of plasma cells ([11], [12]). The only remaining question concerning whether plasma cells arise from lymphocytes was answered 10 years later by the elegant studies of Harris et al. in which they demonstrated indisputably the gradual change of a lymphocyte to an antibody-forming plasma cell by means of ultrastructural studies ([13], [14] and [15]). At the same time, Nowell dispelled the myth that small lymphocytes are end-stage cells incapable of proliferating and taking on new functions ([16]).

The lymphocytes consist of heterogeneous populations of cells that differ greatly from each other in terms of origin, life-span, preferred areas of settlement within the lymphoid organs, surface structure, and function. Although some morphologic characteristics, such as size, granularity, and nucleocytoplasmic ratio, distinguish lymphocyte populations from each other, they provide no clues to their lineage and function. The most important, precise, and quantitative method in use in clinical laboratories is based on the identification of certain glycoproteins displayed on the membrane of lymphocytes and collectively called *markers*. Two remarkable discoveries have helped in the dissemination of routine application of marker analysis in clinical medicine: the development of monoclonal antibodies and the invention of flow cytometry (see Chapter 3).

MORPHOLOGY OF LYMPHOCYTES

Light Microscopy

Most lymphocytes in the blood are small (10 µm or smaller), although larger forms are common (Fig. 15.1A). Some of these large lymphocytes are known as *large granular lymphocytes* because they contain azurophilic granules in their cytoplasm (Fig. 15.1B) ([17], [18]). Often, the distribution of lymphocyte diameters does not yield the commonly described three peaks of small, medium, and large lymphocytes because the dimensions of the cells vary according to the method of preparation ([19]). In blood smears stained with Romanovsky dyes, the nucleus is deep purplish blue, usually round or slightly indented and composed of dense aggregates of chromatin. Nucleoli are not visible with ordinary techniques, although a nucleolus may be seen in wet smears and histologic sections. The cytoplasm forms a narrow rim in small lymphocytes, but it may be abundant in larger cells. The cytoplasm is moderately basophilic and usually is devoid of granules, but larger cells may contain several bright reddish violet (azurophilic) granules that differ from the granules of myeloid cells in that they do not give the oxidase or peroxidase reaction.

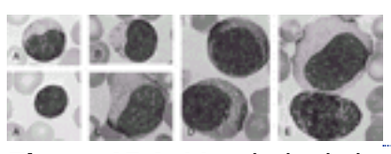

Figure 15.1. Morphologic heterogeneity of human peripheral blood lymphocytes. **A:** Giemsa-stained blood smears: small and large lymphocytes. **B:** Large granular lymphocyte with azurophilic granules. **C:** Atypical lymphocyte. **D:** Lymphocytes resembling plasma cells (plasmacytoid) from the blood of a patient with viral pneumonia. **E:** One atypical lymphocyte and one plasmacytoid lymphocyte from peripheral blood. See Color Plate.

By phase contrast microscopic analysis, a well-defined centrosome can be observed. This area of the cytoplasm is adjacent to the nucleus, and because it is somewhat rigid, it may cause an indentation in the nucleus.

Often, transitional forms between lymphocytes and plasma cells are seen in the blood of patients with viral infections (Fig. 15.1C, Fig. 15.1D, Fig. 15.1E and Fig. 15.1E). These cells are variously known as *lymphocytoid plasma cells* or *plasmacytoid lymphocytes*. They obviously represent morphologic stages of differentiation of antigenically stimulated lymphocytes.

Transmission Electron Microscopy

The small lymphocyte (6 to 9 µm in size) reveals a smooth, bilaminar cytoplasmic membrane that contains only a few microvilli, except in the area of the uropod of motile cells (Fig. 15.2) ([20], [21], [22], [23] and [24]). Occasional blebs, consisting of membrane-bound cytoplasm, are seen on the cell surface and may well be artifacts. The scanty cytoplasm of small lymphocytes shows a remarkable absence of organelles. The Golgi apparatus is small and usually is found near the nuclear notch. One or two centrioles are often seen in the appropriate plane of section. No organized endoplasmic reticulum is observed, although careful scrutiny may reveal one or two profiles. Many free ribosomes and occasional ribosome clusters are evident. Typical mitochondria are common, but lysosomes containing enzymes characteristic of these organelles are sparse. Dense bodies of unknown significance may also be seen occasionally. The cytoskeleton consists of occasional microtubules in the cytoplasm and microfilaments located adjacent to the cell membrane.

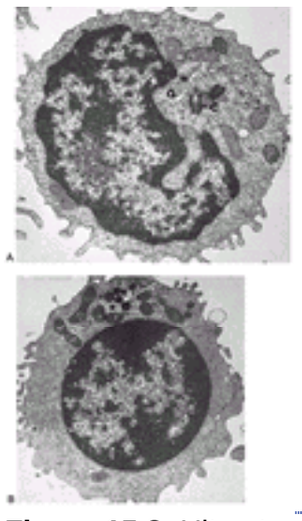

Figure 15.2. Ultrastructure of normal peripheral blood lymphocytes. **A:** A typical resting lymphocyte. The nucleus contains primarily heterochromatin in aggregates along the nuclear membrane. The nucleolus in lymphocytes is usually small. In the cytoplasm, the ribosomes are dispersed, but occasionally, a few short strands of rough endoplasmic reticulum are visible. The mitochondria are well developed and the centrioles (*C*), longitudinally sectioned in this illustration, show evidence that the cell is ready to enter mitosis on triggering. The Golgi apparatus (*G*) is small (×24,000). **B:** This lymphocyte contains granules (*arrow*) and is likely to correspond to the large granular lymphocyte variety. The cytoplasm is abundant and filled with ribosomes with a few strands of endoplasmic reticulum (×12,000). (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

The nucleus is enveloped by a double membrane that fuses at the site of nuclear pores. Abundant dense heterochromatin forms aggregates close to the membrane and less often within the body of the nucleus. These aggregates are separated by interchromatinic spaces containing chromatin, small bits of aggregated chromatin, ribosome-like particles, and fibrils. A nucleolus usually is seen. The medium lymphocyte is larger (6 to 8 µm) because of an increase in the amount of cytoplasm. The nucleus contains chromatin that is looser, is distributed in small blocks, and adheres only in part to the nuclear membrane. The Golgi apparatus is more developed than in the small lymphocyte. The cytoplasm also contains numerous polyribosomes and a few strands of endoplasmic reticulum, mostly parallel with the nuclear membrane.

Lymphoblasts usually are larger cells (8 to 12 µm) with loose nuclear chromatin and a giant nucleolus that has a reticulated appearance. It occupies as much as one-third of the nuclear area. The cytoplasm contains many polyribosomes, but cisternae of endoplasmic reticulum are scarce. Lymphocytes carry the normal diploid number of 44 autosomes and two sex chromosomes.

Scanning Electron Microscopy

It was suggested originally that human peripheral blood lymphocytes could be separated into two broad categories on the basis of findings of scanning electron microscopy, depending on their cell-surface morphology ([25], [26]). One population had a fairly smooth surface, whereas the other was described as hairy, being covered by numerous microvilli (Fig. 15.3). The former was considered to correspond to thymus-derived (or T) lymphocyte, whereas the latter was thought to represent bone marrow–derived (or B) lymphocyte. Results of subsequent studies demonstrated that the surface features of lymphocytes depend on the methods used for preparation of the cells as well as the functional state of the cells ([27], [28]). Thus, lymphocytes stimulated by various mitogens have villi independent of their origin. In addition, both T and B lymphocytes have microvilli while in circulation and especially when they pass through the venules of LNs characterized by high endothelial cells ([29]). On the other hand, all lymphocytes have a smooth surface when they reach their respective home microenvironment ([30]). Therefore, the smooth cell surface likely is associated with resting lymphocytes, whereas the appearance of microvilli is triggered by environmental stimuli that interact with cell-surface receptors. These newly formed microvilli may help lymphocytes to interact with target substrates.

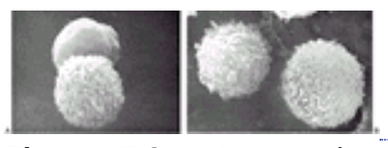

Figure 15.3. Heterogeneity of human lymphocytes by scanning electron microscope. **A:** A smooth and a villous lymphocyte, thought to correspond to that of T and B lymphocytes, respectively. The appearance of the lymphocytes, however, depends on the method of preparation; both lymphocytes are smooth when they rest in their microenvironments (×14,500). **B:** Two villous cells in a preparation depleted of T cells (×14,500). (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

LYMPHOCYTE LOCOMOTION

Lymphocyte locomotion ([31]) was described vividly by Lewis ([32]), who observed that the cell first extends a pseudopod separated from the rest of the cell by a groove that encircles the cell body. Eventually, as the groove deepens, the nucleus is pushed forward through the constriction ring, giving rise to the classic shape of the motile lymphocyte, resembling a hand mirror or pear. The advancing front is occupied by the nucleus, which is separated by a deep constriction from the rest of the cytoplasm that trails behind, forming the handle of the mirror. The cytoplasmic tail is called the *uropod* (from Greek *ura*, “tail,” and *pod*ι, “foot”) (Fig. 15.4) ([33]). It is studded with microvilli and microspikes, which vary in width from 12.5 to 200 nm and to as much as 0.8 µm in length. The motile lymphocyte moves with an average speed of 20 µm/minute. In general, motility increases with the state of cell activation as lymphoblasts demonstrate greater locomotion than small lymphocytes. It could therefore be stated that locomotion is enhanced by stimuli inducing blast transformation ([34]). The uropod not only is associated with locomotion but also serves as a site for a variety of interactions with lymphocytes, macrophages, and other cells ([35]). In mixed lymphocyte cultures, lymphocytes may approach macrophages and then turn around to establish contacts with them through their uropods. The locomotion of lymphocytes around macrophages has been called *peripolesis* ([36]) to distinguish it from emperipolesis (“inside roundabout wandering”), which describes the penetration of malignant cells by lymphocytes ([37]). T lymphocytes also adhere to macrophages by means of uropods, forming clusters or rosettes ([38], [39]). A stable cluster forms only when macrophages and lymphocytes are exposed to antigen. The T lymphocytes within clusters are stimulated into proliferative activity. In general, uropod formation is a morphologic expression of lymphocyte activation as measured by DNA synthesis ([34], [40]).

Figure 15.4. Lymphocyte locomotion. The lymphocyte assumes the characteristic hand-mirror configuration. The nucleus occupies the front, and part of the cytoplasm

forms a tail or uropod (*Ur*), which displays an elaborate pattern of microspikes (*Ms*). A small pseudopod (*Ps*) on the side contains only ribosomes. (From Rosenstreich DI, et al. The uropod-bearing lymphocyte of the guinea pig. Evidence for thymic origin. J Exp Med 1972;135:1037, with permission.)

The locomotion of lymphocytes is strikingly different from that of other cells. Lymphocytes move forward in a steady manner, maintaining the hand-mirror shape, whereas myeloblasts express a wriggling wormlike locomotion, and the cells of the monocytic series change shape and direction continuously ([41]).

Although it was suggested that uropod formation is a characteristic of T lymphocytes ([34]), B lymphocytes also form uropods after stimulation with antiimmunoglobulin antibodies ([42]). In this case, the uropod forms after capping of the surface immunoglobulin (Ig) is completed; the cap ultimately is found over the uropod, where it is endocytosed. The uropod also has been known to serve as a site for endocytosis of foreign substances ([40]). Ultrastructurally, the uropod contains practically all of the cytoplasmic organelles, including the Golgi apparatus, mitochondria, microfilaments, and microtubules.

IN VITRO BLAST TRANSFORMATION

In addition to specific antigens, lymphocytes also can be activated in a nonspecific manner by substances known collectively as *mitogens*. The activation of lymphocytes by nonspecific mitogens is known as *blast transformation*. The term *mitogen* generally refers to all substances capable of inducing cell division by mitosis. The mitogens used most commonly are lectins of plant origin that bind to carbohydrates. Some of these lectins have specificity for either T or B lymphocytes, whereas others stimulate both. The mitogen studies conclusively demonstrated that the two types of lymphocytes differentiate along different pathways. The B lymphocyte becomes a plasma cell with rich endoplasmic reticulum, whereas the T lymphocyte has a different blast morphology, rich in cytoplasmic organelles, something that had not been clearly demonstrated at that time. Thus, phytohemagglutinin (PHA), derived from the red kidney bean *Phaseolus vulgaris*, activates T lymphocytes, and pokeweed mitogen (PWM), derived from the roots of *Phytolacca americana*, triggers Ig secretion from B cells in the presence of T cells. Activation of lymphocytes by mitogens requires binding of mitogen to appropriate receptors, which is an obligatory step in the process of lymphocyte activation ([43]). Cross-linking and receptor redistribution ensue. Certain properties of the ligand, such as its valency, and its physical state, such as its solubility, play important roles in determining the selective response of one or the other lymphocyte populations. For example, concanavalin A in soluble form stimulates only T lymphocytes; when immobilized on plastic surfaces, it also activates B cells ([44]).

Lymphocytes transformed by PHA are large (10 to 20 µm), with dark blue cytoplasm resulting from an increase in the RNA content (Fig. 15.5A) ([45], [46]). Frequent mitotic figures are first seen at 40 hours and peak at 72 hours. By autoradiographic analysis, thymidine grains are concentrated over the nucleus (Fig. 15.5B). The nucleus enlarges and becomes leptochromatic. Changes in the nucleoli are seen early and consist of an increase in the size and concentration of the granules in the granular zone and later in the intranucleolar chromatin (Fig. 15.5C). Striking cytoplasmic changes include an overall increase in the amount of cytoplasm, increased numbers of ribosomal clusters, and an enlarged Golgi complex.

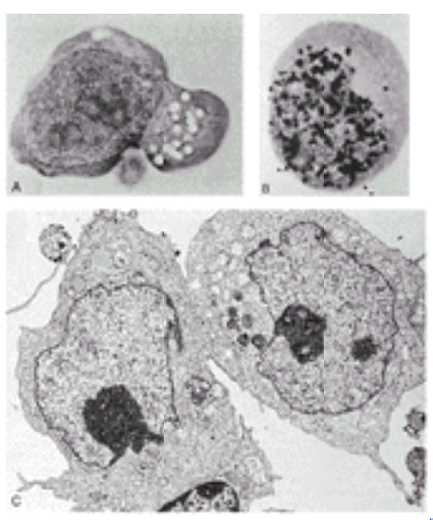

Figure 15.5. Phytohemagglutinin (PHA)-stimulated lymphocytes. **A:** Characteristic blast, 72 hours after PHA stimulation. Note prominent nucleoli and vacuolization of the cytoplasm. **B:** A blast cell incorporating 3H-thymidine 48 hours after PHA stimulation. **C:** Ultrastructure of the blasts is characterized by thinly distributed chromatin in the nucleus (contrast to resting lymphocyte depicted in Fig. 15.2) and a large prominent nucleolus (*dark area*) (×3600). (**A** and **B** from Yoffey JM, et al. Morphological studies in the culture of human lymphocytes with phytohaemagglutinin. Br J Haematol 1965;11:488, with permission.)

Human peripheral blood lymphocytes transformed with PHA acquire a highly elaborate vacuolar system consisting of endocytic vesicles, multivesicular structures, and dense bodies ([47]). The various components of the vacuolar system have their origin in the endocytic vesicles and are involved in uptake, transport, storage, and digestion of endocytosed material. This intense lysosomal vesicle formation constitutes a striking feature of PHA stimulation and correlates with enhanced endocytic activity ([48]). Transformation by PWM peaks at 72 hours and involves 50 to 60% of the lymphocytes. Three types of cells have been identified in culture: nontransformed small lymphocytes, blasts morphologically similar to plasmablasts, and immature plasmacytes (Fig. 15.6) ([49], [50]). The latter have an eccentric nucleus with clumped chromatin. The Golgi complex is well developed, and the endoplasmic reticulum is well organized. These changes provide morphologic evidence of Ig synthesis stimulated by PWM.

New York: Appleton-Century-Crofts, 1969, with permission.)

PLASMA CELLS

Plasma cells are progeny of lymphocytes, although originally they were considered to constitute a separate and independent cell line. Morphologically, they are differentiated easily from other cell types (Fig. 15.7A). The cells are spherical or ellipsoid and range from 5 to 30 µm in size. The cytoplasm is abundant, always is

basophilic, and usually is deep blue; it may have a granular character. Plasma cells have a well-defined perinuclear clear zone that contains the Golgi apparatus. In supravitally prepared films, the cytoplasm of plasma cells is deep yellowish gray. The nucleus is small in relation to the cell size; it is round or oval, eccentrically placed, and contains dense masses of chromatin, often arranged in a wheel-spoke fashion (Radkern).

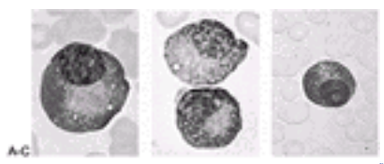

Figure 15.7. Plasma cells. **A:** Normal plasma cell. **B:** Plasmacytes with vacuoles from the bone marrow of a patient with infection and arthritis. **C:** Needle type of inclusions in plasma cell. See Color Plate. (**C** used by permission of the American Society of Hematology Slide Bank, 3rd ed, 1990.)

With use of the electron microscope (Fig. 15.8A), the surface membrane and the nucleus appear to be similar to those of the lymphocyte. The cytoplasm of the plasma cell is characterized by a well-developed rough endoplasmic reticulum that fills most of the cytoplasmic space, except in the area of the perinuclear clear zone containing the Golgi apparatus. The endoplasmic reticulum consists of lamellae arranged in various patterns, usually in parallel convolutions. The inner surfaces of the lamellae are smooth and form the walls of spaces (cisternae) that are filled with amorphous products of varying density. The outer aspects of the lamellae are rough because of attached ribosomes. A few mitochondria may be seen.

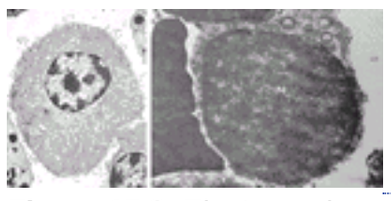

Figure 15.8. Electron micrographs of a plasma cell and an intermediate form. **A:** Typical plasma cell has cytoplasm filled with endoplasmic reticulum (×6000). **B:** A lymphocytoid-plasma cell with scant amounts of cytoplasm filled with endoplasmic reticulum and a few mitochondria (*m*) (9900). N, nucleus. (From Maldonado JE, et al. “Intermediate” cell types and mixed cell proliferation in multiple myeloma: electron microscopic observations. Blood 1966;27:212, with permission.)

The above-described electron microscopic appearance of plasma cells is the most typical. Often, however, intermediate forms are found ([14]). Thus, some cells may resemble small lymphocytes morphologically but may contain an unusually well-developed rough endoplasmic reticulum (Fig. 15.8B). Such intermediate cells (Fig. 15.1C, Fig. 15.1D, and Fig. 15.1E) are common in the blood of patients with plasma cell dyscrasias ([51]) and of those with immunologic diseases characterized by hypergammaglobulinemia ([51]). Similar cells have been encountered in the blood of patients with viral infections (Turk cells) ([20]), including infectious mononucleosis, as well as in the blood of apparently healthy individuals ([23]). Alternatively, immature plasma cells may have an appearance more akin to that of PHA-transformed cells; the nucleus is large and leptochromatic and the cytoplasm contains a rather simple endoplasmic reticulum, but many ribosomes and polyribosomes are present. Thus, it is often difficult to draw sharp cytologic dividing lines. Other plasma cells may contain vacuoles or needle-type inclusions in the cytoplasm (Fig. 15.7B, Fig. 15.7C). The molecular and genomic aspects of plasma cell differentiation are discussed in Chapter 16.

LYMPHOID ORGANS

The tissue aggregates of the immune system are separated into primary and secondary lymphoid organs. In humans, the primary lymphoid organs are the bone marrow and the thymus. The secondary lymphoid organs are the spleen, LNs, the Peyer patches (PPs) of the gut, and the Waldeyer ring (tonsils and adenoids). This division provides an anatomic basis for two fundamental stages of lymphocyte differentiation: the antigen-independent stage and the antigen-dependent stage. The primary lymphoid organs develop before the secondary organs in ontogeny and provide the proper microenvironment for antigen-independent differentiation of lymphocytes from immature precursors. At the end of this early stage of lymphocyte differentiation, immunocompetent lymphocytes are released and home to specific areas of the secondary lymphoid organs. The secondary lymphoid organs provide an optimal microenvironment for attracting antigen-specific lymphocytes, directing the terminal stages of lymphocyte differentiation and distributing the fully differentiated effector cells or their products to other parts of the body. The following section is a description of the architecture of the lymphoid organs as it pertains to the function of the immune system ([52]).

Primary Lymphoid Organs

BONE MARROW A detailed account of the histologic features and function of bone marrow is given in Chapter 6. This chapter briefly concentrates on the contribution of bone marrow in lymphopoiesis as a “primary lymphoid organ.” The bone marrow is the major hematopoietic organ in humans and supports differentiation of all blood cells ([53], [54] and [55]). In some cases, such differentiation is not always complete. T lymphocytes and monocytes, for example, reach their final stages of maturation in locations outside the bone marrow. The bone marrow is divided into two histologically distinct compartments: an extravascular compartment, which is the site of hematopoiesis, and a vascular compartment, composed of wide venous blood vessels known as *sinuses*. These vessels receive blood from the nutrient artery and the periosteal capillary network. The sinuses are radially disposed in the bone marrow and eventually open into larger, centrally located sinuses that exit through the same foramina used by the nutrient arteries. The walls of the venous sinuses consist of an endothelial layer, a basement membrane, and the adventitia. The endothelial cells are flat, with tapering ends, and contain the usual organelles. They contain lysosomes and therefore are endowed with endocytic activity. The adventitial cells have broad sheetlike processes that form a reticulum, the interstices of which are occupied by the hematopoietic cells. Volume changes in the body and the processes of the adventitial cells affect the volume of the hematopoietic space. Under some circumstances, the adventitial cells become swollen because of an increased fat content, and the gross appearance of the marrow turns from red to yellow. In conditions of increased demand on the hematopoietic process, the fatty adventitial cells decrease in size, allowing an expansion of the hematopoietic compartment. The adventitial cells are related to the reticular cells found in the splenic cords and are therefore called *adventitial reticular cells*. The hematopoietic compartment displays a specific cellular arrangement of hematopoietic cells. For example, the megakaryocytes lie close to the adventitial cells and deliver platelets directly into the sinuses through apertures in the sinus walls. Erythrocytes are produced near the sinuses, forming erythroblastic islets. Granulocytopoiesis takes place at a distance from the sinus wall in a diffuse pattern or sometimes in distinct clusters or sheets. Available evidence obtained through labeling techniques suggests that new lymphocytes are formed at the periphery of the bone marrow and move toward the center in a centripetal fashion. In mice given 3H-thymidine, the largest number of labeled cells and cells with the highest number of grains indicating the highest rate of DNA synthesis are found near the periphery when the marrow is examined 1 hour after injection of the label ([56]). Later, labeled cells are detected in all regions. However, RAG1 transcribing cells were identified scattered throughout the marrow, even in mice homozygous for RAG/GFP, in which progression beyond the prolymphocyte stage is blocked ([57]). The lymphocyte progenitors are enriched in a prolymphocyte population Lin $^{-}$ c-kit ^{lo}, which can be separated from RAG1/GFP knock-out mice. They contain progenitors for B cells, which are CD122 $^{-}$ [interleukin (IL)-2ß] and for natural killer (NK) cells, which are CD122 $^{+}$, and under defined culture conditions can mature toward B or NK lineage. B-cell differentiation can be blocked in the presence of ß-estradiol. Stem cells, or early lymphoid progenitors, or prolymphocytes populate the thymus under certain conditions. The labeling index of lymphocytes within the sinuses is intermediate between those of the whole bone marrow and those in the peripheral blood, suggesting that newly synthesized lymphocytes are discharged into the circulation. Identifiable lymphocytes are found singly or in small groups near the sinusoidal walls, with some of them in transit through the wall of the sinus ([58]). B lymphocytes acquire membrane Ig while located extravascularly. B lymphocytes are not stored in the bone marrow except for brief periods before their release into the circulation. Histologically, no lymphoid follicles are distinguishable in the normal bone marrow. Mature cells pass into the lumen of sinuses. The bone marrow resembles the red pulp of the spleen with its vascular sinuses and a reticular meshwork formed by the adventitial cells or the cordal reticular cells, respectively. It differs in that the bone marrow circulation is closed; the circulation of the red pulp is at least partially open, with no endothelial continuity between the arteries and the veins.

THYMUS The thymus is a lymphoepithelial organ situated in the superior mediastinum ([59], [60] and [61]). It consists of two lobes that are divided into lobules that form the basic anatomic units of the thymus. The thymus is covered by a fibrous capsule from which fibrous bands (trabeculae) penetrate the parenchyma, dividing it into lobules. Histologically, the lobules have two distinct regions (Fig. 15.9): the peripheral region, which is called the *cortex* and is divided into the outermost or subcapsular cortex and the inner or deep cortex, and the central region, which is called the *medulla*. In hematoxylin-eosin–stained sections, the cortex appears dark blue to purple because of the predominance of lymphocytes (80 to 85%), whereas the medulla appears eosinophilic because of the predominance of the epithelial cells. These anatomic divisions correspond to functionally distinct microenvironments that support specific phases of thymocyte differentiation. The subcapsular or superficial cortex contains large, actively dividing blasts with many mitotic figures. The deep cortex is composed principally of nondividing, small thymocytes, and the

medulla contains predominantly medium-sized thymocytes. The relationships between the thymocytes in each compartment and the mechanisms underlying thymocyte differentiation are discussed in detail in Chapter 17.

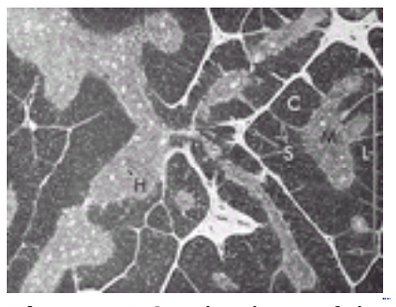

Figure 15.9. Histology of thymus shows lobules (*L*) consisting of cortex (*C*) and medulla (*M*). H, Hassall corpuscles; S, septa (trabeculae).

Ontogeny The human thymus develops from the third branchial pouch on each side, and, at the 10-mm embryo stage, it consists of a cylindric prolongation that extends caudally. By the 35-mm stage, the part closest to the mediastinum is separated from its connection to the pharynx and lies free in the mediastinum. Although evidence suggests that endoderm from the third pharyngeal pouch and ectoderm from the third pharyngeal cleft provide epithelial elements to the thymic anlage, the extent of the contribution from each layer is the subject of some controversy. Initially, the thymic anlage is hollow (cervical vesicle), but in the mouse, the cavity disappears by day 13 of gestation, and the epithelial rudiments become solid. However, small ductular or cystic structures are recognizable during thymic involution in immune deficiencies and in certain thymomas that are thought to reproduce early ontogenetic stages (62). Polycystic structures are the histologic hallmark of the thymus of the nude mouse (62) and the nude rat (63), animals that lack normal T lymphocyte differentiation and constitute the definitive model of immune deficiency. Normally, the original tubular epithelial structures, one on each side, descend into the anterior superior mediastinum where they fuse, forming the mature organ with two lobes. At this stage, the thymus is triangular, with the base resting on the pericardium and the apex pointing toward the neck. The first step in thymic development is the formation of the alymphoid thymic anlage, which originates from epithelial cells from the third pharyngeal pouch (64). The genes important at this stage are Pax9 (pharyngeal endoderm) and Hox-a3 (pharyngeal endodermal mesenchyme) (65, 66). Targeted mutations of Hox-a3 (Hox1.5) gene results in athymic embryos with other craniofacial abnormalities (67). Once the anlage is formed, the function of the whn (winged helix nude) gene is required (68, 69). The whn gene encodes a nuclear protein, Whn, which is a transcription factor of the forked/winged/helix family. It contains a DNA binding domain and a strongly acidic transcriptional activation domain, which is functionally indispensable. Mutations affect the DNA binding domain or the C-terminal transcriptional activation domain and are associated with athymia and hairlessness because the gene regulates the keratin-ization of hair. Mesenchyme of neural crest origin also plays an important role in thymic development (70). It migrates into the thymus early in development, surrounding the epithelial rudiments, and is closely associated with the developing thymocytes. It forms the connective tissue capsule and trabecular septa that penetrate the parenchyma, dividing it into lobules (70). It is also likely that it provides extracellular matrix into the cortex and medulla, such as hyaluran, collagen, and fibronectin, which may be important for the presentation of growth factors to the thymocytes (71). This part of mesenchymal development occurs after the lymphocytic invasion. The undifferentiated epithelial cells are large, with dispersed chromatin, short, blunt cytoplasmic processes, and sparse tonofilaments. As the cell matures, the amount of cytoplasm decreases, and long dendritic processes form. By day 14 in the mouse, tonofilaments and desmosomes develop (72), which permit tight junctions between adjacent cells and the formation of the epithelial framework, within the interstices of which T lymphocyte differentiation takes place. Around day 11 to 13 in mice, the epithelium is colonized by basophilic blast cells that originate outside of the thymus and give rise to the lymphocytic population. Migrating lymphoid progenitors initiate a symbiotic relationship with the epithelial cells and contribute to the organization of the thymic microenvironments. Whereas prothymocytes (i.e., immature cells) regulate induction of the cortical microenvironment (73), mature TCR^{+} thymocytes organize thymic medullary epithelial cells (74, 75). E-cadherin plays an important role at this stage because it mediates the interactions that shape the architecturally distinct cortical and medullary thymic microenvironments (76). In mice, blocking the homophilic E-cadherin interactions interferes with differentiation into these two distinct epithelial phenotypes and blocks early thymocyte differentiation (i.e., progression from the double negative to the double positive stage). E-cadherin is strongly expressed on epithelial cells as well as on the double negative ($CD4^{-}$ $CD8^{-}$) thymocytes in mice, suggesting its participation in the interaction between these two cell types. However, in human thymus, homophilic interactions cannot occur because E-cadherin is not expressed in thymocytes but is detected on epithelial cells. CD103 ($a_{E}ß_{7}$ integrin), the ligand for E-cadherin, is expressed on a subpopulation of double negative ($CD4^{-}$ $CD8^{-}$) and single positive $CD8^{+}$ thymocytes. Therefore, heterotypic interactions enhance thymocyte proliferation in the human thymus (77, 78). The thymic anlage is permeated by blood vessels, which also contribute to a well-organized medullary epithelial compartment, even in the absence of $CD3^{+}$ mature thymocytes (i.e., in Rag-$2^{-/-}$ mice. These animals develop a hypoplastic thymus (due to lack of mature T cells), but the medullary epithelium is otherwise well organized. Addition of keratinocyte growth factor, a member of the fibroblast growth factor family secreted from mesenchymal cells, results in the expansion of the epithelial medullary compartment in the Rag$2^{-/-}$ mice (79). The relB gene encoding a subunit of the nuclear factor-?B complex is critical in coordinating several aspects of the development and organization of medullary epithelial cells and dendritic cells (DCs). Overexpression of CD40L on thymocytes disrupts the thymic architecture and the epithelial differentiation, with loss of cortical epithelial cells, expansion of the medullary compartment, and infiltration of the capsule with a mixture of $CD3^{+}$ cells, B cells, and macrophages (80). These findings point out that regulation of normal development of thymus is a highly complex process, delicately regulated by multiple cellular interactions and soluble factors released as a result of these interactions. The medullary epithelium is quite heterogeneous and expresses several molecules, which are considered tissue specific, such as parathyroid hormone, thyroglobulin, insulin, C-reactive protein, and even structures with features of respiratory epithelium and others, which phenotypically and structurally resemble thyroid follicles. This may represent “promiscuous” gene expression or a “mosaic” of epithelial differentiation (81). Nevertheless, it is highly intriguing, and it may form the basis for the establishment of self-tolerance. This view is supported by the demonstration that the gene aire, which is defective in autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy, is expressed by medullary thymic endothelial cells (82). Expression of aire is regulated by rel-B signaling. Indisputable evidence from experiments involving interspecies grafting leaves little doubt that the lymphoid elements of the thymus are always derived from the recipient of the endodermal pharyngeal graft and therefore did not arise from the graft. Furthermore, the migration of the lymphoid stem cells into the epithelial rudiment takes place in waves of stem cells entering the rudiment only at certain periods during which the epithelium is receptive. This receptivity apparently is determined by chemoattractants released from the epithelial cells (83).

Nonlymphoid Cellular Elements

Epithelial Cells Ultrastructurally, the epithelial cells are phenotypically highly heterogeneous, probably reflecting their divergent origins (see Chapter 17) (84, 85 and 86). In the past, the epithelial cells have been referred to by a variety of designations, such as *reticular, syncytial, epithelioid*, and *squamoid.* The epithelial cells in the cortex have cytoplasmic processes as long as 25 µm that are now known as *dendritic epithelial cells* (Fig. 15.10). The characteristic features that distinguish them from other cells in the thymic parenchyma are the presence of tonofilaments and desmosomes. The tonofilaments are filamentous structures approximately 3.0 nm in diameter and 0.1 to 3.0 µm in length. They often form bundles and are located close to the nucleus. Desmosomes are detected at the junctions of the dendritic processes of adjacent epithelial cells (59, 84). Their oval nuclei have evenly distributed chromatin and prominent nucleoli. The epithelial cells joined by desmosomes form a continuous meshwork that surrounds the trabeculae, the blood vessels, and the inner surface of the capsule. Between the epithelial sheath and the supporting scaffolding of the trabeculae and blood vessels is a continuous basement membrane distinct from the basement membrane of the capillaries. The epithelial meshwork thus separates cavernous spaces filled with thymocytes.

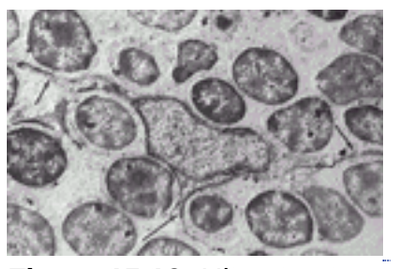

Figure 15.10. Ultrastructure of the thymus. An epithelial DC at center (*E*) extends long cytoplasmic processes (*arrows*). Note the intimate contact between the epithelial cell and the surrounding thymocytes (4400). (From Bloodworth JMB Jr, et al. Ultrastructure of the human thymus, thymic tumors, and myasthenia gravis. Pathol Annu 1975;10:329, with permission.)

Dendritic epithelial cells are found predominantly in the cortex, and because they do not have secretory granules, they probably do not participate in the secretion of thymic hormones. They guide thymocyte differentiation through cellular interactions taking place on their surface. Such interactions are regulated by products of genes of the major histocompatibility complex. Indeed, the presence on epithelial cells of class I and II molecules in mice (87) and humans (88) has been demonstrated. The distribution of class II antigens is typically dendritic in the cortex, but it is confluent in the medulla (89). The class II antigens are of higher density than the class I antigens in cortical epithelial cells, but they are of the same high density in the medullary epithelium. Using immunohistochemical techniques and electron microscopy, investigators have shown that these molecules are of epithelial origin because they are located on cells containing desmosomes and

tonofilaments ([90], [91]). Class II antigens are first detected on fetal epithelial cells on day 14 of gestation in the mouse ([92]), approximately 2 to 3 days after the arrival of lymphoid stem cells. It is intriguing that nude mice, animals absolutely deficient of mature T lymphocytes, have a total lack of class II antigens in the thymic rudiment. The thymocyte–epithelial cell interaction in the outer cortex results in the formation of lymphoepithelial complexes known as *nurse cells* (Fig. 15.11) ([93]). These complexes are composed of large clusters of lymphocytes surrounded by cell membrane and appear to reside within the cell body of an epithelial cell. Their significance in T-cell differentiation is discussed in Chapter 17. The epithelial cells of the medulla do not have long dendritic processes and are known as *epithelioid* or *spatulate epithelial* cells. They are more pleomorphic and contain dark granular inclusions that may have secretory functions. Another variety of epithelial cells, known as *squamoid*, is found exclusively in the medulla ([84]). These cells probably give rise to Hassall corpuscles and contain dense bundles of tonofilaments and masses of keratohyalin.

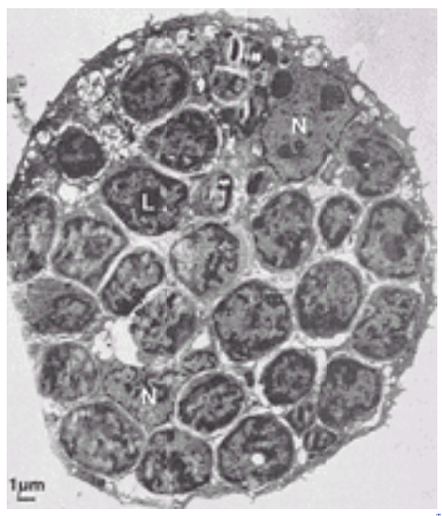

Figure 15.11. A typical large nurse cell containing many thymocytes (*L*) and two epithelial nuclei (*N*). Between the internalized thymocytes are cytoplasmic vesicles and tonofilaments. Some nurse cells contain thymocytes in mitosis. (From Wekerle H, et al. Thymic nurse cells. Lympho-epithelial cell complexes in murine thymuses: morphological and serological characterization. J Exp Med 1980;151:925, with permission.)

The Hassall corpuscles are solid or cystic, and their origin is highly disputed. In 1906, Hammar suggested that Hassall corpuscles arise as solid structures through the tight apposition of as many as 20 to 50 epithelial cells in a concentric fashion. Degenerative changes in the centrally located cells produce the cystic forms. The cavity of the cystic forms of these corpuscles is lined with epithelial cells with villous projections, and sometimes it is filled with debris and degenerated cells. In some solid corpuscles, keratinization is prominent and is similar to that of the skin. Monoclonal antibodies specific for high-molecular-weight keratins that react with terminally differentiated epithelial cells of the skin also bind to Hassall corpuscles ([60], [94]). Epithelial cells of the deep cortex are phenotypically different from those in the medulla ([95], [96]), which undergo terminal keratinocyte differentiation ([97]). Schambacher (97a) suggested that the lining cells of small ductules give rise to the solid forms as a result of proliferative activity. Whatever their origin, their function remains unknown. Some authors suggest that Hassall corpuscles function as the graveyard of thymocytes ([98], [99]) or that they represent remnants of the medullary duct epithelium.

Macrophages Macrophages are found throughout the thymus: among thymocytes, in capsular and septal connective tissues, and in the perivascular space. Some macrophages are surrounded by thymocytes and form rosette-like structures. Thymic macrophages direct thymocyte maturation. Others contain debris and lymphocytes in various stages of degeneration and appear to be involved in the disposal of many thymocytes dying within the thymus. Macrophages are more prominent in involuted thymuses after stress or steroid hormone treatment, rendering the histologic picture of a starry sky. Lymphocyte phagocytosis is found in the germinal center (GC), a site that also is characterized by high proliferative activity.

Interdigitating Dendritic Cells A third population of nonlymphoid cells in the medulla is known as *interdigitating* DCs (IDCs). These cells are of bone marrow origin and belong to the newly recognized family of IDCs present in the T-cell–dependent areas of the peripheral lymphoid organs. They contain an irregularly shaped nucleus and clear cytoplasm, but they lack the Birbeck granules characteristic of Langerhans cells (LCs). In interspecies avian grafting experiments, investigators showed that the interdigitating cells enter the thymus with the first lymphoid stem cell wave and continuously thereafter ([100]). In the mouse, the DCs are CD8a $^{+}$, derived from a common precursor with T cells ([101]). The thymic DCs are lymphoid related [i.e., granulocyte-macrophage colony-stimulating factor is not required for their development (in contrast to the myeloid DCs), and they need functional Ikaros transcription factors for their maturation] ([102]). In humans, pluripotent stem cells, which leave the bone marrow to migrate to the thymus, have the potential to develop into T cells and DCs ([103]).

Myoid Cells Myoid cells contain numerous intracytoplasmic filaments arranged in a haphazard fashion and are seen in many lower vertebrates. Their presence in human fetal thymuses has been documented, but their identification in postnatal thymuses remains controversial. One suggestion is that myoid cells originate from mesenchymal or epithelial cells. The latter seems likely because of their attachment to epithelial cells by desmosomes.

Lymphoid Cells Lymphoid cells constitute 80 to 85% of the cortical and 15% of the medullary cells. The outer cortex lymphocytes are large blast cells with dark blue cytoplasm that proliferate actively. They are the immediate descendants of bone marrow–derived prothymocytes, which enter the thymus and migrate to the subcapsular cortex. As they mature, they move into the deeper cortex, which is occupied by small nondividing thymocytes. The medullary thymocytes are of medium size and are considered emigrant cells, although this fact has not been proven conclusively. The differentiation and the relationship between subcapsular, deep cortical, and medullary thymocytes are discussed in Chapter 17.

Thymic Vasculature: Blood–Thymus Barrier The thymic anlage initially is avascular. Vessels penetrate the thymus at approximately 12 to 14 weeks of gestation. The thymic arteries, which are branches of the inferior thyroid, internal mammary, and pericardial phrenic arteries, enter the thymus from the surrounding tissues, pass down to the medulla, and branch into arterioles that penetrate into the deep cortex. Capillaries that arise from the arterioles run toward the subcapsular cortex, where they anastomose and turn inward toward the medulla, eventually forming venules ([104], [105], [106], [107] and [108]). This arrangement may serve as a countercurrent exchange mechanism to reduce the concentrations of substances present in the blood of the centrifugal capillaries ([109]). The vessels are ensheathed with epithelial cells and connective tissue that is continuous with the capsule. Histologically, therefore, a number of layers can be distinguished from the lumen of the blood vessels outward: endothelium; the vascular basement membrane; a mesenchymal perivascular connective tissue space occupied by collagen fibers, fibroblasts, some macrophages, and other cells; an epithelial basement membrane; and the epithelial cell syncytium. These layers constitute the blood–thymus barrier. The mesenchymal interstitial space is probably formed in the early stages of development when the thymic epithelial cells envelop the blood vessels. This space is considered extraparenchymal. The tightness of the barrier has been tested with particulate and protein tracers. It is tight in the cortex, mainly because of the impermeability of the endothelial junctions. Traces of protein transported by plasmalemmal vesicles of the endothelial cells and released on the parenchymal front are removed rapidly by the macrophages along the vessels in the interstitial space and thereby are prevented from coming into contact with the thymocytes. The barrier is incomplete in the medulla, however, especially along the site of thymocyte migration through the wall of venules ([107]). The fact that antigens can be detected in the thymus indicates that the “barrier” has leaks ([110]). Nevertheless, experimental tracers never reach the cortical parenchyma. This arrangement of the vasculature and epithelial sheaths separates the thymus into the intraparenchymal compartment, composed of the lymphoepithelial complex, and the extraparenchymal compartment, composed of the blood vessels and the surrounding interstitial space.

Involution Beginning at puberty, the thymus undergoes a gradual process of involution, characterized by loss of the cortical lymphocytes and atrophy of epithelial cells and their replacement by fat originating from mesenchymal cells present in the connective tissues along the vasculature and capsule. More than 50% of the thymus is replaced by adipose tissue by the age of 40 to 45 years, but the fat is still contained in the extraparenchymal compartment, separated from the remaining lymphoepithelial complex by the epithelial basement membrane and the sheet of epithelial cells. The speed of age-related involution may be influenced by stress and other factors. In contrast to the chronic involution occurring as a result of aging, the thymus undergoes acute involution as a result of stress. This involution is mediated by adrenal corticosteroids ([111], [112] and [113]). Injections of glucocorticoids eliminates as much as 75% of the thymocytes within 2 to 3 days. The changes affect both the cortex and the medulla but are more pronounced in the cortex. Most of the cortical thymocytes are cortisone sensitive, whereas the medullary thymocytes are cortisone resistant. After acute stress, the lymphocytes undergo pyknotic changes, fragmentation of the nuclei, and a decrease in size; eventually, they are phagocytosed by macrophages. Recovery takes place within 8 to 10 days and is marked by an early increase in mitotic activity in the subcapsular cortex.

Pathology of the Human Thymus

Myasthenia Gravis The thy-mus from patients with myasthenia gravis typically shows histologic changes characterized by the development of follicles with GCs composed of B cells typical of reactive peripheral lymphoid organs ([84], [114], [115], [116] and [117]). They are located outside the epithelial basement membrane, predominantly in the medulla, and are surrounded by many Hassall corpuscles. Many plasma cells are easily discernible ([118]). In some cases, an increase in the number of medullary epithelial cells containing thymic hormones is noted ([119]). The cause of these histopathologic lesions is unknown. Antibodies against the acetylcholine receptor in the neuromuscular junction play an important role in the pathogenesis of myasthenia gravis ([120]), and it is intriguing that the receptor, or a structurally similar antigen, has been detected on thymic cells ([121], [122]). Antibodies from patients with myasthenia gravis react with striations of myoid cells from animal and human thymuses in culture and muscle cells expressing acetylcholine receptors ([123], [124]). Approximately 10 to 15% of patients with myasthenia gravis have thymomas, but these histologic changes are not characteristic of myasthenia gravis in that they have been observed in patients with other diseases, such as endocrinopathies (Addison disease and thyrotoxicosis) and autoimmune diseases (such as systemic lupus erythematosus). Similar lesions have been identified in

thymuses from patients with multiple sclerosis ([125]). A well-documented fact is that the thymus and the brain share some antigens, such as the Thy-1 antigen (CD90).
Dysplasia The thymus of patients with severe combined immunodeficiency disease is characterized by scant lymphocytes with reduced numbers of epithelial cells.
Thymomas Tumors of the thymus are epithelial or lymphocytic, or they contain a mixture of both cellular elements ([84], [126]). In some cases, ductal and glandular structures are detected, mixed with other epithelial cells. These cases are thought to imitate the early ontogenetic stages of the thymic anlage and support the view of the double origin of the thymic epithelium. Thymic lymphomas that appear as mediastinal masses are associated with T-cell acute lymphatic leukemia in children ([127]). The cells of these tumors bear the phenotype of cortical thymocytes in the early stages of their development.

Secondary Lymphoid Organs

LYMPH NODES

Ontogeny The ontogeny of the secondary lymphoid organs, LN, PPs, and spleen, is highly complex ([128], [129]). The fundamental concepts of lymphoid organ neogenesis were generated approximately 100 years ago ([130]). But only now are they verified by the identification of the genes, their products, and the cells that orchestrate the building of the “homes” where the mature T and B lymphocytes, out of the primary lymphoid organs, will be homing to. The first stage in the development of the LN and PP is the budding from large vessels of lymph sacs, which are then penetrated by connective tissue and lymphatic vessels. These vessels interconnect with other vessels, forming a network ([130]). These original observations have been verified by the identification of the genes and the determination of the time of their expression during embryogenesis. The Prox-1 gene is expressed on lymphatic endothelial cells and is required for budding and sprouting of the lymphatic endothelium ([131]). Sabin ([130]) observed that one spot of budding to generate a lymph sac occurs in the anterior cardinal veins of the neck. This lymph sac gives rise to the lymphatics of the neck, thorax, heart, lungs, and forelegs. In the same location, the expression of the Prox-1 gene was identified. Lymphotoxin (LT) is essential for the formation of LN and PP, as shown in LTa $^{-/-}$ mice in which there is a profound defect in the formation of LN, complete absence of PP, and grossly disturbed splenic microarchitecture. The membrane form of LT is the active signaling molecule in LN and PP biogenesis ([132]). LTa forms heterotrimers with LTß (LTa $_1$ß $_2$) and exists as a membrane-bound form on the cell surface. LTa $_1$ß $_2$ does not bind to either of the two tumor necrosis factor (TNF) receptors but to its own receptor, the LT-ß receptor (LTßR) ([133]). After completion of the connective tissue structure, the first cells to colonize the LN in mice express the phenotype CD4 $^+$ CD45 $^+$ ([134]). These cells are not T cells because they are TCR $^-$ and CD3 $^-$ but express LTa $_1$ß $_2$. They cannot differentiate to either T or B lymphocytes but stimulated by IL-2, they can differentiate towards NK cells and with a combination of other cytokines give rise to antigen-presenting cells ([134]). The precursors of these cells are IL-7R positive and reside in the liver ([135]). The generation of the CD45 $^+$ CD4 $^+$ CD3 $^-$ cells, from the liver precursors, requires the function of the ROR? gene ([136]). Another gene that has also been implicated in the generation of the CD45 $^+$ CD4 $^+$ CD3 $^-$ is Id2. Id2 $^{-/-}$ mice lack all LN and PP but have normal spleen ([137]). Id2 gene is a negative regulator (i.e., its product blocks the helix-loop-helix proteins and thus allows differentiation of the CD4 $^+$ CD3 $^-$ cells). Finally, the development of all LN (but not of the PP) depends on the TRANCE/TRANCE-R signaling. TRANCE (or RANK-L, OPG-L) is a member of the TNF family of cytokines, and mice deficient in TRANCE have absent LN and a serious defect in bone development due to the absence of osteoclasts ([138]). The TRANCE $^{-/-}$ (RANK) mice also show a complete absence of LN but normal PP ([139]). Mutation of another gene “aly” (alymphoplasia) results in complete absence of LN and PP and lack of well-defined lymphoid follicles in the spleen ([140]). Development of B-cell–rich lymphoid follicles requires the function of the B lymphocyte chemoattractant (BLC) or CXCL13 and its receptor CXCR5, which stimulates homing of B lymphocytes to the follicles. BLC induces up-regulation of a $_1$ß $_2$ LT, which promotes follicular DC development and BLC expression, establishing a positive feedback loop ([141]). Colonization of the paracortical areas by T cells is regulated by another system of chemokine and its receptor (see Lymphocyte Homing and Recirculation).
Structure The LNs are ovoid structures ranging in size from a few millimeters to more than a centimeter ([142], [143] and [144]). They are particularly common at the base of extremities, in the retroperitoneum and the mediastinum, and along blood vessels. LNs are surrounded by a fibrous capsule from which trabeculae penetrate the parenchyma, forming a fibrous supporting meshwork. Blood vessels enter and leave LNs through the hilum. Histologically, two regions can be distinguished: a peripheral cortex and a central medulla. The cortex is subdivided into the superficial cortex, located immediately beneath the capsule, and the deep cortex or paracortex, which is located toward the center of the node (Fig. 15.12). To gain a clear understanding of LN function, it is useful to regard LNs as consisting of the reticulum and the cellular compartment.

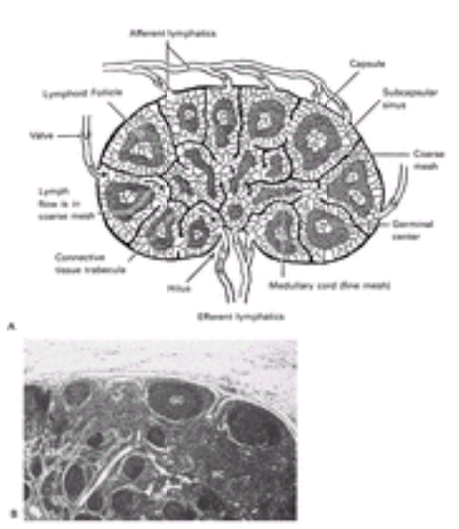

Figure 15.12. Lymph node. **A:** Drawing of a lymph node. **B:** Cross section of a normal lymph node. GC, germinal centers; LF, lymphocytic follicles; MC, medullary cords; PC, paracortical lymphoid areas. See Color Plate.

Lymph Node Reticulum The basic framework of the LN is composed of trabeculae made of bundles of collagen and a few elastic fibers ([145], [146]). This fibrous reticulum is argyrophilic when silver impregnation techniques are applied, forming a closely knit spongelike framework, with the fibers branching frequently and anastomosing freely with each other. The fibers penetrate dense lymphatic tissue and also surround the sinuses. They are ensheathed by two kinds of cells (Fig. 15.13). On the side that borders the dense lymphoid tissue, the fibrous reticulum is covered by thin, elongated cells that have been identified as fibroblasts or fibroblastic reticulum cells. They have large nuclei and endoplasmic reticulum in their cytoplasm. Cytoplasmic processes join similar processes of adjacent cells and form a continuous cellular sheath (cellular reticulum), which separates the fibrous reticulum from the dense lymphoid tissue. On the side bordering the sinuses, the fibers are covered by flat cells containing multiple vesicles. These are the littoral or endothelial cells lining the sinuses. The littoral cells have no basement membrane. Fibers sometimes cross the sinuses and are covered by endothelial cells (Fig. 15.14). They divide the lumen into smaller interconnecting compartments. These trabeculae not only provide mechanical support for the sinuses but also slow the flow of the lymph, enhancing the opportunities for phagocytosis by macrophages present along their course or lining the sinus walls. The sinuses originate from a foramen on the inner wall of the subcapsular sinus where afferent lymphatics terminate. The outer wall of the subcapsular sinuses are formed by the capsule of the LN. The sinuses follow the fibrous trabeculae through the LN parenchyma. Viewed from this perspective, the reticulum divides the LN into two distinct spaces. One consists of conventional vascular channels, the sinuses, which are sparsely occupied by cells and have a rapid rate of flow. This compartment of the LN facilitates lymphocyte traffic. The other division may be regarded as vascular spaces with unique characteristics: they are lined by fibroblasts, are tightly packed with lymphocytes and other cells, and have slow rates of flow. Immune responses take place in this compartment through cellular interactions. Both of these spaces communicate through pores in the inner wall of the subcapsular sinus.

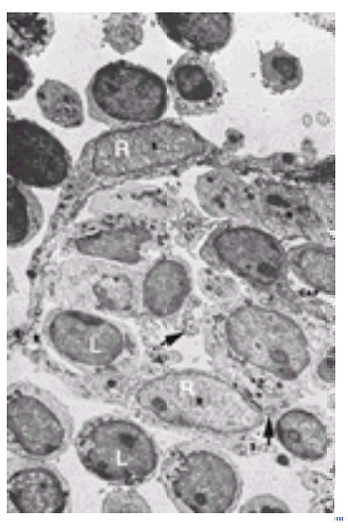

Figure 15.13. Ultrastructure of a lymph node. The area in the center and to the right is occupied by dense lymphoid tissue with many lymphoid cells. It is separated from the sinus (*upper area*, *left*, and *below*) by flat endothelial cells lining the sinus (*s*), bulky reticular cells (*R*) bordering the dense lymphoid tissue, and collagenous fibers (*c*) between the two cellular layers. Arrows indicate collagenous fibers traversing the dense lymphoid tissue. Cap, blood capillary. (From Clark SL Jr. The reticulum of lymph nodes in mice studied with the electron microscope. Am J Anat 1962;110:217, with permission.)

Cellular Compartments The most abundant type of cell in the LN is the lymphocyte. In the region beneath the capsule, known as the *cortex*, the lymphocytes are arranged in clusters known as *follicles*. If the follicle is composed of uniform small lymphocytes, it is a primary follicle; if it contains pale, lightly stained, blastlike cells with a euchromatic nucleus at its center, it is a secondary follicle. The central zone of the secondary follicle is called a *germinal center* (GC). The GC is the hallmark of antigenic stimulation. In the secondary follicles, the lymphocytes that surround the GC constitute the mantle or crescent. These cells were so named by Flemming in 1885 because he considered them “breeding grounds for the generation of lymphocytes” ([147]). Later, Hellman called them “reaction centers,” important in the induction of immunity ([148]). In the areas between the follicles, lymphocytes are distributed diffusely (diffuse cortex). The region that separates the cortex from the medulla is the deep cortex or paracortex and contains tightly packed lymphocytes. The histologic arrangement of lymphocytes in the LN corresponds to distinct functions performed by separate classes of lymphocytes (Fig. 15.15). The follicles are occupied by B lymphocytes and represent the sites of intense activity during humoral (antibody) responses (see Chapter 16). Two types of lymphoid cells are present in the GC: the centroblasts (noncleaved), which are large and activated B lymphocytes, and the centrocytes (cleaved), which are small and are derived from the centroblasts. The centroblasts are located at the bottom of the GC (dark zone), and the centrocytes are located at the upper part (apical zone). The role of the GC in the maturation of the antibody response is discussed in Chapter 16. A subpopulation of centroblasts expresses a phenotype characteristic of Burkitt cells ([149]). GCs also contain a subset of T cells ([150]), which are $CD4^+$, $CD45RO^+$, and $CD57^+$ ([151]), and belong to the Th2 subset. These T cells are important in initiating T–B cell interactions for antibody formation. A large number of B lymphocytes not selected for antibody synthesis (or generation of memory cells) die by apoptosis and are disposed of by phagocytic macrophages known as *tingible body macrophages*.

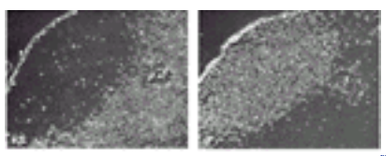

Figure 15.15. B- and T-cell–dependent areas of the lymph node. Frozen section of a mouse lymph node was examined by immunofluorescence with an antiimmunoglobulin antiserum **(A)** or an antiserum to T cells **(B)**. **A:** Only the follicle fluoresces (B-cell–dependent area). **B:** The paracortex fluoresces brightly (T-cell–dependent area), whereas the follicle remains dark except for a few scattered fluorescent T cells. These are $CD4^+$ helper T cells, which migrate to the germinal center because they express the chemokine receptor CXCR5 and are attracted to its ligand, BCA-1 chemokine released from cells in the follicle (see Lymphocyte Homing and Recirculation). (From Weissman IL, et al. The lymphoid system. Its normal architecture and the potential for understanding the system through the study of lymphoproliferative diseases. Hum Pathol 1978;9:25, with permission.)

The mantle of the follicle is composed of small lymphocytes that morphologically appear identical. However, they are functionally and phenotypically heterogeneous. A small number are small lymphocytes not yet antigenically stimulated that have arrived from the bone marrow, are immunologically competent, and express both IgM and IgD ([152]). The majority are small, recirculating, and indistinguishable from the previous set but may have responded to T-independent antigens. A third population are memory B cells, which are long lived and recirculating, and express IgG or IgA. Some of the B lymphocytes of the mantle are $CD5^+$. The relationship of this lymphocyte to $CD5^-$ B cells is discussed in Chapter 16. The paracortex and diffuse cortex constitute the T-cell compartments that undergo histologic changes during cell-mediated immunity. Sometimes in the paracortex, nodules consisting of IDCs and T cells are formed after an immune response ([153] , [154]). Cross sections of paracortex stained with special stains show a set of concentric rings, which form barriers or walls separating vascular spaces in between, where the lymph flows (Fig. 15.16). This structure constitutes the paracortical cord ([155]) with its center in the high endothelial venule (HEV) (see description later in this section). Lymphocytes exit the HEV through an interendothelial route and emerge into the perivenular channels (PVCs) ([156]), which is the space between the abluminal side of the endothelium and the surrounding pericytes. These channels are bounded by pericytes or fibroblastic reticular cells (FRCs). FRCs circumscribe the HEV with at least two layers of overlapping cells. Flow of lymphocytes through PVCs is rate limiting because the PVC around the HEV is extremely narrow, and lymphocytes must distend the channel to flow through it. On emergence from PVCs, the lymphocytes enter a space packed densely with cells, known as the *corridor*. The wall of the corridor is a network of FRCs. Corridors are wide and can accommodate two lymphocytes side by side. Their walls are reticular fibers consisting of collagen, which are enclosed by FRCs. The FRCs leave a tiny space surrounding the fibers, which is called the *conduit*. The corridors allow cellular interactions. Slowly moving T cells sample antigens on stationary DCs, “shaking hands much like the receiving line at a wedding” ([156]). The conduit, on the other hand, is a specialized system where fluid carries soluble factors important for the immune functions of the lymphocytes. The corridor space, where flow is slow, is separated from the sinuses, where flow is fast, by the reticular fibers and the endothelium of the sinuses.

Figure 15.16. Cross section of a paracortical cord showing the corridor, outlined by reticular fibers stained by Gomori stain. **A:** The corridor encircles the high endothelial venule in the center (*H*). **B:** The drawing represents an “idealized” cross section of panel **A**. See Color Plate. (Courtesy of Drs. Gretz, Anderson, and Shaw. From Gretz JE, Anderson AO, Shaw S. Cords, channels, corridors, and conduits: critical architectural elements facilitating cell interactions in the lymph node cortex. Immunol Rev 1997; 156:11–24, with permission.)

In the medulla, the cells are arranged in cords (medullary cords) composed of lymphocytes, macrophages, and plasma cells.

Other Cells: Dendritic Cells The functions of lymphocytes are predicated on their interactions with other cells, such as macrophages and DCs. Macrophages are found in large numbers in the walls of the sinuses and in the dense lymphoid regions. They phagocytose and rapidly remove foreign substances. Within minutes after injection, foreign substances are found in the phagolysosomes of medullary macrophages. Macrophages therefore contribute in an important way to the filtering functions of LNs as they capture and destroy infectious agents. In the process of phagocytosing foreign material, macrophages process antigen for presentation to lymphocytes, especially the T lymphocytes. Antigen presentation, however, is mediated by other non-phagocytic professional antigen-presenting cells, generally known as *dendritic cells* (DCs) ([157]). Their name vividly describes their morphology, with long arborizing cytoplasmic processes or dendrites (from the Greek *dendron*: tree), extending from the cell body for long distances. Within the LN, there are two distinct populations of DCs: one resides in the follicles, known as a *follicular DC* or *FDC*, and the second in the paracortex, known as *interdigitating DC* or *IDC*. Their origins, functions, and cellular associations are distinct. FDCs are autochthonous, whereas IDCs are immigrants that arrive from remote parts of the body using the routes of the lymphatic vessels. FDCs are found in the follicles and have an irregularly shaped nucleus with long, beaded cytoplasmic processes. They are not phagocytic and retain antigen for prolonged periods. The FDCs capture immune complexes and function as arbiters of life and death for emerging centrocytes based on high or low affinity, respectively, of their receptor for antigen (see Chapter 16). They also have been implicated in the generation of memory lymphocytes, the maintenance of antibody production with the formation of plasma cells. Two types of FDCs have been described, one with filiform and one with beaded dendrites ([158]). The FDCs interact with B lymphocytes through adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) (CD54) and vascular cell adhesion molecule-1 (VCAM-1) (CD106), which interact with the ligands LFA-1 (CD11a/CD18 or

a $_{L}$ß $_{2}$ integrin) and VLA-4 (CD49d), respectively, on the surface of the B cells ([159]). The FDC network may be disrupted in angioimmunoblastic lymphadenopathy, acquired immunodeficiency syndrome, and Hodgkin disease ([160] , [161]). Electron microscopic studies of the primary follicles detected reticulum cells, with little or no evidence of phagocytic activity, making contacts with neighboring cells by very tight adhesions or desmosomes ([162]). These “reticulum cells” are stellate in shape, have long cytoplasmic processes, and are probably of mesenchymal origin. GC FDCs probably derive from the primary follicle reticulum cells. Dendritic reticulum cells do not ensheathe collagenous fibers and therefore are distinct from the fibroblastic reticulum cells that form and ensheathe the collagenous fibers. The IDCs are located in the paracortex ([163]). They extend numerous cytoplasmic processes that surround T cells. The IDC is not phagocytic but carries antigen from the periphery to present it to T cells in the paracortex of the LNs. Tight junctions between IDCs and T lymphocytes have been detected by electron microscopy and become particularly prominent after stimulation with antigens that elicit strong cell-mediated immunity. Their cytoplasm is electron lucent and contains lysosomelike vesicles and tubular structures extending to the periphery of the cell. The IDCs are S100 $^{+}$ and CD1a $^{+}$. The paracortical T-cell nodules consist of T cells, large numbers of IDCs, and endothelial venules, and may be the *in vivo* equivalent of the clusters formed *in vitro* between T cells and antigen-presenting cells. Therefore, they are important in the generation of antigen-specific T lymphocytes. T-cell nodules are detected next to B-cell follicles, forming the “composite nodules.” Prominent T-cell nodules are detected in dermatopathic lymphadenitis where large numbers of LCs migrate from the areas of inflamed skin. Similar changes are also seen in regional LNs draining areas of T-cell lymphomas involving the skin. Mechanisms and routes of migration of IDCs are discussed in the section Dendritic Cell Migration.

Vasculature

Ontogeny Growth factors of the vascular endothelial growth factor (VEGF) family control lymphangiogenesis. They activate VEGF-specific receptors of which VEGFR-3 (Flt4) has been implicated in the regulation of lymphatic development and lymphangiogenesis. VEGF-C and VEGF-D are important in lymphangiogenesis. Both are processed after synthesis and form mature dimers of the VEGF domain. Both bind with high affinity to VEGFR-2 and VEGFR-3 expressed on endothelial cells. VEGFR-3 is a receptor tyrosine kinase with seven extracellular Ig-like domains and cytoplasmic tyrosine kinase domain ([164] , [165] and [166]).

Lymphatic Vessels Afferent lymphatics pierce the capsule and empty into subcapsular sinuses ([167]). Cortical sinuses originate from the subcapsular sinus and often run along the tra-beculae and through the cortex to the medulla, where they become medullary sinuses. Eventually, the sinuses give rise to the efferent lymphatic vessels that leave the LN at the hilum.

Blood Vessels The artery enters the LN at the hilum, gives rise to arterioles that reach the cortex along the trabeculae, and finally split into a rich network of capillaries. The capillaries empty into venules that extend from the cortex to the medullary cords and eventually exit from the hilum as veins. The venules linked most immediately to the capillaries possess unique endothelial cells that are tall and cuboidal and therefore contrast with the endothelial linings of other venules that usually are low or flat. The HEVs (Fig. 15.17 and Fig. 15.18) are the sites at which lymphocytes migrate from the blood circulation into the lymphatic circulation ([168]). The high endothelial cells have abundant cytoplasm, and their luminal surface is covered by a 1.5-nm-thick coat composed of filamentous and granular material. This coat may signal passing lymphocytes to cross the HEV wall ([169]). On the basis of the content of their polyribosomes, two types of cells are distinguished by electron microscopy; one is lighter and one darker ([170]), and the latter is also intensely pyroninophilic. The cytoplasm also contains numerous microtubules that radiate from the centriole, as well as multiple dense bodies that probably are related to lysosomes but also may function as storage sites for glycoproteins used in the formation of the cell coat. One striking morphologic feature is the large Golgi complex with myriad vesicles, a characteristic associated more commonly with actively secreting cells than with endothelial cells ([169]). Indeed, these cells secrete chemokines, which direct transendothelial migration of lymphocytes in HEV (see section Lymphocyte Homing and Recirculation).

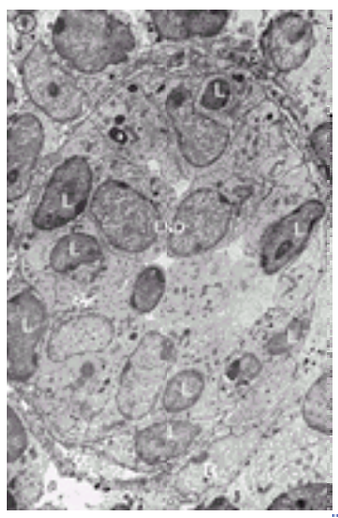

Figure 15.17. A postcapillary venule is practically occluded by the tall endothelial cells *(End).* Some lymphocytes *(L)* are crossing the wall of the high endothelial venule and enter the lymph node. The wall is surrounded by reticular cells *(R)* (×4500). (From Clark SJL Jr. The reticulum of lymph nodes in mice studied with the electron microscope. Am J Anat 1962;110:217, with permission.)

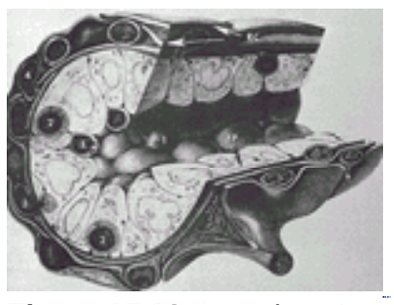

Figure 15.18. Lymphocytes crossing the high endothelial venule (HEV). Lymphocyte migration is shown in successive stages (*1–4*). After attachment to the luminal surface of an endothelial cell (*1*), the lymphocytes insinuate between endothelial cells (*2*) and cross the basement membrane (*3*) and a sheath of reticular cells (*RC*) surrounding the HEV (*4*). The endothelial cells are attached to the neighboring cells by junctional complexes and to the perivascular sheaths by foot processes (*FP*). (From Anderson AO, Anderson ND. Lymphocyte emigration from high endothelial venules in rat lymph nodes. Immunology 1976;31:455, with permission.)

The bulky nucleus protrudes into the lumen and contains a well-developed reticulated nucleolus ([143]), characteristics of a metabolically highly active cell. Acid hydrolase activity and nonspecific esterases that are not present in other endothelia have been detected in these cells, as well as a peculiar ability to shift to anaerobic metabolism. The height of the endothelial cells and their metabolic activity are influenced by the number of circulating T lymphocytes. Neonatal thymectomy and chronic thoracic duct drainage ([171] , [172]) in mice and rats result in flattening of the endothelium, loss of pyroninophilia, and absence of lymphocytes migrating through the HEV wall. Infusion of lymphocytes into these animals reconstitutes the normal morphologic appearance of HEV. In congenitally athymic (nude) mice ([173]) and rats ([174] , [175]), the endothelium of HEVs is flat. Some evidence also has implicated the macrophages as playing a regulatory role in determining the morphology and metabolic activity of the endothelial cells ([176]). The HEVs are surrounded by layers of sheaths that derive from cytoplasmic plates of reticular cells linked to the fibrous reticulum of the LN ([167]). These sheaths may regulate the passage of lymphocytes to the LN while limiting fluid leakage and providing vascular support (Fig. 15.16B). When Marchesi and Gowans ([177]) originally identified the HEVs as the site for lymphocyte migration, they thought that lymphocytes cross the HEV wall by penetrating the cytoplasm of the high endothelial cells. This crossing is now recognized as an artifact because all lymphocytes that appeared on electron microscopic sections to be surrounded by endothelial cells were in fact outside of these cells when evaluated with tracer studies. Thus, the lymphocytes migrate across the HEV wall by insinuating themselves between endothelial cells ([178] , [179]). The interactions of lymphocytes and the HEV during homing and recirculation are described in the section Transendothelial Migration.

Morphologic Changes during the Immune Response Antigens enter the LN via the afferent lymphatics that empty into the subcapsular sinus. Antigen then percolates in the sinuses through the parenchyma and is eventually found in two areas of the LN. In the medulla, it is localized within the lysosomes of macrophages ([180] , [181]), whereas in the cortex, it is associated with the membranes of FDC ([180] , [182]). Antibody facilitates this follicular localization. During a humoral response, intense proliferative activity is observed in the center of the follicles 1 to 2 days after immunization. By 72 hours, large pyroninophilic cells are seen in the GCs of draining LNs ([183]). These cells have been given various names, such as *immunoblasts*, a term introduced originally by Dameshek ([184]). They also have been known as *germinoblasts* ([185]). To avoid confusion with gonadal cells, however, they were renamed *centroblasts*. This blast is a large cell (larger than 10 µm) and has a nucleus with loose chromatin and a giant reticulated nucleolus that may occupy as much as one-half of the nuclear area. The Golgi apparatus is moderately developed and contains many free polyribosomes but only few cisternae of endoplasmic reticulum. As the endoplasmic reticulum becomes more abundant, these cells are known as *plasmablasts* ([186]). At this stage, their nucleus possesses clumps of heterochromatin and a moderate-sized nucleolus. Free polyribosomes are still present, and the cisternae of the endoplasmic reticulum do not fill the cytoplasm entirely. By day 5, an increase is noted in the number of tingible body macrophages

that give the GCs the appearance of a starry sky. Tingible body macrophages (Korper of Flemming) are macrophages that have phagocytosed nuclear debris of lymphocytes (the graveyard theory) ([187]). Because of their intense basophilic cytoplasm, the immunoblasts (or centroblasts) demarcate a histologic area known as the *dark zone* (also known as the *basal* or *lower zone* because it is located in the area of the GC that is toward the interior of the LN) ([188]). As they become more mature (immunocytes, centrocytes), they occupy the light zone (also called the *upper zone* because it is located above the dark zone toward the capsule). Small numbers of plasma cells are detected in the GCs. Kinetic studies with 3H-thymidine provided evidence of the origin of centrocytes from the centroblasts and the dissemination of the activated cells beyond the confines of the GC ([189]). Some GC blasts contain antibody ([190]). Little doubt remains that the GC blasts originate from B lymphocytes. They display a unique phenotype characterized by lack of membrane IgD. The formation of GCs depends on the presence of T lymphocytes ([191]). The significance of the GC reaction is discussed in Chapter 16. They are the source of plasma cells ([192]), seen in the medullary cords by day 3 or 4 after immunization. In addition, they give rise to memory cells ([193]). For antigens that stimulate strong cell-mediated immunity, the proliferative activity and increase in the pyroninophilic blast cells are noted in the paracortex, which is the T-cell–dependent area.

Functions LNs should be viewed as dynamic structures, the cells of which are constantly on the move. The functions of LNs can be considered in two broad categories. As an efficient mechanical filter, the LN includes an exquisite arrangement of the reticular meshwork and the sinuses with strategically located master phagocytic cells, the macrophages. If the filtration function fails to control infectious agents, the LNs become new foci for spread of disease. The LNs also constitute important sites of immune functions that depend on complex interactions between lymphocytes and other cells. To this effect, LNs provide a suitable microenvironment, which includes the HEVs that permit lymphocytes to enter (home) and recirculate; stromal cells that direct lymphocytes to distinct domains, such as the IDC of the paracortex that attract T lymphocytes and present them antigens; and the FDC in the follicles that interact with B cells. LNs thus are important sites for the generation of effector mechanisms, including antibodies and T-cell–mediated immune responses. Both responses are exported from LNs and are carried to remote sites to control infections.

SPLEEN The orphan homeobox gene 11 (Hox11) controls the expression of the spleen ([194]). Knock-out mice (Hox $^{-/-}$) lack the spleen but otherwise appear normal. No defects in other secondary lymphoid organs or bone marrow and thymus have been detected. Although the spleen is considered a secondary lymphoid organ, it serves several other functions unrelated to the immune system. The spleen affects all blood cells throughout their life-span ([195]). It provides the microenvironment for the final differentiation of reticulocytes, platelets, and monocytes; it removes aged or deformed red blood cells; and it is a reservoir for erythrocytes and granulocytes.

Structure The spleen is covered by a connective tissue capsule that is several millimeters thick ([142] , [143] , [196] , [197]). The human spleen contains only a few muscle cells and thus is not capable of marked contractions. The internal surface of the capsule is the point of origin for an extensive network of trabeculae several millimeters in each dimension that divides the organ into communicating compartments. The appearance is spongelike, with the spaces containing the parenchyma or pulp tissue. The capsule is indented on the medial surface where the blood vessels, lymphatics, and nerves enter and leave. Sections of the spleen stained with hematoxylin and eosin reveal two kinds of parenchyma: one is stained dark blue to purple because of the predominance of small lymphocytes (the white pulp) and the second is red because of the predominance of blood-filled sinuses (the red pulp) (Fig. 15.19).

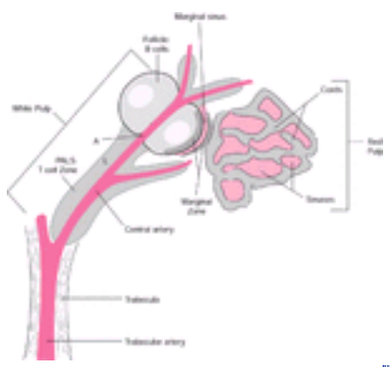

Figure 15.19. Drawing of the splenic structure and circulation. PALS, periarteriolar lymphatic sheath.

White Pulp The white pulp is the main lymphatic tissue of the spleen and surrounds the blood vessels (Fig. 15.19 and Fig. 15.20). The splenic artery branches into trabecular arteries that follow the trabeculae and in turn give off branches that leave the trabeculae. These structures are now called *central arteries* because of their central position in the white pulp (Fig. 15.20). They are muscular vessels that can alter blood flow by their contraction and relaxation. The white pulp is composed of the supporting reticulum, the free cells, and the blood vessels.

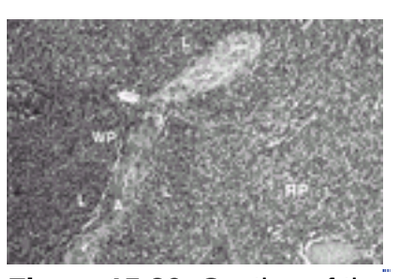

Figure 15.20. Section of the spleen. White pulp (*WP*): lymphocytes (*L*) packed around an arteriole (*A*). Red pulp (*RP*) surrounds the white pulp and consists mainly of sinuses, the cords, and cordal spaces. See Color Plate.

The reticulum is a scaffolding made of reticular fibers produced by reticular cells. The reticulum cells are spindle shaped with conspicuous microfilaments in their cytoplasm and prominent endoplasmic reticulum. The nucleus contains finely dispersed chromatin. This reticulum provides support for the free cells and the blood vessels. It runs circumferentially around the central artery and becomes particularly pronounced in the periphery of the white pulp, where the reticular cells extend sheets of membranes concentrically ([198] , [199]) (Fig. 15.21A).

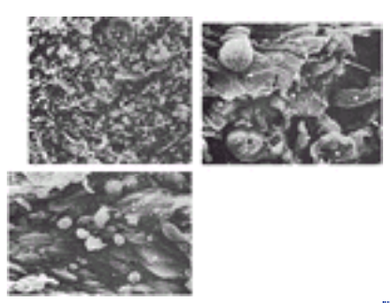

Figure 15.21. Ultrastructure of the spleen by scanning electron microscope. **A:** Periarteriolar lymphatic sheath with a central artery (*A*). Tightly packed lymphocytes lie between fibers and reticular cells (*arrows*) that run circumferentially around the artery. **B:** Lumen of a sinus at upper left has elongated endothelial lining cells. The cord below contains bulky reticular cells (*asterisks*) and fibers (*white arrows*). Some erythrocytes (*E*) are visible in the cordal spaces. The large cell in the lumen of the sinus is probably a macrophage with several thin cytoplasmic strands (*arrow*). The beaded black lines identify at the cut edge of the sinus its adventitial layer (terminal bead) and its endothelial layer (subterminal bead). **C:** Lumen of a sinus that bifurcates to the right. The elongated endothelial cells are in close apposition without any visible gaps. (From Weiss L. A scanning electron microscopic study of the spleen. Blood 1974;43:665, with permission.)

The central artery gives off secondary branches that radiate through the white pulp with different destinations. Some vessels terminate before they reach the edges of the white pulp, and some go beyond and terminate in the marginal zone (MZ) or extend even further into the red pulp. In the human spleen, some branches curve back from the red pulp and form a delicate network around lymphatic follicles located at the periphery of the white pulp. The predominant cell type of the white pulp is the lymphocyte, which occupies the interstices of the spongelike meshwork of the reticulum, forming two histologically distinct arrangements. Immediately surrounding the central artery, lymphocytes are tightly packed in a diffuse sheath that follows the central artery much like a cellular cylinder, eventually becoming thinner as the artery divides into small arterioles. This diffuse lymphocytic collection is known as the *periarteriolar lymphatic sheath* or *PALS* (Fig. 15.20 and Fig. 15.21A). The PALS is divided into the central and peripheral areas. The central area immediately surrounding the artery is occupied by tightly packed T lymphocytes. The stroma in this area contains the interdigitating cells seen also in the T-dependent area (paracortex) of the LN ([200] , [201]). T lymphocytes usually are found in intimate contact with the interdigitating cells. The periphery of PALS lacks the interdigitating cells and contains B and T lymphocytes. Lymphocyte collections in the form of follicles are seen in this region, some of them containing blastlike cells at their center that form the GC (secondary follicle). The small lymphocytes that surround the GCs constitute the mantle that separates the GC from the MZ. These GCs, like their counterparts in the LN, can be divided histologically into a dark zone occupied by large pyroninophilic blasts with high mitotic activity and a light zone with more mature cells. The light zone, which faces the MZ, has an abundance of the characteristic FDCs that also are present in the nodules of the LN. They are large cells with unusually shaped nuclei that are poor in heterochromatin, and the cytoplasmic extensions are thin sheets rather than dendrites. The FDCs are not phagocytic but retain foreign substances on their membranes for long periods. In experiments conducted with animals, it was shown that their numbers increase after immunization. No FDC can be located in the central section of PALS. Their presence in the

mantle of the nodules facing the MZ places them in a strategic location to capture foreign substances entering the spleen. Findings of studies involving animals reveal that antigens are localized first in the MZ and then cross the marginal sinus to lodge in the mantle of the nodules, forming a crescentic cap. The nodules of the peripheral section of PALS constitute the B-dependent regions of the spleen. The segregation of the two major lymphocyte populations into distinct settlements within the secondary lymphoid organs seems to be determined by the nature of their underlying neighbors.

Marginal Zone The MZ is the part of the parenchyma that lies between the white and red pulps (Fig. 15.19 and Fig. 15.20). This area of the spleen is important because it comes in contact with large quantities of circulating blood. Many arterial vessels terminate in this region, some of them in funnel-shaped orifices that empty their contents into the interstices of the marginal zone. Unlike the red pulp, the MZ has no sinuses. In rodents, a marginal sinus separates the MZ from the white pulp, but the human spleen lacks a marginal sinus. Some authors suggest that the marginal sinus may be functionally equivalent to the postcapillary venule and, in rodents, the site at which lymphocytes enter the splenic parenchyma. The lymphocytes entering the marginal sinus have multiple microvilli with which they establish contacts with reticular cells as they find their way toward their microenvironments. Once they reach their destination, the microvilli disappear. However, the marginal sinus does not have the tall endothelial cells that direct traffic in the LNs. Some authors speculate that this function is performed by splenic macrophages located in the marginal sinus. These cells have distinct phagocytic and morphologic properties that distinguish them from macrophages in other locations of the spleen, including the ability to bind lymphocytes ([202]). Splenic processing of blood cells begins in the MZ.

Marginal Zone Lymphocytes: Functions and Malignancies The nature and function of the MZ B cell is not well understood. In human spleen, the MZ contains clusters of B cells and macrophages in the vicinity of the periphery of the white pulp. Morphologically, phenotypically, and genotypically, these cells differ from naïve B cells. They are large with pale cytoplasm and irregular nucleus. They are IgD $^{-}$, CD5 $^{-}$, CD10 $^{-}$, and CD23 $^{-}$, and have mutated their Ig-V genes ([203] , [204]). MZ B cells are memory cells, but constitute a heterogeneous population in response to antigens and V $_{H}$ gene rearrangements. In terms of response to antigens, there are three types, those responding to T-cell–dependent antigens ([205]), and those responding to T-independent antigens, which are of two types: type 1 [i.e., lipopolysaccharides ([205])], or type 2 [i.e., bacterial capsular polysaccharides ([203])]. B-cell neoplasms involving a cell with strikingly similar morphologic, phenotypic, and cytogenetic characteristics have been reported to have different anatomic localizations (splenic, nodal, and extranodal) and clinical presentations ([206] , [207]). Variations detected by mutational analysis were considered as evidence that these lymphomas originate from different subsets of marginal cells ([208]). Furthermore, the evidence that mucosal-associated lymphomas preferentially disseminate to the spleen was considered as evidence of the relationship of these cells to the splenic MZ cell ([209]).

Red Pulp On a histologic section, the red pulp consists of sinuses, which give the pulp its color, and cords ([210] , [211]). The cords are composed of a meshwork of reticular fibers and cells. The reticular cells are large and extend membranous processes into the interstices (Fig. 15.19, Fig. 15.20, and Fig. 15.21) that contact those of adjacent cells, forming cavernous spaces. The large reticular cell sheets have microfilaments that endow them with the capacity to retract and extend, thus determining the available space and regulating blood flow. These cordal spaces receive blood directly from the arterial vessels. The central artery gives off many branches and terminates in slender, straight, nonanastomosing arterioles that enter the cords of the red pulp, not the sinuses. Some of the arterioles divide into arterial capillaries that are enveloped by a sheath of phagocytic cells. These sheaths were called *ellipsoids*, but now are called *periarterial macrophage sheaths*. In the human spleen, the periarterial macrophage sheath is not well developed. As well as functioning as a major source of phagocytic cells, the periarterial macrophage sheath also may regulate blood flow. The cords have been considered to represent a unique vascular space, the flow through which is regulated by the cordal reticular cells. In addition, removal of old or damaged red cells take place in the cords. The red pulp sinuses are 35 to 40 µm in diameter and are tortuous vascular channels lined with an endothelium consisting of elongated, tapered cells arranged with their long axes parallel to that of the vessel (Fig. 15.21B, Fig. 15.21C). The endothelial cells have three distinctive morphologic features: (a) micropinocytotic vesicles, (b) loosely organized cytoplasmic filaments, and (c) tightly organized filaments along the basal side, which provide the cell with rigidity and contractility. Slitlike gaps between the endothelial cells allow the penetration of blood cells from the cordal spaces into the lumen. The slits never exceed 0.2 to 0.5 µm in width. The intraendothelial filaments run parallel to the slits and restrict their opening ([212]). They arch between adjacent ring components of the basement membrane. Although normal red blood cells are flexible and capable of passing through the slits, the presence of rigid inclusions, such as Heinz bodies, interferes with their passage. The basement membrane is not continuous but consists of a network of reticular fibers that resemble a roll of chicken wire. Fibers running circumferentially (annular fibers) are thick and are joined by thinner fibers that run longitudinally (Fig. 15.22). The network is connected to the reticulum of the cords. Some reticular cells are in close contact with the wall of the sinuses. Through the fenestrations of this network, blood cells pass from the cords to the sinuses. Adventitial cells cover the sinus wall from the cordal side. They contribute to blood flow regulation by covering or exposing the interendothelial slits.

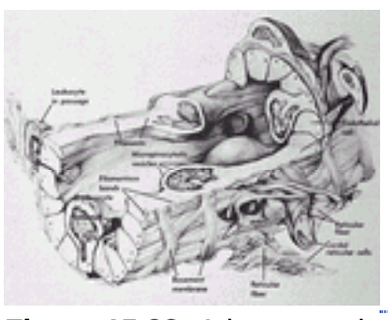

Figure 15.22. A human splenic sinus. The elongated lining cells run parallel to axis of the sinus. The vessel is supported by cordal reticular cells and fibers and a fenestrated basement membrane consisting of heavy fibrous strands running circumferentially and lighter longitudinal strands. Thus, the circular bands, like the hoops of a barrel, hold the endothelial cells (staves of the barrel) tightly. (From Weiss L. The spleen. In: Weiss L, ed. Cell and tissue biology. Baltimore: Urban and Schwarzenberg, 1988, with permission.)

The splenic circulation has been the subject of debate. According to some investigators, the circulation is closed, with endothelial continuity from the arteries to the sinuses and veins. Others believe the circulation is open—that the arteries empty their blood into the MZ and red pulp cords and the blood percolates through the cavernous spaces of the cords and finally crosses the wall of the sinuses through the interendothelial slits. According to this view, the circulation is anatomically open but is functionally closed. This question has not been resolved, but it is likely that both types of pathways exist. In keeping with this last hypothesis is the finding that the largest amount of blood passes through the spleen as rapidly as it does through other organs, whereas a smaller portion of blood has a considerably slower rate of flow.

Morphologic Changes during the Immune Response Within 24 hours of antigenic stimulation, an accumulation of polymorphonuclear leukocytes is detected in the red pulp ([186]). Large pyroninophilic blast cells are first seen 3 to 4 days later in the PALS. They then migrate toward the periphery as they mature to plasma cells. They eventually reach the cords of the red pulp and are found even within the sinuses. GCs are well developed by the end of the first week. When viewed by electron microscopy, the most immature blasts have a large nucleus, a prominent nucleolus, and an increase in the number of ribosomes, but no organized endoplasmic reticulum is evident. These blasts are known as *immunoblasts*. When they develop dilated endoplasmic reticulum, they are known as *plasmablasts*. Proplasmacytes are the next stage of maturation. These cells have abundant endoplasmic reticulum and a few remaining free ribosomes, findings that differentiate this stage of development from mature plasma cells.

Immunologic Significance of the Spleen The two most important immunologic functions of the spleen are phagocytosis and the development of the effector mechanisms of humoral and cell-mediated immunity ([213]). The labyrinthine structure of the spleen is ideal for the effective removal of invading microorganisms by phagocytes that come to reside in the spaces of the reticulum. Phagocytosis is facilitated by the coating of bacteria with complement, antibody, or both. Although the phagocytic function of the spleen is well recognized, its contribution to humoral or cell-mediated immunity in humans has generated considerable controversy ([214] , [215]). Originally, it was reported that children who underwent splenectomy for congenital hemolytic anemia had an increased incidence of overwhelming, fatal infections ([216]). Not all subsequent studies, however, yielded results that confirmed these findings. Splenectomy for hematologic disorders apparently has far more serious consequences than splenectomy for trauma. The incidence of overwhelming sepsis in the former cases is 24.8% as compared to a 1.45% incidence for the latter group ([217]). The contribution of the spleen to humoral responses in laboratory animals has been known for a long time ([218]). In humans, the loss of the spleen also compromises the immune system and its ability to form antibody ([219] , [220]). Even impaired antibody synthesis by peripheral blood lymphocytes has been detected in postsplenectomy patients ([221]). In spleenless Hox $^{-/-}$ mice, there is no major defect in antiviral immunity except for some delay in antibody response by 1 to 2 days ([222]).

LYMPHOCYTE HOMING AND RECIRCULATION

Homing to Secondary Lymphoid Organs

Migration of leukocytes across the vascular endothelium is a complex, multistep process and involves different types of endothelia for different leukocytes, as well as a variety of adhesion molecules ([223] , [224] , [225] , [226] and [227]).

When B and T lymphocytes finish their maturation in the bone marrow and thymus, respectively (primary lymphoid organs), they are still naïve—that is, they have not yet encountered antigenic stimulation. The migration patterns of naïve lymphocytes differ from those of the activated (or memory) lymphocytes. Naïve lymphocytes

enter the secondary lymphoid organs and settle in specific (T dependent and T independent) compartments (homing). Subsequently, they use the blood and lymphatic circulation as traffic routes and migrate between secondary lymphoid organs without any specific preference (recirculation). Antigen-activated or memory lymphocytes migrate specifically to sites where they have encountered antigen. Thus, memory T lymphocytes tend to accumulate in extranodal tissues where they have previously been antigenically stimulated. These lymphoid accumulations are sometimes called *tertiary lymphoid tissues* and are associated with epithelial surfaces such as the gut, respiratory tree, and sites of inflammation in skin and synovium. In some of these accumulations, however, there are also small numbers of naïve lymphocytes.

If antigen is drained to regional LNs, it triggers accumulation of antigen-specific memory T lymphocytes to these nodes. In general, two fundamentally distinct routes of entry of lymphocytes to the LN can be distinguished. The first is by crossing of the HEV, which is primarily followed by the naïve lymphocytes, and the second is by the afferent lymphatics after the lymphocytes have entered tissue spaces by crossing flat endothelium. The second route is followed by the activated T lymphocytes ([228] , [229] and [230]).

Homing of lymphocytes to secondary lymphoid organs takes place through the HEVs, which are abundant in T-cell–dependent areas of the LN, but are used as entry sites for both T and B lymphocytes ([230]). In the spleen, homing takes place through blood sinusoids in the MZ. HEVs are also found in other extranodal locations, such as PP, tonsils, adenoids of the pharynx, appendix, and other lymphocyte aggregates of the stomach and small intestine.

The best HEV marker currently available is a carbohydrate epitope recognized by the monoclonal antibody MECA-79 ([231] , [232]).

Crossing of HEV by lymphocytes involves three steps, which have been defined for interactions of all leukocytes with endothelia: (a) tethering and rolling, (b) integrin activation and arrest or tight adhesion, and (c) transendothelial migration (Fig. 15.23).

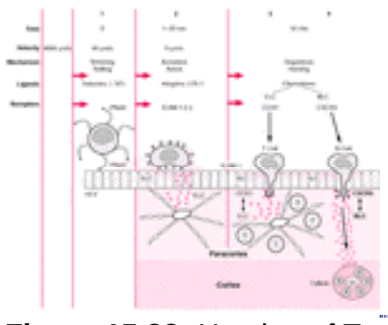

Figure 15.23. Homing of T and B lymphocytes to peripheral lymph nodes. *1.* Rolling: Lymphocytes entering the high endothelial venule (*HEV*) slow down as a result of interaction of the L-selectin (*L-SEL*) (lymphocytes) with its ligand the peripheral node addressin (*PNad*) on endothelial cells. *2*. Arrest: Secondary lymphoid tissue chemokine (*SLC*) chemokine, constitutively produced by HEV cells, activates integrin a $_{L}$ ß $_{2}$ (CD11a/CD18) and tightly adheres lymphocyte to the endothelial surface. *3*. Diapedesis: SLC (produced by HEV cells) and Epstein-Barr virus–induced molecule 1 ligand chemokine (*ELC*) (produced by dendritic cells and trancytosed to the surface) act on appropriate receptors (CCR7) and attract T (stronger) and B (weaker) cells that insinuate themselves through the endothelial cells. *4*. Home settling: Entering the node, T cells settle in the paracortex (ELC production), while B cells and a few antigenically experienced CD4 $^{+}$ T cells move on, being attracted by another chemokine, B lymphocyte chemoattractant (*BLC*) (or BCA-1), acting on both of them, expressing the receptor CXCR5 to settle in the follicles. Gc, germinal center; ICAM, intercellular adhesion molecule; INT, integrin.

TETHERING AND ROLLING Tethering is the establishment of loose and transient contacts between the lymphocyte and the endothelial cell. This adhesion is weak, and the shear forces of blood flow result in the rolling of the lymphocyte along the endothelium. Tethering to and rolling along the vascular endothelium, in this case HEV, is mediated by L-selectin (CD62L, previously known as *LECAM-1*, *MEL14*, and *LAM-1*) on lymphocytes and its counterreceptors on HEV cells. For L-selectin to mediate rolling, it must be located on the tips of the microvilli ([233] , [234]). The L-selectin mediates the primary adhesion (rolling) on HEVs of peripheral LN. However, for homing of naive lymphocytes to the secondary lymphoid organs of the gut (PP), L-selectin requires the cooperation of the integrin, a $_{4}$ ß $_{7}$, which is not required for peripheral LN homing. This integrin is important for activated T lymphocytes that lack L-selectin expression ([235]). The importance of L-selectin for lymphocyte adhesion to HEV was shown with blocking antibodies ([236]) and by gene knockout, which decreases the lymphocyte migration to LN by 99% ([237]). Rolling by L-selectin requires linkage to cytoskeletal proteins such as a-actinin, vinculin, and talin through its 11 carboxy terminal amino acids ([238]). Rolling enables leukocytes to reduce speed and thus be able to sense chemoattractants in order to activate firm adhesion. The tether bond dissociation increases exponentially as shear stress increases, but this is compensated for with an increase in the number of selectin-ligand bonds between the lymphocyte and the endothelial cell, while at the same time, the bonds are clustered and collectively resist breaking more efficiently than individually. At higher shear, the average lifetime of rolling tethers is much longer as a result of elongation of microvillous tethers. This type of kinetics stabilizes leukocyte rolling over a wide range of shear forces ([239]). It is accepted that a ligand for L-selectin needs to carry three critical structural elements: sialic acid, fucose, and sulfate. Monoclonal antibodies specific for sialyl 6-sulfo LewisX oligosaccharide stain HEV and almost completely inhibit binding of L-selectin to human HEV. Cotransfection of complementary DNAs for 6-sulfotransferase and a1?3 fucosyl transferase VII (Fuc-TVII) generates significant L-selectin binding. L-selectin, however, prefers that this ligand is sulfate at carbohydrate-6 ([240]). Antigens that carry L-selectin–binding saccharides are known as *vascular addressins*. One is known as *glycosylation cell adhesion molecule 1* or *GlyCAM1*, and is a secreted protein not found on the cell membrane, which argues against a direct function as a cell adhesion molecule. In mice deficient in the GlyCAM1 gene, lymphocyte trafficking still occurs. A second antigen is CD34, detected on endothelial cells throughout the vasculature, therefore not HEV specific. Furthermore, disruption of CD34 gene does not abolish trafficking through HEV. At the present time, the nature of the macromolecule that carries the epitope detected by the monoclonal antibody MECA79, which defines an HEV-specific carbohydrate epitope, remains elusive and is known as *peripheral node addressin* or *PNad* ([241] , [242]). Biochemical and genetic evidence infers that, for the synthesis of sulfated glycan moieties, sulfation precedes the 2?3 sialylation, which in turn would be followed by a1?3 fucosylation, required for an L-selectin ligand. With targeted deletion of FucT-VII locus, which encodes an a1?3 fucosyltransferase expressed in HEV, there is an 80 to 90% reduction of short-term lymphocyte homing. And yet, some other work suggested that although sulfate on the epitope is required for L-selectin binding, neither sialic acid ([243]) nor fucose ([244]) are directly involved in the binding.

INTEGRIN ACTIVATION AND ARREST In preparation for transendothelial migration, lymphocytes need to adhere firmly on the endothelial cells. Arrest is achieved by activation of LFA-1 (a $_{L}$ ß $_{2}$) integrin, which interacts with ICAM-1 or ICAM-2 ([245]). On resting lymphocytes, LFA-1 exists in an inactive form but within less than 1 second, it is activated by chemokines constitutively expressed on lymphoid tissues (“lymphoid chemokines”) ([246] , [247]), such as secondary lymphoid tissue chemokine (SLC, or CCL21) ([248] , [249]) and Epstein-Barr virus–induced molecule 1 ligand chemokine (ELC, or CCL19), also called *macrophage inflammatory protein-3*ß (MIP-3ß) ([250]). SLC induces arrest of naïve T cells to ICAM-1 ([251]) with sixfold higher efficiency for naïve than memory T cells ([252]). The arrest is pertussis toxin sensitive, implying that the signaling mechanism is mediated through G-proteins. The ELC shares the same binding specificity with SLC, but its role is less obvious. ELC transcripts are restricted to nonendothelial cells in the perivascular area of paracortex ([253]). However, it is brought to the luminal surface of the HEV by transcytosis and is able to participate in LFA-1 activation and arrest of the lymphocytes through the same receptor CCR7 as SLC ([254]).

TRANSENDOTHELIAL MIGRATION SLC induces strong chemotaxis for T cells and to a lesser extent on B cells ([248]). Entry of lymphocytes to the secondary lymphoid organs, especially T cells, requires the expression of CCR7, the high-affinity receptor for its ligand SLC. SLC is very important for entry of T cells into secondary lymphoid organs, as shown in mice with the plt mutation (paucity of LN T cells). These mice lack SLC, cannot enter through HEV, and the structure of the paracortical areas is severely disorganized. SLC gene in mice is located on chromosome 4 ([255]), which corresponds to human chromosome 9p13, where SLC is located. Furthermore, T cells lacking the SLC receptor (CCR7) have a markedly reduced ability to enter LNs and PPs. In CCR7-deficient mice, B-cell homing into secondary lymphoid organs is not disturbed. The arrest of B cells on HEV takes place in the absence of SLC, indicating that other chemotactic activities regulate entry of B cells into secondary LNs. Stroma cell–derived factor 1 (SDF-1) is recognized by the CXCR4 receptor, expressed on resting T and B cells. This chemokine/receptor system may also contribute to lymphocyte entry into LNs. However, this interaction is not important for T cells as CXCR4-deficient mice have normal T-cell areas. The redundancy of the mechanisms for B-cell homing explains the normal B-cell homing in plt mice, as well as on SDF-1 and CXCR4-deficient mice. Transgenic mice that do not produce SLC on the normal anatomic locations but have expression directed to pancreas under the control of the insulin promoter II, have collections of CD4 $^{+}$ and CD8 $^{+}$ cells near the center of the islets and only a few scattered B cells surrounding them ([256]). In older mice, these clusters in the islets develop stromal reticulum, seen in LNs and vascular endothelium with morphology of HEV. B cell follicular-like clusters without GCs merge with the T-cell areas. This study clearly demonstrates the important role of SLC in LN neogenesis. Once naïve lymphocytes have crossed the HEV, chemokines direct the lymphocytes for compartmental homing (i.e., T lymphocytes to the paracortex and B lymphocytes to the follicles). SLC is expressed not only on HEV, but also by stromal cells within the T-cell areas of LNs, spleen, and PPs. A second ligand for CCR7 is ELC, which is also expressed in T-cell areas. ELC is made by macrophages and the DCs of the paracortex. *In vitro* SLC and ELC attract T cells effectively, but B cells only weakly. In conclusion (Fig. 15.23), T cells cross HEV by the SLC and ELC chemokines

and their receptor CCR7. ELC attracts them to the paracortical areas. B cells cross the HEV by more than one chemokine/receptor system. However, once inside the LN, they are attracted to the follicles by chemokine BLC (CXCL13) or BCA-1 (B-cell–attracting chemokine 1, CXCL13), which binds to the receptor BLR1 (Burkitt lymphoma receptor 1) or CXCR5. The CXCR5 is expressed by mature as well as activated B cells and in addition by $CD4^+$-activated T cells. Antigen-activated $CD4^+$ T cells down-regulate CCR7 (receptor for SLC and ELC) and up-regulate CXCR5. Therefore, this $CD4^+$ T-cell subset, in contrast to naïve T cells that stay in the paracortex, travels with B cells to the follicles. This explains the early fluorescent antibody results, which detected small numbers of scattered T cells within the GC (Fig. 15.15A). They induce strong antibody responses in culture with B cells ([257]). CXCR5-deficient mice show defective follicular localization of B cells. BLC is expressed constitutively by FDC in lymphoid follicles of LNs and other secondary lymphoid organs. BLC-deficient mice show severe defects in the development of secondary lymphoid organs. Histologically, B cells do not appear organized in follicles but form a ring around the T-cell areas ([258]). The importance of BLC for organization of B cells into follicles was shown by the ectopic expression of BLC in pancreatic islets. Only B lymphocytes accumulate in these sites ([259]). Organization of primary follicles requires the network of FDCs, which in turn depends on LT $a_1ß_2$ and TNF expressed on B cells. BLC, for its action, is strongly dependent on these cytokines ([260]). In conclusion, for proper formation of follicles and localization of B lymphocytes, two ligand-receptor systems are mandatory: the TNF/LTa $_1ß_2$ ligand and its receptor LTßR, and the BLC ligand and its receptor CXCR5.

SIGNALING IN LYMPHOCYTE HOMING The Ras-homologous A protein (Rho A), a guanosine triphosphate–binding protein, is involved in the intracellular signaling for the integrin activation pathway ([261], [262]). The mechanism of coupling to the Ras/Map kinase cascade is not yet well defined. Activation of Ras leads to stimulation of a cascade of protein kinases that ultimately phosphorylate and activate mitogen-activated protein kinase. Mitogen-activated protein kinase is linked to several cellular functions such as regulation of transcription factors and cytoskeleton. Phospholipase Cß activation results in the production of inositol triphosphate and diacylglycerol. Inositol triphosphate is important in mobilizing Ca^{2+} from intracellular sources, whereas diacylglycerol is important in the activation of protein kinase C. PI3-K is also activated in response to chemokine stimulation, which links further downstream with phospholipase D activation, actin rearrangements, and vesicular trafficking ([263]). Transendothelial migration occurs rapidly, and the lymphocyte reaches the basement membrane within minutes. The cell moves toward the cell–cell junctions. Adhesive contacts with the endothelium are modulated so that the cell is not immobilized. Modulation may involve decrease of activation signals. A substance secreted by the HEV cells called *hevin* has been isolated and shown to be homologous to the extracellular matrix adhesion modulator known as *secreted protein acidic and rich cysteine* or *SPARC* ([264]). It may be a factor modulating lymphocyte transendothelial migration.

Dendritic Cell Migration

The traffic of DCs is regulated by cytokines (IL-1, TNF-a), chemokines, and ß-defensins. Immature DCs, regardless of their origin, express the chemokine receptor 6 (CCR6), which binds the chemokine MIP-3a (CCL20) ([265]). In the case of LCs ([266]), it directs them to the skin, where the ligand from CCR6 (i.e., MIP-3a) is constitutively expressed by keratinocytes, which provide the homing signals for the positioning of LCs to the suprabasal layer of epidermis. ß-defensins produced by mucosal membranes after microbial infection bind to CCR6 and thus attract immature DCs to submucosal areas ([267]).

LCs are connected physically with keratinocytes through homotypic interactions mediated by E-cadherin. Inflammatory or allergic stimuli down-regulate E-cadherin, resulting in “maturation” and detachment of LCs ([268]). CD40-CD40 ligand may also play a role for their emigration ([269]). Detached LCs downregulate CCR6 and up-regulate another chemokine receptor, CCR7, which allows the now mobile LCs to move toward the lymphatic vessels in response to its ligand, SLC ([270]). The barrier to their migration, imposed by the basement membrane of the skin (collagen IV), is brought down through the matrix metalloproteinase-9, released by LCs with specificity to collagen IV ([271]). LCs cross the abluminal side of the lymphatic vessels, probably with the involvement of P-glycoprotein, and eventually enter LNs. In the lymphatic vessels, they are known morphologically as *veiled cells* on the basis of their morphology [i.e., large lamellipodia (veils), which, like sails, propel them forward]. They enter the LN from the afferent lymphatic vessel into the subcapsular sinus to reach the T-cell areas, attracted by SLC and MIP-3ß (or ELC), both of them ligands of CCR7 receptor ([272]). In the T-cell areas, they are known as *interdigitating DCs* or *IDCs*, as their elaborate long cytoplasmic processes interdigitate between T cells. IDCs present to T-cell antigens they have captured in the periphery, initiating an immune response (see Chapter 18).

Special Homing Pathways

SKIN HOMING Memory lymphocytes tend to return to the type of tissue where they have encountered the antigen ([273]). Lymphocytes that entered the afferent lymphatics from the skin have a distinct phenotype ([274]). T lymphocytes localized in the skin express a marker called *cutaneous lymphocyte-associated antigen* (CLA), which binds to E-selectin ([275], [276]). E-selectin is induced on dermal endothelial cells in delayed type of hypersensitivity and in chronically inflamed skin ([277]). Other molecules also mediate strong adhesion of memory T cells to skin, such as a $_4ß_1$ (VLA-4) interacting with VCAM-1, and the integrin a $_3ß_1$ with the extracellular matrix component epiligrin ([278]). However, T lymphocytes may penetrate the epidermis using E-cadherin.

HOMING TO THE GUT Lymphoid cells in the gut are found in three areas: as well-organized collections known as *Peyer patches* or *PPs*, which are secondary lymphoid organs; in the lamina propria underlying the intestinal epithelium; and after penetration of the basement membrane interspersed between epithelial cells—that is, the intraepithelial lymphocytes (IELs). Naïve lymphocytes home to PPs, whereas memory cells home to extralymphoid sites—that is, the intestinal lamina propria as a result of variations in the expression of highly specialized homing receptors. The HEV of the PPs is weak for ligand of L-selectin and MAdCAM-1 ^{hi}, whereas the naïve lymphocytes are L-selectin $^+$ and a $_4ß_7{}^{lo–med}$. Therefore, neither set of molecules alone is capable of mediating tethering and rolling to initiate integrin activation, but cooperation between the two sets of molecules allows naïve lymphocytes to enter the PPs. The endothelium of the lamina propria is negative for L-selectin ligand, but strong for MAdCAM-1 expression. Naïve lymphocytes are unable to use L-selectin and, being weak in a $_4ß_7$ expression, they cannot initiate rolling and are blocked from entering the lamina propria. On the other hand, memory lymphocytes, although they lack L-selectin (and as a result cannot enter PPs), have strong a $_4ß_7$ expression and are able to initiate rolling and enter the lamina propria. Some of the lymphocytes are able to penetrate the basement membrane of the intestinal epithelium and settle between enterocytes to become IELs. IELs interact with intestinal epithelium through an integrin known as the *human mucosal lymphocyte* molecule ([279]), now shown to be the a $_Eß_7$ integrin ([280], [281]). a $_Eß_7$ is expressed in approximately 2 to 6% of blood T cells, which are a memory subset and are $CLA1^-$ and L-selectin $^-$ ([282]). The a $_Eß_7$ integrin is induced by transforming growth factor-ß ([283]). The same cytokine also is known to trigger class switch of IgM^+ B cells to IgA, which is the predominant Ig class produced by the gut lymphocytes. It is of interest that MAdCAM-1, a gut mucosal addressin, contains an IgA-like domain ([284]).

HOMING TO INFLAMMATORY SITES Lymphocytes are known to accumulate in sites of chronic inflammation and tissues with active autoimmune mechanisms. The phenotype of these lymphocytes indicates that they are activated, and therefore antigenically stimulated ([273]). Cyto-kines produced from macrophages, such as IFN-? and TNF-a, regulate lymphocyte traffic to inflammatory sites. Accumulation of lymphocytes at chronic inflammation sites involves several adhesion molecules such as LFA-1 and a $_4$ integrins, as well as E-selectin and VCAM-1. Chemoattractants, such as macrophage inflammatory protein 1ß (MIP-1ß) enhance binding of $CD8^+$ T cells ([285]), whereas RANTES attracts selectively memory T cells ([286]). The monocyte chemoattractant protein 1 (MPC-1) is a major lymphocyte chemoattractant (in addition to its strong activity on monocytes) ([245]); this explains the mixed composition of cellular infiltrates, rich in lymphocytes and monocytes, in sites of chronic and autoimmune inflammatory reactions. MCP-1 is present in abundance in areas of antigenic challenge and autoimmune diseases ([287]). The data suggest that -C-C chemokines provide the triggering signal for the integrin-dependent tight adhesion of lymphocytes to endothelia for emigration to inflammatory sites.

HOMING TO OTHER SITES Hemopoietic progenitors in bone marrow transplantation use the a $_4ß_1$-VCAM-1 set to home to bone marrow ([288]). Interaction of P-selectin with its ligand, P-selectin–dependent ligand (PSGL-1), is also implicated ([289]). Lymphocyte homing to tonsils is mediated by L-selectin and CD34 ([290]), whereas the attachment of lymphocytes to brain microvasculature is mediated by the sulfoglucuronosyl paragloboside, a ligand for L-selectin ([291]).

Significance of Lymphocyte Homing and Recirculation

It is estimated that as many as 5×10^6 lymphocytes/second leave the blood and cross HEVs in the body. The process of rolling and sticking to the HEV takes only 1 to 20 seconds and the transendothelial passage approximately 10 minutes ([292]). From *in situ* microscopic observations of PPs, the velocity of the lymphocyte before contact with HEV is approximately 4000 µm/second, and rolling effectively reduces this to approximately 40 µm/second ([235]). Thus, rolling increases the chances for firm adhesion, but at the same time the cell may escape if proper triggering for activation of integrin mechanisms fails to be initiated. Triggering mechanisms involve G-protein–linked chemoattractant receptors and their ligands, and they can bring about integrin activation within 1 to 3 seconds after contact for tight adhesion.

Homing and recirculation are not random, but the result of active interactions determined by the phenotypes of the HEV cells and the lymphocytes. Homing to specific microenvironments of the secondary lymphoid organs is developmentally determined (i.e., T dependent vs. T independent), and carried out under the guidance of chemokines and their receptors, and the cellular composition of the microenvironments (i.e., IDCs vs. FDCs) ([293]). When lymphocytes are antigenically stimulated, the pattern of migration, known as *recirculation*, is modified as a result of this experience. Antigenically specific lymphocytes are directed to particular tissues so that

they may influence more effectively the intensity of the immune response. This ultimately is the significance of lymphocyte recirculation as reflected in the difference between naïve lymphocytes and the lymphocytes that become antigenically experienced. Homing and recirculation are forms of lymphocyte differentiation. These, like many other aspects of their differentiation (i.e., IgM vs. IgG production or Tho vs. Th1 or Th2 cytokine pattern secretion), are refined in the periphery in response to antigenic stimulation so that they best meet the environmental challenges for the protection of the body. Immune responses within the secondary microenvironments ([294], [295]) as well as “tertiary” microenvironments (i.e., the areas of disease and inflammation) are all under the control of the chemokines ([296]). Knowledge of the mechanisms of chemokine regulation will allow the development of therapeutic strategies to control inflammatory diseases ([296]).

ONTOGENY

Pluripotential stem cells give rise to all hematopoietic lineages, including B and T lymphocytes. These cells undergo asymmetric division; as a result, one daughter cell follows a pathway of differentiation, whereas the other remains a self-renewing stem cell. These stem cells differentiate into various lineages depending on their interaction with the appropriate stromal cells as well as growth and differentiation factors. Stem cell differentiation is guided by the type of stromal elements to which the stem cells are exposed. Stem cells placed into the thymic microenvironment develop into T cells, whereas those in contact with bone marrow–derived stromal cells develop into B lymphocytes or myeloid cells. B-cell development and differentiation can be divided into two broad periods: the first period, from stem cell to immature immunoglobulin (Ig) M $^{+}$ B cell, is antigen independent; the second period, from immature B cell to plasma cell, is antigen dependent. The first period can be further subdivided into two stages: from stem cell to *progenitor B (pro-B)* cell, and from pro-B cell to immature Ig $^{+}$ B cell.

B-cell differentiation has been studied in animals and humans on cells obtained from different stages of development (embryonic vs. adult) as well as cells from patients with lymphoproliferative disorders, which, by some, are considered “frozen windows” of normal differentiation. This approach, however, is not accepted by all because some evidence suggests the existence of some degree of asynchronous maturation in acute leukemias, with phenotypes not found normally ([1]).

Stem Cell to Progenitor B (Pro-B) Cell

See Figure 16.1.

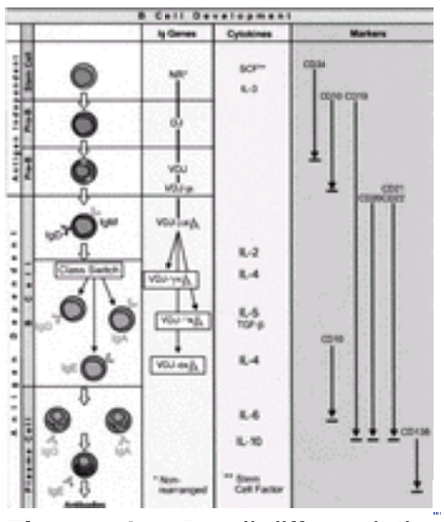

Figure 16.1. B-cell differentiation. The first stage of B-cell development takes place in the bone marrow. B-cell progenitors stimulated by direct contacts with cells of bone marrow stroma and the cytokines secreted by them differentiate by initiating rearrangements of their immunoglobulin (Ig) genes and the expression of lineage-specific antigens. This stage of differentiation is antigen-independent, and the emerging B lymphocytes develop their antigen-specific repertoire (VDJ recombinations). The second stage of their development takes place in the secondary lymphoid organs under the influence of antigenic stimulation and the interaction with several types of cells, such as dendritic cells, T cells, and the cytokines secreted by them. During this stage, depending on the nature of signals, B cells generate

plasma cells or memory cells. Antibodies of various classes are synthesized and secreted (class switch), while their affinity for antigen is increased. This is achieved by a process of “hypermutation,” which introduces new bases to DNA sequences not existing in the germ line. The backbone of differentiation over the entire pathway is the Ig gene rearrangements. Because they occur randomly, the cells in both stages are subject to selection, which secures survival of cells possessing the appropriate V(D)J configuration. IL, interleukin; TGF, transforming growth factor. (From Paraskevas F. B lymphocytes. In: Israels L, Israels E, eds. Mechanisms in hematology. With permission from Core Health Services, Inc.)

TRANSCRIPTIONAL REGULATION Hematopoiesis is a highly complex process coordinated by several genes that orchestrate through their products multiple cell interactions and the release of growth and differentiation factors ([2]). During this process, more than eight specific cell lineages arise from pluripotent stem cells. Their differentiation is guided through a well-defined hierarchical sequence to mature functional cells ([3]). Lymphopoiesis, during fetal life, takes place in the yolk sac and liver but, after birth, like the rest of definitive hematopoiesis, takes place in the bone marrow ([4]). “Master” genes regulate differentiation of lineages through transcription factors, which activate target genes, progressively narrowing their differentiation potential to specific lineages ([3]). Several genes coordinate the various stages of lymphocytic development ([5]). The transcription factor PU.1 of the Ets family is identical to the Spi-1/Sfpi1 protooncogene expressed mainly in monocytes, macrophages, and B lymphocytes. Lack of PU.1 gene function in mice affects the development of B lymphocytes, monocytes, and neutrophils, and the animals die before birth ([6]). Myeloid and lymphoid lineages come from a common progenitor, but it is difficult to define precisely the point of commitment for lymphocytic differentiation. Mice mutant for PU.1 have no evidence of initiation of lymphopoiesis [i.e., no B220 $^{+}$ cells (marker specific for B cells) in the liver and no transcripts of IgH, ?, *recombination activating gene* (RAG)-1, or RAG-2 genes]. Normal development of lymphopoiesis depends on the Ikaros family of transcription factors, which selectively regulate lymphocytic development. *Ikaros* is a zinc finger factor expressed in B and T cells at different stages of differentiation (except plasma cells) ([7]). Ikaros generates eight protein isoforms by alternative splicing, and some of them bind through an *N*-terminal zinc finger motif to DNA sequences that contain GGGA core motifs ([8] , [9]). Ikaros $^{-/-}$ mice have a complete block of B-cell differentiation ([10]), with lack of pro-B and precursor B cells (pre-B cells) in fetal liver or bone marrow. Ikaros is localized in the nucleus of most primitive hematopoietic stem cell subsets, particularly at two stages: (a) in long-term self-renewing stem cells and (b) in non–self-renewing multipotent progenitors able to differentiate into lymphoid-committed progenitors ([11]). The isoforms detected in hematopoietic stem cells differ from those detected in lymphoid progenitors, but all of them share two *C*-terminal zinc fingers that mediate their self-association, forming multiple heteromeric complexes. Other members of the Ikaros family (i.e., Aiolos and Helios) encode transcription factors that form multimeric complexes with Ikaros ([12]). The Ikaros gene is required not only for early stages of lymphocytic differentiation but also for late stages, especially in T-cell maturation ([13]). Another important gene for lymphoid development is Pax5. Multiple isoforms are generated by alternative splicing, and one of them is the B-lineage–specific activator protein (BSAP) ([14]). BSAP activity is detected in all stages of B-cell development except plasma cells. A complementary DNA (cDNA) of BSAP encodes an *N*-terminal–paired domain, an octapeptide conserved among Pax genes, and a partial homeodomain. The paired domain is necessary for DNA binding. The target genes for BSAP are CD19 ([15]), VpreB1, and ?5 ([16]) and several intronic sites of C $_{H}$ gene. In the bone marrow of homozygous mutant mice, the B220 $^{+}$ IgM $^{+}$ cells are selectively reduced to less than 1% of normal, and development of B1 and B2 lineages is severely compromised. Pax5 is needed for VDJ heavy chain Ig gene rearrangements, and the precise block is after the first DJ $_{H}$ rearrangement ([17]). As a result, Pax5 mutation does not block recombinase induction per se and allows a significant pro-B-cell population to be formed. The target for BSAP is the adaptor protein BLNK (*B*-cell *l*i *nk*er protein) (SLP-65), which acts as scaffolding in linking Syk tyrosine kinase with downstream signaling proteins [i.e., PLC? $_{2}$, Bruton tyrosine kinase (Btk), and so forth] ([18]). BSAP regulates the BLNK gene by binding to its proximal promoter region. BLNK expression is a checkpoint in the pro-B to pre-B transition and mediates the constitutive signaling of the pre-B-cell receptor (pre-BCR) in cell proliferation, growth factor responsiveness, and V(D)J recombination. BSAP also diverts differentiation of a common myeloid/lymphoid progenitor to lymphocytic differentiation as a result of its ability to suppress the response of the progenitor to myeloid growth factors ([19]). This was shown by expression of BSAP ectopically in stem cells. The E2A gene is highly important for lymphocytic differentiation. The E2A gene encodes two proteins—E12 and E47 of the basic helix-loop-helix family—by differential splicing. The proteins encoded by E2A bind to DNA as a homodimer, uniquely in B cells ([20] , [21]), and are essential for coordination of Ig gene rearrangements ([22]); therefore, in their absence, B-cell differentiation is blocked before entrance into the pro-B-cell stage. The basic region mediates DNA binding, whereas the HLH domain is required for protein dimerization. The target genes for E12 are the early B-cell factor (EBF) and Pax5 ([23]). E12 acts on a progenitor cell directing differentiation along B lineage while blocking myeloid differentiation. The EBF is a transcription factor essential for early B-lymphocyte development in regulation of the expression of Iga (mb-1) and Igß (B29) co-receptors. The EBF-deficient mice lack Iga and Igß transcripts in pro-B cells ([24]), and isolated human EBF factor has been shown to bind to Iga and Igß promoters ([25]). Combined E2A and EBF mutations arrest B-cell development at a stage earlier than that of Pax5, because recombinase expression is blocked, and there is no expression of pre-BCR genes, ?5, and VpreB and, consequently, no formation of the pre-BCR ([26] , [27]). The three transcription factors Pax5, E2A, and EBF form a cross-regulatory network. E2A is essential for Pax5 expression and normal expression of EBF. On the other hand, EBF is needed for Pax5 expression, as well as the expression of the E47 product of the E2A gene, which is the most potent for B-cell regulation. Collectively, gene targets of the Ikaros, E2A, PU.1, EBF, and Pax5 transcription factors, regulate stages of B-cell differentiation before the expression of Ig genes. Lately, it has been shown that the E2A gene plays a central role in some aspects of B lymphopoiesis in subsequent stages ([28]). In mice, E2A proteins are required for the interleukin (IL)-7–dependent expansion of pro-B cells and their progression to the pre-B-cell stage and, even later, for the regulation of rearrangements of the Ig? genes and heavy chain isotype switching.

CELL INTERACTIONS IN EARLY B-CELL DEVELOPMENT Study of B-cell differentiation has become feasible with the development of long-term bone marrow culture techniques ([29]). This approach has helped to define the cells that are essential for the development of B cells and the factors that support B-cell growth and differentiation. It has been understood that the bone marrow stroma makes a critical contribution to hematopoietic differentiation. The term *stroma* (Greek for *mattress*) is used in a collective sense to include a variety of cells, such as adventitial reticular cells, adipocytes, fibroblasts, and endothelial cells of the sinuses ([30] , [31]). The stroma also includes extracellular matrix, composed of various fibrous proteins, glycoproteins (gps), and heparan sulfate, effective in binding cytokines. Granulocyte-macrophage colony-stimulating factor can bind to marrow stromal glycosaminoglycans and be presented to hematopoietic stem cells. Stromal cells have been isolated from adult bone marrow ([32]) or fetal bone marrow after removal of adherent cells (i.e., macrophages, endothelial cells). These cells have the morphology of an adventitial/reticular/fibroblast cell, which expresses several adhesion molecules ([33] , [34]). They support, in cultures, differentiation of fetal bone marrow cells (CD34 $^{+}$, CD19 $^{-}$) ([35]) toward B-cell lineage (i.e., with loss of CD34 and acquisition of CD19 and the VpreB protein). Several adhesion molecules have been implicated in the mediation of interaction between B-cell progenitors and stromal cells; critical among them are vascular cell adhesion molecule-1 (VCAM-1) on stromal cells and very late antigen-4 (VLA-4) on B-cell progenitors ([34] , [36] , [37] and [38]). CD34 is expressed not only on stem cells ([39]), but also on stromal cell precursors ([40]) and endothelial cells ([41] , [42]), thus mediating their interactions with its counter-receptor, L-selectin ([43]), expressed on progenitor cells. Among cytokines that could mediate growth and differentiation of lymphocytes in the bone marrow, IL-7 attracted attention because it was shown in experiments in mice that it plays a critical role in B-cell development ([44] , [45] and [46]). For human lymphocytes, however, although IL-7 transduces signals, it is not essential for B-cell differentiation ([47]). One might expect that deficiency of IL-7 or IL-7R should block B-cell differentiation in mice at the same stage. This, however, is not the case, because IL-7R deficiency blocks differentiation at a point of differentiation just before the pro-B cell, when the DJ $_{H}$ recombination has not yet taken place and the cell has the CD19 $^{-}$B220 $^{+}$ phenotype. IL-7 deficiency acts a step later, that is, between the pro-B and the pre-B cell ([48]). B220 is a murine B-cell–specific marker, which is one of the CD45R isoforms. In mice lacking IL-7R, the recombination process comes to a halt, because the IL-7R normally targets V $_{H}$ segments to the recombinase complex; furthermore, Pax5, which normally stimulates recombination, is silenced ([49]). Although the block of IL-7 deficiency is after the pro-B cells, these cells have certain abnormalities, such as failure to up-regulate terminal deoxynucleotidyl transferase (TdT) and the high-affinity IL-7R a-chain ([50]). The net result of IL-7 deficiency is the lack of expression of µ-chain and the pre-BCR—events that normally promote the advancement from pro-B-cell to pre-B-cell stage. The stimulation of proliferation and µ-chain expression follows distinct signaling pathways, because mutation Y449F in the cytoplasmic region of IL-7Ra abrogates proliferation induced by IL-7, but it does not block µ-chain expression ([51]). A cytokine isolated from thymic stroma, thymic stroma lymphopoietin (TSLP), binds to the IL-7Ra receptor, and it is likely that, in the absence of IL-7, thymic stroma lymphopoietin binds to IL-7R and promotes continuation of B-cell differentiation in the absence of IL-7, with development of IgM $^{+}$ B cells from IgM $^{-}$ precursors ([52]). Support for the experiments, which demonstrated the lack of an essential role for IL-7 in human B-cell development, was also provided from one of nature's experiments. The human X-linked severe combined immunodeficiency (X-SCID) is due to mutations of the ?c-chain, a common subunit for several cytokine receptors (i.e., IL-2, IL-4, IL-7, IL-9, and IL-15). Patients with X-linked SCID lack T and natural killer (NK) cells but have normal or even elevated B cells ([53]). Likewise, patients with mutations of the IL-7Ra chain have normal numbers of B cells ([54]). Although IL-7 is not essential for human B-cell development, it nevertheless exerts some changes in gene expression, especially in concert with other growth factors or stromal cells ([55]). It synergizes with flt-3 ligand and induces strong expansion of fetal B cells *in vitro* ([56]). Furthermore, IL-7R has been detected on human B-cell progenitors, which lack expression of CD19 and have a pro-B-cell phenotype as well as clonogenic capacity ([57]). These cells are also CD34 $^{+}$, have messenger RNAs (mRNAs) for Igß, RAG-1, and Pax5, and are TdT $^{+}$. In addition, IL-7Ra $^{-}$/CD19 $^{-}$/CD34 $^{+}$ cells do not differentiate in short-term cultures into pro-B cells. Therefore, IL-7Ra expression defines an entry into a stage characterized by up-regulation of multiple B lymphoid–associated markers. A number of reports have shown that B lymphocytes arise from progenitors common to B cells and myeloid cells ([58] , [59]). Single adult human CD34 $^{+}$/Lin $^{-}$/CD38 $^{-}$ cells in culture over a murine fetal liver adherent cell line (AFT024) supplied with IL-7, flt-3 ligand, and IL-3 differentiate into B cells, NK cells, myeloid cells, and dendritic cells ([58]). Another pluripotent stem cell isolated from cord blood with the CD34 $^{+}$/CD38 $^{-}$/CD7 $^{+}$ phenotype differentiates *in vitro* into B cells, NK cells, and dendritic cells but is devoid of myeloid or erythroid potential ([59]). Because of variation in the external microenvironments used in all these reports, it is difficult to define the pathway for B-lineage commitment, from early multilineage

progenitors, to the pro-B-cell stage, which expresses D $_H$ Ig gene rearrangement. Expression of the CXCR4 chemokine receptor has been detected in CD34 $^+$ hematopoietic progenitors ([60]), and a cell committed to B-cell development was positive for the chemo-kine receptor CXCR4 (being the fourth chemokine receptor to be cloned) ([61]). The ligand for CXCR4 is the stromal cell–derived factor-1/pre-B-cell growth-stimulating factor (SDF-1/PBSF) ([62]). CXCR4, also known as *fusin*, together with CCR5, acts as a co-receptor for human immunodeficiency virus (HIV) to infect host cells, and SDF-1 blocks the entry of HIV to T cells ([61]). CD34 $^+$, CXCR4 $^-$ bone marrow cells can generate myeloid and lymphoid progenitors, but the CD34 $^+$, CXCR $^+$ cells, although they lack myeloid, erythroid, megakaryocytic, and mixed colony-forming potential, give rise to B- and T-lymphoid progenitors ([61]). CXCR4 is expressed earlier than IL-7R and TdT; therefore, it defines a B-lineage–committed progenitor better and more accurately than other commonly used markers.

Pro-B Cell to Immunoglobulin + B Cell

Molecular definition of the stages of early B-cell development started with the demonstration of cells that display in the cytoplasm µH-chains without L-chains and no mature IgM molecules on the cell surface. These cells were called *pre-B cells* ([63]). Further definition followed two different avenues: phenotypic markers or Ig gene rearrangement status ([64]). Single cell polymerase chain reaction analysis allowed, however, the stages of B-cell development to be ordered better by the sequence of the Ig gene rearrangements than by phenotype.

Ig gene rearrangements are the most important indication of B-lineage commitment and the transition from stem cells to the pro-B-cell stage (Fig. 16.1). With the continuation of Ig gene rearrangements, the pro-B cell becomes a pre-B cell, which, sometimes, is divided into pre-BI and pre-BII stages. When the Ig gene rearrangements reach their final stage and IgM is expressed on the cell surface, differentiation reaches the end of the first period (i.e., the immature B lymphocyte). During the pro-B-cell and pre-B-cell stages, three sets of genes prepare for the expression of the complete Ig molecule on the B-cell surface. One set includes RAG-1 and RAG-2, the second set the *surrogate light chain (SLC)* genes, composed of the products of the two genes VpreB and ?5, and the third set consists of the genes CD79a (mb1) and CD79b (B29). Their products, Iga and Igß, respectively, form the co-receptor, which supports the expression of IgM on the surface of the B cell. Throughout these stages, the expression of IgM, as well as B-cell-receptor repertoire and allelic exclusion (i.e., expression of only one of the two alleles), become possible.

Rearrangements of the Ig genes start with the joining of a D to J $_H$ segment in the pro-B cells. Pro-B cells proliferate in contact with stromal elements and express the SLC linked to a gp30 protein, which is sometimes referred to as *surrogate heavy chain*, to form the pro-B-cell receptor ([65], [66] and [67]). Expression of SLC is easily detected on mouse ([68]) but more difficult to detect on human pro-B cells ([66], [67]). The SLC consists of two non–covalently associated proteins, VpreB and ?5 (Fig. 16.2), encoded by genes located on chromosome 22, where the ?-chain genes are also located ([69], [70]). There is only one VpreB gene in humans.

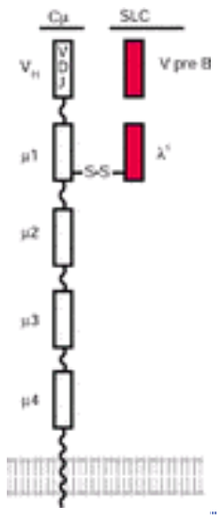

Figure 16.2. The hypothetical structure of the pre-B cell receptor. The pre-B cell receptor is composed of the µ chain and a surrogate light chain that consists of two components, the ? ^{5} and the VpreB. The µ chain is linked by disulfide bond to the ? ^{5} component, whereas the VpreB is non-covalently attached. It is not yet clear whether surrogate light chain can be expressed on the surface without µ chain.

VpreB and ?5 have several unusual features that distinguish them from conventional light chains. Both have atypical sequences that target them to the endoplasmic reticulum (ER) ([71]). The VpreB is composed of 102 amino acids with homology to a conventional V domain. However, the conventional V domain has a total of nine ß strands, including a sequence encoded by a J segment. VpreB has no sequence similar to the J segment and is shorter by one strand—the ß $_7$ strand. The *C*-terminal portion of VpreB has no homology to any other known protein. The *N*-terminal end of the ?5 protein is unique with only marginal sequence homologies to conventional domains. The *C*-terminal end of ?5 has an Ig-like fold, homologous to the conventional ?-chain C domain. This is followed by a sequence with marginal homology to the Ig structures and an extra ß strand homologous to the J region of the conventional V? domains. The unique regions of the VpreB and ?5-chains do not contribute to the assembly of the SLC, which is mediated by the extra ß $_7$ strand of ?5, because deletion of this strand abolishes formation of SLC ([71]). The unique region of the ?5-chain, however, acts as an intramolecular chaperon by preventing the folding of the protein when it is expressed in the absence of VpreB. This extra ß strand complements the missing VpreB ß strand. Thus, it appears that the Ig domains in each protein split between the two of them the control of the folding and the assembly of SLC ([71]). The assembled SLC associates with the µ-chain to form the pre-BCR. In the meantime, the C $_{H1}$ domain of the µH-chain is protected from improper folding by the hsp70 protein BiP, which retains the µH-chain in the ER ([72]). Protection from improper folding of C $_{H1}$ is taken over by the C?5 protein as long as it is associated with the VpreB as SLC ([73]). SLC escorts the µH-chain to the surface of the cell. However, not all µH-chains can pair with the SLC because some V segments have structural features that prevent their association. At this point, the RAG-1, RAG, and TdT genes are turned off, securing allelic exclusion ([74]).

In the pre-BCR, the ?5-chain represents the equivalent of the C domain of the conventional L-chain of BCR, a reasonable assumption considering that ?5 has 85% homology with the C? domain. The VpreB, on the other hand, is the equivalent to the V $_L$ domain ([75]).

SLC is linked to µ $_H$-chain through the first constant domain (Cµ1) by a disulfide bond ([76]). The role of the SLC in the formation of the pre-BCR is dual. The C domain of ?5 protein interacts with Cµ1 (which was bound by BiP). The second interaction involves VpreB (and part of ?5) with the V $_H$ domain of the µ $_H$-chain ([77]). This interaction is likely to be the first step in the selection of the B-cell repertoire ([76]). The pre-BCR in contact with unknown ligand on stromal cells induces asymmetric divisions of pre-B cells ([78]). One of the two cells retains contact with stroma and continues to divide (large pre-BI cell), whereas the second cell loses contact and differentiates to pre-BII-cell stage (small cells).

With the pre-B cell ceasing to divide, the rearrangement machinery is turned on again. L-chain genes start to rearrange; if the rearrangement is productive, an L-chain is synthesized to form a complete IgM molecule, expressed on the cell surface. This marks the transition to the immature B-cell stage. The strong proliferative capacity of the pre-B cells was analyzed in Pax5 $^{-/-}$ mice. Pre-B cells from these animals have an extensive renewal capacity, multipotency, and ability to reconstitute recipient animals with lymphoid and myeloid lineages ([79]). Signaling is transmitted by the Iga/Igß partners of the pre-BCR, which is linked to several protein tyrosine kinases [i.e., Syk, lyn, BLNK, and phosphoinositide 3-kinase (PI3K)] ([80]). Ligand binding causes aggregation of the pre-BCR, resulting in endocytosis of pre-BCR, loss of cell-surface expression, and accumulation of pre-BCR within membrane lipid microdomains.

From its location in lipid rafts, the pre-BCR initiates signaling, which achieves two important outcomes for the subsequent fate of the differentiating B cell: (a) it activates MAP kinases to block apoptosis usually triggered by the engagement of CD24 ([81]); and (b) it down-regulates RAG-1/RAG-2 expression to turn V(D)J recombination off so that the second µH allele closes ([75]) and allelic exclusion is accomplished ([82]).

The RAG-1/RAG-2 proteins are still expressed at the active proliferating pre-BI stage but are silenced during the quiescent pre-BII stage. Because the cell has achieved its objectives (i.e., survival and allelic exclusion), it reactivates the V(D)J recombination machinery to allow rearrangements of the conventional ?/?-chains,

to be able to form the complete IgM molecule, and to enter the immature B-cell stage.

The nontranscribed allele is in close association with heterochromatin and the transcription factor Ikaros, both markers of transcriptionally silent genes ([83], [84]). The importance of pre-BCR signaling for progression from pro-B-cell to pre-B-cell stages and beyond is emphasized by deficiencies of any component of the pre-BCR or downstream signaling molecules that block developmental progression of B cells at the pro-B or pre-B stage ([85]). Targeting the genes for VpreB ([86]), ?5 ([87]), or the exons of the µ-chain ([88]) blocks B-cell differentiation at the pro-B- to pre-B-cell stage in mice, although the VpreB expression in ?5-deficient mice is normal ([89]). An 11-year-old boy with ?5 deficiency had virtually no B cells and was agammaglobulinemic ([90]).

The proteins of the SLC are not detected on the surface or in the cytoplasm of the majority of B cells in the bone marrow or circulation, except in a subpopulation of self-reactive B cells found in germinal centers ([91]) and circulation ([92]). VpreB $^{+}$ B cells with RAG mRNA have also been described in normal human tonsils and the joints of patients with rheumatoid arthritis ([93], [94]). It seems that SLC is perhaps produced intermittently during B-cell differentiation.

In conclusion, the pre-BCR plays a major role in the expansion of pre-B cells, allelic exclusion, and repertoire selection.

IMMUNOGLOBULIN GENES

Among the first successes of recombinant DNA investigation was the characterization of the Ig genes. They exist in three loci—one each for the heavy, ?-, and ?-chains. For human Ig, these loci are located on chromosomes 14 ([95]), 2 ([96]), and 22 ([97], [98]), respectively. Separate genes encode the V and C domains of the Ig molecule. The human heavy chain genes are not completely linked. The Cµ gene is closest to the V-D-J segments. At the 3' end of the H-chain locus, there are two copies of a ?-?-e-a unit (Fig. 16.3). One of the duplicated e sequences is a pseudogene (?e) in which the C $_{H1}$ and C $_{H2}$ domains have been deleted. The genome contains a third closely homologous e-related sequence: a “processed” pseudogene found on chromosome 9. These kinds of pseudogenes probably are products of a reverse transcription from RNA and then are inserted at locations in the genome unrelated to the original locus.

Figure 16.3. Human immunoglobulin heavy chain gene locus. The heavy chain gene locus contains the µ and ? genes close to the J $_{H}$ genes, whereas the remaining heavy chain genes are further downstream in two clusters from duplications. See text.

A ?-related pseudogene lacking the switch region is present between the two ?-?-e-a duplications. The recombination events occur in a region on the 5' side of the C $_{H}$ coding sequences. This region contains repetitive DNA sequences and has been known as the *switch region* (S) or *sequence*. Within the switch regions occur the recombination breakpoints during isotype switch (see Chapter 18). Usually, the stimuli for switch recombination, like IL-4 and CD40, promote transcription across the S regions to produce switch junctions, one of which is retained in the chromosome and the other is found in a circular DNA (see Chapter 18).

V $_{H}$-D-J $_{H}$ GENES

The heavy chain of the IgM molecule is encoded by four sets of DNA: *variable (V $_{H}$)* , *diversity (D)*, *joining (J $_{H}$)* , and the *constant (Cµ) genes*.

V $_{H}$ Genes

A V $_{H}$ gene encodes the first 95 or 96 amino acids of a V domain. The exact number of V $_{H}$ genes is not known but is estimated to be 100 to 200. From the available V $_{H}$ genes, only a portion of them are functional, and an even smaller portion is available for rearrangement ([99], [100]). The V $_{H}$ genes constitute seven families based on their homology at the DNA level and are known as *V $_{H}$ I* to *V $_{H}$ VII*. The number of members in each family varies, the smallest being V $_{H}$IV-V $_{H}$VI. Most V $_{H}$ genes are polymorphic, but the degree of variation varies, usually being small ([101]). The V $_{H}$ segment encodes the hydrophobic leader sequence, the three framework regions, and the two *complementarity-determining regions (CDR)*. Diversity varies among the families.

D Genes

The term *D gene* or *segment* was proposed to indicate the “diversity” of an antibody at positions after amino acid 99 to the beginning of the J segment ([102]). This sequence spans the third CDR. The D segments are located in chromosome band 14q32, with the major locus between V $_{H}$ and J $_{H}$ loci and several D segments interspersed within the V $_{H}$ segments. The segments are sandwiched between signal sequences (see below).

The CDR3 is encoded by the 3' end of the V $_{H}$ segment, the D gene segment, and the D-J $_{H}$ junctional area. There are approximately 30 D segments grouped in seven families. The D segment spans approximately 70 kb. Each segment has a promoter on its 5' end and allows initiation of transcription when Ig genes at the pre-B-cell stage start rearrangements. The first rearrangement produces a DJ $_{H}$ complex, which, together with the µ gene, encodes a protein known as *Dµ protein*.

J $_{H}$ Genes

There are six functional J $_{H}$ genes and three pseudogenes. The J $_{H}$ gene encodes the 3' end of CDR3 and the fourth framework region.

V(D)J Recombination

FORMATION OF CODING AND SIGNAL JOINTS Immediately next to the V, D, and J genes are conserved sequences of seven nucleotides (heptamers), which are attached to the 3' side of the V segments, the 5' side of the J segments, and both sides of the D segments (Fig. 16.4). The heptamer is followed by 12 or 23 nonconserved base pairs (bp) (spacers) followed by another sequence of nine bp (nonamer), which may diverge from the consensus sequence. This noncoding sequence is known as *recombination signal sequence* (RSS) and, in its consensus form, is as follows: 5'-coding sequence–CACAGTG–12 or 23 spacer–ACAAAAACC-3. The 12-bp spacer corresponds to one turn of the DNA a helix, whereas the 23-bp spacer corresponds to two turns. This way, the recombining segments are juxtaposed on the same side of the DNA helix, so that they can be recognized by the enzymes of the recombination machinery ([103], [104] and [105]). Joining of the various segments is limited between an RSS with a 12-bp spacer and one with 23 bp ([106]) (the 12/23 rule). Recombination follows strictly the 12/23 rule of spacers, which prevents inappropriate recombination (i.e., a V $_{H}$ segment joining directly to a J $_{H}$ segment, as both of them have a 23 spacer between their heptamers and nonamers) ([106]). The pattern of the RSS at each locus is uniform. For example, in the Ig locus, all V $_{k}$ segments have next to their heptamers a 12-bp spacer, whereas all J $_{k}$ segments have a 23-bp spacer. This prevents accidental joining of two V $_{k}$ or J $_{k}$ segments. The RSSs are the only sequences that are required for recombination, whereas the coding sequences (V, D, or J) can be replaced by other DNA, and joining still occurs if the 12/23 rule is satisfied.

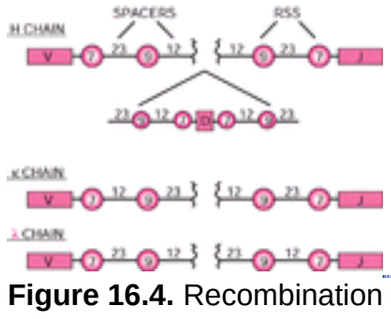

Figure 16.4. Recombination signal sequences (*RSS*) and heptamer/nonamer spacing sequences. The coding sequences of the immunoglobulin genes are flanked by a 7-nucleotide sequence (heptamer), which is followed by either 12 or 23 nucleotides, which in turn are followed by a 9-nucleotide sequence (nonamer) and again by

a 23- or 12-nucleotide spacer. This order allows rearrangements only between a segment in which the 7/9 sequences are separated by a 12mer spacer and another segment in which they are separated by a 23mer spacer. This is known as the *12/23 rule*.

During recombination, two new structures are formed: the joining of the coding sequences (*coding joint*), which is imprecise, and the joining of the RSS (*signal joint*), which is precise. The V(D)J recombination (Fig. 16.5) is mediated by two enzymes known as *RAG proteins*. RAG-1 and RAG-2 are not related to other proteins, and RAG-2 has no known relatives. Their expression is normally limited to immature B and T cells and continues after the expression of surface antigen receptor but then ceases when the receptor is cross-linked. Deficiency of RAG proteins in mice ([107], [108]) or humans ([109]) results in SCID.

Figure 16.5. V(D)J recombination. Shown in this figure is the recombination of two hypothetical segments, D27 and J5. The recombination begins with recombination activating gene-1 (RAG-1) and RAG-2 recognizing the heptamers and monamers (see text) (**Panel 1**). They cut out one strand at the junction between the heptamer and the coding sequence. The other strand is severed by a nucleophile attack from the cut end (**Panel 2**). The two blunt ends of the heptamers form the signal joint (**Panel 3**), while a hairpin seals the cut coding ends (**Panel 4**). Hairpin is nicked open either by the RAG proteins or by a ubiquitous DNA double strand repair complex (**Panels 5 and 6**). The opening is usually asymmetric and creates “overhangs,” with the nucleotides at the end of the “overhang” being complementary as they derive from the complementary opposite strand. These are known as “palindromic” (*P*) nucleotides (**Panels 5 and 6**) (from the Greek *palindromicos*, meaning moving forward and backward in succession). The double DNA strand breaks of the coding joint receive nucleotides from the function of TdT (non–germ-line nucleotides) known as *N-nucleotides* (**Panel 7**). Improperly paired nucleotides are removed (**Panel 8**), and the coding joint is completed with the addition of missing nucleotides (**Panel 9**). The P and N nucleotides added to the coding joint constitute the junctional diversity. (From Paraskevas F. The immunoglobulin molecule. In: Israels L, Israels E, eds. Mechanisms in hematology. With permission from Core Health Services, Inc.)

The RAG-1/RAG-2 proteins, as a tetramer, initiate the V(D)J recombination, which proceeds in three steps ([110], [111], [112] and [113]). The RAG-1 binds to the nonamer, which acts as an “anchoring” platform while the heptamer stabilizes the complex in the presence of RAG-2. The recognition by RAG proteins of the RSS is assisted by sequence-nonspecific DNA bending proteins, HMG1/2 (high motility group), which enhance binding and cleavage ([114]). Originally, it was postulated that HMG proteins “bend” the DNA to bring heptamer and nonamer closer together for binding. However, RAG itself also is able to bend the DNA (approximately 60 degrees); thus, HMG proteins probably maintain this position, functioning like a clamp ([115]). HMG proteins do not bind specific DNA sequences but recognize unusual structures like DNA bends. During the first step of V(D)J recombination, the RSSs are recognized by the recombinase and are brought in juxtaposition, forming the synaptic complex or paired complex. In the second step, the “recombinase” nicks the phosphoester bond between the last nucleotide of the coding sequence and the first nucleotide of the RSS (Fig. 16.5, panel 1). The precise mechanism of the hydrolysis of the phosphate ester bond is not known. The nicking reaction requires the physiologic divalent cation Mg^{2+}. Cleavage leaves blunt phosphorylated signal ends and hairpin sealed coding ends (Fig. 16.5, panels 2 and 3). The hairpin in the coding ends is formed between the 3'-OH of the top strand and the central phosphor atom of the phosphate group on the lower strand. Formation of the hairpin requires significant bending of one or both DNA strands (Fig. 16.5, panel 4). In the third step, the hairpin must be nicked open, so that the two coding ends form the coding joint. Opening of the hairpin may be done by a DNA repair complex ([116]) or RAG proteins themselves ([117]). Because nicking may not be exactly in the center of the hairpin, the opening creates an overhang in one strand formed by the nucleotides from the other strand (Fig. 16.5, panels 5 and 6). These are known as *P-nucleotides* and are coming from the opposite or complementary end of the hairpin or palindrome [from the Greek *palindromic*, meaning movement forward and backward successively (i.e., the piston of an engine)] ([118]). As a result, they have an inverse complementary relationship with the adjacent coding end. Most of the coding ends detected in normal lymphoid precursors have 3' overhangs ([119]). TdT adds nucleotides known as *N-nucleotides* (non–germ line) to the strand with the missing nucleotides (Fig. 16.5, panels 7 and 8). Disruption of TdT drastically lowers junctional insertions. In fetal and neonatal periods, the N insertions are low or absent as a result of the developmental regulation of TdT. TdT knock-out mice are not significantly immunodeficient, but their repertoire, even as adults, is similar to that of normal newborn mice, which lack N-nucleotides ([120]). The alterations in the coding joint as a result of P- and N-nucleotides are the basis for “ *junctional diversity*” (Fig. 16.5, panel 9). The RAG proteins continue to be bound to the signal and coding ends in a four-end complex, known as *cleaved signal complex*, at least while the coding ends are still processed. The repair of the DNA cleavage involves the machinery for double-strand break repair ([121], [122] and [123]). A DNA-dependent protein kinase (DNA-PK) (Ku86, Ku70 complex), XRCC4, and DNA ligase 4 (Lig4) are essential for efficient V(D)J recombination and double-strand break repair. Mice with defects in this complex normally join signal sequences but not coding segments ([124]). The DNA-PK consists of a catalytic subunit ($DNA\text{-}PK_{CS}$) and a DNA-binding component called *Ku*, which is a heterodimer of 70-kd and 86-kd polypeptides. The kinase activity is activated when Ku binds to altered DNA structures such as double-stranded breaks, nicks, and hairpin loops ([125]). Once activated, the kinase phosphorylates a number of proteins, including p53, Ku, Lsp90, transcription factors, and so forth. In Ku86-deficient mice, the V(D)J recombination is arrested after the cleavage step. Ku86 probably disassembles DNA-protein complexes containing broken ends to allow further processing ([126]). The RSSs are highly conserved among vertebrates from sharks to humans. In the RSS, the three heptamer nucleotides closest to the recombination site are the most important, whereas mutations at other heptamer positions still allow recombination. RSS variations may influence the use of gene segments. For example, the RSSs of mouse Ig? are closer to the consensus sequence than those of Ig?; this possibly explains the greater use of Ig? than Ig? chains in mouse Igs.

DNA DOUBLE-STRAND BREAK REPAIR At the end of the recombination, the coding segments remain in the chromosome, and the signal joint forms a circular DNA ([123]). The RSS joint is assumed to be lost from the cells, converted to reactive, broken DNA, to be disposed of in the next cell division: This is known as *deletional recombination*. However, the existence of inverted segments of DNA in these loci indicates that, sometimes, signal joints are retained in the chromosome: This is known as *invertional recombination*. This mechanism restores chromosomal integrity ([127]). The fate of the signal joint has taken an unexpected direction as a result of findings indicating that the RAG proteins may be able to perform genetic transposition (i.e., act as transposases) ([128], [129] and [130]). As the name indicates, *transposases* transpose or insert pieces of DNA in a new location. The transposase MuA of the bacterio-phage Mu is the best characterized of these types of enzymes ([131]). It consists of a tetramer in which two of the subunits nick the two ends of the Mu genome and the other two catalyze the transfer of the ends into the target DNA. These reactions are important in the transmission of drug resistance among bacteria and integration of retroviruses, like HIV and so forth, into the genome. In fact, the MuA active site exhibits a striking similarity to the HIV integrase. It is interesting that the RAG-1/2 also act as a tetramer in V(D)J recombination. RAG-1/2 resembles the HIV integrase responsible for inserting DNA copies of the viral genome into the cellular chromosomes. Notable differences, however, exist in the nick cleavage mechanisms between the two ([132], [133]). As a result of these recent insights into the nature of V(D)J recombination and the function of RAG-1/2, the question of the fate of the signal joint becomes very important. Signal joints have been found to be cleaved quite efficiently ([134]). *In vitro* experiments showed that transposition is targeted not to a particular DNA sequence, but to structural features, such as hairpins, inverted repeats, supercoiling of DNA forming cruciform structures, and generally distorted DNA structures ([135], [136]). Active transposition events are detrimental to the host due to the mutagenic potential of genomic rearrangements. *In vitro* experiments demonstrating transposition were performed with only the core part of RAG-1/2; it is conceivable that other parts of the molecule exert an inhibitory effect on this potential function of RAG-1/2. Although the *in vitro* experimental evidence suggests that there is a bias toward transposition, there is no evidence that this occurs *in vivo*, as it severely compromises genomic stability in the lymphocytes. On the other hand, lymphoid malignancies are associated with chromosomal translocations, many of which involve the Ig on T-cell receptor (TCR) loci and potentially may be mediated by the V(D)J recombinase ([137]). Cleavage of DNA is always potentially dangerous. Although the recombinase function is essential for the integrity and normal function of the immune system, it is, at the same time, perilous. The genes essential for double-strand repairs encode the DNA-PK and its “associates” and the Ku autoantigen, a DNA end-binding protein ([138]) (see above). Mutations in this system result in the accumulation of V(D)J-specific double-strand breaks, indicating a defective repair mechanism, which causes SCID ([139], [140]). Loss of function of the ATM gene, a relative to DNA-PK, results in ataxia telangiectasia (AT) in humans ([141]). A new gene has recently been added to those already known that regulate double-strand DNA break (DSB) repairs. It has been named *Artemis* ([142]) after the Greek goddess who was the protector of small children and animals ([143]). It belongs to the superfamily of metallo-ß-lactamase enzymes and is associated with the DNA-PK complex ([144]). It is involved in the nonhomologous end-joining pathway, a DNA repair process used by eukaryotic cells ([145], [146]), as well as in the repair of broken DNA ends from the V(D)J recombinase activity. The repair requires that the hairpin in the coding joint is opened by the DNA-PK–Artemis protein complex ([144], [147]). In such a complex, Artemis acquires endonuclease activity, which does not possess by itself ([148]). Artemis has been shown to be mutated in patients with SCID expressing radiosensitivity ([142]). Patients with hypomorphic mutations in Artemis have not only immunodeficiency, but also predisposition to lymphoma ([147]).

RAG-1 AND RAG-2 PROTEINS

Both RAG proteins are required for V(D)J recombination because lack of function of either one leads to SCID ([148], [149]). A region that retains the recombinase activity is known as *core* and has been used for studies *in vitro*. For RAG-1, the core is located in the sequence 384-1008 of a total of 1040 and for RAG-2 in amino acids 1-383 of 527. The core of RAG-2 contains six repeats, each consisting of an antiparallel ß sheet formed by four ß strands. The repeats are arranged in a circular formation like blades of a propeller ([149]), a structure known to mediate protein–protein interactions. The *C*-terminal quarter of RAG-2 consists of a plant homeodomain fold, which is found in proteins with chromatin-binding properties ([150]).

Mutational analysis of the RAG proteins has provided some clues of structure–function relations. The catalytic properties of the proteins have similarities with members of the retroviral integrase superfamily ([137]) and require divalent metal ions for their function—a requirement characteristic of some nucleases, the function of which depends on acidic amino acids. Indeed, in RAG-1, several acidic amino acids are critical for both nicking and hairpin formation, without affecting the DNA binding ([151]). For RAG-1, the N-terminus is important for activity ([152]), and the binding of RAG-1 directly to DNA is supported by basic residues of RAG-2 ([153]). Deletion of the *C*-terminal region of RAG-2 results in the reduction of the number of B and T cells ([154]). The plant homeodomain of RAG-2 regulates differential access to sites of recombination, and although dispensable for the D/J $_H$ recombination, it is essential for the V $_H$/DJ $_H$ step ([155]).

HUMAN LIGHT CHAIN GENE LOCI

The two light chain isotypes, ? and ?, comprise approximately 60% and 40% of all Igs, respectively. They consist of a V domain and a C domain of approximately 107 residues in length. The V domain is encoded by the V and J segments, the former encoding the first 95 to 96 residues and the latter encoding the remaining 12 to 13. There is a single C? gene, and there are several C? genes.

The ? locus contains approximately 76 V? segments grouped into six families and five J? segments but no D segments.

The ? locus contains ten families of V? segments, a high number of pseudogenes, and several C? genes, each preceded by a single J? segment.

HEAVY AND LIGHT CHAINS GETTING TOGETHER

One of the consequences of the imprecision of the V(D)J recombination is a change in the reading frame at the junction between the two gene segments. When the segments join out of phase so that the triplet reading frame for translation is not preserved, the rearrangement results in V(D)J combinations with numerous stop codons that interrupt the translation. Such recombination events are known as *nonproductive rearrangements*. When gene segments are joined in phase, the reading frame is maintained, and the rearrangement is productive. If the junction lies within a codon, the resulting amino acid is encoded by nucleotides from both gene segments involved. The identity of the amino acid depends on the exact position of the joint and on the sequences of the individual gene segments. It is estimated that only one in three recombination attempts are productive, but the imprecision in the joints between variable gene segments increases their diversity by at least 100-fold.

The Ig gene rearrangements occur in an ordered fashion. They show preference for using certain gene segments, result in allelic exclusion, and follow a certain sequence in the order of rearrangement of the various loci. This indicates that there are regulatory mechanisms underlying the process of rearrangement. The IgH heavy chain gene is rearranged first and results in the formation of a complete V gene from three individual segment clusters. One of the D segments joins one of the J $_H$ segments, but the D to J $_H$ rearrangement does not take place exclusively in B cells because it has also been found sometimes in T cells. In the next step, which is regulated by the Dµ protein, a V segment joins the DJ $_H$ complex. Dµ protein is encoded by the DJ $_H$ complex and the µ–heavy chain constant gene—that is, it is a µ-chain lacking a V $_H$ segment. Dµ protein can be expressed on the membrane of the cell with an SLC. Expression of Dµ protein prevents further V $_H$ to DJ $_H$ rearrangement, or rearrangements are diverted to another pathway such as ?-chain rearrangements, which are accelerated. Productive, complete µ-chain rearrangement inhibits further rearrangements in the opposite allele (allelic exclusion) ([156]). Completion of the µ-chain rearrangement is followed by rearrangements of the ?-chain, and if both ? alleles fail to rearrange productively, the ?-chain gene is rearranged last (Fig. 16.6). However, this hierarchical order of Ig gene rearrangements has been challenged because examination of B cells at different stages of early development showed that the heavy and light chain genes rearrange independently ([157]). At the end of its early developmental stage, the B cell emerges with the expression on its surface of a unique antigen receptor consisting of IgM accompanied by two accessory molecules, Iga and Igß ([158]).

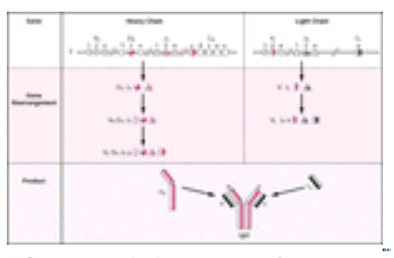

Figure 16.6. Heavy immunoglobulin (Ig) M chain–kappa light chain rearrangement. With the completion of the V(D)J recombination of the µ chain and the formation of a complete µH chain, the L $_K$ chain rearranges, and, if successful, it forms the complete IgM $_K$ molecule. If both ? alleles rearrange unsuccessfully, the ? gene rearranges. If successful, an IgM? molecule is formed. If both ? genes cannot rearrange successfully, the cell dies by apoptosis. REGULATION OF V(D)J RECOMBINATION

For the recombinase to initiate rearrangements, the gene must be accessible—that is, the locus must be able to act as a template for the recombinase. In cells competent to rearrange, it was found that J $_K$ and V $_H$ genes have already been transcribed, but these RNAs (called *germ-line* or *sterile transcripts*) are incapable of encoding the protein. There is correlation between transcription and gene rearrangement. Several possibilities may exist to explain this finding. Because inactive genes are not accessible to the recombinase, it is possible that the altered structure of the chromatin allows the recombinase to recognize the RSSs. Alternately, enhancers establish altered chromatin regions where both the recombinase and the transcription machinery have access ([161]). This is known as the *accessibility hypothesis* ([104], [159], [160] and [161]).

Enhancers play an important role, but promoters and silencers also function in gene accessibility. The Ig heavy chain enhancer (Eµ) is located within the intron between the J $_H$ segments and the Cµ gene and is associated with matrix attachment regions. Targeted mutations of Eµ have resulted in a dramatic decrease in J $_H$ recombination ([162], [163]). There are three additional enhancers within the Ig heavy chain locus, and one of them (DQ52) seems to compete more efficiently for conferring accessibility to the J $_H$ region. Interaction between DQ52 and Eµ is likely responsible for the ordered rearrangement (i.e., D to J $_H$ followed by V $_H$ to DJ $_H$) ([164]). The ?–light chain intronic enhancer is only active in mature B cells and plasmacytomas, and its stage restriction is dictated by a single motif that binds the transcription factor nuclear factor-?B (NF-?B) ([165]). NF-?B recognizes a 10-bp motif termed ?B, which is crucial for ?–light chain intronic enhancer activity. NF-?B consists of two subunits with the smaller one containing the DNA-binding function.

Other enhancers lie in the vicinity of the Ca gene, two others in the ? locus. The one between J? and C? genes becomes trans-criptionally active during pre-B- to B-cell transition ([166]). The mechanism by which promoters regulate accessibility is not known. The matrix attachment regions are regions rich in AT, bind nuclear matrix, and demarcate regions of chromatin that undergo base unpairing and other regions that mediate binding of topoisomerase II. This regional division of chromatin may also be regulated from a distance by *trans*-acting factors, which bind to specific motifs within the enhancer and promoter elements. For example, disruption of E2A and EBF transcription factors results in block of B-cell development at a stage before Ig heavy chain gene rearrangements. Despite the promiscuity and redundancy of regulatory elements, transcription is still tissue lineage and stage specific.

V GENE REPERTOIRE

Certain aspects of the study of the Ig V gene repertoire and the Ig gene rearrangement have found wide applications in clinical medicine ([167]). The total number of V genes defines the available repertoire. However, not all genes are equally expressed; as a result, the expressed repertoire is usually biased because some V genes are expressed in significantly higher frequency than would be expected if all had an equal chance for rearrangement. This biased expression affects all gene segments—V, D, and J. For example, the J_H4 segment (one of the existing six), on the basis of equal opportunity with the other five segments, should be detected in 17% of B cells, yet it is found in 32% of B clones from fetal liver ([168]) and in 42% of pre-B-cell acute lymphocytic leukemia (ALL) ([169]). The bias of the expressed repertoire shows striking association with certain diseases. For example, a member of the V_H4 family, V_H4-21, is found in cold agglutinins ([170]). Preferential expression of certain V_H segments is also detected in ALL clones. In ALL, the frequency of N-nucleotide additions differs in children younger than 3 years of age (12.5%), as compared with children with ALL older than 3 years of age (89%) ([171]). Because in fetal B lymphocytes the frequency of N-nucleotide additions is low, it is suggested that the transforming event in the younger age group probably occurred during fetal life.

In chronic lymphocytic leukemia (CLL), the use of V genes is also restricted; the same is true in non-Hodgkin lymphomas. It is interesting that in certain cases of follicular lymphoma, the V genes have not only undergone somatic mutations, but also continue to do so during the course of the disease, suggesting that the malignant clone is responsive to an antigen ([172] , [173]). Somatic mutations have also been detected in multiple myeloma as expected, because the malignancy derives from an advanced stage of differentiation of B cells ([174]).

Defects in V(D)J recombination have been identified with human diseases ([175]). For example, loss of RAG-1/RAG-2 function results in SCID. In certain autosomal-recessive diseases, hypersensitivity to DNA-damaging agents results in chromosomal breaks and rearrangements with an increased incidence for development of leukemia and other malignancies. They have been classified as DNA repair disorders and include AT, Fanconi anemia, xeroderma pigmentosum, and Bloom syndrome. V(D)J recombination with artificial substrates is normal in these patients.

In mice, an autosomal-recessive mutation, the SCID mutation, results in absence of B and T cells as a result of impairment of the V(D)J recombination. Both lymphoid and nonlymphoid SCID cells are hypersensitive to killing by ionizing radiation because of a DNA double-strand base repair defect. It is rather important that a human gene on chromosome 8q11 has been identified that restores V(D)J recombination, double-strand base repairs, and normal resistance to irradiation in SCID cells ([176] , [177]). The DNA binding protein, DNA-PK, is a strong candidate for the defect in SCID mice ([178] , [179]) (see V(D)J Recombination Defects: DNA Repair). This protein binds to DNA termini to prevent nucleotide loss through exonucleases, and it is assumed that it regulates the activities of DNA repair and recombination.

PATHOLOGY OF V(D)J RECOMBINATION: IMMUNE DEFICIENCIES

One of the widest applications related to V(D)J recombination is in regards to the diagnosis of lymphoproliferative diseases. Identification of gene organization of Ig and TCR has been one of the most sensitive methods to identify lineage and clonality of neoplasms. Application of molecular genetics enables the identification of unique markers of rearranged genes. These applications explore not only normally rearranged genes, but also detect translocations involving Ig or TCR genes and provide major insights into the cause of the malignant transformation. The diagnostic applications of V(D)J recombination are widely covered in other chapters of this book and are beyond the scope of this brief summary.

V(D)J recombination is absolutely necessary for immune diversity and survival. However, this objective can only be achieved through DSBs that threaten genomic stability. The complexity of the recombinase function is matched by complex DNA repair machinery. Disorders related to V(D)J recombination may be considered in two categories: those related to the first step (cleavage) and those related to the second step (cleavage repair).

SEVERE COMBINED IMMUNODEFICIENCY MUTATION

An experiment of nature in mice has revealed the two fundamental processes operating in V(D)J recombination (i.e., DSBs with gene rearrangements followed by DNA repair). Bosma reported the SCID mutation in mice ([180]). It is associated with severe combined immune deficiency, lack of mature lymphocytes, and agammaglobulinemia. Productive rearrangements occur only at a low level, and coding joints are absent, whereas signal joints are normal. SCID T cells have long P-nucleotide sequences and accumulate hairpins at the TCR? coding ends. In addition to the lack of rearrangements, there is an inability to repair damage from irradiation. The SCID mutation is located on mouse chromosome 16; however, human chromosome 8 can complement both mouse SCID defects. This indicates that the SCID defect for humans is in chromosome 8. However, human chromosome 8 is not associated with any known immunodeficiency or DNA repair diseases. The gene for DNA polymerase 8 is in chromosome 8p11-12.

V(D)J RECOMBINATION DEFECTS: DNA CLEAVAGE

Two types of RAG-1 and RAG-2 gene inactivations have been identified in mice. The first type results in inactivation of the recombinase so that V(D)J recombinations cannot be initiated ([107] , [108]). The mice have no mature T and B lymphocytes, but there is an increase of immature lymphocytes in the lymphoid organs. The second type of mutation consists of a single conservative amino acid substitution in both proteins. It does not affect the initiation of V(D)J recombination but severely impairs the coding and signal joint formation ([181] , [182]). The mutant enzymes are defective in hairpin opening *in vitro* and the formation of the coding joint *in vivo*. This evidence indicates that the RAG proteins, in addition to their cleavage function, are important for the formation of the joints; therefore, they must remain associated with the postcleavage complex to achieve opening of the hairpin.

No human syndrome has yet been identified comparable to the mouse SCID mutation. In humans, approximately 20% of SCID patients lack both T and B lymphocytes and have normal NK cell counts ([183]). Some of these patients have RAG-1 or RAG-2 gene mutations ([184]); others are characterized by an increased radiosensitivity of their bone marrow cells and fibroblasts (RS-SCID) ([185]).

The predicted RAG-2 structure consists of two globular domains separated by a hinge of approximately 60 amino acids. The largest domain (350 residues) includes the previously described core region of RAG-2, which is enzymatically active. This domain forms a ß propeller with six blades arranged in a circle from a center. Each blade is a ß sheet consisting of four ß strands. The ß-propeller fold (present in some integrins and other proteins) is known to mediate protein–protein interactions. Six out of seven mutations described today in humans are clustered on one side of the propeller in regions exposed to the solvent ([186]). This side is involved in RAG-1–RAG-2 interactions, which are absolutely critical for functional activity. Two of these mutants (C41W and M285R) have been found to reduce the interaction between RAG-1 and RAG-2 *in vitro*, and no DNA binding activity of the complex was detected ([187]). This is consistent with the hypothesis that RAG-2 stabilizes the RAG-1/RAG-2 complex ([188]).

OMENN SYNDROME (OMIM NO: 603554)

Omenn syndrome is an inherited disorder characterized by absence of circulating B cells and infiltration of the skin and intestine by activated oligoclonal T lymphocytes (HLA-D^+). There is eosinophilia and elevated serum IgE ([189] , [190]). The patient has diffuse erythrodermia, hepatosplenomegaly, protracted diarrhea, and failure to thrive. The activated T cells secrete Th2 types of cytokines ([191] , [192]), highly restricted in their TCR repertoire ([193]). They infiltrate skin, gut, liver, and spleen, causing a graft-versus-host–like disease ([194]).

Inherited mutations in RAG-1 and RAG-2 genes have been reported ([195] , [196]) in a series of 20 patients with Omenn syndrome resulting in partial V(D)J recombinase activity ([197]). Because similar mutations have been detected in patients with T/B SCID, it has been suggested that an additional factor exists in Omenn syndrome to account for the different clinical picture, such as an autoantigen or an external antigen that drives T-cell activation. In an interesting mutation in a 5-week-old girl with Omenn-like SCID, the RAG-1 gene had a deletion of a nucleotide (631 delT) ([196]); as a result, the *N*-terminal region of RAG-1 protein was deleted by a premature stop codon. The patient had a high number of T cells with almost a polyclonal TCR gene rearrangement, but there were no B cells and hardly detectable Ig gene rearrangements. The truncated RAG-1 protein apparently could still support TCR but not Ig gene rearrangements. This suggests that the N-terminus of RAG-1 is specifically involved in Ig V(D)J rearrangements.

V(D)J RECOMBINATION DEFECTS: DNA REPAIR

A DSB is one of the most significant lesions that threaten cell integrity. The cells have developed exquisite repair machinery to maintain genomic stability. Immune diversity, another function vital to the survival of an organism, has to cross the dangerous path of DSBs ([198]). The body uses the DSB machinery to repair the "damage" caused by the recombinase ([199]). The major mechanism for repair of DNA DSBs in mammalian cells is nonhomologous end-joining, a process that rejoins breaks with the use of little or no homology. Five proteins operate in nonhomologous end-joining; three of them form the DNA-PK complex (Ku70, Ku80, and DNA PK), the XRCC4, and the DNA ligase IV ([200]). The Ku protein is an autoantigen that induces autoantibodies in patients with scleroderma, polymyositis, or systemic lupus erythematosus. Two proteins, Ku70 and Ku82, form a stable heterodimer, which binds DNA ends irrespective of sequence composition. The heterodimer forms a complex with a third component—the DNA-PK. DNA-PK complex phosphorylates many DNA binding proteins, including transcription factors c-Jun and p53. However, the most efficiently phosphorylated substrates are those bound close to DSBs, including the Ku components of the DNA-PK complex. It appears that the main function of the DNP-PK complex is the regulation of the nonhomologous end-joining process. Mice defective in Ku proteins have SCID ([126] , [201] , [202]); in general, defects in the DSB repair machinery are associated with immunodeficiencies ([203]).

ATAXIA TELANGIECTASIA (OMIM NO: 208900)

AT is an autosomal-recessive disorder characterized by immunodeficiency, progressive cerebellar ataxia, oculocutaneous telan-giectasias, clinical radiosensitivity, chromosomal instability, and elevated risk for development of lymphoid malignancies ([204]). Immunodeficiency affects both T and B cells, and there is a decrease of serum IgA. The AT cells display ?-irradiation sensitivity and cell cycle checkpoint control (i.e., inability to arrest at the G_1-S- and S-phase checkpoints and, at the time of irradiation, an impaired G_2-M arrest). AT cells also have a DNA repair defect ([205]). They can rejoin DNA BSB efficiently, but the defect is localized on a protein member of the PI3K family of kinases with serine threonine protein kinase activity ([206]), which phosphorylates a number of proteins involved in mechanisms of damage repair (i.e., p53 and Chk1) ([207] , [208]). The majority of patients have frameshift mutations, which inactivate the gene.

NIJMGEN BREAKAGE SYNDROME (OMIM NO: 251260)

Nijmgen breakage syndrome is a rare autosomal disorder with clinical features overlapping with those of AT. The patients have defective humoral and cellular immunity, radiosensitivity, chromosomal instability, and predisposition to cancer ([209]). The patients have recurrent bacterial sinopulmonary infections, hypogammaglobulinemia, and impaired antibody responses to antigens. The cells from the patients have defects at some checkpoints of the cell cycle ([210]). The defective protein is nibrin or p95 (NBS1), which shows homology with the protein Xrs2, involved in DNA repair response in yeast.

BLOOM SYNDROME (OMIM NO: 210900)

Bloom syndrome is a rare autosomal-recessive disorder with immunodeficiency, genomic instability, and predisposition to cancer. It presents with a variable clinical picture—respiratory infections, chronic lung disease, and low IgM levels. Affected individuals show sun sensitivity in the face and infertility ([211]).

DEFECTS IN LIGASES

There are multiple DNA ligases in higher organisms. A point mutational change in DNA ligase I, which does not abolish the activity of the enzyme, was found in an individual who experienced recurrent sinopulmonary infections leading to bronchiectasis ([212]).

XERODERMA PIGMENTOSUM (OMIM NO: 278700)

Xeroderma pigmentosum is a rare disorder associated with sun sensitivity, high risk of cutaneous malignancy in sun-exposed areas, and immunodeficiency in some of the patients ([213]). Some aspects of immunosuppression associated with xeroderma pigmentosum are due to defects in the DNA repair machinery. The patients have impaired NK-cell cytotoxicity.

GENETIC DEFECTS OF EARLY B-CELL DEVELOPMENT

Cell Signaling during B-Cell Development

After the V_H to DJ_H rearrangement of the H-chain gene, the cytoplasmic µ-chain pairs with the SLC and traffics to the cell surface in association with the signal transducing chains Iga and Igß to form the pre-B-cell complex. Signaling for the transition from pre-B cells to Ig^+ B cells requires the *immunoreceptor tyrosine-based activation motif (ITAM)* motifs of the cytoplasmic domains of the Iga and Igß chains because inactivation of ITAMs by mutation blocks the transition to Ig^+ B cells ([214] , [215]). Deficiency of Igß chain by gene targeting abolishes formation of the Iga/Igß dimer and blocks assembly of the SLC. As a result, differentiation of B cell is arrested at the pro-B-cell stage ([216]).

Interactions of pro-B and pre-B cells with stromal elements are necessary for progression through the early stages of B-cell development, but a ligand for the pre-BCR has not yet been identified, and it is conceivable that the receptor may be signaling constitutively. It is apparent that the presence of ITAM motifs and the concentration of signaling molecules around them are the critical factors in determining progression through the early stages of B-cell development. Pro-B cells are able to become pre-B cells in the absence of the µH-chain as long as the Iga/Igß chains are aggregated and thus can recruit sufficient numbers of signaling molecules around their ITAMs ([217]). Furthermore, signaling by other molecules unrelated to pre-BCR, such as Epstein-Barr virus (EBV) latent protein 2A (LMP2A), can drive pro-B- to pre-B-cell transition. LMP2A constitutively possesses its own signaling activity in nontransformed cells ([218]). It is a protein spanning the membrane 12 times, with ITAM motifs in its cytoplasmic region. Phosphorylation of these motifs recruits Syk and Src kinases and thus bypasses the normal checkpoints of B-cell development. Surface Ig (sIg)–negative B cells with latent EBV infection are released in the periphery to colonize peripheral lymphoid organs.

Of all the signaling molecules assembled around the cytoplasmic tails of the pre-BCR complex, the Syk kinase is important for the pro-B- to pre-B-cell transition ([219]). The ITAMs of Iga and Igß chains act as docking sites for Syk kinase and trigger its activation ([220]). An important function for signaling is provided by the adaptor protein BLNK, which acts as a scaffolding to link Btk (and other molecules) to downstream signaling molecules. In $BLNK^{-/-}$ mice, the transition from pro-B- to pre-B-cell stage is blocked ([221] , [222]), and a similar defect has been detected in a patient with deficiency of BLNK and block of B-cell development ([223]). The arrest of B-cell development is more severe in the Syk- than BLNK-deficient mice. It is likely that the Syk kinase uses other signaling pathways bypassing BLNK.

Signaling Defects

Failure of B-cell development may result from defects in signaling through the pre-BCR. These experiments of nature have helped in delineating the molecular mechanisms of early B-cell development ([85]). Immune deficiencies due to arrest of B-cell development are usually associated clinically with recurrent bacterial infections, laboratory findings of markedly reduced numbers of B cells, and hypogammaglobulinemia. Of all the patients, 85% have mutations in Btk, whereas the remaining 15% constitute a heterogeneous group with defects of various signaling molecules.

Defects of ?5

The SLC is formed from two components: the VpreB and the ?5. In humans, there is one VpreB gene and three ?5 genes ([224]). A boy with mutations in both alleles of the gene ?5/14-1 has been described with recurrent infections, hypogammaglobulinemia, and lack of B cells detected in early age. The patient had three base pair changes in a single allele and alterations within exon 3. Changes in codons 131 and 140 were silent whereas that in codon 142 resulted in the replacement of proline, which in this place is highly conserved, to leucine (P142L) ([90]). The boy at 9 years of age had 0.1% $CD19^+$ cells in the blood, but these cells were of the mature

phenotype. In contrast to this patient, mice deficient in ?5 have a leaky block at the pro-B-cell stage and still maintain 10 to 20% of the B cells.

Defects of Immunoglobulin a (CD79a)

While screening several patients with defects of B-cell development, one 2-year-old girl was identified with an A to G substitution in the splice acceptor site preceding exon 3 of Iga ([225]), resulting in Iga transcripts that were aberrant, because most of them had no exon 3. The patient showed failure to thrive, had diarrhea in the first month of life, and, later, had bronchitis and neutropenia. She had severe hypogammaglobulinemia and absent B cells. The block of B-cell development was at the pro-B-cell stage.

Defects of µ–Heavy Chain

Defects in µH have been associated with agammaglobulinemia in individuals from two families. The defects consist of a large deletion of a 75- to 100-kb segment, including D, JH, and µ genes, or a base pair substitution in the alternative splice site, with inhibition of the synthesis of the membrane form of Ig ([226]). µH mutations with agammaglobulinemia should be distinguished from the X-linked agammaglobulinemia, because the disease from µH mutations can occur in females. Another report described a female patient with a cytosine insertion at the beginning of the CH1 exon of the µ gene, which resulted in premature codon and absence of the µH-chain ([227]).

Defects of B-Cell Linker Protein

The gene for human BLNK is located on the long arm of chromosome 10, at 10q23.22. BLNK is an adapter protein, which, after phosphorylation by Syk, recruits several signaling molecules (i.e., PLC?, Vav, Cbl, and Btk). A 20-year-old man with absent B cells and hypogammaglobulinemia was found to have two bp alterations: One of them did not change the amino acid (proline), but the second one, which was an A to T substitution, affected the +3 position of the splice donor site for intron 1 approximately 20 bp downstream from the first alteration. The second defect resulted in a marked decrease in BLNK transcripts and the protein ([223]). The patient had recurrent infections, undetectable serum Ig, and at the age of 20 years, less than 0.01% of CD19 $^{+}$ cells in the blood. Mice with BLNK deficiency have only a leaky block of B-cell differentiation at pro-B cell stage.

In general, mutations of ?5 or BLNK cause a more profound block of B-cell differentiation in the human as compared to the mouse ([228]).

BRUTON AGAMMAGLOBULINEMIA (OMIM NO: 300300)

In 1952, Bruton described a male child with hypogammaglobulinemia and early onset of bacterial infections ([229]) later found to be inherited in an X-linked pattern and became known as *X-linked agammaglobulinemia* ([230]). The constellation of findings consists of very low serum Ig levels (i.e., for IgG, approximately 10% of the normal control), no antibody production after immunization, markedly decreased B cells (0.3% of normal levels) ([231]), and no germinal centers, the hallmark of antibody production, in the lymph nodes. The genetic defect is located in the midportion of the long arm of the X chromosome (i.e., Xq22) ([232]). There are several variants of the disease in relation to immunologic function and clinical heterogeneity ([233]). The product of this gene was identified as a Src protein tyrosine kinase (PTK) that was called *Bruton tyrosine kinase* or *Btk* ([234] , [235]). More than 400 mutations have been characterized to date ([236]).

Btk is a member of the Btk/Tec family of PTKs, which includes Btk, Tec, Itk, Rlk, and Bmx ([237]). In the C-terminal end, Btk contains the catalytic (SH_1) domain. Next lies the SH_2 domain, which associates with phosphorylated tyrosines. It is followed by one SH_3 domain, which binds proline-rich sequences in protein-protein interactions. Next to the SH_3 is a Tec homology (TH) domain, which contains the Zn^{2+} binding Btk motif and a proline-rich stretch. At the N-terminus is the pleckstrin homology (PH) domain, which binds with high-affinity phosphatidylinositol-3,4,5-triphosphate (PIP_3) and is responsible for the translocation of Btk to the membrane. Btk and Tec kinases lack the unique N-terminal myristylated SH_4 region, which is carried by other Src kinases. Btk occupies a central position in BCR signaling and regulation of lineage development, and is linked to multiple downstream signaling pathways through BLNK [also known as *SH_2 domain–containing leukocyte protein* (SLP)-65]. BLNK functions as a scaffolding protein and binds to the SH_2 domain of Btk ([238]). It connects Syk to Btk and links Btk to downstream signaling molecules, like PLC?$_2$, a linkage essential for Ca^{2+} signals ([239]). Btk also associates with Wiskott-Aldrich syndrome protein via the SH_3 domain; this is the reason that in XLA patients with defective Btk, the collagen-induced tyrosine phosphorylation of Wiskott-Aldrich syndrome protein in platelets is reduced ([240]). Different regions of Btk are critical for Btk activation and signal transduction [i.e., the PH domain binds to Ca^{2+}-dependent (a, ßI, ßII) and Ca^{2+}-independent isoforms of protein kinase C (PKC) (e and ?) in mouse B cells ([241]), to IP_3 ([242]), and to heterotrimeric G proteins ([243])]. Sequential phosphorylations of regulatory tyrosines by the BRC-associated Src kinases activate Btk, such as the phosphorylation of Tyr551 in the kinase domain or Tyr 223 in the SH_3 domain ([244] , [245] , [246] and [247]).

In Src kinases, negative regulation is mediated by the Tyr527 in their C-terminal region, but Btk has no equivalent residue, and it is likely that such a function is mediated by the recently identified inhibitor of Btk (IBtk). IBtk binds to the PH domain and down-regulates Btk function, such as Ca^{2+} mobilization and NF-?B activation ([248]).

It appears that Btk is a bi-directional regulator with the capacity to deliver survival or apoptotic signals depending on the expression of surface receptors and the stage of the cell differentiation ([249] , [250]). The molecular mechanism of Btk function in XLA is still not quite clear. Mutations of Btk gene include deletions, insertions, or substitutions ([251]) and produce variable degrees of immunodeficiency, whether in the kinase domain ([235]) or in other domains.

Evidence from the bone marrow of XLA patients shows that there is an expansion of pro-B cells, whereas the numbers of more mature B cells are negligible ([252]). Based on the expression of VpreB, the pre-BI cells are SLC positive, and a number of them are large in size and cycling, whereas the pre-BII cells are negative. It appears that Btk blocks normal B-cell maturation at a point just before that stage (i.e., it interferes with the transition of pro-B cells to pre-BI stage) ([252]). Some patients express an inactive form of Btk and have a more severe form of XLA than those expressing no Btk molecule ([253]).

PHENOTYPIC CHANGES IN THE EARLY STAGES OF B-CELL DEVELOPMENT

The study of phenotypes of B-cell precursors in normal adult bone marrow is hampered by the relative paucity of these cells. Therefore, some investigators have resorted to the study of leukemias under the assumption that they accurately reflect normal B-cell development. Because aberrant phenotypes in acute leukemias have been identified, suggesting asynchronous antigen expression, the validity of the results from such an approach has been challenged ([1] , [254]). Normal adult bone marrow ([255]) or fetal bone marrow and fetal liver ([256] , [257]) have been used as a source of B-cell precursors in cultures *in vitro* or after injection in SCID mice. B lymphocytes derive from cells expressing high levels of CD34 ([258] , [259]).

Phenotypically, B-cell development can be separated into three stages: (a) precursor B cell (which includes pro-B cells and pre-B cells), (b) immature B cells, and (c) mature B cells (Fig. 16.1). Markers defining the first stage are CD19, and, occasionally, some other “promiscuous” markers, such as CD2 or CD7, are detected, but probably the best marker is the detection of the SLC by a monoclonal antibody, a hallmark of a B cell, progressing through the progenitor stages. Entrance into the immature B-cell stage is defined by the surface expression of IgM, with antisera not only for µ chains but also for light chains ? or ?. This indicates that the µ chain is associated with a light chain and not with the SLC, suggesting that the Ig gene rearrangements are complete. The immature B-cell stage is characterized by expression of only IgM without IgD. Functionally, this is important because the former phenotype defines a cell vulnerable to tolerogenic stimuli indicative of its “immaturity.” At this stage, the cell expresses other markers, such as CD10 and CD24, at high density. The mature B-cell stage is simply identified by coexpression of IgD as well as other markers such as CD20, CD21, and CD22.

Another useful phenotypic marker for precursor B cells is the nuclear enzyme TdT ([260]). Tdt is a DNA polymerase catalyzing the elongation of polynucleotide chains without template ([261]) and adds N-nucleotides at the DNA cleavage site during V(D)J recombination. CD24 is expressed at a very early stage, and it is present at a much higher density as compared with the mature sIg $^{+}$ B lymphocyte ([262]). CD2 expression has been detected on biphenotypic ALL cells and also on their normal counterparts in human fetal hematopoietic tissues ([263] , [264]). Whether they represent common T and B lineage progenitors remains to be seen. Pre-B cells have been

detected during fetal life first in the liver (by 8 weeks) and later in the bone marrow (by 12 weeks) ([265], [266]). In the liver, they are mixed among other myeloid cells next to liver parenchyma in extrasinusoidal areas ([267]).

The small pre-B cell is the immediate precursor of the immature B cells and starts to express sIgM by the end of the first trimester. In adults, pre-B cells are present in the bone marrow, where they constitute 0 to 7% of the nucleated cells and only rarely are noted in the peripheral lymphoid organs.

During the last phase of pre-B cell, CD34 and TdT disappear, CD10 is down-regulated, and the cell expresses first CD22 and later CD20. Before its appearance on the cell surface, CD22 is detected in the cytoplasm very early during development. It is identical to the surface CD22 and is B-lineage restricted ([268]). The receptors for Fc are not present on pre-B cells but receptors for C3b have been detected in some large pre-B cells and in approximately 40% of the small pre-B cells ([269]).

MATURE B LYMPHOCYTES

The hallmark of maturing B lymphocytes is the appearance of sIg, and the first one expressed is IgM. During fetal life, the IgM^+ cells (which are mostly $CD5^+$) populate the lymph nodes and settle in the primary lymphoid follicles after 16 to 20 weeks of gestation. By 13 weeks, most of the B cells are IgM^+IgD^+, and later IgG or IgA is added. This triple phenotype of fetal B cells persists until birth but is converted to the adult single phenotype during the first few months of life. In adult life, cells expressing IgG or IgA are mostly IgM^- and IgD^-. By 10 weeks of age, practically all B cells in the spleen are IgM^+IgD^+, whereas in the bone marrow only 30 to 40% coexpress the two isotypes. Maturation of B lymphocytes is associated with a change in the density of the two isotypes from $IgM^{high}IgD^-$ to $IgM^{high}IgD^{low}$ and finally to $IGM^{low}IgD^{high}$. New markers appear on B lymphocytes with the expression of IgM (Fig. 16.1). CD21 is present in more than 90% of resting B lymphocytes and is the same as the C3d/EBV receptor. With activation, CD21 and CD22 are lost, and, concomitantly, CD23 is expressed. CD23 is up-regulated by IL-4 ([270]) and the EBV nuclear antigen-2 (EBNA-2) ([271]) and is down-regulated by interferon-?. CD24 expression decreases with B-cell maturation, and, in combination with the expression of CD45, it can be used to determine stages of B-cell maturation relevant to B-cell neoplasias ([272]). CD45 expression also varies with B-cell maturation. Its expression is low on the most immature precursors in the bone marrow, is up-regulated as normal B-cell differentiation progresses, and then declines at the terminal stages of differentiation as plasma cells become negative for CD45 ([273]).

Probably the most important application of the phenotypic changes occurring during B-cell differentiation is in B-cell malignancies because it is widely accepted that B-cell leukemias/lymphomas correspond to distinct stages of differentiation. An attempt to incorporate immunophenotypes (and genetic techniques) into the traditional morphologic features has resulted in a revised classification with well-defined disease entities ([274]) and more recently in the revised World Health Organization classification ([275]).

SURFACE IMMUNOGLOBULIN

sIg serves as the receptor for antigen on B lymphocytes. It is identified most commonly with the use of fluorochrome-conjugated anti-Ig antisera. The first Ig to appear on the membrane of B lymphocytes is IgM. In contrast to the secreted pentameric form, the membrane IgM (mIgM) is composed of only one subunit (8S) containing two H and two L chains. The second isotype to appear is IgD, which is present either as a complete four-chain molecule or as a half molecule. The ratio of secretory to mIg increases with maturation from resting B cells to plasma cells. The transmembrane and secreted forms are encoded by the same gene. There are two transcription termination of polyadenylation sites: One is 3' to the last constant chain exon, and the second is 3' to the second transmembrane exon (Fig. 16.7). Termination at the first site results in loss of transmembrane exons and production of the secreted form, whereas polyadenylation at the second site produces the membrane form.

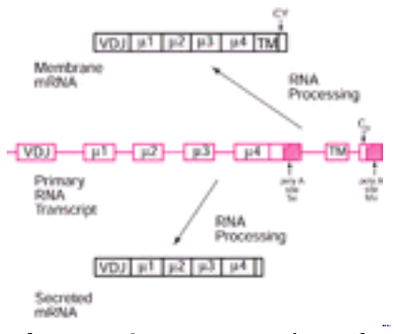

Figure 16.7. Expression of membrane versus secreted immunoglobulin (Ig) depends on alternative processing of the primary RNA transcript. There are two polyadenylation (*poly A*) sites, one for secreted *(Se)* and one for the membrane *(Me)* forms. $C\mu_1$–$C\mu_4$ are the exons of IgM. Cy, cytoplasmic region; mRNA, messenger RNA; TM, transmembrane region.

Between 50,000 and 100,000 molecules of Ig are found on each B lymphocyte. This number is an average, because the density of sIg varies among individual B cells ([276]). The mIg is distributed throughout the membrane in small clusters, including the microvilli ([277], [278]). In human B lymphocytes, the clusters are separated from each other by a few thousand Ångstroms of bare membrane, indicating restriction in the free distribution of mIg. In the mouse, the clusters are interconnected by strands composed of a few molecules, forming a lacy, continuous network. When examined at 4°C in the fluorescent microscope with fluorescein conjugated anti-Ig antibodies, the mIg appears distributed as a ring, but an increase in the temperature to 37°C prompts the formation of clusters (patching) that move rapidly toward one pole of the cell, forming a cap ([279]) (Fig. 16.8 and Fig. 16.9). Shortly after the formation of the cap, changes in cell shape occur accompanied by cell movement. The cell pushes out a projection located opposite to the cap that corresponds to membrane ruffles noted on scanning electron microscopic analysis ([280]) (Fig. 16.10). After the formation of the cap, a constriction under the cap encircles the cell, and the cell takes the shape of a hand mirror, with the cap occupying the area of the uropod with numerous microvilli. A dense band of microfilaments is noted under the constriction that separates the cell into the uropod containing the cap and the area opposite the cap containing the cell organelles and the nucleus. The uropod is well formed after the cap is completed.

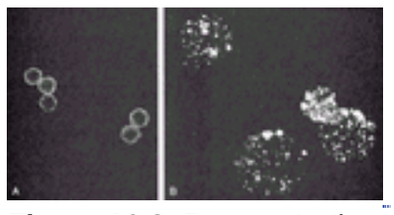

Figure 16.8. Demonstration of surface immunoglobulin (Ig) by immunofluorescence on B lymphocytes. Viable normal B lymphocytes treated with anti-IgM antiserum at 4°C present a staining pattern of a uniform ring around the periphery of the cell **(A)** or discrete patches uniformly dispersed over the cell surface **(B)**. (From Zucker-Franklin D, Greaves MF, Grossi CF. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

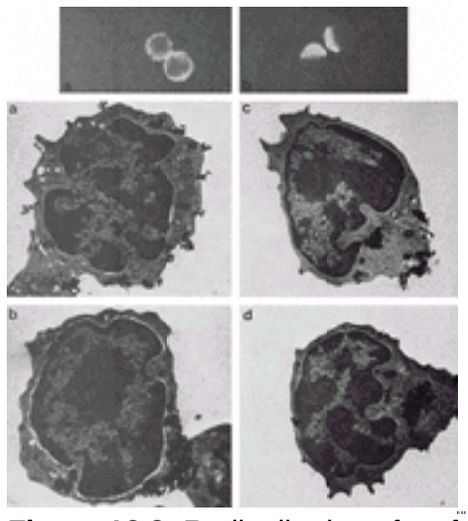

Figure 16.9. Redistribution of surface immunoglobulin (Ig). **A:** Mouse B lymphocytes treated with fluorescein-conjugated anti-mouse Ig antibody. **a:** Surface Ig is uniformly distributed around the cell (ring pattern). This pattern is seen only if the cell is kept at 0°C. **b:** Warming the cell to room temperature causes redistribution of the Ig so that it occupies only one pole (cap pattern). (From Taylor RB, et al. Redistribution and pinocytosis of lymphocyte surface immunoglobulin molecules induced by anti-immunoglobulin antibody. Nature 1971;233:225, with permission. Copyright ©1971 Macmillan Magazines Limited.) **B:** Mouse B lymphocytes treated with rabbit anti-mouse Ig-conjugated with iodine-125 were examined by high resolution radioautography. **a:** At the ultrastructural level, Ig is distributed around the entire surface of the cell, if it is maintained at 4°C. **b:** Surface Ig accumulates to one of the poles of the cell (uropod), forming a cap when it is warmed at 37°C. **c** and **d:** The cap is eventually endocytosed. (From Unanue ER, Perkins WD, Karnovsky MJ. Ligand-induced movement of lymphocyte membrane macromolecules. I. Analysis by immunofluorescence and ultrastructural radioautography. J Exp Med 1972;136:885–906. Reproduced by copyright permission of the Rockefeller University Press.)

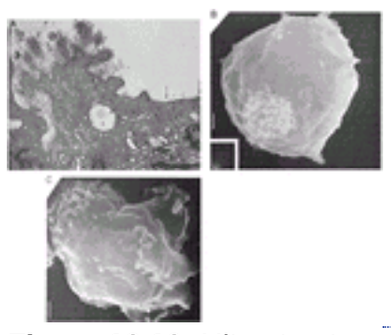

Figure 16.10. Ultrastructure of a cap. **A:** Anti-immunoglobulin (Ig) labeled with hemocyanin in mouse spleen B lymphocyte is heavily concentrated in the uropod around short microvilli. Some of the capped Ig has been endocytosed *(E).* The label in the cap is densely packed, whereas the adjacent areas are clear of label (arrows). (From Karnovsky MJ, Unanue ER, Leventhal M. Ligand-induced movement of lymphocyte membrane macromolecules. II. Mapping of surface moieties. J Exp Med 1972;136:907–930. Reproduced by copyright permission of the Rockefeller University Press.) **B:** A cell with a tightly packed cap with smooth surface in the remaining body. **C:** The cap is separated by a constriction from the rest of the body, which shows intense membrane ruffling. G, Golgi apparatus. (**B** and **C** from Karnovsky MJ, Unanue E. Cell surface changes in capping studied by correlated fluorescence and scanning electron microscopy. Lab Invest 1978;39:554–564, with permission.)

Although patches are observed at 4°C, capping can take place only at temperatures above 20°C and preferably at 37°C ([281], [282]). The formation of patches is a passive phenomenon resulting from the aggregation of small complexes on the plane of the membrane. Capping requires energy provided by the respiratory chain and glycolysis. In most human B lymphocytes, capping does not take place because the Ig clusters on the surface of the cells are widely separated from each other. As a result, cross-linking is not possible because cell motility can be blocked without any effect on Ig capping ([281]), and capping in many B cells is already complete before any amoeboid movement is noticed.

Colchicine, which disrupts microtubules, has no effect on capping, and only a slight effect is noted with cytochalasin B, which disrupts the microfilaments. The combination of these drugs, however, inhibits mIg capping profoundly. Calcium, which plays an important role in contractile systems, is also critically involved in mIg capping ([281], [282], [283]), probably through calmodulin, which is found under the caps ([284]).

During the process of capping, mIg becomes physically associated with the cytoskeleton, and after treatment with nonionic detergents, it remains bound to the insoluble cytoskeleton. After binding of the anti-Ig antibody, two constituents of microfilaments, myosin as well as actin, are redistributed and are found in the uropod under the caps.

The fate of the complexes in the cap has been studied morphologically using autoradiography, electron microscopy, and measurements of radioactivity. The bulk of the complexes is internalized (endocytosed) in the presence of adequate antibody. Endocytosed material is catabolized within the lysosomes, and small fragments are released into the culture medium. With the completion of endocytosis, the B lymphocyte remains free of mIg until it is resynthesized to the original level by 24 hours.

B-CELL ANTIGEN RECEPTOR COMPLEX: STRUCTURE AND SIGNALING

The sIg of B lymphocytes forms a complex with several components assembled into two structurally and functionally distinct modules: an antigen recognition module (sIg), and a signal transducer module (a heterodimer of two polypeptide chains Iga/ß) (Fig. 16.11) ([285], [286], [287] and [288]). sIg provides the specificity for antigen recognition through its antigen-binding sites. However, the cytoplasmic tails of the two heavy chains of mIgM consist of three amino acids and therefore are not suitable in signal transduction. Two other polypeptide chains known as *Ig*a, containing a 61-residue cytoplasmic tail, and *Ig*ß, with a 48-residue tail, are associated with mIgM. The genes encoding for these proteins are known as *mb-1* and *B-29*, respectively. In their cytoplasmic tails, these proteins carry a sequence motif of six conserved and precisely distributed amino acids (tyrosines and negatively charged amino acids) over a sequence of 26 residues. This motif has been termed *immunoreceptor tyrosine-based activation motif* or *ITAM* ([289]). ITAMs have been found in ?, ?, e, ?, and ? chains of CD3 and Fc receptors.

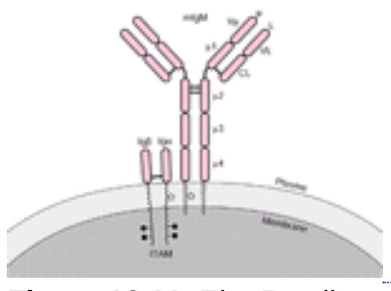

Figure 16.11. The B-cell receptor (BCR). The surface immunoglobulin (Ig) (two heavy and two light chains) constitute the antigen-specific component of BCR, which is associated noncovalently with a heterodimer consisting of two chains Iga and Igß. This heterodimer constitutes the signal transduction component. The Iga chain associates with the H chains through ionic interactions. ITAM, immunoreceptor tyrosine-based activation motif; mIgM, membrane immunoglobulin M.

The transmembrane region of Cμ is required for binding to Iga/Igß heterodimer, and it is one of the highly conserved portions of the Ig molecule between species and isotypes. The conserved amino acids are not all hydrophobic but contain several hydrophilic residues. This amphipathic nature indicates again that mIg forms complexes with other proteins.

The genes mb-1 and B-29 are active only in B lineage and are expressed even before the assembly of the V gene. In myeloma cells, only the B-29 is expressed but

not the mb-1, and that prevents expression of Ig in plasma cells. For surface expression of Ig, the complete assembly of the Ig with Iga/Igß heterodimers is required. This explains the lack of detection of mIg on plasma cells ([290]). Transfection of plasma cells with the mb-1 gene results in expression of sIg ([291]). A patch of polar amino acids within the transmembrane region of Cµ signals retention of IgM within the ER until the Iga/Igß heterodimer associates with IgM for transportation to the cell surface.

B-cell activation leads to proliferation (i.e., clonal expansion) and differentiation (i.e., generation of plasma cells for antibody secretion). Signaling for both processes is initiated on the surface of a naïve B cell when antigen binds and cross-links specific receptors (i.e., sIgM). The signal is transmitted to the cell interior by co-receptors and then propagated via complex signaling pathways to the nucleus. A well-orchestrated sequence of events leads to cell enlargement (“blast”), progression from G_0 to G_1 phase of the cell cycle, and incorporation of H_3-thymidine [i.e., proliferation (clonal expansion)]. The same signals activate other genes, resulting in protein synthesis and formation of antibodies (differentiation).

B-Cell Receptor Structure

After the synthesis of IgM is completed, it becomes associated with Iga and Igß to reach the cell membrane. Iga and Igß are encoded by the genes mb-1 and B-29, respectively ([292]). The B-29 gene is expressed throughout the life of the B cells, whereas mb-1 is turned off in plasma cells. All Ig isotypes need to associate with the Iga/Igß heterodimer for their expression on the cell membrane and for their function. Analysis of the transmembrane regions of the heavy chains of mouse Igs shows that 11 out of 13 conserved amino acids lie on one side of the transmembrane a-helix, suggesting that this side interacts with transmembrane regions of other proteins. Because only Iga has polar residues on both sides of the transmembrane a-helix, it was assumed that Iga forms contacts with transmembrane regions on both sides ([285]). These considerations formed the basis for a model of the B-cell receptor complex in which the IgM component is in the center with one Iga/Igß heterodimer on each side ([293]). Based, however, on new evidence, this model has been challenged. It is believed that each IgM molecule is associated with only one Iga/Igß heterodimer (Fig. 16.11) ([294]). If this model is correct, the question remains whether both chains are linked to IgM, or only Iga binds to both heavy chains, and Iga-BCR forms oligomers with additional molecules of the same isotype. In the arrangement of the components of the oligomers, in the resting state of B cell, one side of the transmembrane helix of the Ig associates with the Iga while the other with a similar Ig isotype.

B-Cell Receptor and Lipid Rafts

The oligomers continuously deliver signals at a low level needed to maintain the B cell alive. Ligand binding changes the orientation of the BCR molecules so that their ITAMs become more accessible to phosphorylation that causes *signal spreading* restricted to BCRs of the same isotype ([294]). Signal spreading indicates that the oligomeric receptors form arrays in which the receptors are in close proximity ([295]). These early events of BCR reorganization provide a mechanism for detecting low concentrations of antigens, thus increasing the threshold of activation.

Cross-linking of BCR by multivalent antigen leads to a series of morphologic and molecular events that are interrelated (i.e., BCR aggregation and loading to “lipid rafts,” signaling, internalization of BCR, and antigen presentation).

In the resting state, BCRs “float” on the cell membrane as monomers, but at the time of “signal spreading,” they form oligomers and gather in specialized membrane microdomain referred to as *lipid rafts*. Cross-linking with antigen enhances the transfer of BCRs to lipid rafts ([295] , [296] , [297] and [298]), but the pre-BCRs are constitutively located on lipid rafts ([299]). Lipid rafts are areas of the membrane enriched in cholesterol and glycosphingolipids with saturated fatty acid side chains consisting of GM1 gangliosides. They are resistant to solubilization in nonionic detergents at low temperatures. Most of the proteins are excluded from the lipid rafts, except proteins modified by saturated fatty acids. Such proteins include acylated Src kinases and the a subunits of trimeric G proteins. Lipid rafts facilitate BCR signaling by co-localizing signaling molecules, but also by excluding molecules that inhibit BCR signaling such as CD22. Furthermore, in anergic or tolerized B cells, the BCR is unable to enter lipid rafts, indicating that inclusion of BCR within these microdomains is an absolute requirement for initiation of signaling ([300]). Similarly, localization of BCR within the rafts occurs only in mature, but not immature, B cells ([301]). The translocation of the BCR into lipid rafts is independent of any signaling initiated by the receptor and does not require actin cytoskeleton polymerization or the Iga/Igß complex ([302]). Lipid rafts facilitate not only activation, but also apoptosis, because cross-linking of CD24, a glycosylphosphatidylinositol-anchored protein that is down-regulated during B-cell differentiation, induces apoptosis via a lipid raft signaling system ([303]). CD24 cross-linking brings some BCR within the lipid rafts activating Lyn kinase.

B cells are not only antibody-producing cells after BCR-mediated differentiation, but in addition are antigen-processing and -presenting cells. With this function, they can attract antigen-specific T cells to receive T-cell help ([304]). Lipid rafts mediate also this function of B cells, diverting the antigen captured by B cells to the endocytic pathway for further processing ([305]). From evidence cited above, it appears that the association of immune receptors with rafts is regulated and is part of the mechanism that determines the fate of BCR signaling during development and antigen-driven differentiation. As indicated above, in immature or anergic cells, BCRs have no access to lipid rafts, but the of the CD21/CD19 complex co-receptor, which markedly enhances BCR activation, significantly stabilizes the residence of BCR within rafts and thus prolongs B-cell activation ([306]). The Fc?RII, which acts as an inhibitor of B-cell activation, on the other hand, destabilizes BCR-raft association ([307]).

After translocation of BCR (or other immune receptors) into lipid rafts, the rafts appear to form clusters [i.e., clustered rafts ([295])] increasing the range of their diameter from hundreds of nanometers to micrometers. Clustering results from receptor cross-linking between rafts and eventually linking rafts with linker proteins such as LAT (linker of activation of T cells) in T cells. In addition, cytosolic proteins that have been associated with cytoplasmic domains of receptors residing within a raft may also contribute to the bridging of individual lipid rafts to form larger conglomerates. Cytoskeletal components are also linked to activated receptors and their reorganization bridges clustered rafts.

Continuation of raft clustering eventually leads to the formation of the “synapse,” a highly ordered membrane structure in which immune receptors, signaling molecules, and cell adhesion molecules are clustered ([308]). Synapse formation is a highly organized structure with a cluster of immune receptors in the center ringed by adhesion molecules and several signaling molecules and cytoskeletal components on the cytoplasmic side. The formation of the synapse was first identified on T cells, but it has now been identified also on B cells ([309]). The B-cell synapse is associated with antigen capturing for processing, and when antigen is captured by other antigen-presenting cells, such as dendritic cells, they trigger the formation of the synapse on B cells. During this close encounter between the dendritic cell with synapse formation, the B cells sample and gather antigen for internalization and processing.

The mechanisms of internalization have been discussed earlier with the Ig redistribution after anti-Ig binding (see Surface Immunoglobin). Lipid rafts are the middle point between signaling and internalization, and these two events are interrelated ([310]) because signaling regulates the BCR internalization ([311]). Cells with deficiency of expression of Src kinases, which normally initiate B-cell signaling, fail to internalize the receptor ([312]), and the targeting of antigen to the major histocompatibility complex class II peptide-loading compartment is also disrupted ([313]). Internalization of BCR occurs when clathrin is associated with rafts and is tyrosine phosphorylated after BCR cross-linking ([314]). When lipid rafts are disrupted either by expression of LMP2A protein of EBV or reagents that sequester cholesterol, internalization does not occur ([312] , [314]).

B-Cell Receptor Signaling

The most important structural elements of signaling molecules for the initiation of B-cell activation and differentiation is the ITAM motifs of the Iga/Igß heterodimer and the PTKs associated with the complex (Fig. 16.12). The ITAM is characterized by a sequence of 26 amino acids D/E-X_7-D/E-X_2- **YXXL/I**-X_6([7])- **YXXL/I**, with six of them being conserved (X = any amino acid). Critical for signaling are the two tyrosines (Y), and one or both of them are phosphorylated when the BCR is engaged by antigen.

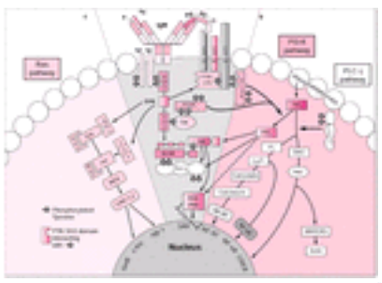

Figure 16.12. B-cell activation. Signal transduction initiated by the engagement of the B-cell receptor (BCR) is a highly complex process. For a better understanding, it is divided arbitrarily into three main signaling pathways: (a) initiation: with the assembly by adapter proteins such as BLNK (*B*-cell *l*i *nk*er protein), Cbl, and others of signaling protein tyrosine kinase (*PTK*) complexes such as Src (Lyn, Fyn), Syk, and Btk; (b) inositol phosphatides generation by the activation of PI3K and PLC-?; (c) the ras/Erk pathway assembled by adapter proteins Grb, Shc, and Sos. These pathways carry the signals downstream to other signaling molecules Akt, calcineurin, and Erk/1,2 and to activation of transcription factors nuclear factor-AT (NF-AT), NF-?B, Creb, c-fos, etc. (From Paraskevas F. B lymphocytes. In: Israels L, Israels E, eds. Mechanisms in hematology. With permission from Core Health Services, Inc.)

BCR signaling is a highly complex process ([315], [316] and [317]), but for the sake of understanding, the interactions are divided somewhat arbitrarily into three major pathways: (a) initial interactions, (b) phosphoinositide pathways, and (c) the ras pathway.

INITIATION PATHWAY BCR has no intrinsic PTK activity but uses several distinct families of cytoplasmic PTKs. Three distinct types of PTKs are activated on BCR engagement: (a) the Src-PTKs (Lyn, Blk, and Fyn), (b) Syk, and (c) Btk ([315]). Activation of Lyn is one of the earliest events in BCR-induced signaling, which is constitutively acylated and as a result localizes in the cell membrane. It is responsible for the initial phosphorylation of the ITAMs of Iga and Igß. The kinase activity of Lyn is regulated by phosphorylation of a carboxyterminal regulatory tyrosine by the kinase Csk ([318]) and dephosphorylation by the phosphatase CD45 ([319]). Lyn has one SH_3 domain on its N-terminus, followed by one SH_2 domain and the kinase domain in the C-terminus. The SH_2 domains bind phosphorylated tyrosines, whereas the SH_3 domains bind proline-rich sequences. BCR engagement triggers dephosphorylation of Tyr508 by the CD45 phosphatase, whereas Ty394 within the catalytic domain is rapidly phosphorylated. Syk kinase is recruited to the phosphorylated ITAMs of Iga and Igß, and is phosphorylated by Lyn or by an autophosphorylation mechanism ([320]). Activation of Syk is a critical event in BCR signaling and for recruitment of BLNK, or SLP-65, a linker protein with a major scaffolding function connecting several downstream signaling molecules ([321]). BLNK assembles macromolecular complexes that include PLC?, Vav, and Btk and additional linker proteins Grb2 and Nck ([322], [323]). Phosphorylation in five tyrosine residues of BLNK is required for coordination of the assembly of multimolecular complexes. Btk belongs to the TEC family of kinases and differs in several aspects from the Src kinases [i.e., it is not myristoylated, does not contain a negative regulatory phosphorylation site in the C-terminus, and has a pleckstrin homology domain (PH) in the N-terminus]. Btk function is regulated by phosphorylation of the Tyr551, which is essential for Btk participation in signal transduction ([324]). Btk also interacts with phosphatidylinositol-3,4,5-triphophosphate (PIP_3), an interaction required for recruitment of Btk to the cell membrane ([325]). Because PIP_3 is generated from activated PI3 kinase, Btk is targeted to the membrane after PI3 kinase activation, where it could be phosphorylated by Lyn or Syk.

GENERATION OF PHOSPHOINOSITIDES Hydrolysis of inositol-containing phospholipids is mediated by the lipid metabolizing enzymes PLC-? and PI3K. There are several pathways leading to activation of PLC-? in B cells ([326]). BLNK associated with PLC-? $_2$ (which is the main isoform in B cells) brings it in an appropriate position for activation by Syk kinase. On the other hand, Btk also contributes to PLC-? $_2$ activation because B cells from XLA patients show a profound reduction of IP_3 production on BCR engagement ([327]). PIP_3, the product of PI3 kinase activation, binds to the PH domain of PLC-? $_2$, thus providing another pathway for PLC-? $_2$ activation. PLC-? $_2$ activation leads to hydrolysis of phospholipids, generating IP_3 and DAG (diacylglycerol). IP_3 binds to appropriate receptors on the ER, leading to Ca^{2+} release from internal stores. PI3 kinase is activated by at least two pathways. A prominent substrate for tyrosine phosphorylation is the product of the oncogene c-cbl. BCR engagement phosphorylates p12-cbl, which is then associated with the 85-kd component of PI3 kinase ([328]). A second pathway is through the CD19/CD21 co-receptor complex ([329], [330]). BCR stimulation phosphorylates the two YXXM motifs of CD19, which then bind the SH_2 domain of the p85 regulatory subunit of PI3 kinase. Enhanced phosphorylation occurs when the CD19/CD21 complex binds C3d fragments. Furthermore, the proline-rich region of the p85 subunit binds to SH_3 domains of Lyn and Fyn, further enhancing PI3K activation. Ca^{2+} binds to calmodulin and promotes calmodulin-dependent protein kinase activation and calcineurin, a serine-threonine-specific protein phosphatase. Calcineurin directly dephosphorylates the NFAT family of transcription factors ([331], [332]). DAG, one of the two second messengers produced by PLC-? $_2$ activation, activates PKC. One target of PKC on B cells is MARCKS, a protein that regulates actin reorganization. Ca^{2+} elevation also activates a number of other transcription factors, such as NF-?B and ATF-2. Phospho-inositides generated by PI3K bind to Akt/PKB kinase, an evolutionarily conserved kinase across species ([333]). Akt is the product of an oncogene transduced by the acute transforming retrovirus (Akt-8). The viral and cellular oncogenes encode a serine-threonine protein kinase consisting of a C-terminal kinase domain and an N-terminal PH domain. Mutations of the PH domain blocks Akt activation by growth factors or phosphoinositides. Akt activation is also mediated by the serine/threonine kinase PDK1, which is stimulated by PIP_3 (not PIP_2) and phosphorylates Akt on Thr308. Akt inhibits glycogen synthase kinase 3 (GSK3), which destabilizes Myc and cyclin D, both required for cell cycle progression. A combination of various Akt activation effects play a role for its transforming and oncogenic potential. Some of its multiple effects include transcriptional regulation of gene expression, inhibition of apoptosis, cell cycle regulation, insulin-induced metabolic signals, endocytosis, etc.

RAS PATHWAY BCR cross-linking leads to an increase of the guanosine triphosphate (GTP)-bound ras and its accumulation in the membrane under BCR. Ras is a guanine nucleotide–binding protein, which cycles between a guanosine diphosphate (GDP)-bound (inactive) and a GTP-bound (active) state. The proteins of the Ras family are protooncogenes, which, on mutation, accumulate in the GTP-bound state in human tumors. On activation of B lymphocytes, Ras is rapidly converted to the GTP-bound state. The cycle between GDP and GTP binding is controlled by guanine nucleotide exchange factors (GEFs) that promote the transition from a GDP- to a GTP-bound state. This is reversed by guanosine triphosphatase (GTPase)-activating proteins, which stimulate GTPase activity of Ras and result in hydrolysis of GTP to GDP. The balance between GEFs and GTPase-activating proteins regulates Ras activity ([334]). The most likely pathway of ras activation is through the adapter protein Shc, which is phosphorylated after BCR engagement. Shc binds to a second adapter protein Grb-2, which in turn binds to Sos, a nucleotide exchange factor. This multimolecular complex is associated with the membrane ([335], [336]). A guanine nucleotide exchanger protein, Vav, with selectivity for Ras, is recruited to the phosphorylated Tyr341 and Tyr345 of Syk through its SH_2 domain and is, subsequently, phosphorylated in B cells ([337]). Vav is a GEF in the Rho family for GTPases. These Ras-like proteins are molecular switches that are active in the GTP-bound state and can promote site-specific actin polymerization to create alterations in plasma membrane structures such as filopodia and lamellipodia. Vav has a Dbl homology domain, which has the GEF activity, a PH domain (binds phosphoinositides), and SH_2 domain, and two SH_3 domains. The PH domain of Vav uses PIP_3 for recruitment to the cell membrane. Vav may also be recruited to the membrane by binding to Tyr391 of CD19. A negative regulator of the ras pathway is Cbl, which competes for the binding to Sos. Cbl (*c*asitas *B*-linage *l*ymphoma) is the cellular homolog of v-Cbl, part of the transforming gene of the Cas-NS1 retrovirus, a murine virus, capable of causing pre-B cell lymphomas. It contains a proline-rich region (residues 481 to 688), a leucine zipper motif (residues 855 to C-terminus), and multiple potential SH_2 binding motifs. It binds to PTKs such as Fyn, ZAP-70, and Btk, to the adapter molecule Grb2, and to PI3K ([338]). In B-cell signaling, Cbl binds to BLNK through its SH_2 domain and inhibits association of PLC-? $_2$ phosphorylation ([339]). Binding of Sos and Cbl to Grb-2 is mutually exclusive because the proline-rich domains of these proteins compete for the same SH_3 domain of Grb2. A group of signal transduction pathways is characterized by successive phosphorylations of serine/threonine kinases. This group consists of a mitogen-activated protein kinase (MAPK), a MAPK kinase (MAPKK), and a MAPKK kinase (MAPKKK). Ras-GTP phosphorylates Raf-1, which is the MAPKKK of this cascade. Raf-1 phosphorylates and activates MEK1 and MEK2, which in turn phosphorylates ERK1 and ERK2. Phosphorylated ERKs form dimers and are translocated to the nucleus where they phosphorylate transcription factors c-fos and Jun members of the Ets family.

ADAPTER MOLECULES: SIGNALING PLASTICITY AND DIVERSITY

Adapter proteins possess domains mediating protein-protein or protein-lipid interactions, but have no enzymatic activity. Two groups of adapter proteins can be identified: transmembrane adapter proteins and cytosolic adapter proteins (CAPs). In general, adapter proteins assemble multimoleculear signaling complexes and direct their formation to specific cellular locations ([340], [341], [342], [343] and [344]). At the initial stages of B-cell activation, Lyn, Syk, and Btk kinases are activated. A transmembrane adapter protein, PAG (*p*hosphoprotein *a*ssociated with *g*lycosphingolipid-enriched microdomains), links Lyn to the kinase that phosphorylates the C-terminal tyrosine for Lyn activation. The CAP adapter protein BLNK (SLP-65) connects Btk to Syk and brings PLC-? $_2$ on the lipid rafts. There are inhibitors for adapter proteins, such as IBtk, which binds to the pleckstrin domain of Btk and negatively regulates its activation. BLNK is directly associated with Iga/Igß co-receptors connecting several important molecules to BCR for the initial stage of signaling. BLNK is indispensable for LMP2A (latent membrane protein), a constitutively activated EBV protein in infected B cells. LMP2A signaling can substitute for the signaling of BCR and maintains survival of EBV infected B cells, leading to infectious mononucleosis or Burkitt lymphoma. The CAP BLNK is clearly required for the translocation of PLC? $_2$ from the cytosol to the plasma membrane

and its subsequent activation. BLNK is critical for assembling the signaling complex for Ca^{2+} increase.

B-CELL SIGNALING THROUGH ACCESSORY STRUCTURES

Many other cell-surface molecules participate in B-cell signaling. The co-receptor complex CD19/CD21 activates the CD19-associated PTKs, which induce phosphorylation of tyrosine residues on CD19 motifs ([345]). These then become potential SH_2 binding sites for PI3 kinase, which generates phosphoinositides. Recruitment of PI3K to CD19 requires phosphorylation of Tyr484 and Tyr515. Activation of PI3K generates PIP_3, which functions to localize Btk to the plasma membrane where it is phosphorylated and activated by Src and Syk kinases. BCR activation of Btk is dependent on CD19 expression, whereas activation of Lyn and Syk is not ([346]). PLC activation generates DAG, which activates PKC, and 1,4,5-triphosphate, which increases cellular Ca^{2+} ([345]). CD22 is associated with BCR, which on engagement phosphorylates some of the six tyrosines of CD22. This in turn leads to recruitment of SHP-1 via its SH_2 domain to CD22 ([347]). CD22 contains ITAMs and four immunoreceptor tyrosine-based inhibition motifs (ITIMs) in the cytoplasmic region. PI3K and PLC-? $_1$ associate with CD22 through the YXXM motif recognized by the N-terminal SH_2 domain of the p85 subunit of PI3K, whereas the protein tyrosine phosphatase SHP1 binds to ITIMs. As a result of multiple ITIMs, CD22 is probably a negative regulator of B-cell activation. (For more details, see CD22 in Chapter 2.)

INTERLEUKIN-4

Although several cytokines act on B cells, the action of IL-4 was first demonstrated on B lymphocytes, and on these cells IL-4 evokes the strongest reactions. IL-4 binds to a transmembrane receptor and results in cross-linking with another protein termed *common gamma chain* (?c), which is shared by other cytokines ([348], [349] and [350]). Mutations in ?c chain results in X-linked SCID, an inherited disease with profound suppression of cell-mediated and humoral immunity ([351], [352]). IL-4 binding induces phosphorylation of a substrate of 170 kd designated as *4PS*, which is unique because no other cytokine except IL-13 binding phosphorylates a similar substrate. However, insulin and insulin growth factor-1 result also in 4PS phosphorylation. 4PS is structurally similar to insulin receptor substrate-1 (IRS-1). The gene for 4PS has been cloned and is called *IRS-2*. IRS-1/2 contains more than 20 potential tyrosine phosphorylation sites and 30 potential threonine/serine phosphorylation sites. The tyrosine phosphorylation sites bind with high affinity to cellular proteins possessing SH_2 domains and thus act as docking sites for several signal-transducing proteins such as PI3 kinase and growth factor receptor-bound protein 2 (Grb2). Mutational analysis has mapped a region of the IL-4R between amino acids 437 and 557, which is important for IRS-1 phosphorylation and therefore signal transduction ([353]). This region contains a single tyrosine, is shared by the IL-4 receptor (IL-4R) and the insulin receptor, and is known as *I4R motif*.

Although the insulin receptor and IL-4R have many similarities, they have an important difference. The insulin receptor is a receptor tyrosine kinase, whereas the IL-4R and ?c are not, but are associated with non-receptor PTKs. Association of IL-4R and ?c activates kinases associated with IL-4R, which then phosphorylates the tyrosine in the I4R motif. This allows 4PS to bind to the IL-4R and be phosphorylated by the kinases associated with the IL-4R. The phosphorylated motif I4R interacts with the PTB domain of IRS1/2. PTB domains are found in adapter proteins, such as Shc, and bind phosphopeptides. IRS1/2 becomes phosphorylated as a result of interaction with IL-4Ra receptor and binds to the p85 subunit of PI3K, which as an adapter links IRS1/2 to the catalytic subunit p110. PI3K is activated as a result of conformational changes, acts on phosphatidylinositol of the cell membrane, and transfers phosphate groups from adenosine triphosphate to the D_3 position of inositol-generating PIP_3 and phosphatidylinositol 3,4, biphosphate. The phosphoinositides act on downstream kinases (i.e., PKC and Akt) that make important contributions to cell survival. Activation of the IRS1/2 signaling proteins is associated with activation of the ras/MAPK pathway (see Ras Pathway).

IL-4R is also associated with the Janus kinases (or JAKs) ([354], [355]). The a chain binds to JAK1, whereas the ?c chain binds to JAK3. The receptors bind to these kinases through their membrane proximal domains, which are known as box 1 and box 2 motifs and have some similarity among cytokine receptors.

The sequence between residues 557 and 657 of the a chain (known as the *gene regulation domain*) is critical for expression of IL-4 responsive genes. It contains three conserved Tyr residues (Y575, Y603, and Y631), which can potentially be phosphorylated and thus be able to associate with SH_2 domains. IL-4 utilizes the STAT-6 member of the transcription factor family known as *STATs* (*s*ignal *t*ransducers and *a*ctivators of *t*ranscription) ([356]). IL-4–responsive genes include class II HLA, CD23, germ-line Ige and ? $_1$ chains and IL-4Ra chain ([357]).

Engagement of IL-4R results in the activation of JAK1 and JAK3, which phosphorylate tyrosines of the cytoplasmic region of the receptor. STAT-6 binds through its SH_2 domains to the phosphorylated tyrosines and becomes itself phosphorylated at its C-terminus by the activated JAK kinases. The phosphorylated STAT-6 dimerizes and binds to promoters of the IL-4–responsive genes ([358]). (See Chapter 18 for more on IL-4.)

INTERLEUKIN-5

The a chain of IL-5R is a type I membrane protein of 415 amino acids, its extracellular region comprising three sets of fibronectin type III domains, whereas the intracellular domain does not contain sequences of tyrosine kinase but shows homology with a part of the actin-binding domain of ß-spectrin ([359]). It also has a region rich in prolines conserved among receptors of other cytokines (e.g., IL-3, granulocyte-macrophage colony-stimulating factor receptor or CD116; see Chapter 2).

A second ß chain is important for signal transduction, but it does not contribute to IL-5 binding. A membrane proximal region contains a conserved box 1/box 2 motif that is responsible for the interaction with JAK2, and the distal domain is responsible for the activation of the ras-related pathways. IL-5 signaling increases Btk activity.

INTERLEUKIN-6

IL-6 is a pleiotropic cytokine that, among many other functions, is involved in terminal differentiation of B cells ([360], [361] and [362]). The extracellular region of the IL-6R consists of one constant region domain of the Ig superfamily and two fibronectin type III domains, which have four conserved cysteine residues and a motif containing two tryptophans and two serines. This motif is located in a groove between the two fibronectin domains. The intracellular domain is short and is not involved in signal transduction. Associated with the IL-6R is a protein known as *gp130*, which dimerizes when IL-6 binds to the IL-6R. The gp130 protein is shared by other cytokine receptors and initiates signal transduction. Homodimerization of gp130 induces activation of JAK kinases, which are associated with the membrane proximal region of gp130, known also as *box 1*. This leads into phosphorylation of a tyrosine in the distal part of gp130 (box 3), resulting in binding through an SH_2 domain of the transcription factor STAT-3, previously known as *acute phase response factor* or *APRF*. JAK kinases activate STAT-3 by phosphorylation.

Another nuclear target for gp130 signaling is the transcription factor NF-IL-6 with a leucine zipper motif. This factor is inducible in hepatocytes and monocytes by IL-6 and other cytokines and mediates the expression of IL-6–inducible genes. NF-IL-6 has a consensus sequence for MAP kinase, suggesting that it is activated through this pathway, which is ras-dependent. (For further details, see Chapter 18.)

CD40

CD40 is a member of the tumor necrosis factor receptor family, which interacts with its ligand, CD154, expressed on T cells. [See CD40 and CD40 Ligand (CD154) Interactions in Chapter 18.] Signal transduction by CD40 is mediated by certain proteins that bind to its cytoplasmic region and are known as *TRAFs* (*t*umor necrosis factor *r*eceptor *a*ctivation *f*actor). (See Chapter 2, CD40.) Engagement of CD40 by its ligand activates the Src kinases Lyn and Fyn and Btk. Signaling follows the Ras pathway via the nucleotide exchanging factor SOS, leading to JNK and ERK activation ([350]). The functional outcome of CD40 depends on the state of activation of B cells and the intensity of stimulation. On naïve B cells, it induces proliferation and Ig production, but on memory cells, it induces apoptosis. CD40 activation induces homotypic adhesion of B cells mediated by CD54 (intercellular adhesion molecule-1)–CD11/CD18 (LFA-1), or CD23–CD21. The functional outcomes depend on the type of TRAFs that are associated with CD40. For example, trimers of TRAF-2 mediate apoptosis, whereas trimers of TRAF-6 or TRAF-5 mediate proliferation ([363]). Germinal center formation and Ig class switch are hallmarks of T-cell–dependent responses, and TRAF-6 plays a role in class switch (see Chapter 18).

POLYCLONAL ACTIVATION

Certain substances can activate B lymphocytes independent of their antigenic specificity. The response to these substances involves all B-cell clones, and, for this

reason, these substances became known as *polyclonal B-cell activators* (PBAs).

PBAs are primarily microbial cell constituents such as lipopolysaccharide (LPS), purified protein derivative, staphylococcal protein A, streptolysin O, pneumococcal polysaccharide III, a water-soluble antigen from *Nocardia*, and EBV ([364]). Other PBAs often used are dextrans, polyvinyl pyrrolidone, and the extract of a poisonous plant, *Phytolacca america'na*, pokeweed mitogen. PBAs can be separated into two categories on the basis of their need for T cells; some, such as pokeweed mitogen, are T-cell–dependent, whereas others, such as EBV, are T-cell–independent. An optimal number of macrophages (accessory cells) is also necessary for the function of some PBAs, but in large numbers, they exert a suppressive effect.

PBAs can be categorized also on the basis of their effect on B lymphocytes. Some PBAs promote B-cell proliferation only, whereas others, in addition, stimulate Ig secretion. There are species and organ differences in the response of B lymphocytes to PBAs.

In studies involving the use of PBAs, the T to B cell ratio is critical in Ig secretion ([364]).

For several years, LPS has been used experimentally as PBA, but only recently was its receptor shown to be the CD14 molecule ([365]). LPS binding to CD14 is enhanced in the presence of a plasma protein, LPS-binding protein ([366]). CD14 is primarily expressed on monocytes and granulocytes. Its structure, function, and role in human disease has been reviewed ([367]). (See more in Chapter 2, CD14.)

MORPHOLOGIC CHANGES ASSOCIATED WITH B-CELL DIFFERENTIATION

Plasma Cell

Elegant studies of morphologic differentiation in immunized animals at the ultrastructural level were performed by Harris et al., who isolated individual cells involved in antibody synthesis ([368]) (Fig. 16.13). These authors showed that antibody production is detected while the cell still retains a “lymphocytic” morphology and contains no ER. These cells can be differentiated from inactive lymphocytes by the abundance of free polyribosomes and a large nucleolus. A spectrum of cells actively secreting antibody can be ranked according to the size and development of their ER ([369], [370], [371], [372] and [373]). During early differentiation, the ER is scarce and unorganized. Later, the lamellae increase in length and become parallel until they fill the entire cytoplasm and give rise to its onion-skin appearance. The Golgi apparatus increases concomitantly. No dividing line exists that distinguishes the cells that make IgM from those that make IgG antibody, although a preponderance of IgM producers with lymphocytic morphology and of IgG producers with plasmacytic morphology is noted ([369], [374]).

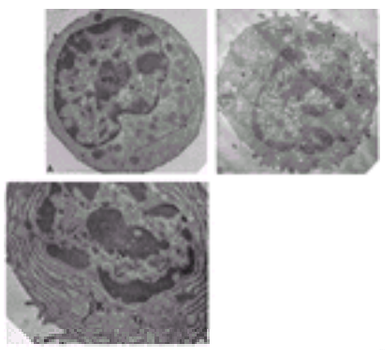

Figure 16.13. Morphology of antibody production. Terminal B-cell differentiation (antigen-dependent) is characterized morphologically by the gradual increase of the amount of cytoplasm and, concomitantly, the appearance of strands and eventually well-organized endoplasmic reticulum. **A:** An antibody-producing lymphoid cell with sparse endoplasmic reticulum *(ER).* (From Harris TN, Hummeler K, Harris S. Electron microscopic observations on antibody-producing lymph node cells. J Exp Med 1966;123:161–172, with permission.) **B:** Endoplasmic reticulum *(ERVS)* is slightly distended, containing amorphous material. (From Hummeler K, Harris TN, Tomassini N, et al. Electron microscopic observations on antibody-producing cells in lymph and blood. J Exp Med 1966;124:255–262, with permission.) **C:** Mature plasma cell displaying well-organized ER and distinct Golgi apparatus *(G)*. (From Gudat FG, Harris TN, Harris S, Hummeler K. Studies on antibody-producing cells. I. Ultrastructure of 19S and 7S antibody-producing cells. J Exp Med 1970;132:448–474, with permission.) M, mitochondrion; N, nucleus; NOS, nucleolus; NU, nucleus. (Figures A, B, and C, reproduced from J Exp Med, as cited, by copyright permission of the Rockefeller University Press.)

The term *plasma cell* was first used by Waldeyer in 1875 ([375]). His description, however, included several types of cells, and in 1881, Unna ([376]) redefined the cells as he observed them in a case of lupus, emphasizing the characteristic basophilia of the cytoplasm (“granuloplasm”). In a subsequent report ([377]) containing pictures of methyl green- and pyronin-stained cells, several cells are identified easily as characteristic plasma cells. In 1895, Marschalko took issue with Unna's description and emphasized that the appearance of the nucleus with its characteristic arrangement of angular chromatin blocks and its eccentric position within the cell are to be used as stringent criteria for the identification of plasma cells ([378]). The characteristic nuclear morphology was given the name *radkern* by Pappenheim. Early analytic reviews of plasma cells were provided by Downey ([379]) and later by Michels ([380]). In those early years, whether the plasma cell was a normal constituent of tissues was the subject of considerable debate. Its origin was disputed, but several prominent investigators believed that it originated from lymphocytes.

The modern period of plasma cell study was introduced in 1937 by the clinical observations of Bing and Plum, who noted the close association of hyperglobulinemia and the presence of plasma cells ([381]). Subsequent studies in hyperimmunized rabbits were carried out by Bjornboe and Gormsen ([382]), who demonstrated that antibody production correlated with massive plasma cell proliferation in the spleen. In his doctoral thesis, Fagraeus ([383]) left little doubt about the importance of plasma cells in antibody formation. Differences among animals in their capacity to produce antibody could be related to differences in the number of plasma cells, particularly immature plasma cells. Fagraeus thought that mature plasma cells had “passed the stage of their greatest functional intensity.”

Indisputable evidence in favor of antibody production by plasma cells was provided by Coons, who introduced the powerful technique of immunofluorescence to immunology ([384], [385]). Plasma cells containing antibody were detected in the red pulp of the spleen, the medullary cords of the lymph nodes, and focal granulomata of immunized animals. Excellent detailed descriptions of the morphology and ultrastructure of plasma cells have been published ([386], [387], [388] and [389]).

The plasma cell is round or oval with an eccentrically located nucleus and chromatin arranged in pyramidal blocks against the nuclear membrane, giving the characteristic “cartwheel” appearance (Fig. 16.14). The cytoplasm is intensely basophilic because of the high content of ribonucleoprotein. Certain plasma cells stain red to violaceous rather than blue and are known as *flaming plasma cells*, a name coined by Undritz. This coloration is attributed to the accumulation within the ER cisternae of Ig with a high carbohydrate content. Electron microscopic studies revealed that the nucleus is surrounded by a double membrane. The outer membrane is covered with ribonucleoprotein particles and is continuous with the cytoplasmic ER. The Golgi is well developed and consists of vesicles and tubules. The centrosome lies next to the nucleus surrounded by the Golgi apparatus. Several microtubules radiate from the centriole. Many prominent mitochondria are scattered between the ER lamellae. A striking ultrastructural feature of the plasma cell is the rich and well-organized ER. It consists of membranes studded on one side by ribosomal particles and arranged in parallel arrays. In the mature plasma cell, the ER fills the entire cytoplasm. The cisternae are sometimes distended with granular or homogeneous material, giving rise to cytoplasmic inclusions known as *Russell bodies* ([390]). The Russell bodies are composed of Ig ([390], [391]), although sometimes Ig cannot be demonstrated ([392]). One suggestion is that these inclusions are not made from Ig aggregates. Alternately, the Ig is condensed to such a degree that it cannot be penetrated. Russell bodies sometimes are detected within the nucleus (intranuclear inclusions). Under certain circumstances, the plasma cell contains large quantities of a homogeneous material that distends the cell and stains gray or sometimes red as in the flaming cells. These cells, called *thesaurocytes* ([393]), reveal, under electron microscopic analysis, dilation of the ER cisternae ([394]) (Fig. 16.15). The flaming cell likely represents an early stage of the thesaurocyte in terms of storage of synthesized Ig ([395], [396]). Two lines of evidence suggest that these forms are the result of disturbances in the secretion of Ig. In nonsecretory myelomas, the cells often are similar to thesaurocytes ([397], [398] and [399]) or flaming plasma cells ([400]). Mott cells, which are considered plasma cells with multiple Russell bodies, also can result from a complete or partial block in the secretion of Ig causing localized distention of ER cisternae ([401]).

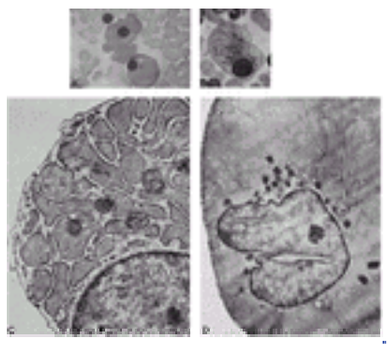

Figure 16.15. Unusual forms of plasma cells. Under certain circumstances related to immunoglobulin (Ig) secretion, the cisternae of endoplasmic reticulum are distended as a result of the accumulation of Ig. Plasma cells with accumulation of a homogeneous material that sometimes stains pink or red on Giemsa preparations (thesaurocytes). **A**, **B:** Giemsa stain of bone marrow from two patients with IgA myeloma. Cell in **A** is bright red; that in **B** stains bluish-gray. **C**, **D:** Ultrastructure of thesaurocytes with different degrees of distention of the cisternae of the endoplasmic reticulum. (From Bessis M, et al. Étude comparée du plasmacytome et du syndrome de Waldenstrom. Nouv Rev Fr Hematol 1963;3:159, with permission.)

The most immature plasma cell is the plasmablast. It has a nucleus with evenly dispersed chromatin and a large nucleolus. The ER is sparse, and the cytoplasm is filled with clusters of polyribosomes. As the cell matures, the chromatin forms clumps, and the ER becomes more abundant and well organized. As typical lymphocytes mature into plasma cells, they pass through intermediate stages. These cells are evident in the blood of patients who have plasma cell dyscrasias or immunologic diseases characterized by hypergammaglobulinemia. Similar cells sometimes are encountered in the blood of patients with viral infections (Turk cells), including infectious mononucleosis. The intermediate forms have blue cytoplasm with abundant ER, but not as much as that seen in mature plasma cells. Some intermediate forms resemble the less mature transformed lymphocytes with simple ER and many ribosomes and polyribosomes.

B-Cell Differentiation: Plasma Cells

Plasma cells down-regulate a large number of cell-surface molecules, such as BCR, Major Histocompatibility Complex class II, CD19, and CD20. Plasma cells express the cell-surface molecule Syndecan-1 (CD138) and, strongly, CD38. Differentiation of plasma cells requires the transcription factor Blimp-1, which is a transcriptional repressor (402). Blimp-1 represses c-myc transcription, which explains cessation of cell cycle in plasma cells, as well as represses Pax5, which is required for lineage commitment of B-cell development and for isotype switching in germinal centers. Down-regulation of Pax5 is necessary for development of antibody-producing cells because it represses XBP-1, J chain, and Ig heavy chain gene transcription (403). Blimp-1 promotes plasmacytic differentiation by extinguishing expression of genes important for BCR signaling, germinal center function, and proliferation, but allows expression of XBP-1 (389). XBP-1 is the only transcription factor required specifically for terminal differentiation of B lymphocytes to plasma cells (404). XBP-1 (X-box–binding protein) is a basic-region leucine zipper protein essential for the growth of hepatocytes and has been implicated in the proliferation of malignant plasma cells (405).

A small subpopulation of germinal center cells in the light zone express Blimp-1, which functions upstream from XBP-1 (406). These cells have survived the selection and are probably destined to become plasma cells. Blimp-1 represses BCL-6, a germinal center–restricted transcriptional repressor required for germinal center function. A negative feedback loop operates in the germinal centers between Blimp-1 and BCL-6. When BCL-6 is expressed, Blimp-1 expression and plasma cell differentiation are blocked. However, Blimp-1 activation represses BCL-6, and plasmacytic differentiation is irreversible. (See also Chapter 18.)

Molecular and Ultrastructural Aspects of Immunoglobulin Biosynthesis

Knowledge regarding the biosynthesis, assembly, and secretion of Ig has been derived from studies involving normal lymphoid organs, mouse plasmacytomas, human tumors, and cell-free systems (407 , 408). The bulk of Ig is made on membrane-bound ribosomes.

Heavy (H) and light (L) chains are synthesized separately, the H chain on large 270S to 300S polyribosomes composed of 16 to 20 subunits, the L chains on smaller 190S to 200S polyribosomes composed of 7 to 8 subunits. The size of these polysomes is such as to suggest synthesis of each chain as a single unit. Under normal conditions, L chains may be synthesized in slight excess.

After separate synthesis of H and L chains, intramolecular folding and assembly of the individual chains begins on nascent proteins, but the assembly is completed primarily after the release of polypeptide chains from the ribosomes into the cisternae of the ER. Depending on the Ig class, the assembly begins with the formation of the H-L half molecules, two of which then combine to form a complete Ig monomer. Alternately, two H chains combine to form H2 followed by H2L, suggesting that the final H2L2 structure may be reached by several pathways (407 , 408). Assembly of H chains is restricted between chains of the same class so that dimers between different H chain isotypes are not formed in cells expressing both. In most instances, polymeric Ig, such as IgM (19S) and IgA (9S, 11S, 13S), are assembled intracellularly from their constituent subunits, but results of a few studies suggest that assembly occurs at the time of secretion or extracellularly (409).

The attachment of core oligosaccharides to the N glycosylation acceptor site begins on the ribosome, but glycosylation is completed in the Golgi apparatus where the polypeptides are transported from the ER (410). The Golgi apparatus is also the site of final processing of the carbohydrate (411) and where the molecule is attached to membrane and then packaged into vesicles for secretion or incorporation into the plasma membrane (411). This mechanism of secretion is a form of reverse pinocytosis. Disruption of the traffic of the vesicles containing Ig inhibits Ig secretion.

The carbohydrate moiety may facilitate the secretion of Ig by the cell, although this effect depends on the Ig class and the amount of Ig synthesized. For some classes, such as IgM, Ig secretion is blocked when glycosylation is inhibited. H chains that have not assembled with L chains form complexes with an H-chain–binding protein (BiP) (412 , 413). BiP prevents transportation of H chains to the Golgi complex until they become associated with the L chains that displace BiP. The presence of such complexes provides an explanation for the lack of secretion of μ chains in pre-B cells when L chains are not available. In contrast to the normal situation, free H chains are secreted in association with certain lymphomas such as H-chain disease (414 , 415). In these disorders, the H chains have a large deletion involving the CH1 domain (416). This deletion explains how these mutant chains can be secreted in that complexes with BiP can be formed only through the CH1 domain (417 , 418).

Although the synthesis of L chains and H chains takes only 30 and 60 seconds, respectively, the addition of carbohydrates and the process of secretion take at least 30 minutes. An adult synthesizes approximately 2.3 g of Ig daily (419 , 420).

Most Ig-synthesizing cells contain one type of H chain and one type of L chain ([421], [422]), but a few cells (usually less than 1%) contain more than one type of H chain, usually μ and ?.

The ultrastructural aspects of Ig and antibody formation have been elucidated through elegant studies by Avrameas et al., who used immunoenzyme techniques ([423], [424], [425], [426], [427] and [428]).

Antibody first appears in the perinuclear cisternae ([426]) and eventually is detected in the rest of the ER ([426], [429]) (Fig. 16.16). Activation of the ER cisternae is gradual, because not all of them within the same cell contain antibody at any one moment ([426]). Antibody is found in association with the ribosomes of ER and is not detected outside the ER cisternae. In most immature blasts with a sparse or nonexistent ER, antibody is present in the cytoplasm, presumably synthesized on polyribosomal clusters. Not only the intracellular distribution but also the rate of synthesis increases with time, and Ig, in some cases, distends the cisternae, forming large spheric masses reminiscent of Russell bodies. Not all plasma cells contain antibody during the primary response. In the first 2 to 3 days after immunization, most of the plasma cells contain Ig that has no antibody activity ([430], [431]). Antibody-containing plasma cells appear later in the response. In neoplastic myeloma cells, Ig also is located within the ER cisternae ([432]). Not all cisternae are active in Ig synthesis within the same cell. Throughout plasmacytic differentiation, the Golgi apparatus always contains antibody.

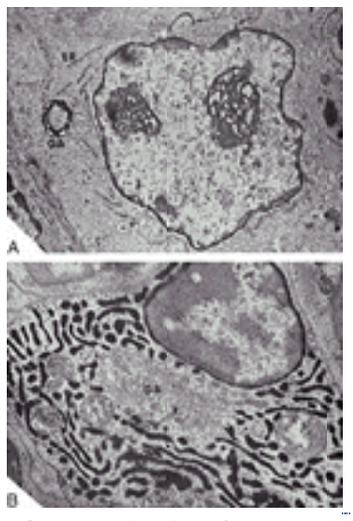

Figure 16.16. Ultrastructural localization of antibody. **A:** An immature plasma cell demonstrates antibody primarily in the perinuclear area. Antibody is also detected in the few strands of endoplasmic reticulum *(ER, arrows)* and the Golgi *(GA)* apparatus. **B:** Plasma cell with well-developed endoplasmic reticulum filled with antibody. Both cells were isolated from rabbits immunized with peroxidase. For the intracellular localization of the antiperoxidase antibody, the cells were treated with peroxidase before incubation with diaminobenzidine. (From Leduc EH, Avrameas S, Bouteille M. Ultrastructural localization of antibody in differentiating plasma cells. J Exp Med 1968;127:109–118. Reproduced by copyright permission of the Rockefeller University Press.)

Global Gene View of B-Cell Activation and Differentiation

The history of the lymphocyte as discussed in the previous section (Plasma Cells) evolved during the entire length of the twentieth century through four distinct stages: (a) microscopic morphology (late 1800 to 1940); (b) ultrastructural morphology (linking lymphocyte to plasma cell and antibody production) (1940 to 1960); (c) distinction of lymphocytic lineages, T and B [first by functional assays, middle 1960s, and then by cell-surface markers after the Nobel prize–winning discovery of monoclonal antibodies (1975) by Köhler and Milstein] ([433]) (immunophenotypic period); and (d) molecular genetics, ushered in by a second Nobel prize–winning discovery by Tonegawa ([106]).

The Ig gene is assembled from multiple gene segments, and every B cell is characterized by its own unique rearrangement [see V(D)J Recombination] maintained throughout its life and is transferred to all the members of its progeny when it forms a clone of antibody-producing cells, with idiotypes characteristic of the parent B cell.

Malignancies arise from one cell, therefore are monoclonal, and inherit this unique Ig rearrangement. However, in any normal cell, other genes are activated in support of its function, but it has not been possible to identify these genes, because it was not known what to look for.

The new technology of “gene profiling” enables identification of the genes that are activated and, very likely, characteristic of each stage in the life of the B cell. This technology has already been applied on normal B cells to characterize their genetic profile at various functional states. It is hoped that gene profiling will promote the understanding of genes individually or in groups expressed in each stage and identify the functional stage of the malignant transformation. Most of the work on genes in the past was done by the identification of the role of changes in individual genes, one at a time, with correlation of these changes to the function in question. This has been compared to “examining a few pixels” in an attempt to “understand a movie” ([434]).

Gene profiling inspects activation and gene transcription of hundreds or thousands of genes, providing a global “genomic” view. In contrast to gene sequencing (“structural genomics”), gene profiling is considered a new field of “functional genomics.”

Several methods were developed in the 1990s to examine expression of genes on a large scale. One that applies serial analysis of gene expression (SAGE) uses gene-specific 14-bp sequence tags for enumeration of genes expressed in a cell ([435]). In the new methods, DNA fragments from individual genes are placed on a solid support in an ordered array. Total cellular mRNA isolated from cells is used to generate by reverse transcription cDNA probes, which are tagged by a radioactive or fluorescent probe. The cDNA probes are then applied to the arrays for hybridization with the DNA on the array. The hybridization results are quantitated by phosphorimagers for radioactive probes or a scanning confocal microscope for fluorescent probes. In one commonly used microarray system, oligonucleotides are produced by *in situ* synthesis in a technique called *photolithography* and are hybridized by fluorescent cDNA probes ([436], [437]). In another technique, PCR products from cDNA clones are spotted onto coated glass slides ([438], [439]). In this technique, two cDNA probes from different samples, labeled with different fluorochromes (usually Cy3 or Cy5), are applied on the microarray simultaneously for hybridization. The expression for each gene is evaluated by the ratio of the fluorescence, and interpretation of data uses algorithms. Various analytical tools are available, and no single tool is better than others. Their use may well depend on the experimental design and the questions asked ([440], [441]).

One approach uses hierarchical clustering ([442]). This algorithm begins by clustering pairs of genes with most similar pattern of expression, eventually building larger and larger clusters. Clustering may be unsupervised (i.e., the arrangement of gene expression follows predefined parameters built in the algorithm). In supervised clustering, the investigator introduces other parameters such as clinical data. Several algorithms have been designed for data analysis, and more than one may be necessary for the analysis.

Three B-cell functional states were evaluated in an experimental model: naïve B cells, B cells activated *in vitro* by a foreign antigen (hen egg lysozyme, HEL), and B cells tolerant against self. In this case, B cells were obtained from transgenic mice (i.e., expressing HEL from birth); therefore, the B cells have developed tolerance against HEL as for any other natural self-antigen ([443], [444]).

The results show that the naïve or resting state is maintained by several inhibitory genes, whereas activation is associated with loss of expression of some of the inhibitory genes rather than induction of genes that regulate entry into the cell cycle. B cells tolerant to “self” are characterized by increasing expression of more inhibitory genes at the same time that they maintain the expression of the basal inhibitory gene profile.

Some other data reveal that the gene profile of *in vitro* activated B cells differs from that of germinal center B cells where they are activated by T cells ([434]). Germinal

center B cells actually differ from naïve B cells in the expression of hundreds of genes ([445]). The function of signaling molecules has been studied by inactivation of the appropriate gene, but this approach does not provide the total picture. Repercussions from changes in the expression of other genes cannot be heard. An attempt was made to provide an answer to this question from the effect of reduction of the function of PI3K or Btk to other genes. Reduced function of PI3K or Btk significantly affected 5% of BCR-dependent gene expression ([446]). The data also suggested that PI3K acts through Btk in regulating genes critical for determining entry into the cell cycle.

By hierarchical clustering, it has been possible to identify groups of genes characteristic of a lineage or a specific stage of differentiation or proliferation (i.e., germinal center B cell). Each group of genes defines a “signature” of a cell type or of a function, etc.

Plasma cells, which represent the end stage of B-cell differentiation, were found to have 1476 known genes, which were differently expressed as compared to B cells ([447]). A number of factors characteristic of terminal differentiation (i.e., related to RNA polymerase I) were down-regulated, while a number of transcription factors were maintained (e.g., AP-1, NFAT, and NF-?B). Two genes for factors associated with neuronal cell positioning, reeling and neuropilin-1, were unexpectedly expressed. Their role in plasma cell life remains to be determined.

A large body of data has already been collected in the short period since this technology was developed for large-scale application. The early findings in B-cell malignancies hold a number of unexpected results ([448]). Diffuse large B-cell lymphomas (DLBCLs) have been shown to have two different gene profiles ([448]). In one group of patients, the cells had a germinal center gene profile, whereas in the second group, the lymphoma cells showed a profile of mitogenically activated B cell. These two groups also differ in several other genes. DLBCL with the germinal center B-cell profile has retained the hypermutation machinery, but not the second group, resembling mitogenically activated B cells ([449]). Germinal center B-like DLBCL also closely resembles follicular lymphoma ([450]). On the basis of sharing some gene expressions with a small population of B cells within the germinal center as well as with plasma cells, it has been suggested that the activated B-like DLBCL may arise from a cell in its transition of becoming a plasma cell.

Another important finding so far is the possibility that B-CLL, which, phenotypically, has been separated into two groups on the basis of CD38 expression, may actually be one “genomic” disease with two variants ([451]). A small number of less than 30 genes may, however, be able to distinguish cases with IgV mutated versus unmutated profiles ([452]). Furthermore, the gene profiles have indicated that in the majority of cases, the cells are related to memory B cells rather than naïve B cells or B cells of any other category. This may not be unexpected, because the somatic hypermutation machinery is active in CLL and could play a role in intraclonal diversification development ([453]). Microarray gene profiling has been used to identify B-CLL cases with cells resistant to apoptosis after DNA damage. Thirteen of 16 genes were found specific for resistant B-CLL cells ([454]). A study of mantle cell lymphoma also detected resistance to apoptosis gene profiling. The FADD gene, a key gene associated with Fas mediated apoptosis, was down-regulated tenfold in this lymphoma ([455]).

In multiple myeloma, the profiling suggests a classification into four subgroups ([456] , [457]). Group 1 patients (MM1) have a gene profile similar to MGUs, whereas the patients in MM4 group have poor prognosis with a gene profile similar to myeloma cell lines. Numerous unaccounted genes with “unknown” function have been detected so that only 10% of all these genes have matched entries in the database Expressed Sequence Tags ([458]).

The origin of Hodgkin and Reed-Sternberg (HRS) cells have remained elusive, and, recently, strong evidence has been presented that in most cases with this disease, the cell is of B-lineage origin and only rarely originates from a T cell ([459]). Identification of gene profiling demonstrated that the HRS cell expresses a distinct gene profile irrespective of its B- or T-cell derivation. The gene profile is similar to that of EBV-transformed B cell or cell lines from large cell lymphomas with features of *in vitro*–activated B cells ([460]). Among the genes specifically identified in HRS are a cluster of genes for transcription factors (i.e., GATA-3, ABF-1, EAR3, and Nrf3). Down-regulation of several genes that are active in B cells were identified. Several of these genes are positively regulated by the transcription factor Pax5 [see Stem Cell to Progenitor B (Pro-B) Cell]. However, the Pax5 gene is still expressed in HRS cells, and, therefore, the loss of B-cell specific gene expression remains unknown ([461]).

Btk mutations influence the expression of other genes in EBV-transformed cell lines, and, in the absence of functional Btk, 11 genes were identified that were induced more than 1.9-fold ([462]).

Microarray gene profiling has been applied to develop a molecular predictor of survival after chemotherapy for DLBCL. The study used 17 genes to construct a predictor of overall survival ([463]). Four gene groups were identified and clustered within individual signatures. The proliferation signature was the best predictor for adverse outcome. Signatures identifying good prognosis were the lymph node signature, encoding extracellular matrix, and the connective tissue growth factor, which promotes fibrosis and synthesis of extracellular matrix. Some of these genes are linked to histologic or other lymph node reactions, known already for their favorable prognosis. For example, the lymph node signature is associated with expression of genes also expressed in macrophages and NK cells, presumed to indicate a cellular antitumor response. The other favorable signature is the major histocompatibility complex class II gene expression.

B-Cell Subpopulations

A subpopulation of B cells can be detected on the basis of expression of the CD5 antigen ordinarily present on T cells. The CD5 antigen (formerly T1 or Leu1) is a 67,000-d gp detected on all normal T cells ([464] , [465]), on a small subpopulation of normal B cells ([466]), and on all cells from patients with CLL ([467] , [468] and [469]). The CD5 B cells possess unique properties. They are phenotypically identical to CD5 $^{-}$ B cells ([470]), but they are larger; in mice, they have ten times more mIgM with ? chains, which is expressed only rarely in mice. The CD5 $^{+}$ B cells are present in high numbers in fetal and neonatal life (50% of all IgM $^{+}$ B cells), but they progressively diminish in number after birth and are present in small numbers in secondary lymphoid organs in adult life ([471] , [472] and [473]). At birth, most of the B cells in cord blood are CD5 $^{+}$ ([472]), but they constitute less than 10 to 30% of B cells in adult spleen, lymph nodes, and peripheral blood. Their proliferative capacity is high, and as a result they give rise spontaneously to cell lines that demonstrate c-myc amplification ([474]). The CD5 binds to CD72.

Presently, there are two views regarding the origin of the CD5 $^{+}$ subpopulation. According to one of them, the CD5 $^{+}$ cells (also known as *B1a*) belong to a lineage of B cells distinct from the conventional B lymphocytes (CD5 $^{-}$) ([475] , [476] and [477]). The CD5 $^{+}$ (B-1) cells develop early in ontogeny and, in the adult, predominate in peritoneal and pleural cavities and are self-replenished—that is, they do not arise from undifferentiated progenitors. Progenitors of CD5 $^{+}$ cells are present in fetal liver and omentum but not adult bone marrow, whereas conventional B-cell progenitors are present in fetal liver and adult bone marrow. According to the second hypothesis, the B-1 cells derive from conventional B cells ([478] , [479]), based on *in vitro* evidence of stimulation of conventional B cells with anti-IgM antibodies and IL-6, which generated the B-1 phenotype ([480]). B-1 cells may have different antibody repertoires (e.g., have few N-region insertions in their rearranged V genes), and the V $_{H}$ repertoire is biased toward V gene families proximal to J $_{H}$, whereas in adult B cells it is more randomized.

Perhaps the most controversial aspect is the production of autoantibodies. In NZB mice, a strain well known for autoimmune phenomena, the CD5 $^{+}$ B cells are increased in number and spontaneously secrete IgM autoantibodies ([473] , [474] , [475] , [476] , [477] , [478] , [479] , [480] and [481]). Increased numbers of CD5 $^{+}$ B cells are found in patients with rheumatoid arthritis ([482]), Sjögren syndrome ([483]), and progressive systemic sclerosis ([484]) but not in patients with systemic lupus erythematosus ([485]). Numbers of CD5 $^{+}$ B cells are also increased after bone marrow transplantation ([486]). In 95% of patients with B-cell CLL, the leukemic cells express the CD5 antigen ([467] , [468] , [487]), which is also detected on cells from other B-cell lymphomas. The CD5 $^{+}$ B cells from normal subjects ([488]) or from patients with CLL ([489]) produce autoantibodies, such as cold agglutinins, antibodies against cytoskeletal elements, and rheumatoid factor, but according to another view, these Ig are not autoantibodies but are polyreactive or natural antibodies with specificities against some self-antigens, such as the Fc fragment of IgG, DNA, and thyroglobulin ([488]). The CD5 $^{+}$ B-cell subpopulation may therefore play an important role in the development of B-cell repertoire related to natural immunity, which develops in the absence of an encounter with exogenous antigens ([490]). Certain V genes are selectively expressed in CD5 $^{+}$ B cells, and those are not changed by somatic hypermutation normally observed in CD5 $^{-}$ B cells responding to exogenous antigens ([490]).

The marginal zone B lymphocytes share many phenotypic characteristics with B-1 cells and, like them, develop in response to T-independent type 2 antigens. The B-2 repertoire is selected by self-antigen and therefore tends to be autoreactive. Selection into B-1a population is favored during fetal life because TdT is not expressed during this period; therefore the repertoire is limited in its specificity range. This dangerous repertoire is kept under control by the CD5-mediated negative signaling, thus preventing inappropriate activation. On the other hand, this repertoire is useful because the B-1 cell specificities are directed against several

pathogens and are important in mucosal immunity ([491]).

Frixos Paraskevas

T Lymphocytes and Natural Killer Cells

MORPHOLOGY

The T lymphocyte, under routine staining procedures (Giemsa or Wright), is 5 to 8 µm in diameter, with a high nucleocytoplasmic ratio. The nucleus is purple with densely packed chromatin, and the cytoplasm forms a narrow light-blue rim.

By transmission electron microscopy, the nucleus shows shallow indentations with dense heterochromatin along the nuclear membrane and euchromatin occupying most of the remaining nuclear surface. One or two nucleoli are visible (Fig. 17.1). The cytoplasm shows a few organelles, such as mitochondria and a small Golgi apparatus. By scanning electron microscopy, T lymphocytes show either smooth surface or only small numbers of microvilli, depending on the method of preparation as well as the state of activation ([1], [2]).

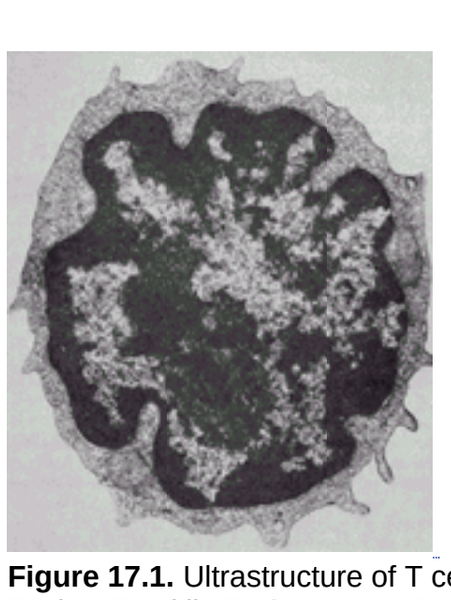

Figure 17.1. Ultrastructure of T cells. The normal T cell has a small rim of cytoplasm with only a few organelles. Nucleus shows dense heterochromatin. (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

Some T lymphocytes present in normal subjects are characterized by a highly indented nucleus and are known as *cerebriform mononuclear cells* ([3]). These cells are not detected in T lymphocyte–depleted fractions and constitute approximately 3 to 4% of the unfractionated T lymphocytes. They possess scanty cytoplasm, and the

degree of their nuclear indentation is expressed as a nuclear contour index (nuclear perimeter/area) ([4]). Their structural similarity to the cells present in cutaneous T-cell lymphomas suggests that they represent the normal equivalent of Sézary cells, which are derived from T lymphocytes.

ONTOGENY OF THE THYMIC MICROENVIRONMENT

The ontogeny of thymus and its structure are discussed in Chapter 15.

The thymic anlage develops from epithelial structures of the third branchial complex ([5]). However, the exact embryonic origins (i.e., ectodermal vs. endodermal or both) are still controversial. Most investigators believe that the medullary and cortical epithelia arise from the third pharyngeal cleft (ectoderm) and the third pharyngeal pouch (endoderm), which express the Pax1 gene (Fig. 17.2). Neural crest cells (Hoxa3-positive) invade the epithelial cluster to form the thymic rudiment. Several studies support the view that the cortical and medullary epithelia originate from a common precursor, and, in the early stages, the epithelium coexpresses markers that are later segregated to the cortical or medullary compartments. After completion of thymic organogenesis, the cortical epithelia are cytokeratin 8 $^{+}$, whereas medullary epithelia are cytokeratin 5 $^{+}$ ([6]), except for a small subpopulation in the corticomedullary junction, which is cytokeratin 5 $^{+}$/8 $^{+}$ ([6]). Furthermore, neoplastic human thymomas often express both cortical and medullary epithelial markers ([7]).

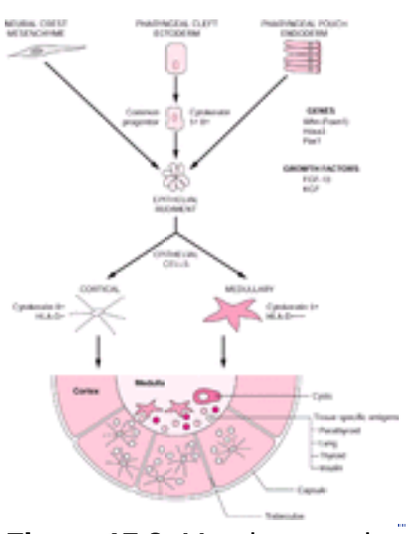

Figure 17.2. Morphogenesis of thymus. Elements from the third pharyngeal cleft form the epithelial rudiment, joined by mesenchymal cells from the neural crest. The common epithelial progenitor differentiates into cortical and medullary epithelium under the influence of the mesenchyme. The presence of endodermal cysts and tissue-specific “antigens” and “organoids” suggests some contribution from the endoderm. FGF, fibroblast growth factor; KGF, keratinocyte growth factor.

The best evidence of the origin of thymic epithelia from a common progenitor is the identification by monoclonal antibodies of a cell that, on differentiation *in vivo*, generates the full thymic microenvironment ([8] , [9]). The monoclonal antibody, MTS24, detects a glycoprotein with mucinlike characteristics and a peptide backbone ([8]). The antigen is detected during the early embryonic stages in the anterior endodermal epithelium, pharyngeal endoderm, and a portion of intermediate mesoderm, which develops the urogenital epithelium. The MTS24 $^{+}$ cells are major histocompatibility complex (MHC) class II positive and express cytokeratin 5 and cytokeratin 8, which are markers of the medullary and cortical epithelium, respectively. Highly purified MTS24 cells, inserted under the kidney capsule, are able to develop into a complete thymus and, furthermore, provide the complete milieu necessary for T-cell development.

Because primordial epithelial cells normally need the cooperation of mesenchymal cells for thymus organogenesis ([10]), it is conceivable that, in the case of the ectopically placed MTS24 cells, this is provided by comparable cellular elements from the kidney capsule. The MTS24 antibody completely blocks T-cell development in fetal thymic organ cultures, supporting the conclusion that the molecule recognized by the MTS24 antibody regulates normal epithelial function.

During this early stage in the development of the thymus, the cell interactions are regulated by a number of transcription factors, such as Hoxa3 and Pax1, which initiate the formation of the thymic primordium in mice ([11] , [12]). An important step in our understanding of the genetic control of thymic development came from the study of the “nude” mouse and the cloning of the gene that confers the nude phenotype, designated *whn* for *w*inged *h*elix *n*ude ([13]), and more recently renamed *Foxn1*. The Foxn1 gene encodes a transcription factor with a DNA-binding domain of the forkhead/winged helix class. The defect responsible for the nude phenotype is a single base pair deletion in the third exon of the Foxn1 gene. It results in hair loss, the arrest of the thymic epithelial cell expansion, and inability to attract the hematopoietic precursors into the epithelial rudiment ([14] , [15]). Formation of the epithelial primordium is not affected by the loss of whn function, but subsequent differentiation of the primitive epithelial precursors into subcapsular, cortical, and medullary epithelial cells is arrested ([16]), and the epithelial rudiment becomes cystic.

In normal development, the epithelial rudiment is invaded by mesenchymal cells from the neural crest ([17]), which stimulate epithelial progenitor differentiation into cortical and medullary subpopulations ([18] , [19] , [20] and [21]). These mesenchymal–epithelial interactions are mediated by growth factors and their receptors, such as the fibroblast growth factor 10 (FGF10) and its specific receptor, FGFR2IIIb, on thymic epithelial cells. Deficiency of either the factor or the receptor results in severe thymic hypoplasia ([22] , [23]). When immature lymphoid cells begin to arrive in the thymic rudiment, another wave of cellular interactions takes place between the developing lymphoid cells and the stromal epithelial cells. This second stage of thymic development establishes thymic microenvironments conducive to thymocyte differentiation and repertoire selection.

Further differentiation and maturation are under the regulation of interactions with thymocytes. Experiments in animals and experiments of nature in humans (disease processes), have clearly shown the symbiotic relationship between epithelial cells and lymphocytes. Prothymocytes regulate differentiation of cortical epithelial cells ([24]), whereas mature thymocytes organize the medullary microenvironment ([25] , [26] and [27]). The pharmacologic action of cyclosporine A blocks thymocyte maturation at the double-positive (DP) stage (i.e., CD4 $^{+}$CD8 $^{+}$) ([28]). As a result, the histologic architecture of cortex and the cortical thymocytes remain intact, whereas the medulla is depleted of epithelial cells and mature thymocytes. The evidence cited above indicates that the thymocytes contribute to the development and survival of the epithelial cells in their respective anatomic compartments.

The epithelial cells in the cortex and medulla differ by ultrastructure, by immunophenotype, and by functional characteristics. Ultrastructurally, three subsets have been detected on the basis of cytoplasmic processes, secretory organelles, and desmosome connections ([29]). Type I cells, located in the cortex, have stellate cytoplasmic processes and make contact with their neighbors, forming a syncytium. Type II cells are found in the medulla, are voluminous with many secretory intracellular vesicles, and have short cytoplasmic processes. Type III cells are rare, may contain vacuoles (pseudocysts), and are located in the medulla.

By immunophenotype, six clusters of thymic epithelial staining (CTES) have been identified. Ultrastructurally, type 1 epithelium (CTES II) ([30]) produces thymic hormones. Type 2 (pale), type 3 (intermediate electron lucency), and type 4 (dark with oval nuclei) are in the cortex proper (CTES III). These cells extend fine cytoplasmic processes, establishing contacts with neighboring cells, and are connected by desmosomes forming a syncytium, the interstices of which are filled with thymocytes. Some tend to engulf up to 20 to 40 thymocytes in a lymphoepithelial cluster, known as *nurse cells*, detected in human thymus ([31] , [32]) (see Chapter 15, Fig. 15.11). The internalized thymocytes are located within caveolae lined by plasma membranes. The lack of penetration by certain dyes indicates that the nurse cells are not an artefact, are completely sealed from the rest of the thymus, and may play a role in T-cell selection. Their formation is not dependent on interactions of T-cell receptors (TCRs) with MHC because they are present in knock-out mice deprived of TCR-aß ([33]).

A better understanding of the thymocyte–epithelial cell interdependence for survival came from experiments with a variety of TCR-transgenic mice ([34]). The final organization of the cortical and medullary epithelium depends on interactions of the TCR on the thymocytes with ligands on stromal cells. Thymocytes expressing a transgenic TCR that triggers strong positive selection, resulting only in maturation of CD4 $^{+}$8 $^{-}$ T cells, lose the normal reticular pattern of cortical epithelial cells, and

the epithelium in the medulla forms small scattered groups of cells surrounded by macrophages and dendritic cells ([35]).

Several other transgenic models demonstrated that maintenance of a balance between positive selection, negative selection, and nonselection is necessary to preserve normal compartmentalization and architectural integrity of the thymic epithelia ([36], [37]). It is the diversity of signals emanating from these physiologic processes within the thymus during thymocyte maturation that are critical for the maintenance of epithelial organization. These signals are generated from the endogenously rearranged TCRs, which regulate positive and negative selection.

In addition to thymocytes, the thymic vasculature is also an important epithelial organizer ([38]). In RAG2 $^{-/-}$ mice, the medullary epithelium forms cuffs around intermediate-sized vessels, particularly the postcapillary venules. This anatomic arrangement may have important functional implications. The medullary epithelial cells have been linked to negative selection and tolerance induction ([39], [40] and [41]) and are therefore strategically located around the postcapillary venules where the concentration of autoantigens would be high. The possible functional importance of this peculiar anatomic arrangement of the medullary epithelium is also suggested from the detection of several molecules and structures considered to be tissue specific within the medulla (i.e., parathyroid hormone, thyroglobulin, insulin, and even organized epithelial “organoids” with ultrastructural features of respiratory epithelium and thyroid follicles) ([42]). The ectopic location of these molecules and structures is supported by the detection of the expression of the appropriate genes ([42]). It has also been postulated that, because these “ectopic” tissues within the medulla have their origin from primordial endoderm, the precursors of the epithelial cells in the medulla also may arise from pharyngeal endoderm. Further support of this view comes from the histologic appearance of medulla in athymic mice, in which further differentiation of these cells fails and the epithelium remains in the primordial condition of endodermal cysts.

Whereas epithelial development depends on FGF, its functional integrity is maintained by other growth factors contributed by the mesenchyme. The keratinocyte growth factor (KGF), a member of the FGF family, is a paracrine growth factor produced by mesenchymal cells. It acts on epithelial cells that express a splice variant of FGF (i.e., FGFR2IIIb). In fetal thymic organ cultures, exogenous KGF expands the medullary epithelium, and in RAG $^{-/-}$ animals deprived of thymocytes, which normally produce KGF, the administration of KGF restores the normal medullary epithelial architecture ([43]).

The architectural integrity of the thymus is maintained throughout life, but eventually, thymus atrophies with age ([44]). Changes in signals between epithelial cells and thymocytes may determine thymic involution ([45]). Stat3 has been identified as an important signaling molecule between epithelial and mesenchymal cells in the thymic microenvironment ([46]). Stat3 gene disruption in mice results in severe thymic atrophy and enhanced susceptibility of the thymus to environmental stress, such as glucocorticoids or ?-irradiation.

The extracellular matrix (ECM) is the second important component of thymic stroma after the cells ([47]). It consists of multiple collagens, reticulin fibers, glycosaminoglycans, and glycoproteins, including laminin and fibronectin. Heterotrimeric laminin molecules consist of at least 15 naturally occurring isoforms, which are formed by five a, three ß, and three ? subunits. In the human thymus, laminin with a $_2$-chains (LN-2/4) or a $_5$-chains (LN-10/11) are detected in the subcapsular epithelium and blood vessels ([48]). The CD4 $^-$/CD8 $^-$ (double negative) thymocytes are located in the subcapsular area by strong attachment to LN-10/11 through their a $_6$ß $_1$ integrin. The CD4 $^+$/CD8 $^+$ (DP) thymocytes, however, lose their capacity to adhere to LN-10/11 and move down to the cortex. Another laminin receptor, a $_6$ß $_4$, is also strongly expressed in CD4 $^-$/CD8 $^-$ thymocytes in postnatal life ([49]).

These thymocyte–stroma interactions facilitate intrathymic migration and regulate positioning of the developing thymocytes to appropriate microenvironments during differentiation. The ECM proteins support the growth of thymocytes and epithelial cells and facilitate cell–cell interaction, especially migration of thymocytes in and out of nurse cells. Receptors for ECM proteins are highest in the double-negative precursors but gradually decrease with maturation.

T-CELL PROGENITORS

There are differences between embryonic and adult thymocyte development. The T-cell progenitors in fetal life derive from the liver, whereas in adult life, they come from the bone marrow. The difference in stem cell origin has implications in subsequent lymphoid development, apparently as a result of precommitment or restriction of developmental options at the level of stem cell ([50]). For example, fetal liver stem cells in a fetal thymic microenvironment generate ?/? T cells expressing the V?3 gene, whereas adult stem cells have lost this property ([51]). Another difference is related to the expression of the terminal deoxynucleotidyl transferase (TdT) enzyme in adult but not in embryo cells. TdT introduces N-nucleotides during the antigen receptor gene rearrangements and thus is responsible for an additional level of diversity, known as *junctional diversity*. Thus, fetal lymphoid cells have an “immature repertoire” ([52]).

Human thymus becomes fully differentiated by approximately the fifteenth week of gestation (i.e., approximately 7 to 8 weeks after colonization of the thymic rudiment). These early migrants contribute to the development of the thymic microenvironment. Cells with the CD34 $^+$/CD38 ^{weak}/CD90 $^+$ phenotype contain T-cell progenitors when they grow in fetal thymic organ cultures. In human adult bone marrow, CD34 $^+$/CD38 $^-$HLADR $^+$ stem cells have the potential to differentiate toward lymphoid and myeloid lineages ([53]). These cells are CD45RA $^+$, lack Thy1 (CD90) antigen, and may represent an intermediate oligopotent stem cell with T-cell–reconstituting ability ([54]). By phenotype, there are three subpopulations in the bone marrow, which can differentiate to T cells in the thymus: CD34 $^+$/CD2 $^+$, CD34 $^+$/CD7 $^+$, and CD34 $^+$/CD2 $^+$/CD7 $^+$, and all three are negative for CD3/CD4/CD8 ([55]). It has been suggested that T-lineage commitment takes place in the bone marrow and that these cells carry the distinct phenotype CD34 $^+$, CD7 $^+$, CD2 $^+$, CD5 $^+$, and LECAM-1 ^{high} ([56]). Bone marrow T-lineage–committed cells, however, can differentiate into nonlymphoid lineages (i.e., myeloid/erythroid) by cytokines from thymic epithelial cells, ([57]), and precursors from fetal liver are still “pluripotential” as thymic microenvironment is permissive for development of cells of other lineages than T lineage ([58], [59]). These cells form granulocyte-macrophage colony-forming units but have lost the multilineage hematopoietic potential present on the most primitive stem cells ([54]). The CD45RA (a high molecular isoform of CD45) is not present in primitive progenitors that initiate long-term cultures ([60]) but is found on more committed bone marrow progenitors and on subsets of mature T cells. It is expressed in the early stages of intrathymic development and remains until T cells become mature ([61]). Bone marrow progenitors arriving in the thymus respond to interleukin (IL)-7 secreted from stromal cells and change to a CD34 $^+$ and strongly CD7 $^+$ phenotype, the first fully committed T-lineage cells with loss of the potential for myeloid differentiation ([62]).

Because the cells arriving in the thymus are multipotent or at least oligopotent but the cells coming out of the thymus are exclusively T lymphocytes, the question to be answered is about the nature of the signal(s) that determine T-lineage commitment.

NOTCH AND T-CELL COMMITMENT

Signaling through the Notch receptor is a key factor for T-cell commitment ([63], [64], [65] and [66]). Notch plays a pivotal role in determining T/B-lineage choice, and signaling through Notch drives commitment of lymphoid precursors to T lineage ([67], [68] and [69]). Notch belongs to a family of conserved proteins that function as cell-surface receptors and direct regulators of gene transcription ([70]). It was first isolated as a gene involved in chromosomal translocations with the TCR-ß gene in a subset of cases of human T-cell acute lymphoblastic leukemia ([71]). The extracellular domain of Notch contains a variable number of tandem epidermal growth factor–like repeats and three Lin/Notch repeats, which function for ligand binding and Notch activation ([72]). The intracellular region contains six Cdc10/ankyrin repeats characteristic of protein–protein interactions and essential for signal transduction. The Notch protein initially is synthesized as a single-polypeptide chain, but, as a result of proteolytic processing, it is split into two parts. The extracellular region is separated and forms a noncovalent heterodimer with the remaining portion consisting of the transmembrane and the cytoplasmic regions.

Ligands for Notch are Delta, Serrate, and several other molecules corresponding to these two classes. In general, those homologous to Delta are referred to as *Delta*, and those homologous to Serrate are called *Serrate* or *Jagged* ([72]). These ligands are transmembrane proteins with an extracellular domain with a variable number of epidermal growth factor–like repeats and the unique domain for this family, the DSL (*D*elta/ *S*errate *L*ag-2) domain, which mediates binding to Notch and activation. Which of the two groups of ligands is important for T-lineage commitment remains controversial ([73]). In cells of the immune system, there are two Notch receptors, Notch 1 and Notch 2, and four signals ([74]). The pleiotropic signaling by Notch regulates differentiation, proliferation, and cell death, but it is not yet clear which function most precisely determines cell fate and ultimately directs T-cell commitment ([75], [76]). With Notch inactivation, the double-negative T cells diminish in the thymus, whereas B-cell precursors increase, probably from a more efficient production of B cells within the thymus ([77]). On the other hand, transgenic expression

of Notch in the bone marrow permits the accumulation of CD4 $^{+}$/CD8 $^{+}$ T cells. Notch 1's functional role seems to be in developmental specification, driving T-cell precursors at the expense of B-cell precursors and perhaps directing the choice of a common precursor between these two fates. A role of Notch 1 in subsequent stages of T-cell differentiation (i.e., lineage commitment and positive vs. negative selection) is still questionable.

PHENOTYPIC DIFFERENTIATION

The first migrants to the thymus settle to the subcapsular cortex and are large, dividing pluripotential cells, CD34 $^{+}$/CD45RA $^{+}$, with the TCR genes in the germ-line configuration ([56], [78], [79], [80], [81], [82] and [83]). CD2 and CD7 expression may precede arrival in the thymus (Fig. 17.3). Potentially, they are able to differentiate to other lineages, such as natural killer (NK) cells, dendritic cells, and monocytes. The CD34 $^{+}$ cells then coexpress other markers such as CD38 and CD71 (transferrin receptor) associated with proliferating cells, and a portion of them are CD10 $^{+}$. Shortly after they acquire CD1a, they up-regulate CD4 followed first by CD8a and then CD8ß. The majority of the CD34 $^{+}$ cells at this stage are negative for CD3, CD4, and CD8 (triple negative, or TN), but a small subpopulation expresses low levels of CD4 (CD3/CD4 ^{low}/CD8) ([84]). This population may be an intermediate between the TN thymocytes and the main cortical population that are positive for both CD4 and CD8 (DP). Researchers have detected other intermediate phenotypes such as CD3/CD4 $^{+}$/CD8a $^{+}$ß $^{-}$ ([85]). These intermediates may indicate that, in the progression from TN to DP, acquisition of the CD4 and CD8 is not synchronous. In mice, intermediates have also been detected that are CD4 $^{-}$/CD8 $^{+}$ ([86]) or CD4 $^{+}$/CD8 $^{-}$ ([87]). Expression of CD1 begins while the cell is still TN. CD1 is absent from the most immature and most mature thymocytes and peripheral T cells. In conclusion, progression from TN to DP is characterized by several intermediate stages, expressing in sequence CD1, CD4, and finally CD8 and CD3 before they acquire the typical phenotype of the cortical thymocyte [i.e., CD3 $^{+}$/CD4 $^{+}$/CD8 $^{+}$/CD1 $^{+}$ (DP)] ([79]).

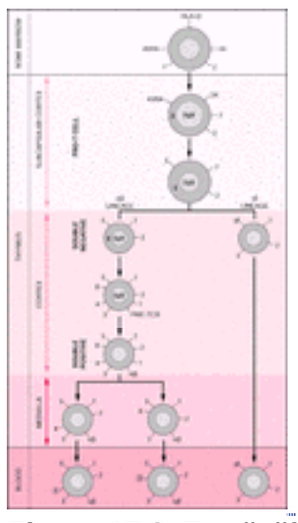

Figure 17.3. T-cell differentiation in the thymus. Progenitor cells from bone marrow are first detected in the subcapsular cortex expressing the CD7 and CD2 on the cell surface and CD3 in the cytoplasm. At this stage, rearrangements of the T-cell receptor (TCR) genes and a gene encoding the pre-Ta protein form the pre-TCR. The pre-TCR controls the separation of the two T-cell lineages, ?/d and a/ß. The a/ß cells eventually contribute to the majority of T cells within the thymus and in the periphery. On the basis of expression of the CD4 and CD8 markers, thymocytes are divided into four subpopulations: absence of both markers (double negatives), presence of both on the same cell (double positives), and expression of each marker on separate cells. See text for details. TdT, terminal deoxynucleotidyl transferase.

In the process of differentiation, CD34 is progressively lost while the intensity of CD7 decreases. Myeloid and NK cells have been detected in various *in vitro* systems arising from thymocytes ([57], [88], [89]), and the thymic microenvironment is able to support myeloid differentiation ([58]). However, others could not detect myeloid differentiation from CD34 $^{+}$/CD7 $^{+}$ thymocytes in response to myeloid growth factors, whereas bone marrow cells with the same phenotype contained myeloid clonogenic cells ([82]).

During the early stages of T-cell development, there are a series of control points in the progression from the earliest precursors to the DP stage. The control points depend on the thymic microenvironment and have been well characterized in the mouse ([90]). In orderly sequence, these control points are the expression of a-chain of IL-2, onset of TCR-ß and ?-gene rearrangements, branching of the TCR-?d lineage, expression of a dimeric form of TCR-ß–chain, and, finally, expression of CD4, CD8, and the TCR-aß. At the stage of DP, the cells are subject to positive selection. If the TCR and CD8 engage a class I peptide complex, the CD4 is down-regulated. The opposite happens for a CD4 class II–restricted cell that down-regulates CD8. The final maturation is gradual and slow and may involve additional changes for the development of the single-positive mature T lymphocytes.

Interactions between stromal cells and the thymocytes are mediated by direct communication (adhesion molecules) and mediators (cytokines and thymic hormones). Adherence of thymocytes to epithelial cells is mediated by CD2 and the lymphocyte function molecule-3 (LFA-3, CD58) ([91]), intercellular adhesion molecule (ICAM), and LFA-1 ([92]). Blocking the receptors for fibronecting (FN), very late antigen-5 (VLA-5), and very late antigen-6 (VLA-6), which are expressed on immature thymocytes, inhibits their differentiation ([47], [48]). Epithelial cells also express several receptors for ECM. Evidence of direct cellular communication between various thymic cells was provided by the demonstration of the existence of gap junctions formed by connexin 43 between two epithelial cells or between epithelial cells and thymocytes ([93]).

Of the cytokines that have been implicated in T-cell differentiation, IL-7 is essential ([94]). It is produced constitutively by epithelial cells, and it induces proliferation of TN thymocytes ([95]) or maintains their viability ([96]). CD34 $^{+}$ thymocytes cultured with IL-7 start to express CD8 and CD4 but remain CD3 and TCR negative, indicating that other stimuli from stromal cells are essential for generating CD3 $^{+}$/CD4 $^{+}$/CD8 $^{+}$ cells. IL-7 also induces TCR-ß gene rearrangements ([97]). Mice genetically deficient in IL-7 receptor have a profound reduction of T and B lymphocytes, and thymocyte development is blocked at a very early stage before the induction of CD25 and TCR-ß gene rearrangements ([98]). IL-7 function is potentiated by stem cell factor ([82]).

Other cytokines, such as IL-1, IL-2, and IL-4, have also been shown to play some role in thymocyte differentiation ([94]). Thymic hormones are produced by epithelial cells and can induce *in vitro* functions associated with mature T cells, such as helper cells in antibody production. Some of the hormones have been isolated in pure form (i.e., the thymosins, a family of peptides present in thymic extracts; thymulin, a peptide of nine amino acids with homology to thymosins; and thymopoietin, which induces expression of T-cell markers in bone marrow cells).

The thymus is continuously colonized by hematopoietic progenitors that have the genes for the TCR in germ-line configuration. In an adult mouse, approximately 100 to 1000 such progenitors enter the thymus daily, and it takes approximately 3 weeks to undergo complete differentiation to mature functional and self-tolerant T cells.

The biologic processes within the thymus are highly complex, but for a better understanding, we divide them, somewhat arbitrarily, into three areas: (a) lineage determination (i.e., TCR-aß vs. TCR-?d), (b) separation of the two main T-cell subsets (i.e., CD4 vs. CD8), (c) selection for survival of those cells with a TCR able to recognize foreign antigens (positive selection) and elimination of those possessing autoreactive configurations (negative selection). Understanding of these events will be facilitated by a prior description of the genes encoding the TCRs.

T-RECEPTOR GENES

Knowledge of the structure and patterns of expression of the various TCR genes is essential to our understanding of antigen recognition by T cells ([99]). The TCR gene, “a needle in the haystack,” was isolated by the technique of subtractive hybridization ([100]). Four human and murine TCR genes have been identified: a ([101]), ß ([102]), ?, and ? ([103], [104]) (Fig. 17.4).

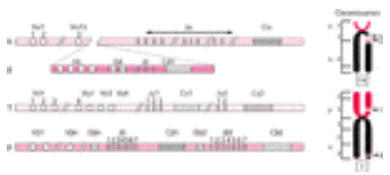

Figure 17.4. Organization of the genes for human T-cell receptor chains (see text for details). (Adapted from Kronenberg M, Siu G, Hood LE, Shastri N. The molecular genetics of the T-cell antigen receptor and T-cell antigen recognition. Annu Rev Immunol 1986;4:529–591; and Raulet DH. The structure, function, and molecular genetics of the ?/? T-cell receptor. Annu Rev Immunol 1989;7:175–207.)

The human a gene is located on chromosome 14 (bands q11-12) ([105]), as are the immunoglobulin (Ig) genes (band q32). Rearrangement involving the region of the chromosome containing the a genes has been detected in patients with T-cell malignancies ([106], [107]). The ? gene is located on chromosome 14 within the a gene (see below) ([108]). The ß and ? genes are located on chromosome 7 ([109], [110]). Translocations and inversions of chromosomes 14 and 7 are often seen in association with ataxia telangiectasia, probably involving fragile sites that normally are used during the TCR gene rearrangements.

All TCR genes display an overall organization similar to that of the Ig genes. They are composed of variable (V) and constant (C) genes. The V gene is made of three segments (V, J, and D) in the ß and ? genes, but only two segments (V and J) in the a and ? genes ([99], [104]). Each V-gene family is divided into subfamilies, like the Ig V genes, on the basis of sequence similarity (more than 75%).

In humans, the TCR genes group consists of one Ca gene ([111]), two Cß genes ([112]), two C? genes ([104]), and one C? gene ([104]). With the exception of C?, which is composed of three exons, all of the genes have four exons. The ? locus is located between the Ca and Ja gene segments. Diversity in the TCR genes is generated through rearrangements with each of the V and J segments and D in the case of ß and ?, forming the complete V gene. The TCR genes, however, contain a large number of J segments as compared to the Ig genes.

Associated with the Ca gene are approximately 50 Va and 61 Ja segments that spread over 100 kb of DNA. The ß-chain gene complex spans around 600 kb ([113]) and incorporates 57 Vß segments. Each of the two Cß genes possesses a set of Jß segments and one Dß segment. The Vß segments are all located upstream from the two clusters of Cß genes. During rearrangements when a Vß segment forms a VDJ complex, the transcript is committed to use the same Cß segment genes. The ? gene locus contains two C? genes, each associated with its own set of J? segments. There are approximately 14 V? segments, all located upstream separately from the two C?-J? clusters. The C? gene complex lies between the V and J segments of the a gene complex. There are eight V?, three D?, and three J? segments.

Like the Ig genes, the TCR gene segments are flanked by heptamer-spacer-nonamer sequences, which serve as recognition sites for the recombinase, the enzyme that initiates recombination of the segments. The same RAGs 1 and 2 (RAG1 and RAG2) regulate the V(D)J recombinations for both T and B cells. But RAG1/RAG2 act in a lineage-specific manner (i.e., Ig genes are assembled only in B cells and TCR genes only in T cells). The recombinations are also developmentally regulated. For T cells, the ß genes are recombined before a genes; as for B cells, the IgH is recombined before IgL. These differences are explained by differential accessibility of V genes during development. Mutations of either one of these genes in mice result in complete arrest of maturation of both B- and T-cell lineages ([114], [115]). The mechanism of V(D)J recombination has been described in detail in Chapter 16.

The mechanisms generating diversity are combinatorial associations of different V, D, and J segments and combinatorial pairing of TCR proteins. However, in contrast to the Ig genes, fewer V segments are available to the TCR genes. The diversity of the TCR is mainly junctional (i.e., a result of additions of nucleotides at the DNA cleavage site). Additions that depend on template are known as *P nucleotides*, and random additions are called *N nucleotides added by TdT* (see details in Chapter 16). TdT is not expressed during fetal life, and, in TdT knock-out mice, the T-cell repertoire is of fetal type (i.e., less diverse). TdT is expressed only in immature lymphocytes and is responsible for the transition from fetal to adult repertoire by contributing enormously to the lymphocyte antigen receptor repertoire. A striking difference between Ig and TCR is the lack of somatic hypermutations, which is very important in generating high-affinity antibodies in the germinal centers (Chapter 18). Assembly of V genes of ß, ?, and ? genes occurs during the DN stage. If the ?d rearrangement is successful, the cell becomes a T-?d cell. If the ß-chain rearranges successfully, it forms a heterodimer with the pre-Ta–chain and differentiates along the T-aß lineage entering the DP phenotypic stage.

TCR gene rearrangements occur in two discrete stages of thymocyte development. The first occurs during the DN stage with the ? gene rearranging first, followed by the ? and ß genes. The a gene rearranges during the DP stage. During the ß gene rearrangement, a Dß segment joins a Jß segment, and, as with the Ig gene rearrangement, a Vß joins the DßJß complex. If the rearrangement is not productive, the cell may have one more chance at rearranging a second Cß cluster, as there are two Cß genes each with its own D and J segments.

T Cell-aß versus T Cell-?d and the Pre–T-Cell Receptor

At this point, the decision needs to be made in choosing a TCR-?d versus a TCR-aß lineage by any one of three proposed models. According to one model, each lineage starts from a separate precursor (*stochastic* or *independent*). A second model proposes that there is a common precursor for both lineages (*instructive*). The third model (*competitive*) postulates that rearrangements for the genes of the respective lineages start concurrently and that those finishing successfully first determine the fate of the cell. Evidence appears to support a variant of the stochastic model ([114]). Whatever the mechanism, it is agreed that the TCR-? gene rearrangement occurs in thymocytes that can adopt either the ?d or aß fates, whereas during the DP stage, activation of the TCR-a gene rearrangement seals the fate of the T cell for the aß lineage.

Determination of lineage is regulated by transcription factors that act on promoters and enhancers and make appropriate genes accessible to the recombinase ([115], [116]). Another regulatory mechanism involves the pre-TCR. At this stage of T-cell development, the ß-chain forms a heterodimer with another protein, referred to as *pre-T*a (pTa), and the complex is referred to as *pre-TCR* ([117]). The pTa is a 33-kd type I transmembrane protein of the Ig superfamily. It consists of a single Ig-like domain. Two cysteines form the intrachain disulfide bond, whereas a third cysteine just above the transmembrane region forms the disulfide bridge with the TCR-ß chain ([118]). The human pTa gene is located on the short arm of chromosome 6, in the vicinity of the HLA locus. The pTa-chain is not essential for CD3 expression.

The pre-TCR has a major role in TCR-aß versus TCR-?d commitment. It generates large numbers of $CD4^+/CD8^+$ T cells with productive TCR-ß rearrangements and directs these cells to the TCR-aß lineage ([119]).

The cells that have undergone rearrangements of the ß, ?, and ? are diverted by the pre-TCR into the aß lineage before they assemble a complete ?d TCR. The pre-TCR stimulation induces expansion of the cells that have rearranged the ß gene, followed by extensive rearrangements of the a locus. The a-gene rearrangements excise the ? gene, which is located within the a locus, and further ?d T-cell differentiation is blocked.

In mice deficient in pTa expression, pre-TCR is not formed, and aß-TCR cells are markedly reduced. These data support the instructive mechanism in the generation of the aß and ?d T cells.

The selection for TCR-ß is initiated at a stage phenotypically characterized by expression of $CD4^+/CD8a^+ß^-$ ([120]). The productive Vß gene rearrangement in one allele prevents rearrangements of the second allele, a process called *allelic exclusion* that is regulated by the pre-TCR. Signaling by the pre-TCR requires the CD3 chains ?, e, ?, and ?, and the Lck kinase ([121]), with the CD3-e and -? chains especially indispensable for the pre-TCR function. Other functions mediated by pre-TCR signaling are cell survival and phenotypic changes. Pre-TCR promotes thymocyte survival, whereas signaling by TCR induces apoptosis ([122], [123]). Because pre-TCR is expressed on DN T cells, the antiapoptotic function of pre-TCR is crucial for their survival and differentiation of DN T cells into the DP stage when the TCR is needed for positive or negative selection.

Both receptors follow initially similar signaling pathways, such as tyrosine phosphorylation and so forth, but in the apoptotic pathway, they diverge at the level of Fas ligand (FasL) induction, which requires induction of Nur77 and nuclear factor of activated T cells (NFAT) transcription factors. These factors can be induced only by the TCR-aß and not by the pre-TCR. No ligand has yet been detected for the pre-TCR. However, the pTa possesses a palmitoyl moiety that spontaneously targets the pTa chain to the cell membrane (lipid rafts) ([124]). This may offset the requirements for a ligand because the pre-TCR from such a location is able to signal

constitutively. Signaling through pre-TCR results in expression of certain transcription factors required for the differentiation of precursors to aß-T cells, frequently referred to as ß *selection*. Some of these factors are the E-proteins of the basic helix-loop-helix transcription activators required for expression of CD4, TCR-a and TCR-ß chains, and so forth ([125]).

CD4/CD8 Lineage Commitment

The DP thymocyte (CD4 $^{+}$/CD8 $^{+}$) differentiates to two phenotypically and functionally distinct lineages of aß T cells: CD4 $^{+}$ and CD8 $^{+}$. The TCR of the CD4 $^{+}$ cells interacts with peptides bound to class II MHC molecules, whereas the TCR of the CD8 $^{+}$ cells recognizes peptide–class I MHC complexes. The CD4 and CD8 proteins are not clonally distributed and are known as *co-receptors* because they corecognize the same ligands as the TCR ([126]). The mechanism by which the separation of the lineages from DP thymocytes is achieved remains unresolved ([127] , [128]).

According to one theory, known as *instructive*, thymocytes carrying an MHC class I–restricted TCR differentiate to CD8 $^{+}$ lineage, whereas engagement of TCR with class II MHC induces commitment to CD4 ([129]) (Fig. 17.5). An alternative model, known as *stochastic*, accepts that the DP thymocytes are already committed randomly to a lineage; they make a choice that is unrelated to the MHC specificity of their TCR ([129]). Data collected from a variety of approaches do not agree with any particular mechanism in lineage commitment. Mice with a class I–specific TCR transgene support predominantly CD8 differentiation, whereas the class II–specific TCR transgene directs DP thymocytes to CD4 lineage ([130]). According to the instructive model, the CD4 or CD8 transduces differentiation-specific signals, but no lineage-specific signals have ever been identified.

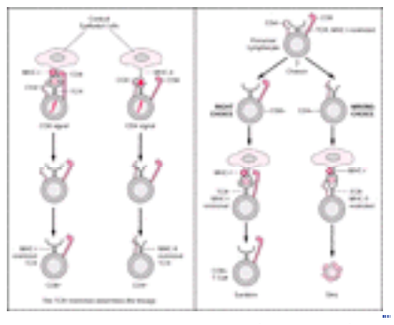

Figure 17.5. CD4 $^{+}$/CD8 $^{+}$ lineage commitment. Two mechanisms have been suggested for CD4/CD8 lineage commitment. According to the instructive model **(A)**, the major histocompatibility complex (MHC) restriction of the T-cell receptor (TCR) determines the lineage commitment (i.e., a cell with an MHC I–restricted TCR becomes CD8 $^{+}$, whereas if the TCR is class II restricted, it becomes CD4 $^{+}$. The stochastic model **(B)** accepts that the double-positive thymocyte is already precommitted randomly to the lineage.

Other data indicate that the cytoplasmic region of CD4 directs CD4 lineage commitment ([131]). A chimeric construct, for example, made of the cytoplasmic region of CD4 and the extracellular and transmembrane region of CD8a, supported the development of cells with the CD4 $^{+}$/CD8a $^{-}$ phenotype with a class I–restricted TCR ([132]). CD4 is preferentially associated with its cytoplasmic tail with the tyrosine kinase Lck. Therefore, CD4 is likely to deliver stronger signals than the coengagement of TCR and CD8 ([133] , [134]).

The *strength of signal model* suggests that strong signals induce CD4 differentiation, whereas weak signals (by the CD8a cytoplasmic tail) induce CD8. Another aspect of signaling that was evaluated was the duration of signals as an important parameter. Accordingly, TCR of a DP thymocyte initiates down-regulation of CD8 and produces a CD4 $^{+}$/CD8 $^{-}$ intermediate cell. At this stage, the duration of signaling determines the final outcome. That is, short signaling produces CD8 $^{+}$ T cells, whereas persistence of signaling in the CD4 $^{+}$/CD8 $^{-}$ intermediate cell causes CD4 $^{+}$ differentiation ([135]).

Variation of Lck function seems to be the single most important parameter in CD4/CD8 lineage decision. Constitutively active Lck promotes CD4 differentiation, even in the presence of class I MHC–restricted TCR. When, on the other hand, Lck is catalytically inactive, all thymocytes, including those with class II MHC–restricted TCR, become CD8 $^{+}$ ([136] , [137]). In the absence of Lck, cross-linking of CD3 induces CD8 differentiation ([138]). The Lck-dependent regulation of lineage commitment is not only phenotypic but also functional, because the class II MHC–restricted CD8 $^{+}$ cells behave as killer cells, whereas the class I–restricted CD4 $^{+}$ cells up-regulate CD40 ligand, a function characteristic of helper T cells ([136]). Signaling initiating from Lck is channelled through the Ras-Erk pathway ([139]).

The various experimental approaches used in these studies make it clear that the signals required for CD4 differentiation are promiscuous, which is believed to indicate that CD4 differentiation is a default pathway ([140]).

The multiplicity of the models entertained and the ambiguity of some of the results are also a testimony that the precise mechanism of T-cell lineage commitment remains still elusive and certainly complex ([128] , [141]).

In summary, Lck is a key regulator, but other signals originating from the TCR in the absence of a co-receptor or in the absence of a significant recruitment of Lck provide sufficient Src activity for a response. Such signals depend on the nature of the peptides involved in positive versus negative selection, which is linked to lineage selection ([138]). Although the prevailing opinion accepts that lineage commitment and the selection of thymocytes with useful TCRs are linked, some of the models proposed point to the opposite ([142]).

Positive and Negative Selection

The random nature of rearrangements of TCR genes generates specificities directed not only against foreign antigens but also against self-antigens. Self-reactive T cells are harmful if they have the opportunity of exiting the thymus. Mechanisms have therefore been developed that allow the thymus to “select the useful, neglect the useless and destroy the harmful” ([143]). The decision on which pathway each cell will ultimately follow is made by the TCR. The time for selection appears to begin at the DP stage when the TCR is expressed at low levels ([144] , [145] , [146] and [147]). The TCR of the thymocytes recognizes self-peptides presented by the MHC molecules. The nature of the criteria used by the TCR for directing individual DP thymocytes to three different fates has been, and still is, one of the most challenging questions in immunology.

It has been widely accepted that the options for each DP thymocyte are determined by some fine qualities and properties of the TCR and MHC–peptide (pMHC) ligand interaction. If the affinity of interaction is “weak,” the cell is positively selected, and if the binding is of high affinity, the cell is negatively selected ([148]). The term *avidity*, however, incorporates the affinity of the individual TCR, the level of occupancy of all TCRs, and, therefore, the receptor-ligand densities. Low avidity, therefore, triggers positive selection, and high avidity triggers negative selection (Fig. 17.6).

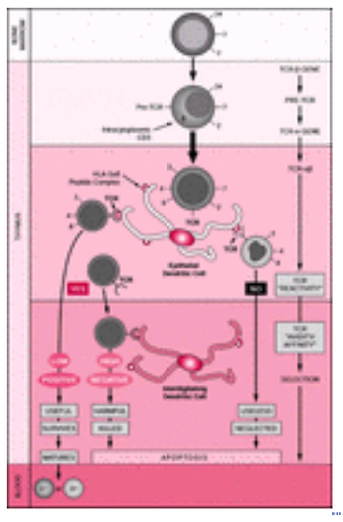

Figure 17.6. T-cell repertoire selection. Functional T-cell differentiation and repertoire development can be distinguished in three steps. In the first step, the CD4 ¯/CD8 ¯ or double-negative thymocyte initiates rearrangements of the T-cell receptor (TCR)-ß gene and forms the pre-TCR by associating the ß-chain with another protein, called *pre-T*a. The pre-TCR controls the transition from the double-negative step to the double-positive step (coexpression of CD4 and CD8). The transition is characterized by rearrangements of the TCR-a gene and expression of the aß TCR complex, as well as expression of the CD4 and CD8 co-receptors. The second critical step is the separation of thymocytes with a TCR reacting with a self–peptide–major histocompatibility complex (MHC) presented by cortical epithelial cells from those with a nonreactive TCR. The latter are ignored and die by apoptosis, whereas the former are subject to selection. In the third critical step, the thymocytes are selected for either survival (positive selection) or deletion (negative selection). The TCR complex controls this step, and thymocytes with high affinity for the self–peptide–MHC complex are killed by apoptosis because they probably contain the autoreactive clones. Thymocytes with low-affinity TCRs survive and further differentiate to the CD4 $^{+}$ or CD8 $^{+}$ T cells (single positives). Positive and negative selections are mediated by different cells: positive by cortical epithelial cells and negative by interdigitating dendritic cells (bone marrow derived). (From Paraskevas F. T lymphocytes. In: Israels LG, Israels ED, eds. Mechanisms in hematology. Core Health Services, Inc., 2001, with permission.)

Another proposal suggests that engagement of TCR with the ligand induces two distinct types of activation (*qualitative model*). The positively selecting ligand induces one type of mechanism, whereas the negatively selecting ligand activates by both mechanisms ([149], [150] and [151]). In another version of the same theme, instead of *quality* of signal, we consider *quantity* or *intensity* of signaling. Positive selection represents a specialized or partial activation, whereas full activation (like that of a mature T cell) is lethal for that thymocyte. Cells with TCRs that cannot bind with sufficient avidity are neglected and die by apoptosis.

When the cell is positively selected, the expression of recombination-activating genes (RAG), which encode the proteins for V(D)J recombination, and the PTa gene are turned off, and the CD4 and CD8 are partially down-regulated. As the cell at this stage moves from the cortex to the medulla, one of the co-receptors is reexpressed and the cell lineage is defined ([139], [152]).

Just as for lineage differentiation, signaling for positive and negative selection largely depends on Lck, and in the absence of Lck, both selection mechanisms are compromised ([153]). Lck interacts with the co-receptors CD4 and CD8 through two cysteines in the cytoplasmic region of each co-receptor and two cysteines in Lck ([154]).

The binding of TCR to the ligand induces phosphorylation of the three immunoreceptor tyrosine-based activation motifs (ITAMs) of the ?-chain and the single ITAM in each of the CD3 e-, ?-, and ?-chains. The ?-chain is constitutively associated in thymocytes with the ZAP-70 kinase, suggesting that a low level of activation takes place continuously ([155]). Receptor clustering from greater ligand engagement results in further phosphorylation and Lck involvement.

ZAP-70 is indispensable for positive and negative selection because both processes are abrogated in ZAP-70–deficient mice ([156]). The Src-like adaptor protein (SLAP) down-regulates the TCR expression during the DP stage of development and rescues T-cell development in the absence of ZAP-70. Overall, SLAP acts as a negative regulator and probably “marks” activated receptors for retention and degradation ([157]). The main downstream signaling pathway for positive selection is the Ras/map kinase (MAPK) cascade ([158]). TCR signaling alone is not sufficient to induce selection for survival or death ([159]). CD2 expression exerts a strong influence on TCR repertoire. In the absence of CD2, the thymocytes with high affinity for peptide-MHC escape negative selection ([160]). CD2 also influences pre-TCR function in the usage of Va genes, which is substantially altered in CD2-deficient mice.

The co-stimulatory interaction of CD40/CD40L is a master regulator of negative selection, usually acting in the regulation of the ligands of other co-stimulatory molecules, such as CD80 and CD86 ([161]). CD40 may also induce other co-stimuli required for thymocyte deletion, such as CD54 (ICAM-1), FasL, or tumor necrosis factor (TNF) ([162], [163] and [164]). These molecules could regulate negative selection separately or in combination with CD5 and CD28. The CD28 co-stimulatory molecule engaged with TCR signals thymocytes to undergo apoptosis or maturation, depending on the intensity of co-stimulation ([165]).

Stimulation of maturation of DP thymocytes follows activation of the extracellular signal-regulated kinase (ERK)/MAPK pathway and up-regulation of the antiapoptotic protein Bcl-2. Apoptosis is triggered with the expression of the Nur77 family of transcription factors and occurs only if TCR engagement is accompanied by co-stimulation. Ca $^{2+}$ fluxes in mature T lymphocytes regulate proliferation, differentiation, and survival. Some of the functions of Ca $^{2+}$ are mediated by the Ca $^{2+}$-dependent phosphatase calcineurin. The function of calcineurin is disrupted by cyclosporin A and FK506. Both of these substances form complexes with cellular proteins, termed *immunophilins*, that bind and sequester calcineurin. Cyclosporin A and FK506 block the initial steps of positive selection ([166], [167]). On the other hand, intracellular chelators reduce deletion ([168]), which suggests that interference of Ca $^{2+}$ fluxes and function exerts several effects on the selection process.

All signaling pathways end up targeting regulation of transcription factors, and various studies have examined the roles of NFAT and nuclear factor-?B (NF-?B), but only members of the Nur77 family have been clearly shown to be involved in the process of selection, with a major role in apoptosis of massive numbers of thymocytes ([169]). It has been estimated that 90 to 95% of thymocytes die inside the thymus, and the appearance of very large numbers of dead cells on histologic sections is the reason that histopathologists called the thymus the “graveyard” of T cells.

The timing of positive versus negative selection has been difficult to define. Negative selection was believed to occur relatively late because the TCR affinity increases with time, and it is the high affinity of TCR that triggers negative selection ([148]). However, with the progression of maturation, lineage commitment also takes place, and data have shown that CD4 or CD8 expression may not be an obligate requirement for negative selection and that negative selection can occur at the DP stage ([170]). Other evidence, however, suggests that negative selection occurs only after cells have been positively selected ([171]). It is probably difficult to pinpoint precisely the stage for negative selection because removal of autoreactive cells requires stringent criteria, which may be satisfied only in connection with not only the maturational stage but also with distinct microenvironmental conditions and special stromal cells.

Cells and Molecules in the Selection of Thymocytes

The approach taken for identification of the cells that govern positive and negative selection was the construction of radiation-resistant chimeras. Hematopoietic components of the thymic stroma are radiosensitive, whereas the epithelial components are radioresistant. These differences allowed the construction of chimeric thymuses (i.e., thymuses composed of epithelial and hematopoietic elements with a different MHC background). These experiments indicated that the thymic cortical epithelium is responsible for positive selection ([172], [173], [174] and [175]). The hematopoietic stromal cells, on the other hand, are potent inducers of negative selection ([151], [176]). Other data make the separation between distinct cell types for each of the two selection processes less sharp ([177]). Because the cortical epithelial cells have weak MHC expression and the developing DP thymocytes at that stage have low TCR expression, the interactions are only of low avidity, which is required by positive but not by negative selection. Similarly, the hematopoietic cells in the corticomedullary junction express MHC molecules at higher density, and the T cells have up-regulated their TCRs. As a result, the interactions in this anatomic location are appropriate for negative selection.

The mobility of the developing thymocyte from cortex to the medulla during this period accommodates the functional needs of these two processes by discrete

microenvironmental regions. By experiments *in vitro*, it has been concluded that different cell types may mediate positive and negative selection, but conditions may not be the same in unmanipulated thymuses.

In conclusion, the anatomic constraints rather than the functional capacities of various cells could explain the observation that positive selection occurs predominantly on cortical epithelial cells and negative selection on medullary hematopoietic stromal cells.

The ligands for positive and negative selection are self-peptides bound to MHC molecules (177a, [178]). A thymocyte bearing a TCR specific for class I–peptide complex is positively selected if the peptide it carries is in a low concentration and is killed if the peptide concentration is high ([179], [180]). However, the weak interactions required for positive selection and the strong interactions operating in negative selection can also be provided by the half-life of the pMHC complex (i.e., short half-life for positive and long half-life for negative selection).

The original question of affinity versus concentration was better answered with manipulation of the pMHC. Positive selection is driven by peptides with varying affinities; however, by increasing the concentration of the peptide, even low-affinity ligands can positively select ([181]).

Another important question regarding selection in the thymus relates to the specificity of the ligands and the selected TCRs. The T lymphocytes exiting the thymus express a highly diverse repertoire of specificities to effectively respond to the universe of microbial peptides ([182]). It is, however, unlikely that the positive selection of every $CD8^+$ T cell relies on the recognition of a unique self-peptide during thymic development. This is because the diversity of self-peptides expressed on thymic stromal cells would not be sufficiently large to select a repertoire of T cells that can respond to all existing foreign peptides. Therefore, it has been argued that the recognition of self-peptides in positive selection must be relatively degenerate. In other words, a single pMHC can trigger the positive selection of multiple thymocytes ([183]); therefore, the peptide recognition during positive selection is cross-reactive ([184]). This apparent degeneracy of the peptide binding to TCR is the result of a significant contribution to the binding by the MHC molecule. It is well known that an unusually large number of T cells (approximately 1%) react against allogeneic MHC ([185]). Therefore, the MHC contributes to the specificity of the selected TCRs ([186]).

Other parameters of a pMHC complex, such as the conformation ([187]) and the concentration ([188]) of the peptide, contribute to the repertoire selection. Despite the evidence that each pMHC complex selects more than one TCR, the large diversity of the fully developed T-cell repertoire depends on a large number of pMHC ([189]) as well as on the quantity and quality of the stromal cells ([190]). Peptide diversity during the selection seems to have a greater effect on negative than on positive selection. In thymus organ cultures, the epithelial (positive selection) and bone marrow dendritic cells (negative selection) could be regulated. In testing with a diverse array of peptides, the addition of 1% of dendritic cells reduced the number of $CD4^+$ T cells selected by 80% compared to that of the controls in the absence of dendritic cells. Thus, the quantity and quality of the selecting stromal cells have a significant impact on the selected repertoire by multiple peptides ([190]).

At the end of the selection process, mature T lymphocytes exit the thymus and home to the secondary lymphoid organs (see Chapter 15). There are two types of TCR-aß T cells, the $CD4^+$ (T helper cell) and the $CD8^+$ (cytotoxic T cell), and one TCR-?d cell.

a/ß T-CELL RECEPTOR COMPLEX

The TCR complex is composed of two components: One component is unique in each T cell and is involved in antigen recognition (ligand binding), and the second component is the same in all T cells and is involved in signal transduction leading to T-cell activation ([191], [192] and [193]).

Ligand-Binding Component: aß and Peptide–Major Histocompatibility Complex Interaction

The aß receptor is formed by two chains, a and ß (Fig. 17.7). Each chain consists of a constant domain, Ca and Cß, and a variable domain, Va and Vß. The Va domain is encoded by two genes, Va and Ja, and is homologous to the V domain of the Ig heavy chain. The Vß domain is formed by three polypeptides, Vß, D, and Jß. The constant domains correspond to the IgC-domains, but there are certain differences. The Ca-Cß interface is highly polar, whereas that of C_L-C_{H1} is hydrophobic. Cß has a large loop, which extends out to the side of the domain. It has been proposed that it may interact with the co-receptors. The Ca domain has several structural deviations from the C-type Ig domain.

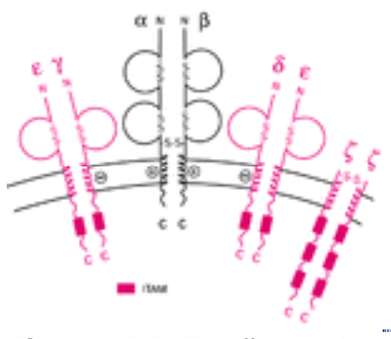

Figure 17.7. T-cell receptor complex. The T-cell receptor complex consists of two components: ligand binding (antigen recognition) and signal transduction. The antigen recognition component consists of two polypeptide chains, a and ß. Because of their short intracytoplasmic tails, they cannot link themselves to the signal transduction cascade. The signal transduction component consists of the CD3 proteins: ?, ?, and e, members of the immunoglobulin superfamily, and two other proteins forming either a homodimer (two ? proteins) or a heterodimer (?-?). The ?-, ?-, and e-chains have one immunoreceptor tyrosine-based activation motif each, and the ?-chain has three. See text for details.

The V domains are highly similar to the V domains of an antibody molecule. They contribute to the formation of the TCR-combining site, which is made up of hypervariable loops or complementarity-determining regions (CDRs) 1, 2, and 3 from the a- and ß-chains and another loop termed *HV4*, which exhibits some hypervariability. The CDR1 and CDR2 are formed by the V segments, which are less polymorphic in the TCR than in Ig because fewer V segments are available for TCR, whereas the CDR3 is polymorphic as a result of the larger number of J segments available for ß-chain contributing to CDR3.

The loops of Vß that form the expected antigen-binding site of the TCR are similarly placed as in the Ig V region. The chains are linked by a disulfide bond, and the heterodimer is anchored to the cell membrane by the transmembrane region, ending in the cytoplasm by a short (three- to five–amino acid) cytoplasmic tail. Crystallization of the TCR shows that it resembles the Fab fragment of the Ig molecule ([193]). However, the TCR-aß is extensively glycosylated with up to seven N-linked sites distributed between the a- and ß-chains. The combining site is usually flat, similar to antiprotein antibodies and consistent with the TCR's function of binding to the generally flat, undulating surface of the pMHC ([194]). The diversity of the CDR3s is much higher, implying that the function of CDR3s is in peptide discrimination, whereas CDRs 1 and 2 interact with more conserved structural elements of the MHC. The TCRs contain many more J segments and thus are able to increase V-Ja and V-D-Jß junctional diversity in the CDR3s ([195]). The residues of the TCR that contact the pMHC are always in the apices of the CDRs (i.e., for CDR1a, residues 27 to 30; for CDR2a, residues 50 to 52; for CDR1ß, residues 27 to 30; and for CDR2ß, residues 52 and 53).

The TCR interacts with peptides bound to MHC molecules (Fig. 17.8). The aminoterminal domains, a_1 and a_2 of the MHC class I heavy chain, form the binding site for the peptide. The site consists of a floor of eight strands of antiparallel ß-pleated sheets, which support two a helices, one contributed by the a_1 domain and the other by the a_2 domain aligned in an antiparallel orientation. The floor of the groove is supported by two Ig domains from below; one is the a_3 domain of the heavy chain and the other the $ß_2$-microglobulin. This arrangement forms a groove, on the floor of which lies the peptide from an antigen to be presented to the TCR. Some of the residues of the peptide are exposed above the groove and interact directly with the TCR, whereas others point to the floor of the groove. Depressions in the floor of the groove, known as *pockets A through F*, interact with some side-chains of the bound peptide ([196]).

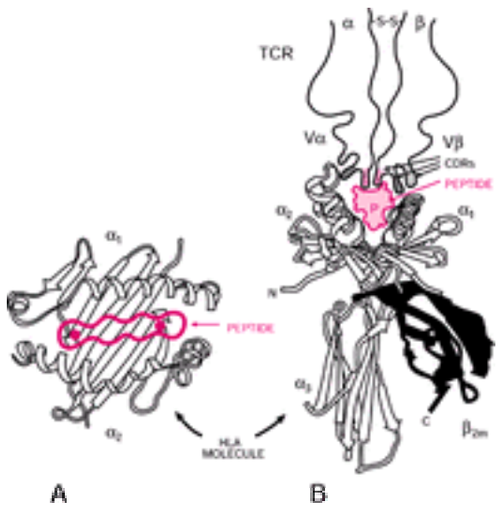

Figure 17.8. T-cell receptor (TCR) interaction with HLA/peptide complex. Crystallographic studies of the HLA class I molecule have shown that the two variable domains (a $_1$ and a $_2$) form a groove that binds the peptide that is released as a result of antigen processing. The peptide groove is formed by the helices of the a $_1$ and a $_2$ domains **(A)**. Binding of the peptide is mediated through anchor amino acids near both ends of the peptide (in **A**). The TCR binds to both the major histocompatibility complex molecule and the peptide. The complementarity-determining region (CDR) 3 of both the a- and ß-chains interacts with amino acids of the peptide, whereas the CDR1 and CDR2 interact with the major histocompatibility complex molecule **(B)**.

For HLA-B27, the side-chain of the *C*-terminal of the bound peptide sits deep in the F-pocket, whereas the *N*-terminal forms strong hydrogen bonds with the hydroxyl groups of conserved amino acids at the end of the groove ([197]). (For details of interaction with the pMHC, see Chapter 18.)

For crystallization of TCR-pMHC, the peptide was attached covalently through a linker to the amino terminus of the ß-chain of an MHC class II molecule ([198]) or covalently connected to the amino terminus of the ß-chain of the TCR ([199]) and thus tethered to the MHC groove. Such approaches provided stable complexes of HLA-DR1 and HLA-DR4 that permitted their crystallization. TCR extracellular domains were produced in *Escherichia coli*. Several TCR-pMHC have been analyzed to clarify the contributions of Va for the buried surface area (i.e., the interface between TCR and the pMHC). The buried surface area varies extensively (1239 Å ^{2} to 1931 Å ^{2}). The contribution of Va is on the average 57% and that of the Vß 43%, but individual chain contributions vary between complexes ([200]). The overall orientation of the TCR over the pMHC is diagonal ([201] , [202]) rather than orthogonal ([203]). It is more likely that the TCR twists over the MHC molecule by approximately 35 degrees and varies also in its roll (range, 19 degrees) and tile (range, 30 degrees) ([204] , [205]).

The interactions that position the TCR in a diagonal orientation also place the CDR1 and CDR2 loops over the a $_1$/a $_2$ or a $_1$/ß $_1$ helices for the MHC class I and class II molecules, respectively. The Va domain is critical in setting up these orientations and the read-out of the peptide sequence. Thus, the CDR1 and CDR2 interactions of Va are conservative ([192]) and provide the basic affinity of the TCR, whereas the CDR3 loop is positioned to primarily contact the peptide in the peptide-binding groove and the Vß interaction is more variable in the *C*-terminal half of the peptide. The contribution of the individual CDR loops to the interaction varies. CDRs 1ß and 2ß actually contribute little or nothing to the interaction in those studied. In general, the CDR3 loops are centrally located and usually dominate the interactions ([200]).

The contributions of the peptide to the interactions with the TCR also vary. Usually, approximately two to five side-chains of the peptide make direct contact with the TCR. These contact points, known as *hot spots*, are peptide residues that bulge out of the groove, and this bulging is more prominent in MHC class I and is sometimes profound ([206]). Such extensive bulges need to be accommodated in the TCR-MHC interface. Ridges in the MHC molecule sometimes force the peptides to bulge high out of the groove, and these residues of the peptide provide intimate contact with the TCR ([207] , [208]). For MHC class I, the hot spots are predominantly residues P $_5$, P $_7$, and P $_8$ for nonamer peptides and P $_4$, P $_6$, and P $_7$ for octamer peptides. In MHC class II–TCR interactions, the contributions of the side-chains of the peptide are more uniformly dispersed (P $_1$, P $_2$, P $_3$, P $_5$, P $_8$), and the peptides are slightly deeper in the MHC binding groove ([206]).

No single contact dominates the TCR–pMHC interactions, as is often observed in the antigen–antibody interactions. A small number of amino acids dominate the energy landscape in antigen–antibody interaction, as shown by somatic mutations that result in higher affinity binding ([209]).

In the case of TCR, any change of the affinity or even prolongation of interaction, which may happen in the thymus during selection, results in negative selection. Based on these considerations, it appears likely that the CDR1 and CDR2 loops interacting with the helices of the MHC are responsible for positive selection, whereas the CDR3 loops probably play a more important role in negative selection. As an extension of these considerations in delineating the roles of V region loops of the TCR, the CDR1 and CDR2 loops provide the basic affinity in the interaction, whereas the CDR3 provides the specificity ([200]). The residues of the peptide that protrude highest from the groove provide the basis for discrimination of peptide and for altering affinity or half-life of the TCR–pMHC interaction.

An important point that came out of these crystallographic studies is the role of the water that fills the TCR–pMHC interfaces. This water provides additional complementarity by filling the cavities in the interface, and some of these molecules mediate contact between TCR and pMHC ([210] , [211]).

Overall, the consistent feature of TCR–pMHC interaction is that the peptide contributes a smaller portion of the binding interface (21 to 34%) and a smaller proportion of contacts (26 to 47%) than the MHC. The central positions of the peptide play the critical role, and those define the peptides as agonists, partial agonists, and antagonists ([212] , [213]). The binding of TCR to the pMHC results in T-cell activation. Usually, there is a broad correlation between affinity, half-life, and the functional outcomes ([214] , [215]). Mutational analysis of the role of the centrally located residues indicates that in some systems, the biologic activity increases ([216]), yet in others, the peptide is converted from an agonist to an antagonist ([217]); nevertheless, the affinities of the pMHC for TCR change only marginally.

Contacts on certain hot spots are very sensitive in changing the functional read-out but are not based on changes in the affinity of binding or half-life differences in the TCR–pMHC complexes ([218]). It has been argued that affinities usually have been measured in isolated TCR–pMHC complexes, and true affinity measurements may require the presence of co-receptors and signaling components and need to be measured with cellular assays ([217]).

Because changes in the TCR–pMHC complementarity interface are important for triggering biologic reactions, the conformational changes that have been observed in the TCR-complex crystal structures have been considered for initiation of signaling, but their role is not clear ([219]). Conformational changes contribute to an increase in the binding of a number of other peptides (i.e., an expansion of the repertoire) ([220]).

Co-Receptors in Peptide–Major Histocompatibility Complex Interaction

The TCR is not alone in its interaction with the pMHC but is associated with co-receptors (i.e., CD4, CD8, and the CD3 chains). The monomorphic CD3 ?-, ?-, e-, and ?-chains, together with the aß heterodimer, form the TCR complex. The CD4 or CD8 acts as assistant to the TCRs of the helper or cytotoxic function of the cells, respectively. Therefore, they have been known as *co-receptors* ([126] , [221]). In the current model, the CD4 binds to the same MHC II as the TCR of the CD4 $^+$ T cell, and similarly, the CD8 binds to the same MHC I as the TCR of the CD8 $^+$ T cell. The binding of the co-receptors occurs with another site of the MHC molecule than that involved in the TCR binding. The TCR binds to pMHC surface at an angle between 45 and 80 degrees relative to the axis of the two a helices of MHC ([222]), which excludes the possibility for direct association of the co-receptors with the TCR that binds the same pMHC. One possibility is that the co-receptors could be linked with TCR in the cytoplasm through signaling molecules (i.e., ZAP-70 and Lck) ([223] , [224]). Another possibility is that the co-receptor associated with a TCR binds to a different pMHC to which a second TCR binds, forming a *pseudodimer* ([225]).

The CD8 acts as a dimer that includes either two a-chains or one a- and one ß-chain, whereas CD4 is a monomer with four Ig-like domains (see Chapter 2). Both CD8 chains consist of an Ig-like V domain and a long mucinlike stalk. The Ig-like domain binds to the a $_3$ domain of MHC ([226]), forming also some hydrogen bonds with the a $_2$ domain and the ß $_{2M}$-chain, away from the peptide interface. In CD4, only the fourth Ig-like domain binds directly to pMHC. The ternary complex

(TCR-pMHC-CD4/CD8) within the T cell–antigen-presenting cell (APC) interface of the immunologic synapse has a V shape ([227]) (Fig. 17.9). Although the CD8a stalk is longer than the CD8ß-chain, even in its full extension, it reaches only 50 to 60 Å, which is not long enough to traverse the distance of approximately 100 Å to the TCR–pMHC complex. As a result, the TCR–pMHC has to tilt for the CD8 to reach the MHC. The stalk of the CD8-chains is heavily glycosylated, and changes in glycosylation (which occurs after T-cell activation) result in a decrease of binding to MHC ([228]).

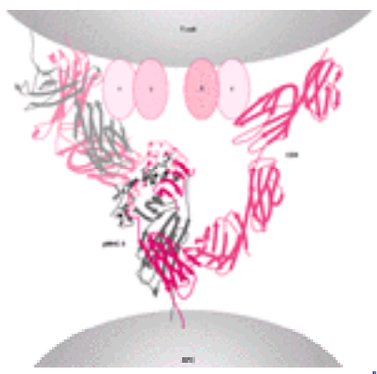

Figure 17.9. T-cell receptor (TCR)–major histocompatibility complex (MHC)–co-receptors interaction. The CD4 and CD8 are co-receptors of the TCR [i.e., "assistants" in the interaction of TCR with peptide–MHC complex (pMHC)]. In this function, the *N*-terminal domain of CD4 (D1) makes contact with the a $_2$ and ß $_2$ domains of MHC II. In the CD8, the CD8a subunit of the CD8aß heterodimer contributes the binding energy, interacting with both the a $_2$ and a $_3$ domains of pMHC I, and CD8ß binds only to a $_3$. Therefore, both co-receptors recognize different sites of MHC from the TCR. The length of each receptor is not long enough to reach the MHC binding site, traversing alongside the TCR-MHC complex. It is proposed that TCR-MHC has to tilt for the co-receptor to reach the MHC, forming a V-shaped ternary complex. The CD3 components of the TCR (?, ?, e) probably are located inside the V-shaped structure. APC, T cell–antigen-presenting cell. (Courtesy of Dr. G.F. Gao.)

The co-receptors enhance TCR signaling by strengthening the stability of the TCR–pMHC complex ([229] , [230]). The V-shaped ternary complex accepts that the co-receptors bind to the same pMHC as the TCR ([227]), whereas the CD3 components probably lie inside the "open angel" of the V-shaped structure (Fig. 17.9). Such an arrangement makes possible the association of signaling molecules, such as ZAP-70, Lck, and Src kinases, with CD4 and CD8. With this topologic model, direct interaction of the co-receptors with TCR is not likely as was previously indicated ([231]).

The CD2 binds to CD58 (LFA-3) in humans and to CD48 in rats. Interaction is based on electrostatic complementarity, with the CD2 surface heavily populated by basic residues, whereas the CD58 is acidic. The interactions span approximately 134 Å—very similar to that of TCR–pMHC. Therefore, the CD2/CD58 interaction in the contact zone between T cell and the APC would facilitate the scanning of pMHC by TCR ([232]). CD2 lowers thresholds for TCR triggering *in vitro* and T-cell activation *in vivo* ([233]).

CD28 and CTLA-4 (CD152) are type I membrane proteins consisting of one moderately to heavily glycosylated V Ig-like domain. They are expressed as disulfide-linked homodimers. Their counterreceptors B7-1 (CD80) and B7-2 (CD86) consist of two Ig-like domains, a membrane-proximal C2 type, and a membrane-distal V-type. B7-2 binds CD28 more effectively than CTLA-4 and, as a result, enhances co-stimulatory effects when CD28 and CTLA-4 are coexpressed.

In contrast, B7-1 binds preferentially CTLA-4, and its inhibitory effect would not be affected in the presence of CD28. Delayed expression of B7-1 on APCs appears to be timed to enhance the inhibitory function of CTLA-4. The CTLA-4 periodic arrays of crystal lattices enhance the avidity of interaction, whereas the CD28/B7-2 interaction does not have this potential. As a result, during an immune response, the CD28/B7-2–activating complexes are 10,000-fold less stable than the inhibitory complexes formed later by CTLA-4/B7-1 ([234]).

Signal-Transducing Component of T-Cell Receptor Complex

The TCR-aß is accompanied by five other polypeptide chains, collectively known as *CD3 proteins*: ?, ?, e, ?, and ?. They form disulfide-linked heterodimers ?d, ed, ??, or a homodimer, ?? ([235] , [236]) (Fig. 17.7). The ?, ?, and e proteins show a significant degree of similarity to one another. The ?, ?, and e proteins consist of an Ig-like domain similar to the C domain with an intra-chain disulfide bond. The extracellular region of the ?-chain is only nine amino acids long and contains the only cysteine of the molecule, which forms the disulfide bond with the other chain or with an ?-chain. In the transmembrane region, the ?, ?, and e proteins have a negatively charged amino acid complementary to a positively charged amino acid of the transmembrane region of the TCR-aß chains. The cytoplasmic regions of ?-, ?-, and e-chains are long, ranging from 40 to 80 amino acids, whereas that of the ?-chain is even longer with 113 amino acids. The ?-chain is a splice variant of the ?-chain and, as a heterodimer with the ?-chain, exists only in a small number of T cells.

The CD3 proteins have a dual mission in the function of the TCR: escort the receptor to the cell membrane and mediate the signals generated by the TCR–pMHC complex. The complex is assembled in the endoplasmic reticulum, transported to the Golgi apparatus, and then transferred to the plasma membrane. The amount of the ?-chain is rate limiting because it is synthesized at only 10% of the level of the other chains. This results in the degradation of a vast majority of the newly synthesized a, ß, or CD3 components within 4 hours of their synthesis ([237]). The remaining undegraded chains are long-lived and form complete TCR–CD3 complexes with the limiting ?-chain. The TCR–CD3 complex lacking the ?-chain migrates through the endoplasmic reticulum and Golgi intact and then is transported to the lysosomes where it is degraded. A lysosome-targeting motif has been identified in the ?- and ?-chains and consists of a dileu-cine-based motif (DKQTLL) and tyrosine-based motif ([238]) in the carboxyterminal region. In the completed complex, the TCR a-chain pairs with CD3 ?- and e-chains, and the TCR ß-chain pairs with CD3 ? and e. The ?-chain joins the TCR and the CD3 chains in the last stage of the assembly. The topology of the TCR–CD3 complex is shown in Figure 17.6. Two TCR aß heterodimers are associated with one each of ?e and de heterodimers and one ?? homodimer. The signal transduction function of the CD3 proteins is based on the presence of one ITAM in each of the ?, ?, and e proteins and three in the ?-chain. An ITAM consists of two YXXY/L sequences separated by six to eight amino acids (in the one letter code for amino acids: Y, tyrosine; L, leucine; and X, any amino acid) ([239]).

Phosphorylation of the tyrosines turns the ITAM motifs into docking sites for protein tyrosine kinases, which bind to the ITAM through their SH $_2$ domain (see below). An important protein tyrosine kinase in T-cell activation, the ZAP-70, is recruited to the ?-chain ITAM motifs. The multiplicity of ITAM motifs in the cytoplasmic tails of the CD3 proteins results in signal amplification and increases the sensitivity of the TCR to ligand stimulation. Triplication of a single ITAM motif significantly enhances Ca^{2+} mobilization, association with ZAP-70, and transcriptional activity in the NFAT complex involved in IL-2 gene regulation ([240]). Cross-linking of a single isolated ITAM results in approximately threefold induction in NFAT-regulated activity, and cross-linking of a triplicated motif results in approximately eightfold increase in NFAT-regulated activity (i.e., comparable to the intact ?-chain).

Co-Receptors to T-Cell Receptor: CD4 and CD8

CD4 CD4 is the characteristic marker of aß T cells with helper activity and cytokine secretion. The molecule consists of four Ig-like domains, with domains D1 and D3 similar to a V domain, and D2 and D4 similar to C domains (C-2 type) with patches of sequences similar to V domain. In D1 and D3, the nine ß strands form two ß sheets (ABED and GFCC'?). The D1 shares all the features conserved and characteristic of the V antibody domain. In the D3, the intersheet disulfide bond as well as the salt bridge are absent. As a result, the two sheets move apart and "slide" relative to each other. D2 also has no intersheet disulfide bond. The domains are linearly arranged, forming a rod with limited flexibility between the domains ([241] , [242]). The binding of CD4 to MHC II molecules and to HIVgp120–envelop protein was studied by mutational analysis. The binding is mediated by a sequence of two ß strands, C'C?, within the D1 domain that form a ridge (residues 35 to 46) ([243]). Phe43 within this sequence is critical for binding to gp120, as well as for CD4 co-receptor function ([244]) because it provides the major binding energy, whereas the surrounding charged amino acids facilitate specificity ([245]). Crystal structure of the D1/D2 domains from CD4 complexed with class II molecule shows that the CD4 *N*-terminal V domain is directed and reaching into the two membrane-proximal domains of MHC II molecule ([246]). Both TCR and CD4 are tilted rather than oriented vertically, forming a V-shaped CD4-pMHCII-TCR ternary complex (Fig. 17.9). In this complex, the antigen-binding groove of pMHC II is no longer parallel to the cell surface but makes an approximately 45-degree angle with the membrane. However, despite the V shape of the ternary complex, the membrane-proximal domains of each of the components are all roughly vertical, including domain 4 of CD4 and the a $_2$ and ß $_2$ domains of pMHC II as well as the Cß domain of TCR. Only the Ca domain of TCR

hangs almost parallel above the membrane with its lengthy stalk bridging the space. The extracellular fragment of CD4 crystallizes as a dimer associated via the D4 domains ([247]). Oligomers of CD4 have been extracted from isolated lymphocytes ([248]). The CD4 dimers are associated with superdimers or dimers of dimers of the MHC II molecules ([249]). Each CD4 molecule interacts with one dimer of MHC II. Amino acid substitutions in the faces of the MHC II molecules that participate in the formation of the superdimers block activation of $CD4^+$ T cells, implying that superdimer formation is a prerequisite for T-cell activation ([249]). Stable binding to MHC II requires oligomerization of CD4, and this is facilitated by the D3/D4 domains. Collectively, data gathered from a variety of approaches suggest that CD4 oligomerizes once it binds to one MHC II molecule, forming tetramers or even larger oligomers and cross-linked lattices ([250]). In this process, CD4 oligomerization is influenced not only by MHC II but also by the TCR. When CD4 and TCR co-localize to interact with the same pMHC II molecule, the CD4 brings $p56^{lck}$, which is associated with its short cytoplasmic tail, to the site of immune recognition. This may constitute one of the main contributions of CD4 to TCR signaling ([251]).

CD8 CD8 consists of an Ig-like ectodomain, a membrane-proximal stalk (or hinge) region, a transmembrane region, and a cytoplasmic region. The Ig-like domain is involved in the binding to MHC, as shown by crystallographic evidence ([252]) and mutational analysis ([253]). The CDR loops of the A and B strands of the CD8aa molecule contact the a_2, a_3, and ß $_2$M domains of MHC I ([254]). The ß subunit of the CD8 interacts only with the a_3 domain, whereas the a subunit interacts with the a_2 and a_3 domains ([255]). In these interactions, the a_3 domain is shifted to better accommodate the CD8 binding ([256]). Multiple contacts between the co-receptor and MHC I promote the functional contributions of the co-receptor to T-cell activation ([257]). CD8 enhances cytotoxic T lymphocyte (CTL) activation by enhancing the stability of interaction between the APC and the T cell ([258]). In addition, the a-chain of the CD8 is associated with the $p56^{lck}$, which is brought closer to the ZAP-70 kinase associated with the TCR, a role that has also been assigned to the CD4 co-receptor. The contributions, therefore, of both co-receptors in ligand recognition and enhancement of TCR signaling are multiple and involve facilitation of TCR clustering, stabilization of the TCR–pMHC complex, and promotion of signaling by bringing together signaling molecules attached separately on the cytoplasmic tails of the TCR and co-receptors ([259]). The availability of pMHC tetramers has encouraged studies on the function of CD4 and CD8 co-receptors in TCR binding to pMHC. The CD4 is critical for signal transduction with pMHC tetramers ([260] , [261] and [262]), but the CD8 co-receptor also contributes to the initial phase of interaction (binding), the duration of interaction (stability), and the delivery of signal transduction ([263] , [264]). The final result of CD8 function depends on the epitope of CD8 involved in the interactions, which are more pronounced with low-affinity ligands ([264]). Blockade of CD8ß may affect TCR–CD8 rather than CD8–MHC interaction. The CD8ß is more efficient than CD8a at association with the TCR ([265]). An important new function of the co-receptors in TCR-mediated activation is the demonstration that CD4 and CD8 associate with LAT (linker for activation of T cells), a 36- to 38-kd membrane-associated adaptor protein that plays a central role in TCR signaling ([266] , [267]). As a result of LAT association with surface co-receptors and the coengagement of the TCR with the co-receptors, LAT is phosphorylated and recruits downstream signaling molecules ([268]). In conclusion, the contribution of the co-receptors in TCR signaling results from (a) the physical approximation of the Lck, which is associated with the co-receptors; (b) phosphorylation of the ITAMs of the CD3 chains of TCR; (c) recruitment of ZAP-70; and (d) phosphorylation of LAT, also associated with the co-receptors. Individual TCR molecules are probably associated with either Lck or with LAT ([268]).

T-CELL ACTIVATION

Topology of Immune Recognition

The aß-TCR recognizes short peptides (i.e., eight to ten residues long) for class I–restricted TCRs or 13 to 25 amino acids for class II–restricted TCRs. However, only approximately nine amino acids contact the TCR. The peptide is held by the MHC molecule embedded in a groove formed by the a_1-a_2 domains of MHC I or by the a_1-ß $_1$ domains of the MHC II (see Chapter 18). Interaction of TCRs initiates signal transduction leading to transcription of genes encoding cytokines in $CD4^+$ T cells or assembling and mobilizing the lytic machinery in $CD8^+$ T cells for killing cells infected by viruses, transformed to a malignant state, or being “strangers,” such as in transplanted tissues. The crystal structure of aß-TCR has been solved and, for several of them, in complex with their cognate pMHC ligand ([257] , [269] , [270] , [271] , [272] and [273]). The data support the docking model of the TCR ligand interaction, in which the TCR approaches the peptide held on an MHC platform. In this model, the Va domain of the TCR is closest to the *N*-terminal residues of the peptide, whereas the Vß domain of the TCR is closest to the *C*-terminal end of the peptide. In this orientation, the TCR Vß domain contacts the MHC I a_1 domain, whereas the TCR Va domain interacts with the a_2 of MHC I. The TCR orientation relative to the long axis of the MHC platform varies between 45 and 80 degrees (i.e., the angle formed between a line passing through the centers of the Va and Vß domains of the TCR and a second line defined by the peptide on the MHC platform) ([274]). The peptides in all MHC I structures have their N- and C-termini anchored into two fixed pockets approximately 20 Å apart in the MHC I platform. Longer peptides usually bulge in the center. In MHC II, the peptides assume an extended conformation, and the middle portion is smooth and concaves away from the TCR. Residues 1 and 5 of the peptide (p-1, p-5) in MHC II point toward the TCR and are critical in TCR recognition. The co-receptors bind to the same pMHC ligand as the TCR, but the binding of the co-receptor is independent of the TCR binding and is severalfold weaker ([251] , [275]).

The TCR, the pMHC, and the co-receptor form a ternary complex that assumes a V shape with the pMHC II at the apex and the TCR and CD4 as the two arms.

Overall, the data from crystallized complexes of TCR with pMHC suggest that TCR docking on the MHC platform involves residues that are conserved within the CDR1 and CDR2 of the TCR and provide basal level of stabilizing energy in the formation of the complex ([276]). Variations within the CDR3a and CDR3ß loops affect the way the TCRs footprint on the pMHC surface.

The Gathering Storm: Lipid Rafts and the Immunologic Synapse

A model for T-cell activation proposes that a naïve or resting T cell needs to cross several stages to achieve full activation ([277]). During the first stage, which lasts a few seconds, contacts need to be established by adhesion molecules that overcome charge repulsions between cells. In the next stage, active cytoskeletal rearrangements bring together accessory molecules and the TCR and concomitantly exclude unligated molecules, such as CD45 (a protein tyrosine phosphatase) as well as CD43. CD43 is a highly glycosylated protein with strong repulsive forces forming a thick glycocalyx “cloud” approximately 45 nm thick around the cells. Because the distance spanned by the TCR–MHC complex is a mere 15 nm, for TCR to sample the pMHC ligand, clearing the area of contact between TCR and MHC from the interfering tall molecules, like CD43 and CD45, is mandatory. This takes minutes. Finally, the fundamental signaling units of several signaling molecules are “loaded” on a lipid raft, sustained by the cytoskeleton. This takes hours.

Lipid rafts are evolutionarily conserved structures that gather receptors involved in signaling in various cell types ([278] , [279] , [280] and [281]). The lipid rafts are defined as cholesterol-dependent microdomains resistant to solubilization in nonionic detergents at low temperatures ([282]). The lipids contained within the cellular plasma membrane include glycerophospholipids, glycosphingolipids, and sterols. Rafts consist of sphingolipids and cholesterol, which can move through the more liquid-disordered phase of the membrane containing glycerophospholipids ([283]). Because of their lipid consistency, lipid rafts have also been referred to as *glycosphingolipid-enriched membrane microdomains* or *GEMs*. Lipid rafts are anchored by filamentous actin, and actin polymerization causes their coalescence. Phosphatidylinositol-([4] , [5]) biphosphate (PIP_2) activates proteins involved in actin–membrane interactions, such as binding of the ezrin-radixin-moesin family to CD44, a protein broadly expressed on detergent-resistant membranes. Detergent-resistant membranes are presumed to be isolated rafts. PIP_2 activates actin nucleation and polymerization of raft domains. Raft size is poorly understood because they cannot be visualized by light microscopy without clustering ([284]). In resting T cells, the TCR and GM1 are homogeneously distributed. Cross-linking, however, produces large enough aggregates to be visualized using epifluorescence microscopy. Fluorescence resonance energy transfer is sensitive to distances in the order of a few nanometers. Because fluorescence resonance energy transfer was detected between glycosylphosphatidylinositol (GPI)-anchored transferrin receptors interacting with natural ligands, it was concluded that rafts exist but that they are smaller than 70 nm in diameter ([284]). Others could not find microdomains enriched in GPI-anchored proteins or GM1. Some MHC II molecules loaded with a select set of peptides are detected on microdomains made up of tetraspan proteins, such as CD9, CD63, CD81, or CD82 ([282]). These tetraspan microdomains are recognized by CDw78 antibody (mAb FN1), which originally was believed to recognize an epitope of HLA–class II molecules.

A central feature of lipid rafts is that they allow for the lateral segregation of proteins within the plasma membrane. This provides a mechanism for compartmentalization of signaling components within the membrane, concentrating certain components in lipid rafts and excluding others (Fig. 17.10). Proteins with GPI linkage, such as CD14, CD16, CD48, and CD58, are associated with the outer leaflet of lipid rafts. Cytoplasmic proteins, on the other hand, associate with the inner leaflet of lipid rafts through acylation. Most of the Src signaling proteins are acylated and raft associated. The vast majority of transmembrane proteins are excluded from rafts constitutively and cannot be induced to partition into rafts on cross-linking.

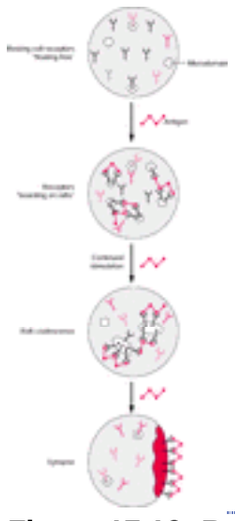

Figure 17.10. Rafts: elementary units of the immunologic synapse? In the resting state, the multichain immune recognition receptors (MIRR) (i.e., T-cell receptor, B-cell receptor, and so forth) “float” free on the lipid membrane, or transiently, some may get on board on certain membrane “microdomains,” also known as “lipid rafts.” Interaction with a multivalent ligand aggregates several receptors that accumulate within the rafts, forming multimolecular clusters. On prolonged exposure to the ligand, the MIRR clusters result in raft coalescence with the formation of a large aggregate, the immunologic synapse. Cytoskeletal reorganization from multichain immune recognition receptor and chemokine signaling promotes immunologic synapse formation. (Adapted from a model proposed by Dykstra M, et al. Location is everything: lipid rafts and immune cell signaling. Annu Rev Immunol 2003;21:457–481.)

Some proteins important in T-cell activation, such as LAT, CD4, and CD8, reside on rafts. Other proteins reside constitutively outside of the rafts but, when activated, become translocated to rafts. The multichain immune recognition receptor family is an example ([285], [286]). Translocation into rafts after ligand binding appears to be immediate, occurring within seconds of engagement of the receptors, and is selective. For example, CD45, a4 integrin, and IL-1 receptor are excluded from rafts and do not translocate into rafts, even on cross-linking ([287], [288]). The transmembrane domains of the receptors appear to have a significant influence on translocation, as exchange or mutation of the transmembrane regions alters the translocation properties of the receptors. Translocation of the receptor into the lipid rafts does not need actin reorganization. However, stable residency into the rafts depends on interaction with actin cytoskeleton.

The constitutive presence of receptors in rafts may be related to their role in cell survival. For example, the pre-TCR is constitutively associated with rafts and, with its signaling, instructs lineage commitment. TCR/CD28 is excluded from rafts in immature thymocytes, and signaling leads to apoptosis ([289]).

In addition to their role in signaling, lipid rafts serve as platforms for B-cell receptors (BCRs) to transport bound antigen for processing and presentation. The internalization of BCR with captured antigen is initiated from rafts.

Retention of receptors in rafts is a mechanism for augmentation of cell activation. The CD19/CD21 complex is excluded from rafts, but its colligation with BCR by antigen-antibody-complement complexes causes translocation of BCR and CD19/CD21 complex into rafts, where the complex prolongs the retention of BCR within the rafts ([290]).

T-cell activation causes rearrangement of the actin cytoskeleton and polarization of the cell toward the site of activation, such as the APC. This polarization is reflected by reorientation of the microtubule-organizing center toward the APC ([291], [292]). The TCR is clustered together with associated molecules (CD4, CD8, CD2, CD28, and so forth), a process known as *capping*. Capping depends on actin reorganization regulated by phosphoinositides, which activate Vav [a guanosine diphosphate–guanosine triphosphate (GTP) exchange factor] and the Wiskott-Aldrich syndrome protein (WASp). In patients with Wiskott-Aldrich syndrome, WASp is lacking or markedly reduced, and they have defects in actin polymerization, capping, and antigen-induced proliferative responses ([293]). WASp regulates the Arp2/3 complex, which mediates actin branching and polymerization (see Chapter 14).

PIP_3 is a strong activator of Vav, which is targeted to detergent-resistant membranes after TCR activation. In Vav-deficient mice, the capping is severely disrupted, and T-cell proliferation is reduced. Raft aggregation is disrupted by the negative regulator of T-cell activation, Cbl (Casitas B-cell lymphoma-b), which is a molecular adaptor and part of the ubiquitin ligation machinery involved in the degradation of phosphorylated proteins. Cbl inhibits TCR clustering and sustained tyrosine phosphorylation. In Cbl-deficient mice, TCR/CD3 stimulation alone can activate receptor clustering without the need for CD28 co-stimulation ([294]).

Immunologic Synapse in Three Stages

The TCR interactions with pMHC take place in an intercellular junction between the T cell and the APC. In this junction, signal 1 (TCR) and signal 2 (co-stimulation) are processed. This interface reveals a dramatic reorganization of signaling components, forming what is called the *immunologic synapse* (IS), a term borrowed from Sherrington's turn-of-the-century definition of the interconnections of neurons as synapses (from the Greek *synapsis*, meaning joining, linking, connecting) ([294a]). The IS relays information across the cell junction in both directions ([295]).

The IS is organized into two major compartments: the central supramolecular activation cluster (*cSMAC*), enriched in TCRs and CD28, and the peripheral supramolecular activation cluster (*pSMAC*), which contains the LFA-1 molecule and talin ([296]) (Fig. 17.11). On the side of the APC, correspondingly, the cSMAC contains the pMHC and CD80 (ligand for CD28) and the pSMAC contains the ICAM-1 (counter-receptor for LFA-1) and CD58, ligand for CD2. The IS develops over a period of minutes after interactions of the T cell and the APC. Formation of the synapse depends on an intact cytoskeleton ([297]). T-cell activation is accompanied by a dynamic reorganization of cortical actin with increase of filamentous actin. These cytoskeletal changes are accompanied by progressive morphologic changes of the T cells, which first become round, followed by spreading of the cell ([298]). In the absence of antigen, the T cell maintains its motility, continues to crawl around the APC, and may even leave for another partner. Some receptors on the APC may convey a “danger signal” for the T cell to pay particular attention and explore the APC in search of antigen ([299]).

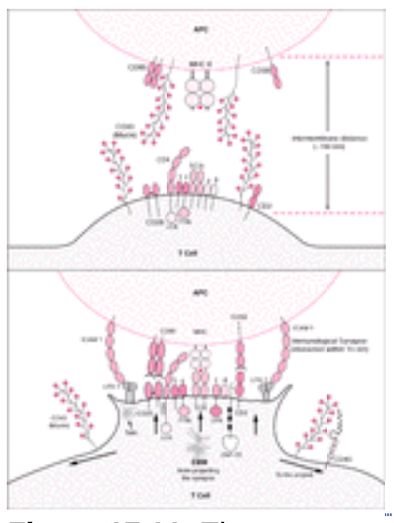

Figure 17.11. The structure of the immunologic synapse. The immunologic synapse is formed between T cell and an antigen-presenting cell (APC) (in the case of $CD4^+$ T cell) or with a target cell (in the case of $CD8^+$ T cell). Immunologic synapse formation is a multistep process. A thick glycocalyx on both cells, made predominantly from the mucin molecule CD43, comes in conflict with the approaching T cell and APC. This distance (50 to 100 nm) is too long for the T-cell receptor (TCR)–peptide-major histocompatibility complex (MHC), which interacts at 15 nm. The integrin lymphocyte function molecule (LFA)-1 and its counterreceptor, intercellular adhesion molecule (ICAM), which interact at 40 nm, may bring the cells for an initial contact. More important, chemokine signaling that activates heterotrimeric G-proteins activates myosin II, and the cortical cytoskeleton collapses, disanchoring CD43 by the ERM (ezrin/radixin/moesin) adaptor proteins. With

loss of the cell rigidity, a new F-actin network creates a pseudopod that propels the leading edge of the T cell toward the APC. This approach at an intercellular distance of 15 nm prevents CD43 reentry in the central area of T cell–APC contact. Concomitantly, talin (a large cytoskeletal protein with attachment to integrins) maintains LFA-1 immobilized in a ring around the central part of the synapse. Although LFA-1/ICAM-1 interacts initially at a distance of 40 nm (extended LFA-1 form), after activation, it assumes a bent form (high affinity) that brings the cell membranes closer ("ratchet"-like effect). Multiple other adhesion molecules of low affinity, such as between CD2 and CD58, contribute to the alignment of the two cell surfaces at 15-nm distance, allowing the TCR to sample the small numbers of peptide–MHC ("proofreading"). The final mature immunologic synapse ("bull's eye") consists of a central supramolecular activation cluster and the peripheral integrin-rich zone. (Dustin ML, et al. The immunological synapse and the actin cytoskeleton: molecular hardware for T cell signaling. Nat Immunol 2000;1:23–29; and Delon J, et al. Imaging of T-cell interactions with antigen presenting cells in culture and in intact lymphoid tissue. Immunol Rev 2002;189:51–63.)

In the *first stage*, the contact is antigen independent and is mediated by CD28 on the T cell with CD80/CD86 on the APC, which are more abundant (>10^4) than the pMHC (approximately 100 to 200). The CD28 affinity for CD80 is at least two orders of magnitude above that determined for the TCR–pMHC interaction. These interactions of CD28 preceding the TCR encounters are actually contrary to the original definition of the co-stimulatory function of CD28, believed to parallel or even follow TCR signaling.

The *second stage* of IS formation is antigen dependent. The T cell extends large cytoplasmic, pulsatile protrusions toward the APC ([300], [301]). Tyrosine phosphorylated Vav-1 and tyrosine phosphorylated SLP-76 assemble with the p21-activated kinase (Pak) via the adaptor protein Nck ([302], [303] and [304]).

The T cell/APC complex is stabilized in the *third stage*, which is regulated by increases of intracellular Ca^{2+}. By the end of the third phase, SMAC is in place with all the receptors and the signaling molecules, held together with clusters of GEMs (lipid rafts) on the surface and an elaborate cytoskeleton scaffolding underneath.

The kinetics of the IS from its early beginnings are coordinated and organized by the cytoskeleton ([297]). The TCR–pMHC can only interact at a distance of 15 nm, which is significantly below the thick glycocalyces of the two cells that separate their membranes by a 50- to 100-nm distance. Adhesion molecules, such as L-selectin, located on the tip of microvilli, may very well initiate the T-cell–APC interaction, until LFA-1, lying on flat surfaces of the membrane, is released from its inhibitory state by activating signals delivered by chemokines.

These signals also result in the formation of myosin II thick filaments, which disrupt and pull the thick network of polymerized actin away. In this clearing, new actin polymerization pushes forward new filopodia and lamellipodia (i.e., the cell becomes motile). Now that the T cell is polarized, the long interfering molecules of the glycocalyx, such as CD43 and CD45, are pulled to the rear end, or *uropod*, of the cell.

In the meantime, activated high-affinity LFA-1 released from inhibition stabilizes the contact area between the cells, moving laterally and forming strong bonds with ICAM-1 across the cell junction ([305]). In the membrane clearing created and stabilized by LFA-1 adhesion, the TCRs sample MHC on the APC surface for complementary peptides. It has been noted that paradoxically, a large cluster of TCRs has been pulled to the rear of the cell but, through the mediation of myosin II, are brought to the front, reinforcing the frontal cluster ([306]). Nascent IS is further stabilized by TCR links with the cytoskeleton. These links are mediated by some of the components of CD3 (i.e., ?-chain), which, through its phosphorylated ITAMs, induces actin polymerization ([291]).

If pMHCs are present on the APC surface, the T cell stops moving ([301], [307]). The central area of T cell closest to APC includes the bulk of the TCRs, which are surrounded by the further away integrins ([296], [308]).

The final arrangement defines the *mature IS* or the *bull's eye* ([296]) (i.e., the cSMAC, a central area 1 to 3 µM in diameter that contains TCR, CD28, and CD2, surrounded by pSMAC, an adhesion ring that contains the LFA-1 and talin). Formation of mature IS with APCs (instead of artificial lipid bilayers) shows that the TCR signaling precedes the completion of the mature IS ([309]). Bull's eye IS also has been observed with $CD8^+$ T cells during recognition and killing of target cells ([310]). Granule secretion occurs after the microtubule organizing center (MTOC) polarization in cSMAC, where membrane fusion occurs. Cellular functions between T cells and the target cells have been demonstrated by transmission and scanning electron microscopy several years ago. These junctions are followed by disruption and blebbing of the target cell membrane ([311], [312]).

Synapses with dendritic cells are formed even in the absence of antigen or MHC ([313], [314]). Encounters with dendritic cells are relatively short as compared to B cells ([315]). This may be due to chemokine secretion by dendritic cells, which stimulate T-cell migration. There also seems to be other differences between dendritic cells and B cells, such as the length of time of the encounter, which is short for dendritic cells but longer for B cells. The role of the dendritic cell in the formation of IS is active with full involvement of its cytoskeleton, whereas the B cell remains passive and the T cell makes the major contribution ([316]). The functional consequences of the formation of a mature IS are believed to be primarily related to polarized secretion ([317], [318]) and signaling ([319]). IS may help to retain secreted substances close to the targeted cell. Although this is true for the synapses formed by killer lymphocytes such as $CD8^+$ cytotoxic T cell or the NK cell, it may not apply to the $CD4^+$ T cell, which uses the APC to pull the trigger for its activation. In this case, the IS concentrates crucial molecules, such as CD28, that provide co-stimulatory signals and enhance TCR-mediated signaling ([320], [321]).

T-Cell Receptor Signaling

Two models have been proposed for sustained T-cell signaling: (a) *serial engagement* (migration), when the T cell migrates from one APC to the next and thus renews its signaling capacity ([315]); and (b) signaling based on *formation of IS*. Both models achieve similar results but require different molecular mechanisms. The mature IS forms a specialized mode of signaling and enables T cells to remain responsive to antigen while still with the initial APC. For a better understanding of the complexities of signaling, we organize it into three phases: (a) initiation, (b) generation of phosphoinositides, and (c) the Ras pathway (Fig. 17.12, Table 17.1).

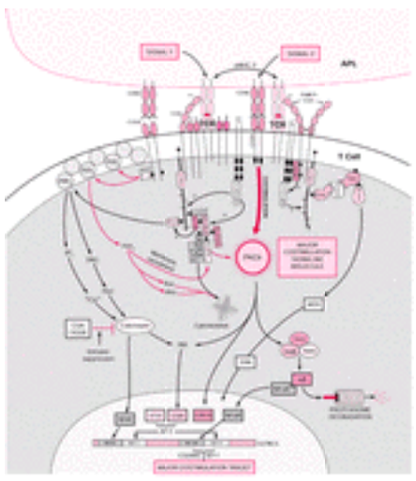

Figure 17.12. T-cell activation. T cells are activated by two signals: Signal 1 is delivered by the T-cell receptor (TCR) interacting with peptide–major histocompatibility complex (pMHC), and signal 2, or co-stimulatory signal, by CD28 interacting with CD80/CD86. A number of adaptor proteins (i.e., proteins acting as scaffolding) assemble a supramolecular signaling complex. Foremost among them are LAT (linker for activated T cells) and SLP-76 (SH_2-domain–containing leukocyte-specific phosphoprotein of 76 kd). LAT expression is limited to T cells, natural killer (NK) cells, platelets, and mast cells and is not expressed on B cells or monocytes. LAT is a membrane adaptor protein as compared to SLP-76, which is cytoplasmic. Engagement of TCR activates Lck, which is associated with the co-receptor (CD4 or CD8). Lck phosphorylates ZAP-70 (?-chain–associated protein). ZAP-70 in turn phosphorylates LAT, which at this point makes the transition between proximal and downstream signaling events initiated by TCR. LAT is also associated with the co-receptor, competing in the binding with Lck. LAT and Lck are linked to individual co-receptors, rather than both of them being linked to the same molecule. LAT as an adaptor protein is a scaffolding that is associated with several downstream molecules: Phospholipase (PLC)-? generates phosphoinositides and increases Ca2+, which activate protein kinase C (PKC) and calcineurin respectively. Another cluster is formed with Gads (Grb-related protein), SLP-76, Vav, and so forth that regulates the cytoskeleton together with the PIP_3 product of

phosphoinositide-3-kinase (PI3K). The other signaling pathway linked to LAT is through the Ras activation, linking to the activation of MAPK/ERK kinase (MEK) and extracellular signal-regulated kinase (ERK). A central position in T-cell signaling is occupied by the novel PKC isoform, PKC?, which is selectively expressed in T lymphocytes and is recruited to the immunologic synapse. It induces essential activation signals for interleukin-2 synthesis in cooperation with calcineurin. It is a master inducer of NF?B activation and its translocation to the nucleus. PI3K associated with CD28 generates PIP_3 that recruits Vav and PKC? to the membrane. APC, antigen-presenting cell; DAG, diacylglycerol; SLPP, serum lipophosphoprotein. (Important information from Bosselut R, et al. Association of the adaptor molecule LAT with CD4 and CD8 co-receptors identifies a new co-receptor function in T cell receptor signal transduction. TABLE 17.1. T-Cell Receptor-aß Activation Machinery

Receptors/Ligands	Antigen Recognition	Signal Transduction	Adhesion	Ligand/Counterreceptors
a/ß	+	–	–	Major histocompatibility peptide complex [a]
e/?–e/?	–	+	–	—
?/?	–	+	–	—
CD4	–	+	–	HLA Class II
CD8	–	+	–	HLA Class I
CD2	–	+	+	CD58 (LFA-3)
CD28/CTLA-4	–	+	–	CD80/CD86
CD40L	–	+	–	CD40
CD11a/CD18 (LFA-1)	–	+	+	CD54 (intercellular adhesion molecule-1)

LFA, lymphocyte function molecule.

[a] See text for details.

INITIATION PHASE Signaling is initiated by activation of Lck, which is regulated by two tyrosines: Tyr 394 in the activation loop and Tyr 505 in the C-terminus. Lck is kept inactive or “closed” by two intramolecular bonds: One is between Tyr 505, which is phosphorylated by the *C*-terminal Src, Csk, and binds to the SH_2 domain of Lck; a second bond is formed between the SH_3 domain of Lck and a sequence connecting the SH_2 and the kinase domains. For activation of Lck, the Tyr 505 needs to be dephosphorylated by CD45, a protein tyrosine phosphatase ([322]), whereas Tyr 394 is autophosphorylated and activates the kinase domain. The large-size CD45 isoforms are excluded from the IS ([323] , [324]), but some move back to cSMAC adjacent to the TCRs ([325]). Lck, recruited by CD4, is maintained in the activated state by CD28 ([321]) and phosphorylates the ITAMs of the ?-chain of TCR in a sequential and ordered manner, establishing thresholds of T-cell activation ([326]). This mechanism determines whether a sufficient number of tyrosines are phosphorylated for full activation and supports the kinetic proofreading model of T-cell activation, which examines the relationship between kinetics of TCR–ligand interaction and intensities of T-cell activation ([327] , [328] , [329] and [330]). ZAP-70 is recruited to the phosphorylated ITAMs of the ?-chain and in turn activates the adaptor protein LAT, which then is localized in the rafts. LAT has a short extracellular and long intracellular region and possesses a central position in T-cell activation because it assembles other adaptor molecules and signaling proteins. There are two groups of adaptor proteins: transmembrane adaptor proteins and cytosolic adaptor proteins ([331]). LAT (a transmembrane adaptor protein) is located in the rafts and is phosphorylated by ZAP-70. As a result, it recruits PLC-?1, phosphoinositide 3-kinase (PI3K), IL-2–inducible T-cell kinase (Itk), adaptor proteins Grb2 and Gads, and, indirectly, Vav and Slp-76 ([332] , [333] and [334]). SLP-76 is a cytosolic adaptor protein that has three protein-binding motifs and plays an essential role in signaling pathways required for IL-2 secretion ([335]). It is expressed on thymocytes, T cells, mast cells, NK cells, and platelets. Through Gads, it binds indirectly to LAT after TCR ligation. So LAT and SLP-76 function as mutually dependent intermolecular scaffolds, together recruiting crucial signaling regulators to sites of raft aggregation. In mice deficient in SLP-76 (or LAT), thymocyte development is arrested at the stage at which the TCR ß-chain is coupled to the pre-Ta-chain. SLP-76 recruits Itk to lipid rafts and allows for optimal phosphorylation of PLC-?1, which also associates with ZAP-70.

PHOSPHOINOSITIDE METABOLISM Phosphoinositides are produced by the action of PLC-?1 and PI3K. PLC-?1 binds to LAT and is activated as a result of phosphorylation of multiple tyrosines by ZAP-70. PLC-?1 hydrolyzes inositol phospholipids generating diacylglycerol and inositol ([1] , [4] , [5])-triphosphate (IP_3). Diacylglycerol contributes to activation of protein kinase C (PKC), whereas IP_3 increases Ca^{2+} released from intracellular sources. There are multiple isoforms of PKC serine kinases, which are regulated by Ca^{2+}, diacylglycerol, phospholipids, the classic PKC (a, ß, ?), and the novel PKC (?, e, ?, and ?) ([336]). PKC? is recruited to the plasma membrane and is the only isoform detected in cSMAC together with TCR ([337]). PKC?'s targets are nuclear factor-?B activation, IL-2 production, regulation of integrin function, and control of cytoskeleton through association with Vav. Both Ca^{2+} and PKC synergize in the increase in transcriptional activity of NFAT. Ca^{2+} acts through calcineurin, a calmodulin-dependent phosphatase that contributes to induction or function of NFAT. The immunosuppressive drugs cyclosporin A and FK506, bound to their binding protein, immunophilin, inhibit Ca^{2+}-mediated signaling of T lymphocytes by sequestering cytosolic calcineurin. This is the mechanism of inhibition of IL-2 secretion. The PI3K produces phosphatidylinositol 3,4,5-triphosphate (PI-3,4,5-P_3), which acts as a second messenger. It binds to proteins that contain a pleckstrin homology domain and recruits them to the inner leaflet of the cell membrane ([338]). PI3K overall is involved in survival and cytoskeletal signaling processes and is essential for adhesion signals. Important targets for PI3K products are the GTPases, Rac and Rho, stimulated by GEF (guanine nucleotide exchange) proteins promoting transition from the inactive guanosine diphosphate–bound state to the active GTP-bound conformation. Rac and Rho regulate several functions in the life of the T cell, and during T-cell activation, they regulate cytoskeletal rearrangements. The PI-3,4,5-P_2 product of PI3K is converted to PI-3,4-P_2 by the phosphatidylinositol-5 phosphatase (SHIP). This product binds to the pleckstrin homology domain of the protein kinase B or Akt. Akt moves to the nucleus, where it acts on several substrates regulating cell survival, NF-?B activation, metabolism, and energy generation ([339]). It also regulates transcription factors (i.e., NFAT and the Forkhead family), promoting cell survival and progression through the cell cycle. All signals from PI3K products are eventually terminated by the inositol phosphatase SHIP.

RAS PATHWAY The adaptor protein Grb2 is a bifunctional molecule having an SH_2 domain with which it binds to phosphorylated tyrosines of LAT, whereas its SH_3 domain binds other proteins that have proline-rich sequences. These proteins are cytosolic, but through association with LAT, they are translocated to the membrane ([333]). Grb2 functions in many cells and associates with a large number of proteins ([340]). In T cells, it is associated with the proline-rich domain of SOS, the mammalian homolog of the *Drosophila* “son of Sevenless” protein. SOS is a critical activator of the small G protein Ras ([341]). Grb2-SOS binding is mediated by another small linker protein, Shc. Cbl, an inhibitor of activation, also binds to Grb2. The Ras pathway activates Erk kinase and MAPK. MAPK pathway may induce integrin activation, and, in reverse, the integrin may induce MAPK pathway through PI3K. There are other bidirectional signaling pathways that, in general, send signals to the nucleus and activate membrane molecules by a feedback pathway.

T-Cell Activation and the Cytoskeleton

The cytoskeleton plays an important role in IS formation and T-cell activation. T cells polarize toward their target, focusing the signaling on the secretory apparatus at the APC or target cell. Cytochalasin D, which disrupts the cytoskeleton assembly, blocks T-cell activation. Actin dynamics are controlled by a biphasic model at the IS. TCR engagement initiates actin solubilization through changes in the phosphorylation of ezrin, radixin, and moesin that allow certain molecules to move away from the points of contact with APC ([342]). With the formation of new actin filaments, LFA-1 is anchored and stabilizes the adhesion between T cell and APC ([343]). Polarization of the MTOC requires TCR and involves members of the Rho family of GTPases Cdc42, Rac, and Rho.

Disruption of the Rho family members perturbs survival of T cells, proliferation, differentiation, migration, and effector functions ([298] , [344]). Cdc42, like all members of the Rho family of GTPases, functions as a binary switch regulated by nucleotide binding. When Cdc42 binds GTP, it is converted from the inactive to the active form and binds effector molecules with high affinity. One of its important substrates is WASp (see Chapter 14). Mutations of the WASp gene are responsible for the clinical manifestations of Wiskott-Aldrich syndrome (i.e., thrombocytopenia, eczema, and recurrent infections). T cells from Wiskott-Aldrich syndrome patients lack microvilli and have abnormal cell shape. Mutants with inactive Cdc42 prevent efficient conjugation of T cells with APC. In contrast, T cells with constitutively active Cdc42 mutants form extensive filopodia rich in F-actin, which interfere with the formation of IS because Cdc42 accumulates in the T-APC contact area. Activation of WASp is achieved by a complex formed by SLP-76 adaptor protein, Vav, and Nck (phosphorylated by ZAP-70). In this trimolecular complex, SLP-76 binds Vav, which converts Cdc42–guanosine diphosphate to the GTP form. Cdc42-GTP binds to the GTPase binding domain domain of WASp. At the same time, the Nck binds by its SH_3 domain to the polyproline sequence of WASp. These interactions release WASp from its autoinhibitory state and enable it to activate the Arp2/3 complex for

actin-branching polymerization ([345], [346], [347] and [348]) (see Chapter 14). Other studies suggest that WASp may not be the critical or even the sole regulator of actin polymerization, but other molecules, such as its homolog N-WASp, are involved. However, mice with a WASp deficient in the VCA domain have defects in T-cell development ([349]).

A significant contribution to the T-cell interaction with the APC is made by the ERM cytoskeletal proteins (i.e., ezrin-radixin-moesin) ([350]). These proteins act as linkers between cortical actin and plasma membrane, connecting the F-actin to cytoplasmic tails of several transmembrane proteins (i.e., ICAMs, CD43, Fas, and so forth). In the resting T cell, the plasma membrane is rigid because of the thick actin network kept by phosphorylated moesin. With TCR engagement, moesin is dephosphorylated, the actin network "thaws," and the proteins linked to the cytoskeleton are freed to move. The tall ones, CD43, are "squeezed" out of the narrow junction between T cell and APC ([351]). At the same time, new F-actin networks create pseudopod extensions for contact with the APC. Moesin in the back of the cell is rephosphorylated and keeps the excluded molecules actively out of the IS. CD43, and other molecules that are excluded to the uropod, form a cluster called *distal pole complex*. This cluster may not be simply a negative contributor to T-cell activation by collecting tall molecules interfering in the formation of the IS, but it has its own signaling mechanism in some aspects of T-cell activation, such as cytokine secretion ([352]).

Regulation of T-Cell Activation: Co-Stimulation and Inhibition

T-cell activation depends on signals delivered by the TCR engaged with pMHC. However, additional signaling is needed, and this function is known as *co-stimulation*. Co-stimulatory signals are delivered to the T cell through the CD28 molecule reacting with ligands (counter-receptors) on APCs [i.e., CD80 (B7-1) and CD86 (B7-2)]. These receptors do not act independently but modify the responses mediated by TCR. The CD28 consists of one Ig-like domain of V-type, whereas the two ligands contain two Ig domains, one V-type and one C-type. CD28 is constitutively expressed on T cells (all $CD4^+$ and approximately 50% of $CD8^+$). Another receptor, the CTLA-4 (CD152) shares approximately 30% identity with CD28; it is not detected in naïve T cells but is induced after T-cell activation.

Both CD28 and CTLA-4 share the same ligands. In co-stimulation, the critical event is up-regulation of the B7 molecules on the surface of the APCs ([353]). The major role of CD28 function is to stimulate cell cycle progression and prevent apoptosis. It also enhances production of various cytokines, such as IL-1, IL-2, IL-4, IL-5, and interferon (IFN)-?, and plays a fundamental role in Th1-Th2 differentiation. CD28/B7 interactions also play a critical role in B-cell stimulation. The importance of CD28/B7 interaction was established in transplantation. The importance of the CD28/B7 costimulation pathway was established with studies in transplantation in mice in which blockade of the pathway by CTLA4-Ig prolonged cardiac graft survival and prevented development of vascular lesions associated with chronic rejection (353a). Mice deficient in CD28 or in both B7-1 and B7-2 are resistant in the development of experimental allergic encephalomyelitis (353b).

Another co-stimulatory receptor homologous to CD28 and CTLA-4, termed *ICOS* (inducible co-stimulator), is a disulfide-linked homodimer ([354]). ICOS lacks the extracellular motif present in CD28, which is implicated in binding with the B7 molecules. It is an inducible molecule expressed in activated, but not resting, T cells. ICOS augments T-cell proliferative responses and cytokine secretion, particularly IL-10 ([355]). The ligand for ICOS (ICOS-L or B7h) is a B7-like molecule expressed constitutively on B cells and macrophages. Co-stimulation by ICOS promotes germinal center reaction and isotype switching. ICOS and CD28 regulate Th2 responses, but whereas CD28 is critical in the priming stage to induce Th2 differentiation, ICOS plays a role in regulating Th2 effector functions ([356]). Activation of the ICOS pathway of co-stimulation initiates acute and chronic graft rejection, which indicates that the ICOS co-stimulatory pathway also regulates Th1 responses ([357]).

CD4 T-CELL DIFFERENTIATION

Activated naïve $CD4^+$ helper T cells (Th), in response to signals from TCR engagement with pMHC, proliferate and differentiate into cytokine-secreting effector cells, which have been distinguished into two major categories ([358]). Th1 cells produce primarily IFN-?, IL-2, and TNF-ß, whereas Th2 cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13. Both types of cells produce IL-3, TNF-a, and granulocyte-macrophage colony-stimulating factor. Once the initial stimulus from TCR is received, the cells proliferate in response to the autocrine growth factor IL-2. At this stage, they are called pT helper cells (pTh) because they have not yet differentiated enough to secrete cytokines. Both Th1 and Th2 cells derive from a single precursor, and several factors regulate their differentiation ([359], [360] and [361]). The Th1 cells induce predominantly inflammatory immune reactions and control intracellular bacterial infections (cellular immunity). They are also associated with some autoimmune diseases. The Th2 cells provide defense against extracellular pathogens, regulating the humoral antibody-mediated immune response. They are also the mediators of allergic reactions.

Th1 versus Th2 differentiation takes place in two stages. During the first stage, the activation signals delivered by TCR precondition the naïve T cell for one or the other pathway of differentiation. In the second stage, final development of effector cells is dependent on IL-12 or IL-4 (Fig. 17.13).

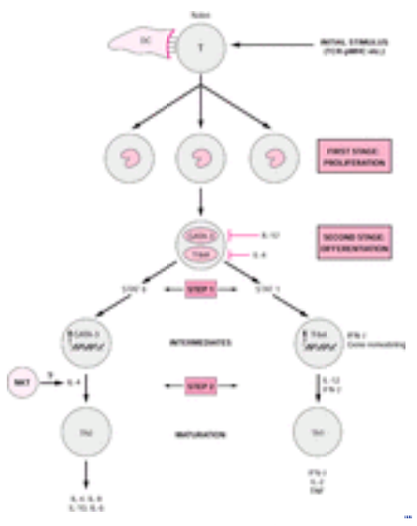

Figure 17.13. $CD4^+$ T-cell differentiation. After their differentiation in the thymus into the two main lineages, $CD4^+$ and $CD8^+$, the $CD4^+$ or Th cells differentiate further in the peripheral lymphatic organs into effector cells with distinct patterns of cytokine secretion. The initial stimulus is delivered by the T-cell receptor (TCR) and results in the proliferation of the naïve T cell. These activated T cells (pTh) have only a limited potential of interleukin (IL)-2 secretion, and they acquire the propensity to respond to additional signals for further differentiation. Primary stimuli via the TCR (dose of antigen, intensity and duration of TCR triggering) influence downstream signaling (Ca^{2+}, protein kinase C, map kinase, and so forth) that regulates transcription factor expression. Expression of GATA-3 leads to Th2, whereas T-bet leads to Th1 differentiation. In the second stage, exposure to cytokines [i.e., IL-4 or IL-12/interferon (IFN)-?] drives the final steps of differentiation to the Th1 or Th2 pattern of cytokine secretion. NKT, natural killer T cell; TNF, tumor necrosis factor. (Adapted from Noble A. Review article: molecular signals and genetic reprogramming in peripheral T-cell differentiation. Immunology 2000;101:289–299; Murphy KM, et al. The lineage decisions of helper T cells. Nat Rev Immunol 2002;2:933–944; and Diehl S, et al. The two faces of IL-6 on Th1/Th2 differentiation. Mol Immunol 2002;39:531–536.)

Stage I: Transcriptional Regulation

In the early stages of Th cell differentiation, TCR stimulation activates a number of downstream signaling pathways. Differential signaling of MAPKs, PKC, and calcineurin preconditions Th cells toward one or the other pathway in the absence of cytokines from the environment ([362]). A number of parameters related to antigenic stimulation and co-stimulation influence the final outcome. Low doses of antigen or low affinity of binding favors Th2 development, whereas large doses of antigen or high affinity of binding support predominantly Th1 differentiation. Co-stimulatory signals modulate the outcome. CD28 ligation favors Th2 development, perhaps by enhancing IL-4 production ([363]) or by direct activation of signal transducer and activator of transcription 6 (STAT-6) ([364]).

The CD40/CD40L interactions selectively induce Th1 cells, but this is the result of the production of IL-12 from APCs ([365]). During the early stage of Th activation, key genetic and epigenetic events take place that lead to accessibility and activation of specific genes. Expression of certain transcription factors is critical in the early

regulation of differentiation ([366], [367]).

TH1 REGULATION The most prominent factor for Th1 differentiation is IL-12. In naïve T cells, the IL-12 receptor is not functional but is induced by IFN-a/ß. Binding of IL-12 to its receptor induces phosphorylation of Janus kinases Jak2 and Tyk2, which phosphorylate STAT-4. STAT-4 translocates to the nucleus and activates target genes. The GTPase, Rac 2, which is selectively expressed on Th1 cells, activates the IFN-? promoter via NF-?B and MAPK ([368]). During the early Th1 polarizing signaling, the key transcription factor for Th1 development is T-bet (for *T- b*ox *e*xpressed in *T* cells) induced in naïve T cells ([369], [370]). T-bet transactivates IFN-? promoter, induces chromatin remodeling of the gene that encodes INF-? ([371]), and induces expression of the ß $_2$ subunit of IL-12 receptor ([370]). The importance of T-bet in Th1 differentiation is underscored by the susceptibility of T-bet knock-out mice to challenge with *Leishmania major* ([372]) and their predisposition to allergic disease.

TH2 REGULATION The key transcription factor for Th2 differentiation is GATA-3 ([366]), induced in the early stages under Th2 polarizing signaling. STAT-6 activation enhances expression of GATA-3. GATA-3 induces expression of another Th2-specific factor, c-maf. C-maf is a basic region/leucine-zipper transcription factor that binds to and transactivates the IL-4 promoter ([373], [374]).

EPIGENETIC MODIFICATION OF CYTOKINE GENES Detailed description of these early events is beyond the scope of this brief review. The reader is referred to reviews of the topic ([366], [375]). Transcriptionally inactive gene loci have a condensed chromatin with DNA tightly packed around the nucleosomes. For gene transcription, “open” chromatin is associated with acetylated histones and hypomethylation of DNA. Accessibility of IL-4 and IFN-? genes is initiated promptly after TCR and CD28 activation, but for sustained transcription, STAT-6 or STAT-4 signaling and induction, GATA-3 and T-bet are required. Within the first few days of Th1 and Th2 differentiation, signs of accessibility of the cytokine gene loci are observed in Th-activated cells. These signs are hypersensitivity to DNAase I and DNA demethylation.

Stage II: Maturation of Th1/Th2 Cells

In the second stage, IL-12 and IL-4 play a major role in the maturation of Th1 and Th2 cells, respectively. IL12 and IL18 act synergistically to produce IFN-? from terminally differentiating Th1 cells. IL-23 is composed of the p40 subunit of IL-12 paired with the IL-23 a-chain related to one of the chains of IL-12. It binds to IL-12 ß-chain but interacts with its own IL-23R. It activates STAT-4 and may act during the induction of Th1 and the production of IFN-? in cooperation with IL-18.

The IL-27 is produced by APCs and induces proliferation of naïve T cells. It acts together with IL-12 in promoting IFN-? production and is the ligand for the T-cell cytokine receptor in the early development of Th1 cells ([376]). Th2 maturation is promoted by IL-21, which is produced from Th2 cells, and specifically inhibits IFN-? production and decreases responsiveness of T cells to IL-12, thus amplifying Th2 development ([377]).

IL-6 is produced by several types of cells, especially APCs. It activates NFAT, leading to production of IL-4, which promotes Th2 differentiation. However, IL-6 also inhibits Th1 development because it up-regulates the suppression of cytokine signaling (SOCS) 1. SOCS, also known as *STAT-induced STAT inhibitor*, belongs to a family of regulators of cytokine production. SOCS1 inhibits IFN-? production and the development of Th1 cells. Thus, IL-6 plays a dual role in Th1/Th2 differentiation through induction of IL-4 and SOCS-1 ([378]). IL-10 has also been reported to promote Th2 differentiation, but its main effect is in suppressing Th1 cells.

Another cytokine with double regulatory function is IL-18. IL-18 is produced from macrophages and synergizes with IL-12 for IFN-? production from NK cells and T cells. In collaboration with IL-2, it promotes Th1 differentiation in activated T cells ([379]). Overproduction of both cytokines induces severe inflammatory disorders. In addition to its function as Th1 inducer and as proinflammatory cytokine, under certain experimental conditions, IL-18 stimulates Th2 cell differentiation, increase of IgE, and allergic manifestations ([380]). The role of dendritic cells in humans is not clear as the production of cytokines varies depending on signals received from T cells.

CD8 T-CELL DIFFERENTIATION

CD8 $^+$ T cells produce primarily type 1 cytokines because CD8 $^+$ T cells have no requirement for STAT-4 signaling via IL-12 to develop into Tc1 effectors. The Tc1/Tc2 regulation is mediated by transforming growth factor (TGF)-ß with IL-4 promoting Tc1 development and cytotoxicity in the presence of TGF-ß ([382]). There is some kind of cross-regulation between CD4 $^+$ and CD8 $^+$ T cells. CD8 $^+$ T cells produce relatively high levels of IFN-? and, as a result, enhance Th1 immunity. On the other hand, Th2 cell–derived IL-4 stimulates development of Tc2 cells in allergic states.

Another Th cell that secretes high levels of TGF-ß together with varying amounts of IL-4 and IL-10 is known as *Th3* and is associated with a suppressor function. Secretion of these cytokines by Th3 cells requires antigenic stimulation before they function as active suppressor cells ([381]). Another suppressor T cell, known as *T regulatory-1* (Tr1) produces high levels of IL-10 and IL-5. (For regulatory T cells, see below.)

GENOMIC VIEW OF TYPE 1 AND TYPE 2 DIFFERENTIATION

Application of the new technology of gene expression by gene microarrays on polarized type 1 and type 2 CD4 and CD8 T cells identified similarities in the broad pattern of gene expression in both CD4 and CD8 T cells for type 1 and type 2 polarization, but differences were also identified between the two lineages ([383]). Large numbers of apoptosis-related genes were expressed, particularly in Th1 cells, which correlates with the propensity of these cells to undergo activation-induced cell death ([384]). A large number of cytokine and growth factor genes are preferentially expressed by either type 1 or type 2 cells. Th2 cells resemble Tc2 cells in their cytokine gene profile. Differences are also noted in genes involved in synthesis of cell migration molecules, such as CCR1, CXCR4, and ß $_7$ integrin in Th2 cells and a $_4$ integrin in Th1 cells. This is something that should be expected because the two Th populations home to different locations ([385]).

TH1 AND TH2 PARADIGM: STRONG DEFENSE SYSTEM

The adaptive immune system evolved to recognize, discriminate, and memorize foreign antigens and pathogens. It has developed specialized cells that are able to capture anything that manages to cross into the body's interior and present it to lymphocytes possessing specific receptors.

The “supreme commander” in this system is the T lymphocyte that regulates all defense operations. It became clear in recent years that T lymphocytes constitute a diversified population. One of them (CD4 $^+$, Th2) activates the B cells for antibody production, and a second (CD4 $^+$, Th1) activates macrophages for cell-mediated immunity. The first provides defense against extracellular and helminthic infections. The second acts against intracellular bacterial infections, fungi, and protozoa (Fig. 17.14).

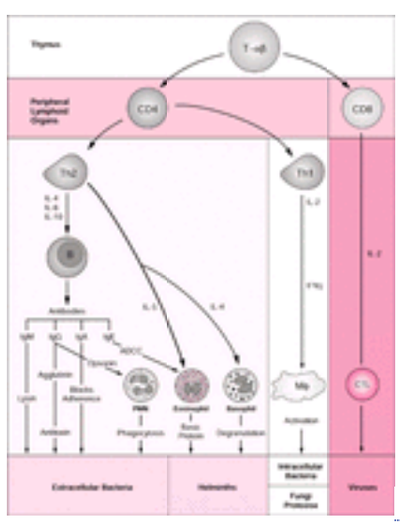

Figure 17.14. Th1 and Th2 cells and effector mechanisms against pathogens. See text for details. ADCC, antibody-dependent cell-mediated cytotoxicity; CTL,

cytotoxic T lymphocyte; IFN, interferon; Ig, immunoglobulin; IL, interleukin; PMN, polymorphonuclear cells. (From Paraskevas F. T lymphocytes. In: Israels LG, Israels ED, eds. Mechanisms in hematology. Core Health Services Inc., 2001, with permission.)

Th1 cells coordinate the activation of macrophages and constitute the most important cellular defense mechanism against intracellular pathogens. Macrophage activation is mediated by IFN-?, the principal cytokine produced by Th1 cells. Macrophages activated by IFN-? rapidly kill susceptible intracellular bacteria. They produce TNF-a, which synergizes with IFN-?. IFN-? has been used successfully as adjunct to chemotherapy in the treatment of leprosy, tuberculosis, and atypical mycobacteriosis. In induction of Th1 immunity, IL-12 is rapidly produced by infected macrophages, which activates NK cells and stimulates production of IFN-?, which subsequently induces Th1 differentiation. However, overproduction of IL-12, by a positive feedback mechanism triggered by IFN-?, results in inflammatory responses. IL-12 production is inhibited by IL-10.

There is compelling evidence that the Th1 cells have an essential role in protection during mycobacterial infection ([386]). Mice deficient in IL-4, a major Th2 cytokine, have a normal response to *Mycobacterium tuberculosis*, whereas increased production of IL-4 correlates with disease progression ([387]). Mice infected acutely with *M. tuberculosis* are protected by adoptive transfer of Th1 cells with a tenfold reduction in bacterial counts, whereas recipients of Th2 cells suffer from weight loss and lung fibrosis ([388]).

Leishmanial disease currently affects some 12 million people in 88 countries. The annual incidence is approximately two million new cases. Experimental studies have clearly documented that Th1 response is associated with restriction of the disease and cure, whereas a Th2 response is associated with progressive systemic disease. Balb/c mice are susceptible to leishmania infection because they are unable to generate a Th1 response, whereas C57Bl/6 mice are resistant to the infection as a result of strong Th1 response. In Balb/c mice, the draining lymph nodes show elevated transcripts for IL-4 but not for IFN-? ([389]).

The most critical unifying effect able to induce resistance has been the successful attenuation of IL-4 expression in the draining lymph node of infected susceptible animals during the first 24 hours of infection. The extent of IL-12 responsiveness is also a critical determinant for the development of a curative immune response because it induces a Th1 response ([390]).

Another example of the importance of a balanced Th1/Th2 response is related to the allergic inflammation ([391]). The pathophysiologic mechanisms of asthma seem to be based on dysregulation of the Th1/Th2 balanced response with a preponderance of Th2 cytokines. Asthma affects 8 to 10% of the population in the United States and is the leading cause of hospitalization among children younger than 15 years of age, causing an exorbitant financial burden on society. Th2-dominant responses stimulate antibody-mediated responses, activate mast cells, and elicit tissue eosinophilia (i.e., the predominant response in the asthmatic airway) ([392]). IL-13 is one of the Th2 cytokines, and overexpression of IL-13 in transgenic mice induces an inflammatory response with an infiltrate rich in eosinophils and macrophages. Furthermore, it causes airway fibrosis, mucous metaplasia, and airway hyperresponsiveness ([393]). It is likely that asthma is the result of a dysregulated mucosal immune system and pathologic T-cell response in genetically susceptible individuals ([394]).

CD8 T LYMPHOCYTES

The $CD8^+$ T lymphocyte is one of the two professional cytotoxic lymphocytes, the other being the NK cell. The $CD8^+$ T lymphocytes, also known as *CTL*, differ from NK cells in the basic mechanism of target recognition. CTL expresses an aß-TCR, recognizing processed peptides presented by MHC class I molecules (pMHC), whereas the NK cell cytotoxicity is regulated by the C-lectin type of NK cell receptors (CD94) or members of the killer cell Ig-like receptors (KIRs), which recognize class I HLA allotypes rather than pMHC ([395]).

Two fundamentally different groups of methods of evaluation of target cell lysis have been developed: One evaluates disruption of cell membrane and release of tracers incorporated into the target, and the other evaluates DNA fragmentation resulting from apoptotic nuclear damage. In the first category, the most widely used method has been the release of radioactive chromium, ^{51}Cr, preloaded into the target ([396]). More sensitive techniques using fluorescent impermeant dyes have been developed. DNA fragments released from the nuclei are harvested, and a “ladder” pattern is identified ([397]). Direct comparisons of the cytotoxic potency of different cell populations cannot be made by these methods because the target cell death is not linearly related to the cytotoxic input. Usually, the number of cytotoxic cells required to achieve a given level of target cell lysis is expressed in lytic units, which are inversely related to the effector cell number.

Activation of Cytotoxic T Lymphocytes

For the CTL to become an active effector, the precursor cell must be stimulated by antigen to undergo proliferation and differentiation ([398]). The activation or priming results from the interaction of the naïve $CD8^+$ T cell with professional APCs. As a result of priming, they form secretory granules, to which the killing machinery is delivered (i.e., perforin, granzymes, and FasL) ([399] , [400]). Before activation, granules are not always visible. The granule by electron microscopy is 0.5 to 1.0 µ in diameter and is heterogeneous in its structure ([401]). The core is homogeneous, is sometimes surrounded by double membranes, and contains the perforin enclosed by a thin membrane ([402]). Multiple small vesicles surround the core toward the periphery of the granule. Depending on the preponderance of these two components, granules have been distinguished as type I (dominated by the cores) or type II (with dominant multivesicular component but no cores). Other granules are intermediate between types I and II. The granules are similar to late endosomes and have the properties of two usually separate organelles: those of the secretory type and those of the lysosomes ([403]). Similarities with lysosomes include the acidic pH, the mannose-6-phosphate receptor (MPR), and the lysosomal marker, lysosome-associated membrane protein. Endocytic components carrying CD3/TCR, CD8, and MHC molecules reach the perforin-containing granule and are displayed in the outer leaflet of the membrane.

Granule Contents

PERFORIN (CYTOLYSIN) *Perforin* is a 65- to 75-kd glycoprotein with patchy homology to C9 complement component. It is synthesized as an inactive precursor, which is cleaved to yield a 60-kd active form ([404]). The protein consists of two regions: One has homology to complement proteins (C_6 to C_9), and the other is a C2 domain related to Ca^{2+}-binding proteins ([405]). The *C*-terminal portion is cleaved by proteolytic enzymes activating the C2 domains for phospholipid binding ([406]). The *N*-terminal is involved in interaction with the membrane and polymerization. However, the central portion contains four membrane-spanning domains, potentially capable of forming amphipathic a helices of ß sheets. At the carboxy terminal, a short peptide (pro-piece with a bulky glycan attached) is removed, and the remaining perforin monomer undergoes conformational changes in the presence of Ca^{2+}, inserting itself in the membrane. Interaction with other perforin monomers forms the polyperforin pores ([407] , [408] and [409]). At least three to four monomers are needed to form a functional channel, whereas 10 to 20 aggregated monomers are needed to produce a pore visible by electron microscopy.

GRANULYSIN Granulysin is a member of the saposin ([410] , [411]) family of lipid-binding proteins, related functionally to defensins and other bacterial peptides, but is structurally different. It is active against gram-positive and gram-negative bacteria, fungi, and parasites. It disrupts artificial liposomes, damages mitochondria, and activates caspase 9 to induce apoptosis. It probably plays an important role in innate and acquired antimicrobial defenses. It kills extracellular *M. tuberculosis* and decreases their viability inside the cell ([412]).

GRANZYMES Granzymes are serine proteases of the chymotrypsin family ([413] , [414]). The crystal structure of granzyme B has been solved, and its structural similarity with chymotrypsin has been verified ([415]). On the basis of the gene structure, proteolytic specificity, and biologic function, these enzymes are divided into three subfamilies. They are produced as proenzymes, with an acidic inactivating peptide. During their transport through the endoplasmic reticulum and Golgi apparatus, they are processed so that they are targeted to the secretory pathway. The activation peptide is removed by dipeptidyl peptidase I (DPPI), and a sequence motif interacts with proteoglycan in the granule to maintain proper conformation for activation. Granzyme B has a unique specificity among mammalian serine proteases in that it requires aspartic acid as P1 amino acid (i.e., the cleavage leaves a carboxy-terminal aspartic acid). Granzymes are highly positively charged proteins at neutral pH and form complexes with proteoglycans in the granule and extracellularly with polyanionic components.

CALRETICULIN Calreticulin is a Ca^{2+} storage protein and carries a sequence that retains it in the endoplasmic reticulum. It co-localizes with perforin and is released together with perforin, which binds to the P-domain of calreticulin. Calreticulin functions as a chaperone protein for perforin and protects the CTL during biogenesis of the granules ([416]). Fragments of individual calreticulin domains used in lytic assays showed that the Ca^{2+}-binding C-domain, which does not bind perforin, has the strongest capacity for inhibitory activity ([417]). However, lysis is independent of calreticulin's ability to sequester Ca^{2+}. It is suggested that calreticulin stabilizes membranes and thus prevents polyperforin pore formation.

OTHER COMPONENTS Chondroitin sulfate proteoglycans are negatively charged and are exocytosed during target lysis. They probably regulate delivery of the

positively charged granzymes ([418]). The multivesicular domain of the granule is rich in MPR, which is normally absent in mature lysosomes but present in early endosomes. The dipeptidyl peptidase (cathepsin C) is a lysosomal cysteine protease responsible for posttranslational processing in the generation of activated myeloid and lymphoid granule serine proteases.

Mechanism of Target Cell Lysis

SECRETORY SYNAPSE As we have seen with the CD4 T lymphocyte, recognition of the antigenic determinants by TCR is associated with the formation of the IS. In the synapse, the SMAC is organized by TCR and adhesion molecules. CTL also forms a synapse with the target cells, and within the synapse, there is a defined secretory domain ([419]). LFA-1 and talin form an outer ring of adhesion proteins with a distinct secretory domain in the center and separate from the cluster of the TCR and signaling molecules ([420]). Electron microscopy shows granules on the point of degranulation. The CTL acquires the hand mirror configuration during movement, with the nucleus leading in front and cytoplasmic organelles trailing behind. The Golgi is apposed tightly to the membrane at the point of contact, and organelles appear to be “streaming” toward the contact site. Confocal microscopy shows that the granules initially cluster just behind the MTOC and then go around the MTOC to reach the secretory domain. Intimate interdigitations are visible over a large area, but a thin extracellular space separates the two cells that are held together by gap junctions ([421]) (Fig. 17.15). Gap junctions exist normally between cells in various tissues and probably serve the function of cellular communication. The nucleus moves away, and the granules take up position next to the area of adherence with the target.

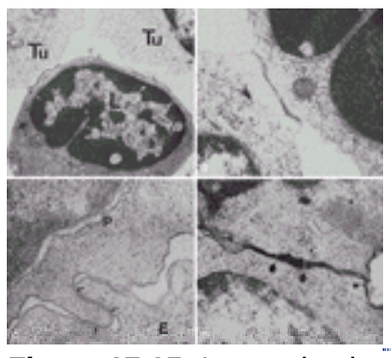

Figure 17.15. Interaction between a cytotoxic T cell and its target. **A–C:** Cytotoxic T cell attaches to its target over broad areas of the cell membrane. The formation of the conjugate involves interdigitations of microvilli between the two cells. **D:** Lanthanum nitrate fills the gap between cytotoxic T lymphocyte and its target and reveals junctions (*arrows*) that stretch between the two cells. The function of these junctions remains unknown. E, EL-4 tumor cell; L, lumphocyte; P, peritoneal exudat cell (i.e., cytotoxic T cell); Tu, tumor. (**A,B**, and **D** from Grimm E, Price Z, Bonavida B. Studies on the induction and expression of T cell-mediated immunity. VIII. Contact regions of cytotoxic T lymphocyte-target cell conjugates. Cell Immunol 1976;25:41–51, with permission.)

Confocal microscopy identifies regions of the secretory synapse where granules are secreted between lck and talin or CD11a (Fig. 17.11). The granules stream around the nucleus along microtubules and accumulate behind the MTOC and the Golgi apparatus. Then they move around the Golgi and reach the synapse, where secretion occurs between the adhesion ring and the signaling domain. They fuse with the membrane within 4 minutes after contact with the target ([422]). This fusion marks the beginning of the Ca^{2+}-dependent second stage characterized by striking intracellular changes. The most remarkable of these changes is the reorientation of the MTOC, which, together with the Golgi, takes a position facing the area of contact with the target ([423] , [424] and [425]). The Ca^{2+} requirements for lysis may also be due to the Ca^{2+} dependency of the MTOC reorientation that is a prerequisite for CTL killing ([426]). Granules attach to and then move along microtubules toward the MTOC and finally are secreted at the MTOC. Disruption of microtubules by certain drugs severely impairs killing ([425]). For the last stage of granule secretion, a GTP-binding protein, Rab27a, is critical for moving the granules from the MTOC to the synapse ([427]). In a rare autosomal-recessive disease known as *Griscelli syndrome*, Rab27 is defective. These patients have albinism because melanocytes require Rab27a to secrete melanosomes. WASp, which activates the Arp2/3 complex for actin polymerization, is also required for cytotoxicity ([428]). Lymphocyte-mediated killing can be confined to two pathways: the perforin-granzyme–mediated and the Fas-mediated pathways ([429]). Independent of the importance of the contribution of each pathway in target cell lysis, the fact is that lysis absolutely requires exocytosis of granules and their contents. Exocytosis requires signaling from PI3K and ERK. The importance of exocytosis is emphasized by markedly decreased cytotoxicity of CTLs and NK cells in Griscelli syndrome and the ashen mouse. The ashen mice have a profound decrease of cytotoxicity, even though they have normal FasL expression and FasL cytotoxicity ([430]). Patients with Griscelli syndrome and the ashen mouse have a loss of function mutation in the RAB27A gene that abrogates the expression of Rab27a GTPase (one of approximately 50 GTPases). Rab27a affects the functions of the dense granules of platelets, melanosomes of melanocytes, and secretory lysosomes of CTLs. In platelets, Rab27a regulates secretion only of the dense granules. Increase of Ca^{2+} is critical for cytotoxicity, which results from extracellular sources, because it does not occur if extracellular Ca^{2+} is removed ([431]).

ROLE OF PERFORIN *Perforin* was the name given to a protein within the granules that perforates the cell membrane and opens pores, which originally were believed to be the cause of lysis and cell death. The *C*-terminal domain of perforin is the Ca^{2+}-binding site that initiates the insertion of the molecule into cell membrane ([406]). The insertion is mediated by exposure of several aspartate residues after cleavage of the C-terminus to yield a 60-kd active form. These residues are presumed to become approximated in three dimensions and bind Ca^{2+}, and the molecule becomes highly reactive for lipids from exposure of amphipathic domains. Some data suggest that perforin actually is inserted into the lipid bilayer with the help of a receptor. NK cells release a lysolipid, the platelet-activating factor, which binds to its receptor and forms a bridge between the platelet-activating factor receptor and perforin ([432]). At 37°C, perforin inserts into the membrane, and approximately 20 perforin monomers form a tubular structure (16 nm wide) with a torus in the upper ring ([433]), similar to that formed by the C9 component of complement (Fig. 17.16). Purified perforin causes cell lysis but not the DNA fragmentation and condensation associated with apoptosis, which is a hallmark of target cell lysis by CTLs ([434]). Furthermore, nuclear changes occur before cell membrane damage ([435]).

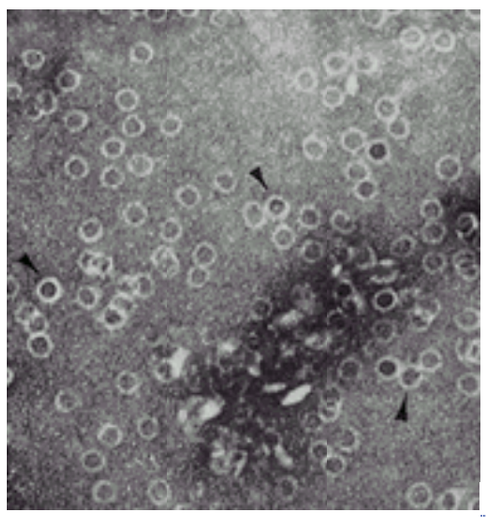

Figure 17.16. Lesions (arrows) inflicted on its target by cytotoxic T lymphocytes. Cytotoxic T lymphocytes form punched-out lesions on the membrane of the target similar to those formed by complement. (From Dennert G, Podack ER. Cytolysis by H-2-specific T killer cells. Assembly of tubular complexes on target membranes. J Exp Med 1983;157:1483–1495, with permission.)

Target cell death requires combined action of perforin and granule-associated granzymes. However, mice deficient in perforin suffer more serious consequences of lack of or diminished cytolytic functions ([436]) as compared to mice deficient in granzymes A and B ([437]). It has been assumed that granzymes enter passively through perforin pores (Fig. 17.17). Large pores that allow passive diffusion of the granzymes are formed only with large concentrations of perforin. The pore size formed by small concentrations of perforin does not permit diffusion of proteins larger than 8 kd. However, even under these conditions, granzymes (32 to 65 kd) have access to the cytosol, although evidently not by direct diffusion through perforin pores. A lysin from *Listeria monocytogenes* also permits granzyme access to cytosol even in the absence of any measurable plasma membrane damage ([438]).

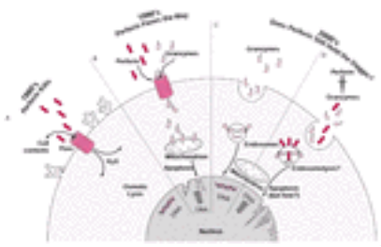

Figure 17.17. What is the role of perforin in cell lysis? The perforin lesion used to be considered the cause of cell death by osmotic lysis (as with complement) (*A*). When the granzymes were implicated in the cause of cell death by the apoptotic pathway, it was believed that the pores of perforin allow the entrance of the granzymes into the cell (*B*). Granzymes, however, can still enter the cell without perforin, but by themselves, they cannot cause cell death (*C*). Because granzymes enter the cell by endocytosis and are within endocytic vesicles, it is argued that perforin is needed to release them in the cytosol by punching holes in the vesicles (endosomolytic mechanism) (*D*). At this point, it is known that cytotoxic T lymphocytes kill their targets, and for this function, they need at least two of the contents of the granules: the granzymes and the perforin. The exact mechanism, however, is still strongly debated.

The entrance of granzyme B into the cell at low perforin concentrations is suggested to occur, probably as a result of endocytosis ("facilitated access" hypothesis). Perforin endocytosed together with granzyme disrupts the endocytic pathway and releases granzyme for delivery to the nucleus. Support for this interpretation comes from the observation that brefeldin, which interferes with redistribution of proteins out of the endosomal system, inhibited perforin-induced release of granzyme B, blocked its translocation to the nucleus, and inhibited cell death ([438]). Granzyme B is therefore able to enter into the interior of the cell autonomously in the absence of perforin. However, apoptotic death does not occur unless perforin is added ([439]). Granzyme binds to MPR when it is trafficking within the cell at the time of synthesis but also on the surface of the target cell ([440]). However, MPR is not critical for transportation of granzyme B within the target cell because cells lacking MPR are still subject to apoptosis by granzyme B, which enters the cell by constitutive fluid-phase micropinocytosis ([441] , [442]) or some other, probably specific, receptor. Endocytosis follows the binding to the receptor, and the granzyme B is detected first within Rab5-positive endocytic vesicles and subsequently in Rab5-negative, novel endocytic compartments that are not identifiable by any of the known endocytic markers ([443]). The granzyme B is released to the cytoplasm by a second signal provided by perforin or replication-deficient adenovirus (Ad2). From the cytoplasm, the granzyme B reaches the nucleus, initiating the apoptotic pathway. The localization in the nucleus occurs before the nuclear events of apoptosis, suggesting that nuclear translocation of the granzyme B transmits an apoptotic signal that is communicated to the nucleus ([444]).

ROLE OF GRANZYMES Independent of the role played by each of the constituents of the granules, it is absolutely clear that *exocytosis* is crucial for target cell death. In T cells, the granules are synthesized when the cells receive activation signals, whereas in NK cells, the granules are preformed. At least four granzymes are present ubiquitously in human cytotoxic cells (i.e., A, G, H, and K). After their synthesis, the granzymes undergo posttranslational modifications and, as a result, assume an active conformation. First, the signal peptide is removed and, subsequently, a short propeptide, which for granzymes A and B is DPPI ([445]). Subsequently, they are glycosylated and then sorted by the MPR in the Golgi apparatus on the way to the granules ([446]). Granzyme B is a serine protease originally defined as an *aspase* because it cleaves after aspartic acid in the P1 position and is the only granzyme with the preference for proteolytic cleavage after aspartate residues. In this respect, it has a specificity similar to caspases and has an extended substrate specificity with nine amino acids making contact with the substrate. The first substrate of biologic significance of granzyme B was found to be a member of the caspase family ([447]). Cleavage of target-cell caspases ([448]) results in the activation of the cellular apoptotic cascade (Fig. 17.18). Granzyme B activates apoptosis by two distinct pathways [i.e., by directly cleaving its substrates, caspase 3 or caspase 8 ([449]), and by a caspase-independent pathway through mitochondria]. Mitochondria have a central role in the execution of apoptosis, involving disruption of electron transport and energy metabolism, production of reactive oxygen radicals, and the release of apoptotic proteins, such as cytochrome *c* ([450] , [451]).

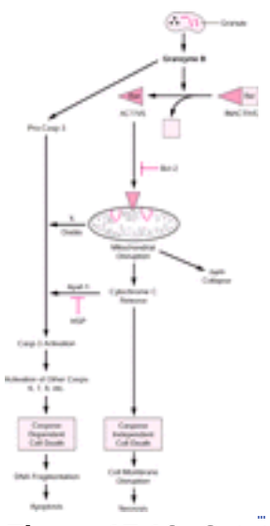

Figure 17.18. Cytotoxic T lymphocyte killing of target cells. The cytotoxic T lymphocyte killing of its targets is mediated by both the granzyme(s) (Gr), especially GrB, and the perforin, and because both of them share the same intracellular residence (i.e., the granule), the killing mechanism is known as the *granule exocytosis mechanism*. GrB activates caspase (Casp)-3, either directly or, most likely, *in vivo* by cleavage of the proapoptotic member of the Bcl2 family, Bid. The active Bid acts on the mitochondrion and causes opening of the permeability transition (PT) pore of the inner mitochondrial membrane that causes (or is the result of) the collapse of the ??m (mitochondrial transmembrane potential). ??m normally results from the asymmetric distribution of protons and other ions on both sides of the inner mitochondrial membrane. It is essential for normal mitochondrial function. ??m disruption occurs before cells exhibit nuclear DNA fragmentation or aberrant exposure of phosphatidyl serine on the outer cell membrane; therefore, it constitutes probably the earliest common event of the apoptotic cascade. Mitochondrial disruption activates a factor not yet well identified (X) and contributes to amplification of activation of Casp-3 and other Casps subsequently (Casp-6, -7, -8, -9, -10). The factor X may be Diablo [direct inhibitor of apoptosis proteins–binding protein], which facilitates processing of Casps through inhibition of inhibitor of apoptosis proteins. The Bid pathway of Casp-3 activation provides a greater lethal threshold of amplification of activation of Casps than the direct GrB activation. In addition to the Casp-dependent pathway (apoptosis), disruption of mitochondria by GrB-activated Bid leads to cell death by necrosis. HSP, heat-shock protein. [Kroemer G, et al. Mitochondrial control of apoptosis. Immunol Today 1997;18:44–51; Heibein JA, et al. Granzyme B-induced loss of mitochondrial inner membrane potential (Delta Psi m) and cytochrome c release are caspase independent. J Immunol 1999;163:4683–4693; Sutton VR, et al. Initiation of apoptosis by granzyme B requires direct cleavage of bid, but not direct granzyme B-mediated caspase activation. J Exp Med 2000;192:1403–1413; and Barry M, et al. Cytotoxic T lymphocytes: all roads lead to death. Nat Rev Immunol 2002;2:401–409.]

Mitochondrial factors enhance the extramitochondrial caspase activation. Bcl2 can rescue cells from granzyme B–mediated cell death, specifically blocking the pathways that operate directly through mitochondrial perturbations. Bcl2 suppresses the mitochondrial pathway because it prevents loss of mitochondrial membrane depolarization and inhibits the release of cytochrome *c* and apoptosis-inducing factor into the cytosol ([452]). The mitochondrial apoptotic pathway is triggered by direct cleavage of Bid ([453]), which results in the translocation of tBid to mitochondria, where it interacts with its receptors, Bax and Bak, to cause cytochrome *c* release. Cytochrome *c* then activates the apoptosome, which activates caspase 9 and ultimately caspase 3 ([454]). Bcl2 apparently blocks granzyme B–induced apoptosis by acting at an upstream point of the granzyme B pathway (i.e., blocking the translocation of the granzyme to the nucleus) ([455]).

Granzyme A Granzyme A is a tryptase and induces caspase-independent cell death. It concentrates in the nucleus of the targeted cells and degrades histone H1 into small fragments ([456]). Histone H1 plays a critical role in chromatin hypercondensation, which protects genomic DNA from endonuclease digestion. Histone digestion provides a mechanism for unfolding compacted chromatin and facilitating endogenous DNAase access to DNA during T-cell granule–mediated apoptosis. Another target for granzyme A is protein HMG2 (*h*igh- *m*obility *g*roup protein 2). HMG2 is a nonhistone protein that binds to the internucleosomal linker region of DNA and to core histones and is involved in critical steps in DNA replication and transcription. It binds preferentially to distorted DNA and unwinds damaged DNA for its repair. It facilitates the assembly of higher-order nucleoprotein structures by bending and looping DNA or by stabilizing underwound DNA. Granzyme A cleaves HMG2 protein and thus opens up chromatin and blocks the *de novo* transcription required for cellular repair responses. Opening up chromatin probably contributes to the observed synergy of granzyme A with granzyme B in the induction of oligonucleosomal DNA fragmentation during CTL lysis ([457]). Both granzyme A and B directly cleave lamin B ([458]), a member of the lamin family of proteins that maintain the integrity of the nuclear envelope. Granzyme A, bound to proteoglycans, has been detected in the blood of patients with viral diseases and rheumatoid arthritis ([459]). In complexes with proteoglycans, it is protected against inactivation by protease inhibitors (a_2-macroglobulin and so forth). However, its role in the blood in these conditions remains unknown. The entry of granzyme A into the nucleus requires the signal from perforin, and once inside the nucleus, it binds to insoluble factors because it does not leak out, even after the nuclear membrane is permeabilized ([460]).

DEATH RECEPTOR PATHWAY Cytotoxic lymphocytes use two pathways for killing their targets: the exocytosis pathway (perforin-granzyme) and a death receptor pathway. Although there are multiple receptors on the cell surface that can initiate an apoptotic cascade, they converge at one point downstream to a common final pathway. The point of confluence is the adaptor molecule FADD (*F*as- *a*ssociated *d*eath *d*omain). These alternate apoptotic pathways may be considered as the FADD pathway ([461]). The pathways that converge to FADD are initiated by Fas (CD95), the most physiologically important receptor in the family of TNF receptors.

FADD binds and recruits caspase 8, which stands at the apex of the cascade of all caspases ([462]) and forms the DISC (*d*eath- *i*nducing *s*ignaling *c*omplex) ([463]). Caspase 8 may target the mitochondria through Bid or caspase 3, depending on the cell type ([464] , [465]). In the FADD pathway, the FasL is not stored even in activated cells, and as a result, it requires the induction of a new ligand after TCR stimulation, which requires 1 to 2 hours after stimulation. The half-life of the ligand is long (2 to 3 hours), and the CTL can kill innocent bystanders (as long as they express the appropriate receptor, Fas) without the need for TCR signaling ([466]). In this respect, the FADD pathway is much more promiscuous than the perforin pathway. The death receptor pathway is important for $CD4^+$ Th1 cells ([467]).

MEMBRANE MORPHOLOGY OF TARGET CELL LYSIS In the early stages of cell death induced by CTL, plasma membrane components are translocated to intracellular membrane structures, including nuclear envelope and mitochondria. Membrane-bound perforin and the granzymes are internalized at the same time, and it is postulated that, subsequently, perforin releases the granzymes to the cytosol by an endosomolytic action for activation of the caspase pathway (Fig. 17.17 and Fig. 17.18). In the early stage, the target does not undergo extensive permeabilization during perforin-dependent CTL lysis. The first detectable change in the target cell–surface morphology consists of the formation of small dilatations of the surface microvilli, forming small vesicles that eventually expand into large blebs even before ^{51}Cr release can be detected. Some of the detached vesicles attach to neighboring CTLs, suggesting that they carry some target-specific antigens on their surface (Fig. 17.19).

Functions Mediated by Lymphocyte Toxicity

DEFICIENCIES OF GRANULE CONTENTS Virus-specific cytotoxic $CD8^+$ T cells are induced on infection against many viruses (Fig. 17.14). Lysis of an infected cell may occur in the eclipse phase before any infectious virus has been produced, and CTLs kill virus-infected cells before new viral antigens can be detected on the surface with antibodies ([468]). Fas deficiency has no effect on the role of viral clearance, but elimination of both Fas and perforin leads to uncontrolled infection ([469]). Normal mice easily survive a high inoculum (10^6 PFU) of the ectomelia virus, a murine-specific poxvirus. However, perforin-deficient mice succumb with a dose as small as 10 PFU. Perforin deficiency in mice is associated with increased susceptibility to a variety of infections by viruses, protozoa (plasmodium, *Trypanosoma cruzi*), and bacteria (i.e., mycobacteria, salmonella, chlamydia, *Listeria*, and so forth) ([470]). Defense involves not only cytolytic mechanisms but also cytokines (i.e., IFN-?, TNF, and so forth), as well as microbicidal molecules. In the experimental model of lymphocytic choriomeningitis virus infection in mice, a nonlytic viral infection, perforin-dependent cytotoxicity is crucial in the control of the acute stage ([471]). During the chronic stage of this infection, perforin down-regulates $CD8^+$ T-cell expansion and prevents immunopathology ([472]). In perforin-deficient mice, however, the lack of this immunoregulatory control results in expansion of $CD8^+$-activated T cells, with approximately 50% of the animals dying within 2 to 4 weeks as a result of the immunopathologic damage from uncontrollable $CD8^+$ proliferation and activation. Infusion of normal $CD8^+$ T cells fully reverses pathology and the associated mortality. This example clearly differentiates between defense and immunopathology, which normally is averted from an “exocytosis”-mediated mechanism of regulation of $CD8^+$ cytolytic cells. In another model involving the lpr/lpr mice, which are deficient in the Fas receptor, deficiency of perforin markedly accelerates the spontaneous lymphoproliferative disease, which normally occurs at a slower pace in these mice. This evidence also supports the notion that perforin plays a role in immune regulation, prevention of immunopathology, and autoimmunity. Recently, a homozygous loss of function defect in the human perforin gene has been detected that is associated with several clinical manifestations, mainly due to uncontrolled T-cell and macrophage activation with overproduction of inflammatory cytokines. The syndrome is known as *familial hemophagocytic lymphohistiocytosis* (FHL) ([473]). The disease is mapped in chromosome 10q21-22 (i.e., the location of the perforin gene). Overall, the incidence of the mutation is approximately 20% in all FHL patients. For the development of FHL syndrome, a viral infection or a defect of an additional pathway that controls lymphocyte homeostasis is required. Perforin-deficient mice, for reasons unknown at the present time, do not develop symptomatology similar to human FHL. Mice deficient in granzyme B lose the ability to induce DNA fragmentation, even though perforin causes membrane damage. Deficiency of both granzymes A and B causes susceptibility to ectromelia infection ([474]), although cytotoxic lymphocytes with the same deficiency and inability to cause DNA fragmentation are still able to exert a potent antitumor effect ([475]). DPPI, also known as *cathepsin c*, is a lysosomal cysteine protease expressed in most tissues, and in CTLs, it is found in the secretory compartment. It belongs to the papain superfamily of proteases and shares similarities to lysosomal cysteine proteases cathepsins B, H, and L. Granzymes A and B become enzymatically active only after cleavage of the *N*-terminal dipeptide by DPPI and are stored in the lysosomal granules in the active form along with perforin. DPPI knock-out mice resemble the perforin-deficient mice: Both fail to cause apoptosis. DPPI deficiency results in failure to activate the granzymes, whereas perforin deficiency fails to deliver the granzymes into target cells ([476] , [477]). Deficiency of DPPI has been detected in humans with Papillon-Lefèvre syndrome, which is characterized by keratosis palmoplantaris with perio-dontopathia ([478]). There is premature tooth loss due to periodontal disease and thickening of the skin.

GRAFT-VERSUS-HOST AND GRAFT-VERSUS-LEUKEMIA REACTIONS Lymphocyte cytotoxicity has been implicated in graft-versus-host disease after allogeneic bone marrow transplantation, with contribution to the pathogenesis by both the perforin and Fas pathways ([479] , [480] and [481]). It is agreed that cytotoxic lymphocytes contribute to the development of the disease, but there is no agreement about the underlying mechanism. The graft-versus-leukemia effect, however, seems to be mediated predominantly by the perforin pathway.

GRANZYME INHIBITORS An important characteristic of the function of cytotoxic cells is that they avoid successfully the damaging effect of the lethal weapons they deliver to kill their targets. As a matter of fact, the CTLs, after a successful hit, disengage and are directed against another target. Some recent observations provided a molecular explanation for their protection from “suicide.” The effector cells contain a potent inhibitor of granzyme B, known as *proteinase inhibitor 9* ([482] , [483]). The inhibitor is a serpin, is found in both the cytoplasm and the nucleus, and forms tight complexes with granzyme B but does not inhibit most of the caspases. Serpins are a large family of intracellular and extracellular protease inhibitors. Many viruses encode serpins that block caspases, the enzymes of apoptosis. Inhibitors of granzyme B can be encoded by several viruses. Best described is the poxvirus-encoded cytokine response modifier A (Crm A). Overexpression of Crm A in target cells inhibits CTL-mediated killing, but predominantly through a Fas-mediated pathway. Crm A inhibits granzyme B and several caspases. With several of the steps of CTL cytotoxicity now understood, therapeutic interventions are possible for several of the steps of lymphocyte cytotoxicity in a number of human conditions.

How Many Roads Lead to Death?

Despite the wealth of information on the mechanism of this important pathway, there are several areas that are not well understood. Perforin has an indispensable role in the delivery of granzyme B, but certainly not simply as a pore-forming molecule. Granzymes, on the other hand, induce the nuclear changes affecting the DNA (i.e., by apoptosis), but even if they enter the cell in the absence of perforin, they cannot be translocated to the nucleus without perforin ([484]). The mechanism of granzyme delivery by perforin is not clear. It has been postulated that intracellular delivery of granzymes is through an endosomolytic mechanism ([485]). Translocation of a fluorescent probe from the target cell membrane to interior membranes, including the nuclear envelope and mitochondria, is supportive of this prediction ([486]).

The relationship of the roles of perforin and granzymes in cytotoxicity was examined in the gld/gld mice, which have a FasL deficiency and therefore cannot have Fas-mediated cytotoxicity. The additional deficiency of granzyme B in gld/gld mice (i.e., mice with the phenotype GrB gld/gld) leads to CTLs with residual cytotoxicity, which can only be perforin dependent. This can be concluded also from the fact that perforin $^{-/-}$ gld/gld CTLs have no residual cytotoxicity ([487]). It is reasonable to conclude that the cytotoxicity, which is independent of granzyme B, is normally accounted for partially by a Fas pathway and partially by a second perforin-dependent mechanism. Finally, inhibitors of caspases block the Fas death pathway, but in CTL granule exocytosis, the target cell lysis is not detectably blocked, although the

accompanying apoptotic nuclear damage is efficiently blocked. Thus, caspase inhibitors prevent the hallmark phenotype of apoptosis without affecting cell death, as evidenced by lysis ([488]). At this point, not all the roads used by the CTL that may lead to cell death have been fully explored.

Regulatory T Cells

During the 1970s, $CD8^+$ cells were separated into two functional groups, with one being cytotoxic and another having a distinct function of regulating ongoing immune responses or inducing tolerance to autoantigens. These *suppressor T cells* were defined by the ability of T cells from animals tolerant to an antigen to suppress the immune response to the same antigen ([489]). Suppressor cells could be distinguished by cell-surface markers from helper T cells, as both could be induced after immunization ([490]). Molecular biologists could not identify genes that could encode the plethora of suppressive factors that could only be demonstrated functionally in supernates of suppressor cells or clones ([491]).

The field of suppressor cells was broadly dismissed ([492]). For a period of time, the role of “suppression” in immune regulation was attributed to the balance between Th1 and Th2 cells. Th2 cells, for example, regulate Th1 responses by exerting a suppressive effect on Th1 differentiation by their cytokines, a phenomenon called *immune deviation*.

More recently, the notion of suppressor cells has been revived, and their existence has been demonstrated ([493] , [494]), but in their resurrection, they have been given a new name: *regulatory T cells*.

Regulatory T cells (Tr1) develop in the thymus, maintain homeostatic equilibrium of immunity and tolerance, and are able to control destructive autoimmunity specific to different tissue antigens. The nonobese mouse is a strain genetically susceptible to development of spontaneous insulitis; the incidence of diabetes between 3 to 5 months of age correlates with progressive loss of Tr1 cells as the disease progresses ([495] , [496]).

Another strain of mice develops an inflammatory bowel disease that has several similarities to human Crohn disease and ulcerative colitis. In this model, inflammatory disease of the bowel develops in response to intestinal pathogens and depends on the accumulation of activated dendritic cells ([497]). However, the Tr1 cells impede the ability of dendritic cells to induce a sustained inflammatory response. IL-10 and TFG-ß produced by Tr1 inhibit intestinal inflammation and T-helper cell responses, type 1 or type 2 ([498]).

The presence of Tr1 cells has been demonstrated in severe combined immunodeficiency disease (SCID) patients successfully transplanted with mismatched hematopoietic stem cells ([499]), as well as in recipients of kidney or liver allografts ([500]), indicating that the Tr1 cells regulate transplantation tolerance. Oral tolerance is a long-recognized mechanism of tolerance, induced by partially degraded dietary antigens presented to the gut-associated lymphoid tissues ([501]). Regulatory cells induced by this method secrete TGF-ß and have been called *Th3 regulatory cells* ([502]). These cytokines can be induced by high doses of antigen, given by mouth, in a number of experimental autoimmune diseases and also in patients with multiple sclerosis after oral administration of myelin proteins ([503]).

In patients with the helminthic infection by fliaria Onchoercia volvulus, strong inflammatory responses, and thus damage to the patient, are suppressed by TGF-ß and IL-10 cytokines produced by Th3 regulatory cells and not by a shift from Th1 and Th2 responses ([504]). The same cytokines have also been associated with remissions of chronic idiopathic purpura ([505]).

Although the emphasis of immunosuppressive mechanisms by Tr cells has been placed on the secretion of the immunosuppressive cytokines TGF-ß and IL-10, Tr cells activated by their TCR ([506]) suppress immune responses by killing Th cells by apoptosis ([507] , [508]) or by blocking up-regulation of co-stimulatory molecules (CD80, CD86, CD54, CD58) ([509]) or inhibiting their transcription by NF-?B and the CD40/CD40L pathways ([510]).

The source of Tr is the thymus, which, like other developing thymocytes, is submitted to the scrutiny of selection processes for its specificity. The criteria of their positive selection appear unorthodox because they are based on high-avidity interactions involving a limited peptide repertoire ([511]). High-avidity interactions between the TCRs of developing thymocytes and their ligands on the thymic stroma mediate negative selection of autoreactive cells.

Another functional deviation from the normal pathways is that the $CD8^+$ Tr cells recognize antigen in the context of class II molecules. Such $CD8^+$ T cells have been isolated from leprosy patients ([512]). Their specificity is very unusual considering that the co-receptor for the TCR is CD8. Recently, important insights into the mechanisms of autoimmunity by $CD8^+$ Tr were realized through studies on the control of experimental allergic encephalomyelitis, which is considered to be an instructive model for the human demyelinating disease multiple sclerosis, as both share similar pathology and the same functional abnormalities. The pathogenic effector cells in the mouse model are $CD4^+$ (Te), which recognize an immunodominant *N*-terminal peptide of the myelin basic protein, and their TCR uses the Vß8.2-Jß2.7 gene segments. Two regulatory cells have been identified, one $CD4^+$ and the other $CD8^+$. Activation of the $CD4^+$ Tr cell recruits and activates the $CD8^+$ Tr, the ultimate effector of regulation ([508]), but secretion of IFN-? by the $CD4^+$ Tr is necessary. The most interesting aspects in this multicellular complex of regulation of autoimmunity are the specificities of the TCRs of the $CD4^+$ and $CD8^+$ Tr cells ([513]). The TCR of the $CD4^+$ Tr recognizes a peptide from the framework 3 region of the Vß8.2 TCR of the pathogenic $CD4^+$ Te. The TCR of the $CD8^+$ Tr recognizes a peptide from the CDR of the Vß8.2 TCR of the same pathogenic $CD4^+$Vß8.2 cells. The net result of these interactions is the elimination of the pathogenic T cell with amelioration of the disease.

T lymphocytes with diverse functions (i.e., helper as well as pathogenic inflammatory) develop concurrently during an immune response, and as a result of differential expression of chemokine receptors, they are diverted by different migratory pathways to separate sites ([514]). It is therefore highly important that Tr induction is a component of the same response to regulate the function of potentially pathogenic T cells. The rapid explosion of research on suppressor T cells since their resurrection is an indication of their significance in protection from immunopathology as well as for regulation of the immune responses ([515] , [516]).

?d T CELLS

?d T-Cell Repertoire

Commitment to the ?d T-cell lineage takes place in the thymus, and the operating mechanisms have been discussed earlier in this chapter. (See T Cell-aß versus T Cell-?d and the Pre–T-cell Receptor.)

Rearrangements of the human ? and ? loci appear to occur in a developmentally ordered fashion ([517]). Initially, the ?d TCR repertoire is small because rearrangements involve a small number of V segments, and the junctional diversity is limited.

In human embryos between 8.5 to 15.0 weeks of gestation, the most common V fragments are V?2 joined to D?3 and V?1-8 or V?9 with J?1. These cells are referred to as the *V? 2 cells*. Rearrangements after birth at approximately 4 to 6 months of age involve joining other ?d segments such as V?1 to D?1 and D?2 and the V?1 family with the J?2 cluster. Postnatally, in the thymus, the V?2 subset represents 15% and the V?1 85% of the ?d cells, and these proportions remain relatively constant throughout adult life ([518]). However, in the blood, the V?2 subset increases with age from 25% in cord blood to more than 70% in adult blood, whereas the V?1 subset decreased from 50% in cord blood to less than 30% in adult blood ([519]).

Although intrinsic or genetic factors generate subsets of ?d T cells, extrinsic or environmental factors act further to shape and select specific clones. An enormous selective pressure is exerted on the development of ?d T cells throughout life to produce populations of cells that express antigen receptors that are encoded by specific gene segments. The predominance in adult human blood of the V?2 to V?9 population is explained by such antigen-mediated expansion ([518]). These expansions create oligoclonal populations due to selection pressures from environmental microbes and certain edible plants. In contrast to the V?2/V?2 (V?2 is the same as V?9) T cells that are a major circulating population, the V?1 cells account for the vast majority of the ?d T cells in tissues such as intestine and spleen ([520]).

?d T-Cell Receptor Structure and Antigen Recognition

Antigen recognition by the ?d TCR resembles recognition by antibodies ([521]). The V and C domains are organized into “Ig folds” (i.e., approximately seven ß strands packed face to face in two antiparallel ß sheets, constrained by intradomain disulfide bonding). The V regions are subdivided into framework and hypervariable regions, which have three CDRs. The orientations of V? and V? are similar to the relative orientations between the V domains in the Fab Ig fragment or the aß TCR. However, the CDR3 of V? is diverse in length and composition (8 to 21 amino acids), a range similar only to the IgH (3 to 25). Furthermore, the CDR3 loops of the ?d TCR protrude above the rest of the molecule and create clefts between them, which strikingly distinguishes them from the equivalent loops of the aß TCR, which are flat and bind to pMHC, and from the antibodies that bind large proteins ([522]).

In general, the ?d TCR is broadly conserved but with unique structural features. Antigen recognition by ?d TCRs is fundamentally different from that of aß TCRs. Antigens are not required to be processed and there is no MHC restriction; as a result, the ?d TCR is allowed to recognize a wide array of antigens ([521], [522], [523] and [524]). The antigens recognized are those with a wide distribution that are constitutively expressed by host cells and by microbial pathogens and those that are inducibly expressed or might be restricted to certain cell types. Examples of the former category are nonprotein substances such as pyrophosphates and alkylamines that are found in bacteria, plant, or animal cells ([525], [526] and [527]), and bacterial and mammalian homologs of heat-shock protein 60 kd (HSP-60) ([528]).

Human peripheral blood V?2V?2 cells are present in large numbers in lepromatous lesions reactive with monoalkyl compounds of mycobacterial cell walls. The most potent compound is monoethylphosphate, which stimulates cytotoxic activity of these cells. The phosphate group is very important in the recognition of this substance by the ?d TCR. Several other phosphorylated compounds could be shown to have reactivity with the ?d TCR. Alkylamines, such as isobutylamine and so forth, derived from plant food products or from bacteria also stimulate V?9V?2 $^{+}$ T cells ([527]).

A third class of antigens (i.e., the aminobiphosphonates) that are used to inhibit osteoclastic bone resorption, particularly in cancer patients, can also stimulate V?9V?2 cells ([529]). Antigens recognized by ?d TCR are also found in other infectious agents (i.e., *Listeria*, *Plasmodium coccidia*, and so forth). V?9 $^{+}$ T cells also respond to superantigens, such as staphylococcal enterotoxin A ([530]). Superantigens interact with the MHC class II molecules and TCRs in a way distinct from that of normal peptide antigens. They bind independently to MHC class II and to TCRs. They interact with the Vß domain of the TCR outside of the CDRs and with the outer faces of the MHC molecule, outside the peptide-binding groove.

The functional ?d TCR exists as a complex with the CD3 polypeptide chains. Some mucosal ?d T cells interact with MHC-encoded proteins, MICA and MICB ([531]). Recognition is through the activating NKG2D C-type lectin receptor ([532]), but the contribution of the ?d TCR is not clear. MICA and MICB class I molecules identify stressed cells and have a very restricted pattern of expression, primarily limited to intestine. MICA and MICB do not present peptides because the peptide-binding groove is of limited size ([533]) (see Chapter 18). These molecules may function in innate immunity as important targets for V?1 $^{+}$ cells for elimination of stressed cells ([520]). Some V?1 $^{+}$ cells recognize the nonpolymorphic CD1c member of the CD1 family of molecules, expressed on APCs, that presents lipid and glycolipid foreign antigens to T cells ([534]). These ?d cells activated in response to CD1c produce IFN-? and direct aß T cells to Th1 differentiation. Furthermore, they are cytotoxic and express granulysin, and they could lyse infected dendritic cells via the perforin pathway and kill released bacteria by granulysin. Therefore, their role is significant in host defense before antigen-specific T cells have differentiated ([535]).

Direct recognition of CD1c may represent a bridge between innate and adaptive immunity in a similar fashion to recognition of CD1d by murine and human NK $^{+}$aß T cells ([536]), which polarize T cells to a Th2 phenotype. The CD1c-restricted ?d T cells promote the maturation of myeloid-derived dendritic cells, which, at the immature stage, express high levels of CD1a, b, and c antigens. When these dendritic cells mature, they are able to present antigens to CD4 $^{+}$ T cells. This function of ?d T cells is important because they rapidly provide mature dendritic cells early during microbial invasion and, at the same time, secrete IL-12 to drive T-cell polarization to the Th1 type ([537]).

?d T-Cell Function

The recognition of antigens by the ?d TCR is more akin to that of antibodies rather than the aß TCR. It does not need antigen processing by APC and presentation by MHC. The available crystal structure of human V?9/V?2 shows that the functional similarities are, as expected, based on structural similarities with the heavy as well as the light chains of Igs, as discussed earlier.

Subsets of ?d T cells are characterized by the expression of distinct sets of V? genes, the V?1 and V?2. They are believed to represent separate lineages with different developmental pathways ([538]) and different tissue distribution. Most of the ?d T cells with intraepithelial localization (i.e., nasal mucosal, small intestine, and colon) are V?1, whereas the V?2 are detected in the peripheral blood, where they constitute approximately 5% of all T cells.

In general, the function of the ?d T cells in infectious diseases includes an immediate response to invasion by pathogens and a long-term regulation of the inflammatory response. The V?9/V?2 T cells release proinflammatory chemokines ([539]), and provide protection against mycobacteria by directly killing infected macrophages ([540]) and extracellular bacteria by granulysin with the help of perforin ([541]). The ?d T cells represent the largest population of mycobacteria-reactive T cells in the blood of humans, and more than 85% of them are V?9/V?2 and proliferate vigorously in response to the infection.

Persistent chronic disease correlates with a decline and eventual disappearance of mycobacteria-reactive ?d T cells ([542]). This loss is due to Fas-FasL–mediated apoptotic death as a result of activation-induced cell death from chronic stimulation by mycobacterial antigens. After clearance of the mycobacteria at a late stage of the disease, the ?d T cells contribute to the resolution of the response and prevention of chronic inflammatory disease by directly killing activated macrophages ([543]). This may be facilitated by the expression of CCR5, the receptor for the chemokine RANTES (MIP-Ia) produced by macrophages ([545]). ?d T cells participate in responses against several other infectious agents ([524]). The evidence of a role of ?d cells against cancer is still circumstantial ([544]).

A role of ?d T cells in autoimmune disease has been demonstrated in some experimental models. As has been discussed earlier, their mucosal localization places the ?d T cells in a unique position for defense against infectious agents, but also in induction of mucosal tolerance. Induction of oral tolerance is a very old observation ([546]). Antigens given by mouth induce specific systemic unresponsiveness, an observation that has been documented repeatedly in animals and humans.

Nonobese diabetic mice develop spontaneous insulitis and diabetes, a disease that shares a number of immunologic and pathogenetic features with human type I diabetes. Conformationally intact but biologically inactive insulin administered in these animals intranasally induces immunoregulatory ?d T cells, which secrete IL-10, accounting for the antidiabetic suppressor effect ([547]).

?d T cells accumulate in the synovium of patients with rheumatoid arthritis ([548]). In an animal model of collagen-induced arthritis, the role of ?d T cells is controversial; whether ?d T cells promote or reduce exacerbation of inflammation may depend on the stage of the disease (early or late, respectively) ([549]). The evidence so far for the role of ?d T cells in defense, immune regulation, and surveillance as a result of their broad reactivity places this cell in a critical position as a “sentinel” between innate and adaptive immunity ([550]). This function is supported by its receptors, which share broad structural features of the Ig domains.

NATURAL KILLER CELLS

NK cells were originally described on a functional basis according to their capability of killing certain tumor cells of hematopoietic origin in the absence of prior stimulation. Subsequently, they were identified by monoclonal antibodies as a discrete population of cytolytic lymphocytes and were implicated in several activities *in vivo*, such as activity against tumor cells, resistance to viral infections, and regulation of hematopoiesis ([551], [552] and [553]).

NK cells are a heterogeneous population with respect to phenotype and target specificity. Although the majority of the CD56 $^{+}$ NK cells are CD3 $^{-}$, small numbers of CD45 $^{+}$/CD3 $^{+}$ cells have been detected, and large granular lymphocyte (LGL) leukemias with the same phenotype have been reported ([554]).

Morphology, Cytochemistry, and Surface Markers

LGLs are large cells with pale blue cytoplasm and a high cytoplasmic to nuclear ratio. Their main histologic feature is the presence of azurophilic granules ([555]). These cells constitute 2 to 6% of the peripheral white cells and approximately 10 to 15% of the peripheral blood lymphocytes. They are larger than the typical lymphocytes (10 to 12 µm) with a larger amount of cytoplasm that contains peroxidase-negative granules (Fig. 17.20). The a-naphthyl acetate esterase distribution is similar to that found in monocytes, with a diffuse membrane-associated pattern in the cytoplasm, and is different from the dotlike pattern of T lymphocytes. LGLs do not adhere to surfaces and have no phagocytic activity. Ultrastructurally, they are heterogeneous in terms of size and the density of the granule matrix ([556]). The granules are located next to the Golgi apparatus, which also contains several smooth membranes and coated vesicles. The Golgi apparatus apparently is involved in the packaging of the granule contents. The granules have an electron-dense center surrounded by a layer of lesser opacity. Like the granules of CTL, the NK-cell granules contain perforin and granzymes, which are both important for their cytotoxic function ([557]). The granules may be present in various forms, such as smooth or coated, depending on the stage of cell activation.

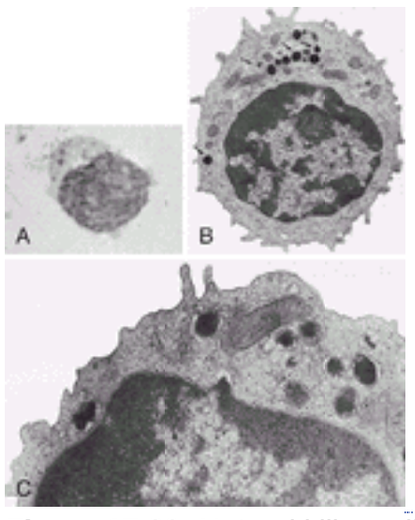

Figure 17.20. Natural killer cell morphology and ultrastructure. **A:** Natural killer cell is characterized by large amounts of pale blue cytoplasm and the presence of azurophilic granules. **B:** By electron microscopy, the granules in the cytoplasm appear heterogeneous in terms of size and density (*arrows*). A few scattered mitochondria are present. **C:** The granule consists of an electron-dense center that contains the perforin and may be enclosed by a thin membrane. Surrounding the core is a layer of lesser opacity containing the granzymes. The granules of the cytotoxic cells are probably derived from two separate organelles—those of secretory granules and those of lysosomes—and are sometimes called *granulosomes*. (From Zucker-Franklin D, Greaves MF, Grossi CE. Atlas of blood cells, 2nd ed. Philadelphia: Lea & Febiger, 1988, with permission.)

LGLs are phenotypically and functionally heterogeneous (i.e., CD56 $^{+}$/CD3 $^{-}$/CD8 $^{-}$), and the majority of them are CD16 $^{+}$ (approximately 80 to 90%); others are CD57 $^{+}$/CD3 $^{+}$/CD8 $^{+}$TCR-a/ß $^{+}$. Both populations are cytolytic, but the CD57 $^{+}$ cells are T (or NK-like) cells that are non–MHC restricted. The CD56 $^{+}$ population is sometimes known as *NK-LGL*, whereas the CD57 $^{+}$ population is known as *T-LGL*. Both populations are CD2 $^{+}$ and CD7 $^{+}$. The separation of the two cell types is not absolute, and we often detect an intermediate cell population that is CD56 $^{+}$/CD57 $^{+}$. The relationship of these cells to those expressing only one of the two markers is not known. Clonal diseases have been described from both the NK-LGL and T-LGL lineages, with distinct clinical syndromes.

Ontogeny of Natural Killer Cells

PHENOTYPIC STUDIES The presence on NK cells of some markers (CD2, CD7) characteristic of T cells raised the question of common ontogenetic origins between these two lymphocytes. However, interference with T-cell development, as in athymic or SCID mice ([558]) or in mice with targeted disruptions of RAG, has no impact on NK-cell development. It is conceivable that the two lineages derive from a common progenitor with separation of their developmental pathways. Some evidence for a common T/NK precursor has been obtained ([559], [560]) and relates to expression of cytoplasmic CD3?, ?, and e. Cytoplasmic expression of CD3?, ?, and e proteins has been detected in fetal NK cells ([561], [562]), and overexpression of CD3e blocks T/NK-cell development without affecting other hematopoietic lineages, including B lymphocytes ([563]). Progenitors of NK cells have been identified in the thymus based on the expression of CD56 within the TN thymocyte population ([564]), and a common T/NK-cell precursor was detected among the CD34 $^{+}$ TN population ([565]). The common progenitor has a CD45/CD5 phenotype and becomes an NK-committed cell with loss of the capacity for T-cell differentiation with the expression of CD56. The common precursor is present among TN thymocytes that are CD34 $^{+}$ and become CD34 $^{-}$ as the cell is committed to NK lineage. NK-cell differentiation requires a combination of stem cell factor, IL-7, and IL-2 in the presence of a stromal feeder layer. Precursors of NK cells have also been identified in fetal thymuses of mice ([566]). These cells express CD16 and can differentiate into DP (CD4 $^{+}$/CD8 $^{+}$) thymocytes if they remain in contact with the thymic stroma or into NK cells if they are removed from the thymic microenvironment. This again supports the notion that the thymus is not essential for NK-cell development. The common T- and NK-cell progenitor in fetal mouse thymus is CD117 $^{+}$/CD44 $^{+}$/CD25 $^{-}$/NK1.1 $^{+}$ and shows commitment to NK lineage with loss of CD117 expression ([567]). The overall scheme of differentiation in fetal mouse thymus suggests that multipotent precursors entering the thymus first lose B-lymphoid potential as they up-regulate NK1.1 and commit to a T/NK lineage. Then CD25 is up-regulated while CD117 is down-regulated, and cells commit to T- and NK-cell lineages, respectively. Bone marrow is also an important location of NK-cell progenitors. They are CD34 $^{+}$/CD7 $^{+}$ and differentiate to mature NK cells either in the presence ([568]) or absence of stromal cells ([569], [570] and [571]). The progenitors express CD34 and CD7 but are CD33 $^{-}$, and cytokines such as stem cell factor, IL-2, and IL-7 are essential, especially at the early stage of their differentiation. Depending on the conditions of culture, other cytokines, such as IL-7 and IL-3, are needed. Cytolytic activity against NK-cell targets is detected at the time of CD56 expression. Mature NK cells can be stimulated by IL-2 for further enhancement of cytotoxic activity, increase of cytotoxic granule content, expression of adhesion molecules, and acquisition of properties attributed to lymphokine-activated killer cells. Other cytokines, such as IL-7 and IL-12, have similar effects, albeit to a lesser degree than IL-2. For example, IL-12 potentiates suboptimal concentrations of IL-2 ([572]). The common lymphocyte precursor in the bone marrow with the CD34 $^{+}$/CD10 $^{+}$/CD45RA $^{+}$ phenotype is able to develop into NK cells *in vitro* ([573]). Uncommitted hematopoietic progenitors are CD34 $^{+}$/C38 $^{-}$, but up-regulation of CD38 indicates enrichment of cells committed to a particular hematopoietic lineage. CD34 $^{+}$/CD38 $^{2+}$ progenitors in fetal thymus develop into T cells, but CD34 $^{+}$/CD38 $^{2+}$ progenitors in fetal liver have no T-cell precursor activity. This population has no TCR-? rearrangements and no pre-TCR a chain expression and develops *in vitro* into NK cells through an intermediate stage of CD3 $^{-}$/NKRP-1 $^{+}$/CD34 $^{-}$/CD56 $^{-}$ ([574], [575]). A similar NKRD-1 $^{+}$/CD56 $^{-}$ population has been detected in cord blood and develops into mature CD56 $^{+}$ NK cells in the presence of IL-12 ([576]).

FUNCTIONAL STUDIES AND DIFFERENTIATION The cytokine environment regulates NK-cell maturation for the two distinct human NK-cell populations, one IFN-?- and a second IL-13–producing. IL-4 regulates the size of the IL-13 population primarily by inducing their proliferation, whereas IL-12 has minimal effects on the proliferation of IFN-? $^{+}$ NK cells. Cells with the CD161 $^{+}$(NKRP-1)/CD56 $^{-}$ phenotype produce IL-13 but do not produce IFN-? and have no perforin-mediated cytotoxicity ([577]). CD161 is encoded by the NK-gene complex, which includes CD69 and CD94. The CD161 $^{+}$56 $^{-}$, IL-13–producing cells differentiate to phenotypically mature IFN-?–producing cells in the presence of IL-12 and feeder cells. As cells mature, they pass through an intermediate stage of IL-13 $^{+}$/IFN-? $^{+}$ NK cells and eventually acquire the mature irreversible phenotype IFN-? $^{+}$/IL-13 $^{-}$/CD56 $^{+}$ ([578]). The molecular defect of X-linked severe combined immunodeficiency conclusively demonstrated that cytokines are critical for T- and NK-cell development ([579], [580]). These X-SCID patients present with a severe block of T- and NK-cell development, whereas normal or even elevated numbers of B cells are present. The cause of the disease is the lack of the common ?c-chain shared by several interleukin receptors (i.e., IL-2, IL-4, IL-7, IL-9, and IL-15). The most important among these interleukins is IL-7, which promotes development of human thymocytes (and, in the mouse, B lymphocytes also). Deficiency of Jak-3, a tyrosine kinase associated with the ?c-chain, also blocks NK-cell development ([581]). Other data suggest a critical role for IL-15 ([582], [583]). Of the transcription factors, the Ikaros family is required for trans-criptional regulation of NK-cell development ([584], [585]).

Natural Killer Cell Receptors

NK cells are one of the important cellular components of innate immunity, with the mission to defend the body immediately against pathogens or in the early stages of tumor development. As a consequence, the recognition molecules or receptors of the NK cells are displayed on the cell surface without the need of assembly (i.e., rearrangements from multiple DNA segments after the antigenic encounter) ([586], [587], [588] and [589]). Another important difference from other receptors such as BCRs or

TCRs is that NK receptors do not directly recognize pathogens or their products but the quantitative change of MHC molecules induced as a result of the infection. In humans, three distinct families of genes have been defined that encode for receptors of HLA class I molecules. One family belongs to the Ig superfamily and are called *killer Ig-like receptors* (KIRs). The second family is structurally Ig-like, named *Ig-like transcripts* (ILTs). Ig-like transcripts are expressed mainly on B, T, and myeloid cells, but some members are also present on NK cells. They are also called *LIRs* for *l*eukocyte *I*g-like *r*eceptors. The third family consists of *C-type lectin receptors*. C-type lectins are a superfamily with homologous modular carbohydrate-recognition domains (CRD) that bind carbohydrates in a Ca^{2+}-dependent manner. The proteins of this family of NK receptors form group V (outside of a total of seven groups) of the c-type of lectins superfamily ([590]). The C-type lectin receptors, however, have structural differences from the other (more than 200) members of the superfamily, and it has been proposed that it be renamed as a new family of *C-type lectin–like NK-receptor domains* (*CLTD*) ([591]).

IMMUNOGLOBULIN-LIKE RECEPTORS: THE KIRS AND LIRS The KIRs have two or three Ig-like domains and hence are designated *KIR2D* or *KIR3D receptors*, respectively ([592]) (Fig. 17.21 and Table 17.2). The cytoplasmic domains of the KIRs can be either long (L) or short (S), corresponding to their function, either inhibitory or activating, respectively. The inhibitory receptors contain one or two immunoreceptor tyrosine-based inhibitory motifs, or ITIMs, (I/V/L/S)-X-Y-XX-(L/V) (where *X* denotes any amino acid) ([593]). When tyrosine (Y) is phosphorylated, it recruits and activates SHP-1 phosphatase, leading to inhibition of signaling. Activating receptors do not signal directly but must associate noncovalently (via a salt bridge linking the transmembrane regions) with other signaling adaptor molecules that have ITAMs in their cytoplasmic domain (consensus sequence, -Y-X-X-L-X_{6-8}-YXXL/I) ([594]). NK cells express three ITAM-bearing transmembrane proteins: ?, FceRI?, and DAP12. The first two are present as homodimers or heterodimers, whereas DAP12 is exclusively a disulfide homodimer. (The KIRs are known under the CD designation CD158a-m and CD158z. See Table 17.2 and Chapter 2 for details.)

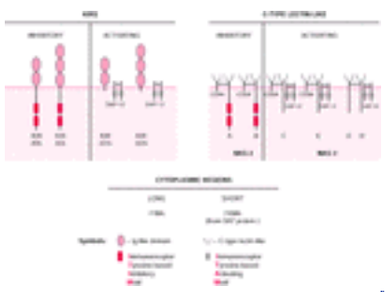

Figure 17.21. Natural killer (NK)-cell receptors. The NK-cell receptors in humans structurally belong to two different families: One family has immunoglobulin (Ig) domains in the extracellular region and are known as *killer Ig receptors* (KIRs) and the other family has a C-type lectin–like domain. The C-type lectin domain recognizes oligosaccharides (and sometimes polypeptides), but the binding is directly mediated by Ca^{2+}, hence the term *C-type lectin*. However, the NK-cell receptors with the C-type fold lack the Ca^{2+}-ligating elements and thus have been termed *C-type lectin–like*. (See Kogelberg H, Feizi T. New structural insights into lectin-type proteins of the immune system. Curr Opin Struct Biol 2001;11:635–643.) The NK-cell receptors in both families are functionally divided into *inhibitory* and *activating*. The labyrinthine jargon of the NK-cell receptors becomes simpler with the acquaintance of some rules: The inhibitory KIRs have either two or three Ig domains in the extracellular region (i.e., 2D or 3D) and a long or short cytoplasmic tail (i.e., 2DL or 2DS and 3DL or 3DS). Those with long cytoplasmic tails are inhibitory, whereas those with short tails are activating. Thus, the receptor KIR 2DL is an inhibitory receptor with two Ig domains, whereas the receptor KIR 3DS is an activating receptor with three Ig domains. (See more details in text and in Table 17.2.)

TABLE 17.2. Natural Killer Cell Receptors and CD Designation

A	KIRs	B	LIRs/ILTs
CD158a	KIR2DL1	CD85a	LIR3 (ILT5)
CD158 b1/b2	KIR2DL2/L3	CD85b	ILT8
CD158c	KIR2DS6	CD85c	LIR8
CD158d	KIR2DL4	CD85d	LIR2 (ILT4)
CD158 e1/e2	KIR3DL1/S1	CD85e	LIR4 (ILT6)
CD158f	KIR2DL5	CD85f	ILT11
CD158g	KIR2DS5	CD85g	ILT7
CD158h	KIR2DS1	CD85h	LIR7 (ILT1)
CD158i	KIR2DS4	CD85i	LIR6
CD158j	KIR2DS2	CD85j	LIR1 (ILT2)
CD158k	KIR3DL2	CD85k	LIR5 (ILT3)
CD158z	KIR3DL7	CD85l	ILT9
		CD85m	ILT10

NOTE: See also Figure 17.20 for structural classification. (Designations were assigned during the seventh HLADA Workshop, Harrogate, UK, June 2000.)
ILT, immunoglobulin-like transcript; KIR, killer cell immunoglobulin-like receptor; LIR, leukocyte immunoglobulin-like receptor.

A fundamental difference between recognition by KIRs and TCRs is that the KIRs recognize more than one MHC allele. They do this by recognizing conserved residues within the polymorphic regions of MHC, whereas TCR recognizes the polymorphic residues. In addition, KIRs display a precise specificity for a particular MHC allotype. This is achieved by variations in single amino acids of KIR molecules ([595]). The ligands for KIRs are alleles of all three MHC class I molecules, HLA-A, HLA-B, and HLA-C, which can confer protection from lysis by NK cells. Generally, KIR3D receptors recognize HLA-A and -B, whereas KIR2D receptors recognize HLA-C alleles. A number of techniques have been used to study the binding and specificity of the receptors. No other molecule is necessary for binding except the HLA alleles ([596] , [597] and [598]). Crystal structures of some KIR receptors with their ligands have been solved. The KIR2DL2 in complex with HLA-Cw3 and peptide shows that KIR binds in nearly orthogonal orientation across the a1 and a2 helices of HLA-Cw3. It contacts positions 7 and 8 of the peptide, but most contacts are between the KIR and conserved HLA-C residues ([599]). Allotypic specificity is determined by the interaction between Lys44 of KIR2DL2 and Asn80 of the HLA-Cw3. In general, the peptides play a minimal role in the interaction, a point that strikingly distinguishes TCR–MHC from the KIR–MHC interactions ([600]). LIR-1 is a member of the LIR family (LIR-1 to LIR-8) expressed on monocytes, B cells, dendritic cells, and some NK cells. LIRs have two to four extracellular Ig-like domains and ITIMs in the cytoplasmic region; therefore, engagement with MHC molecules protects target cells from lysis. The first aminoterminal domain of LIR-1 binds to the nonpolymorphic a_3 domain of MHC I, an interaction that is more similar to that of CD4 with the MHC-II than to that of KIRs. LIR-1 also recognizes the human cytomegalovirus protein UL18, which has a structure similar to MHC-I and associates even with $ß_2$-microglobulin and host peptides. LIR-1 binds to this human cytomegalovirus protein with an affinity that is more than 1000-fold higher than the host MHC-I. This mechanism illustrates an example of viral subversion of host defenses and protection of infected cells from lysis ([601]) because the binding of LIR-1 to UL18 sends an inhibitory signal.

C-TYPE LECTIN–LIKE RECEPTORS The members of the C-type lectin–like receptor family are either homodimers (the large murine family Ly49A-W, CD69, and NKR-P1) or heterodimers, which consist of an invariant chain CD94 and a second subunit from the NKG2 family members A, B, C, and E ([602]). The function of the heterodimeric proteins depends on the cytoplasmic regions of the variant chains [i.e., whether long (NKG2A,B) or short (NKG2C,E), corresponding to inhibitory or activating functions, respectively]. The inhibitory subunits have one pair of ITIMs in the cytoplasmic region, whereas the activating subunits associate with the ITAM-containing adaptor molecule DAP12. The NKG2D protein forms a homodimer (does not pair with CD94) and is an activating receptor. Each subunit is composed of an extracellular C-type lectin–like domain known also as *NK-receptor domain* or *NKD*. The NKD, however, binds proteins and not carbohydrates, which are the ligands for the classical C-type lectins, and furthermore, their structure differs from the classical C-type lectins ([603]). C-type lectin–like NK-receptor domains include other important molecules of innate immunity, macrophage mannose receptor, collectins (i.e., pulmonary surfactants), and so forth. The ligands for CD94/NKG2 proteins are the nonclassical HLA-E molecule, which binds peptides from the leader sequence of the HLA-A, -B, -C, and -G molecules ([604] , [605]). Expression of HLA-E depends on the presence of the signal peptides, thus providing a safe strategy for NK cells to monitor the presence of polymorphic HLA molecules ([606]) because absence of HLA-E would indicate absence of some of the HLA-A, B, or -C. HLA-E is also capable of binding signal sequence of heat shock protein (HSP)-60. HSP-60 is present in all living cellular organisms ([607]) and serves as a mitochondrial chaperone. HSP-60 levels are increased in response to stress stimuli (i.e., temperature increase, nutrient deprivation, exposure to toxic chemicals, inflammation, and so forth). HSP-60 protects these cells from harmful stimuli, but at the same time, the

HLA-E/HSP-60 peptide is not recognized by the inhibitory receptor, CD94/NKG2A, and these cells are eliminated by NK-cell activation ([608]). The ligands for the NKG2D receptor are the MHC class I–related molecules MICA and MICB, which are up-regulated in virally infected cells and many tumors ([609] , [610]). They are minimally expressed in normal tissues but up-regulated in stressed cells ([611]). MICA is composed of two structural domains: one in the form of a platform formed by a $_1$/a $_2$ and the second in the form of a C-type Ig-like a $_3$ domain ([612]). The NKG2D receptor binds orthogonally to the MICA platform in a way similar to the docking of TCR on pMHC (see above) ([613]). For signaling, it uses the adaptor protein DAP10, which has no ITAMs but contains the sequence YXXM that recruits the p85 subunit of PI3 kinase and is thus less susceptible to the SHP-1–coupled receptors ([609]). Another family of ligands for NKG2D is made up of proteins that bind the UL16 cytomegalovirus protein, known as *UL16-binding proteins* (ULBP) ([614] , [615]). The UL16-binding proteins possess a $_1$ and a $_2$ domains but differ from MIC and MHC-I in lacking the a $_3$ domain, and they are GPI-anchored proteins without ß $_2$M protein. Binding to NKG2D receptor has been demonstrated by blocking of ULBP binding by anti-NKG2D antibodies ([616]).

CONCLUSION The major breakthrough in the regulation of NK cell function came with the formulation of the “missing self” hypothesis ([617] , [618] , [619] and [620]) (Fig. 17.22). The hypothesis states that NK cells can recognize and selectively lyse targets that fail to express self–MHC-I antigens. The validity of the hypothesis has been demonstrated in multiple *in vivo* and *in vitro* systems as summarized ([619]). The basic premise is that when appropriate MHC-I molecules are expressed, the lysis of target is inhibited, but when the target is deficient in MHC-I expression, the target is lysed. Specific inhibitory receptors engaged with normal MHC-I molecules prevent activating receptors to kill the target. Cells that have lost a normal MHC-I expression (“missing self”) (i.e., tumors or infected cells) are unable to deliver an inhibitory signal to NK cells and become susceptible to lysis. Cells susceptible to lysis by NK cells as a result of deficiency of MHC-I molecules could be protected by transfection of MHC-I alleles. This experiment provided formal demonstration of the validity of the missing self hypothesis. The NK cell displays two functionally distinct receptors: inhibitory and activating. They are also structurally divided into the Ig-like receptors and the C-type lectin–like receptors ([621] , [622]). The human lectinlike receptor gene complex is on chromosome 12p13.1, and the genes for the Ig-like receptors are in chromosome 19q13.4.

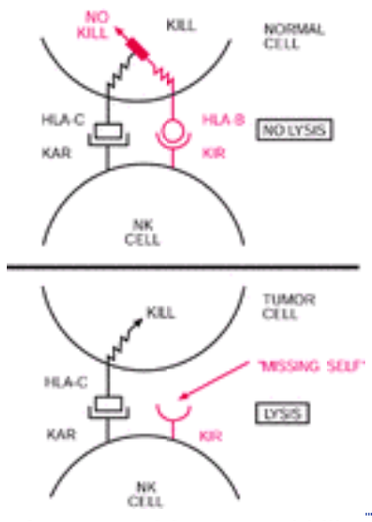

Figure 17.22. Natural killer (NK)-cell cytotoxicity: the missing self. NK-cell cytotoxicity is a delicate balance between activating receptors and inhibitory receptors. Both (whether of the immunoglobulin SF or C-type lectin) have HLA class I specificity, although some receptors recognize non–major histocompatibility complex molecules. The presence of activating receptors against normal cells causes no problem as long as the NK cells possess at least one inhibitory receptor, the signal of which is always dominant. However, with alterations of the structure of a class I molecule or complete loss of the molecule, the binding of the inhibitory receptor is abolished and the activating signal remains unopposed. This is the essence of the missing self hypothesis. KAR, killer-activating rececptors; KIR, killer Ig receptors. (Kärre K. How to recognize a foreign submarine. Immunol Rev 1997;155:5–9.)

The effector functions of the NK cell receptors are controlled by the transmembrane and cytoplasmic regions. The inhibitory receptors have ITIMs in their cytoplasmic tails and recruit SHP-1 phosphatase. Activating receptors have a short cytoplasmic region, but for signaling, they borrow the function of ITAMs by associating with adaptor molecules like DAP-12. Association is mediated by a positively charged residue of the receptor and an oppositely charged (i.e., aspartate) residue of the adaptor ([623]). Further research into the regulation of NK-cell function by the NK receptors is expected to expose new initiatives for investigating tumor immunosurveillance ([624]) and autoimmunity ([625]). In hematology specifically, the manipulation of receptor–ligand interactions may help in allogeneic bone marrow transplantation to prevent leukemia relapse and graft-versus-host disease ([626] , [627] , [628] and [629]).

Natural Cytotoxicity

The cytotoxic mechanism of NK cells is similar to that of CD8 $^+$ T cells.

Natural Resistance

NK cells are one of the main effectors of innate immunity. Their role against viral infections has been well documented ([630]). NK cells selectively lyse virally infected cells but spare noninfected cells. The mechanism of natural resistance against viral infections may involve direct lysis of the infected cells or production of TNF-a, which stimulates NK-cell activity. A patient with selective deficiency of NK cells has been described who had life-threatening viral infections ([631]). NK cells also play a role against certain intracellular parasites, such as *Toxoplasma gondii*. Production of TNF-a and IL-12 activates NK cells for production of IFN-?, which is important for macrophage activation in the defense against intracellular parasites ([632]).

Regulation of Adaptive Immunity

NK cells enhance responses of B and T cells during the early stages of an immune response. As a result of stimulation by IL-12, produced by macrophages in response to infectious agents, NK cells produce large amounts of IFN-? ([633]). IFN-? acts on macrophages and enhances their antigen-presenting function by increasing expression of class II antigens. IFN-? is important in directing T-cell differentiation to Th1 cytokine responses. Induction of predominantly Th1 responses leads to enhancement of cell-mediated immunity. Finally, IFN-? activates macrophages, enhancing their microbicidal function.

Natural Killer Cells and Malignancies

NK cells provide surveillance against tumor cells and virus-infected cells. Circumstantial evidence consistent with the role of NK cells in surveillance against tumors includes the higher incidence of lymphoproliferative diseases in patients with Chédiak-Higashi syndrome, who have profound deficits in NK activity. In patients with X-linked lymphoproliferative disease, NK activity is deficient as well ([634]), and the same is true for people with high familial incidence of cancer ([635]). Similarly, beige mice have a defect of NK cells and a high incidence of lymphoproliferative diseases. On the other hand, nude mice that are T cell–deficient but have normal NK activity do not have increased susceptibility to tumor development. Certain carcinogenic substances have been shown to suppress NK-cell activity. Long-term studies of NK-cell activity in patients with solid tumors revealed a positive correlation between NK-cell activity and survival time without metastasis ([636]). Decrease of NK-cell activity has been detected in patients with malignant lymphoma, in patients before relapse of leukemia, and also in women with breast cancer and metastasis to regional lymph nodes but not in those without involvement of lymph nodes.

Natural Killer Cells and Bone Marrow Stem Cells

When mice from inbred strains are crossed, the F1 progeny can accept organ grafts from either parent. Acceptance of the organ grafts results from the fact that the F1 animals express codominantly the class I antigens from both parents, and therefore, the F1 T cells recognize them as self. In contrast to organ grafts, however, the F1 mice reject bone marrow stem cells from either parent ([637] , [638]). This is known as *hybrid resistance* and is mediated by NK cells but not T cells.

Bone marrow stem-cell rejection is based on another set of antigens known as *hematopoietic histocompatibility* (Hh) antigens, which are inherited in a recessive pattern. The nature of Hh antigens and the mechanism of rejection of bone marrow stem cells in hybrid resistance are not well understood. NK cells may recognize the Hh antigens, or the lack of an MHC class I antigen on the donor cells may also play a role (missing self).

Natural Killer Cells and Bone Marrow Transplantation

NK cells engraft quickly after bone marrow transplantation and constitute the majority of the peripheral blood lymphocytes during the first few weeks after transplantation ([639], [640]). In approximately one-third of the patients after autologous or allogeneic bone marrow transplantation, a normally minor NK subpopulation ($CD56^{+}/CD16^{-}$) was markedly expanded (up to 40% of peripheral blood lymphocytes) ([641]). This population may represent a different stage of differentiation from the major $CD56^{+}/CD16^{+}$ population.

In human bone marrow transplantation, NK activity may help in graft take by controlling viral infections, eliminating leukemic cells, or stimulating hematopoiesis ([635]).

Regulation of Hematopoiesis

Existing evidence suggests that NK cells exert both inhibitory and stimulatory effects on hemopoietic progenitors. These effects are mediated predominantly by the release of cytokines from NK cells rather than by cytotoxicity.

Strong evidence exists that an increase in the number of LGLs is associated with anemia or granulocytopenia. NK cells inhibit *in vitro* granulocytopoiesis in the granulocyte-macrophage colony-forming cell assay ([642]). NK cells also exert a promoting effect on hematopoiesis, however, and the net effect may actually depend on the stage of maturation of the progenitor cells ([643]).

In some patients with neutropenia, there is an increase of NK-like cells in the bone marrow but not in the peripheral blood. These cells can be identified only by immunophenotyping ([644]).

Natural Killer Cell Proliferations

Expansions of LGLs can be either transient or persistent. The former are reactive, whereas the latter can be either reactive or clonal. Markers for clonal expansions of LGLs are not available in practice. Diagnosis of LGL expansions can be made by morphology and then confirmed by phenotype. Most patients have a chronic elevation of LGLs without other signs of malignancy, and their clinical course is not progressive, even without treatment. In many cases, an associated disease (such as rheumatoid arthritis, hepatitis, or malignancy) has been observed. Artificially, a level of 2000/µl of LGLs in the peripheral blood, which is five to seven times the normal value (250 to 450/µl), is believed to represent a lymphoproliferative disease of LGL if it persists for longer than 3 months ([645]). Some of the most common clinical presentations are fever, infections, neutropenia, anemia, and thrombocytopenia. Mortality was associated with moderately elevated counts of LGLs (2000 to 3000/µl) and very high counts (more than 7000 µl), which indicates that LGL proliferations are, in general, highly heterogeneous.

The clonality of LGL proliferations cannot be demonstrated by immunophenotype. However, cytogenetic abnormalities have been detected ([646], [647]), and in LGL cases that are $CD57^{+}$ (and therefore express TCRs), rearrangements of TCR-ß genes are detected in most of the cases ([648]). Because these cases are also associated with widespread involvement of several organs, such as the spleen, liver, and bone marrow, the term *LGL leukemia* has been proposed ([646]).

In some studies, the predominant phenotype of the LGL is $CD57^{+}$ ($HNK\text{-}1^{+}$) $CD3^{+}$, and these patients often have rheumatoid arthritis, neutropenia, and splenomegaly; a combination resembling Felty syndrome ([649]). Anemia and thrombocytopenia are not uncommon, and serologically, rheumatoid factor, antinuclear antibodies, hypergammaglobulinemia, and immune complexes are detectable.

Two major subtypes have been distinguished in terms of clinical presentation and the phenotype of the cells ([650], [651] and [652]). The LGL in type A, also known as *T-LGL*, are $CD57^{+}/CD3^{+}/CD8^{+}/CD2^{+}$, and those in type B, also known as *NK-LGL*, are $CD56^{+}/CD3^{+}/CD8^{+}/CD2^{+}$. Patients with T-LGL often have neutropenia (84%), rheumatoid arthritis, and autoantibodies. However, these clinical and serologic findings in patients with T-LGL ($CD57^{+}$) could not be confirmed in other studies ([653]). The patients had clonal proliferations, as shown by TCR gene rearrangements, and the pathognomonic finding is neutropenia with an otherwise indolent course. NK-LGL leukemias are observed in younger patients and run an aggressive course ([654]). The most characteristic clinical presentation is hepatosplenomegaly and involvement of the gastrointestinal system with ascites. The course of the disease is acute, and often the patients die within 1 to 2 months after diagnosis.

NATURAL KILLER T CELLS

Natural killer T (NKT) cells have been identified as a novel lymphocyte lineage, which, in humans, express the cell-surface marker CD161 (NKR-PIA) (see Chapter 2), that is structurally related to several other proteins encoded by the NK-gene complex, including CD94, NKG2, CD69, and, in the mouse, Ly49 ([655]). These cells are specific for aGalCer presented by CD1d ([656]). They express V regions that are homologous to those that are expressed by mouse Va14i T cells and have a rearrangement of Va24 to Ja15, which forms the CDR3a that is highly similar to Va14i of mice.

The NKT cells in mice are characterized by the NK1.1 marker and undergo rearrangements involving Va14 and Ja18 (formerly Ja281) segments that always have a glycine residue at position 93. This generates an invariant Va14 receptor (V *a*14iTCP), which is used only by the NKT cells but not by T cells. The expression of an invariant TCR suggests that the selection is mediated by a monomorphic rather than polymorphic MHC molecule ([657]). Using CD1d/a-GalCer tetramers (see Chapter 3 for details on this technique), $Va14i^{+}$ cells could not be detected in athymic mice, indicating that maturation and selection of NKT cells take place in the thymus ([658]) and represent a separate T-cell lineage. In a striking difference from the selection of mainstream T cells (i.e., by thymus epithelial cells), the NKT cells are selected by DP $CD4^{+}/CD8^{+}$ thymocytes expressing CD1d ([659]). After selection, the Va14i precursor population is exported and acquires the NKT phenotype in the periphery ([660]). The distribution of the Va14i T cells in the periphery is unique. In mice, they migrate to the liver and from there to sites of inflammation responding to stimuli, such as chemokines and glycolipids.

The cells have a surface phenotype characteristic of recently activated or memory T cells, even when the cells are obtained from cord blood ([661]) or from germ-free mice ([662]). This is consistent with the postulated autoreactivity of the NKT cells *in vivo* and their peripheral expansion in the presence of autologous ligands, presented by CD1d.

Inhibitory receptors prevent unchecked autoreactivity for CD1d ([663]). The role for these NK receptors in directing the distribution and function of NKT cells in the body remains to be seen.

Natural Killer T-Cell Function

The cells with Va14 (in mice) or Va24 (in humans) TCR play a critical role in immune responses. Va14 cells are important for regulation of immune responses, inhibition of tumor development, and protection from autoimmune disease development. These cells have a cytolytic function ([664]) and rapidly induce cytokines after stimulation ([665]). In response to these cytokines, they recruit and activate other cells (i.e., NK cells, T cells, B cells, and macrophages).

In humans, $CD4^{+}$Va24i cells preferably produce IL-4, which is believed to regulate Th1/Th2 differentiation ([666], [667]), but the Th1 versus Th2 polarization is more complex and depends on additional factors such as the number of antigenic stimulations with a shift to Th2 after multiple challenges ([668], [669]).

Shift to Th2 cytokine secretion prevents the development of type I diabetes in mice with genetic predisposition ([670]), as well as allergic encephalomyelitis in another strain susceptible to the development of this disease ([671]). In experimental autoimmune diseases that develop spontaneously, there is a direct correlation between the development of the disease and the decline of Va14 cells ([672]).

Selective reduction of Va24 cells has also been shown in patients with systemic sclerosis ([673]), systemic lupus erythematosus, rheumatoid arthritis ([674]), and type I

diabetes ([675]).

NKT cells have been implicated in the prevention and metastasis of tumors in mice ([676]). However, tumor suppression is regulated by more than one subset of NKT cells secreting IL-13 ([677]). Ultraviolet irradiation induces immunosuppression and skin cancer, and the suppression can be transferred by CD1-restricted NKT cells, which act as suppressor cells ([678]). Others have also found that NKT cells are not critical in the IL-12–mediated rejection of tumors ([679]), and it appears that the conflicting results in the literature about the role of NKT in tumor responses are due to complex factors, including the types of tumors and their microenvironment, and other cells interacting with NKT cells and, not least, with the functionally different subsets of NKT cells ([680]). NKT cells have been implicated in protective immunity against several pathogens [i.e., mycobacteria ([681]) and malaria parasites ([682])].

In conclusion, NKT cells are phenotypically and functionally heterogeneous, endowed with cytolytic and cytokine secretion functions. They regulate several functions in the immune response that are related to host defenses against infections, autoimmunity, and tumor immunity. Their function seems to depend on their “age,” state of activation, regional microenvironments, and, of course, interaction with other cells. They have been called “nonconformist” and “unconventional” and probably for good reason, because they are suited to get involved in such a great variety of homeostatic disequilibrium conditions of the host.

Effector Mechanisms in Immunity

MAJOR HISTOCOMPATIBILITY COMPLEX

The function of the immune system is under genetic control ([1]). Immunogenetic studies and molecular genetic techniques have helped to elucidate the mechanisms by which genes regulate immune functions.

The genes that regulate immune functions are found in a chromosomal region known as the *major histocompatibility complex (MHC)*. This general term is applied to a group of loci that contain genes encoding the structure of molecules involved in transplantation reactions, thus the word *histocompatibility*. The designation *major* indicates that this locus is the most important of many defining histocompatibility.

The antigens that are defined by the MHC have been given specific names in different species, for example, human leukocyte antigens (HLA) in humans and histocompatibility-2 or H-2 in the mouse.

The HLA complex extends over approximately 4000 kilobases (kb) on the short arm of chromosome 6, precisely 6p21-3; the H-2 complex is located on chromosome 17 and occupies a segment that is halfway between the centromere and the telomere. Approximately 180 genes have been located within the HLA region, and the number increases constantly with the increase in the sensitivity and sophistication of techniques of molecular biology.

The complex is divided into three regions: (a) The class I region occupies the most distal (telomeric) end of the short arm of the chromosome and spans approximately 1.8 megabases (Mb); (b) the class II region (approximately 1 Mb) occupies the most centromeric end of the chromosome; and (c) the class III region is between the other two regions ([2]) (Fig. 18.1).

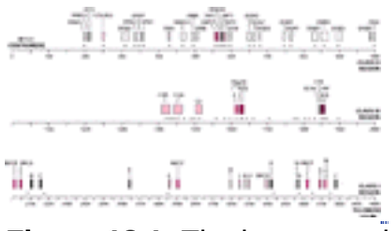

Figure 18.1. The human major histocompatibility complex contains genes that are grouped in three regions. Closest to the centromere is the class II region, followed by the class III region, and finally the class I region. Within the class II region are proteasome genes and TAP-1 and TAP-2 genes. The class II genes are located from the centromere in the order DP, DQ, and DR. The class III region contains genes of the complement system heat shock protein 70, tumor necrosis factor-a, and tumor necrosis factor-ß. The class I region contains the genes for the a-chain of the HLA-A, HLA-B, and HLA-C molecules and the genes that encode the newly discovered class Ib molecules, such as HLA-E, HLA-F, HLA-G, HLA-H. (Useful information was found in Campbell RD, Trowsdale J. Map of the human MHC. Immunol Today 1993;14:349–352; Beck S, et al. The complete sequence of human major histocompatibility complex. Nature 1999;401. Text hyperlink: Supplementary information.)

Class I Region

Of the polymorphic class I genes, HLA-A, HLA-B, and HLA-C, HLA-B is the most centromeric, and HLA-A is the most telomeric, with HLA-C in between and closest to HLA-B. There are several nonclassical class I or Ib genes that include HLA-E, HLA-F, HLA-G, HLA-H, HLA-I, HLA-J, HLA-K, and HLA-L, as well as several pseudogenes and gene fragments ([2], [3], [4] and [5]). Pseudogenes give products that do not associate with ß $_2$ microglobulin (ß $_2$m), probably as a result of deleterious mutations, and the gene fragments are not expressed, because the genes are severely disrupted.

The human MHC class I region spans 1.8 Mb from the MICB gene to the HLA-F gene at the telomeric end of the HLA region. There are 118 genes (73 known and 45 new genes) with one gene for every 15.2 kb. The G+C content on the average is 45.8% ([6]). It contains three classical HLA class I genes, HLA-A, HLA-B, and HLA-C; three nonclassical class I genes, HLA-E, HLA-F, and HLA-G; and two of the nonclassical MHC class I chain-related (MIC) genes MICA and MICB. The class I region also contains 50 non-HLA genes.

Many diseases (e.g., Behçet syndrome, ankylosing spondylitis, ulcerative colitis, Takayasu arteritis, Hashimoto thyroiditis) are associated with a particular class I allele. The large-scale genomic sequencing has greatly facilitated the clarification of gene organization and the identification, as well as mapping, of the disease-susceptible genes ([7]).

A total of 758 microsatellite repeats have been identified, consisting of two, three, four, or five nucleotides. They can be used as markers for mapping the exact location of the disease that is associated with the HLA genes.

Class I genes are composed of eight coding sequences or exons that are separated by noncoding sequences or introns ([8]). The eight exons correspond to the domains of the protein. The first exon encodes the hydrophobic N-terminal precursor or leader sequence; the second, third, and fourth exons encode the three extracellular domains. The fifth exon encodes the hydrophobic transmembrane segment and the basic residues that act as an anchor. The sixth and seventh exons are small, coding for the cytoplasmic domain of the molecule. The second and third exons are the most polymorphic, whereas the fourth exon is the most conserved ([9]).

Class II Region

The human class II molecules were defined originally by mixed lymphocyte cultures, and because participation of the products of class I, HLA-A, HLA-B, and HLA-C was excluded, the region for the new genes was called *D*. Later, serologic reagents obtained from multiparous women defined specificities related to HLA-D (DR). The D region is located on the centromeric (left) side of the HLA-B. Three subregions are recognized, DP, DQ, and DR, in a telomeric direction. The class II region has a 40% G+C content and has only one gene for every 25 kb, much lower in density than the class I (15.2/kb) or class III (14.3/kb).

Recombinant DNA technology has helped to reveal the three basic subregions, each with its own a and ß genes. The a gene is composed of five exons: (a) the signal sequence; (b) the a $_1$ domain, (c) the a $_2$ domain, (d) the transmembrane region and cytoplasmic tail, and (e) an untranslated 3' region. The ß gene consists of six exons.

By comparison with murine class II genes, considerable gene expansion has apparently taken place in the evolution of human MHC—that is, many more a and ß genes are in the human class II region ([10]). The DR molecule is homologous to the murine E molecule, and the human DQ molecule is homologous to the murine A molecule.

The genes encoding the a- and ß-chains of a class II molecule are designated as A and B, respectively. The DR contains one A gene, three B genes, and pseudogenes ([11]). The a-chain can associate with two different ß-chains to give two different molecules. In the DQ and DP subregions, only one set of genes (A and B) is expressed, and the genes in the other set are pseudogenes. Not all class II molecules that are encoded by these genes are polymorphic. For example, the DRa chain is not polymorphic, and the DPa shows only limited polymorphism.

Within the class II region, several genes encode proteins that are related to antigen processing. Two of them, LMP-2 and LMP-7 (large multifunctional protease), are subunits of the proteasome that cleaves peptides from antigens that are present in the cytoplasm to be transported and loaded on class I molecules ([12]).

Close to these genes are also the TAP-1 and TAP-2 genes (transporters associated with antigen presentation), which encode the proteins that transport the peptides from cytosol across the endoplasmic reticulum (ER) membrane to be loaded on class I ([13], [14]). The DR subregion has several haplotypes. In general, this subregion has multiple DRß genes and pseudogenes, which arise from duplication or recombination events, or both. The DRa gene is the most telomeric of all class II genes.

The DQ subregion has two pairs of DQ genes, but one of them is nonfunctional. The DP also has two pairs of genes, but only one is expressed, and the others are pseudogenes.

Within the class II region are the genes for the nonclassical molecules DMA and DMB which are distantly related to classical loci (approximately 30% amino acid identity) and must have duplicated from them at an early stage. There are no polymorphic variations in humans in the DM gene. The DN and DO genes, like DM, may play a role in peptide editing ([15]).

Other genes in the class II region are antigen-processing genes. They constitute a cluster of four genes. Two of them, TAP-1 and TAP-2, are adenosine triphosphate (ATP)–binding cassette (ABC) transporters (for structure and function, see the section Antigen Processing and Presentation). The proteasome genes, LMP-2 and LMP-7, are both members of the catalytic subunit of proteasome (see the section Antigen Processing and Presentation).

Class III Region

The class III genes encode proteins that do not participate in antigen presentation, such as the genes of certain components of the classical and alternative complement pathways (C4, C2, and B), as well as the genes of tumor necrosis factor (TNF)-a and TNF-ß, HSP-70, and the 21-hydroxylase–producing gene. Telomeric to the class III region is a group of genes that encode the proteins that are involved in inflammation or infection. One cluster consists of genes that encode the TNF-a, TNF-ß (LTA), and LTB cytokines, and several other genes, such as B144, which is expressed only on monocytes and macrophages; the I?B-like gene, which is related to I?B, which is a regulator protein for nuclear factor-?B (NF-?B). It has been proposed that this region should be named the *class IV region* ([16]).

The genes of class I and class II regions are present in multiple alleles or, in other words, alternate forms that are defined by distinct DNA sequences. The combination of all HLA-I and HLA-II alleles is known as the *haplotype*. Because the HLA genes are expressed codominantly, each individual therefore inherits two haplotypes. Each class I locus has several alleles, and, according to an adopted nomenclature, each allele is defined by its locus, an asterisk, and a four-digit number. The number that defines the allele relates to the serologically defined antigen that is detected on a molecule that is synthesized by the allele (first two digits) and allows discrimination between closely related alleles (last two digits). For example, the B27 locus has at least seven identifiable alleles, which are defined as HLA-B*2701 through HLA-B*2707.

The HLA antigens are serologically recognized epitopes on molecules that are synthesized by the alleles; for example, the B27 determinant is present on all seven different products of the seven B27 alleles.

MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULES: CLASSICAL

Class I Molecules

Class I molecules include those that are traditionally detected by serologic reagents that are encoded by the MHC genes HLA-A, HLA-B, and HLA-C. More recently, another group of molecules that are structurally homologous to the class I molecules (44 to 82%) has been detected. These molecules are known as *class Ib* ([17]) to distinguish them from the classical class I molecules that are now sometimes called *class Ia*. Some of the class Ib molecules are encoded by MHC-linked genes, such as HLA-E, HLA-F, and HLA-G, whereas others, such as CD1, the low-affinity immunoglobulin (Ig) G Fc receptor of murine neonatal intestine, the zinc-a $_2$ globulin, and certain CTMV genes, are encoded by non-MHC genes. In our discussion, the traditional molecules are identified as *class I*, and the new members are identified as *class Ib*.

The class I molecule is a heterodimer that consists of an H chain or an a-chain (44 kd) and a noncovalently associated light (L) chain (12 kd) that is known as ß $_2$*m* ([18]) (Fig. 18.2).The ß $_2$m gene is not linked to MHC and is located on chromosome 15.

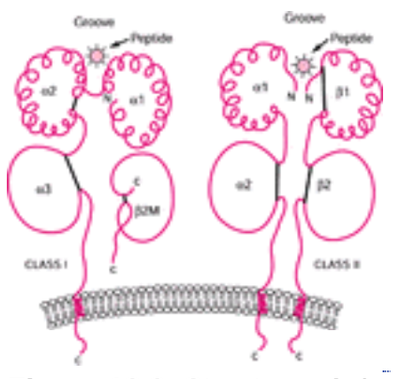

Figure 18.2. Structure of class I and class II major histocompatibility complex molecules. The class I molecule is a heterodimer of a heavy chain or a-chain and a noncovalently associated light chain, ß $_2$ microglob-ulin (ß $_2$m). The a-chain consists of three domains: the N-terminal a $_1$, followed by a $_2$ and an immunoglobulin-like a $_3$ domain. The a $_1$ and a $_2$ domains are polymorphic and form a groove, which accepts a peptide from foreign antigens to be presented to T cells (see the chapter text). The membrane proximal domain is nonpolymorphic. The ß $_2$m protein is homologous to the C $_H$3 immunoglobulin domain. It is located underneath the a $_1$ domain. The class II molecule is a heterodimer of two chains, a and ß. Each consists of an N-terminal polymorphic domain that forms the peptide groove. The membrane proximal domains are nonpolymorphic.

The a-chain is divided into three extracellular domains, a $_1$, a $_2$, and a $_3$. Except for the domain that is most distal to the membrane (a $_1$), the other two consist of a loop that is formed by a disulfide bond. The transmembrane portion consists of hydrophobic residues and terminates in five amino acids, including three arginines (Args) and one lysine (Lys) that anchor the molecule to the membrane. There is extensive homology between human and mouse MHC molecules (70 to 75%). Variability within the products of allelic genes of the MHC is much greater than it is between the products of other allelic eukaryotic genes, which usually differ only by one amino acid. The variable residues are clustered in seven sequences ([19]), three of which are in the a $_1$ domain and four of which are in the a $_2$ domain. The a $_3$ domain is highly conserved. Amino acids 223, 227, and 229 in the a $_3$ domain are critical for interaction with CD8 ([20]). The extensive antigenic polymorphism that is identified in class I molecules is the result of a combination of many variable positions, each one of which has a low degree of variability.

The H chain is glycosylated in the Golgi apparatus, with the carbohydrate moiety consisting of neutral sugars, galactosamine, and sialic acid.

The L chain, ß $_2$m, was first isolated from human urine and migrates in the ß $_2$ region by electrophoresis. The structure of ß $_2$m is highly conserved, consisting of one Ig domain with one disulfide bond. It has a high degree of homology between species and minimal allelic variation. It is homologous to the C $_H$3 domain of human Ig and to the a $_3$ domain of the class I molecule to which it is associated noncovalently.

The L chain plays an important role in the transport of the a-chain, because cells that are derived from patients with Burkitt lymphoma, who are unable to synthesize the ß $_2$m, do not express HLA antigens. On the basis of results from *in vitro* biosynthetic studies, it appears that the a-chain is associated with ß $_2$m within minutes after its completion. All three extracellular domains of the a-chain are in contact with ß $_2$m ([21]). The majority of these features have been conserved in the class I-b molecules.

ß $_2$m is present on all cells, and small amounts are shed into body fluids. Because of its low molecular weight, it is filtered out rapidly by the glomeruli, but it is reabsorbed from the kidney tubules and then catabolized. In patients with kidney diseases in whom tubular function is impaired, increased amounts of ß $_2$m are detected in the urine. It is also found in increased quantities in the serum and in other fluids from individuals with certain malignancies, such as lymphomas and

myelomas.

The most significant homology exists between the a $_3$ domain and the constant Ig region.

The crystallographic structure of HLA class I markedly helped the understanding of the function of the molecule ([22]). ß $_2$m and the a $_3$ domain form the base that supports the a $_1$ and a $_2$ domains. Each of the a $_1$ and a $_2$ domains consist of four antiparallel ß strands and one a helix. This structure is similar to that of the class II molecule shown in Figure 18.3. Seeing them from the top, the way the T-cell receptor (TCR) does, the juxtaposition of the two domains isolates a longitudinal *cavity*, which is commonly known as *the groove*, which is 30 Å long and 12 Å wide in the middle. Its floor consists of the ß pleated sheets of the a $_1$ and a $_2$ domains ("intramolecular dimer"), and the sidewalls are two a helices, one each from the a1 and a2 domains. The MHC I groove tapers at both ends to a width of approximately 5 Å and then is blocked completely by bulky amino acid side chains (Tyr84, Trp167), which are conserved in virtually all class I MHCs ([21]). It is lined by a series of pockets (A to F), which are sites of interaction with the peptide.

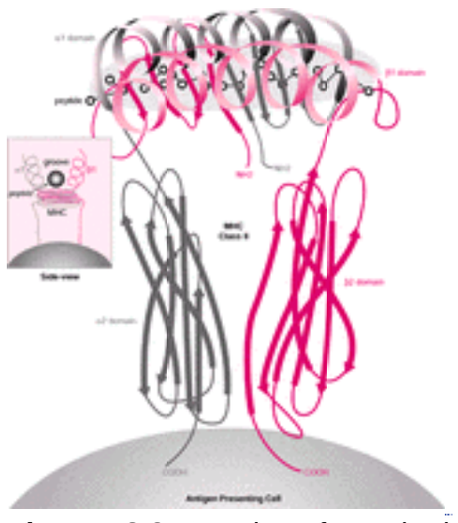

Figure 18.3. Drawing of a major histocompatibility complex (MHC) class II molecule–peptide complex. The MCH class II molecule forms a groove with walls that are made by a helices from the a $_1$ and ß $_1$ domains and a floor by ß pleated sheets that is formed by antiparallel ß strands from each chain. The peptide is usually long (15 to 25 residues) and projects out of both ends, which are not closed (as with MHC class I molecules).

The polymorphism of the class I molecule is particularly concentrated in the groove ([23]), and yet certain residues are strongly conserved among virtually all class I molecules. These residues surround, on the left and right ends of the groove, the first and last pockets (A and F), which bind the N-terminus and C-terminus of the peptide, respectively. The other pockets line the central portion of the groove and are also involved in peptide binding ([24]). Many of the MHC side chains that contribute to the formation of the pockets are polymorphic, and, as a result, the architecture of the pockets varies among the class I molecules. In some molecules, a bulky side chain may block a pocket that is open in another molecule. In other molecules, a smaller polymorphic amino acid may extend the size of the pocket ([25]). The binding pocket for the C-terminal peptide side chain appears to be the most universal of the primary class I side pockets. This may explain the fact that there are sequence restrictions on the final residue of the peptides ([26]). A given groove can bind hundreds or even thousands of different peptides, which are identical or homologous at only a few side chain positions ([26] , [27]). Side chains from the MHC residues protrude into the groove from the a helices and the ß sheet and form an irregular surface along the length of the groove, so that side pockets extend out from the main cavity ([28]).

A class I molecule usually accommodates within the groove peptides that are nine amino acids long and that bind with an affinity that is 100- to 1000-fold higher than longer or shorter peptides. The binding of the peptides is mediated by certain amino acids that are known as *anchor residues* (sequence-dependent binding). The set of anchor residues that bind to a certain MHC molecule is known as a *sequence motif*. It allows the identification of peptides within a complex immunogen that are likely to bind to class I MHC. Hydrogen bonds between the peptide and conserved MHCI side chains provide stability to the peptide binding, which is sequence independent ([29]). A prominent kink or arch is found approximately one-third of the way from the N-terminus that lifts the peptide up, away from the main floor.

The arch that is formed by the peptide contributes to the antigenic specificity of the complex, despite the fact that 73 to 83% of the peptide surface is buried by the MHC in the complex. A number of side chains that do not affect the binding of the peptide to the MHC contribute strikingly to the TCR binding (flag side chains) ([30] , [31]). Antigenic specificity is provided not only by the flag side chains, but also by the conformational flexibility of the peptide. Peptides that differ in length are usually accommodated by buckling at the center of the cleft, and even peptides of the same length adopt strikingly different conformations ([32]).

In many different peptides, the flag side chains are prominently exposed at the surface of the complex and provide TCR with a direct access to the antigenic identity of the bound peptide ([30]). The upward-pointing orientation of flag side chains, such as P1 and P4, is conserved in many different HLA-A2–peptide complexes. Some peptides are sandwiched between the MHC and the TCR and make contact with both molecules.

In conclusion, the requirements to satisfy the vast and exquisite specificity of the TCR are provided by the peptide-MHC complex, which is formed with only a small number of nonvariable MHC molecules. To the peptide-MHC complex formation, the peptide binding is contributed by sequence-dependent binding and is supplemented by sequence-independent interactions of the primary anchor side chains in specific MHC pockets. These interactions, although constraining the conformation of class I–bound peptides at both ends, leave the center relatively free to adopt a conformation that optimizes the secondary anchor and other interactions with the MHC molecule. The MHC molecule is a remarkable tool with which evolution has achieved so much by so little.

Class II Molecules

The second group of MHC genes, the class II genes, encode glycoproteins that regulate cell interactions in the immune response. The genes reside in the D region of the MHC in humans and in the I region of the MHC in the mouse. The class II proteins are also referred to as *Ia antigens* (immune response antigens). They are not as widely distributed as the class I molecules. They are found in high concentrations on B lymphocytes and on a subpopulation of macrophages, as well as on dendritic cells (DCs). On T cells, small quantities are detectable under conditions that are associated with T-cell activation *in vitro* ([33]) or during the course of certain diseases ([34]). However, human T cells may acquire Ia antigens from other cells ([35]), and, with murine T lymphocytes, Ia antigens are passively acquired from macrophages ([36]). A variety of cell types respond to interferon (IFN)-? and express Ia antigens, including vascular endothelial cells ([37]), melanoma cells ([38]), and brain astrocytes.

The human class II molecule is a heterodimer of two noncovalently linked proteins, an a-chain (34 kd) and a ß-chain (29 kd) ([39]). Each chain can be divided into four domains, two of which form the extracellular region in each chain, and the third and fourth correspond to the transmembrane segment and the intracellular part of the chain, respectively. With the exception of the a $_1$ domain, the other three domains (a $_2$, ß $_1$, and ß $_2$) are loops that are formed by disulfide bonds. The two domains that are most proximal to the cell membrane (a $_2$ and ß $_2$) are homologous to the Ig constant domain. All a-chains and ß-chains in humans are homologous, sharing between 60 and 70% of their respective amino acid sequences. Between different loci, the amino acid differences are distributed randomly in the ß-chains ([40]). The human DR, DQ, and DP ß-chains and DQ a-chains are polymorphic, and only the DR a-chains and DP a-chains seem to be invariant.

The assembly and expression of class II molecules involves a third chain that is known as *invariant (I)* (CD74) ([41]), which is encoded by a gene on chromosome 5. Complementary DNA clones have been isolated, and the amino acid sequence indicates that the I chain is a type II transmembrane protein—that is, the N-terminal is inside the cell. When synthesized in the absence of MHC class II molecules, the invariant chain exists as a trimer or even as a hexamer ([42]). The complex of the I chain with the class II a- and ß-chains is a nonamer that consists of a core of three I chains, each one associated with an a and ß class II dimer ([43]).

The mechanism of binding the I chain to the a/ß dimer is not completely known. However, a peptide from the N-terminal two-thirds of the I chain, which is known as

class II–associated invariant chain peptide (CLIP), inhibits the binding of the antigenic peptides to the class II molecule ([44]). The assembly of the class II–invariant chain complex occurs in the ER. Class II a/ß dimers that are formed in the absence of the invariant chain are poorly expressed on the cell surface and remain in the ER, as they cannot maintain their normal folded structure. In the assembly of multimeric proteins, certain ER-associated proteins stabilize the partially folded subunits, thus preventing aggregation. These proteins are known as *chaperons* ([45], [46]). HLA-DR chains bind during their synthesis to ER resident proteins GRP94 and ERp72 but, in the absence of the I chain, remain bound to these ER chaperons for prolonged periods of time ([47]) (see the details for the I chain: CD74, Chapter 2).

Another ER resident protein that associates with class II chains is calnexin ([48]). The class II molecule is transported to the Golgi apparatus and enters the endosomal-lysosomal system, where it is loaded with an antigenic peptide on its way to cell surface expression ([49]) (see Processing Antigen for Class II Presentation).

The polymorphism of the class II molecule is localized in the a $_1$ and ß $_1$ domains. HLA-DR, HLA-DQ, and HLA-DP have three hypervariable regions in their ß $_1$ domains, whereas the a $_1$ domain of HLA-DQ has only one hypervariable region ([50]). The CD4 molecule interacts with amino acids 134 to 148 of the ß $_2$ domain ([51], [52]).

The crystallographic structure of the HLA-DR1 molecule reveals similarities with the structure of the HLA class I molecule ([53], [54]). The a $_1$ and ß $_1$ domains form the peptide-binding groove (Fig. 18.3). As with the class I molecule, the floor is the ß pleated sheet, and the walls are the a helices from the a and ß chains. The first two hypervariable regions are found on the floor, whereas the third hypervariable region is on the a helix of the ß chain. The class II groove can accommodate longer peptides (10 to 25 residues), because, in contrast to the class I groove, it is open on both ends ([55]). Long peptides, which range from 15 to 25 residues, can bind in an extended conformation, projecting out of both ends of the groove. This contrasts with class I peptide binding, in which mostly nonamers bind with extended, but kinked, conformations, and the N- and C-termini of the peptides are bound to groove pockets. In class I molecules, the residues at the end of the groove are conserved, imposing a tight binding for the peptides, but, in the class II molecules, conserved residues are located at different intervals along the groove, making the peptide-binding side chain independent. Even the strictest pocket in class II accommodates a variety of hydrophobic and aromatic side chains. The peptides in class II bind through the central region, and their N- and C-terminal ends protrude from the open ends of the groove ([54]). The reasons for these differences between class I and class II are not known.

The evidence from the crystallographic studies indicates that the class II molecules exist as tetramers on the cell surface ([53], [56]). The TCR may also exist as a dimer of dimers on the T-cell surface ([57]). Therefore, the geometry of the TCR-MHC peptide interaction places the complementarity-determining region (CDR) 3 loops of the Va and Vß chains of TCR in contact correspondingly with the N- and C-terminal ends of the peptide, whereas the CDR1 and CDR2 loops are in contact with the ß $_1$ and a $_1$ domains. Dimerization of soluble class I molecules that are loaded with a specific peptide is also required for T-cell activation ([58]). Ligand-induced dimerization of receptors is a general feature for cell activation and involves most of the known receptors.

MAJOR HISTOCOMPATIBILITY COMPLEX MOLECULES: NONCLASSICAL

Class I: HLA-E, HLA-F, and HLA-G

The nonclassical class I HLA molecules are HLA-E, HLA-F, and HLA-G. These molecules are also known as *class Ib*, to distinguish them from class Ia (HLA-A, HLA-B, and HLA-C). They constitute one group of the class Ib molecules, the other being the CD1 molecules, a non-MHC linked group with genes that are located in chromosome 1. The nonclassical class I HLA molecules show limited polymorphism, and their tissue expression is low, but they play a significant role as molecules of antigen recognition ([59]). They all form heterodimers with ß $_2$m. They have conserved the key residues that interact with CD8.

HLA-E The structure of HLA-E is similar that of to class Ia molecules ([60]). The sites for ß $_2$ and CD8 interaction are conserved. The size of the HLA-E groove is structurally similar to that of the classical molecules, but it is highly hydrophobic to accommodate the leader peptides, which are profoundly hydrophobic. Changes in crucial positions within the groove with certain residues determine the peptide preference, such as tryptophan (Trp) at position 97 instead of Asn or Arg in class Ia molecules and phenylalanine at position 116, so that the C-terminal half of the peptide can interact. Peptides occupy all the pockets in HLA-E, and these interactions keep the peptide tightly bound with some additional help from hydrogen bonds along the length of the groove. The secure fastening of the peptides reinforces the favorable selection of a specific peptide (60a). HLA-E binds nonamer peptides from the leader peptides of most but not all class Ia alleles, which facilitate the expression of the molecule on the cell surface ([61]). Peptides with alterations in any position of the canonical peptide drastically reduce the binding and, as a result, the HLA-E expression. The leader peptides of class Ia HLA molecules enter the cytosol after they are cleaved from the coding sequence and are then transported to the inside of the ER by the TAP transporter, to be loaded on to HLA-E ([62]). Detection of HLA-E on the cell surface of CD56 $^+$CD16 $^+$ natural killer (NK) cells can be achieved accurately with HLA-E tetramers ([63]) (further information regarding HLA-tetramers can be found in Chapter 3). The tetramers react with the CD94/NKG2A receptors, and HLA-E is a major ligand for this inhibitory receptor on NK cells ([64]) (Chapter 17). Recognition of HLA-E by this receptor inhibits activation of NK cells and thus protects cells from being killed by the cytotoxic NK cells ([65]). Because HLA-E is expressed with the leader peptides of MHC class I molecules, its presence on the cell surface sends signals to surveilling NK cells that there is no “missing self,” that is, an absence of MHC class I molecules, and thus protects cells from being killed by NK cells. Rare CD8 $^+$ T cells have been detected that bind HLA-E directly through the TCR ([66]). Subversion of the protective mechanism that is conferred by HLA-E has been demonstrated with the cytomegalovirus (CTMV). The leader peptide of the CTMV glycoprotein gpUL40 is the same as the class Ia leader peptides, and, as a result, it binds to HLA-E ([67]). Although CTMV down-regulates MHC class I expression on infected cells, thus rendering them susceptible to lysis by NK cells (“missing self,” Chapter 17), it concomitantly up-regulates HLA-E, thus inhibiting lysis. This mechanism represents an escape route for CMTV. Another example of subversion of HLA-E function is the binding of heat shock protein (HSP)-60 signal peptide ([68]). HSP-60 is present in all normal cells and in eukaryotic cells. It serves as a mitochondrial chaperon. Stress stimuli, such as heat, nutrient deprivation, toxic chemicals, and inflammation, up-regulate HSP-60. Binding of the HSP-60 signal peptide to HLA-E results in loss of its recognition by the CD94/NKG2A receptor and renders stressed cells susceptible to NK cell lysis.
HLA-F The structure of HLA-F is not known in great detail, but some predictions have been made based on the known structure of HLA-E and the sequence analysis of HLA-F ([59]). HLA-F tetramers stain monocytes and bind to Ig-like transcript (ILT)-2 and ILT-4 ([63], [69]). ILT molecules, also known as *leukocyte Ig-like receptors*, are structurally and functionally related. They recognize HLA class I allotypes, rather than individual peptide-MHC complexes, and are expressed on monocytes, macrophages, and DCs. HLA-F is retained intracellularly, empty, but reaches cell surface after acquisition of its ligand ([70]).
HLA-G HLA-G shows limited polymorphism, restricted tissue distribution, and low levels of expression and therefore belongs to the nonclassical MHC molecules. In the HLA-G gene, all of the regulatory elements of HLA class I genes are missing, thus suggesting that its expression and distribution is uniquely regulated ([71]). HLA-G is expressed strongly in extravillous cytotrophoblast, endothelial cells of fetal vessels, and in other tissues, such as the thymus. It is not detected in syncytiotrophoblast. Messenger RNA (mRNA) of HLA-G is detected in peripheral blood T and B cells, keratinocytes, fetal liver, and other cells ([72]). Tetrameric complexes of HLA-G bind to monocytes, especially the CD16 $^+$ subpopulation, and react with ILT-2 and ILT-4 receptors, but they do not bind T, B, or NK cells ([63], [73]). The HLA-G gene transcribes six different transcriptional isoforms, membrane bound and soluble forms ([72]). The complete transmembrane isoform HLA-G1 consists of three extracellular domains, whereas isoforms HLA-G2, HLA-G3, and HLA-G4 have one or two domains. HLA-G1 and HLA-G2 exist in soluble form. The HLA-G molecule binds peptides that have primary anchors in positions 2, 3, and 9. The peptide-binding pocket residues determine the specificity of the molecule. The isoforms HLA-G2 and HLA-G3 lack the a $_2$ domain and, as a result, do not bind peptides. They also do not bind the CD8 molecule and are therefore unable to present peptides. The HLA-G molecule has an antigen-presenting potential, but, because of the limited diversity of the peptides and its low polymorphism, the function of the molecule is rather restricted. However, it may still be sufficient, considering the limited species of viruses that infect the placenta ([72]). Other than antigen-presenting functions, HLA-G may be more important for its role during pregnancy. HLA-G exerts inhibitory functions by several mechanisms. First, it directly binds to CD94/NKG2A, which is an inhibitory receptor ([74], [75], [76] and [77]); second, it binds to receptor KIR2DL4 on all NK cells that inhibit lysis of cells that express HLA-G ([78]); third, the leader peptide of HLA-G binds to HLA-E, which interacts with the inhibitory receptor CD94/NKG2A. These inhibitory mechanisms are important for the protection of the fetus, because HLA-G is strongly expressed in the placenta.

Class II: HLA-DM and HLA-DO

HLA-DM There are two nonclassical class II proteins with their genes within the class II region. For HLA-DM, there are two genes, DMA and DMB, on the centromeric site of TAP and LMP genes. DMA and DMB encode the a- and ß-chains of the DM molecule ([79]), which is detected in all class II expressing cells and is up-regulated by IFN-?, together with classical class II molecules. Class II molecules associate with the invariant (Ii) chain after they enter the ER and form nonameric complexes (aßIi) $_3$. Through the CLIP, the Ii chain prevents class II molecules from binding peptides within the ER (see details in the following discussion). The heterodimer DM

is formed in the ER, and, by the time class II molecules pass through the endosomal system on the way to the cell surface, the DM protein has already arrived there by a multivesicular system that is known as the *MHC class II compartment (MIIC)*. It is retained in MIIC by a tyrosine (Tyr)-based targeting motif (YTPL) that is located in the cytoplasmic tail of the ß-chain. DM transiently binds directly to the HLA class II–CLIP complex ([80]) and induces the release of CLIP, whereas DM remains associated with the class II molecule until the peptide to be loaded has been found and is safely in place within the groove ([81]). DM rescues empty HLA-II molecules from denaturation and loss of their peptide-binding capacity. Both HLA-II and DM are in an “acidic” environment, and conformational changes of both molecules seem to facilitate their interaction ([82]). Another important function of the DM molecule after the removal of CLIP and maintenance of an intact three-dimensional structure of the class II molecule is the *editing* of peptide loading. *Editing* implies a selection, from a variety of available peptides, of a *good* peptide, which is defined by the stability of its interactions within the groove ([83]). Intrinsic stability is determined by multiple hydrogen bonds between the peptide backbone and the conserved residues of the binding groove and by the anchor side chains and the specificity pockets ([84]). The mechanism of the ultimate release of DM from HLA-II is not clear. It appears that DM binds more stably to an empty HLA-II than to one that contains a peptide ([85]).

HLA-DO The genes that encode the a- and ß-chains of the DO molecule are similar to the class II genes. The DO proteins have a more restricted distribution and are detected in B cells, DCs, a melanoma cell line, and cortical and medullary epithelial cells in the thymus ([86]). On completion of its synthesis, DO associates with DM, and the tetramer is transported mainly to lysosomes in which most of it is localized ([87] , [88]). The lysosomes that contain DO also contain class II molecules. Loading of peptides to class II is slower in the presence of DMDO tetramers, thus suggesting that DO is a negative regulator of DM function ([89]), and overexpression of DO results in accumulation of MHC class II–CLIP complexes at the cell surface. The regulation of peptide presentation by DO limits only one of the mechanisms of antigen uptake—that is, by free fluid phase—whereas membrane Ig-mediated uptake is augmented ([90]).

Major Histocompatibility Complex Class I Chain-Related Genes and Proteins

A distinct family of genes, the last and final to be detected within the MHC class I region, is known as *MIC* ([91]). MICC, MICD, and MICE are in close proximity to HLA-E, HLA-A, and HLA-F, respectively. MICE and MICG are between HLA-G and HLA-F, and MICF is centromeric to HLA-G. MICC, MICE, MICF, and MICG are pseudogenes. MICA and MICB are unusually large genes (11 to 13 kb) compared to an average of 3.5 kb for HLA-A to HLA-G genes. However, their overall genomic structure parallels those of the other MHC genes and of the Ig superfamily genes in general, in which distinct functional domains are encoded by separate exons. The crystal structure of MICA shows that the molecule has a general configuration of a class I molecule—that is, a membrane that is proximal to the Ig-like C-type domain—with the a_3 domain and the two a_1 and a_2 distal domains forming together an eight-stranded antiparallel ß pleated sheet that is bordered at the edges by two a helices ([92]). The groove is less spacious than that of class Ia molecules—10 Å within the first four ß strands and 7Å across the second four ß strands (compared to >18Å of classical MHC I and 14.4 Å for CD1). This agrees with the inability to detect MICA-associated peptides previously ([93]). The most striking finding is that the groove is oriented down toward the membrane ([94]), so that the whole molecule appears like a wilting flower ([95]).

Another major difference from other MHC molecules is the lack of $ß_2m$ binding due to restructuring of the interface of binding, which ablates the interaction ([92]).

The surprising findings about the structure of these proteins were matched by equally surprising findings about their function. The MIC proteins are recognized by the ?d T cell, especially the Vd1 cell, but not by the aß T cells ([93] , [96]).

In addition, MICA is the ligand for NKG2D activating receptor of NK and ?d T cells, triggering cytolytic responses against epithelial tumors that express MICA ([97]). NKG2D is the most common NK cell receptor that is known, but it may require a synergistic action by a TCR ([98]).

The polymorphic residues are concentrated in the a_2 domain ([92]), which apparently is reoriented after binding with the ligand NKG2D ([99]). This ligand-induced repositioning of the MICA molecule brings the a_1-a_2 platform with the same polymorphic residues in contact with the NKG2D receptor. This receptor-induced conformational change is probably facilitated by the coil of the a_1 to a_3 domains.

A number of disease associations have been detected with MIC alleles, such as ankylosing spondylitis, Behçet syndrome, psoriasis vulgaris, and Kawasaki disease.

In summary, the MICA and MICB polymorphic HLA-like molecules present several unresolved enigmas. Their distribution is relatively restricted to epithelial and endothelial tissues (not on T or B cells), and their expression is associated with some form of stress ([100] , [101]). In spite of their polymorphism, they are recognized by ?d T cells in a genetically unrestricted manner. Their groove under normal conditions is unavailable for binding owing to their disorganized structure. However, conformational changes are induced on interaction with a receptor. New surprises await further research into their structure and function.

CD1 System: Genes and Proteins

One of the first monoclonal antibodies, which was made after the discovery of hybridoma technology by Milstein et al. ([102]), was specific for a protein that later was given the first number, CD1, when the CD nomenclature was introduced at the First International Workshop on Human Leukocyte Differentiation Antigens, which was held in Paris in 1982.

The CD1 family consists of four proteins, CD1a, CD1b, CD1c, and CD1d, which are encoded by genes CD1A, CD1B, CD1C, CD1D, and a fifth gene, CD1E, which is not transcribed. The genes are located on chromosome 1q22-23, and the proteins that they encode have significant homology to MHC class I and II proteins. They are divided into group 1, which contains CD1a, CD1b, CD1c, and CD1e, and group 2, which contains CD1d.

Group 1 genes do not exist in mice and rats. This is interpreted as an indication that pathogens that usually select and maintain genes with a defense function are not pathogens anymore for these species. CD1 molecules represent an ancient family of antigen-presenting molecules. The fact that CD1 molecules are homologous to the MHC molecules suggests that both evolved from a common ancestor with the subsequent diversification into the two main CD1 lineages or groups. CD1 consists of three extracellular domains, a_1, a_2, and a_3. The a_1 domain has minimal, if any, homology to MHC I, whereas with the other two, homology is approximately 35%, which is still far below the average of 70% between different class I proteins.

All CD1 proteins are transmembrane and associate with $ß_2m$. $ß_2m$ is necessary for folding and membrane expression ([103]). The crystal structure of mouse CD1d1 shows a remarkable similarity in overall shape to MHC class I proteins ([104]). The a_1 and a_2 domains form a groove with ß pleated sheets. The groove is different from that of the MHC molecules, with three channels, A, C and F', and a distinct tunnel, which is designated T'.

Another difference between CD1 and MHC is that the CD1 groove is formed by hydrophobic residues, so it is unlikely to form hydrogen bonds with the peptide. It is also closed at both ends and is covered for much of its length.

A complex of CD1b with ligands has been crystallized, and its structure has been solved ([105]). The total volume of the groove (220 $Å^3$) is filled with hydrocarbons. Two alkyl groups are necessary for stable ligand binding, and the four interconnected channels are occupied by the alkyl groups. Mycobacterial mycolates, which play a crucial role for the survival of mycobacteria in the intracellular environment, have been the first characterized ligands for CD1b ([106]) and are large molecules. Lipids with three alkyl groups, such as triacylglycerols that are found in atherosclerotic plaques, are presented by CD1, are expressed on macro-phages of the atherosclerotic lesions, and activate T cells ([107] , [108]). The role of this mechanism in the formation and evolution of such lesions remains to be determined.

UL-16 Binding Proteins: The Latest Member of the Major Histocompatibility Complex Family

The UL-16 binding proteins (ULBPs) are novel class I–related surface proteins. Their identification was based on their ability to bind the UL-16 glycoprotein of the human CTMV ([109]). The ULBP family has three members, ULBP-1, ULBP-2, and ULBP-3. The ULBP genes are located on chromosome 6q25 and not within the MHC complex. However, sequence alignments show clearly that the ULBPs belong to the MHC class I family. The ULBP proteins are glycosyl phosphatidyl inositol (GPI)–linked, do not have the a_3 domain of class I MHC, and do not associate with $ß_2m$. Expression of ULBPs or the MICs on target cells confers susceptibility to NK cell killing. The ULBP transduces signals that override the negative signal that is generated by an inhibitory receptor. ULBP messages are expressed by a variety of cells, tissues, and tumors. The ULBPs are ligands for the homodimeric NKG2D C-type lectin receptor ([110] , [111]), which is expressed not only on NK cells, but also on T cells and activated macrophages ([112] , [113]). The cytoplasmic domain of NKG2D is short, and, as a result, signaling is delivered by the DAP-10 adaptor protein that is

associated with NKG2D (Chapter 17). DAP-10 binds to the p85 subunit of phosphoinositide 3-kinase (PI3K) and adaptor Grb2, transmitting downstream signals from NKG2D through Janus kinase 2 and Akt activation pathways ([111]). NKG2D delivers co-stimulatory signals to T cells ([114]), stimulates proliferation, and induces increased production of cytokines and other activation-associated molecules ([110]). UL-16 mediates an additional evasive function of the human CTMV by inhibiting MICB expression, because it binds directly to MICB, causing its intracellular retention ([115]).

ORIGINS OF MAJOR HISTOCOMPATIBILITY COMPLEX

The human MHC is close to 4 Mb long with approximately 180 to 200 genes, which traditionally have been divided to three regions—starting from the centromere to telomere, class II, class III, and class I. During evolution, genetic events, such as insertions, duplications, deletions, inversions, conversions, and translocations, have introduced modifications, but the conserved genes have escaped identification with ancestral chromosomal regions. Genes that arose within a species by duplication are termed *paralogous genes*, and the chromosomal segment that contains the duplicated genes is termed the *paralog-ous region*. In the late 1990s, it was realized that three other chromosomes, 1, 9, and 19, have genes that are organized in the same manner as MHC ([116], [117]).

Some genes, such as NOTCH and PBX, are represented in all four chromosomal paralogous regions, whereas others are only represented in two or three. Two hypotheses have been proposed for the explanation of these observations: (a) All four paralogous regions arose from large-scale chromosomal duplication ([118], [119]), and (b) the paralogous regions arose from independent duplications of genes, which were brought into proximity by selective forces (the *functional clustering* hypothesis) ([120]). It is possible that chromosomal duplication may have played a primary role, and functional clustering may only have played a minor one.

The hypothesis proposes that the “block duplication” that generated the four paralogous regions had taken place before the emergence of jawed vertebrates. Because all vertebrates have four paralogous regions, the duplication from one ancestral region must have occurred twice. It is postulated that the first occurred before the emergence of jawless fishes, which have two paralogous groups, and the second occurred before the emergence of jawed vertebrates. In the vertebrates, the gene order within each region is poorly conserved, probably as a result of structural rearrangements over the past 500 million years since the second duplication. The hypothesis of “block duplication” draws severe criticism from others who have data from phylogenetic analyses of individual gene families that are considered to be inconsistent with “block duplication” ([121]). Comparison between class I and class II genes between mouse and man shows that, although the genes of class II subregions in the mouse, A and E, are orthologous to the corresponding human class II subregions DQ and DR, the class I genes between human (primate) and mouse (rodent) are not orthologous.

Class Ia genes cluster with class Ib genes but have risen independently by gene duplication from classical genes.

Furthermore, the polymorphism of MHC molecules is localized within the peptide-binding region. Within this region, the number of nonsynonymous nucleotide substitutions (amino acid altering) far exceed the synonymous, whereas the opposite is true with the rest of the molecule. Because the synonymous substitutions are almost neutral, it becomes evident that polymorphism is supported by a form of natural selection, which favors peptide-binding region diversity. Other genomic evidence from the *Xenopus laevis* (frog) indicates that, in this amphibian, there are class I, II, and III genes, which are linked ([122]). Similarly, in cartilaginous fish (sharks), the most primitive organisms with MHC, the gene structures and sequence variations are impressively similar to humans. Sharks also share with humans the MHC class I and class II linkage ([123]) that is common to all amphibian, bird, and mammalian species ([124]). The proposed primordial MHC (proto-MHC) consists of the linkage group class I–LMP-2–LMP-7–TAP-2–RING-3–RXRB–class I and several genes that are involved in the preparation of class I presentation, that is, LMP-2 and LMP-7 (for proteasome) and TAP-2 for peptide transporter. It is likely that, with further genomic sequencing analyses and phylogenetic tree analyses, the nature and composition of proto-MHC will be determined.

For many years, the HLA haplotype has been considered to be the most important genetic marker of susceptibility to many diseases. It has been found that the strongest disease associations are with alleles at multiple loci rather than with individual alleles. The expression of alleles from multiple loci has been called the *ancestral haplotype (AH)*. AHs are conserved genomic sequences that are separated by recombination hotspots. For example, the 8.1 AHs (A1, CW7, B8, CHAQ0, DR3, and DQ2) are associated with multiple immunologic diseases ([125], [126]). No single gene predisposes to all diseases, but different regions of 8.1 AH are associated with diseases, such as insulin-dependent diabetes, systemic lupus erythematosus (SLE), gluten sensitive enteropathy, dermatitis herpetiformis, common variable immunodeficiency, IgA deficiency. The AH 8.1 is also associated with rapid loss of $CD4^+$ T cells and impaired survival after human immunodeficiency virus (HIV) infection. The precise immunologic mechanisms that give rise to such diverse diseases are not completely known. It affects the balance of cyto-kines with low interleukin (IL)-2 and IFN-? and normal IL-4 production, with a bias toward T helper cell (T_H) 2–type of immune responses.

ANTIGEN PROCESSING AND PRESENTATION

Antigen-Presenting Cells

The development of humoral and cell-mediated immunity depends on complex cellular interactions that involve lymphocytes and nonlymphoid cells. Activation of lymphocytes by antigen requires its processing and presentation by another cell that is commonly known as an *antigen-presenting cell (APC)* (Table 18.1). Macrophages promptly capture foreign substances, and antigen processing and presentation was first demonstrated. Other APCs are the DCs (see Dendritic Cells) and B lymphocytes.

TABLE 18.1. Antigen-Presenting Cells

	B Cell	Macrophage	Dendritic Cell
Antigen uptake	+++ Surface immunoglobulin (antigen specific)	+++ Phagocytosis	+++
Major histocompatibility complex expression	Constitutive +++ to ++++	Inducible - to +++	Constitutive ++++
Co-stimulatory activity	Inducible - to +++	Inducible - to +++	Constitutive ++++

Processing Antigens for Class I Presentation

Antigen processing begins in the cytoplasm with an ATP-dependent, proteolytic machine that is known as a *proteasome*, which is highly conserved, from yeast to mammals ([127], [128], [129], [130] and [131]). Most of the MHC class I presented peptides are generated outside the endosomes and lysosomes, and energy that is supplied by ATP is required. The proteolytic subunit of the proteasome is a large cylindric structure of 20S, which is arranged in four stacked rings. Based on structural analysis, the 20S proteasome is composed of two types of sequences, a and ß. The central two rings of the 20S proteasome is composed of seven distinct, but homologous, ß subunits, which surround a central chamber at which proteolysis occurs (Fig. 18.4). The other two outer rings are made of a subunits, which form openings from which substrates enter and leave. Isolated subunits have no proteolytic activity, therefore the subunits must assume a precise conformation in the ß ring to be active. It has been determined that the proteolytic mechanism depends on the hydroxyl group of the N-terminal threonine (Thr) of the ß subunits. This mechanism of

proteolysis by the proteasome is distinct from any other known protease. The function of the a subunits may be related to the formation of a scaffolding for the self-assembly of the ß rings ([132]), as well as the facilitation of the entry of the substrates.

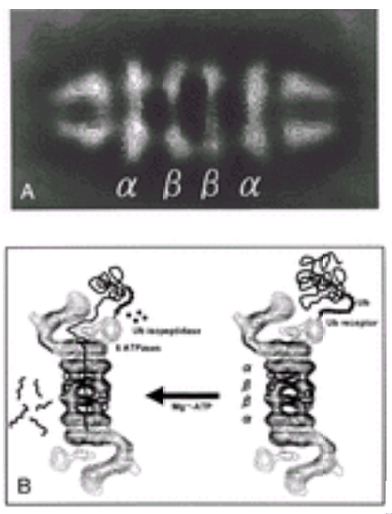

Figure 18.4. The proteasome. **A:** Photograph of the 26S proteasome, which consists of a central unit (20S proteasome) that is composed of seven a and seven ß subunits that are arranged in four rings in the order of aßßa. The central unit performs the catalytic functions. On each side of the central cylinder, there is a regulatory unit. **B:** Proteins to be degraded are first coupled to ubiquitin (Ub), which binds to an appropriate receptor in the regulatory unit that directs the protein to the central canal (“digestive tract”) of the proteasome. ATP, adenosine triphosphate. (From Tanaka K, Tanahashi N, Tsurumi C, et al. Proteasomes and antigen processing. Adv Immunol 1997;64:1–38, with permission.)

The 20S (650 kd) proteasome is capped on each side by a 19S (700 kd) regulatory complex ([129] , [131]) to form the 26S (2000 kd) proteasome with proteolytic activity. Each 19S cap contains approximately 20 distinct subunits. It has been known as *PA700 proteasome activator*, because, in the presence of ATP, it associates with the 20S particle and stimulates peptidase activity. In the absence of P700, the 20S particle cannot degrade ubiquinated proteins. At least six of the P700 subunits are putative ATPases and account for the ATP requirements in proteasome-mediated proteolysis. The 26S proteasome has a dumbbell shape, with the 20S proteasome as a cylinder in the center and the two PA700 V-shaped subunits attached on each end. IFN-? induces expression of three ß-type subunits, two of them encoded by genes, LMP-2 and LMP-7, within the class II region, and a third one, MECL-1, which is encoded outside the MHC ([133]). IFN-? also down-regulates three of the normally constitutively expressed subunits. The net result of INF-? stimulation is the exchange of three constitutive ß subunits by those that are IFN-? inducible and that are incorporated into the 20S proteasome ([134]). This function of INF-? changes the activity of the immunoproteasome.

Another regulatory complex, PA28 (11S), a 200-kd conical structure, also forms a cap at either end of the 20S proteasome ([135]). It stimulates multiple peptidase activities with faster kinetics. PA23 consists of two components, a and ß, which are structurally related to the Ki antigen, a nuclear antigen that is detected by autoantibodies in patients with SLE. Ki antigen is now renamed *PA28*?. The PA28 at the two ends of the 20S proteasome consist of a heterohexameric complex with alternating a and ß subunits. PA28 proteasome is not involved in the initial cleavage of proteins but rather degradation of polypeptides of intermediate size. It is thought to work after the initial action of the 26S proteasome.

How, from a long polypeptide or a protein, the specific peptide that precisely fits to the groove of the MHC is generated is a tantalizing question. These *specific* peptides are *embedded* within the polypeptide chain, and, to be extracted, two precise cuts are needed, one at the N-terminal (start) and one at the C-terminal (end). The importance of proteasomes for the generation of MHC class I–restricted peptides is widely recognized ([136] , [137] and [138]). Antigen processing in the cytoplasm does not generate exactly the final product in one step. The view that proteasome makes the C-terminal cut is favored by several studies ([139] , [140]). According to this view, the proteasome releases intermediates with a precisely cut C-terminal end but with an extended N-terminal end. Proteasome cleaves peptides on the carboxyl side of basic and hydrophobic residues of substrates. This specificity satisfies an important requirement for the binding of peptide to the MHC class I groove, that is, basic and hydrophobic residues normally serve in anchoring the peptide in the groove. In addition, the C-terminally cut peptides are also more efficiently transported by the TAP transporter.

N-terminal trimming is necessary to produce the antigenic peptide and may occur probably by aminopeptidases in the ER ([141]). It is estimated that the 26S proteasome generates an antigenic peptide from an intact protein with an efficiency of one peptide for every 20 molecules that are degraded ([142]). The peptides generated are 3 to 22 residues long, but only 20% are in the range that is favored for high affinity binding (eight to ten residues) ([143]). Crystal structure of proteasome has revealed that the distance between active Thr residues of adjacent ß subunits is approximately 28 Å. This distance determines the length of the generated peptides ([144]).

The ubiquitin proteolytic pathway has a crucial role in the degradation of short-lived and regulatory proteins that are important in a variety of cellular processes. Proteolytic cleavage by the proteasome requires the conjugation of the substrate by ubiquitin ([145]). The ubiquitin (8.5 kd) is one of the most conserved proteins in evolution and is activated to a high-energy thioester bond at its C-terminal by an activating enzyme, E1. After activation, one of several E2 enzymes (ubiquitin-carrier proteins) transfers ubiquitin to an E3 protein (ubiquitin-protein ligase) to which the substrate protein is specifically bound. This E3 protein covalently attaches ubiquitin to the substrate at which it binds to epsilon NH_2 groups of an internal Lys residue. This step is repeated until a polyubiquitin chain is formed, which serves as a recognition marker to the 26S proteasome. After degradation, ubiquitin molecules are released to participate in another cycle of proteolysis.

The proteasome exhibits three distinct peptidase activities that are associated with ß subunits. One is *chymotrypsin-like* because it hydrolyses peptides after a large hydrophobic residue, a second is *trypsin-like* because it cleaves after basic residues, and a third hydrolyzes after acidic residues. Occupancy of the chymotryptic site by a peptide substrate allosterically activates cleavages by the postacidic site, which in turn inhibits the chymotryptic site. By these cycles of activation-inhibition, the proteins are cleaved in pieces and are propagated for further fragmentation by other active sites.

PEPTIDE TRANSPORT Peptides that are generated by the proteasome must be transported across the ER membrane to meet the MHC class I molecules at which they are synthesized (Fig. 18.5) ([146] , [147]). The first indication that peptides are actively transported to the interior of the ER came from the study of mutant cell lines that had low MHC class I expression and could not present antigen, although their capacity to synthesize the molecules was intact. In the absence of peptides, the class I molecule cannot maintain its quaternary structure, folds up, and is incapable of moving along the constitutive pathway to the cell surface. Two genes have been identified within the MHC complex that encode the transporters of cytosolic peptides ([148] , [149] and [150]). They are called *transporters associated with antigen presentation (TAPs)*. Transfection of these genes to the mutant lines that were mentioned previously corrected their defect in antigen presentation. Profound defects in MHC class I restricted antigen presentation were detected in humans lacking TAP-2 ([151]) and in mutant mice lacking TAP-1 ([152]).

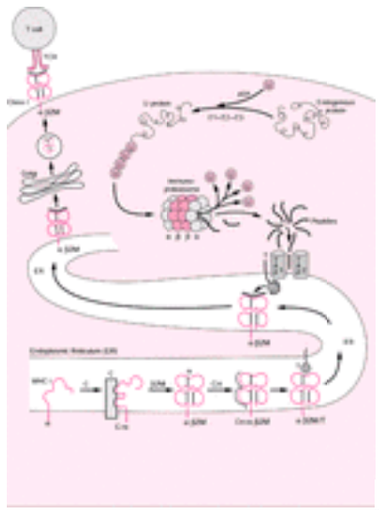

Figure 18.5. Processing and presentation for major histocompatibility complex (MHC) class I. Peptides (approximately eight to ten amino acids long) are generated by proteolysis of endogenous proteins by a multisubunit protein-degradative machine that is known as a *proteasome*. The protein to be degraded is first ubiquinated. Ubiquitin (U) is attached by a covalent bond to the e-NH_2 group of a lysine residue by an enzyme complex. The peptides are carried across the membrane of the endoplasmic reticulum (ER) by the transporter associated with antigen presentation (TAP) to be loaded on the groove of MHC class I molecules. The nascent a-chain of MHC retains its proper conformation by calnexin (C) and after the addition of the ß $_2$ microglobulin (ß $_2$m) chain by calreticulin (Crt). When the peptide passes inside the ER and lands on the MHC groove, with the help of tapasin (T), calreticulin is relieved from its chaperon duties, because the peptide stabilizes the MHC conformation. ATP, adenosine triphosphate; TCR, T-cell receptor.

The TAP proteins are members of the ABC family that is found in prokaryotes and eukaryotes ([153]). In mammals, the ABC proteins are grouped into four subfamilies: the P-glycoproteins, the cystic fibrosis transmembrane conductance regulators, the peroxisomal membrane proteins (PMP), and the TAP proteins. From the genomic structure of the human TAP-1 and TAP-2 genes, it is predicted that the TAP-1 protein has ten transmembrane-spanning segments (Fig. 18.6). The sixth segment is joined to the seventh and the eighth is joined to the ninth by hydrophilic cytoplasmic segments ([146]). The nucleotide-binding domain (NBD), which is located in the cytoplasm, is large and consists of several modules. Two are involved in nucleotide binding (Walker motifs), and three others are hydrophilic. The direction of transport varies. Some members transport their substrates away from the NBD (such as P-glycoprotein), and others transport their substrates toward the NBD. The TAP proteins are functional only as heterodimers ([154]) and are located in the ER and the *cis*-Golgi ([155]). In addition to the ATP-binding site ([156]), a peptide-binding site is formed by both subunits ([157]). Peptide binding is ATP independent, but its transport is ATP dependent ([158], [159]). It is of interest that peptides with 7 to 12 residues and a C-terminus are more efficiently transported, and those are precisely the requirements for optimal binding by the class I MHC molecule ([159], [160]). Because peptides are usually rapidly degraded in the cytoplasm, it is suggested that they may be carried from the proteasome to the TAP proteins by chaperon proteins, such as those of the HSP-70 family. Genes that encode such proteins have been found in the MHC region ([161]). Peptide binding to TAP precedes its translocation across the ER membrane. TAP could act as a peptide channel if binding activates TAP and permits the diffusion of peptides across the membrane. Most data, however, are consistent with the transporter function, that is, binding that is followed by translocation. ATP binding releases the peptide as a result of conformational changes of the NBD.

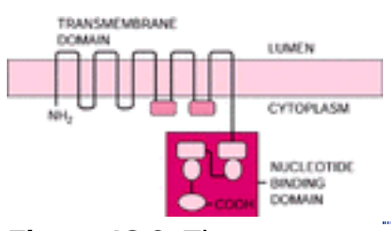

Figure 18.6. The transporter associated with antigen processing (TAP). This model for TAP-1 protein is predicted from the structure of the gene. The exons of the gene probably encode structural units (modules), which correspond to distinct functional domains of the protein. Thus, TAP-1 consists of ten transmembrane segments that form the transmembrane domain (N-terminus) and a large nucleotide-binding domain (NBD) (C-terminus) that is localized within the cytoplasm. The NBD consists of several modules (two of them bind adenosine triphosphate, Walker motifs, *crosshatched*) and three hydrophilic segments *(open rectangles and open circle).* The TAP proteins form a functional unit only as heterodimers (TAP-1 and TAP-2). (From Elliott T. Transporter associated with antigen processing. Adv Immunol 1997;65:47–109, with permission.)

An important question that is related to class I antigen presentation is the mechanism by which viral proteins or tumor antigens, which are synthesized within the ER, are targeted to the cytosol to be handled by the processing machinery. There is an *ER retrograde* pathway that transports proteins from the ER to the cytosol ([162]). Until these proteins are assembled and folded properly, they are retained within the ER by calnexin or calreticulin. Misfolded or aberrant proteins are released for proteasomal degradation ([163]). However, the ER possesses proteolytic activity, that is, aminopeptidases that may also process N-terminally extended precursors of antigenic peptides for loading to MHC class I molecules.

ASSEMBLY AND LOADING OF CLASS I MOLECULES The size restriction for peptides to bind to class I molecules is eight to ten residues. The restriction is imposed by the structure of the MHC class I groove, which is closed at the two ends. The class I a chain and ß $_2$m are synthesized on membrane-associated ribosomes and are inserted cotranslationally into the ER through a specialized structure that is known as the *translocon*. *N*-glycosylation takes place in the ER during the translocation process. HLA-A, HLA-B, and HLA-C have a single *N*-glycosylation site. The ER chaperon, BiP, a HSP-70 homolog, interacts with proteins during this stage and, through ATP regulation, provides the energy that is required for the movement of the protein through the ER membrane. BiP binds with free HLA heavy (H) chains. Calnexin is the most important chaperon and binds to newly synthesized free class I a chain ([164], [165]) but not to the heterodimer (Fig. 18.5). *Calnexin* is a transmembrane lectin and binds to *N*-linked glycans that bear a single glucose after removal by glycosidases of the extra glucose residues. How calnexin facilitates folding is not known, but the glucose is removed by a glycosidase II and calnexin is released. If the MHC class I molecule has not achieved its proper folding, a second glycosylation cycle follows with another attempt at refolding. Removal of calnexin permits the MHC class I molecule to leave the ER. Another chaperon that has been detected by some studies is calreticulin, which is a soluble homolog of calnexin. The TAP heterodimeric proteins transport the cytosolic peptides that are generated by the proteasome across the ER membrane. They bind to MHC class I molecules through an additional component that is called *tapasin* (TAP-associated glycoprotein) ([166]). Tapasin is a transmembrane glycoprotein that has an ER retention signal in the cytoplasmic region. The gene that encodes tapasin is in the centromeric end of the human MHC region. Tapasin probably forms a bridge between TAP and MHC class I molecules ([167]) (Fig. 18.5). However, tapasin also stabilizes class I molecules in the absence of peptides by occupying the groove, a function that is performed by the Ii chain in class II MHC molecules. In addition, tapasin is involved in peptide loading ([168]) and also influences the peptide selection ([169]). An additional molecule that associates with MHC class I molecules at the assembly stage is ERp57, an enzyme that ensures the correct formation of intrachain and interchain disulfide bonds ([170]). ERp57 is a thiol-dependent reductase and a cysteine (Cys) protease. As a protease, it may play a role in the trimming of peptides, because it remains attached to the complex until the time of the peptide loading. The order and kinetics of the assembly of the various components of the loading complex is as follows ([171], [172]): H chain ß $_2$m heterodimers can be recovered within 4 minutes after translation, and the peptide joins 2 minutes later. Shortly after the synthesis of the H chain, one disulfide bond forms in the a $_2$ domain, and a second forms in the a $_3$ domain. Disulfide bond formation is necessary for ß $_2$m binding and peptide loading. The ß $_2$m is required for physical support of the peptide-binding groove. Calnexin may be bound to a nascent H chain, but calnexin dissociates as ß $_2$m binds to the H chain, and calreticulin is taken up by the heterodimer. The other one-half of the complex is being assembled in the meantime, that is, TAP forms a complex with tapasin, and both are joined by calnexin and ERp57. When the two halves of the final complex join together, calnexin dissociates, and the final loading complex is complete. Loading of the peptide at this point releases the MHC class I–ß $_2$m heterodimer for the secretory pathway to reach the cell membrane.

PRESENTATION OF EXOGENOUS ANTIGEN BY MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I MOLECULES The class I MHC system evolved to identify cells that bear peptides that derive mostly from infectious agents. The vast majority of peptides that are presented by MHC I derive from proteins that are synthesized by the cell's own ribosomes. The proteins or polypeptides that generate these peptides are referred to as *endogenous*, whereas peptides that derive from proteins or microorganisms that are phagocytosed are termed *exogenous*. It has been widely accepted that endogenous antigens trigger a $CD8^+$ class I restricted response, whereas exogenous antigens activate $CD4^+$ class II restricted cells. However, several examples over the years have detected class I restricted $CD8^+$ T-cell responses with dead phagocytosed viruses, bacteria, transplants, dead cells, and others, which were handled by the immune system as exogenous antigens and were targeted to the endocytic system ([173]). This has been known as *cross-priming*, which was originally described in mice that were immunized with cells that expressed minor histocompatibility antigens ([174]). Today, it is also known as *cross presentation*. Several examples exist for $CD8^+$ responses that are induced with dead viruses ([175]) or purified proteins ([176]). Hepatitis B surface antigen, given by the exogenous route and submitted to efficient endolysosomal processing, can lead to peptide loaded MHC class I molecules ([177]). An interesting example of cross presentation is the uptake by APCs of antigens that are chaperoned by HSP ([178]).

HSPs are highly conserved peptide-binding molecules that control the folding of proteins and prevent their aggregation. HSP-70 that is complexed with a variety of synthetic peptides is taken up by APCs and elicits $CD8^+$ T-cell class I restricted antitumor cytolytic responses ([179]). The HSP-peptide complexes are internalized by a receptor-mediated mechanism and are subsequently processed by a proteasome-dependent TAP-dependent mechanism or through the endosomal route ([180]). This is a highly efficient mechanism whereby antigens that follow an exogenous route induce strong $CD8^+$ responses against tumors ([181]) or viruses ([182]). Peptides that are introduced into the cytosol induce a strong class I restricted response only if they are chaperoned by HSP but not alone ([183]). Receptors for HSP have been detected on $CD11b^+$ cells ([184]), and, recently, the receptor was identified to be the CD91 protein for all HSPs ([185]) (see Chapter 2). CD91 is a receptor for a $_2$-macroglobulin and, with calreticulin, binds and stimulates uptake of apoptotic cells ([186]); together, they act as receptors for the collectin family, and, through them, organ clearance is regulated to enhance removal of apoptotic cells and cell debris ([187]). It is postulated that HSP-peptide complexes that are given by the exogenous route might be used in the future to elicit protective immunity against cancer on viruses ([188]). Although macrophages, DCs, and B cells have been reported to be able to mediate cross presentation, the evidence collectively suggests that the most important cell is a DC. Interactions between CD4 and CD8 T cells that interact with the same APC are apparently needed ([189]). Cross-priming is involved, predominantly in response to virus infection, cancer cells, and histoincompatible tissues. Although cross-priming is associated with an immune response, depending on the nature of the antigen (e.g., normal healthy cellular antigens), cross presentation leads to the opposite of the immune response—cross-tolerance.

Processing Antigen for Class II Presentation

BIOSYNTHESIS OF MAJOR HISTOCOMPATIBILITY COMPLEX CLASS II MOLECULES Expression of class II MHC molecules is restricted mainly to certain cell types, such as macrophages, DCs, and B lymphocytes. However, MHC class II molecules can be induced in other cells by IFN-?. Regulation of MHC class II molecule expression occurs at the level of transcription. Many factors that regulate their expression are DNA binding and are ubiquitously expressed ([190]). An important mediator is the MHC class II *trans*-activator molecule (CIITA) that is not a direct DNA-binding molecule and is detected in cells that express class II, constitutively or after induction with IFN-?. CIITA also regulates the expression of the Ii chain and HLA-DM molecules. The MHC class II molecules and Ii chain are cotranslationally inserted into the membrane of the ER through a signal peptide. Once in the ER, the Ii forms trimers through the association of its luminal sequence, followed by association with MHC II, forming nonamers ([191]). Ii is a type II membrane protein (NH_2-terminus at the cytosolic face of ER) and is associated rapidly with three MHC class II molecules ([192]), which are added sequentially. A central region of the Ii, which is termed *CLIP*, occupies the peptide-binding region of MHC class II. The MHC class II–Ii association conceals a motif that retains Ii into the ER, and, as a result, the nonamer complex moves to the Golgi apparatus ([193]). Leucine (Leu) signals in Ii bind the AP-1 and AP-2 adaptors ([194]), but more than one sorting mechanism probably exists, depending on the cell type. The MHC class II–Ii complexes are targeted to late endosomes ([195], [196]), possibly with an intermediate stopover, on the cell membrane or on the early endosome. Permanent localization in the early endosomes (by exchanging the cytoplasmic tail of Ii with that of transferrin receptor) blocks class II presentation, indicating that late endosomes or lysosomes provide the appropriate milieu for class II presentation ([197]).

GENERATION OF ANTIGENIC PEPTIDES FOR CLASS II MAJOR HISTOCOMPATIBILITY COMPLEX PRESENTATION Proteolytic breakdown of exogenous antigen in the endocytic pathway is essential for peptide loading. Specific uptake involves endocytosis and phagocytosis, mediated by various receptors in different cells, such as the B-cell receptor (BCR) in B cells, mannose receptors and Fc receptors in macrophages. The mannose receptor recognizes patterns of carbohydrates on the surface of the cell wall of infectious agents, and this increases dramatically the efficiency of class II–mediated presentation by DCs (Fig. 18.7).

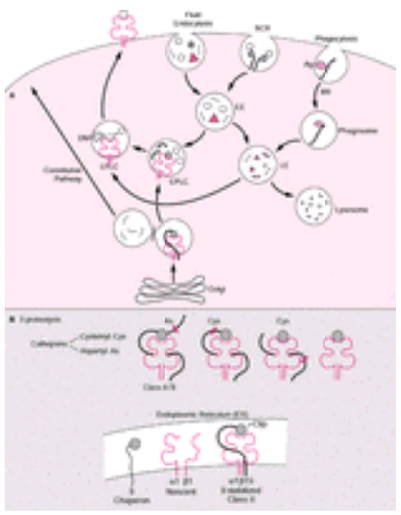

Figure 18.7. Processing and presentation for major histocompatibility complex (MHC) class II. Pathogens or their products are captured by phagocytic or dendritic cells and are carried to the interior of the cell enclosed within endocytic vesicles. **A:** Endocytosis may be mediated through receptors, such as the mannose receptor (MR) or a B-cell receptor (BCR), such as antigen (Ag)-specific immunoglobulin, or may be simply carried along with fluid. Depending on the method of entrance, they end up within typical phagosomes or early endosomes (EEs). The endocytic pathway is relatively complex, which is reflected in changes of their composition and pH. There is a dramatic morphologic change from a simple vesicle to multilamellar and multivesicular compartments that are known as *MHC class II compartments*. The endocytosed material is targeted to early peptide loading compartment (EPLC) and late peptide loading compartment (LPLC), vesicles with class II MHC. Their conformation and groove are maintained by the invariant (Ii) chain in EPLC and HLA-DM in LPLC. The MHC class II molecule is synthesized in the endoplasmic reticulum (ER) and its conformation is stabilized by the chaperon protein Ii chain. A region of Ii that is termed *class II–associated invariant chain peptide (CLIP)* occupies the groove and prevents the collapse of MHC class II molecules. MHC class II molecules and Ii exist as nonamers. The complex moves out of the ER, passes through the Golgi apparatus, and reaches the EPLC, where the Ii chain is proteolytically destroyed, but CLIP still remains in the groove. Exchange of CLIP with the antigenic peptide is catalyzed by the nonclassical HLA-DM protein. In the last step of this long and tortuous path, the MHC class II–peptide complex is delivered to the plasma membrane by the EPLC vesicle, where it interacts with the appropriate T-cell receptor on $CD4^+$ T cells. **B:** Proteolysis of the Ii chain is mediated by cathepsins, which cleave at a cysteine or aspartic acid residue. LE, late endosome.

The endocytic route that is taken by endocytosed foreign material consists of a complex network of compartments that vary in morphology, physiochemical properties, and content. Three major regions, however, can be distinguished: the early endosomes with slightly acidic pH are barely proteolytic; the late endosomes are more acidic and contain some components that are classically used as markers of lysosomal compartments, LAMP-1 and LAMP-2 and the lysosomes that have a low pH and are rich in hydrolytic enzymes. This route is intersected by another route that originates in the *trans*-Golgi network (TGN). This route is taken by molecules that come out of the ER, and, depending on specific signals such as dileucine or mannose-6-phosphate, they follow the secretory pathway on the way to the cell membrane or secretion. Foreign antigens that enter the endocytic pathway are subject to gradual proteolysis, which may generate peptides that are suitable for receptive MHC class II molecules ([198]). Antigens follow different routes in the endocytic pathway, and antigen processing is different ([199]). “Exit tracks” from the endocytic pathway join the constitutive secretory pathway for reaching the membrane. Proteolytic activities along the endocytic pathway are acquired progressively. Acidification is an important factor for protein unfolding, and, as the pH decreases progressively, it influences several steps in the processing of incoming antigens and in peptide loading, such as protease activity, MHC class II molecule aggregation, peptide receptivity, and function of chaperones HLA-DM and HLA-DO. Antigen processing is primarily carried out by proteases, and most of the lysosomal proteases are known as *cathepsins*. The final peptide that is suitable for loading on to MHC class II molecules is prepared by the action of the protease alone or with the assistance of the MHC molecule. A *protease-guided* initial step breaks down large proteins into smaller polypeptide chains, which may partially be accessible to MHC class II molecules. At this point *MHC class II–guided* processing allows the protease to trim down unnecessary protrusions outside the binding site ([200]). Several proteases exist within the endocytic system, endoproteases and exoproteases, and some cooperation between them is anticipated ([201]). It appears that the first key protease is a Cys endopeptidase that cleaves after Asn residues ([202]). Once this enzyme takes the first step, other enzymes complete the digestion for the generation of peptides.

PEPTIDE LOADING ON THE MAJOR HISTOCOMPATIBILITY COMPLEX II MOLECULE As indicated in the section Class II Molecules, the MHC class II molecule arrives in the endocytic system as a nonamer with the Ii chain. The CLIP region of Ii is inserted in the peptide-binding groove and prevents interaction with ER-resident proteins or other proteins on the way to the endosomes. CLIP also keeps the MHC class II molecule stable until the time of peptide loading. The precise location of the peptide loading within the endocytic system has been debated for a long time. Electron microscopic studies demonstrate that the MHC class II molecule is found throughout the endosomal pathway, including mannose-6-phosphate–positive late endosomes and in late endosomes and lysosomes, a compartment that is rich in MHC II but negative for the mannose-6-phosphate receptor, which is known as *MIIC*. This compartment consists of vesicles 200 to 300 nm in diameter with heterogeneous morphology, such as multivesicular, multilamellar, tubulovesicular. Various functional stages of MIICs are distinguished on the basis of the Ii detection, for example, in some of them, the intact Ii chain is detected; in others, only the amino-terminal region is detected; and, in others, the Ii chain is absent. Loss of the Ii chain is associated with a change from multivesicular to multilamellar MIIC ([203]). Another endocytic compartment, which is known as the *CIIV* (for class II vesicles), from a B-cell line is similar to MIIC. Both are considered the site for peptide loading ([204]). The MIIC compartment is set aside from the remaining endosomal vesicles, and several endocytic markers are absent. These vesicles receive newly synthesized MHC class II molecules by virtue of the targeting motif of the Ii chain. Once they

arrive, the Ii targeting motif is removed (C-terminal region), and the MHC II–Ii complex is retained within the MIIC for prolonged periods of time ([205]). The MHC class II compartment is particularly abundant in DCs, which are the professional APCs. The first step in the peptide loading is the digestion of the Ii chain in the MHC class II–Ii chain nonamer complex (Fig. 18.7). The carboxyterminal region of Ii is cleaved by a protease that releases an MHC class II–Ii trimer ([206]). Ii degradation occurs in an orchestrated fashion until only the CLIP remains attached to the MHC class II molecule. Proteolysis proceeds in two stages, and, for proteolysis of the second intermediate, different cathep-sins are used in different APCs. Of the lysosomal enzymes, cathepsin S plays an essential role in the degradation of Ii in B cells and DCs, and its absence has major consequences for the onset of humoral immune responses ([201]). Cathepsin L, on the other hand, is expressed on thymic epithelial cells ([207]). Removal of CLIP from the peptide binding groove and subsequent loading with antigenic peptide is catalyzed by the nonclassical class II HLA-DM, which binds directly to MHC class II–CLIP complex ([79]), near the N-terminus of MHC class II ([208]). It is thought that the DM induces a transitional “open” state to the MHC class II groove that releases CLIP. This occurs by disruption of a few H-bonds between MHC class II and CLIP ([209]). It is intriguing that HLA-DM does not interact with MHC class II that is associated with intact Ii chain. The HLA-DO molecule is a negative regulator of HLA-DM, and, when it is overexpressed, it results in an accumulation of MHC-CLIP complexes. MHC class II–peptide complexes are transported to the cell surface by vesicles, the movement of which depends on the cytoskeletal elements. MIIC transport is microtubule dependent ([210]). Microtubules are assembled from aß tubulin heterodimers in the microtubule organizing center and extend toward the periphery. A large family of motor proteins, which are known as *kinesins*, mediate transport of vesicles of the secretory pathway, cytotoxic granules, lysosomes, etc. On microtubules, kinesin transports vesicles towards the plus (+) end of the microtubule (the end away from the microtubule organizing center, towards the cell periphery). Another group of proteins, dynein, creates motion towards the negative (–) end of the microtubule ([211]). Thus, dynein is important to keep vesicles around the nucleus, because inhibition of its function shuttles all the vesicles to the cell membrane. How and when the vesicular movement is regulated is unknown. In monocytes, IL-10 triggers positioning of MIIC in the cell, but, in B cells, the BCR performs this function. The signal for kinesin to transport the mature MIIC—that is, the MIIC that is loaded with the peptide—to the cell surface is unknown. It is also intriguing that only MHC class II–peptide complexes are detected on the cell surface but not the other contents of the MIIC vesicle.

Antigen Presentation by CD1

CD1 was first identified in human cortical thymocytes but later was detected on other cells, such as on antigen-presenting DCs, and CD1a is expressed on Langerhans cell (LC), a specialized DC in the epidermis ([212]). CD1c is detected on a subset of peripheral blood B cells and B cells of the marginal zone, and CD1d is expressed in intestinal epithelia and in a wide variety of hematopoietic cells. The members of the CD1 family are antigen-presenting molecules, and, after their synthesis, they must first reach an appropriate vesicular compartment for peptide loading on the way to the cell surface. There are striking differences in the intra-cellular distribution of the CD1 isoforms ([213] , [214]). CD1a is found mainly on the cell surface but also in early endosomes ([215] , [216]) and in LCs that are present in the Birbeck granules. Together with CD1d, CD1b accumulates in the late endosomes and lysosomes, whereas CD1c is found in the early endosomes (transferrin receptor positive). The ratio between surface expression and intracellular concentration also varies between the isoforms. The differential expression of the isoforms is regulated by a Tyr-based motif in the intracellular region that is present in all isoforms except CD1a ([217] , [218]). This sequence, YXXZ (Y represents Tyr; X represents any amino acid; and Z represents an amino acid with bulky side chains), interacts with a member of the cytosolic adaptor proteins AP-1-AP-4 ([219]). AP-2 is positioned in the TGN and mediates delivery from TGN to the endosomal-lysosomal system, whereas AP-2 is localized in the plasma membrane, where it directs proteins to clathrin-coated pits that lead to entrance into the endocytic pathway. The AP-3 is implicated in the sorting of proteins from TGN to endosomes and lysosomes. The AP proteins determine the specificity of destination for the CD1 molecules, but the binding to a specific AP member is determined by the residues that surround the Tyr-based motif ([220]). The YXXZ motif is essential for localization in the endosomal and lysosomal compartments, because mutations that are introduced into the sequence inhibit presentation of mycobacterial glycolipids to T cells ([221]). Although the YXXZ motif predicts the final destination, it does not indicate the route that is to be followed. The CD1d first follows a direct route from the ER to the cell surface, where, through the YXXØ motif (Ø represents phenylalanine), it binds to AP-2. It is subsequently internalized and is directed to the MIIC compartment ([221]). MIIC overlaps considerably with lysosomes and may represent a fusion product between endosomes and lysosomes. CD1d is associated with the invariant chain, which directs CD1d to the same compartment independently of the Tyr-based motif ([221]). The invariant chain needs to be degraded by cathepsin S to allow loading of the CD1d and to be directed to the cell membrane ([222] , [223]).

The antigens that are presented by CD1 molecules are lipids and glycolipids (Fig. 18.8). Mycolic acids are a class of long-chain, branched, free fatty acids and constitute the predominant component of the thick outer layer of the mycobacterial cell wall. It confers the acid-fast staining property to mycobacteria. They contain approximately 80 carbon atoms and are known to be required for mycobacterial survival. In addition to mycolic acids, two glycolipids, the lipoarabinomannan (LAM) and lipomannan are large molecules that contain 20 to 100 glycosyl residues and are presented also by CD1 molecules ([224]). Other antigens include selected phosphatidylinositol mannosides and glycosylated mycolates, including glucose monomycolate.

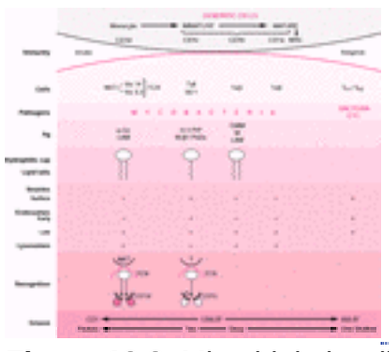

Figure 18.8. Microbial glycolipid presentation to T cells. The CD1 molecule, an orphan family of major histocompatibility complex (MHC)–like molecules, presents long carbon-chain glycolipids from mycobacteria and other similar pathogens, to natural killer T cells (NKT), T-cell receptor (TCR)-?d, and TCR-aß cells, linking innate and adaptive immunity. The CD1 molecules are expressed in various compartments of the endocytic system, providing a broad surveying mechanism for the detection of intracellular mycobacterial infections. Localization of CD1 molecules depends on endosomal targeting sequences for loading of glycolipids. The glycolipids in general consist of a hydrophilic head of carbohydrate molecules and one or two lipid tails. The head interacts with the TCR, whereas the lipid tails are accommodated within the large groove of the CD1 molecules, penetrating into two deep pockets. Ag, antigen; a-Gc, a-galactosylceramide; GMM, glucose monomycolate; H-1 PIP, hexosyl-1-phosphoisoprenoid; LAM, lipoarabinomannan; M-ß1-PhDo, mannosyl-ß1-phosphodolichols.

The first identification of the CD1 role in the presentation of glycolipids was on a double negative T-cell line that was isolated after repeated stimulations with crude *Mycobacterium tuberculosis* antigen ([225]). Only later was it found that the presentation requires the loading of mycobacterial antigens in acidified late endosomes and lysosomes. Mycobacteria are taken up by phagocytosis and reside within nonacidified phagosomes (due to a paucity in the vacuolar H^+ ATPase). Therefore, they are restricted in their capacity to fuse with late endosomes and lysosomes ([226]). The macrophage mannose receptor that has been implicated in glycolipid uptake by APC ([227]) is absent from mycobacterial phagosomes.

The mechanism of distribution of various mycobacterial antigens to the subcellular compartments is not well understood. LAM has been found in late endosomes and lysosomes, either by being released from the phagosome or after uptake from the extracellular environment by the mannose receptor ([227]). Nevertheless, mycobacterial antigens are distributed throughout the endocytic system after their release from the phagosome ([228] , [229]). Antigens that are released from phagocytosed mycobacteria reach various compartments of the endocytic lysosomal system, where all CD1 isoforms, that is, CD1a, CD1b, and CD1c, gain access to mycobacterial glycolipids at these different sites (Fig. 18.8). CD1a and CD1c sample the antigens in phagosomes that are arrested in the early endosomal stage, whereas CD1b samples antigens in phagosomes that are arrested in the late mature phagolysosome stage ([112]). The CD1 molecule binds the lipid antigens by accommodating the first two lipid tails within the hydrophobic groove, whereas the hydrophilic caps (sugars) are exposed to the solvent and directly contact the TCR ([230]). The buried surface of the groove, as determined from crystallographic studies, is 1400 $Å^2$, which could optimally accommodate a lipid with 32 carbons in length. However, some of the antigens that are presented by CD1 are 44 carbons long, and the mycolic acids are 80 carbons long. Presentation of large lipids takes hours (trafficking to late endosomes), whereas the same antigens with shorter chains are presented rapidly but inefficiently from the cell membrane ([231]). DCs specialize in the presentation of lipids with long alkyl chains, whereas nonprofessional APCs present preferentially short-chain glycolipids. The acidic environment of the late endosomes and lysosomes is an important factor in the interaction of the large lipid antigens with the groove. The properties of the CD1b protein are dramatically altered in an acidic pH to facilitate the interaction with its ligands. There is a reversible unfolding of the a-helical portions of CD1 in an acidic pH, which permits the direct binding of the hydrophobic portions of the molecule, thus burying the alkyl chains ([232] , [233]). The depth, enclosed nature, and hydrophobicity of the interior of

the CD1 groove is well adapted to carry out antigen presentation of lipids and amphipathic glycolipids, for which the hydrophobic component is sequestered within the groove, whereas the carbohydrates are left outside to interact with the TCR.

The structure of glycolipids is altered by APC. Terminal glycosyl residues are removed from certain glycolipids, resulting in the exposure of epitopes that are reactive with TCR ([234]). Glycosylation also generates new antigens, as is the case of glycosylation of mycolic acids during mycobacterial infections, with the use of glucose from the host and a mycobacterial enzyme ([235]). Glycolipid processing generates a large variety of lipid ligands for presentation by CD1 proteins ([236]).

In addition to bacterial glycolipids (i.e., LAM) and glucose monomycolate, CD1b molecules recognize self-glycosphingolipids, such as GM1 ganglioside ([237]). Several of these gangliosides can bind to CD1b, and, in striking contrast to bacterial glycolipids, the self-glycolipids bind on the cell surface without the need of the late endosome and lysosome acidified environment ([238]). Five or more oligosaccharide groups are required to stimulate TCR recognition with a large component of the ligand that is exposed. Apparently, these gangliosides act as blockers to prevent harmful autoreactivity. The number of these autoreactive T cells increases in multiple sclerosis ([237]).

CD1 SYSTEM IN MICROBIAL IMMUNITY The protective value of CD1-mediated immunity is currently under intensive investigation ([239], [240] and [241]). The $CD1^+$ cells correlate with the level of immunity to *Mycobacterium leprae* and are present in the lesion tenfold more abundantly in the tuberculoid form (immunologically responsive) than they are in the lepromatous form (immunologically unresponsive). Low numbers of $CD1^+$ cells correlate with low granulocyte-macrophage colony-stimulating factor (GM-CSF) levels and high IL-10 levels, which inhibits GM-CSF secretion. GM-CSF is a key differentiating factor for mature $CD83^+$ DCs ([232], [242]). CD1-restricted T cells contribute to intracellular bacterial infections, such as *M. tuberculosis*, based on high levels of IFN-? secretion and strong cytolytic activity. The CD1 isoforms survey broadly the endocytic system over pathways that are distinct from those of MHC class I and MHC class II molecules, and, furthermore, they are restricted to presentation of an important class of antigens, lipids, which are not covered by the MHC molecules. Among them, CD1c is particularly important, because it is expressed on LCs (in the absence of CD1b) and B cells (without CD1a or CD1b) ([243]).

DENDRITIC CELLS

DCs, as their name indicates, are characterized by their long and elaborate cytoplasmic branching processes (the Greek word *dendron* means *tree*). The adaptive immune system under evolutionary pressures developed cells with exquisite specific receptors, for sensing components of pathogens, to generate molecular and cellular effector mechanisms for their elimination. Sensing of the pathogens or their products requires their breakdown (processing) and presentation by cells of the innate immunity. Foremost among the APCs are the DCs ([244], [245] and [246]). DCs are a highly heterogeneous group that resides in most peripheral tissues at sites at which the body interfaces with the environment (i.e., skin, intestine, respiratory mucosal). Although DCs, like other hematopoietic cells, ultimately derive from bone marrow progenitors, partially differentiated precursors are outside the bone marrow, such as peripheral blood, cord blood, and thymus. Such progenitors that are exposed *in vivo* to bacterial or inflammatory products, cytokines, etc., differentiate to more mature cells with DC morphology and function. This large plasticity of DC development has created confusing and sometimes contradictory results. Basically, there are two lines of differentiation from stem cells, one along *myeloid* lineage and another along *lymphoid* lineage; thus, the generation of two prevailing terms: *myeloid DC* and *lymphoid DC*. DC precursors circulate in the peripheral blood with a monocytic phenotype $CD14^+CD11c^+CD13^+$. These cells, cultured *in vivo* in the presence of GM-CSF and IL-4, give rise to the DCs that are considered as *myeloid DCs*. However, the same precursors that are cultured with fibroblasts differentiate to macrophages ([247]). IL-6 that is released from fibroblast in contact with the monocytic precursors up-regulates the macrophage colony-stimulating factor receptors. This switches differentiation to macrophages, by an autocrine mechanism, based on the secreted macrophage colony-stimulating factor. Progenitors from cord blood that are considered lymphoid with the potential to differentiate to NK cells could give rise *in vitro* to phenotypically and functionally potent DCs under the stimulation with various cytokines ([248]). *In vitro* studies may not represent the normal *in vivo* pathways of differentiation but, nevertheless, provide evidence that, *in vivo* also, partially differentiated cells of different lineages may choose a DC differentiation pathway when they are exposed to appropriate conditions. The stimuli for DC differentiation vary widely, from inflammatory microbial products ([249]) to simply crossing endothelial barriers ([250]). DCs that develop within the thymus are $CD8^+$ and considered to be of lymphoid origin. However, it is documented that even myeloid DCs can also express CD8, therefore CD8 expression does not define lineage origin ([251], [252]). Origin from lymphoid precursors was suggested by a unique DC that is known as a *plasmacytoid T cell* or *plasmacytoid monocyte*. These cells have a typical plasma cell-like morphology; lack expression of myeloid markers; and are $CD11c^-$, $CXCR3^+$, and L-selectin $(CD62L)^+$. DCs are heterogeneous with respect to their phenotype, anatomic distribution, and function.

Functionally, DCs have been distinguished into two groups, DC1 and DC2; the former derives from myeloid monocytes (pre-DC1), and the second derives from a plasmatoid DC precursor (pre-DC2) ([253]). This separation correlates with functional differentiation. Myeloid DCs from monocytes that are activated by the CD40 ligand (CD40L) produce large amounts of IL-12 and induce preferentially T_H1 development. Lymphoid DC2s from plasmacytoid precursors produce lower amounts of IL-12 and preferentially induce T_H2 development ([254], [255]). Another study, however, reached opposite conclusions ([256]), suggesting that the two DCs represent two separate evolutionary traits. The pre-DC1s express the toll-like receptor (TLR)-2 and TLR-4, and preDC2s express TLR-7 and TLR-9 ([257]).

Pre-DC1s are strongly positive for mannose receptor and rapidly produce large amounts of proinflammatory cytokines, such as TNF-a, IL-6, and IL-12, in response to ligands of TLR-2—bacterial glycoproteins. Pre-DC2s produce IFN-? in response to ligands of TLR-9—bacterial DNA ([258]). The origin, response to stimuli, and pathways of differentiation of DCs vary greatly, depending on conditions that are still poorly understood.

The precursors of DCs from bone marrow progenitors move to the periphery as *immature* DCs and take position at crucial sites of potential entry of pathogens. Once they capture antigens and are exposed to stimuli, they *mature* and migrate to regional lymphoid organs to present antigens and to activate the adaptive immune responses by presenting antigens that are brought from the periphery. DCs are the professional APCs in immunity.

Migration of Dendritic Cells

DCs are cells that are continuously on the move from the moment they come out of the bone marrow to settle in various organs and tissues as immature DCs. In these locations, they are easily exposed to antigens and invading pathogens, and, now as mature, activated DCs, they migrate to the lymphoid organs. Each of these pathways is orchestrated by distinct sets of molecules and receptors, foremost among them being the chemo-kines and their receptors.

Circulating monocytes and immature DCs express receptors for inflammatory chemokines (CXCR-1, CCR-1, CCR-2, and CCR-5), as well as receptors for bacterial and complement chemoattractants (receptor for *N*-formyl-methionyl-leucyl-phen-ylalanine-R and C5a-R) ([259]), and, in response to such mediators, they develop into DCs ([260]). The crossing of the blood wall by DC precursors is mediated by a DC-specific adhesion molecule that is known as *DC-specific intercellular adhesion molecule (ICAM)-3 grabbing nonintegrin (DC-SIGN, or CD209)*. DC-SIGN is a novel cell surface C-type lectin that is expressed on DCs, binds ICAM-3, and mediates interactions between DCs and T cells ([261]). The extracellular region of DC-SIGN has a C-terminal, C-type carbohydrate recognition domain, particularly for mannose. DC-SIGN interacts with ICAM-2 on the endothelial cells and establishes shear-resistant contacts with blood vessel walls for the transmigration of the DCs ([262]). The DC-SIGN-ICAM-2 interaction is involved in the bloodborne DC precursor exit into peripheral tissues and in tissue mature DC to peripheral lymphoid tissues. In the skin and epithelia of lung, intestine, etc., immature DCs are exposed to stimuli that trigger their maturation, such as cytokines (TNF-a, IL-1) and microbial products [e.g., lipopolysaccharide (LPS)].

The mature DCs change to a new phenotype (MHC II^{+++}, co-stimulatory and adhesion molecules positive) and acquire new migratory capacity. As a result, they migrate to the T-cell areas of the regional lymph nodes. DCs first down-regulate CCR-1 and CCR-5 [receptors for macrophage inflammatory protein (MIP)-1a and MIP-1ß] up-regulate CCR-7 and become responsive to secondary lymphoid tissue chemokine (SLC) and Epstein-Barr virus–induced molecule 1 ligand chemokine (ELC), the ligands for CCR-7 ([263], [264]). Maturing DCs first move from their interstitial location to afferent lymphatic capillaries, where SLC is secreted from the endothelial cells and is carried to draining lymph nodes. The migratory pathways of the LCs, the DCs of the epidermis, provide a vivid example of the exquisite regulation of DC migration (Fig. 18.9) ([265]).

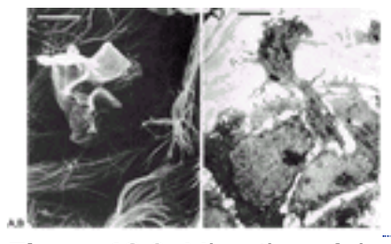

Figure 18.9. Migration of dendritic cells. **A:** A Langerhans cell that is migrating through the labyrinthian space of the dermis, guided by chemo-kine signals that are received by its chemokine receptors. **B:** The Langerhans cell penetrates into the dermis through a hole (*between the two groups of arrows*) in the basement membrane (*asterisk*). (From Romani, et al. Inter Rev Cytol 2001;207:237–270, with permission.)

The LC precursors, $CD11^+$ and $CD1a^+$ ([266]), are recruited into dermis, depending on the selectin expression of the dermal blood vessels ([267]). These cells express the CCR-6 receptor, which binds the inflammatory chemokine MIP-3a (CCL-20) that is produced by keratinocytes of the epidermis ([268], [269]). The LCs remain in the suprabasal layer, physically connected to neighboring keratinocytes by homotypic interactions that are mediated by E-cadherin that is expressed by keratinocytes and LCs. Concomitantly, the CCR-6 is down-regulated, and the CCR-7 is up-regulated, which allows the LCs to move toward the lymphatic vessels in response to SLC. The basement membrane of the skin, however, stands as a barrier to their migration. LCs penetrate the lamina densa, which consists of type IV collagen and is digested by the matrix metalloproteinase of LCs. They cross the dermis and reach the abluminal side of the vessels. Entry into the lymphatic vessel is poorly understood, but P-glycoprotein may be involved.

LCs are carried by the lymph and acquire morphology that is known as a *veiled cel*l as a result of their broad sail-like membranous sheets. Entering the lymph node, they settle in the T-dependent areas in response to SLC (CCL-21) and ELC (MIP-3ß, CCL-19), ligands for the CCR-7 receptor. SLC is produced by the endothelial cells of the high endothelial venule (Chapter 15), and ELC is produced by DCs or other cells in the paracortex ([270]). The LCs that settle in the paracortex are known as *interdigitating DCs (IDCs).*

Accumulation of DCs around tumors follows the same mechanisms that fully depend on the interaction between chemokines that are released by tumors and the appropriate receptors on DCs ([271]).

Dendritic Cell Functions

DCs are best known for their efficient antigen presentation function. They capture antigens and pathogens, which they internalize and process for antigen presentation. DCs use a variety of receptors to take in antigens, such as receptors for Fc and complement, macrophage-scavenger receptors, mannose receptors, and DEC-205. However, of all the receptors that the DCs use to endocytose pathogens, the best studied is the DC-SIGN receptor that binds to HIV ([272]). HIV is not endocytosed by the DC, but the DC-SIGN binds to gp120 envelope glycoprotein, and the DC transfers the HIV to the lymphoid organs, where it enhances infection of T cells that express CD4 and chemokine co-receptors. DCs are efficient APCs for the class II restricted pathway, but endocytose antigens can also be diverted to the class I–restricted pathway. This is known as *cross-priming* or *cross presentation* (see the section Presentation of Exogenous Antigen by Major Histocompatibility Complex Class I Molecules). Immature DCs are crucial for this mechanism of presentation.

Interaction with pathogens by immature DCs not only prepares naïve T cells for priming, but also activates immature DCs for maturation. This is mediated by signaling receptors, such as the toll-like receptors (TLRs) of innate immunity (i.e., TLR-2 that is involved in response to gram-positive bacterial components or TLR-4 that interacts with LPS in response to gram-negative bacteria). An interesting example of the diversity of responses to a single bacterial protein by immature DCs is the bacterial cell wall protein OmpA (from *Klebsiella pneumoniae*). This protein triggers maturation signaling of immature DCs through the TLR-2 receptor, endocytosis via receptor-dependent mechanism, and cross-priming antigen specific $CD8^+$ T cells (in the absence of $CD4^+$ T-cell help) ([273]).

DCs, however, are not simply antigen-delivering cells for lymphocytes. They play a key role in the maintenance of T and B lymphocyte pools in the absence of exogenous antigen.

For T cells, this function depends on the high density of MHC class II molecules ([274]). It is postulated that the MHC class II molecules display self-peptides, and the interaction generates and transmits signals that are sufficient for the survival of T cells and could be traced from the cell surface to the nucleus (increase of IL-12R ß $_2$-chain and IFN-? mRNA). Contact between DCs and naïve T cells in the absence of antigen is established by the interaction of DC-SIGN (DCs) and the ICAM-3 (T cells) ([261]). This strong interaction allows the establishment of interactions with other adhesion molecules to form the immunologic synapse. These synapses are antigen independent and induce local Tyr phosphorylation, small Ca^{2+} responses, and long-term survival ([275]).

DCs can regulate differentiation of naïve B cells. In the initiation of the antibody response, a three-cell interaction takes place between T, B, and D cells with various combinations of cell surface–expressed molecules. This gives time to B cells to process and present peptide through its class II MHC molecules, for a cognate T and B cell interaction ([276]). DCs directly modulate growth and differentiation of B cells and enhance 30- to 300-fold IgG and IgA secretion, whereas, in response to IL-2, they produce large amounts of IgM ([277]). IL-2 is a key cytokine that is produced early after DC stimulation by maturation signals ([278]).

Dendritic Cells in Human Disease

DCs accumulate in the joints of rheumatoid arthritis and within psoriatic plaques, which express high levels of CD1b and CD1c, and are active stimulators of autologous T-cell proliferation. In contact allergy, hapten-modified proteins are processed by LCs that migrate to draining lymph nodes and initiate immune responses. A similar pathway is taken by DCs in the respiratory airways that capture and process inhaled antigens in asthma. The DCs are significantly higher in asthmatics. Targeting DCs may be an important new therapeutic approach for asthma.

In human parasitic infections, immature DCs can phagocytose the organism and restrain parasite replication in dermal infiltrates.

The role of DCs as potentiators and initiators of antiviral immune responses is well documented, especially in stimulating recall of cytotoxic T-lymphocyte responses. Nevertheless, viruses still survive within DCs and subvert the immune response by down-regulation of MHC class I molecule expression, induction of immunosuppressive cytokines (IL-10), or down-regulation of immunostimulatory cytokines (IL-12). In the pathogenesis of HIV disease, the DC-SIGN acts as a dendritic-specific HIV-1 binding protein that does not need a co-receptor and promotes binding and transmission of HIV-1 to T cells rather than entry to DCs. The virus is retained in an infectious state but is not allowed to enter the DC. DC-SIGN literally presents HIV to T cells in a nonprocessed infectious form. Various carcinomas display a heavy infiltrate of DCs with high MHC class II molecule expression that is associated with better prognosis. DCs have been used in trials in cancer therapy. Prospects for future successful DC immunotherapy are promising ([279]). T-cell immunity can be induced, even in patients with advanced stage IV melanoma by vaccination with antigen-pulsed mature monocyte-derived DCs ([280]). When the DCs are loaded with MHC class II molecule–binding melanoma peptides, strong tumor-specific T_H1 responses were elicited.

In a large body of literature regarding animal models, DCs that were loaded with tumor-associated antigens were able to induce antitumor immunity ([281]). Measurements of $CD8^+$ T cells by using MHC tetramers (Chapter 3) help quantify antigen-specific responses ([282]).

Langerhans Cells

LCs were first observed in the epidermis by Langerhans and can be identified only by means of special stains, making use of the affinity of the cell for heavy metal ions or the uptake by the cell of L-dopa, dopamine, and noradrenaline ([283]). The demonstration of a formalin-resistant and sulfhydryl-dependent ATPase is a reliable and specific technique for identifying LC. Their ultrastructure was described first by Birbeck et al. ([284]), who also described a characteristic granule that bears his name.

LCs constitute 3 to 8% of all cells in the epidermis and are present in all parts of the skin, esophagus, and cervix; they are not found in the cornea, trachea, stomach,

or bladder. In humans, the number of LCs per unit of skin varies between 40,000 and 100,000/cm ^{2}. Their precursors originate in the bone marrow, and, in the mature stage, they are located in the suprabasal layers of the skin, within the epidermis, where they can be distinguished from kera-tinocytes on the basis of absent desmosomes and tonofilaments and from melanocytes by the absence of melanosomes.

The long dendritic processes form a continuous network. The nucleus is irregular and lobulated. The cytoplasm is clear and contains microfilaments and multivesicular bodies, as well as the unique Birbeck granule, which is rod shaped with periodic striations, giving it the appearance of a zipper. LCs are present in the dermal lymphatics, the marginal sinus, and the paracortex of draining lymph nodes, which suggests that these cells are mobile (see the previous discussion).

Mature LCs express a granule-associated antigen, E-cadherin ([285]), and HLA-D antigens. Ultraviolet irradiation depletes the skin of LCs and blocks the induction of contact sensitivity.

Veiled Cells

Veiled cells are present in the afferent lymph and resemble LCs ([286]). Their name derives from the possession of long, actively moving processes or veils that are approximately 100 nm thick. The veils do not contain organelles, and their movement must therefore be generated at a distance. Their nucleus is highly convoluted, and the cytoplasm contains bundles of microfilaments. Only approximately 4% of veiled cells contain a Birbeck granule, but all possess a large vacuole under the cell surface. They elicit a strongly positive response when they are tested for ATPase, and they resemble LC in the content of other enzymes. They are not actively phagocytic, but they possess Fc receptors.

After contact sensitization, Langerhans-like cells appear in the dermal lymphatics, and an increase in the number of veiled cells in the lymph that drain the area is noted. Once in the lymph node, most veiled cells localize in the T-cell–dependent areas, where they may function as interdigitating cells. Some veiled cells enhance the response of T lymphocytes to mitogens. Their function possibly consists of transporting antigens into the paracortical area, where they present them to T lymphocytes. Thus, a cellular chain for antigen transport exists in which more than one cell type takes part. Starting from the floor of the subcapsular sinus, antigen is localized first in cells that have the appearance of LCs, but, in deeper regions of the cortex, a second cell with morphologic characteristics of veiled cells has been identified ([287]). These two cells are similar to the cells that are known to migrate from skin areas to the paracortex ([288]).

Interdigitating Dendritic Cells

The T-cell–dependent areas of the lymphoid organs contain substantial numbers of DCs that are known as *IDCs* ([286]). They have a clear cytoplasm and an irregularly shaped nucleus and extend long dendritic processes to contact T cells. They express MHC class II antigens but do not express receptors for the Fc fragment of Ig and complement. IDCs are positive for CD83 and the S100b protein (cytoplasm). The name usually is reserved to describe cells that lack Birbeck granules.

Many common features are shared by IDCs and DCs from other compartments (e.g., skin and splenic white pulp). This led to the view that a single DC system exists in which the peripheral non-lymphoid organs' DCs migrate to the T-cell–dependent areas and become IDCs ([289]). This has been shown by labeling DCs that are isolated from the spleen of mice and injecting them into footpads. The labeled cells migrated to the periarteriolar sheath of the spleen or paracortex of the lymph node ([290]). DCs from the skin that is painted with hapten migrate within 24 hours to the lymph nodes ([291]).

Similarly, *Leishmania* parasites that are injected into the skin are found within IDCs in the T-cell areas of the lymph nodes, probably as a result of uptake of the parasites by skin DCs that migrated to the lymph nodes to become IDCs ([292]). In patients with skin allergies, one finds Birbeck granules in some IDCs of local lymph nodes. Also, the T-cell areas stain strongly for CD12, a marker that is expressed on LCs. This evidence supports the notion that LCs migrate from areas of the skin to the T-cell areas of regional lymph nodes. Transportation of antigen from the periphery to lymph nodes is not only characteristic of the skin DC but is also a function that is performed by intestinal DCs and other DCs in the periphery.

Follicular Dendritic Cells

Follicular dendritic cells (FDCs) are found in the follicles and germinal centers (GCs) of lymph nodes and were identified by a distinct dendritic pattern of antigen localization in the follicles ([293]). Antigen trapping in the follicles requires antibody with an intact Fc fragment and complement. The antigen that is so trapped persists for long periods, in contrast to the antigen that is captured by the medullary macrophages. Cytologically, the FDCs have an irregular nucleus, a narrow rim of cytoplasm, and filiform dendrites, giving the cell the sunburstlike pattern ([294]). On their surface, they express Fc and C3 receptors and MHC class II antigens.

Electron microscopic studies identified two FDC types: FDC with filiform dendrites, which mature to an FDC with beaded dendrites ([295]). After secondary immunization, FDCs form spherical particles that are called *iccosomes* (immune complex–coated body) (Fig. 18.10). The iccosomes are formed through interactions of two FDC types. One cell binds immune complexes, and the second cell with beaded dendrites binds to the areas of the complexes. Thus, the *bead* becomes coated with the complexes and the cytoplasmic membrane of the first FDC that carries the complexes. At this stage, the bead is filled with immune complexes and is subsequently detached as iccosomes that are dispersed among the cells of a developing GC. This process constitutes what is called the *alternative antigen presentation pathway* ([295]) to distinguish it from the more conventional antigen capture and presentation.

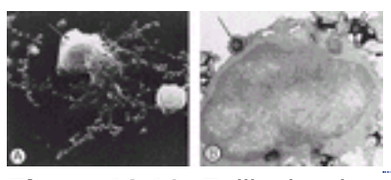

Figure 18.10. Follicular dendritic cell and iccosomes. **A:** Scanning electron micrograph that illustrates a follicular dendritic cell (*arrow*) with beaded dendrites. Each dendrite contains several iccosomes. **B:** Transmission electron micrograph of a lymphocyte from the germinal center with two iccosomes in contact with its surface *(arrows).* (From Szakal AK, Kosco MH, Tew JG. A novel in vivo follicular dendritic cell-dependent iccosome-mediated mechanism for delivery of antigen to antigen-processing cells. J Immunol 1988;140: 341–353, with permission.)

Antigen complexes are poor immunogens because they deliver a down-regulatory signal to the B cell that is related to the phosphorylation of the immune receptor Tyr-based inhibitory motif on the B-cell Fc receptor ([296]). However, the FDC strongly expresses FcR, and it is conceivable that, as FDC binds to complexes, it limits the available Fc on the complexes for binding to the FcR on B cells. FDC also delivers co-stimulatory signals to B cells, probably through complement-derived fragments, C3dg and C3d, which are associated with the FDC-bound complexes. Complement fragments bind on B cells to complement receptor 2 (CR2, CD21), which is a member of the CD19/CD21/TAPA-1 complex, a co-receptor of the B-cell antigen receptor (Chapter 16) ([297]). Thus, the FDC-associated complexes co-ligate the antigen BCR and the CD19/CD21/TAPA-1 co-receptor, providing two signals for B-cell stimulation.

The CD21 exists in two isoforms, one long and one short. FDCs express selectively the long isoform of CD21, whereas the short molecule is expressed by B cells. CD21 on FDC most likely participates in binding of complexes. The FDC-dependent B-cell stimulation is enhanced by IL-2.

FDC traps and retains large numbers of retroviral particles ([298]), which markedly alter the function of FDC and the anatomy of the follicle. Infected FDC brings the virus and CD4 $^+$ T cells together, promoting their infectivity. The antigen presentation function of FDC is lost, and, eventually, the cells are destroyed.

There are two views on the origin of FDCs: One proposes a hematopoietic origin, whereas the other proposes a mesenchymal-fibroblast origin. FDCs have a fibroblastic morphology and express certain molecules, such as vimentin and desmin, which are found in mesenchymal tissues. FDCs are also found in areas of chronic inflammation ([299]). As of today, there is no convincing evidence for either theory. For the time being, FDCs continue to be defined as the cells in the follicles of lymphoid organs that have the property to trap complexes of Ig and antigen. The reticulum cells within the GCs were thought to be different from those in the mantle, but, by ultrastructural studies, DCs in GCs and those of the mantle zone (or primary follicles) are considered to be of the same family ([300]).

GEOGRAPHY OF T-B CELL INTERACTIONS

Immune responses are regulated by the dose and the localization of antigen ([301]). Furthermore, for T and B lymphocytes that need to collaborate, recognition of antigen by their antigen receptors is not sufficient to activate them, but a second signal (co-stimulation) is required. T lymphocytes are in the paracortical areas, and the most abundant APCs in the paracortex are the IDCs.

The complexity of the mechanisms that are involved in activation of naïve T cells *in vivo* was elucidated with TCR transgenic T cells ([302]). When antigen is injected in the absence of an adjuvant, T-cell activation does not take place or is too small in intensity and short in duration and therefore is nonproductive. *Nature's adjuvants* are the DCs, which are interspersed in the tissues behind the physical barriers of the body. In these locations, DCs are immature but nevertheless are still phagocytic and are able to capture pathogens or their products. Under these conditions and further possible stimulation by inflammatory cyto-kines, DCs transform into mature DCs, and although they may have lost their phagocytic capacity, they have acquired two new important properties. First, they change their chemokine receptors to migrate to the T-cell areas of the draining lymph nodes. In addition, they acquire co-stimulatory molecules (CD80 and CD86), adhesion molecules (CD48 and CD58), and class II MHC molecules that are loaded with peptides from newly internalized antigens are expressed on the cell membrane. In addition to these molecular immunologic changes, morphologic signs of their activated state become apparent, with long cytoplasmic dendrites reaching out between T cells. This morphologic appearance contributed to their name as *IDCs.* Inflammatory cytokines, such as TNF-a, that are released from activated macrophages contribute to the activation of DCs ([303] , [304] and [305]) and up-regulate CD40 expression on DCs ([306]), which further promotes interaction with $CD40L^{+}$ T cells ([307]).

Activated DCs lead to significant immune responses, whereas immature DCs can be tolerogenic, as is shown with healthy human volunteers. Immature DCs inhibit $CD8^{+}$ T-cell immunity to viral peptide-specific IL-10–producing T cells ([308]). In contrast, mature DCs (triggered by a mixture of macrophage products, such as IL-1ß, IL-6, TNF-a, and prostaglandin E_2) induce functionally superior $CD8^{+}$ T cells and polarize CD4 T cells toward IFN-? production.

Maturational stimuli direct co-stimulatory molecules and MHC class II–peptide complexes to membrane microdomains (“lipid rafts”), where they are able to interact more efficiently with the CD28 and TCR as the DCs and T cells form the immunologic synapse (Chapter 17) ([309] , [310]). This is the *first cognate interaction*, which takes place between DCs and T cells in the paracortical area and results in full activation of T cells (Fig. 18.11). Co-stimulatory signaling amplifies the TCR signaling to as much as 100-fold, as T cells respond to lower doses of antigen (approximately 100-fold lower dose). The co-stimulatory pathway up-regulates bcl-x_L and prevents Fas-mediated apoptosis of newly activated T cells ([311]). Co-stimulation enhances production of IL-2 from activated T cells and induces expansion of antigen-specific T cells.

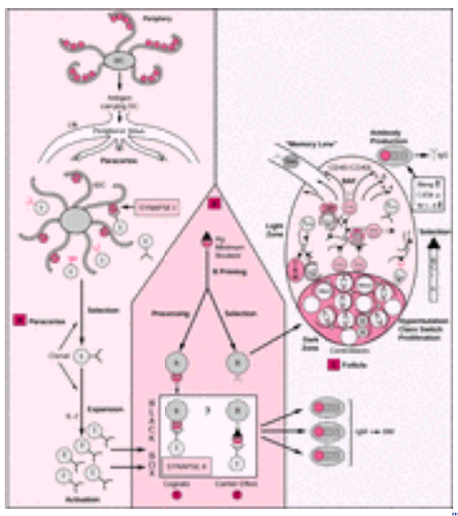

Figure 18.11. Chance and necessity: the germinal center reaction. Antigen (Ag) captured in the periphery by dendritic cells (DCs) is brought to the regional lymph nodes to be presented to naïve T cells (t) (synapse I). Clonally selected naïve T cells become activated by interleukin (IL)-2 (T). They up-regulate the CXCR5 receptor, respond to BLC chemokine that is secreted from follicular cells, and move toward or even inside of the follicle (Chapter 15). In the border between the paracortex and the mantle of the follicle, they interact with B cells. The interactions are not yet well characterized *in vivo*. Some B cells process antigen and may present it to T cells that are selected by DCs (synapse II) ([1]). B cells may have been selected by the same antigen but for a different epitope. B and T cells may bind to the same immunogen but on different epitopes (“carrier effect”) (synapse II) ([2]). Synapse II promotes differentiation of plasma cells that secrete immunoglobulin (Ig) M. B cells move inside the follicle to the pole that is adjacent to the T-cell zone (dark zone) and begin intensive proliferation. They are Ig negative and are called *centroblasts*. B cells undergo mutations in the V gene at a high rate (somatic hypermutation) (Fig. 18.14), and they change their IgM to another Ig class (class switch) (Fig. 18.13). When proliferation subsides, centroblasts move to the center of the germinal center—that is, the light zone—and are known as *centrocytes* (Ig positive). Their B-cell receptor (BCR) is submitted to the scrutiny of antigen-antibody complexes on dendrites of DCs of the densely populated light zone. In most centrocytes, somatic hypermutations have decreased or destroyed the affinity of their BCR and enter the pathway for apoptosis. Their corpses are removed by macrophages that are known as *tingible body macrophages (TBM)*. If the affinity is increased, they are given the green light for survival and growth (BAFF, IL-6, IL-4, CD40-CD40L). Surviving cells have higher affinity than their predecessors (*affinity maturation*). They receive signals from germinal center DCs or follicular T helper cells (T_{FH}). Depending on the instructions that are received, some centrocytes go down the memory lane, whereas others become plasma cells. Two genes are most influential in the regulation of germinal center reaction: B-cell lymphoma 6 (BCL-6) in the early phase represses all genes that regulate the second state; the B-lymphocyte–induced maturation protein-1 (Blimp-1) is released from repression when BCL-6 is down-regulated by high-affinity BCR signals. Blimp-1 regulates plasma cell differentiation. b, naïve B cell; B, primed, antigen-specific B cell; BAF, B-cell activating factor of the TNF family; BM, bone marrow; CIITA, major histocompatibility complex class II *trans*-activator molecule; IDC, interdigitating dendritic cell.

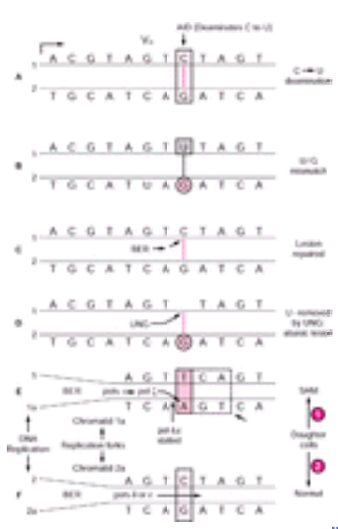

Figure 18.14. Somatic hypermutation. The immunoglobulin M of B cells that leave the bone marrow is of low affinity and has been selected before exposure to antigen. The need to improve the affinity is satisfied by another round of B-cell receptor diversification in the germinal centers, after exposure to antigen. In the dark zone of the germinal centers, mutations are introduced in the V gene at a rate of one million times faster than natural mutations; thus, it is called *somatic hypermutation* (SHM) (see the chapter text for details). During SHM, double-strand breaks occur in the DNA, as well as rapid gene transcription. Furthermore, for SHM, the immunoglobulin gene promoter is essential, as is an enzyme, activation-induced deaminase (AID). AID removes the NH_2 group of deoxycytosine (dC) **(A)**, forming deoxyuracil (dU) **(B)**. The change generates a dU/deoxyguanosine (dG) mismatch **(B)**. The lesion may be repaired by the base excision repair (BER) **(C)**, and mutation is prevented. However, dU may be removed by another enzyme, uracil-DNA glycosylase (UNG). In this case, the DNA strand remains in one spot that is unoccupied by any base (abasic lesion) **(D)**. High-fidelity DNA polymerases (pols) (i.e., ? or e) are stalled at the abasic lesions, and a promiscuous error-prone pol (i.e., ? or ?) takes over. It usually places a deoxyalanine (dA) on the sister chromatid, opposite to the abasic lesion **(E)**. The positioning of thymidine (T) opposite dA repairs the lesion, but pol continues over the lesion (“translesional pols”), altering the bases downstream. This generates a cluster of mutations that are close to the

dU excision. As a result, one of the daughter cells is normal **(F)**, whereas the other (with the abasic lesion) has mutational changes **(E)**. V_H, variable region of the heavy chain.

The factors that drive these two processes are the levels of MHC class II–peptide complexes and, therefore, the TCR stimulation and the intensity of co-stimulation; both are related to the stability of the synapse ([312], [313] and [314]). Recurrent and sustained exposures to antigen and to polarizing cytokines are essential for differentiation of $CD4^+$ T cells ([315]). Early withdrawal of antigenic stimulation arrests differentiation, even in the continued presence of cytokines. For T_H1 differentiation, prolonged signaling is required to induce appropriate epigenetic modifications to maintain high levels of T-bet expression (Chapter 17, see the section on T_H1 and T_H2 differentiation).

An important aspect of T-cell differentiation involves antigen selection of a TCR-restricted repertoire ([316]). This was clearly shown in the immune response against pigeon cytochrome C, in which the specificity is determined by the CDR3 of the TCR a-chain. Out of eight preferred CDR3 features that are rapidly selected early during the response, only one (TCR-a93 glutamic acid) existed to any significant extent before immunization. This TCR restriction and clonal dominance is antigen driven and is propagated by expansion of one or a few clones from the postthymic repertoire.

This selective T-cell expansion for effector and memory function takes place in the T-cell zone, before the GC reaction. Inflammatory cytokines, particularly IL-1 or TNF-a, also mediate some of these effects through CD28 co-stimulation by up-regulating expression of CD80 and CD86 on DCs.

After the peak of clonal expansion, the number of antigen-specific T cells falls owing to cell death, which may occur via Fas-dependent or activation-induced cell death ([316]). For the antibody response to continue, T and B cells, which are specific for different epitopes of the same antigen, must move from their separate locations to meet. Of the surviving activated T cells, most of them move out of the lymph node as memory T cells, but a small portion migrates to the edges of the paracortex next to the follicle, while B cells also move to the same location ([317], [318]). Chemokines and their receptors are the main regulators of primary immune responses, setting the stage for the main players, as well as orchestrating their performance. CCR-7 is the most important to organize the appropriate microenvironment to make the initial interaction possible ([319]). As multiple cells contribute to an immune response, change in the chemokine receptor program regulates the second stage in the cell interactions for antibody synthesis. CCR-7 is the receptor for chemokines SLC (6Ckine, exodus2, CCL-21) and ELC (MIP-3ß, exodus3, CCL-19). SLC is secreted by the cells of high endo-thelial venules and mediates the crossing of T cells to the lymph nodes. ELC is secreted by stromal cells of the paracortex and attracts naïve T cells to settle within the T-cell areas (Chapter 15). DCs in the peripheral tissues up-regulate CCR-7 expression as part of their maturation and are guided to the paracortical areas. The CXCR-5 is the receptor for chemokine BLC (CXCL-13), which is secreted by stromal cells in the follicles and attracts B cells that cross the high endothelial venules to settle in the follicular area. Activated $CD4^+$ T cells up-regulate CXCR-5 and migrate toward and into the follicles ([320], [321], [322], [323] and [324]). Whether the T-cell–B-cell interaction takes place on the paracortical side ([318]) or the follicular side ([317]) of the T-cell–B-cell border is not clear. The fact is that the two cells physically interact (*second cognate interaction*), forming a synapse by adhesion molecules and supported by co-stimulatory molecules, including the inducible co-stimulator (ICOS) on activated T cells and its counterreceptor B7-h on B cells ([325]).

GERMINAL CENTER REACTION

Interaction of B cells with activated T cells initiates their proliferation and migration into the area within the primary follicle, which is now called the *secondary follicle*. Some of the activated B cells differentiate at the edge of the T-cell zone into plasma cells, secreting IgM and migrating to the medullary cords and on to the bone marrow. Plasma cell differentiation in this area could also be induced in a T-cell–independent way, especially from antigens that are known as *T-cell–independent antigens*. The IgM antibody is part of the early phase of antibody production ([326]). The remaining antigen-specific B cells are recruited within the follicle and rapidly expand to form the *GCs* ([327], [328] and [329]). The GCs are oligoclonal, and, with a cell cycle time of the dividing B cells of approximately 6 hours, the number of accumulating blasts within 3 days is in the order of 1 to 1.5×10^4. During this exponential growth, the small recirculating B cells are excluded and are pushed aside to form the familiar *mantle* that surrounds the GC. By the time the B blasts finish their exponential growth, they have filled the FDC network that is close to the T-cell zone, which is known as the *dark zone*, and the B blasts are known as *centroblasts*. Centroblasts are Ig^- and give rise to nondividing Ig^+ cells, which are known as *centrocytes*, which occupy the center of the follicle or the *light zone*. Light zone has been divided into an *apical* (FDC $CD23^{2+}$) and a *basal* component (FDC $CD23^-$) (Fig. 18.12).

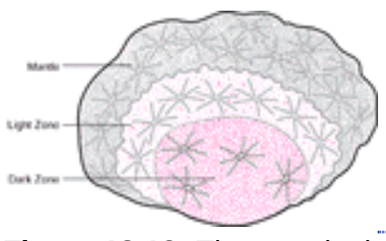

Figure 18.12. The germinal center. Dark zone: centroblasts in cell cycle. Light zone: strong expression of CD23 on dense follicular dendritic cell (FDC) network. Mantle: loose FDC network.

Several important events for the life of B cells take place in the GCs: *clonal expansion*, *somatic hypermutation (SHM)* resulting in affinity maturation, *Ig class switch*, and generation of *memory B cells* and *plasma cells*.

B cells express the CXCR-5 receptor for chemokine BCL and BCA-1 (CXCL-13), which is secreted constitutively by cells within the DC network and is home to the follicular area. Furthermore, the DC-specific chemokine CD-CK1 (CCL-18, also known as *PARC*) attracts preferably $CD38^-$ mantle zone B cells toward the FDC and may well provide the initiation signal for the formation of GCs ([330]). Responsiveness to the BCA-1 chemokine is also shown by a subpopulation of memory $CD4^+$ T cells that express the CXCR-5 receptor for the BCA-1 chemo-kine and, as a result, are attracted to the follicles. They are known as *follicular T helper cells (T_{FH})* ([321], [322] and [323]). The expression of CXCR-5 is transient and occurs before T-cell proliferation during T-cell activation.

DC-CK1 (CCL18), a chemoattractant for B cells and $CD4RA^+$ T cells, contributes to the multicellular interactions between DCs, T cells, and B cells in the initiation of humoral response. The FDCs are strongly positive for CD21 and CD23 and form a dense network in the light zone. In the dark zone, they are weakly positive for CD21 and negative for CD23, and they form a light network. The FDCs express the long isoform of CD21, which is the only specific marker for human FDCs, whereas the B cells express only the short isoform. FDCs trap immune complexes and present antigen to B cells, although the B cells can undergo somatic mutation and memory cell formation, even in the absence of complexes ([331]), probably by other signals that are received from FDCs, which support B cells in the immune response in several ways. Engagement of CD21 in the BCR by complement in the antigen-antibody complexes augments the stimulation that is delivered by FDCs ([332]). Furthermore, engagement of the Fc?RIIB on DCs diverts binding of the complexes from the same receptor on B cells. Fc?RIIB is an inhibitory receptor, and, thus, by trapping the complexes, the FDCs protect B cells from inhibition ([332]), although mRNA for Fc?RIIB could not be detected in B cells ([333]).

There is cross talk between FDC progenitors and B cells, because B-cell signals contribute to FDC maturation and network development. LT-a, LT-ß, TNF-a from B cells and TNFR-1 expression by some non–bone marrow derived cells lead to FDC cluster formation in the lymphoid organs ([334]).

Because FDCs have no phagocytic activity and do not synthesize MHC class II molecules, they are unable to present peptides that are complexed with MHC after processing of internalized antigens. However, there are two other ways that FDCs perform their antigen-presenting function. Cytochemically, antigen has been detected on FDCs along filiform or beaded dendrites. The beads, like pearls on a string, are particles that contain immune complexes, which are called *iccosomes* (immune complex coated body), which are usually detected in the early phase of the formation of the GCs ([295]). Complement in the complexes binds to CD21 on FDC (a member of the CD19/CD21/CD81 co-receptor complex), which delivers a crucial signal that dramatically augments the stimulation that is delivered by the binding of antigen to BCR. FDCs have no phagocytic activity and do not synthesize MHC class II molecules and therefore are unable to process antigen for presentation ([335]). MHC class II, however, has been detected on the surface of FDCs in the form of microvesicles that contain MHC class II molecules and other antigen that are foreign

to the FDC ([336]). These vesicles are exosomes that are enriched in MHC class II molecules and members of the tetraspan family (i.e., CD37, CD53, CD63, CD81, and CD82) (Chapter 2). The exosomes derive from multivesicular endosomes that are released by B cells with specificity for attachment to DCs and the ability to stimulate $CD4^{+}$ T cells ([337] , [338]). This is an interesting example of cell communication, antigen processing, and presentation for T-cell activation. FDCs therefore have a dual mission for B-cell response within the GCs: antigen processing and presentation to B cells and promotion of B-cell differentiation and isotype switching ([339] , [340]).

In addition to FDCs, T cells have a critical role in the GC formation, primarily for the late stages of GC reaction and not during the initial development ([341] , [342]). GCs that are induced in the absence of T cells are of short duration, and the V genes of the antibodies do not undergo hypermutation. The GCs abort dramatically at the time when T cells normally select the high affinity B cells ([341]). The demise of the GCs at this point is a fail-safe mechanism to prevent autoreactive B cells from escaping in the periphery with development of autoimmunity.

In the dark zone, lymphocytes are densely packed, and only fine FCD processes penetrate this area. The FDCs in the dark zone are $CD23^{-}$ and only weakly $CD21^{+}$. The centroblasts are in rapid cell cycle and do not increase in number but give rise to a progeny of *centrocytes* that are nondividing and express surface Ig. Centrocytes are located in the light zone and are CD21 strongly positive and CD23 moderately to strongly positive. In this stage of the evolution of the GC, the B cell is selected for survival or death, based on the affinity of the antigen receptor as the cell emerges from changes that are induced to the receptor by hypermutation (see the following discussion).

B Cells in Germinal Centers: Struggle for Survival

Proliferation of B cells in the GCs is stimulated by antigen, but different mechanisms regulate the proliferation in the two GC zones, dark versus light. The paucity of T cells in the dark zone suggests that this early, expansive B-cell phase is supported by strong stimulatory signals from complement-containing immune complexes, FDC–B-cell cognate interactions, and soluble factors from FDCs ([343]). In the light zone, T_{FH} cells play a more important role, and, although the density of FDCs is much higher, some FDCs are inhibitory for B-cell activation. GCs after primary immunization develop within 4 to 6 days, and centroblasts in the dark zone continue to maintain a high output of centrocytes for 7 to 14 days ([344]). The centroblasts undergo SHM that results in antigen receptor diversification.

The decision between life or death, a process known as *selection*, takes place within the light zone as the B cell emerges from the dark zone. The mechanism of selection is not yet clear, but antigen that is trapped on FDCs is used to “test” the affinity of the BCR of the centrocytes. A key determinant for selection is the CDR3, which has a major contribution to diversity and affinity of the receptor. Structurally identical receptors are handled differently if variations in CDR3 exist between them, and such variations drive the selection process ([345]). The vast majority of these random mutations is deleterious to antigen binding and destroys or diminishes the affinity of the BCR that existed when the antigen-specific B blast entered the dark zone from the paracortex-follicular border. These cells are negatively selected and are diverted to apoptosis.

Other cells have acquired autoreactivity, and these cells receive no signals from FDCs and therefore die from “neglect” ([346]). Of the cells in which BCR expresses reactivity with antigen, some emerge from the mutational process with high affinity, and only those are positively selected to achieve *affinity maturation*. Affinity maturation was discovered 35 years ago ([347] , [348] and [349]) and remained poorly understood until somatic diversification of BCR genes in the GCs was demonstrated ([350]). Affinity maturation signifies the increase of the affinity of antibodies between those that are produced early after primary immunization (low affinity) and those that are produced 2 weeks after immunization or better after secondary immunization (high affinity). Affinity maturation is associated with somatic diversification that occurs during hypermutation. As shown from studies in mice, the D and J regions of the H chain (16 amino acids long) of the antibodies that are synthesized 7 days after immunization have no residue changes that could be attributed to mutations. However, in the 14 days, antibodies carry somatic mutations that have caused an increase in the affinity ([351] , [352]). Positive selection of these high affinity antibodies constitutes affinity maturation.

Survival of the Fittest

One of the puzzling phenomena that is related to the life of B cells after their release from the bone marrow is the fact that approximately 70% of them do not reach maturation and die. B-cell survival and maturation relies on the delivery of signals, most importantly through BCR, and survival depends on a mechanism of positive selection ([353]). The immature B cells that leave the bone marrow undergo a progressive maturation process that takes the cell through three stages, which are known as *transitional stage type 1 (T1)*, *type 2 (T2)*, and *type 3 (T3)* ([354] , [355]). T1 cells are IgM^{hi}, IgD^{-}, $CD23^{-}$, and $CD21^{lo}$, and T2 cells are IgM^{hi}, IgD^{hi}, $CD23^{+}$, and $CD21^{hi}$ ([356]).

Although the location and mechanism by which this huge number of B cells perish has not been identified, it is possible that a prime location is the light zone in which the mechanism of cell death is by apoptosis as a result of a BCR that is incapacitated by hypermutation.

B cells require and receive multiple signals from different cells and molecules for survival. The cognate interaction between FDCs and B cells provides signals through antigen presentation (albeit weak), as well as through several receptor-ligand pair interactions, such as ICAM–lymphocyte function–associated antigen-1, vascular cell adhesion molecule-1–very late antigen-4, and CD23-CD21 ([357]).

In addition, DC stimulates B-cell proliferation and Ig synthesis, which are mediated by the CD137-ligand system ([358]). CD137 is a member of the TNF receptor family that is expressed by FDCs and stimulates the CD137 ligand–expressing B cells by reverse signaling.

Long Live the BAFFled Germinal Center B Cell

An important, recently described B-cell survival factor that is known as the *B-cell activation factor member of the TNF family (BAFF)* promotes maturation of B cells and prolongs their survival and, under certain conditions, B-cell growth ([359] , [360] and [361]). BAFF is also known as *B-lymphocyte stimulator*, *TNF and apoptosis ligand-related leukocyte-expressed ligand 1* ([362]), or *TNF homolog that activates apoptosis, NF-?B, and c-Jun NH* $_2$ *-terminal kinase* ([363]). BAFF forms a trimerlike TNF, as other members of the family, but its unique feature is the presence of two Mg^{2+} ions. The gene for BAFF is located in human chromosome 13q34, a location that is frequently involved in translocations in Burkitt lymphoma. BAFF exists as a membrane-bound form and as a soluble form. It is closely related (approximately a 50% similarity) to another TNF family member, a proliferation-inducing ligand (APRIL). Both BAFF and APRIL bind to two receptors, B-cell maturation antigen (BCMA) and transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI) with high affinity, but preferences by the ligands have been detected ([364]), with BAFF being associated more often with TACI and APRIL than with BMCA ([365]). A third receptor, which is called *BAFF-R*, binds selectively BAFF and not APRIL. BCMA, TACI, and BAFF-R are located on human chromosomes 16p13.1, 17p.11.2, and 22q13.2, respectively.

Structural analysis of the three receptors and the phenotypes of mice that are deficient in each one have shown that BAFF transmits the survival signal to transitional cells through the BAFF-R and not through BCMA or TACI ([366]). All three receptors are devoid of death domains, and BAFF-R is devoid of TNF receptor-associated factor (TRAF) binding domains. TRAFs are adaptor proteins that mediate transmission of downstream signaling in the activation of NF-?B and mitogen-activated protein kinase (MAPK) pathways. BMCA, however, activates NF-?B through binding of TRAF-5 or TRAF-6 but not TRAF-2 ([367]).

Action of NF-?B is associated with strong antiapoptotic function that regulates the end stages of B-cell maturation, Ig class switching, GC organization, and other processes ([368]). In the absence of the TRAF binding domain, BAFF-R uses the C-terminal sequence for survival signaling. Replacement of the last C-terminal amino acids results in loss of BAFF-R function and of peripheral blood B cells in mice (strain A/WySn) ([369]).

The mechanism of action of BAFF is not stimulation of B-cell proliferation but promotion of survival, probably by increasing BCL2 expression ([370]). Loss of signaling by NF-?B blocks up-regulation of BCL2. Mice that are deficient in c-Rel and Rel A, which are members of the NF-?B family of transcription factors, have a block of B-cell maturation and are similar to mice that lack BAFF or BAFF-R. BCL2 expression rescues these mice from B-cell deficiency ([371]). BAFF acts on the T2 transitional stage of B-cell maturation and on marginal-zone B lymphocytes. In mice that are transgenic for BAFF, the T2 and marginal-zone compartments of B cells are enlarged. The effect of BAFF on various transitional stages of B cells is regulated by different downstream mediators, mainly, however, by up-regulation of the

antiapoptotic genes A1 and bcl-x $_L$ in marginal zone cells. The net result is a proportional increase in the survival of the cells that traverse each stage ([372]).

An important consequence of protracted action of BAFF is the development of autoimmunity as a result of excessive survival of T2 B cells. The levels of BAFF in the sera of patients with SLE, rheumatoid arthritis, and Sjögren syndrome are elevated ([373] , [374]). In some of these patients, the BAFF and APRIL have been found in the serum in the form of active heterotri-mers ([375]). The pathogenetic relationship between these two members of the TNF family and the levels of various autoantibodies was shown by the fact that their levels were correlated with titers of the autoantibodies in Sjögren syndrome, such as the levels of Ig, rheumatoid factor, and anti–skin-sensitizing antibody ([376]).

Chronic infection may lead to sustained release of BAFF and emergence of autoreactivity. BAFF therefore appears to be critically involved in certain antibody-mediated autoimmune diseases. Most studies have concentrated on the roles of BAFF and APRIL on B cells. However, APRIL also acts on T-cell survival by a mechanism that involves up-regulation of BCL2 ([377]) and BAFF; although it does not appear to deliver a typical survival signal, it acts nevertheless on T-cell co-stimulation ([378]).

APRIL is up-regulated in many tumors (colon, prostatic carcinoma) and promotes tumor growth ([379]), but a soluble form of BCMA and TACI counteracts the action of APRIL and inhibits tumor growth ([380]). The enhancement by APRIL of tumor growth may be due to up-regulation of BCL2 or signals that are delivered by inflammatory cells in the neighborhood of the growing tumors by cells, such as monocytes (which express APRIL), that provide optimal conditions for growth of some tumors, such as Burkitt lymphoma ([381]).

The tumor promoter function of APRIL contrasts to functions of many other TNF-related ligands. The difference in the level of expression of APRIL between normal and neoplastic cells is dramatic. Because adenocarcinoma cells lack any detectable expression of BCMA or TACI, it is likely that another APRIL receptor exists in these tumors. Because BAFF and APRIL promote the survival of B cells and the development of autoimmunity, the inflammatory milieu of an autoimmune reaction supplies paracrine signals for the development of malignancies on an autoimmune background ([365]), a connection that was identified clinically many years ago ([382]).

Follicular T Helper and Germinal Center B Cells

The CD4 $^+$CD45RO $^+$ recently activated T cells in the blood cross into the lymph nodes, and, because they have down-regulated CCR-7 and have acquired instead the CXCR-5 receptor, they respond to the call from DCs in the GCs—that is, to chemokine CXCL-13 (BLC and BCA-1) ([321]). In the GCs, they become known as *T $_{FH}$ cells*. In this location, T $_{FH}$ cells express high levels of CD40L, a co-stimulatory molecule that is required for B-cell activation and Ig class switch, as well as for the induction of ICOS. CD28 is required for naïve T cells to differentiate into effector GC T cells and for subsequent primary antibody response. Secondary B-cell responses and continuous B-cell activation depend on the CD28 homolog, ICOS—that is, T-cell help is delivered for B cells in an orderly sequence of interactions ([383]). The importance of ICOS for sustained B-cell proliferation is reflected in the ICOS deficient mice that have no GCs after secondary immunizations.

Memory T $_H$ cells, after repeated antigenic challenges, emerge with restricted V-region genes and preferred CDRs that confer peptide specificity ([384]). The memory T cell acquires a functional potential of cytokine secretion early in the primary response, but the delivery of these functions is highly regulated and complex.

T-cell memory is an “operational property of the whole animal or immune system” ([385]), and, under this broad definition, the requirements for its maintenance and the delivery of specialized functions, although precisely regulated, depend on complex microenvironmental influences.

B-cell proliferation and differentiation is down-regulated by cytotoxic T lymphocyte–associated protein-4 (CTLA-4), a negative regulator for B-cell proliferation. CTLA-4 is sequestered in a late or post-Golgi endosomal compartment and is available for rapid delivery to the cell surface, where it interacts with B7 ligands ([385]). Interaction with B7 causes phosphorylation of one of the Tyr-containing sequences of CTLA-4 that binds the SRC homology 2 (SH2) domain of the Syp phosphatase. Syp dephosphorylates signaling molecules in the vicinity of TCR, dampening or inhibiting completely the TCR signaling pathway ([386]).

CD40 and CD40 Ligand (CD154) Interactions

CD40 and CD40L (CD154) are members of the TNF superfamily and play a crucial role in T-dependent and T-independent humoral immune responses. The CD40 gene is localized in chromosome 20q11-13.2. CD40 is homologous to TNF receptor, and CD40L is homologous to TNF. [For details of the structure and expression of CD40 and CD154 (CD40L), see Chapter 2].

CD40 is expressed on DCs and B cells, and CD154 is expressed on T cells. The CD40-CD154 interaction is critical for T-cell activation and development of the T $_H$1 and T $_H$2 responses ([387] , [388] , [389] and [390]). The extracellular region contains four Cys-rich domains, and the intracellular region contains distinct sites for binding the adaptor proteins, TRAF-1, TRAF-2, TRAF-3, TRAF-5, and TRAF-6 and a separate site for direct binding of Jak-3 (the Janus family of protein Tyr kinases).

CD40 engagement delivers signals along two broad pathways: TRAF dependent and TRAF independent. TRAFs are adaptor proteins that link the receptor to signaling molecules and mediate specific biological responses. The specific functional outcomes of CD40 engagement extend to a huge territory of cell biology in general and of B cells specifically, such as clonal expansion, activation, chemokine and cytokine secretion and responsiveness, Ig production, and Ig class switch. The reader is referred to the reviews that were cited previously.

The functions that are induced by CD40 engagement are the result of activation of several transcription factors, more importantly NF-?B, AP-1, and c-AMP response element. Ligation of CD40 on B cells results in proliferation or apoptosis, depending on the differentiation state of the B cell, particularly by linking to different TRAF adaptor molecules. For example, in murine B cells, multimers of TRAF-2 mediate apoptosis, whereas TRAF-3, TRAF-5, or TRAF-6 stimulates proliferation. CD40 induces homotypic adhesion between B cells through expression of lymphocyte function–associated antigen-1-ICAM-1, or CD23-CD21. The same molecules can also mediate interactions between B cells and T cells or DCs.

Important contributions of CD40-CD154 interactions in humoral immunity are the regulation of APC functions, GC formation, Ig synthesis, and Ig class switch ([391] , [392]). A central role in several of these functions of CD40 is played by the duration of expression of the ligand of CD40 by the T cells ([393]). Some memory T cells have preformed CD154 that can be rapidly expressed on the surface after T-cell activation ([394]).

Expression of CD154 for a limited time allows B cells to terminally differentiate and secrete antibody. T $_H$1-differentiated cells express CD154 for longer than 3 days and suppress antibody production, whereas activated T $_H$2 memory cells express CD154 for less than 12 hours and allow antibody to be produced ([393]). Expression of CD154 on T cells is reciprocally regulated by cytokines; although IL-12 sustains CD154 expression, IL-4 represses CD154 expression. These findings provide an explanation for a controversy in the past: whether CD40 engagement promotes ([395]) or inhibits ([396]) B-cell differentiation and Ig secretion. It is clear now that prolonged engagement of CD40 inhibits secretion of Ig ([396]).

Multimers of TRAF-3 and TRAF-5 mediate the signals for T-dependent humoral responses.

Signaling events from CD40 engagement without TRAF involvement are still unclear. CD40 ligation leads to phosphorylation of several protein Tyr kinases, such as Lyn, Blk, Btk, and Syk. Jak-3 binds directly to CD40, but the role of signaling by this pathway remains controversial. Btk leads to expression of CD80 and CD86 after CD40 ligation.

In general, signaling through TRAFs seems to be more important for the CD40-mediated functions.

IMMUNOGLOBULIN CLASS SWITCH

Class or *isotype switch* refers to the change of the H chain of the antibody molecule, by the constant domains of another H chain class. When the antibody changes to another Ig class, it still retains the entire L chain and the V domains of the H chain. In other words, the antibody retains the same specificity for antigen but changes all

effector functions that are determined by the H chain domains, such as complement fixation, and phagocytosis ([397]). The change involves a recombination of H chain genes that results in deletion of DNA. It is called *switch recombination*, as it occurs between the *switch (S) regions*. Class switch affects all Ig classes except IgD, which has no S region of its own and is coexpressed with IgM by termination of transcription and RNA processing. Switch recombination occurs in mature B cells after exposure to antigen, T dependent or independent; simply by T-cell signals alone in the absence of antigen (i.e., CD40 and CD40L); or by cytokines. Before switch recombination, RNA transcripts of germline genes of the constant region of the H chain (C_H) are detected from the same isotype at which switching takes place. Transcription initiates within the promoter of the intronic (I) exon, proceeds through the S region, and terminates in the 3' end of the C_H gene, at the poly (A) site of secreted or membrane C_H gene ([398]) (Fig. 18.13).

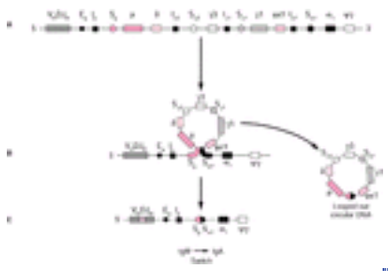

Figure 18.13. Class switch recombination (CSR). In CSR, the surface immunoglobulin (Ig) M of the B cells is replaced by an Ig of another class. The IgM gene, which is located in the variable region of the heavy chain (V_H) proximal end of the constant region of the light chain (C_H) gene cluster **(A)** is replaced in that position by a gene of another class. In the 5' side of each C_H gene is the S region (switch) **(A)**, followed by a specific intronic (I) promoter, which regulates cytokine-induced transcription of the target gene. The intronic enhancer (Eμ) makes Sμ accessible for recombination with other downstream S regions (“accessibility model”). Beyond accessibility, an enzyme that is known as *activation-induced deaminase (AID)* (Fig. 18.14) is involved in CSR. The contribution of AID is not yet clarified, but AID deficiency in mice blocks completely CSR, although germinal center reaction is still intact. The S region of the new Ig gene is brought in juxtaposition to Sμ, and the intervening sequence is looped out **(B)**. The new C_H is brought in next to the V_H **(C)**. The new Ig has the same specificity (V_H) but possesses different biological functions that are dictated by the C_H.

A unique sequence 5' to each I exon determines the selectivity of the switch recombination, acting as the site for binding of a series of regulatory proteins that are expressed after activation. The I region targets class switching to specific S regions that initiate transcription ([399]), and an intact I region is required for recombination. The factors that initiate recombination confer accessibility of the switch *recombinase* to the C_H locus (*accessibility* model) ([397]). Basically, what *accessibility* means is that the gene that undergoes switching must be transcriptionally active and therefore accessible. Although accessibility allows transcription, which is targeted to a specific S region to be initiated, it is not the only operating mechanism in class-switch recombination (CSR) ([400]).

Understanding CSR took an unexpected turn with the discovery that CSR and SHM are mediated by the same or similar mechanisms ([401] , [402]). An enzyme that is known as *activation-induced cytidine deaminase (AID)* is an RNA-editing enzyme that is induced after cell activation ([403] , [404] and [405]). RNA editing is a posttranslational modification of RNA. The type of editing that occurs in mammalian cells involves deamination of a base that converts it to another base (e.g., cytidine to uridine or adenosine to inosine). Usually, the editing enzyme is associated with other proteins, forming an editing complex or editosome. AID is structurally similar to the RNA-editing enzyme, APOBEC-1, which deaminates deoxycytidine. APOBEC-1 is involved in editing of the mRNA for apolipoprotein-B, generating a new mRNA that encodes a protein, which is an essential component of chylomicron. B-cell activation is important for the induction of CSR recombinase and the selection of the target S region. Both of these events are absolute requirements for CSR.

Activation of the B cell usually occurs through BCR or CD40/CD40L or a cytokine. CSR has always been considered highly dependent of CD40L, and IgG, IgA, and IgE production is severely impaired in the X-linked hyper-IgM (HIGM) syndrome (see the section Hyper–Immunoglobulin M Syndrome). The CSR activation through CD40/CD40L is T-cell dependent, because CD40 signaling depends on its ligation by the CD40L that is expressed on T cells. Viral glycoproteins and bacterial LPSs can stimulate IgG and IgA production in the absence of CD40L-expressing T cells. A more physiologic T-independent CSR is induced by DCs through BlyS and APRIL ([406]).

A cytokine that selects a specific S region as a target activates the I promoter located 5' to the S region of that isotype and induces the germline transcripts that contain the I and C_H exons. The S region is removed by splicing, leaving the 5'-$I_H C_H$-3' germline RNA. Each cytokine selects a specific I promoter.

Cytokines direct switching for certain Ig classes; IL-4 specifically directs switching to IgG4 and IgE, whereas IFN-? antagonizes some of the effects of IL-4 on germline transcription. TGF-ß increases IgA transcripts followed by IgA switching.

Upstream (i.e., 5') of the I exons are sequences that are considered as sites of action of cytokines, which generate DNAase hypersensitive sites to be used for germline transcription.

For example, IL-4, which is a switch factor for IgE, binds to the IL-4 receptor and activates the Jak kinases. The Jak kinases induce the signal transducer and activator of transcription (STAT)-6, which binds to IL-4 responsive elements that are found upstream of the IgE gene and switch on IgE transcription.

The S regions that are used for CSR consist of tandemly repetitive units with many palindromic, that is, inverted, repeats. S regions are essential for CSR and in all isotypes have similar sequences that are recognized by the CS recombinase. These sequences form stem-loop structures when the DNA is single stranded. Therefore, CS recombinase may recognize the secondary structure of the S region DNA rather than the primary sequence. In this respect, it differs from V(D)J recombinase, which targets consensus heptamer and nonamer sequences around the V, D, and J segments. In CSR, the germline transcripts and AID are not sufficient to induce class switch, as was originally thought ([407]), but *trans*-acting factors may play a role ([400] , [408]). These *trans*-acting factors are thought to act as docking proteins that recruit AID to the S regions ([409] , [410] and [411]).

The initial event in CSR is a double strand, blunt, or staggered break that produces 3' or 5' overhangs. If, for example, the class switch is between the IgM constant gene and IgA-1 constant gene (Fig. 18.3), CSR brings the IgA heavy chain gene ([1]) close to the V ($V_H DJ_H$) gene. Thus, after the IgM/IgA class switch the IgA antibody has the same specificity as the IgM. The intervening DNA sequence between the Sμ and Sa regions forms a circular structure that is looped out ([402]). The circular DNA that is looped out includes the I promoter of the target S region, which is driven by specific cytokine stimulation before the CSR. This I promoter is still active in the looped-out DNA and directs production of transcripts, termed *circular transcripts*, which depend on the expression of AID. Circular transcripts may be used as a hallmark of active CSR ([411]) and were detected in the majority of patients (14 out of 20) with CLL. This indicates that some cells of the clone are able to differentiate *in vivo* along the pathway that induces CSR ([412]) by stimuli provided from bystander immune cells. The double-strand break (DSB) repair machinery is recruited to repair the DNA breaks. Since the S regions are heterogeneous in nature, the joining of the DNA is completed by the nonhomologous end-joining (NHEJ) system. Mutations in the NHEJ system inhibit class switch ([413]).

NHEJ is a process that rejoins DNA breaks with the use of little or no homology. There are five proteins that operate in NHEJ: Ku70, KU86, and DNA-dependent protein kinase (DNA-PK). DNA-PK consists of a catalytic subunit (DNA-PK_{CS}) and a DNA-binding component that is called *Ku*, itself a heterodimer of 70- and 80-kd polypeptides. The protein kinase activity of DNA-PK is activated when Ku binds to altered DNA structures, such as DSB, nicks, or hairpin loops ([414]). Mice that are deficient in Ku80 exhibit severe combined immunodeficiency (SCID) and defective processing of V(D)J recombination intermediates. DNA-PK is a member of PI3K family of kinases.

The discovery of the mechanism of CSR is a major advance in our understanding of the complexity of mechanisms that are used by the immune system in the diversification of genetic information to meet the needs and challenges by pathogens ([402] , [415] , [416]), and it is even more intriguing that the same machinery that is used for CSR is also used for a second diversification mechanism that takes place also in the GCs, SHM ([401] , [402] , [417]).

SOMATIC HYPERMUTATION

The first diversification of genetic information in B lymphocytes takes place in the bone marrow during B-cell development. It involves the building of a BCR by random selection of a few DNA segments that are joined by V(D)J recombination. The assembly of these segments constitutes the *combinatorial diversity (CD)*. CD is enhanced further by the addition during the repair of the cut ends of the DNA of palindromic and nongermline nucleotides that generate another level of diversity, the *junctional diversity*. (See Chapter 16, Figure 16.5.)

When the IgM $^{+}$ B lymphocyte moves out of the bone marrow to the real world of the secondary lymphoid organs, it finds itself not well prepared to meet the existing challenges. It further diversifies its BCR during the evolution of the immune response within the GCs by two additional mechanisms: antibody CSR and SHM. Both of these pathways of diversification use similar mechanisms, with a prominent role played by an enzyme, which is known as *AID*, that functions as a deaminase and is induced after cell activation. Under conditions of stimulation of murine splenic B lymphocytes (e.g., LPS or IL-4, which do not induce SHM), large numbers of mutations were detected in the 3' subregion of the Sµ region (417). The Sµ mutations are independent of the CSR, because they are detected in the Sµ of switched and unswitched alleles. These mutational changes of Sµ have been considered similar to the mutations that are introduced by SHM during B-cell activation in the GCs (418). Comparison of the amino acid sequence of L chains from mouse myeloma proteins, with the sequence of the same gene from bone marrow B cells (germline) confirmed that the amino acid differences have occurred as a result of mutations (419). SHM is the mechanism by which the affinity of antibodies increases after antigen stimulation, a phenomenon that was discovered in the late 1960s and has been known as *affinity maturation* (348).

The mutations are largely confined to the V domains (420, 421) and occur in the framework regions, as well as the hypervariable regions. They also tend to occur on some residues (hot spots) more often than on others. Hot spots of SHM overlap with the CDRs, which directly contact the antigen. However, the SHM mechanism does not seem to target a specific sequence, because SHM has even been detected in other molecules, such as the BCL6 gene (422), Iga, and Igß genes (423) and CD95 (424), or even in completely artificial sequences that are inserted into an Ig? transgene (425). Comparison of the mutability of triplets shows that some are more often targeted than others. For each of the triplets, one can calculate an expected ratio of replacement (R) to silent (S) mutations. For example, in triplets that encode glycine (Gly), six of the nine possible nucleotide substitutions result in an amino acid replacement mutation that gives an R:S value of 2 (6/3). In the case of histidine, eight out of nine possible substitutions generate an amino acid exchange, and the ratio is 8 (8:1). Evolution has selected for CDRs in which the codon usage leads to a high ratio of R:S mutations. Those are mutations that are likely to affect the antibody-binding site, and the R:S value in the CDR is used as a marker for affinity maturation.

The process of SHM occurs during the period in which the B cell undergoes a high rate of divisions (approximately one every 6 hours); this period is observed in the dark zone of GCs and is also linked to transcription, with which it is positively correlated (426). GCs have been considered the centers of hypermutation (427), although in lymphotoxin-a–deficient mice that lack GCs, mutations can still be induced with strong antigenic stimulations (428). The nature of the signals that are necessary for SHM is not well understood. CD40/CD40L interaction is important for the development of GCs and for proliferative activity, both of which are requirements for SHM. Under conditions *in vitro* that allow SHM to take place, three signals have been identified to be required: signals from anti-Ig, anti-CD40, and anti-CD38 (429).

With the use of several phenotypic markers, the B lymphocytes have been separated into different groups that represent different stages of B-cell differentiation. The majority of the B cells in humans expresses IgM (as much as 90%) and can be distinguished into IgM $^{+}$/IgD $^{+}$, IgM $^{+}$/IgD $^{-}$, and IgM $^{-}$/IgD $^{-}$ groups.

The IgM $^{+}$/IgD $^{+}$ do not carry mutations, except for a subpopulation that expresses CD27 (430). IgM $^{+}$/IgD $^{+}$ B cells are newly released from bone marrow and are considered still antigenically inexperienced. The two other groups IgM $^{+}$/IgD $^{-}$ and IgM $^{-}$/IgD $^{-}$ have mutations and therefore belong to their postGC lymphocytes (431).

Mechanism of Hypermutation

The hypermutation domain—that is, the region in which mutations occur—spans 1.5 to 2.0 kb downstream of the Ig promoter (Fig. 18.14). The frequency of the mutations increases in the 5'- to 3'-direction, peaks over the V(D)J recombination site, and then decreases toward the J-C junction. The 5' boundary near the promoter is sharp, but the 3' boundary near the enhancer region is less well defined. The I enhancer is the only sequence in the Ig gene cluster that is irreplaceable and must be in the correct orientation. The need of the enhancer provides the explanation of the strong correlation of SHM with the transcription process. The mutation rate is 10^{-3} to 10^{-4} base pairs per generation, that is, six orders of magnitude higher than the spontaneous mutations (432). The mutations are usually point mutations, but insertions, deletions, or duplications also occur (431, 433). Although mutations are limited within the boundaries of 1.5 to 2.0 kb, they tend to exhibit a characteristic nucleotide substitution preference, which affects not only the primary sequence, but also secondary structures, such as hairpin loops, which are encoded by palindromic motifs. In spite of these preferences, the sequence of the V gene itself does not initiate the mutation, because artificial substrates hypermutate successfully (434).

Two steps have been considered important for SHM: (a) *DNA cleavage*, which results in DSBs, and (b) *DSB repair*, which is done by an error-prone mechanism (435). It is recognized that (a) DSBs occur in hypermutating sequences (hot spots), (b) they are coupled to transcription, (c) they depend on the presence of the Ig enhancer, and (d) they correlate with the appearance of nearby mutations (436, 437). The DSBs are restricted to cells that have completed or almost completed DNA replication and need to be repaired before the end of cell division. In eukaryotes, there are two DNA repair mechanisms: homologous and NHEJ, each of which is used in distinct phases of the cell cycle. The NHEJ is used in G_1 to S phase, and the homologous recombination is used in late S to G_2 phase.

In V(D)J recombination, the DNA breaks occur in the G_1 phase and are repaired by the NHEJ that is activated in the same period of the cell cycle. SHM occurs during the G_2 phase (438), when a sister chromatid is present, and homologous recombination is active, whereas NHEJ occurs in the absence of such a template. The precise phase of the cell cycle for introduction of mutations, however, is not yet agreed on, because they have also been detected during the G_1 phase (439). For SHM, the AID is necessary, because AID deficiency impairs SHM. The relationship of AID to the DSBs is not clear, and AID probably makes no contribution to their generation (440), because, according to some evidence, AID acts after their occurrence (436). Furthermore, DSBs occur with the same frequency in rearranged and germline genes, and yet SHM is preferentially attracted to the rearranged genes (441), which suggests that DSBs do not express any functional affinity for AID attraction. AID has landed on the stage of SHM only recently, evokes considerable wonder, and attracts massive attention. AID's activity is well understood, but its role in SHM remains elusive (442).

Another approach in search for answers for the SHM mechanism concentrates on polymerases (443). Most mutations in SHM are point mutations, but deletions, insertions, or duplications of DNA segments are also common. These changes are recognized as the signature for a DNA polymerase (pol) and are considered as strong evidence against an SHM mechanism that invokes a base-modifying enzyme or chemical DNA modification. Based on these arguments, the SHM could be the result of a DNA polymerase with poor discriminatory capacity for bases. Such a polymerase could be one of the Y family of DNA polymerases—pol ?, pol ?, pol t, pol ? (444)—that are specialized for bypassing DNA lesions (translesional polymerases). Some of these polymerases have been implicated in SHM (445, 446, 447 and 448).

Pol ? is significantly error prone when it copies normal DNA and makes, on the average, several more mistakes than a stringent polymerase (448). Patients with a null mutation of pol ? present a variant form of xeroderma pigmentosum with a propensity for skin malignancies (449). These sloppy polymerases have the capacity to bypass a DNA lesion, which may otherwise bring the DNA replication to a halt and the cell to its death. However, during the replication of normal DNA, they are notoriously unfaithful in the selection of bases.

Where does AID fit into this scenario? AID may function in signaling processes or in editing key molecules in B-cell differentiation in the GCs (see the section Hyper–Ig M Syndrome), at the mRNA level or by direct alteration of the target V gene, at the level of the RNA transcript. However, some recent results point out another pathway that is opened to AID in CSR and SHM. AID, as mentioned earlier, is a deaminase that converts deoxycytosine (dC) to deoxyuracil (dU) (Fig. 18.14A, Fig. 18.14B). This conversion takes place during transcription of target genes and affects only the nontemplate DNA strand that is exposed as single-stranded DNA during the elongation reaction. This evidence supports once more the direct relationship of transcription and mutations that are linked by the deamination function of AID (450). As a result of this function, AID creates a dU/deoxyguanosine (dG) mismatch or lesion in the DNA, which needs to be repaired. A major mechanism in the resolution of the lesion is excision of the uracil, which can be accomplished by several enzymes, one of them being a *uracil-DNA glycosylase*

(UNG) ([451]). UNG is the major DNA glycosylase in the mouse that processes programmed dU/dG lesions in the Ig genes ([452]). If the dU that is created by AID is removed by UNG, an *abasic site* (AP) is generated (Fig. 18.14D). If the base excision repair mechanism (BER) arrives first, ahead of the replication fork, a nick or a gap is created, which is filled quickly by the high-fidelity pol ? or pol e, and no mutations take place. However, if the replication fork wins the race to the lesion, the high-fidelity polymerases are stalled (Fig. 18.14E), and an error-prone polymerase, such as pol ?, pol ?, and pol t, places a base across from the AP site. If the polymerase continues its error-prone function, it introduces many more errors, that is, mutations ([453]). In mice that are deficient for UNG, the class switch is markedly impaired. This indicates that the AP that is created from removal of dU by the UNG is essential for CSR. The generation of double DNA breaks follows through interference with BER assembly by the CSR machinery.

Our understanding of the mechanisms of CSR and SHM has made some spectacular strides in the recent past. The AID appears to be important for somatic diversification of Ig genes, but the question still remains whether AID can unite all gene changes, such as SHP, CSR, and gene conversion ([454]), or if AID needs more than one other aid ([455]). To this point, it is interesting that AID deaminates dC on single-stranded DNA, but it requires the action of RNAse ([456]). As of today, this is the latest aid that comes to AID's help.

GENOMIC VIEW OF GERMINAL CENTER REACTION

The study of the GC reaction by conventional, morphologic, and functional methods has provided a clear picture of the central position of the GC in the differentiation of B cells and the function of humoral immunity. Microarray technology carries our understanding to the last frontier ([457]), the genes that are involved in initiation and evolution of the reaction. Findings by this approach confirm what is known—that the naïve, antigenically inexperienced, B cell does not divide and does not make Ig but is poised to respond to antigen. Indeed, naïve B cells express genes that are inhibitory of proliferation (WAF-1), as well as growth expression (BIN1 and BOK1) genes. They also express mRNA for early response genes (c-Jun and ERF-2) and cyclins D1 and D2 that function during the transition from G_1 to S phase.

The change from naïve B cell to centroblast is as striking at the gene level as it is with the techniques that have been used so far. The centroblast expresses the vast majority of proliferation-associated genes, as well as those that regulate the cell cycle and mitosis. One of the unexpected results was the lack of expression of c-myc protooncogene, which is known to be associated with cell proliferation. Genes that regulate apoptosis are up-regulated, whereas antiapoptotic genes (Bcl2) are down-regulated. Studies of gene expression do not detect significant differences between centrocytes and centroblasts, although these two populations have distinct functional characteristics. It is suggested that one of the two populations may be heterogeneous. The light zone contains detectable subpopulations by phenotype or by the expression of transcription factors.

In general, the global gene profile of naïve B cells is that of suppression, actively maintained by notable inhibitors of signal transduction ([458]). However, the GC B cell is characterized by a proliferation signature, which includes activation of genes that participate in various stages of cell cycle, such as cyclin, cyclin-dependent kinase (cdk), and CDC2, which drive cells through the G2 and M phases. Additionally, other genes that organize the mitotic spindle are also activated ([459]). Somewhat atypical is the lack of c-myc expression, a gene known for its proliferative function. Lack of c-myc expression ([457]) is reflected by the down-regulation of sets of genes involved in energy metabolism that are transcriptionally regulated by c-myc.

The lack of c-myc function may be due to the expression of the human homolog to the mouse Mad 3 gene, which forms dimers with c-myc and thus blocks its function as a transcriptional activator.

The GC B cells are thus poised to undergo apoptosis, which takes place extensively in the light zone, after hypermutation. Well-known antiapoptotic genes, such as Bcl-2 and Bcl-X_L, which are targeted by the NF-?B transcription factor are poorly expressed. Not only antiapoptotic genes are suppressed, but expression of proapoptotic genes, such as BIK (member of the Bcl-2 family), constitute part of the GC B-cell signature.

The BCL6 gene is highly expressed during the GC reaction that promotes the differentiation within GCs but is down-regulated during plasmacytic differentiation ([460]). Mice that are deficient in BCL6 fail to develop GCs, and are deficient in affinity maturation with a reduction in antibody responses. BCL6 represses CD40L-induced and NF-?B–dependent gene transcription of B7-1, a co-stimulatory molecule that is essential for T-cell–B-cell interactions ([461]). Mice that are deficient in BCL6 not only cannot develop GCs, but their memory B cells also have no V_H mutations ([462]). Because BCL6 appears to be a major promoter of GC reaction, the question that is raised is what are the signals that oppose BCL6 signaling and bring GC reaction to a halt? The BCR signaling opposes BCL6 transcription ([463]), probably directing BCL6 degradation by proteasomes as a result of its phosphorylation by MAPKs ([464], [465]). The hypermutated high-affinity BCRs interact in the light zone with antigen, and the signals that are generated are sufficiently strong to phosphorylate BCL6, leading to its degradation and bringing GC reaction to a halt. Important molecules that have been kept suppressed, such as B-lymphocyte–induced maturation protein (Blimp) 1, initiate plasma cell differentiation (see the following discussion). With BCL6 degradation, Blimp, a major plasma cell differentiation factor, is up-regulated and completes the end stage of the GC reaction.

POSTGERMINAL CENTER DIFFERENTIATION

After somatic diversification in the dark zone, the centroblast moves into the light zone as a centrocyte-expressing surface Ig that has undergone SHM. The centrocytes are submitted to the selection procedure by antigen that is carried on the dendrites of the dense FDC network in the light zone. The majority of centrocytes are destined to die, because the mutational changes are detrimental to their affinity and avidity. Loss or diminished binding to antigen leads to programmed cell death, and those dead centrocytes are rapidly removed by macrophages, which are now called *tingible body macrophages*. Some of the centrocytes may be recycled, once more, through the dark zone for further clonal expansion, diversification, and selection.

This recycling provides, once more, the opportunity for reaching the highest affinity peak. In the light zone, the selection process separates the *fittest* B cells (high affinity) for survival and the *unfit* (poor or no affinity) for death (negative selection). Positive and negative selection may work in concert, so that, among the positively selected high-affinity B cells, those with autoreactivity are deleted ([466]) by apoptosis, because overexpression of Bcl2 in B cells allows the survival of autoreactive B cells ([467]). The products of several genes participate in the regulation of the selection processes. The protein tyrosine kinase Lyn plays a rate-limiting role in BCR triggering through phosphorylation of CD22, an inhibitory molecule that recruits SHP-1 to the BCR-CD22 complex ([468]). The transcription factor Aiolos maintains B cells at low reactivity levels, because, in mice that are deficient in Aiolos, there is increase of serum Igs, autoantibody production, and the development of B-cell lymphomas ([469]).

CD21 appears necessary for the survival of GC B cells with high-affinity BCRs. CD21 is a complement receptor (CR2) and, as a component of the CD19/CD21/CD81 co-receptor, mediates the binding of complement-containing immune complexes to B cells and provides a survival signal for B cells ([470]). The CD19/CD21 co-receptor is a major regulator of B-cell function in humoral immunity, for fine tuning of signals that are received by the BCR ([471]). Simultaneous ligation of BCR and the CD19-CD21 complex (i.e., with antigen-antibody-complement complexes) lowers significantly the threshold of antigen that is required to trigger B-cell activation by antigen alone through the BCR. (See Chapter 16, Fig. 16.12)

The centrocyte that has been positively selected is poised for commitment to one of the two pathways of differentiation: memory B cell or plasma cell, depending on whether the normally delivered signals are properly received.

Memory B Cells

Centrocytes can be diverted to the memory B-cell pool by positive signals or by the lack of negative signals. The CD40/CD40L interaction or IL-4 stimulation ([472]) belongs to the first category. The apoptotic pathway that normally deletes centrocytes belongs to the second category. Apoptosis normally deletes centrocytes that have emerged from the dark zone with nonfunctional or low-affinity receptors. Interference, therefore, with the apoptotic pathway blocks negative selection and results in accumulation of heavily mutated B cells that bring forward a “bad” memory of the primary response. Thus, overexpression of Bcl2, an antiapoptotic protein, interferes with negative selection and diverts centrocytes to the memory pool ([473]). Similarly, the lymphoproliferative mutation that incapacitates the Fas receptor results in accumulation of heavily mutated B cells ([474]). These changes disrupt the anatomic organization of lymphatic organs with the development of autoimmune lympho-proliferative disease.

Memory B cells are long lived and do not secrete antibody until they are challenged again. In such a secondary antigenic challenge, they respond to much smaller

doses of antigen, expand clonally, and produce seven to ten times more antibody than the antigen-inexperienced B cells ([475]). Memory B cells have undergone an Ig class switch, and expression of Ig classes can be used for their classification, as well as for the classification of other markers, such as CD27 ([476]) or CD148 ([477]).

The mechanism that maintains the memory B-cell pool is unknown. Antigen is not required to keep them alive, and, according to a hypothesis that has some appeal, B-cell memory (and, for that matter, T-cell memory also) is maintained by idiotypic-antiidiotypic interactions between B cells ([478]). Such interactions take place between B cells that have been antigenically stimulated, therefore their BCR carries distinct *idiotypes* that are specific for this clone. These idiotypes are structures (protein sequences) within the antigen binding site that are specific for this particular BCR. Other B cells that respond to these idiotypes express a BCR with antiidiotypic properties. Interaction between idiotypic cells (memory cells for the primary antigen) and antiidiotypic B cells, according to this hypothesis, stimulates enough proliferative activity to maintain the B-cell memory pool. Such interactions may also link and maintain T-cell memory within a pan-lymphocyte idiotypic-antiidiotypic web.

Plasma Cells

The purpose of the B cell's life is to make antibodies after it reaches maturity, a stage of differentiation that is characterized morphologically by the development of an elaborate ER and functionally by the synthesis of Ig that is released extracellularly. Since the detection and description of the plasma cell by Marshalko and Unna (Chapter 16), clinicians and scientists have become quite familiar with the morphology, ultrastructure, and physiology of the plasma cell. The new techniques of molecular biology and genomics identify the genes that bring about this spectacular morphologic and functional transformation (Fig. 18.15).

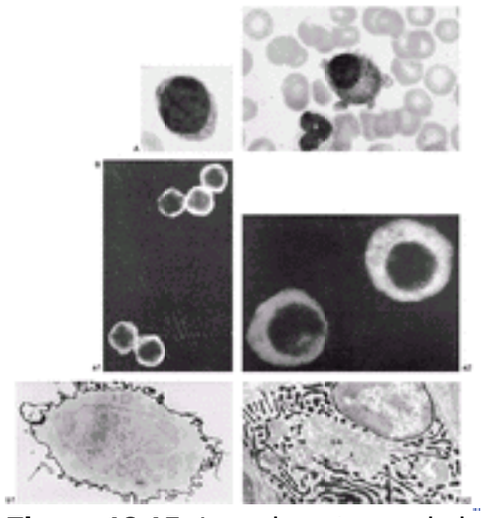

Figure 18.15. Lymphocytes and plasma cells. Morphologic and functional differences between lymphocyte and plasma cells. **A:** Morphology: routine staining. **B:** Immunoglobulin production and expression: B-cell surface versus plasma cell intracellular immunoglobulin. **a:** Fluorescence. **b:** High-resolution autoradiography. GA,Golgi apparatus; Mi, mitochondrion.

The earliest signs of the plasma-cell differentiation are detected within the GCs when the positively selected centrocytes choose one of the two pathways that are available to them. A small number of centrocytes express a partial plasma cell phenotype, CD138 (syndecan-1); the transcription factor Blimp-1; and down-regulation of BLC6 and Pax5 ([479] and [480]). These precursors exit the GCs and migrate to the bone marrow, where they develop into plasma cells, secreting high-affinity antibodies. They are probably the same cells that are detected on bone marrow smears ([481]), surviving with signals that are delivered by marrow stromal cells ([482]), and are able to secrete antibody in the absence of antigen for several months ([483]). These postGC plasma cells should be distinguished from preGC plasma cells secreting IgM antibody, that are generated in the early stage of the primary response.

IL-6 is particularly effective in driving high-affinity B lymphocytes to plasma-cell differentiation ([484] , [485]). Before the acquisition by B cells of plasma-cell characteristics, the cell loses expression of MHC class II molecules, CD19, CD20, CD22, and CD45 ([486]) and up-regulates CD38 (the highest density of all stages during B-cell development) and CD138 (or syndecan-1) ([487]). CD38 is a transmembrane type II protein (i.e., NH_2 terminal intracellular), which is the *ectoenzyme* nicotinamide adenine dinucleotide (NAD^+), converting NAD^+ to adenosine diphosphate ribose (glycohydrolase activity) (Chapter 2, CD38). CD138 binds to hepatocyte growth factor, which is produced by mesenchymal cells and stimulates myeloma cell growth (Chapter 2, CD138). Among transcription factors, Pax5 is down-regulated, whereas Blimp-1 is up-regulated ([479]).

The BCL6 protooncogene exerts a negative effect on plasma-cell differentiation, because it suppresses genes that are critical in the promotion of their differentiation. BCL6 is a pox virus zinc finger (POZ)/zinc finger (ZF) protein, which contains six Krüppel-type ZF motifs at the C-terminal end and a POZ motif at the N-terminal. Therefore, it belongs to the POZ domain and Krüppel-like family (POK) of proteins ([488]).

The ZF proteins contain cysteines and histidines that are spaced at regular intervals with a zinc atom that is coordinated between two cysteines and two histidines. ZF proteins are folded in nine loops, with an invariant Leu and a Tyr or Phe that is located in each loop and is important for the DNA binding. The zinc binds to the consensus core sequence TTCCT (A/C) GAA that is found in several BCL6 target genes, but it also mediates protein-protein interactions, notably with class II histone deacetylases (HDACs), c-Jun transcription factor, etc. The POZ domain is a protein-protein interaction motif that is conserved in evolution and is found in many transcription factors, oncogenic proteins, ion channel proteins, etc. POZ proteins are involved in critical cellular processes, such as development, oncogenesis, apoptosis, and transcription. The most common property of the POZ domain is repression of transcription, based on its ability to recruit the HDAC.

Histone acetylation is mediated by a histone acetyltransferase complex. Acetylation destabilizes the nucleosomal structure by neutralizing the positively charged Lys residues of the N-terminal tail domain of core histone and increases the accessibility of DNA to transcriptional regulatory proteins ([489] , [490]). Therefore, acetylation plays an important role in the regulation of gene expression and DNA replications and repair. Deacetylation has the opposite effect. There are two classes of enzymes that deacetylate histones: Class I (HDAC-1, HDAC-2, HDAC-3, and HDAC-8) is detected in yeasts and similar organisms, and class II (HDAC-4, HDAC-5, HDAC-6, HDAC-7, HDAC-9, and HDAC-10) is detected in vertebrates. BCL6 recruits class II HDAC-4, HDAC-5. and HDAC-7, forming complexes through the N-terminal POZ domain and C-terminal ZF region ([491]). BCL6, lacking four of the six ZF proteins, loses entirely its ability to recruit the HDACs. It is likely that this interaction exerts the transcriptional repression of BCL6 ([492]). Several genes are targets for BCL6, such as CD40, IL-4, Blimp-1, B7-1, and cyclin D2 (Fig. 18.16). Point mutations of ZF indicate that ZF-3, ZF-4, ZF-5, and ZF-6 abolish DNA binding and the ability of BCL6 to bind to its cognate cis element ([488]). BCL6 represses genes that are activated by STAT-6 or NF-?B ([493]), thus regulating IL-4 signaling and IgE production. BCL6 competes with STAT-6 for the same DNA-binding sites and thus inhibits specific STAT-6–dependent gene transcription. BCL6 $^{-/-}$ mice have dysregulation of IgE production and develop type T_H2 inflammation of the heart and lungs ([460] , [493]).

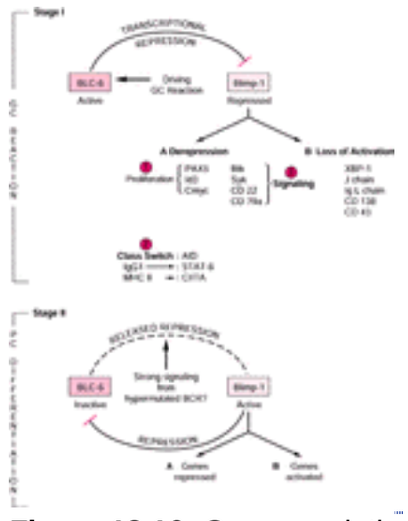

Figure 18.16. Gene regulation of germinal center (GC) reaction. Several genes by their expression or their repression contribute to the molecular and cellular processes that take place within the GCs. More than any others, two genes virtually conduct the GC orchestra: B-cell lymphoma 6 (BCL-6) and B-lymphocyte–induced maturation protein-1 (Blimp-1). BCL-6 is a repressor gene that is identified in diffuse large B-cell lymphomas. It represses several genes and, importantly, Blimp-1 (stage I). As a result, BCL-6 releases from repression all genes that are normally repressed by Blimp-1 (*A*). The net result is "activation" of genes for proliferation (*1*), class switch (*2*), somatic hypermutation, and signaling B-cell molecules (*3*). BCL-6 is down-regulated, probably by strong signals that are delivered by hypermutated high-affinity B-cell receptors (BCRs) (stage II). Loss of BCL-6 function releases Blimp-1 from repression. Genes that are active during the first stage I are now repressed, whereas genes that are important for plasma cell (PC) differentiation are activated, such as XBP-1 and immunoglobulin L chain. Thus, the GC reaction and the generation of antibodies are finely tuned, basically by a repressor loop between the two master genes BCL-6 and Blimp-1. AID, activation-induced deaminase; CIITA, major histocompatibility complex class II *trans*-activator molecule; MHC II, major histocompatibility complex class II; STAT, signal transducer and activator of transcription.

Suppression of STAT-3 by BCL6 blocks plasma-cell differentiation through inhibition of Blimp-1 ([494]) (Fig. 18.16). This function of BCL6 is, at least partially, critical in the role of BCL6 in B-cell differentiation—the block of terminal plasma-cell differentiation to maintain proliferation and hypermutation for affinity maturation (i.e., maintenance of GC reaction). BCL6's function is curtailed by signals from high-affinity BCRs that are initiated from interactions with antigen in the light zone. If BCL6 function achieves constitutive independence through chromosomal translocations, it may lead to B-cell lymphomas. When BCL6 is down-regulated, it releases suppression of Blimp-1, a transcriptional repressor that is important for plasma-cell differentiation ([389]). The genes that are repressed by Blimp are shown in Fig. 18.6. Several of the biologic characteristics of plasma cells are explained by the repressor function of Blimp-1. Blimp-1 represses c-myc and inhibits proliferation ([495]) and also represses the Pax5 gene, releasing XBP-1 from Pax repression, which is needed for plasma cell formation ([496]). Blimp-1 also releases Pax5-mediated inhibition of H-chain ([497]) and J-chain ([498]) synthesis.

Plasma cells have lost the antigen-presenting function of their parent B cells. This is due to loss of MHC class II expression as a result of repression of the gene that encodes the CIITA, which is required for MHC II expression in B cells ([499]).

Blimp-1 is the master regulator of genes of the plasma-cell differentiation program. Genes that are regulated by Blimp are direct targets or are regulated by other Blimp-1 target genes. The basic function of Blimp-1 is repression of transcription, which is active or passive. Factors that act as passive repressors interfere with transcriptional activators by competing with their binding site on the promoter or by binding directly to the activation domain of the activator. In active repression, the repressors interact directly with the components of the transcription machinery or recruit co-repressors, such as the HDACs. *Blimp-1 is an active repressor* that is associated directly with HDACs and carries them to the promoters it binds ([500]). HDACs bring alterations in the chromatin structure, which underlines the basic mechanism of Blimp-1 function. Another co-repressor for Blimp-1 is a complex of the Groucho family proteins ([501]).

HYPER–IG M SYNDROME (HIGM): GENETIC DEFECTS OF CLASS-SWITCH RECOMBINATION

The cognate interaction between CD40L (CD154), which is expressed on activated T cells, and CD40, which is constitutively expressed on B cells, is required for terminal B-cell differentiation. Signaling through CD40 leads to B-cell proliferation, rescue of B cells from apoptosis, SHM, CSR, and GC reaction. Mutations of CD40L result in the X-linked syndrome that is characterized by the lack of GCs in the lymphoid organs and the inability of B cells to undergo CSR, and IgG, IgA, IgE are absent or markedly decreased ([502] , [503] and [504]). Men who are affected with HIGM syndrome are susceptible to bacterial infections, but also experience *Pneumocystis carinii* pneumonia and *Cryptosporidium* intestinal infections, which are usually observed in T-cell deficiencies ([505]). Lack of interaction between T cells and macrophages leads to defective macrophage activation, which is probably the basis for opportunistic infections ([506] , [507] and [508]). This syndrome was the first to be described and is known as *HIGM1 syndrome*. Some patients with HIGM1 syndrome have a few IgM^+/IgD^+ B cells that express CD27, a memory B-cell marker, and have SHM. The B cell from these patients indicates that SHM may follow more than one pathway. HIGM1 is due to mutations in the gene that encodes CD40L ([509]).

Carriers of HIGM1 are considered to be asymptomatic, because expression of CD40L, even in only a small fraction of T cells, is sufficient for effective immunity. A female carrier has been described with HIGM1 syndrome as a result of extreme lyonization of the normal X chromosome ([510]). This patient was the sister of a boy who was affected with HIGM1 syndrome, and only 5% of T cells were $CD40L^+$.

A second HIGM syndrome with autosomal-recessive inheritance (HIGM2) has normal CD40L but does not undergo CSR *in vitro* in the presence of CD40 agonists ([511] , [512]). CD40 gene sequence and CD40 expression are normal. The defect of HIMG2 is linked to chromosome 12p13, where the AID gene also maps. Mutations of the AID have been identified. These patients lack CSR and SHM and have lymph node hyperplasia with giant GCs ([513]). The cells in these GCs are proliferating B cells that coexpress IgM, IgD, and CD38, a phenotype that was previously described as characteristic of the GC founder-cell subset ([514]). Some mutations are predicted to lead to truncated forms of AID by generating stop codons; other missense mutations are localized within the putative cytidine deaminase catalytic region of the protein. The phenotype of HIGM2 is similar to the phenotype of mice with deficiency of AID ([515]).

In a group of 13 patients with HIGM syndrome and normal CD40L, all patients had AID mutations, five of them with a missense mutation of Arg112 His, which indicates that Arg112 is the hot spot of mutations ([516]). Levels of IgG, IgA, and IgE were undetectable, and SHM was impaired, which shows that AID is indispensable in CSR and SHM.

Another group of 14 patients of French-Canadian descent from Quebec, Canada, had a C-to-T transition in codon 112, resulting in the substitution of Arg with Cys. These patients inherited the genetic defect from a common founder ([517]).

In contrast to HIGM1 syndrome, patients with HIGM2 have bacterial, but not opportunistic, infections.

Mutations of the AID gene do not account for all cases of autosomal-recessive HIGM syndrome. Mutations in the CD40 gene, which lead to lack of CD40 expression, cause an autosomal-recessive form of immunodeficiency with HIGM, which is characterized by lack of CSR, impaired memory B lymphocytes, formation, and defective SHM (HIGM3) ([518]). One patient was detected at 4 months of age with severe respiratory distress because of *P. carinii* infection. The other two patients experienced recurrent respiratory infections early in life.

CYTOKINES IN B-CELL DIFFERENTIATION

The structure and function of the main cytokines that are involved in B-cell differentiation and their receptors are briefly described here. Some of the cytokines have similar structural features and have been divided into two groups, type I and type II.

Type I cytokines consist of four a helices (A, B, C, and D) that are connected by long loops. If the molecule is viewed in the direction from the NH_2 to the COOH

terminal, the orientation of the A and B helices is up, and the orientation of the C and D helices is down (i.e., up-up-down-down). Depending on the length of the helix, they are distinguished as short chain or long chain. Cytokines with short chains include IL-2, IL-3, IL-4, IL-5, IL-7, IL-9, IL-13, IL-15, and SCF, and those with long chains include erythropoietin, thrombopoietin, IL-6, IL-11, leukemia inhibitory factor, and oncostatin. Only the short-chain cytokines have ß-sheet structures in the AB and CD loops. There are intrachain disulfide bonds to maintain the overall tertiary structure, but the number varies, for example, IL-2 has one disulfide bond and IL-4 has three. The sequences in helices A and D are the most conserved in evolution, and these helices make contacts with the receptors. The receptors of the cytokines that are discussed here have a characteristic *cytokine-binding domain* (CBD) that consists of two fibronectin type III (FnIII) domains. The N-terminal contains four conserved cysteines that form two disulfide bonds and the membrane proximal conserved sequence WSXWS [Trp–Ser–X-Trp-Ser, where X is any amino acid]. The cytokine receptors use several signaling pathways. Briefly described here is the Jak-STAT pathway, which mediates most of the cytokine effects.

The biological properties of the interleukins described here are listed in Table 18.2.

TABLE 18.2. Biologic Activities of Cytokines

		Effects On:		
Cytokine	**Produced**	**B Cells**	**T Cells**	**Macrophages**
IL-2	T_H1	Growth	Growth	—
IL-4	T_H2	Growth ? Major histocompatibility complex Activation ? Immunoglobulin E	Growth	Activation
IL-5	T_H2	Differentiation ? Immunoglobulin A	—	—
IL-6	T_H2	Growth Differentiation	Co-stimulation	—

IL, interleukin; T_H, T helper cell, ?, increased.

Jaks and Signal Transducers and Activators of Transcription

The Janus family of kinases, which is known as *Jak (just another kinase)*, has been given the name of the Roman god, *Janus*, the god of gates and doorways and the god of all beginnings and endings, who had two faces. Jaks also have two tandem domains, a kinase, and a pseudokinase ([519], [520]). Each molecule consists of seven homology domains, which are termed *Jak homology (JH) domains*. JH1 is the catalytic domain and has the features of a Tyr kinase domain, whereas the N-terminal binds to cytokine receptors. Mutation of the conserved Lys in subdomain II that binds ATP abrogates kinase activity. Jaks are apparently interdependent in their function, because they form homo- or heterodimers with other members of the family when the receptors with which they associate form homo- or heterodimers. Certain domains are used as cytokine receptor–specific binding sites. For example, Jak-1 uses JH7 and JH6 for binding to IL-2Rß and IL-4Ra, but the binding to IFNaRßL and IL-10Ra requires another domain ([521]). The Jak-3 kinase is rapidly phosphorylated by IL-2 and binds to the ?c chain through the JH6 and JH7 domains, whereas the Jak-1 associates with the ß chain.

STATs are latent cytosolic transcription factors with an acronym that accurately reflects the speed of their activation and the urgency of their biological function, in agreement with the STAT (at once) order for immediate action in clinical medicine and emergency rooms. There are seven known mammalian STAT proteins that were conserved in evolution from primitive eukaryotes to humans ([522]). The important structural features of STATs are the SH2 (Src homology 2) domain and the DNA-binding domain ([523]). The SH2 domain is used to bind to phosphorylated Tyr and is used for their dimerization. After phosphorylation of their single Tyr (Y-P), they form homodimers or heterodimers, based on the interaction of the Y-P with the SH2 domain *of another molecule* of a similar or different STAT. Dimerization unmasks a nuclear localization signal that permits STATs to enter the nucleus and bind to DNA ([523]). STATs must take six steps for the full expression of their function: (a) bind to Y-P, (b) become phosphorylated themselves, (c) dimerize, (d) translocate to the nucleus, (e) bind to DNA, and (f) participate in gene transcription. STATs bind to Y-P of cytokine receptors or Y-P of a STAT that is already bound to the receptor or directly to a Jak.

The DNA binding domain in the C-terminal in some STATs contains a Ser whose phosphorylation is important for transcriptional activity.

Jaks and STATs constitute an important signaling pathway for cytokines. All IFNs and cytokines activate one or more STATs. Because there are more cytokines than STATs, it is not possible for each cytokine to have its own STAT. However, cytokines form groups that share the same STATs. For some STATs that are activated by many cytokines (STAT-3, STAT-5a, and STAT-5b), their unique actions cannot be mediated by STATs alone, but with a combination of other transcription factors.

In addition to transcription regulation, some STATs recruit other signaling components. STAT-4 and STAT-5 are two of the most important STATs in the STAT pathway, primarily because of their role in T_H cell differentiation. STAT-3 and STAT-1 have a primary role in the function of IL-5 and IFN-?, respectively, in defense against infectious agents ([524]).

Interleukin-2 and Interleukin-2 Receptor

IL-2 and IL-2R were the first to be isolated, and, although IL-2 was originally thought to be only a T-cell growth factor, subsequent studies demonstrated that it acted on several types of cells, including B cells and NK cells ([525]). IL-2 belongs to the short-chain four–a-helical bundles. IL-2R consists of a complex of three polypeptide chains: the IL-2Ra, IL-2Rß, and ?c (common) chains. The ?c chain is shared by receptors of several ILs, such as IL-4, IL-7, IL-9, and IL-15.

IL-Ra binds IL-2 with low affinity [dissociation constant (K_D) = 10^{-8}], whereas, in association with IL-2Rß, it forms an intermediate affinity complex ($K_D = 10^{-9}$), and all three subunits form the high-affinity receptor ($K_D = 10^{-11}$). The IL-2Rß subunit has two pairs of conserved cysteines that are close to the N-terminal end and the sequence WSXWS in the membrane-proximal end of the extracellular region, which is characteristic of type I cytokine receptors.

The intracellular region has the Box1, Ser (S), acidic (A), and proline (H)–rich regions. The extracellular region of the ?c chain has an N-terminal domain with two pairs of cysteines, and the second membrane-proximal domain contains the highly conserved WSXWS motif. The a and ß subunits are expressed only on lymphocytes, but, after activation, they are also expressed on macrophages. The ?c chain is detected in several other hematopoietic cells ([526]).

The contributions of each of the three chains to IL-2 binding are not quite clear. The a-chain is necessary to form, with the other two chains, the high-affinity IL-2R while the ?c chain contributes three loops from the extracellular region (including two of the cysteines) to the IL-2 and IL-7 binding ([527]). IL-2 expresses lectin properties and binds to the ß-chain in a Ca^{2+} independent manner to oligomannosidic *N*-glycans (five to six mannose residues) ([528]). It is proposed that by this mechanism IL-2 links the ß-chain of IL-2R with CD23 ([528]). The ß and ?c chains are certainly the signal-transducing components of the IL-2R. Signaling through the IL-2R follows several paths to the nucleus (Fig. 18.17). One pathway is the Ras-MAPK cascade that is initiated by the phosphorylation of the Shc adaptor protein ([525]). A second is the PI3K activation, and a third one is through the Jak-STATs.

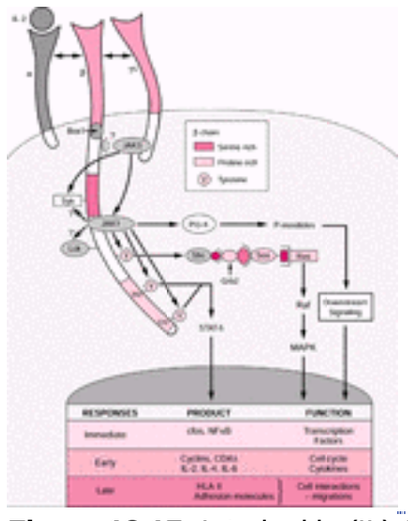

Figure 18.17. Interleukin (IL)-2 signaling. The IL-2 receptor complex consists of three polypeptide chains: a, ß, and ?. High-affinity binding of IL-2 requires all three chains. The ß-chain is associated with Jak 1 kinase, Src kinases (e.g., Lck), and Syk. Jak 1 phosphorylates tyrosines of the C-terminal region of the ß-chain, which become docking sites for signal transducer and activator of transcription 5 (STAT-5). One of them links to the adaptor protein Shc, which connects to the Ras pathway and mitogen-activated protein kinase (MAPK) activation. Jak 1 also connects with phosphoinositide 3-kinase (PI3K) and the downstream signaling that is mediated by phosphoinositides. Jak-3 is associated with the ?c-chain and probably with ß-chain. It probably activates Jak 1 and Syk. IL-2 and IL-2R signaling induces multiple and prolonged T-cell responses, such as immediate responses, transcription factors that activate genes for cell cycle, and cytokine release. Later induction of integrins supports T-cell migration and interactions with other cells. IL-2 was the first cytokine to be discovered and retains a commanding role in the regulation of several aspects in T-cell life. NF-?B, nuclear factor-?B.

The A region of the ß-chain is associated with members of the Src family and PI3K ([529]). The H region mediates activation of the Jak family of Tyr kinases that activate STATs ([529]). The most membrane-proximal Tyr (Y) 338 is involved in the phosphorylation of the adaptor protein, Shc, which is linked to the Ras pathway. The two membrane-distal Tyr Y322 and Y510 associate the ß-chain with the Jak-1 kinase ([530]), which interacts with the PI3K. This pathway leads to maximal T-cell proliferation ([531]). IL-2 and several others are associated with the Jak-STAT signal transduction pathway. The Jak-3 kinase is rapidly activated by IL-2, and, through the JH7 and JH6 domains, it binds to the ?c chain ([532]), whereas Jak-1 is associated with the ß-chain ([533]).

Understanding the mechanism of T-cell progression through the cell cycle has been advanced by the discovery of rapamycin, a potent immunosuppressant ([525]). Rapamycin is a macrocyclic lactone that is derived from the filamentous bacterium *Streptomyces hygroscopius* ([534]) and has structural similarities to another powerful immunosuppressant, FK506, or tacrolimus. Both substances bind to a family of intracellular receptors, FK506-binding proteins (FKBPs), which are peptidyl-prolyl isomerases, that is, they catalyze the *cis*-trans interconversion of peptide bonds that contain proline. The complexes of FK506 and FKBP in T cells inhibit calcineurin, a Ca^{2+}-regulated Ser-Thr phosphatase, which plays a crucial role for the activation of gene transcription by IL-2. However, the rapamycin-FKBP complexes do not bind to calcineurin but to another protein that is called *target of rapamycin (TOR)* ([535]). This protein is expressed in *Saccharomyces cerevisiae*, and provides resistance to the potent antifungal action of rapamycin.

The protein TOR is apparently needed for the transition of T cells from G_1 to S phase. Transition of the cell from G_1 to S phase is regulated by G_1 cyclins and their associated cdks ([536]), which assure the orderly progression from G_1 to S phase. IL-2 stimulates the synthesis of three cyclins, D_2, E, and A ([537]). These cyclins form complexes with cdks, which sequentially (D_2-complexes followed by E-complexes and then A-complexes) lead the cell from G to S phase. Rapamycin affects the assembly and function of all three cyclin-cdk complexes. The D2-complexes function by phosphorylating their substrate, the retinoblastoma protein, which normally is phosphorylated at a low level and restricts the G_1-to-S transition. The function of cyclin-cdk complexes is regulated by another set of proteins that are called *kinase inhibitory proteins (KIPs)* ([538]), which bind and inhibit the kinase activities of the cyclin-cdk complexes. The IL-2R delivers a signal for KIP down-regulation, whereas rapamycin prevents the IL-2–induced reduction of KIP.

The TOR protein regulates the $p70^{56K}$ protein, which is present in mammalian cells, and, as a protein kinase, phosphorylates various intracellular substrates that are involved in protein synthesis and cell cycle control. T-cell activation by antigen induces within the first 30 minutes a number of transcription factors (e.g., c-fos, NF-AT, and NF-?B) (immediate response). These factors in turn activate the transcription of cytokine genes, such as IL-2, IFN-?, IL-4, and IL-5 (early response).

IL-2 stimulates T-cell clonal expansion and dictates proliferation of antigen-selected T cells. Antigenic stimulation induces IL-2R's expression and secretion of IL-2 and other cytokines ([526]). Cross-linking of surface Ig leads to IL-2R expression on B cells and responsiveness to IL-2. IL-2 stimulates proliferation of B cells and Ig secretion and mediates the switch from the membrane form to the secretory form of the µ chain, allowing formation of pentameric IgM molecules. Therefore, IL-2 is critical for primary immune responses that are characterized by the production of IgM antibodies. IL-2 stimulates secretion of other cytokines, such as IL-4, IL-5, and IFN-?, preparing the stage for isotype switch and the maturation of the antibody response. Antigen activation of T cells initiates a series of waves of gene activation that is coordinated by TCR signaling and IL-2 secretion, with the expansion of the role of T-cell cytokines in B-cell proliferation, antibody secretion, affinity maturation, and class switch (late response).

X-Linked Severe Combined Immunodeficiency

The ?c chain gene of the IL-2R is located in chromosome Xq13, which is also the locus for X-linked SCID. X-linked SCID patients are phenotypically identical—T^-, B^+, and NK^- ([539]). From a large group of patients with SCID, ?c deficiency accounts for 42%, and Jak-3 deficiency accounts for approximately 6% of the cases ([540]). This form of SCID is associated with severe T-cell defects in T-cell development and lack of peripheral T and NK cells. Patients have severe persistent infections of the upper respiratory and gastrointestinal tracts by CTMV, fungal, and bacterial pathogens. Patients require bone marrow transplantation to survive. B-cell levels are normal or elevated in the T^-, B^+, and NK^- SCID cases. With the exception of two large deletions, the ?c mutations are missense mutations that involve one or a few nucleotides. Five mutational hot spots have been identified in exons that encode part of the extracellular domain ([541]). In patients with autosomal SCID, a single amino acid substitution Y100C in the JH7 domain of Jak-3 prevents the interaction of Jak-3 with the receptor ([542]).

Interleukin-4 and Interleukin-4 Receptor

The IL-4 is one of the small four-helix bundle cytokines with four a helices, A, C, B, and D, two end-to-end long loops, and a short ß sheet that is packed against the B and D helices ([543]). It has a biological activity that is species specific, in spite of the fact that the main binding residues are conserved.

IL-4 is a pleiotropic cytokine that is produced by $CD4^+$ T_H2 cells, NKT cells, ?d T cells, basophils, and mast cells, and it is essential for T_H2 differentiation (Chapter 17). IL-4 binds with high affinity to the IL-4Ra, and this complex recruits the ?c chain (Fig. 18.18). IL-4 binding induces a conformational change in the receptor, forming a structural mosaic in the binding interface. The interacting residues are grouped into three clusters ([544]), with the first two clusters consisting of a nucleus of polar groups that are surrounded by hydrophobic side chains. They have been compared to the avocado fruit in which a nucleus is enveloped by an oily shell. The first cluster is around Glu9, and the second cluster is around Arg88 of IL-4 and Asp72 of the IL-4Ra.

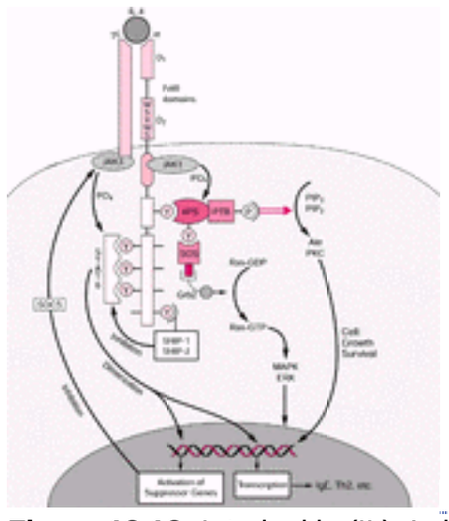

Figure 18.18. Interleukin (IL)-4 signaling. IL-4 binds to a receptor, which consists of two chains, a and ?c. The a receptor has two extracellular fibronectin III domains (Fn) (D1 and D2), with features of a cytokine receptor homology domain, which is seen in type I cytokine receptors. D2 is characterized by the WSXWS motif (amino acid letter code: W is tryptophan, S is serine, and X is any amino acid) that is implicated in folding and transport of the receptor. The binding of IL-4 to the a-chain is mediated by three discrete clusters. Two of them are known as *avocado clusters* because they consist of a central core of polar groups that is surrounded by a hydrophobic (*oily*) shell. The third cluster is dominated by electrostatic interactions and stabilizes the complex. The a-chain associates with Jak-1 and the ?c chain with Jak-3. Distinct domains of the cytoplasmic tail of the a-chain mediate the multiplicity of IL-4 function. A unique feature in the IL-4R a-chain is its association with a protein that is known as *IL-4 phosphotyrosine substrate (4PS)*, which links to phosphoinositide 3-kinase (PI3K) and downstream signaling for cell growth and survival. 4PS also connects to the Ras pathway for mitogen-activated protein kinase (MAPK) activation. 4PS binds to a unique sequence of IL-4Ra that is shared by the insulin receptor. In the insulin receptor, this motif binds a protein-linking signaling pathway, which is known *as insulin receptor substrate 1 (IRS-1)*. 4PS of the IL-4Ra is homologous to IRS-1 and has been called *IRS-2*. Jak-3 phosphorylates tyrosines of the a-chain that are used by signal transducer and activator of transcription 6 (STAT-6) for binding. This phosphorylation is regulated by SHIP phosphatases, which are associated with the C-terminal part of the a-chain. STAT-6 induces the suppressor proteins, suppressors of cytokine signaling (SOCSs), which inhibit Jak-3 activation. GTP, guanosine triphosphate; PTB, phosphotyrosine binding domain.

The third cluster steers and accelerates the binding of the IL-4 with the receptor ([544]). The first and second clusters show cooperativity and additive properties, which reinforce the binding to higher affinity ([545]). IL-4R consists of a complex of two proteins, IL-4Ra and the ?c-chain. The IL-4Ra has two FnIII domains. The N-terminal (D1) has the conserved disulfide bonds of an Ig fold, whereas the second domain (D2) has no disulfide bonds; both have unique structural features ([546]). A membrane-proximal WSXWS domain maintains the favorable conformation for cytokine binding. The cytoplasmic region has the box 1 motif (proline rich) and an acidic region that is adjacent to box 1 that interacts with Src Tyr kinases. Ligand binding causes heterodimerization of the a- and ?c-chains and activation of Jak-1, Jak-2, and Jak-3 kinases ([547]), the first two associating with IL-4Ra and the last associating with ?c.

Activation of Tyr kinases that are associated with the IL-4R leads to phosphorylation of the five tyrosines of the cytoplasmic region of IL-4Ra ([543]), which function as docking sites for Src kinases.

The functions of IL-4Ra are mediated by distinct domains in the cytoplasmic region. The first, most membrane-proximal domain contains the Y497 (Y1), which interacts with the IL-4 phosphotyrosine substrate (4PS), a 180-kd protein related to insulin receptor substrate 1 (IRS-1) that is phosphorylated and generates proliferative signals ([548]). Interestingly, 4PS was found to be homologous to a cytoplasmic protein, which is used as a substrate for the insulin receptor. Insulin binding to the insulin receptor results in a rapid autophosphorylation of the receptor, which is a receptor protein kinase. The receptor subsequently phosphorylates cytoplasmic substrates that link to downstream signaling pathways. One such major substrate of the insulin receptor is the IRS-1. 4PS, which is homologous to IRS-1, has been called *IRS-2* ([549]). IRS-1 and -2 bind to the sequence [^{488}PL-(X) 4 NPXYXSXSD ^{502}] around Y497 of the IL-4R, which is highly homologous to a sequence in the cytoplasmic regions of the insulin receptor, and of the insulin growth factor-1 receptor, both of which activate IRS-1 and -2. This sequence is critical for transducing signals through insulin receptor and IL-4Ra and was termed the *insulin IL-4 receptor* or *I4R motif* (Fig. 18.18). The IRS-2 has a phosphotyrosine-binding domain, which binds to the I4R motif of the IL-4Ra and insulin receptor. IRS-1 and -2 become phosphorylated when they bind to phosphorylated IL-4Ra and act as a docking site for several SH2 domain–containing signaling molecules. Among such signaling molecules are the PI3K that generates phosphoinosi-tides, which in turn activate Akt and protein kinase C (PKC), which are important in cell growth and survival.

The adaptor protein Shc binds to phosphorylated IL-4Ra chain and links through Grb2 to Ras pathway activation. STAT-6 is the primary STAT that is activated by IL-4 stimulation, leading to expression of IL-4 responsive genes. STAT-6 plays an important role in IL-4–induced responses, and, for IL-4 signaling to be maintained, STAT-6 undergoes continuous cycling ([550]). When STAT-6 is deactivated in the nucleus, it is exported back to the cytoplasm, where it becomes available for another cycle of phosphorylation and reactivation. STAT-6 (together with STAT-4) is the most important STAT in the immune response to sepsis, mainly because of its role in T_H differentiation. STAT-6 is essential for T_H2 differentiation on activation by IL-4.

The phosphorylated C-terminal *immunoreceptor tyrosine-based inhibitory motif* (ITIM) of the IL-4Ra acts as docking site for SHP-1 and SHP-2 phosphotyrosine phosphatases. The former is expressed primarily in hematopoietic tissues, whereas the latter is expressed in several other tissues. Another phosphatase, SHIP, regulates the PI3K signaling pathways.

The Jak-STAT pathway is also subject to regulation by a family of newly discovered suppressor proteins that are termed *suppressors of cytokine signaling* (SOCSs) ([551]). There are four members in the SOCS family: SOCS-1, SOCS-2, SOCS-3, and CIS (cytokin-inducible SH2-containing protein). The SOCS proteins have an SH2 domain in the center, an N-terminal variable region, and a region of homology at the C-terminus, which is termed the *SOCS box*, with a unique sequence and an unknown function. Five families (20 members) have been identified with a sequence that is homologous to the SOCS box, but the rest of their structure is different ([552]). SOCS proteins are not constitutively present in the cells but are induced only after cytokine stimulation. The mechanism of their action is different among the members of the family. SOCS-1 binds to the catalytic domain of Jak-2 kinase, whereas CIS competes with signaling molecules, such as STATs, for binding to STAT binding sites ([553]). SOCS-1 and SOCS-3 inhibit IL-4–dependent STAT-6 activation by binding to Jak-1 ([554] , [555]).

IL-4 activates the Ras-MAPK pathway through interaction of IRS-2 with the Grb2 protein. The Ras pathway, and other small guanosine triphosphatases (GTPases) that are related to Ras, is regulated by the Ras GTPase activating protein, which activates the GTPase activity of Ras. Down-regulation of Ras is controlled by a molecule that is termed *interleukin-four receptor interacting protein* (FRIP), which binds to the I4R motif of IL-4Ra and, through Ras GTPase activating protein (Ras GAP), inactivates the Ras GTP active form.

FUNCTIONS OF INTERLEUKIN-4 IN T-CELL–B-CELL INTERACTIONS IL-4 plays a central role in differentiation of naïve T cells to T_H2 cells capable of producing IL-4, IL-5, IL-10, and IL-13 (Chapter 17). Thus, IL-4, through T_H2 differentiation, controls humoral immunity. IL-4 increases MHC class II expression in B cells, DCs, and macrophages, thus enhancing their class II antigen presentation, and up-regulates the CD23 expression of B cells. IL-4 promotes activation and viability of B cells. A major role of IL-4 in B-cell function is in class switch, as it induces the switch to IgG1, IgG3, IgG4, and, most importantly, IgE. In this respect, it plays a major role in allergic reactions and protection against helminthic infestations. The mechanism of promotion of CSR by IL-4 is through up-regulation of AID ([556]). AID is required for CSR and hypermutation (see Immunoglobulin Class Switch). CD45 has recently been defined as a Janus phosphatase (556a). It negatively regulates IgE CSR in human B cells through inhibition of IL-4–induced (plus anti-CD40) IgE germline transcription.

Interleukin-5 and Interleukin-5 Receptor

IL-5 was originally described as a T-cell replacing factor or B-cell growth factor 2. It affects the terminal differentiation of B cells and is a single polypeptide of a total of 134 amino acids with a molecular weight of 30 to 40 kd ([557]). Its tertiary structure reveals two domains with a cytokine fold (four a helices and two ß sheets), as is seen in GM-CSF, IL-2, and IL-4. The IL-5 gene is found on chromosome 5.

The IL-5 receptor is expressed on B cells, eosinophils, and certain cell lines. It consists of an a- and ß-chain. The $ß_c$-chain is shared by GM-CSF and IL-3 receptors and is functionally analogous to other common chains that are shared by several cytokines, such as the gp130 of the IL-6 family and the common ?-chain of the IL-2

receptor family. The ß $_c$-chain consists of 880 amino acids with four extracellular domains that are related to the FnIII domains, a single region, and the intracellular region ([558]). The four extracellular domains consist of seven ß strands (A through G), which form two cytokine receptor modules. The membrane-proximal module contains the recognition contact sites for the a-chain ([559]). The membrane-proximal cytoplasmic region shows similarities to the sequences of box 1 and box 2 of other receptors and serves for recruitment of members of the family of Jaks. The cytoplasmic region also contains several Tyr residues that are phosphorylated after cytokine binding. Binding of the cytokine induces dimerization of the receptor through free Cys that is present in the a subunit and in the first domain of the ß $_c$-chain. The disulfide bonds that are formed involve the a-chain of one receptor with the ß $_c$-chain of the second receptor and vice versa. Dimerization is essential for the Tyr phosphorylation of the receptors. Because the ß $_c$-chain is shared by different cytokines, there are sites that are specific for shared interactions.

Detailed studies of the function of IL-5 on mouse B cells have concluded that IL-5 stimulates production of IgM, IgG1, and IgA. IL-5 acts on surface IgA $^+$ B cells to induce IgA production; therefore, it acts on B cells that are committed to IgA secretion. IL-5 synergizes with IL-4 in augmenting IgM secretion of human B cells and with IL-2 for IgG, IgG, and IgA secretion. The effects of IL-5 are detected on activated B lymphocytes.

IL-5 plays a unique role in the production, activation, and localization of eosinophils ([560]), which are seen in patients with asthma and helminthic infestations. IL-5 is detected in some patients with severe exacerbations of asthma ([561]), and it is conceivable that exacerbations are associated with activation of T cells that secrete IL-5. Local expression of IL-5 was detected by *in situ* hybridization in mucosal bronchial biopsies, which was correlated with the number of infiltrating eosinophils ([562]). Patients who are infected with the filarial parasite *Loa loa* produce high levels of IL-5 ([563]).

Interleukin-6 and Interleukin-6 Receptor

IL-6 is a cytokine with pleiotropic activities produced by a great variety of cells (Table 18.3) that plays a central role in immunity and inflammation. IL-6 induces (a) terminal differentiation and Ig secretion of B cells; (b) growth promotion of B cells, plasma cells, and myeloma cells; (c) support of colony formation by stem cells; (d) induction of acute phase response (APR) proteins; (e) differentiation and activation of T cells and macro-phages; and (f) neural differentiation. It is also involved in the pathology of several diseases, such as rheumatoid arthritis, proliferative glomerulonephritis, and multiple myeloma. At least 11 different activities are known, with an equal number of acronyms; these turned out to be mediated by the same molecule, which was called *IL-6*. IL-6 is a member of a family of structurally and functionally related cytokines, which includes IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), and cardiotrophin-1 (CT-1). Redundancy of function is a result of the sharing of the signal-transducing component of gp130.

TABLE 18.3. Interleukin-6 Production

Producing Cell	Inducer
B cells	IL-4, IL-1, and TNF-a
T cells	Phytohemagglutinin and tissue plasminogen activator
Macrophages	IL-6, interferon-?, granulocyte-macrophage colony-stimulating factor, IL-1, and LPS
Endothelial cells	LPS, interferon-?, IL-1, IL-4, and TNF-a
Fibroblasts	IL-1, TNF-a, and LPS
Keratinocytes	IL-1, IL-4, and phorbol myristate acetate
Osteoblasts	IL-1, TNF-a, and LPS
Kupffer cells	IL-1, TNF-a, and LPS

IL, interleukin; LPS, lipopolysaccharide; TNF, tumor necrosis factor.

IL-6 is a glycoprotein that belongs to the long-chain, four–a-helical bundle of cytokines ([564] , [565] and [566]) and binds to the IL-6R–gp130 complex (see the following discussion) but, in addition, has the intriguing property of a lectin that interacts with a trisaccharide (HNK-1 or CD57) ([567]) (Chapter 2, CD57). CD57 is a sulfated trisaccharide that is carried by *N*-glycans, that is, complex polysaccharides. It has been identified in the nervous system as a major target of peripheral neuropathies in patients with lymphomas.

IL-6R consists of an extracellular region with one Ig-like domain (C2-type) and two FnIII domains, which form the *cytokine-binding domain* (CBD), which is characteristic of the class I cytokine receptors. The first FnIII domain has two disulfide bonds, whereas the second has the sequence WSXWS ([568]). IL-6 binds to the IL-6R–gp130 complex by three contact sites. Site one is located in the loop that connects helices A and B of the IL-6 and interacts with the D2 domain of IL-6R. Site two is located at the C-terminal of helix D of IL-6, and interacts with the D2 domain of gp130 ([569]). A third site interacts with the N-terminal Ig-like domain (D1) of gp130. gp130 is the signal transduction component of the IL-6–gp130 complex, because the cytoplasmic region of IL-6R is short ([570] , [571] and [572]).

The gp130 protein has an extracellular region that consists of six domains. D2 and D3 have the features that are characteristic of the cytokine-binding domain of class I cytokine receptors. D1 is an Ig-like domain, whereas D4 to D6 are FNIII domains. IL-6 induces the formation of a hexamer that consists of two molecules each of IL-6, IL-6R, and gp130. The crystal structure of gp130 shows that the uncomplexed receptor assumes an L-shaped quaternary structure with limited flexibility ([573]). gp130 associates with other cytokines, such as OSM, LIF, and CNTF. The crystal structure shows that there is little domain reorientation of the ligand-binding domains, indicating that the overall structure is adaptable to bind multiple cytokines ([573]). The gp130 protein also has an *N*-glycan that carries the HNK-1 epitope ([574]), which interacts with IL-6. The lectin activity of the IL-6 is necessary for the initial signal transduction ([574]).

Binding of IL-6 to the IL-6R–gp130 complex triggers signal transduction, which follows two pathways: the Src protein tyrosine kinases and the Jaks ([575]) (Fig. 18.19). Activated Jaks phosphorylate several Tyr (Y) residues of the gp130 cytoplasmic region, which then become docking sites for signaling molecules that possess SH2 domains (575a and 575c). The second membrane proximal Y recruits the SHP-2 phosphatase, leading to the activation of MAPK. Activation of the Src kinase, Hck, phosphorylates adaptor molecules that link to the Grb2, SOS, Ras pathway to MAPK activation ([576]). This pathway mediates proliferative signaling and, at the same time, through activation of SHP-2 phosphatase ([577]), dephosphorylates Pyk2 and blocks dexamethasone-induced apoptosis of myeloma cells ([578]).

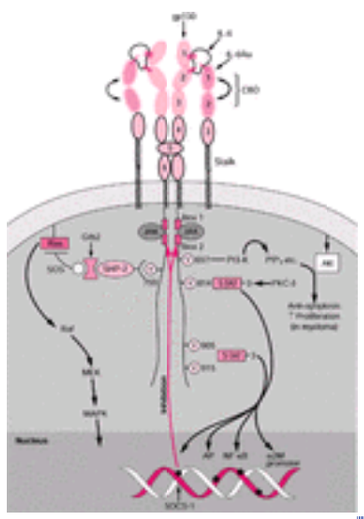

Figure 18.19. Interleukin (IL)-6 and IL-6 receptor (IL-6R) signaling. The IL-6 binds first to IL-6Ra (site I). This binary complex forms a composite site that is termed *site II*, which interacts with the cytokine binding domain (CBD) of gp130 (which includes domains D2 and D3), forming a trimolecular complex. Recruitment of site III on the

immunoglobulin-like activation domain (IGD) (i.e., D1 of the gp130) results in the formation of higher-order activation complexes (i.e., a hexamer), which is fully active (gene transcription). High-affinity binding to the N-terminal domains of gp130 (D1 to D3) is not sufficient for receptor activation. The membrane proximal (D4 to D6) domains of gp130 are necessary for activation, as they facilitate appropriate spacing (especially D5) of the cytoplasmic components of gp130. gp130 is the signaling component of the complex and recruits Jak-1 and Jak-2 kinases, with Jak-1 having an essential role. Jaks bind to box 1 and box 2 of the membrane proximal cytoplasmic regions. The N-terminal domain of Jaks comprises a 4.1-ezrin-radexin-moesin domain, which is crucial to link Jak with the receptor. Proteins 4.1 is a large family of proteins that link the membrane of the cell with the cytoskeleton. Jaks phosphorylate tyrosines (Y), which then act as docking sites for signal transducer and activator of transcription (STAT) 3 factors. On dimerization, STAT-3 is translocated to the nucleus, binding to DNA through its DNA-binding domain. STAT-3 is phosphorylated on serines by PKC-? kinase. Phosphoinosi-tide 3-kinase (PI3-K) is recruited on phosphorylated tyrosine 657. The other important signaling pathway involves activation of SHP-2 phosphatase, which interacts with Grb2-SOS adaptor proteins and leads to Ras activation and the ERK1/2–mitogen-activated protein kinase (MAPK) cascade. STAT binding sites are in close proximity with binding sites of other transcription factors. MEK, mitogen-activated extracellular signal–regulated kinase; PIP, phosphatidylinositol phosphate. Any of the four most distal Tyr residues mediate STAT-3 activation. The STAT-3 structure is similar to that of other STATs: an N-terminal tetramerization domain, a central DNA-binding domain, a conserved SH2 domain (that binds to the cytokine receptor or another STAT molecule for dimerization), followed by a conserved Y and a C-terminal transactivation domain. STAT-3 is the major STAT in IL-6 signaling ([579]). IL-6 signaling is down-regulated by SOCS-1 (see the previous discussion), which is induced via activation of STAT-3 ([580]). Another mechanism of IL-6R down-regulation involves endocytosis of gp130, after IL-6 binding. It is mediated by a dileucine motif after phosphorylation of a Ser residue in the cytoplasmic tail of the gp130 protein ([581]) (Fig. 18.19).

Interleukin-6 in T-B Cell Interaction and Myeloma

On T cells, IL-6 acts as an activation, growth, and differentiation factor. It can replace co-stimulatory signals from APCs to stimulate IL-2 secretion and T-cell proliferation (Table 18.4).

TABLE 18.4. Interleukin-6 Functions

Target	Function
B cells	Production of IgM, IgG, IgA
	Growth of plasma cells
T cells	Activation
	Growth
	Differentiation
Hematopoietic progenitors	Induce progression from G_0 to G_1 phase
	Enhance survival
	Stimulate proliferation
	Enhance megakaryopoiesis
	Macrophage differentiation
Hepatocytes	Acute phase protein synthesis
Skin	Stimulates proliferation of keratinocytes
Blood vessels	Increase permeability
Neuronal cells	Proliferation of astrocytes
	Survival of cholinergic neurons

Ig, immunoglobulin.

IL-6 is the most important growth factor for B cells (normal and malignant). It is a potent stimulator of terminal B-cell differentiation and antibody formation ([582]).

The role of IL-6 in multiple myeloma has been extensively studied ([583]). It is involved in proliferation of plasmablasts and differentiation into mature plasma cells, acting by an autocrine or paracrine mechanism. In addition to its proliferative activity, it blocks the apoptotic pathway (see the previous discussion). The gp130 protein is activated sometimes in the absence of direct ligand binding, i.e. independent of IL-6R and IL-6. IFN-a induces tyrosine phosphorylation of gp130 in myeloma cell lines that are responsive to IL-6 ([584]). The question is raised of whether receptor cross-talk may be a common theme in the biology of multiple myeloma. The human herpesvirus 8 (HHV-8) is associated with all forms of Kaposi sarcoma (KS) as well as primary effusion lymphoma. It is found in the lymph nodes of a high proportion of patients with multicentric Castleman disease, a polyclonal plasmacytosis that is characterized by hyperplastic lymphadenopathy ([585] , [586] and [587]). IL-6 is present at elevated levels in KS and multicentric Castleman disease lesions, and IL-6 promotes the growth of KS cells in culture. HHV-8 encodes a homolog of human IL-6 that is known as *viral IL-6 (vIL-6)*, which acts as a mitogenic factor and induces intracellular signaling that is generally the same as IL-6. vIL-6 induces receptor dimerization and forms complexes with IL-6R and gp130 ([588] , [589]). Signaling by vIL-6 may be dependent or independent of the IL-6Ra.

One of the most striking responses to injury and inflammation is the *acute phase response* (*APR*). APR consists of alterations in several serum proteins that are known as *acute phase proteins (APPs)*, which are synthesized mainly by the liver. The response involves more than 1000-fold increases in C-reactive protein (CRP) and serum amyloid A (SAA) and moderate increases in fibrinogen, a-1 antitrypsin, complement factor B, and others. The biosynthesis of these proteins takes place in the liver and is regulated by a factor that was known as *hepatocytes stimulating factor* (HSF), which later was shown to be IL-6. Several other cytokines, such as IL-1, TNF-a, IL-11, and TGF-ß, are also capable of inducing APP from the liver. In addition to induction of APP, other systemic responses are associated with APR, such as fever and release of ACTH. These responses are also mediated through IL-6.

IL-6 has multiple other effects, such as bone remodeling, proliferation of keratinocytes, increase of endothelial cell permeability, and proliferation of astrocytes.

Interleukin-10 and Interleukin-10 Receptor

The search for a product of T_H2 cells that would inhibit proliferation, effector function, and even development of T_H1 cells resulted in the discovery of a factor that inhibited cytokine synthesis. This cytokine synthesis inhibitory factor (CSIF) was called *IL-10*. It is produced by T_H2 clones and inhibits the synthesis of IFN-? from the T_H1 clones ([590]).

The primary structure of the IL-10 was determined from a complementary DNA that was isolated from T_H2 cells ([591]). It has four a-helices and is expressed as a noncovalent dimer ([592] , [593]). The IL-10 gene is located on chromosome 1. It expresses strong homology to an open reading frame in the Epstein-Barr virus genome, GCRF1 ([591]). This gene may represent an ancestral captured cellular cytokine gene and is designated *viral IL-10* (vIL-10).

In addition to T cells, IL-10 is produced by macrophages in response to LPS, by B cells, especially after Epstein-Barr virus transformation ([594]) and by keratinocytes,

especially after exposure to ultraviolet light.

IL-10 stimulates strongly proliferation of B cells, especially after cross-linking of CD40 by anti-CD40 antibody ([595]), and this effect is synergistically enhanced by IL-4. IL-10 induces B-cell differentiation that is activated by anti-CD40 antibodies, with the production of large amounts of IgM, IgG, and IgA antibodies. This activity is antagonized by IL-4 but is enhanced by TGF-ß, especially for IgA secretion ([596]). In general, the effects of IL-4 and IL-10 on proliferation and differentiation of B cells account for much of the noncontact help that is provided during T-cell–B-cell interactions in antibody responses. As a suppressor cytokine of T-cell proliferation and cytokine response, IL-10 plays an important role in tolerating exogenous antigens, especially in immunotherapy of allergy ([597]). It selectively inhibits the CD28-mediated co-stimulatory pathway and, as a result, inhibits T-cell responses that are initiated by engagement of a small number of TCR, a situation that is critically dependent on CD28 co-stimulation. Blocking of CD28 co-stimulation depends on inhibition of CD28 tyrosine phosphorylation, which is the initial step in co-stimulation by CD28. IL-10 regulates cyclooxygenase-2 expression and reduces production of prostaglandins that act directly on cyclooxygenase-2 expression or through regulation of inflammatory cytokines ([598]).

IMMUNOGLOBULIN STRUCTURE

Antibodies are Igs that are produced by B cells in response to foreign antigens; therefore, they have the property of binding specifically to the antigen that triggered their production. Igs constitute the fraction of plasma proteins, originally defined as ?-globulins, because they were located behind the a- and ß-globulins, as a result of their slow electrophoretic mobility. When it was shown that these ?-globulins are products of cells of the immune system, they were given the name *immunoglobulins*.

Antibodies have two fundamental properties for defense against pathogens: They bind specifically to the antigen that is responsible for their induction by one part of their molecule and then dispose the captured antigen with the cooperation of other molecules (complement) or cells (phagocytes) of the immune system.

Primary Structure: One Polypeptide from Two Genes

One of the most revolutionary hypotheses in the recent history of molecular biology was proposed for the structure of the antibody molecule: The Ig molecule is encoded by two different sets of genes ([599]). The C-terminal region is encoded by one gene that is selected from a small group of genes, whereas the N-terminal region is encoded by two or three genes that are selected from a large number (hundreds) of genes. The Ig molecule consists of two short or light (L) chains and two long or heavy (H) chains, which are held together by disulfide bonds.

The two L chains are of equal length, each consisting of 214 amino acids. The H chains vary in length; the shortest is the ?1-chain, which is made of 446 amino acids, and the longest is the µ-chain, which is made of 567 amino acids. A striking feature of the primary structure of H and L chains is the considerable variation at the N-terminal end of the chains as compared to a significant degree of homology at the C-terminal end. The former region is known as the *variable* or *V region*, and the latter as the *constant* or *C region*. In L chains, the V region of the light chain (V_L) constitutes one-half of the chain (amino acids 1 to 107), and the remaining part of the chain is the constant (C_L) region of the light chain. The L chains are encoded by a V and a J gene (N-terminal one-half) and a C gene (C-terminal one-half). For L chains, the V gene contributes amino acids 1 to 95, and the J gene contributes the remaining 13 amino acids. The V region of the H chains is encoded by three genes, V_H, J_H, and D (Chapter 16). For the V_H region, the V_H gene encodes amino acids 1 to 94, and the remaining amino acids are encoded by the D_H and J_H genes. The rest of the chain is divided into three constant regions, C_{H1}, C_{H2}, and C_{H3}, for IgG, IgA, and IgD, and four constant regions for IgM and IgE.

Within the V regions are three short stretches of amino acid sequences that show extreme variability and are therefore known as *hypervariable regions*. Hypervariable regions contain amino acids that are in contact with the antigen, and, in the primary structure of the molecule, these regions are separated by long stretches of less variable amino acid sequences. However, these hypervariable regions are in close proximity to each other when the molecule assumes its functional tertiary structure. Amino acid sequences that are not part of the hypervariable regions form the *framework regions* and constitute 80% of the V region.

Secondary Structure: Immunoglobulin Fold

Results from crystallographic studies confirm that the Ig polypeptide chain is folded back and forth on itself in opposite directions (antiparallel), forming a sheet, which is known as the ß *pleated sheet*, and is arranged as a sandwich (or ß barrel), with a hydrophobic center. This is known as the *Ig fold* (Fig. 18.20). Each strand bends in a hairpin fashion when it changes direction. Almost all bends contain a Gly that is highly conserved.

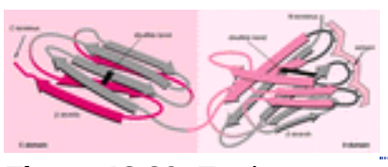

Figure 18.20. Tertiary structure of a light chain that depicts the variable (V) and constant (C) domains. Each domain is composed of two sheets that are formed by strands of polypeptide chains that possess the basic ß pleated structure. In each sheet, the strands run in alternating directions (antiparallel). The strands are shown as broad arrows, pointing in an N-terminal to C-terminal direction. The strands that belong to the same sheet are blank or hatched. Stretches of polypeptide chains that connect the strands form loops. Three of these loops in the V domain include the complementarity-determining regions (CDR), which are involved in antigen binding. The strands are identified by letters, A to G, starting from the N-terminal end. The V domain contains two additional strands C' and C? (which are not shown in the diagram as broad arrows). Interactions between the V_L and V_H sheets contribute to the formation of a cylindric V module that contains the antigen combining site. The black bars represent the disulfide bonds.

Tertiary Structure: Immunoglobulin Domain

The intrachain disulfide bonds divide each chain into globular structures of approximately 100 to 110 amino acids that are known as *domains*. The IgG molecule has four V-region domains, one C_L per L chain and three C_H per H chain. Considerable homology exists between the V domains and between all C domains. The degree of homology suggests that domains originated from one primordial gene and evolved independently rather than as a group comprising a single H chain. Each Fab fragment (see the following discussion) has four domains: the V_L and V_H interact to form the V module, and the C_L and C_{H1} interact to form the C module. Each domain is made of two ß pleated sheets (x and y), one consisting of three, the other of four, antiparallel strands that are labeled A through G. In each of the two V domains, there are two additional strands that are called C' and C?. The sheets are held together by one invariant disulfide bond and by interactions between the strands A-B-E and D for the C modules and C-C-F and G for the V module. The hypervariable regions correspond to the hairpin loops that link the strands as they turn around to run in the opposite direction, which are called *complementarity determining regions CDRs* (Fig. 18.20). Each V domain has three CDRs for a total of six in the V module. They are known in sequence order along the polypeptide chain as L1, L2, and L3 for the V_L domain, and H1, H2, and H3 for the V_H domain. The length of each CDR varies considerably, both as a function of usage of the V gene, mainly affecting CDR-1 and -2, and as a consequence of junctional diversity—that is, additions of amino acids during V(D)J recombination that affect the CDR3 (Chapter 16). All six CDRs contribute to the formation of each combining site. Because of their positioning in the free end of the V module, they are endowed with some mobility, which may be important for binding with the antigen. In the Fab fragment, they form a cavity that is 15 Å long, 6 Å wide, and 6 Å deep. The strands correspond to conserved sequences that are known as *framework (FR) sequences*. Each V domain has four conserved FR sequences, FR1 through FR4. The Ig fold is not unique to the Ig molecule but is also found in other molecules, such as the a-ß and ?-? T-cell receptors; the class I and II MHC molecules; the CD2, CD3, CD4, and CD8; and the $ß_2m$, which represents a free domain. Several other proteins have Ig-like domains that form the Ig superfamily.

Quaternary Structure: Immunoglobulin Monomer

The Ig molecule consists of four polypeptide chains, which are held together by disulfide bonds and noncovalent interactions ([600]) (Fig. 18.21). Two of the chains have a molecular weight of 53 kd (IgG) or 75 kd (IgM) and are known as *H chains*. The other two chains have a molecular weight of 22.5 kd and are known as *L chains*. The former determine the major Ig class of the molecule: IgG, IgM, IgA, IgD, and IgE. The respective H chains are designated by the Greek letters: ? (IgG), µ (IgM), a (IgA), ? (IgD), and e (IgE). Within each class are subclasses: four for IgG ([1], [2], [3], and [4]), two for IgM, and two for IgA. The H chains are distinguished by

isotypes to identify antigenic determinants that are shared by all individuals of a given species. Humans have ten loci for constant region genes and, therefore, 10 isotypes that correspond to the total number of what otherwise are known as subclasses: µ1, µ2, ?, ?1, ?2, ?3, ?4, a $_1$, a $_2$, and e. There are only two types of L chains, kappa (?) and lambda (?). The L chains of the ?-type exist in four isotypes (?1, ?2, ?3, and ?4). Any given Ig molecule has two ?-chains or two ?-chains but never one of each type. The ? to ? ratio varies between species: In humans, it is 70:30, whereas in the mouse, it is 95:5.

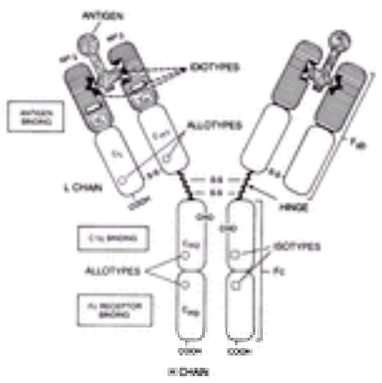

Figure 18.21. Basic arrangement of the polypeptide chains, the enzymatic fragments, and their domain structure of the immunoglobulin G molecule. Locations for structures that are defined as idiotypes, allotypes, and isotypes are shown, as well as the position of the carbohydrate (CHO). Various domains are shown on the left side.

The hinge region is located between C $_{H2}$ and C $_{H3}$ and is rich in proline residues. Cysteines form the interheavy chain disulfide bonds. Because of its unique amino acid sequence, this region does not fold well and thus becomes susceptible to enzymatic attack. The hinge region also affects the flexibility of the molecule and other properties, such as complement binding. IgM and IgE have no hinge region but instead have an extra C domain.

Disulfide bonds are important because they maintain the association of the four chains and divide the Ig molecule into functional domains. The H and L chains are held together by interchain disulfide bonds. Each L chain is attached to the H chain by one disulfide bond, with the exception of human IgA2, which contains no disulfide bond between H and L chains. The disulfide bond is formed between C-terminal cysteine of the ?-chain or the penultimate cysteine in the ?-chain and the cysteine that is closest to the middle of the H chain.

The two half-molecules are held together by interchain disulfide bonds between the two H chains. The number of these bonds varies between classes: the IgG1 molecule has two, whereas IgG3 possesses 15. Disulfide bonds exist within each chain (intra-chain). All L chains have two bonds, and all ?- and a-chains have four bonds; µ-, ?-, and e-chains have five bonds. Because the cysteines that form the intrachain bonds are separated by 40, or even 70, amino acids, the bond can be formed only if the two cysteines are brought into apposition by looping the intervening sequence. The regularity of the distribution of the intrachain disulfide bonds formed the basis of the domain hypothesis, in which the Ig molecule is separated into distinct functional regions (601).

Carbohydrate Moiety

Carbohydrate chains are of variable length and shape. The number of these chains varies between isotypes: two in IgG molecules, ten in IgM molecules, 16 in IgA molecules, and 12 in IgE molecules. The carbohydrate chains are attached to the C $_{H2}$ domain, forming a bond between the first carbon of asparagines and the sugar *N*-acetylglucosamine (GlcNAc). Procedures that interfere with the glycosylation of the a- and e-chains prevent the secretion of IgA and IgE molecules.

Enzymatic Fragments

Treatment of the Ig molecule with papain generates three fragments. Two of these fragments are identical; each contains one antigen-binding site and thus are known as *Fab* (fragment antigen-binding) (602). The third piece, which is known as *Fc* (fragment crystallizable), mediates fixation of Ig molecules to skin and other cells (macrophages and lymphocytes), fixes complement, and mediates transport of the Ig molecule across the placenta. Digestion of the Ig molecule with pepsin yields one large piece, with a molecular weight of 100 kd. This divalent fragment, which is known as *F(ab)* $_2$, consists of two Fab fragments, each capable of binding antigen. The Fc fragment is digested by pepsin into small peptides (Fig. 18.22).

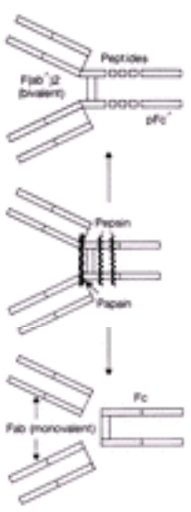

Figure 18.22. Proteolytic fragmentation of the immunoglobulin G molecule by papain and pepsin. Papain hydrolyzes the molecule to the N-terminal side of the interchain disulfide bonds and releases three fragments of approximately equal size, two Fab and one Fc. Pepsin acts on the C-terminal side of the disulfide bonds and forms one large divalent fragment [F(ab')2]; the Fc is fragmented to small peptides and one larger fragment that is known as *pFc'*.

Combining Site

The antigen-combining site is located near the tip of the two arms on the Y-shaped Ig molecule (603 , 604). The size of the combining site was determined initially by Kabat by using antidextran antibodies that reacted with oligosaccharides of different lengths. Maximal inhibition of the binding was obtained with an oligosaccharide that consisted of six isomaltohexose molecules. The structure of the combining site has also been studied by means of affinity labeling. With this technique, the hapten is linked to a chemical group that interacts with the amino acids that are closest to those that form the combining site. This method helped demonstrate that H and L chains participate in the formation of the combining site. The antigen-binding V module may be viewed as a stable, packed FR structure with six superimposed flexible CDRs. Molecular biologists have now constructed hybrid genes that combine FR and CDR from different Igs. On transfection to lymphoid cell lines, these genes produced antibodies with the specificity of the CDR donor (605).

Idiotypes and Allotypes

Antibodies and myeloma proteins possess determinants that are characteristic for each antibody or myeloma protein and are known as *individually specific antigenic determinants* or *idiotypes*. Idiotypes can be detected by means of antisera. Some antiidiotypic antibodies detect determinants that are restricted to a single Ig (individual, or private, IdI), and other antibodies detect determinants that are present in antibodies or myeloma proteins other than those that are used for immunization (public, or cross-reactive, IdX). Idiotypic determinants, which are known as *idiotopes*, have also been classified according to their location in relation to the combining site: a-idiotopes are located outside of the combining site; ß-idiotopes are close to the site, so that the binding of the antiidiotypic antibody interferes

with the binding of the antigen; and ?-idiotopes are formed by the site itself ([606]).

In addition to CDR, the idiotope-determining region (IDR) can be defined not on the basis of amino acid sequence variability, but as a surface-variable structure that is complementary to a structure on the V region of another Ig molecule. Although all CDRs are also IDRs, the partial overlap between these two kinds of regions suggests that IDRs outnumber CDRs ([606]). IDRs, therefore, are functionally involved in antigen recognition, as well as in recognizing and being recognized by other Ig molecules. This functional attribute of IDR is central to the network theory of immune regulation of Jerne ([607], [608]).

Allotypes are allelic variants of Ig polypeptide chains that segregate in mendelian fashion in outbred populations. Allotypes that vary by one or a few amino acids are simple allotypes, whereas those that are characterized by greater differences are complex allotypes. In humans, Ig allotypes have been well characterized for all subclasses of the IgG (?) H chains (Gm allotypes), for IgA (a) H chains (Am allotypes), and for the ?-chains (Km allotypes). The current nomenclature contains the class and subclass of the allotype (G1m, G2m, G3m, and G4m) as well as the specific allotype number in parentheses, for example, G3m(5) ([609]). Some allotypes are conformational and only become reactive with antibody when the allotype-carrying chain is associated with another chain. Km allotypes are detected only when their K chain is linked to an H chain. The Km allotypes, Km(1), Km(1,2), and Km(3), result from amino acid substitutions at positions 153 and 191 in C?. These two positions are in close apposition within the C? domain and form the Km determinant, which appears to be on the surface of the domain and is therefore capable of inducing antibodies. The isotypic markers of C? (known as *Oz* and *KERN*) also are close to those positions. The H chain allotypes of different H chain isotypes are inherited together as a group, which is sometimes referred to as a *haplotype*.

IMMUNOGLOBULIN FUNCTION

Immunoglobulin G

IgG is the major Ig in humans and constitutes approximately three-fourths of the total Ig (Table 18.5). The serum concentration varies from 8 to 16 g/L in adults, but the intravascular pool accounts for less than one-half the total body IgG; approximately 55% is found widely distributed within the extravascular space. The total body content is in excess of 1 g/kg of body weight. IgG molecules have a half-life of 21 days and therefore have the longest lifespan.

TABLE 18.5. Properties of Immunoglobulins

Properties	IgM	IgG	IgA	IgD	IgE
Subclasses	2	4	2	—	—
Molecular weight (kd)	950	150	150 to 300	185	190
Heavy chain	µ	?	a	?	e
Light chain	?, ?	?, ?	?, ?	?, ?	?, ?
Percent carbohydrates	10 to 12	4	10	12	12
Survival ($t_{1/2}$ days)	5	21	6	3	2
Complement fixation					
Classical	+++	+	–	–	–
Alternative	–	–	+	+	+
Cross placenta	–	+	–	–	–
External secretions	+	+	+++	–	+
Cytophilic for:					
Macrophages	±	+++	–	–	–
Mast cells	–	±	–	–	+++
Serum concentration (g/L)	1.5	11.0	2.4	0.03	<0.005
Percent of total Ig	5	80	15	—	—

Ig, immunoglobulin; +, weak; +++, strong; -, negative; ±, borderline.

The four isotypic subclasses of IgG molecules are distributed as follows: IgG1, 66%; IgG2, 23%; IgG3, 7%; and IgG4, 4%. These antigenic differences are the result of variations in amino acid sequences of the carboxy-terminal parts of the ?-chains. All four types of molecules are found in any given normal serum, but individual molecules contain only a single type of ?-chain. The IgG subclasses carry numbers of disulfide bonds that are arranged in different ways. The hinge region is also strikingly different among the subclasses; it is long in IgG3. The length of the hinge region is important for certain functions of the Fc fragment.

BIOLOGIC PROPERTIES Most of the antibodies that are found in secondary antibody responses to antigen are IgGs. IgG is selectively transferred across the placenta, thereby giving a measure of protection to the newborn ([610]) (Table. 18.5). Some biologic properties of IgG proteins, and particularly those that are mediated by the Fc fragment, are distinctly subclass specific. IgGl and IgG3 react most readily with C1q, the first component of complement, and therefore activate complement most efficiently. IgG2 is less reactive, and intact IgG4 proteins are completely unreactive. The binding of Fc to macrophage and granulocyte Fc receptors is most efficient with IgG1 and IgG3, and this reaction is important in the process of opsonization. Anti-Ig antibodies (rheumatoid factors) react most readily with IgG1, IgG2, and IgG4 proteins and not at all with IgG3 proteins ([611]). IgG3, on the other hand, has a tendency to aggregate ([612]), a property that probably is also responsible for the affinity of the molecule for C1q. Aggregation of IgG3 may lead to clinically significant hyperviscosity states, especially in patients with IgG3 myeloma. In addition, IgG3 is selectively retained in the sera of some patients who have generalized hypogammaglobulinemia ([613]). Some antibody activities are subclass specific. Thus anti-Rh antibodies are usually IgG1 or IgG3; anti–factor VIII antibodies are often restricted to IgG4, and other antibodies, such as antidextran and antilevan, have been found to be IgG2.

Immunoglobulin A

The IgA class of antibodies can be divided into two separate systems of Ig ([614], [615]). One system, IgA1, provides IgA antibodies for the circulation and the internal secretions, such as the aqueous humor of the eye, the cerebrospinal fluid, and the synovial, amniotic, pleural, and peritoneal fluids. These IgA antibodies probably are synthesized by nonmucosal lymphoid tissues. The other system, IgA2, is found in external secretions, such as saliva, tears, bile, and colostrum, as well as secretions of the respiratory tract, the gastrointestinal tract, the seminal vesicles, the cervix, and the urinary tract. The IgA of external secretions is, for the most part, not derived from the blood but is produced locally by plasma cells that are situated in proximity to the epithelial mucosa. It is the predominant Ig in external secretions, although smaller amounts of IgM and IgG also may be found.

In the serum, 85% of IgA molecules are monomers, with a molecular weight of 170 kd and a sedimentation coefficient of 7S; 9S, 11S, and 13S polymers make up the remainder. Approximately 1% is secretory IgA; this percentage increases in association with a variety of mucosal inflammatory diseases. The serum concentration of IgA is in the range of 2 to 3 g/L, with a half-life of 6 days. Monomeric IgA is composed of two H (a) and two L chains. The a-chains of IgA1 and IgA2 subclasses are strikingly different in the hinge region. Certain bacterial proteases cleave IgA1, but not IgA2, into Fab and Fc fragments. These IgA1 proteases are exquisitely specific. In the IgA2 subclass, the H and L chains are not held together by a disulfide bond.

Secretory IgA (sIgA) is a large molecule with a molecular weight of 390 to 400 kd. It consists of two IgA molecules forming a dimer and two additional non-Ig components, which are known as the *J chain* and the *secretory component* (SC) ([616], [617]). The J chain joins two IgA molecules through a disulfide bond to form a dimer, whereas the SC is the extracellular part of the polymeric Ig receptor (pIgR), which remains attached to IgA after trans-epithelial crossing (Fig. 18.23) ([618]). The epithelial cells in the glands and basolateral crypts of the gastrointestinal and upper respiratory tracts produce the full-length (100 kd) pIgR located in the nonserosal surface of the epithelial cells. It consists of five V-type Ig-like domains in the extracellular region, a transmembrane, and a 103 amino-acid intracellular region. Binding of polymeric IgA (pIgA) to the first extracellular domain of the pIgR is followed by endocytosis and transcytosis across the epithelial cell ([619]). The initial step is

through clathrin-coated pits and requires two cytoplasmic tyrosines of pIgR and phosphorylation of serine 726. The endocytosed complex is delivered first to Rab+ basolateral early endosomes (BEEs) and then on to Rab17+ common recycling endosome (CRE). In this compartment, the complex is sorted and directed to the apical plasma membrane ([619]).

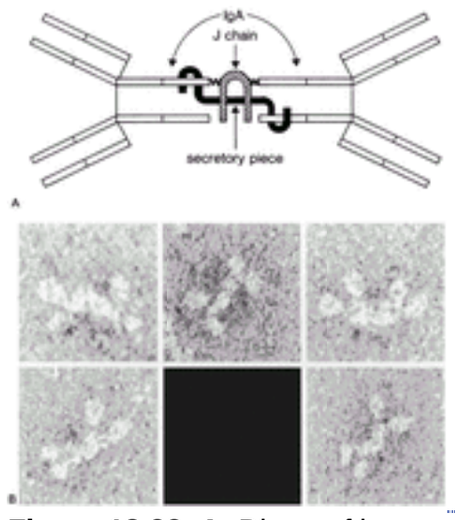

Figure 18.23. A: Dimer of immunoglobulin A (IgA). The J chain is linked through disulfide bonds with the Ca_3 domains of the monomers. The secretory piece attaches through disulfide bonds to the Fc fragments of the monomers. **B:** IgA dimers. (Courtesy of Dr. K. H. Roux.)

The IgA dimer is released on the lumenal side of the epithelial cell, with the extracellular portion of the pIgR (i.e., the SC), still attached, forming the secretory IgA (sIgA) ([620] , [621]). During transcytosis, disulfide bonds form between pIgR and pIgA. The J chain is essential for the transport of IgA, and expression of the J chain by plasma cells is particularly critical for the overall function of sIgA in mucosal surfaces ([622]). A disulfide bond between the J chain and the IgA monomer is sufficient for IgA dimerization. IgA polymers are also formed that retain high affinity for free SC. The SC protects the IgA from intracellular digestion by proteolytic enzymes. The SC is more efficient than IgR in providing protection because, as a result of its carbohydrates, it is able to anchor the sIgA to mucus within infected areas, in contrast to the random distribution of pIgR. Furthermore, pIgR can be used by some bacteria (e.g., *Streptococcus pneumoniae*) to gain access to the transcytosis pathway. The IgA transport system is unique in that, in contrast to other pathways, it does not lead to degradation of its ligand, the IgA molecule. The IgA and the asialo glycoprotein transport of hepatocytes occupy the same compartment inside the cell, yet each follows distinct pathways subsequently.

BIOLOGIC PROPERTIES Although IgA is incapable of fixing complement or acting as an opsonin, the secretory IgA molecule, together with complement and lysozyme, is capable of killing *Escherichia coli*. Secretory IgA does not activate complement by the classic pathway, but chemically aggregated IgA (not 11S IgA) has been shown to have activity in the alternate complement pathway. Like other Igs, secretory IgA is capable of blocking bacterial adherence to mucosal surfaces, thereby preventing colonization. It may also act as a blocking antibody to reaginic reactions on mucosal surfaces and may prevent the absorption of antigenic molecules from the lumen of the gut. Surprisingly, most IgA-deficient individuals appear to be fairly healthy and not overly susceptible to upper respiratory tract infections. IgA antibodies against intrinsic factor have been reported in the gastric secretion of patients with pernicious anemia. It has been proposed that IgA may serve as a carrier of antigens from the blood to the mucosal sites, providing an explanation of how antigens find their way into external secretions through the SC transport system. This antigen clearance function of IgA has been substantiated. Perhaps the mucosal synthesis of IgA makes it particularly suitable for removal of dietary and microbial antigens that are absorbed from the gut. More recently, receptors for the Fc portion of IgA were identified on peripheral and alveolar macrophages, lymphocytes, and neutrophils ([623]). Through such receptors, IgA participates in antibody-dependent cell-mediated cytotoxicity reactions.

Immunoglobulin M

IgM antibodies are proteins with a molecular weight of 850 kd that sediment predominantly at 18S to 19S but also at 22S, 26S, and 35S (Table 18.5). Because of their size, IgM molecules are referred to as *macroglobulins*. Their rate of synthesis is only one-twentieth of that of IgG, whereas their fractional catabolic rate is two to three times that of IgG, which accounts for the relatively short survival (half-life of 5 days) and low serum levels (0.8 to 3.0 g/L) of IgM.

IgM macromolecules are composed of five identical subunits that are called *IgM monomers*, each of which consists of two µ (H) chains and two L chains (Fig. 18.24A). The L chains may be ? or ? and are identical to those of other Ig. The H chains, on the other hand, have some unique structural features. Whereas human ?-chains vary in length from 446 to 450 amino acid residues, µ-chains contain in excess of 500 residues and have a correspondingly higher molecular weight of approximately 70 kd. In addition, µ-chains appear to consist of a variable region and four constant regions, in contrast to the three constant regions of ?-chains. Similar to ?-chains, however, each region (constant and variable) contains a loop of approximately 60 amino acids with an internal disulfide bridge that is flanked on either side by approximately 20 amino acids. Carbohydrates account for 10.7% of the molecule by weight and are distributed over five sites within the constant region: one within the Fd region, one in the hinge region, two within Fc, and one near the COOH terminus. They affect the conformation and other properties of the molecule but do not contribute directly to antibody specificity. Two subclasses of IgM (IgM1, IgM2) have been identified on the basis of antigenic differences within the µ-chain.

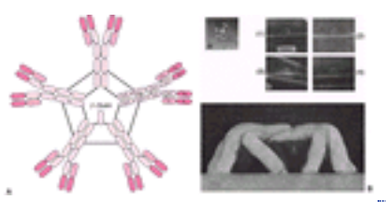

Figure 18.24. A: Immunoglobulin M (IgM) pentameric molecule. The IgM molecule is composed of five subunits that are held together through disulfide bonds. In the polymerization of the subunits, the J chain is involved. (From Roitt IM, Brostoff J, Male DK. Immunology, 2nd ed. St. Louis: Mosby, 1989, with permission.) **B:** By electron microscopy, the IgM molecule appears star shaped **(a)**. When it is bound to antigen, such as the flagellum of *Salmonella*, it assumes the crab or staple form **(b: 1–4)**, a model of which is shown in **c**. (From Feinstein A, Munn EA. Conformation of the free and antigen-bound IgM antibody molecules. Nature 1969;224:1307–1309, with permission.)

In the intact IgM molecule, five monomers are assembled in a star-shaped configuration, with the carboxy-terminal (Fc pieces) being joined at the center through disulfide bonds, whereas the antigen-binding sites (Fab pieces) extend toward the periphery. The molecule appears to have a great deal of rotational freedom, and, although bound to particulate antigen, it may take on the appearance of a staple or a spider (Fig. 18.24B), with its legs (Fab pieces) extending toward the plane of the antigen (a cell surface) and its body consisting of closely linked Fc fragments that protrude from the center, thus making it ideally suited for complement fixation (Fig. 18.25).

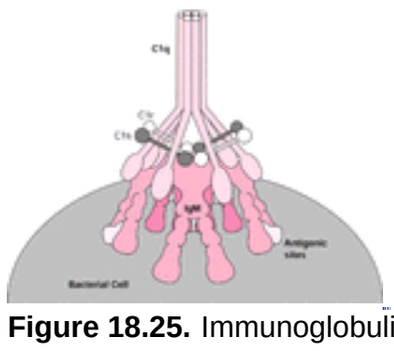

Figure 18.25. Immunoglobulin M (IgM)-C1 esterase interaction. On the surface of pathogens, IgM assumes the staple (as seen sideways) or crab conformation. While

the Fabs touch the surface of a pathogen, or immune complexes deposited on tissues, the Fc fragments form a plateau on which C1q finds space to touch down with the heads of the arms. The C1r-C1s tetramer weaves between the arms as a necklace. Recognition of patterns by C1q creates a conformational shake up, which is transmitted to the catalytic domains of C1r, which is activated. In turn, C1r activates the C1s, which performs the esterase functions of the whole complex, C1 esterase.

Because the IgM molecule consists of five subunits, each with two antigen-combining sites, there are ten combining sites per IgM pentamer. A single J chain has been found attached to the IgM pentamer by disulfide bridges. IgM monomers do not have J chains.

BIOLOGIC PROPERTIES Macroglobulins are restricted mostly to the intravascular pool. Little if any IgM crosses the placental barrier, and the amount that is present at birth is almost entirely of fetal origin. Detectable levels of IgM may be synthesized by the human fetus by as early as the twentieth week of gestation, but high levels of IgM at birth usually are indicative of intrauterine sepsis ([624]). On cell surfaces, a single molecule of IgM readily fixes complement, whereas antibody doublets are required for fixation of complement by IgG. IgG is efficient at 4°C and 37°C, however, whereas IgM is inefficient at the lower temperature. Binding of C1q to IgM has been assigned to both Cμ3 and Cμ4 domains. Mutations that involve a single amino acid in the Cμ3 domain abolishes complement fixation ([625]). Specific macrophage receptor sites for the Fc region of IgM have been described in animal systems. Such receptors may play a critical role in the process of phagocytosis of immune complexes. IgM antibodies are the first to be produced in a primary immune response, to be replaced subsequently by IgG antibodies. However, certain types of antibody responses remain mostly IgM, including those against LPS and the heterophil (Forssman) antigens. Wassermann antibodies, isohemagglutinins, cold agglutinins, and antibodies to the O antigens of gram-negative bacteria are usually IgM.
IMMUNOGLOBULIN M MONOMER IgM monomer (7S IgM) is the predominant Ig on the B-cell surface. Naturally occurring 7S to 8S IgM monomers also have been identified in normal sera, and higher concentrations of monomers occur in association with various diseases, including SLE, Waldenström macroglobulinemia and other hypergammaglobulinemic states, congenital rubella, and immune deficiency disorders, such as ataxia telangiectasia and dysgammaglobulinemia. In some instances, IgM monomers possess antibody activity against blood group substances or cell nuclei (antinuclear factors). IgM monomers may be related to more primitive Ig and appear to be synthesized as such, rather than to represent an *in vivo* or *in vitro* breakdown product of IgM.

Immunoglobulin D

IgD is found in low concentration in normal serum (3 to 400 mg/L) ([626]). It consists of two H (?) chains and two L (? or ?) chains, has a molecular weight of 180 kd, and sediments at 7S. It appears to be catabolized rapidly (half-life of 2.8 days), is confined largely to the intravascular space, and does not cross the placental barrier. The IgD has three constant region domains and an unusual hinge region, which is strikingly different from the hinge regions of other Ig. It is longer than the ?1, ?2, and a $_2$ hinges and has a highly charged C-terminal one-half. Its unusual structure makes it extremely susceptible to proteolytic cleavage. IgD is a major surface Ig of peripheral blood lymphocytes.

IgD plays an important role as antigen receptor in B-cell activation. It is expressed during certain periods of B-cell differentiation. IgD may function as an antigen receptor that is capable of triggering antibody production, whereas binding of antigen to IgM leads to tolerance. Both receptors, however, are capable of inducing proliferation and differentiation of B lymphocytes.

Immunoglobulin E

Reaginic antibodies, which mediate acute and sometimes life-threatening allergic reactions in atopic patients, belong to this distinct class of Igs ([627]). IgE molecules also have 2 H (e) chains and 2 L chains. They have a molecular weight of 200 kd and a sedimentation coefficient of 8.2S, and they contain 12% carbohydrate. The e-chains are approximately the same size as the μ-chains, with four constant region domains totaling approximately 550 amino acids. Each molecule has 15 half-cysteines, eight of which form intrachain disulfide bonds within the four constant domains. The formation of two interchain H–H bonds between two noncomplementary regions, that is, between Ce1 and Ce2 and between Ce2 and Ce3, is unique to e-chains. Carbohydrates are found throughout the chains. All six oligosaccharide units are *N*-linked to Asn. The survival of IgE molecules in the serum is shorter than that of any other Ig (half-life of 2.4 days), and their serum concentration is in the range of 0.1 to 0.7 mg/L, with a mean of 0.3 mg/L. Higher concentrations may be found in the sera of patients who have asthma, hay fever, eczema, Wiskott-Aldrich syndrome, and helminthic infestations. IgE-forming plasma cells are found most commonly in the respiratory, gastric, and intestinal mucosa and in the regional lymph nodes, but a few are noted in the spleen and in other lymph nodes. Thus, IgE, like IgA, is classified as a secretory Ig.

BIOLOGIC PROPERTIES IgE antibodies are capable of sensitizing basophils and mast cells. The Fc portion of the IgE molecule fits into specific receptor sites on the cell surface. When bivalent or multivalent antigens bind at least two adjacent IgE molecules, the mast cell or basophil is triggered to degranulate, thereby releasing vasoactive substances, especially histamine and slow-reacting substance of anaphylaxis, which are responsible for such clinical manifestations as wheal and flare reactions, bronchospasm, small vessel dilation, and shock. Reduction of the disulfide bonds destroys the ability of the molecule to bind to the Fc receptor, and heating of the IgE at 56°C inactivates its cytotropic activity. This inactivation is associated with loss of antigenic determinants in the Ce3 and Ce4 domains, suggesting that these regions are important for binding to the receptor.

J Chain

The J (joining) chain has been detected in association with polymeric forms of serum and secretory IgA, as well as with the IgM pentamer ([617], [628]). This chain has a molecular weight of 15 kd. It is attached to IgA or IgM polymers by disulfide linkages. It is not detectable by antisera while the polymers are in their native state, but it becomes readily accessible if the polymers are dissociated. In contrast to the secretory piece, J chains are produced by plasma cells and appear to play a key role in the process of polymerization of Ig, serving as a clasp or zipper to fasten the last two monomeric components of a polymeric Ig together.

The complete amino acid sequence has been inferred from cloned genomic DNA. The chain is larger than previously determined, containing 137 amino acids. Many cysteine residues are scattered throughout the molecule. Of the 137 amino acids in mouse and human J chains, 106 are identical (77%). This characteristic, plus the fact that the C-terminal regions of the μ- and a-chains are also conserved, suggests that the polymerization of Ig molecules has been conserved in evolution, probably because they confer advantages in defense mechanisms in that they aggregate complex pathogens more effectively.

COMPLEMENT

In the late nineteenth century, studies showed that serum contains a substance that is capable of lysing bacteria. Jules Bordet proved that this substance was present in fresh serum and lost activity when it was heated to 56°C. The name *complement* was suggested by Paul Ehrlich and J. Morgenroth, because it was thought to complete the activity of the antibodies from which it could be distinguished by its distinct properties. Complement activity has been measured ever since its discovery by the release of hemoglobin from antibody-sensitized sheep erythrocytes. It is now recognized that complement represents a multimolecular system. It is activated by three different pathways, the classical, the alternative, and the lectin, with the final lytic or effector function being carried out by a common pathway. This final common pathway leads to the formation of the *membrane attack complex (MAC)*.

Classical Pathway

The classical pathway is initiated by two functional units: the recognition unit, which consists of three proteins, C1q, C1r, and C1s, and the activation unit, which consists of C2, C3, and C4 ([629], [630]) (Fig. 18.26). The MAC is activated by the classical pathway by the generation of three complex enzymes with proteolytic activity, the formation of which requires the association of two or more proteins ([631]). Not all Ig classes are capable of binding to C1q; IgG1 and IgG 3 bind readily, whereas IgG4 does not bind at all. Complement binding to the IgG subclasses is determined by the flexibility of the hinge that prevents steric interference between Fab and C1q binding. IgG3, with the longest hinge region, is the most efficient of all IgG subclasses. Exposure of the C1q binding site of IgM molecules is optimal when the molecule assumes the staple configuration as it binds to the antigen (Fig. 18.25). This site is hidden in the native form of IgM by the closeness of the subunits. IgM has the strongest binding ability because one C1q molecule that is bound to one IgM antibody is capable of lysing an erythrocyte, whereas two IgG molecules in close proximity are required to achieve the same effect. Ig antibodies that are bound to independent epitopes can activate the complement cascade in this way. Depending on the epitope density, activation occurs when at least 800 IgG molecules bind to the cell. For this reason, IgM antibodies are considerably more efficient lysins.

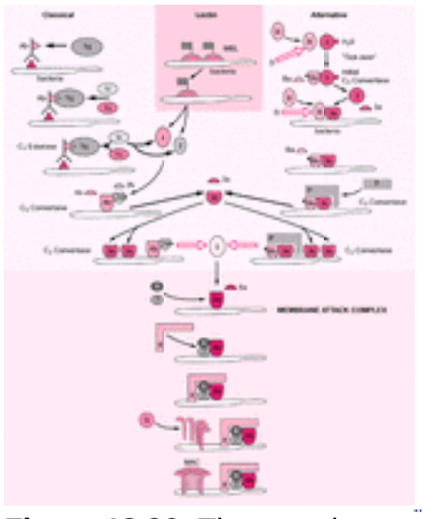

Figure 18.26. The complement (C) pathways. The hemolytic function of the C is activated by three pathways, which converge to the same final common pathway (see the chapter text for details). The classical pathway uses C1q as the recognition molecule, which generates sequentially three enzymatic functions: C1 esterase, C3 convertase, and C5 convertase. The alternative pathway initiates activation by a “tick over” mechanism in the absence of antibody and again generates similar enzymatic functions as the classical pathway. The lectin pathway is triggered by a receptor, mannose-binding lectin (MBL), which, through carbohydrate binding, activates the MBL-associated serine protease (MASP) esterases. A MASP cleaves C4 and C2, generating the same C3 convertase as the classical pathway, which it joins at this point. All pathways converge to the same membrane attack complex (MAC) pathway, which they initiate by cleaving C5.

STEP 1: C1 ESTERASE (C1S) C1 esterase is a complex that is assembled from three proteins: C1q (recognition subunit), C1r, and C1s (catalytic complex) ([632]).
C1q: Recognition Unit of C1s All activators of the complement cascade recognize the C1q, which consists of a total of 18 polypeptide chains, six of each of the three different types, A, B, and C ([633] , [634] and [635]). All polypeptide chains are equal in length, and each is comprised of a short N-terminal region that is involved in the formation of A-B and C-C interchain disulfide bonds. It is followed by collagenlike sequences, which consist of repeating triplets X-Y-Gly, a collagenlike motif (X is often a proline; Y is usually hydroxyproline or hydrolysine). These sequences are not found in human serum proteins but are present in collagen fibrils. At the beginning, three heterotrimers (each consisting of A, B, and C polypeptide chains) associate, forming a stalk. Due to interruption of the collagen sequence, the triplets dissociate into radiating six arms (Fig. 18.27A). At the C-terminal end, each arm ends in a globular head, which consists of heterotrimers of protein domains that are known as *C1q modules* ([636]). When viewed by electron microscopy, the C1q resembles a bouquet of flowers (Fig. 18.27B).

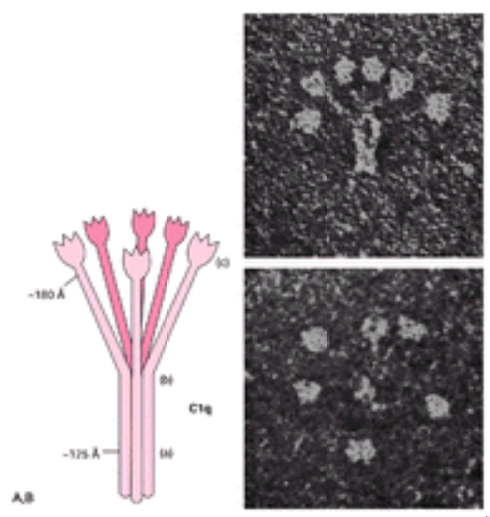

Figure 18.27. A: C1q molecule. Each of the six subunits is made of three polypeptide chains that form a triple helical strand. The N-terminal ends have a collagenlike structure and are packed together, forming a central stalk *(a)*; halfway, they bend and separate from each other *(b)* to end at the C-terminal end in a globular domain *(c)* that binds to the immunoglobulin. **B:** Electron micrographs of the C1q molecule **(upper)** and bird's eye view **(lower)**. (From Knobel H, Villiger W, Isliker H. Chemical analysis and electron microscopy studies of human C1q prepared by different methods. Eur J Immunol 1975;5:78–82.)

Modules of the C1
gC1q Module Most of the C1 activators, such as immune complexes, ß-amyloid fibrils, and HIV, are recognized by the globular heads of C1q ([637]). Each head is composed of trimers of the gC1q domain, which is detected not only in C1q but also in type VIII and type X collagens and several other proteins ([633]). The gC1q modules bear structural features that are seen in members of the TNF family ([638]).
CUB Module: C1r-C1s Uegf Bone Morphogenic Protein-1 Module The acronym CUB was given from the detection of this module for the first time in the sea urchin protein, Uegf, and the human bone morphogenetic protein-1. The CUB modules of C1r and C1s surround the single epidermal growth factor (EGF) module and a pair of complement control protein (CCP) modules. CUB modules are detected in proteins that are involved in developmental processes. They contain four cysteine residues, forming two disulfide bonds, except the N-terminal CUB module of C1r and C1s, which has only two cysteines.
EGF-Module: Epidermal Growth Factor-Like EGF-like modules are detected in diverse proteins that are involved in processes such as blood coagulation and cell adhesion. They have six cysteines that form three disulfide bonds. In C1r and C1s, the EGF module has characteristic consensus sequences with residues Asp and Asn that are hydroxylated and are involved in Ca^{2+} binding.
CCP Module The complement control protein (CCP) module is detected in complement receptors and other CCPs. Their consensus sequence consists of aromatic and hydrophobic residues and four cysteines. The crystal structure has been solved and shows six ß strands around a hydrophobic core ([639]). The modules are ellipsoidal with the ß strands aligned along their long axis with N- and C-termini at opposite ends.
Serum Protease Domain The target bonds in the substrates for cleavage by the C1 esterase have one Arg residue. Indicative of its trypsinlike enzymatic specificity is the Asp residue that is found close to the substrate binding site. Arginyl bonds, such as Arg-isoleucine (Ile), are the targets in the autoactivation of C1r and in the activation of C1s by C1r. Arg-containing bonds are also cleaved in C4 and C2 by the active C1s. C1s esterase activity is expressed only by the multimolecular complex, which is a tetramer that is formed by two C1r and two C1s. Therefore, the enzymatic activity depends on protein-protein interactions between the four components of the esterase, which are facilitated by Ca^{2+} ([640]). Ca^{2+} brings together one CUB and one EGF module to form a compact structure ([641]). During the formation of the tetramer, interactions are flexible to allow a single C1r to cleave the neighboring and the distant C1s ([642]).
C1r and C1s The C1r and C1s are single polypeptide chains of approximately 85 kd, with a Ser protease activity. In the proenzyme form, they are single glycoproteins, which are activated by cleavage of a single Arg-Ile bond, forming a two-chain active enzyme. They are composed of two CUB modules ([643]), an EGF-like module, two CCP modules, and a C-terminal chymotrypsin-like Ser protease domain (Fig. 18.28).

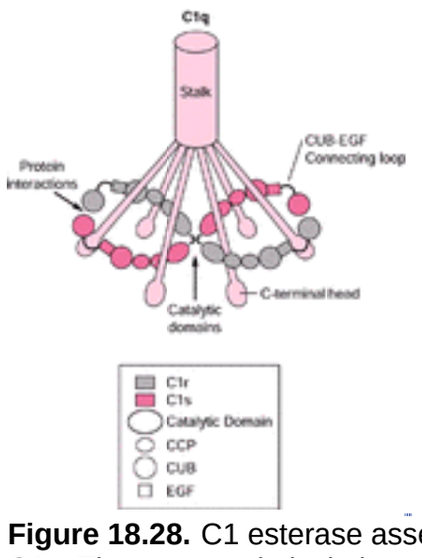

Figure 18.28. C1 esterase assembly. The C1 esterase is a complex that consists of one C1q molecule (recognition component) and a tetramer of two C1r and two C1s. The tetramer in isolation assumes a linear form: C1s-C1r-C1r-C1s. It weaves among the arms of the C1q in a necklacelike way and assumes a figure eight. This arrangement allows access of the catalytic domain of the C1 in the zymogen form, to be in contact with the active catalytic domain of C1r for C1s to be activated. Both

C1rs have access to both C1s. The flexibility of the tetramer allows changes in their relative position, so that the active C1s sites have access to C4 and C2 for their cleavage and formation of the C4a-C2b C3 convertase. The CUB and EGF modules of C1r are connected by a flexible loop and form a high-affinity Ca^{2+} binding site that is involved in the interaction with C1s. The CUB-EGF pair interacts with the C1q arm. When the heads of C1q interact with a pattern of sites on the surface of a target, a conformational stress that is transmitted through the arms of C1q triggers the C1r catalytic domain and results in its activation. CCP, complement control protein.

Assembly of C1 Esterase The first enzymatic activity of the C cascade is assembled from five components, one C1q, two C1r, and two C1s (Fig. 18.28). The C1r-C1s tetramer, in isolation, is a linear structure, with the C-terminal domains responsible for the catalytic function and the N-terminal involved in the Ca^{2+}-dependent protein interactions. In the linear form, the two C1r catalytic domains are in the center, whereas those of the C1s are at the two ends. In the assembly of the C1 esterase, which is the first enzymatic activity of the classical complement cascade, the linear tetramer assumes a compact figure-eight conformation. In this configuration, all four catalytic domains of C1r and C1s are brought in juxtaposition under the cone that is formed by the arms of the C1q. The protein interaction domains are located outside the arms of C1q (644 , 645 and 646). Activation of C1 esterase occurs on recognition by the globular heads of C1q of pattern target sites (e.g., antibody bound to pathogen surfaces and immune complexes). This binding generates transient conformational changes, which activate C1r by disrupting the C1r homodimer. Activated C1r in turn breaks an Arg-Ile bond, activating C1s (640). These transient “earthquakes” do not bring the collapse of the elaborate C1 esterase edifice, because C1r and C1s are associated tightly to the C1q collagen arms by the CUB-EGF modules that were discussed previously. C1s is a highly specific enzyme, but, within the mechanical constraints that are imposed by the superstructure of the whole assembly, it requires some degree of freedom of mobility for its interaction with the substrate. These requirements are provided by the CCP modules, especially CCP-2, which is linked by a flexible hinge to the CCP-1 module. This allows CCP-2 to act as a handle and a spacer, to amplify the shift that is required for the serine protease domain (639 , 646).

C1q Binding Proteins In addition to its function in C activation, C1q binds to other proteins that are sometimes called *receptors*, mediating other C1q functions (647 , 648). There are two types of surface proteins that bind to C1q. One binds to the collagenous portion of C1q (cC1q receptor), and the other binds to the globular heads (gC1q receptor). Some of these proteins are transmembrane, whereas others are intracellular, such as calreticulin (cC1qR) and the gC1q-binding protein (gC1qR). The C1q structure bears similarity to the proteins of the collectin family, which includes the mannose-binding lectin (MBL), the pulmonary surfactant protein A, and conglutinin. However, the collectins are C-type lectins and bind carbohydrates, whereas the heads of C1q recognize protein patterns on immune complexes. The term *C1qR* has been used loosely, sometimes without hard evidence that the receptor triggers cell signaling that leads to some cellular functions (648). The gC1qR is expressed on myeloid cells (649) and microglial cells (650), in which it mediates chemotaxis and phagocytosis, and in platelets (651), modulating their function in injured vascular sites. Calreticulin is a Ca^{2+}-binding protein that is located primarily in the ER of most nucleated cells. It has been found that calreticulin binds C1q and therefore qualifies as cC1qR, but the significance of this interaction remains elusive.

STEP 2: C4 AND C2 COMPLEX: C3 CONVERTASE C3 convertase is formed by the interaction of two fragments from the C4 and C2 components of complement. Complement component 4 circulates in the blood as a disulfide-linked heterotrimer that consists of a- (93 kd), ß- (75 kd), and ?-chains (33 kd). C3 and C5 components share a similar structure considered to be evolutionarily derived from one ancestral gene. The C3 and C4 components share an *internal thioester bond*, which is formed between a cysteine and a glutamine, which are two residues apart (652). **C4** is synthesized as a single polypeptide chain but is later hydrolyzed, giving rise to the three constituent chains. C1s activates C4 by splitting the a-chain, releasing the C4a fragment from the N-terminal end of the chain. The thioester bond, which is normally hidden in the C4b fragment, is exposed, reacts with NH_2 or OH group of the surrounding molecules (Fig. 18.29), and deposits C4b on the surface of potential targets for C attack.

Figure 18.29. C3 degradation. The C3 component not only contributes to the classical pathway in the formation of the C5 convertase, but also, as a result of fragmentation, provides parts of its molecule for other important functions. For example, C3a serves as an anaphylatoxin, C3b serves as a ligand for the CR1 receptor (CD35), C3d serves as a ligand for CR2 receptor (CD21), iC3b serves as a ligand for CR3 receptor (lymphocyte function–associated antigen-1 integrin, CD11b/CD18) and for CD11c/CD18 integrin. (Courtesy of Dr. J.D. Lambris. From Sahu A, et al. Immunol Rev 2001;180:35–48, with permission.)

C2 is a single-chain protein of approximately 100 to 110 kd, with a distinct structure that consists of three globular regions: three N-terminal CCP domains, a single von Willebrand factor (vWF) domain in the center, and a serine protease domain in the C-terminus (653). CCP modules are highly compact structures, folding independently into a ß barrel (e.g., two interacting antiparallel ß sheets) which form an ellipsoid structure. Loops that connect the ß-strands protrude out of the module and may function as the ligand binding sites. The vWF type A module consists of five parallel ß strands and a short antiparallel strand that form a central twisted core, which is surrounded by seven amphipathic a helices (654). Cleavage of C2 by C1s occurs in the N-terminal region of the vWF domain, which results in the generation of two fragments, a larger (70-kd) C2a, consisting of most of vWF and SP domains, and a smaller (30-kd) C2b fragment (CCP-1, CCP-2, and CCP-3). Fragmentation of C2 exposes a C4b-binding site that is located on the C2b fragment, which interacts with C4b. C4b-C2a complex formation depends on Mg^{2+} ions, which are coordinated by residues in the metal ion-binding MIDAS (metal ion-dependent adhesion site) motif of the vWF modules, which is also present in several integrins (Chapter 2, CD61). By electron microscopy, the C2a fragment appears as a two-lobed structure that links the C4b and C3b fragments in the final C5 convertase (see the following discussion). The C4b-C2a complex is a Ser esterase with an esterolytic activity and with the C3 as the natural substrate (655).

STEP 3: C3B-C4B-C2A COMPLEX: C5 CONVERTASE

C3 Component The C3 component of complement is the most abundant in the serum (1.2 mg/ml) and occupies the most critical position in all three C cascades. The prevailing hypothesis is that a gene that was common for all three components, C3, C4, and C5, originated from an ancestral a_2-macroglobulin gene. Subsequent duplication formed the C4 and C3-C5 genes, and a second duplication formed separate C3 and C5 genes. C3 is comprised of an a-chain (110 kd) and a ß-chain (75 kd), which are connected covalently by a single disulfide bond. It is synthesized as a single protein and is modified posttranslationally by a furinlike enzyme, which removes a sequence of four arginines (656). Another disulfide bond within the a-chain connects the N- and C-terminals (Fig. 18.29). C3 convertase cleaves the a-chain at a site that is close to the N-terminus, generating two fragments: a small C3a (9 kd) and a large C3b (176 kd). The C3b consists of the remaining a-chain, which is linked by the disulfide bond to the intact ß-chain. Cleavage of the a-chain of C3 by the C3 convertase exposes the thioester bond, which, in the intact molecule, is well protected within a pocket in the a-chain with a half-life of 231 hours. In the metastable C3b fragment, the bond is exposed with a half-life of 60 microseconds. These differences strikingly express the extraordinary reactivity of the thioester bond for certain groups on the cell surfaces. The thioester bond participates in a chemical transacylation reaction that results in the attachment of C3b on OH or NH_2 groups on cell surfaces, complex carbohydrates, or immune complexes that are within a radius of 600 Å from the point at which it was generated. Attachment of C3b is not discriminatory between self and nonself surfaces but is regulated by CCPs (see the following discussion). The selection, however, of the OH groups on the sites of binding is quite restricted (657). C3b expresses multiple sites for binding to other complement proteins, which determine its fate. C3b is deposited on and around the C4b-C2a complex, binding through the thioester bond. The deposition produces an enzyme with a change in the specificity from C3 to C5, generating the C5 convertase (658). C3b is also deposited on other previously deposited C3b molecules, forming C3b-C3b dimers. The C3b-C4b and C3b-C3b form high-affinity binding sites for C5, and, probably, the role of these dimers is to hold the substrate in a rigid position for efficient cleavage of C5. It also appears that the C3b-C3b-IgG complexes function as better precursors of convertases than monomeric C3b.

C3 Fragmentation C3 is fragmented by several enzymes that generate a variety of functionally active fragments (Fig. 18.29). The activation of C3 by the C3 convertase cleaves the peptide bond between residues 726 and 727 (Arg-Ser) and generates a small C3a (9 kd) and a large C3b (176 kd) fragments. C3a is the N-terminal of the a-chain that functions as anaphylatoxin. C3b consists of the remaining a-chain (a') and the entire ß-chain, which are linked by the disulfide bond. C3b is inactivated by further proteolysis by factor I and one of the cofactors. The first cleavage occurs between residues 1281 to 1282 of the a'-chain and generates the inactivated C3b or iC3b2, which is the ligand for CD11b-CD18 integrin (Chapter 2). A second cleavage by factor I separates a small fragment C3f (2 kd) from the a'-chain and yields another inactivated C3b or $iC3b_2$. Factor I, with CR1 or factor H as cofactors, cleaves once more the a-chain at residues 932 and 933, to yield C3dg and C3c. The C3dg fragment is a ligand for CD21 (CR2), a component of the co-receptor complex CD19-CD21-CD81 on B cells (Chapter 16). C3dg is cleaved

by a protease into C3g and C3d fragments.

Alternative Pathway

The alternative complement pathway represents an important natural defense mechanism that is independent of the immune response (Fig. 18.26). Activation of the alternative pathway involves three components: C3, B factor, and D factor. Polysaccharides (zymosan), bacterial products, aggregated human IgA, cobra venom factor, and many other substances are activators of the alternative C cascade. The mechanisms that initiate this pathway have been the subject of much debate. The enzyme that cleaves C3 contains C3b as one of its components, which is the product of a previous C3 cleavage. The origin of the first C3b becomes a puzzling problem. Normally, the C3 continuously generates a low level of a functionally C3b-like form by a "tick-over" mechanism. The mechanism for the "tick-over" is not a proteolytic process, but involves the spontaneous hydrolysis of the thioester bond by H_2O and the formation of a metastable C3 (H_2O). The hydrolysis occurs *in vitro* at 37°C at a rate of 0.005% per minute (659). The C3 (H_2O) is an uncleaved C3 molecule and yet has the conformation and function of a C3b in the presence of Mg^{2+}, which provides a site for binding of the B factor.

FACTOR B Factor B (90 kd) has a similar structure to C2: It consists of three CCP modules, a vWF type A module, and a serine protease domain that are all connected by short amino acid sequences. By electron microscopy, it appears as a three-lobed structure, presumably with each module corresponding to one of the lobes.

FACTOR D Factor D is a Ser protease with only one known substrate, factor B. The single Arg ^{233}-Lys ^{234} bond of factor B becomes susceptible to the enzymatic activity of factor D only when it forms a Mg^{2+}-dependent complex with C3b. It is the only enzyme in blood that is able to catalyze this reaction and is therefore absolutely required for alternative pathway activation. The concentration of factor D in the blood is 1.8 ± 0.4 µg/ml, the lowest of any complement protein, which makes factor D the limiting factor in the activation of the alternative pathway. It is a single-chain protein (24 kd) and is structurally similar to pancreatic serine proteases. It circulates in blood in a zymogen or profactor form (660) converted to the mature enzyme as a result of conformational changes. However, this first step generates a "resting" enzyme because of an inhibitory sequence loop, which prevents its activation. The active enzyme conformation is induced after binding to the substrate in a second step. Factor D has a structure that is similar to other members of the serine proteases: The polypeptide chain is folded into two antiparallel ß barrels. Each barrel consists of six ß strands with the same topology in all members (661). Efficient catalysis requires three amino acids, Asp ^{102}, His ^{57}, and Ser ^{195}, forming the *catalytic triad*, and the positioning of the three residues is crucial for the synergistic action that is required for hydrolysis of the target bond. In the bottom of the substrate specificity pocket is an Asp residue, which places factor D in the category of the trypsin subfamily of serine proteases and cleaves an Arg-Lys bond of its single natural substrate, factor B.

PROPERDIN Properdin is one of six plasma glycoproteins, which collectively comprise the alternative pathway of complement. It was first described by Pillemer et al. (662) as a novel plasma protein that activated complement in the absence of immune complexes. Properdin consists of a single chain (53 kd), which by electron microscopy appears as a rodlike structure that forms cyclic dimers, trimers, and tetramers in a ratio of 26:54:20 (663). The monomer consists of an N-terminal region of no known homology, followed by six thrombospondin type 1 repeats (TSRs) of approximately 60 amino acids (664). Repeats of this type have first been identified in the cell adhesion molecule thrombospondin and in a variety of other proteins, including thrombospondin types 1 and 2, C6 through C9, and the circumsporozoite protein of malaria parasites (665). Removal of TSR-5 prevents binding to C3b and sulfatide, whereas, with the removal of TSR-4, properdin is unable to stabilize the C3b-Bb complex but is still able to bind C3b and sulfatide (666, 667), while it exists only as a monomer or a dimer. Absence of TSR-3 does not have an impact on any of the functions of properdin, including the formation of the polymers. TSR-5 is important for polymer formation, because, in its absence, no cyclic polymers are detected. Properdin, like thrombospondin, binds sulphated glycoconjugates and sulfatide with especially high affinity when it is activated (668). Properdin significantly contributes to linking innate and adaptive immunity. It is synthesized by endothelial cells, especially under turbulent blood flow conditions (669), and mRNA has been detected in neutrophils, monocytes, and T cells. In response to chemoattractants C5a or IL-8, neutrophils discharge their properdin content promptly, as well as C3 and factor B, which they store within their granules. Factor D is supplied locally by blood, which completes the list of the components that are essential for activation of the alternative pathway. T cells and monocytes participate in the process, because they also secrete properdin, factor B, and C3. Activation-produced fragments C3d and iC3b are essential B-cell activation factors (670), thus linking with the adaptive immune system.

ACTIVATION OF THE ALTERNATIVE COMPLEMENT PATHWAY In the presence of Mg^{2+}, C3 (H_2O) (also referred to as iC3) binds factor B, which is cleaved by factor D into a large Bb and a small Ba fragment (Fig. 18.26). The Bb forms a complex with the iC3, which is termed the *initial C3 convertase*. Although the iC3-Bb complex is destroyed on host surfaces by factor H and factor I (see the following discussion), C3b fragments that are deposited on foreign surfaces associate with factor B in the presence of Mg^{2+}. The C3b-B complex activates factor D, which cleaves factor B into Bb and Ba fragments. The distinction between activator and nonactivator surfaces is not clear. An activator surface is one that allows binding of factor B to C3b in preference of factor H (see the following discussion), thus activating the alternative pathway. The opposite is true for nonactivators. Nonactivators can be converted to activators by removing sialic acid. A widely used activator is cobra venom factor, which binds to factor B and forms a stable C3 convertase. The factor is functionally analogous to C3b but is related structurally to C3c. It is used to deplete serum of C3 in a variety of experimental situations and is resistant to inactivation by factors H and I. The C3b-Bb is stabilized by the serum protein properdin, which amplifies the cleavage and deposition of more C3b molecules (671, 672) to form the *C5 convertase*. The serine protease activity of the C3b·Bb complex, which is located in the Bb component, accelerates deposition of C3b fragments (C3b amplification), a unique feature of the alternative pathway, on and around the C3b·Bb complex. Some will form C3b·C3b dimers, which have a high affinity for C5 (self-amplified C5 convertase) (672) and switch cleavage from C3 to C5, thus initiating the formation of the cytolytic C5b-9 complex. As the activation continues, at the outer ring of this circle, monomeric C3bs form more C3 convertases with factor B, which in turn deposits a new crop of C3bs, forming a new generation of C3b-C3b dimers, that is, C5 convertases. These cycles of successive outward deposition of C3 and C5 convertase activities continues until all surfaces are covered or the supply of individual components is exhausted.

Lectin Complement Pathway

The lectin pathway is an important humoral mechanism of innate immunity. It is activated by pattern recognition receptors, such as mannose binding lectin (MBL), which interacts with carbohydrates (673) (Fig. 18.26).

MBL is a member of the *collectin* family, which includes the lung surfactant proteins, SP-A and SP-D, and a protein that is localized in the hepatic cell cytosol, CL-L1. Collectins are composed of a C-terminal lectin domain (carbohydrate recognition domain) and a neck region that connects to the collagenlike region, followed by a short cross-linking region that contains two to three cysteines. The neck region forms an a-helical coiled-coil structure, which initiates the formation of a trimer. In blood, MBL is found as multimers (i.e., dimers to hexamers). MBL is a C-type lectin, as it requires Ca^{2+} for binding to a carbohydrate ligand.

Associated with MBL are four serine proteases that are known as *MBL-associated serine proteases (MASPs)*: MASP-1, MASP-2, MASP-3 (674, 675), and sMAP or MAp-19, a truncated form of MASP-2. MASP-2 and sMAP are encoded by a single gene, but two different mRNAs are generated by alternative splicing (676). All MASP proteases have a modular structure that is identical to C1r-C1s: a CUB domain, an EGF-like domain, a second CUB domain, two CCP domains, and a serine protease domain. The serine protease domain is homologous to the chymotrypsinogen family. An Asp residue in the substrate specificity pocket indicates trypsinlike substrate specificity. MASP's association with MBL is mediated by the CUB-EGF domain and is Ca^{2+} dependent (676). The MASP proteases are activated when MBL binds to conserved pathogen-associated sugar arrays that form molecular patterns, which are shared by broad classes of pathogens (677).

When MASP is activated, it cleaves C4 and C2, and the C4b fragment binds covalently to the microbial surface or the lectin itself and becomes the focus for C2 binding and activation. The remaining cascade is identical to that of the classical pathway (Fig. 18.26).

MBL binds mannose-acetyl glucosamine or GlcNAc, which are also ligands for other types of GlcNAc-binding lectins, which are termed *ficolins* and are present in the serum. Ficolins contain collagenlike and fibrinogen-like domains. They bind to GlcNAc through the fibrinogen-like domain. They are associated with MASPs and sMAP and have the capacity to activate the lectin complement pathway (678). In the serum, there are two types of ficolins, which are named L-ficolin and H-ficolin (Hakata antigen) (679, 680).

The recognition that is mediated by MBL and ficolins in complement activation is detected as far back in evolution as the ascidians, our closest invertebrate relatives. It indicates that the complement pathway has been important in innate immunity since before the evolution of adaptive immune systems in jawed vertebrates.

Membrane Attack Complex

C5 C5 (191 kd) consists of two polypeptide chains, a (115 kd) and ß (75 kd). C5 convertase selectively cleaves an Arg-Leu bond (74 and 75) of the a-chain, generating

C5a, a potent leukocyte chemotactic peptide that consists of 74 amino acids and has considerable structural homology with C3a and C4a, the other two anaphylatoxins. The remaining larger fragment, C5b, in its nascent state, constitutes the nucleus for the MAC. It possesses a metastable binding site with specificity for C6. By electron microscopy, C5 has the shape of a heart or of an ellipse, but the heart-shaped form is related to the elliptical type by rotation ([681]). The binding sites for C6 and C7 are located in the a-chain of C5b. Interaction with C5b involves the C-terminal of C6, specifically the C6c fragment that consists of two factor I modules (FIMs).

C6 C6 is a single polypeptide chain (104 kd) ([682]), which, by trypsin digestion, can be separated into an N-terminal region (C6a) with some homology to C8 and C9 and a C-terminal region (C6b) with homology to factor H and factor I. Several disulfide bonds separate discrete segments of C6, which is structurally homologous to a variety of other proteins. Overall, the primary sequence is a “patchwork” with several modules that are involved in protein-protein interactions (Fig. 18.30). Starting from the N-terminus, there are several domains: two tandem thrombospondins type 1 (TSP-1s), a class A low-density lipoprotein receptor (LDLR), an extended central segment that is referred to as the membrane attack complex perforin (MACPF) domain with homology to perforin, an EGF, a third TSP-1, two CCPs, and two FIMs, which are related to those in the H chain of the complement control factor I ([683]). The FIMs are specific C5-binding modules, and yet they are not absolutely necessary, probably because other hydrophobic interactions also contribute to the C5 and C6 interactions. As devices that facilitate C5 and C6 interactions, FIMs make a greater contribution to the classical pathway in which C5b density is not as high as it is in the alternative pathway, because fewer C5bs are formed in the classical pathway, and C5b half-life is shorter ([684]).

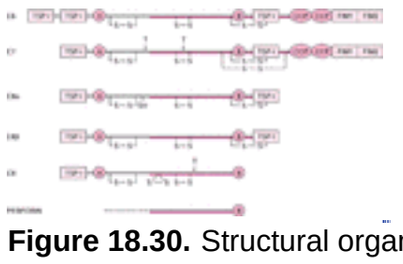

Figure 18.30. Structural organization of the C6 through C9 complement components. The last five complement components (C6 to C9) are structurally and genetically related proteins and form the membrane attack complex family. They all have a similar modular structure. In the middle of each molecule is a sequence-designated membrane attack complex perforin to emphasize its similarity with perforin. Membrane attack complex perforin is the portion of the molecule that is inserted in the membrane to form the pore. C8? is the sixth component, which is not modular and differs structurally from the others. It is considered that the perforin gene gave rise first to the C9 gene, which evolved in retrograde, followed by the appearance of the genes for the other proteins. The modules in the C6 and C7, which are not shared by C8 and C9 [i.e., complement control protein (CCP) and factor I module (FIM)] are used to interact with C5. A, low-density lipoprotein receptor class A; B, low-density lipoprotein receptor class B (or epidermal growth factor precursor module); TSP-1, thrombospondin 1.

The secondary structure of C6 is a mixture of a helices and ß sheets. The a helices reside in MACPF, which is free of disulfide bonds. By transmission electron microscopy, C6 appears like a sickle.

C7 C7 is a single polypeptide (97 kd), which, like C6, is a mosaic of several modules that are found in other proteins. Starting from the N-terminal, C7 has one TSP-1, one LDLR type A (LDLR-A), a second TSP-1, two CCPs, and two FIMs. Its secondary structure is high in ß sheets (38%), and, by electron microscopy, it appears as a flexible elongated molecule (151 × 59 × 43 Å) ([685]). The three components C5-C6-C7 in a fluid phase form rosettes as a consequence of radial aggregation. However, the complexes on a phospholipid area insert themselves, anchoring by the stalk, while the Cys-rich segments fasten the complex for the assembly of the MAC. The C5b-7 complex does not traverse the phospholipid membrane and does not cause lysis. The long, flexible stalk of C7 provides greater surface area for interaction within the membrane.

C8 The C8 component consists of three chains: a (64 kd), ß (64 kd), and ? (22 kd), all being encoded by separate genes. The C8a and C8? are linked by a single disulfide bond, and the C8a-C8ß? heterodimer is associated noncovalently with C8ß through a binding site on the C8 a-chain ([686]). The a-chain interacts with C9, directs the insertion into the membrane of the first C9 in the formation of MAC, and interacts with lipids, thus becoming accessible to MAC formation. Importantly, together with the membrane protein CD59, they inhibit MAC formation in homologous cells and protect them from lysis. The C8 ß-chain has three binding sites for C8a, the C5b-7 complex, and membrane lipids. For binding of C8ß to the C8a-? complex, the N-terminal TSP-1, LDLR-A, and the MACPF segment are most important, and, furthermore, they mediate the incorporation of C8 into the MAC ([687]). The C8 a- and ß-chains are structurally related and are members of the MAC family, whereas the C8 ?-chain is a member of the lipocalin family, which is unrelated to the MAC family ([688]). The lipocalins are widely distributed proteins that are involved in the transport of small lipophilic substances, such as retinol and pheromones, but C8 does not bind retinol ([689]). They all share the same folding pattern, which is known as the *lipocalin fold*. Strikingly, C8? is the only protein from a different family among the 35 proteins of the complement system. Furthermore, C8? is not absolutely required for the expression of C8 activity by the a- and ß-chains; however, it enhances their function ([690]). The crystal structure of C8? has been solved and confirms its lipocalin fold and, furthermore, identifies its structural relationship to the neutrophil gelatinase, a protein that is released from the granules of activated neutrophils ([691]). Overall, it forms a calyx with a distinct large hydrophobic cavity at the base of the calyx for ligand binding.

C9 Complement component C9 is a single polypeptide chain (71 kd), which has a modular structure that is similar to that of the other members of the MAC family: an N-terminal TSP-1; an LDLR-A; the extended central sequence MACPF, which is homologous to perforin ([692]); and an EGF module in the C-terminal end. C9 is endowed with the capacity to polymerize spontaneously in a circular fashion and to create tubules.

MEMBRANE ATTACK COMPLEX FORMATION The C5b-7 complex binds to the cell membrane, and, although it inflicts no harm to the cell, it marks it for subsequent assault by C8 (Fig. 18.26). The C5b-8 complex appears foliaceous by electron microscopy, with branched structures radiating from the central pedicle ([693]), but, on smaller phospholipid vesicles, C5b-8 monomers appear as long rodlike structures that are 250 Å wide ([694]). The C8 a-chain mediates binding and self-polymerization of C9 to form MAC ([695]). The N-terminal TSP-1 and LDLR-A modules are the principal binding sites for C9 with the cooperative function of MACPF domain. MACs are heterogeneous in size, probably as a result of their composition, and the number of the C9 subunits may vary from 1 to 18, whereas all other components contribute only one molecule ([696]). The final molecular weight of the MAC therefore varies between 66 and 1850 kd. The average C9 binding capacity per C8 molecule is 15.4 molecules. C9 polymerizes spontaneously, but the C5b-8-induced rate of C9 polymerization is 10,000-fold greater. Self-associating C9 complexes develop new antigenic determinants that are not present in the monomer. C9 is inserted into the membrane through its C-terminal region, and disulfide bonds stabilize the complex. Electron microscopically, the polymerized C9 appears as a cylinder that extends 120 Å above the cell surface. The extracellular hydrophilic end terminates in an annulus that is 30 Å thick, with an inner diameter of approximately 100 Å ([697] , [698]) (Fig. 18.31). The C5b-8 is attached firmly to the C9 cylinder and actually extends 160 to 180 Å above the annulus. The annulus, which is seen with computer-assisted programs, appears to be made of whorls ([699]) (Fig. 18.31).

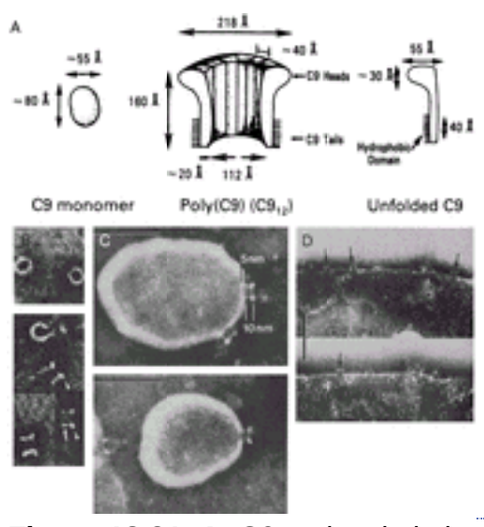

Figure 18.31. A: C9 molecule in its monomeric form, folded **(left)** or unfolded **(right)** and in its polymerized form (center) as a tubular structure that is seen on cell membranes. **B:** Poly C9 as ring structures *(top view)* or tubules *(side view)*. [Courtesy of Dr. E.R. Podack. From Podack ER, Tschopp J. Polymerization of the ninth component of complement (C9): formation of poly(C9) with a tubular ultrastructure resembling the membrane attack complex of complement. Proc Natl Acad Sci U S A 1982;79:574–578.] **C:** Lipid vesicle with a typical cylinder that is formed from polymerization of C9 *(side view)*. The cylinder penetrates the wall and protrudes to the outside, above the surface of the vesicle. **D:** Lesions that are induced by complement on sheep red blood cell membranes clearly show cylindric structures of the membrane attack complex and its penetration into the membrane *(arrows).* (Courtesy Dr. S. Bhakdi. From Bhakdi S, Tranum-Jensen J. Molecular nature of the complement lesion. Proc Natl Acad Sci U S A 1978;75:5655–5659.)

Because the height of the monomeric C9 is only 80 Å, and the poly C9 cylinder is 160 Å, the C9 must be unfolding and must transform into a rodlike structure. Thus, the formation of the cylinder by polymerization of C9 molecules involves the transformation of a hydrophilic C9 monomer into an amphiphilic C9 polymer. The N-terminal part of C9 does not participate directly in polymerization and is located in the upper rim of the cylinder ([699]). The MACPF domain traverses across the

thickness of the cell membrane, forming the wall of the cylinder. The C-terminal part of C9 returns back up near the rim, indicating that polymerization transforms a straight ellipsoid C9 into U shape ([700]). C9 aligns with other molecules side by side, like staves of a barrel forming a volutelike structure (i.e., a capital of an Ionian-style Greek column). Not all agree with the cylinder model of MAC. Others suggest that MAC proteins cause a distortion of the phospholipid bilayer, thus creating “leaky patches” ([701]).

REGULATION OF COMPLEMENT ACTIVATION

Complement activation is an effective host defense mechanism, but, at the same time, it can inflict serious damage to host tissues. For this reason, it must be effectively regulated to distinguish self from nonself, as well as to limit its activation process in time, so that any damage to the host is limited, and the consumption of important components is restricted. A large number of proteins, known as *complement control proteins*, or *CCPs*, are involved in the regulation of complement activation (Table 18.6). This complex regulatory system is best understood if we consider the stages of complement activation that are regulated or whether CCPs exist in fluids versus cellular surfaces. CCPs exert regulation mainly by accelerating dissociation of the convertases, a function that is known as *decay-accelerating activity (DAA)*, or by acting as cofactors to the serine protease factor I, a function that is known as *cofactor activity (CA)*. Some regulators are able to serve both as decay accelerators and cofactors, such as factor H, C4-binding protein (C4bp), and complement receptor 1 (CD35).

TABLE 18.6. Regulatory Proteins of Complement

Factor	Location	Function
Initiation step		
C1 inhibitor	Serum	Inactivates C1r and C1s
Amplification step		
Factor I	Serum	Fragmentation of C3b and C4b
Membrane cofactor protein	Membrane	Cofactor for factor I in degradation of C3b
Decay-accelerating factor	Membrane	Prevents C3 convertase formation
		Dissociates preformed C3 and C5 convertases
C4 binding protein	Serum	Accelerates decay of C4b as cofactor for factor I
Factor H	Serum	Impairs uptake of factor B by C3
		Cofactor for factor I in C3b cleavage
Complement receptor 1	Membrane	Promotes cleavage of C3b
		Impairs uptake of factor B by C3b
		Displaces Bb from C3b
Properdin	Serum	Stabilizes C3 convertases
Membrane attack		
S protein	Serum	Blocks fluid phase membrane attack complex
CD59	Membrane	Blocks membrane attack complex on cells

Adapted from Liszewski MK, Farries TC, Lublin DM, et al. Control of the complement system. Adv Immunol 1996;61:201–283.

Control of the Initiation Step

C1 INHIBITOR C1 inhibitor (C1 INH) is a heavily glycosylated a-globulin with a molecular weight of 105 kd. It is synthesized in the liver and by blood monocytes. Its gene is located on chromosome 11. C1 INH belongs to the superfamily of *serpin proteins* (serine protease inhibitors) ([702]). The inhibitor possesses a site that is structurally similar to the substrate, and, when a protease binds to this site and cleaves a peptide bond, it forms a covalent bond that results in a stable complex between the inhibitor and the enzyme. C1 INH inhibits activation of the classical and alternative pathways. It binds to C1r and C1s, forming stable complexes that prevent them from acting as an esterase. It also binds to the C1r-Cls complex and causes rapid dissociation of the C1 esterase. In the alternative pathway, it prevents factor B from binding to immobilized C3b. Cleavage of factor B by factor D is markedly inhibited when C3b is incubated with C1 INH ([703]). A genetically inherited deficiency of C1 INH is manifested by recurrent acute attacks of circumscribed edema. Hereditary angioneurotic edema (HAE) may cause death from laryngeal edema. The mortality rate that is associated with this condition has been reduced with androgen therapy. This disease assumes two forms. In most (85%) cases (type 1 HAE), the inhibitor is present in reduced concentrations, whereas, in the second form (type 2 HAE), it is present in normal concentrations, but it is biologically inactive.

CONTROL OF C3 AND C5 CONVERTASES The C3 convertase cleaves C3 to C3b and C3a, whereas the C5 convertase cleaves C5 and initiates the final stage that ends with the formation of MAC. These amplification steps are regulated by seven proteins: three of them are present in the serum (C4BP, factor H, and factor I), and four are cell membrane proteins [MCP, decay-accelerating factor (DAF), CR1, and CR2]. The overall function of these proteins is to prevent formation of the two convertases on self cells. Except for factor I, all other proteins belong to a structurally related family of proteins that is known as the *regulators of complement activation (RCAs)* or now *complement control proteins* (*CCPs*). The genes are clustered on the long arm of chromosome 1q32. A striking structural feature that is common to these proteins is the multiple homologous cysteine-rich domains, which are 60 amino acids in length and are referred to as *CCP repeats* (older name is *short consensus repeats*) ([704]). The CCP module or repeat has four invariant cysteines, an invariant tryptophan, and highly conserved prolines, glycines, and hydrophobic residues ([705]). The number of CCP domains varies; thirty are found in CR1, twenty in factor H, and four in CD55. The 60–amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing with domains from the serine protease gene family. The CCP domains are found in other complement proteins, such as C1r, C1s, C2, and factor B, as well as in noncomplement proteins, such as IL-2 receptor, haptoglobin, and coagulation factor XIII. Each CCP domain has a hydrophobic core that is interlaced with ß strands that are connected by protruding loops, which possess a privileged position for interactions with other proteins. The control of the convertases is achieved by two mechanisms: (a) by dissociating the convertase to its individual components (DAA) and (b) by proteolytic degradation of C4b or C3b components as a result of the CA of the RCA proteins that act as cofactors for the serine protease, factor I. Some proteins have DAA and CA activity in the serum (C4BP, factor H) or cell surface (CR1), whereas others possess only one activity for the C4b and C3b components.

Regulators on Cell Surfaces

MEMBRANE COFACTOR PROTEIN (CD46) The extracellular region of membrane cofactor protein (MCP) consists of four CCP domains that contain the binding site for C3b and C4b and a region that is rich in serines, threonines, and prolines. The serine, threonine, and proline region is O-glycosylated and provides protection from proteolysis. A portion of this region may be removed by alternative splicing, which generates two of the four MCP isoforms. Two alternate forms of cytoplasmic regions contribute to the formation of another two MCP isoforms. MCP is present in almost all cells examined, except for the red blood cells. Sites for C3b binding are in CCP-2, CCP-3, and CCP-4 domains. The C3b and C4b binding sites have residues that bind to both complement components as well as others that are specific for each component ([706]). MCP acts as cofactor for the serine protease factor I for inactivation of C4b that is deposited on self tissues ([707]). MCP in the maternal-fetal interface protects the fetal tissue from attack by the maternal complement. It is found on the inner membrane of the spermatozoa and may play a role in protecting the sperm against C3b deposition. MCP is a receptor for several pathogens. The measles virus binds to an extended surface of MCP that encompasses the area from the top of CCP-1 to the bottom of CCP-2 ([708]). The measles virus binding to CD46 is more like that of poliovirus to its receptor: a wider open area that is flexibly hinged between CCP-1 and CCP-2 domains ([709]). This leaves the virus still exposed to immune attack. It contrasts with the narrow, recessed binding site or canyon in the case of HIV and rhinoviruses ([710]). The M protein of *Streptococcus pyogenes* ([711]), which causes serious suppurative skin infections (e.g., cellulitis, necrotizing fasciitis), binds directly to CCP-3 and CCP-4 domains at a site that is distinct from the C3b binding site. MCP mediates adherence of group A streptococci to keratinocytes ([712]). Human herpesvirus 6 also uses CD46 as a receptor and binds to CCP-2 and CCP-3 ([713]).

DECAY-ACCELERATING FACTOR (CD55) DAF contains four CCP domains and is attached to the membrane by a GPI anchor ([714]). Its molecular weight is between 70 to 80 kd, depending on its glycosylation. Soluble forms exist in body fluids that may arise from the action of a phospholipase on the membrane form. It is expressed on all hematopoietic cells, endothelial and epithelial cells, and cells of the gastrointestinal, genitourinary, and central nervous systems. Erythrocytes possess approximately 3000 DAF molecules, and, among the lymphoid cells, the NK cells appear deficient in DAF. Neutrophil activation results in enhanced expression of DAF (from 10,000 to 20,000 molecules per cell). It is present in a soluble form in many body fluids, including plasma, tears, saliva, urine, synovial fluid, and

cerebrospinal fluid. DAF accelerates the decay of C3 convertase for the classical and alternative pathways but prevents its formation ([715]) (Fig. 18.32). Regulation by DAF involves separate sites for the two convertases as well as common sites for both ([716]). For the alternative C3 convertase, DAF acts on the type A domain (vWF type A domain) of the Bb component ([717]). Classical C3 convertase is regulated by a site that is located in the CCP-2–CCP-3 domain junction, which consists of three consecutive lysines and a hydrophobic patch ([718], [719]). DAF is used as receptor by many pathogens, such as several types of echoviruses, enteroviruses, and *E. coli*. It constitutes a functional component of the LPS receptor complex ([720]). CD55 is the ligand (counter-receptor?) of CD97, the prototype of a large seven-span transmembrane family (as many as 2000 members) with variable numbers of EGF domains and sequence homology to the G-protein–coupled peptide hormone receptors ([721], [722] and [723]). CD97 is associated with inflammation and is detected in malignancies.

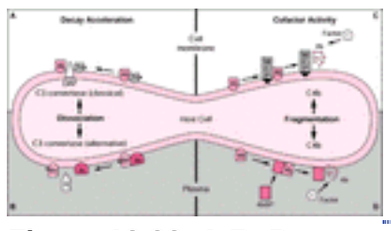

Figure 18.32. A,B: Decay activity on cell surfaces. **A:** Decay-accelerating factor (DAF, CD55) is a GP I anchored protein, which dissociates formed C3 convertase complex, as well as prevents its formation. **B:** Factor H is a serum protein that expresses DA activity by attacking C3 convertases on self surfaces. It binds to the C3b-Bb complex and displaces factor B irreversibly. **C,D:** Cofactor activity. **C:** Membrane cofactor protein (MCP, CD46) is a cell membrane protein, which contains binding sites for C3b and C4b. It acts as cofactor for factor I to cleave both proteins. It is also the measles virus receptor. **D:** The C4b binding protein (C4BP) is a serum protein that acts as a cofactor for factor I for cleaving C4b.

COMPLEMENT RECEPTOR 1 Receptors for complement components or their breakdown products are expressed on many cells and tissues. They mediate various effector functions listed in Table 18.7. Some of the functions of complement receptors that are related to the regulation of complement activation are briefly reviewed.

TABLE 18.7. Cellular Distribution and Function of Receptors for Complement Components

Receptor	Cell Type	Functions
C1q	Neutrophils	Respiratory burst
	Monocytes	—
	B cells	—
	Null cells	Enhanced antibody-dependent cell-mediated cytotoxicity
CR1	Macrophages	Enhanced phagocytosis
	Neutrophils	Same as macrophages
	B cells	—
	T cells	—
	Red blood cells	—
	Eosinophils	—
	Epithelial cells: kidney	—
CR2	B cells	Activation
CR3	Similar to CR1	Similar to CR1
Factor H	B cells	Secretion of factor I
	Monocytes	Respiratory burst
	Neutrophils	—
C5a	Mast cells	Histamine release
	Neutrophils	Chemotaxis, increased adhesiveness
		Enhancement of CR1 expression
	Macrophages	—
C3a/C4a	Mast cells	Histamine release

From Fearon DT, Wong WW. Complement ligand-receptor interactions that mediate biological responses. Annu Rev Immunol 1983;1:243, with permission.

The complement receptor type one (CR1, C3b/C4b receptor, CD35) was the first to be discovered as the *receptor for immune adherence*, a fundamental event in the initiation of the immune response. It is a polymorphic membrane protein of 190 to 280 kd composed of 2039 residues and present on all peripheral blood cells except platelets, NK cells, and most T cells ([724]). CR1 is expressed on kidney podocytes and FDCs. Cell membrane expression of CR1 is up-regulated by chemotactic peptides, such as C5a, endotoxin, and cytokines. Blood cells at resting state express only 5 to 10% of the total cellular CR1 at the plasma membrane, whereas the remaining CR1 is found intra-cellularly. The red blood cells express 100 to 400 receptors per cell, and the leukocytes have 10,000 to 50,000 receptors per cell. However, because the number of red cells is approximately 1000 times more than white cells, they possess more than 85% of the total CR1 that is available in the blood. CR1 contains 30 CCP domains with three sites for C4b binding and two sites for C3b binding ([725]). CCP-15 domain is critical for C4b binding and, together with CCP-16 domain, is required for C3b binding ([726]). The CCP domains are arranged in larger domains that are known as *long homologous repeats* (LHR), with each one containing seven CCPs. It is likely that this arrangement facilitates the binding of CR1 with clusters of its ligands. There are four allotypes of CR1 (A to D). CR1, one of the most versatile RCAs, possesses DAA and CA, which are restricted to reducing the complement activity on cells that have absorbed immune complexes. The DAA of CD35 is mediated by CCP-1 to CCP-3 domains for the classical and alternative pathways ([727]). In the classical pathway, CR1 inhibits the uptake of C2 by C4b as well as displaces C2a from C4b2a C3 convertase and from C4b2a3b C5 convertase. It also promotes the cleavage of C4b to C4c and C4d by factor I and the cleavage of C3b to iC3b (ligand of CR3) and C3dg (ligand of CR2) by factor I. In the alternative pathway, the CR1 impairs uptake of factor B by C3b and displaces Bb from C3bBb C3 convertase. Complexes that are bound to erythrocytes are eliminated in the spleen. Conversion of C3b to fragments leads to binding of the complexes to macrophages and monocytes that possess CR3 or to lymphoid follicular areas in which all three CR are expressed. The CR1 has the capacity to inhibit complement activation on cells and tissues other than those in which it is expressed (extrinsic protection). In contrast, DAF and MCP protect only the cells on which they are expressed (intrinsic protection). CR1 facilitates phagocytosis, one of the first recognized functions. Direct phagocytosis by CR1 in the absence of other ligands does not occur with resting neutrophils or monocytes. However, activation of these cells up-regulates CR1 expression and alters its function, so that phagocytosis of C3b-coated particles may occur. Soluble human CR1 inhibits complement-dependent tissue damage and reduces inflammatory responses.

Regulators in Body Fluids

FACTOR H Factor H is a soluble glycoprotein that is present in blood at concentrations of 0.3 to 0.5 mg/L. It is a single polypeptide chain of 150 kd with a highly elongated shape. It is composed of 1213 amino acids that are assembled in 20 CCP domains. Factor H is synthesized mainly in the liver by hepatocytes and Kupffer cells ([728]) but also in other extrahepatic sites (myeloblasts). IL-6 is the main cytokine that regulates its synthesis. The main functions of factor H are: (a) binding to the a-chain of C3b ([729]), blocking the amplification cycle in the alternative pathway (“tick-over”), and preventing the generation of C3 convertase, C3bBb; (b) binding to the C3bBb enzyme and irreversibly displacing the Bb component (DA activity); and (c) acting as cofactor for factor I and enhancing its affinity for C3b. By these three activities, factor H prevents formation of the C5 convertase and, thus, the generation of MACs by the alternative pathway. Factor H possesses an impressive number of discriminatory functional sites. Its 20 CCP domains and its long and flexible structure allow factor H to scan a large surface area. The affinity of factor H for C3b is affected by the properties of the cell or tissue surface. Carbohydrate-rich polymers that are found on yeast and bacterial cells prevent binding of factor H to C3b, thus enabling the complement activation to react against these pathogens. Removal of sialic acid from sheep erythrocytes prevents binding of factor H to C3b and allows activation of complement. Factor H binds to polyanions, and blocking of this site enhances its affinity for C3b ([730]). The propensity of factor H to bind on polyanions, such as heparin, on host tissues may function as a protective mechanism against the alternative complement pathway ([731]). The discriminatory ability of factor H depends on its differential binding to various types of surfaces to which C3b has been initially deposited (Fig. 18.33). The nonactivating surfaces have sialic acid and other negatively charged glycosaminoglycans to which factor H binds through domain CCP-20. The same domain is important for binding within approximately 30 Å from the C3d attachment site, indicating that the binding sites of factor H for polyanion and C3d overlap ([732]). It is possible that discrimination by factor H occurs by a joint recognition of C3 and polyanions. CCP-11 to CCP-20 domains are important for binding to activator surfaces ([733]), but the DAA or CA varies among these CCPs,

depending on the nature of the surface on which C3b has been deposited ([733]). It appears that factor H uses different CCP domains, individually or in combinations, for recognition of C3, host, or foreign tissues. CCP-1 to CCP-4 domains are used to bind intact C3b, CCP-6 to CCP-10 domains are used for binding C3c within the C3b, and CCP-16 to CCP-20 domains are used for the C3d part of the C3b ([734]).

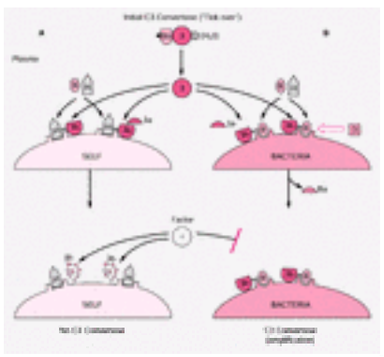

Figure 18.33. Self- nonself-discrimination by factor H. **A:** Factor H prevents alternative complement activation by blocking the amplification cycle of the alternative pathway. It enhances its affinity to C3b as a result of binding to certain polyanions (negatively charged glycosaminoglycans) on self surfaces. Binding to C3b invites factor I to fragment C3b (cofactor activity). **B:** On pathogen surfaces, factor B expresses a higher affinity to deposited C3b and, with a lack of appropriate carbohydrate ligand for factor H, forms the alternative C3 convertase.

Recently, single base mutations or base-pair deletions have been demonstrated in sporadic and familial cases of hemolytic uremic syndrome (HUS) ([735]). HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure in affected individuals and is classified as diarrheal (D+HUS) or nondiarrheal (D-HUS) and sporadic or familial. A set of 12 missense mutations in the CCP domains between CCP-16 through CCP-20 is associated with HUS. Nine of them are in CCP-20 and are inferred to lead to a functional defect ([736]). The positions of these mutations correspond to basic residues that are involved in binding to heparin. It is suggested that these mutations interfere with the normal function of factor H to bind to sulphated glycosaminoglycans and to prevent the activation of the alternative complement pathway. These experiments of nature strongly imply that the host versus foreign discrimination by factor H resides in CCP-20 and is lost by these mutations ([737]). Lack of host recognition results in uncontrolled complement activation and, eventually, renal failure. Mice that are deficient in factor H develop membranoproliferative glomerulonephritis as a result of uncontrolled activation of the alternative complement pathway ([738]). Factor H is a member of a family that consists of a total of six members. Factor H–like protein 1 (FHL-1), or reconectin, shares the complement regulatory functions with factor H and interacts with heparin. It contains the first seven of 20 CCP domains of factor H and has four unique residues that are attached to the C-terminal end ([739]). Both factor H and FLH-1 are synthesized by the same gene, but their transcripts are differentially regulated. They are produced by the liver, monocytes, and neuronal cells. Other members of the family are factor H–related (FHR) proteins 3 and 4 (FHR-3 and FHR-4) ([740]). FHR-3 and FHR-4 bind to C3b, particularly the C3d region. They do not express DAA for C3bBb convertase, and CA is detected only weakly ([741]).

C4b-BINDING PROTEIN The C4b-binding protein (C4BP) is a regulator of the classical complement pathway C3 convertase. C4BP possesses CA and DAA. It consists of eight subunits that radiate from a central core in a spiderlike formation (Fig. 18.34). The peripheral end of each subunit is capable of binding one C4 molecule. Each of the seven subunits known as a *-chains* has a molecular weight of 75 kd, and the eighth subunit, known as *ß-chain*, is 45 kd. They are flexible, 33 nm in length, and are linked together by disulfide bonds near the carboxy termini. In addition to the most common form of C4BP, a7:ß1, there are two other minor forms, a7:ß0 and a6:ß1. The a-chains are composed of 549 amino acids that are divided between eight CCP domains, with 58 residues left in the C-terminus to form the disulfide bond with the other a-chains in the core region. The ß-chains have three CCP domains and are attached by a disulfide bond in a similar way to the a-chains. The genes for C4BP are within the gene cluster of the other RCA proteins. The C4b-binding site is localized in the CCP-1 and CCP-2 domains of the a-chain, in a cluster of positively charged amino acids ([742]). The same region is also important for binding to heparin, *Bordetella pertussis*, and the M-protein of *S. pyogenes*, *Neisseria gonorrhoeae*, and *E. coli*.

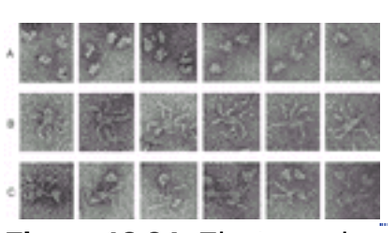

Figure 18.34. Electron micrographs of the C4b **(A)** and the C4b-binding protein **(B)** that form complexes with C4b **(C)**. (Courtesy of Dr. B. Dahlback. From Dahlback B, Smith CA, Muller-Eberhard HJ. Visualization of human C4b-binding protein and its complexes with vitamin K–dependent protein S and complement protein C4b. Proc Natl Acad Sci U S A 1983;80:3461–3465, with permission.)

C4BP is synthesized in the liver under stimulation of IL-6 and TNF-a ([743]) and is present in the blood at a concentration of 0.2 mg/L. The mechanism of control of the classical pathway by C4BP depends on the binding to C4b and the displacement of C2a from the C4b2a convertase (DAA), as well as its function as a cofactor for cleavage of C4b by factor I. Dissociation of C2a from the classical pathway C3 convertase destroys its activity and prevents rebinding of the C2a to C4b. C4BP acts also as cofactor for cleavage of C3b by factor I ([744]). Protein S binds with high affinity to the ß-chain of C4BP ([745]). Protein S of the coagulation pathway is a vitamin K–dependent anticoagulant protein. It acts as the cofactor for activated protein C that inactivates factor Va and is also the direct inhibitor of factor Xa. The concentration of free protein S is determined by the concentration of C4BP, as 50% or more of protein S is bound to C4BP. Protein S that is bound to C4BP is unable to participate in the anticoagulant protein C system. It is critical that the balance between free and C4BP-bound protein S is maintained stable, as lack of free protein S leads to thrombosis. Protein S–bound C4BP is probably localized on negatively charged surfaces that are found in platelets and apoptotic cells. Conditions with elevated C4BP (autoimmune diseases) may be associated with increased clotting tendency as a result of increased binding of protein S to C4BP.

FACTOR I Factor I is a serine protease that mediates proteolytic degradation of C3b, iC3b, and C4b only if a cofactor binds to the substrate to promote the binding of the enzyme. These cofactors for C3 and C4 degradation on host cells are MCP (Fig. 18.32), and, to a lesser extent, CR1, whereas, in plasma, the cofactors are C4BP and factor H (Fig. 18.32 and Fig. 18.33). Factor I is constitutively active and essential for control of the fluid and cellular complement reactions. Genetic deficiency of factor I leaves the generation of C3 convertases uncontrolled, leading to incapacitation of the complement system as a result of the continuous low level conversion of C3. Fragmentation by factor I of C3 and C4 determines the specificity of their derivatives for CR1, CR2, and CR3. Factor I is a two-chain disulfide linked protein that is synthesized from a single chain precursor. The H chain is 50 kd, and the L chain is 38 kd in molecular mass and has the Ser esterase domain. The H chain is composed of three different types of modules that are derived from different gene superfamilies. One module, which is also found in C6 and C7, is from members of the follistatin family of the extracellular matrix, a second type is a scavenger receptor cysteine-rich module, and the third type are two LDLR-A modules. The only known substrates for factor I are C3b and C4b. C3b is cleaved at Arg ^{1303}-Ser ^{1304} and Arg ^{1320}-Ser ^{1321}. For this cleavage, the cofactors are factor H, MCP, and CR1. C4BP acts as a cofactor for cleavage of C4b and C3b. C4b is cleaved at Arg ^{1336}-Asn ^{1337}. In general, for C3b and C4b and all subsequent fragments, factor I acts on the C-terminal side of an Arg.

Control of the Membrane Attack Complex Assembly

PROTEIN S Protein S is identical to vitronectin (serum spreading factor). It is a 75- to 80-kd protein that is synthesized from a single polypeptide chain that is subsequently cleaved to give the mature polypeptide as a single- or double-chain protein. At the NH_2-terminus, there is a somatomedin B domain (containing eight cysteines) followed by a linear sequence, which contains the RGD sequence that is responsible for the binding of integrins. Two domains of the S protein have homology to hemopexin. The C-terminus is rich in basic residues that mediate the binding of S protein with sulfated polysaccharides. Protein S binds to the metastable C5b-7 complex and prevents the formation of MAC. Because MAC in the process of its formation can be inserted on any cell membrane, the most important function of S protein is the protection of the cells of the body that may be attacked by MAC as innocent bystanders. Protein S acts through its heparin binding site, which prevents the polymerization of C9. The protein S is important in cell matrix interactions, and, through its multiple binding sites, it participates in several other functions of adherence, phagocytosis, the coagulation cascade in which it interacts with thrombin.

CLUSTERIN (CYTOLYSIS INHIBITOR) Clusterin is an 80-kd protein composed of two chains (a and ß). The gene is located on chromosome 8p21. It is present in a variety of tissues and in the serum at concentrations of 35 to 105 µg/L. It forms complexes with lipoproteins and binds to C7, C8b, and C9, to inhibit MAC formation ([746]). Clusterin is involved in several other poorly understood functions. It has been found to be up-regulated in injured tissues and in Alzheimer disease, as well as in tissues undergoing apoptosis.

Control of Deposited MAC: CD59

CD59 is an 18- to 20-kd protein that inhibits MAC formation ([747]). It has been known by a variety of other names, such as *homologous restriction factor 20* (HRF20), *membrane inhibitor of reactive lysis* (MIRL), and *protectin*. It is a GPI-anchored protein and is widely distributed in human tissues and most body fluids (see the following discussion). CD59 expression is lacking in patients with paroxysmal nocturnal hemoglobinuria (PNH).

Conclusion

The RCA proteins exert several important functions in the regulation of complement activity: (a) They prevent complement activation in the blood (factor H and C4BP); (b) they interfere with the assembly and function of convertase activity on cell membranes (DAF, MCP), protecting the cells of the body from complement attack; (c) they transport and clear immune complexes (CR1); and (d) they mediate transmembrane and intracellular trafficking (CR1) and transmembrane signaling (CR2).

The CCP units that are characteristic of the members of the proteins of the RCA gene cluster are present also in C1r, C6, C7, factor B, properdin, and noncomplement proteins, such as coagulation factor XIII and IL-2 receptor. The 60–amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing with domains from the serine protease gene family.

ANAPHYLATOXINS

Activation of the complement cascade leads to the release of important inflammatory factors that are known as *anaphylatoxins*: the C3a, C4a, and C5a molecules. They induce numerous inflammatory responses and also play a role as immunomodulatory molecules; therefore, they act as local hormones. Their amino acid sequence varies from 74 to 78 residues. The cysteines are conserved in all anaphylatoxins and form three disulfide bonds that stabilize the conformation and form the core of the molecule. The C-terminus forms the active site, with the C-terminal Arg being essential for function. Under physiologic conditions, the molecule is folded or compact.

C3a and C5a have a high content of a helix in a compact hairpin configuration that is maintained by the three disulfide bonds. The C-terminal end protrudes from this helical core and is considered to be the active site of the molecule that mediates biologic activities. Removal of the last Arg (C5a desArg) results in a loss of spasmogenic activity, but the chemotactic and other neutrophil activation functions are retained ([748]). The N-terminal region of C5a binds to its high-affinity receptor on neutrophils, which spans the membrane seven times with the N-terminus on the extracellular side ([749]). It belongs to the rhodopsin family of receptors, the members of which are linked to G proteins. Binding of C5a to its receptor on neutrophils induces a variety of responses, depending on its concentration, such as chemotaxis, granule secretion, up-regulation of adhesion molecules, changes of cytoskeleton, and activation of NADPH (nicotinamide adenine dinucleotide phosphate oxidase). These responses are mediated by G proteins, and the downstream signaling involves activation of phospholipase C, tyrosine kinases, and MAPKs or phosphatidylinositol-3-kinase, which are important for chemotaxis.

All anaphylatoxins are cleaved rapidly in the serum by carboxypeptidase-N, an enzyme that removes the C-terminal Arg that is found on all three anaphylatoxins. The main biologic function of anaphylatoxins is related to their ability to increase vascular permeability. Vascular permeability may be increased by several mechanisms, foremost among which is the release of histamine. Mast-cell degranulation has been observed at the site of anaphylatoxin injection. Generation of prostaglandin E_2 also causes vasodilation. Anaphylatoxins also cause serious lung injury because of their capacity to recruit and sequester circulating leukocytes in the pulmonary circulation and the subsequent release of mediators at the site of sequestration. Finally, production of oxygen- and nitrogen-derived radicals, leukocyte margination, release of granule-associated proteolytic enzymes, capillary leakage, and all components of an inflammatory response are also mediated by anaphylatoxins.

COMPLEMENT COMPONENT DEFICIENCIES

C1 Esterase Inhibitor: Hereditary Angioneurotic Edema

HAE is an autosomal-dominant disease that afflicts persons of all races with no sex predominance ([750]). It manifests as recurrent attacks of intense, massive localized edema without pruritus. The attacks occur in the absence of any identifiable initiating event. Most commonly involved viscera are the respiratory and gastrointestinal systems. Involvement of upper airways may result in severe life-threatening symptoms, including risk of asphyxiation. There are two types of HAE: type 1 (80 to 85% of cases) is caused by decreased production of C1 INH; type 2 (15 to 20%) is caused by a functionally impaired C1 INH. Quantitative and functional analyses of C1 esterase inhibitor and complement components C4 and C1q should be performed in cases that are suspected of HAE.

C1 INH belongs to the same family as a $_1$-antitrypsin, and antithrombin IFN-? and IL-6 stimulate its synthesis and release from the liver and monocytes. The main function of C1 INH is prevention of autoactivation of the complement cascade. It also inactivates coagulation factors XIIa, XIIf, and XId and activated kallikrein. The mechanism of action involves formation of irreversible covalent bonds with the substrates.

It is proposed that, under physiologic conditions, small quantities of factor XII are autoactivated to factor XIIa after contact with certain surfaces. Factor XIIa triggers the contact system, which cleaves prekallikrein to kallikrein, which in turn cleaves kininogen, thus generating excessive release of kinins, especially bradykinin. This pathway normally is blocked by C1 INH, which inhibits factor XIIa. In the absence of the normal control function of C1 INH, not only factor XIIa is not inhibited, but kallikrein also generates plasmin from plasminogen, which in turn activates factor XIIa for more kallikrein and activation of the C1 esterase.

Deficiency of Other Early Complement Components

Homozygous deficiencies of the early components of the classical pathway are associated with SLE ([751]), and the severity of the associated disease is greatest with C1q deficiency. C1q deficiency is caused by failure of C1q synthesis or synthesis of a dysfunctional molecule. C4 deficiency is associated with early onset of severe SLE. C2 deficiency is the most common homozygous complement deficiency in whites. C3 deficiency is associated with recurrent pyogenic infections. Deficiency of factor H has been associated with membranoproliferative glomerulonephritis (see the previous discussion).

Paroxysmal Nocturnal Hemoglobinuria: Decay-Accelerating Factor (CD55) or Clustering (CD59) Deficiencies, or Both

PNH is an acquired hematopoietic stem cell disorder, which is manifested by intravascular hemolysis, venous thrombosis, aplastic anemia, myelodysplasia, and leukemia. The defect is the result of somatic mutations that consist of deletions, insertions, or point mutations of the PIG-A [phosphatidyl inositol (PI) glycan complementation class A] gene, which is involved in the synthesis of GPI ([752] , [753]).

The GPI anchor consists of three components: (a) phospho-ethanolamine (PEA), (b) a glycan core (consisting of three mannose molecules and one GlcNAc), and (c) PI.

GLYCOSYL PHOSPHATIDYL INOSITOL BIOSYNTHESIS GPI synthesis involves multiple steps and takes place in the ER (Fig. 18.35). In the *first step*, GlcNAc is attached to PI, a common product of cellular metabolism. The transfer of GlcNAc is catalyzed by the GPI- *N*-acetyltransferase, a complex enzyme that is composed of at least six proteins ([754] , [755]). The first gene that has been cloned is PIG-A (*p*hosphatidyl *i*nositol *g*lycan class *A*), which is located in the short arm of the X chromosome. The other proteins of the GlcNAc transferase are PIG-H, PIG-C, PIG-Q, PIG-P, and dolichol phosphate mannose (DPM) 2. The PIG-A (GPI-3) component performs the catalytic function of the complex ([756]). PIG-H (GPI-15) interacts with PIG-A, and PIG-C (GPI-2) forms a scaffolding for the other components to facilitate their interactions. PIG-Q (GPI-1) contributes to the association between PIG-C, PIG-A, and PIG-H, stabilizes the transferase, and blocks its destruction from cellular systems that screen highly hydrophobic proteins.

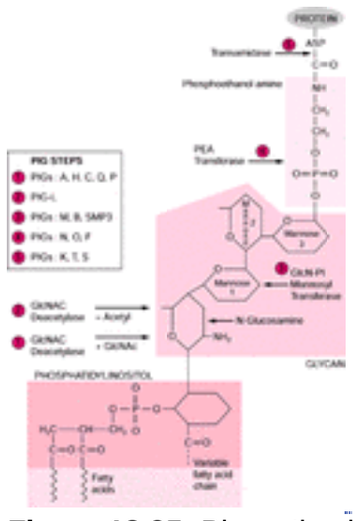

Figure 18.35. Biosynthesis of glycosyl phosphatidyl inositol (GPI). GPI consists of three components: (a) phosphatidyl inositol (PI), (b) glycan (made of one *N*-glucosamine and three mannose molecules), and (c) one phosphoethanolamine (PEA). GPI anchored is synthesized in the endoplasmic reticulum and to proteins, expressing a signal that is encoded in the C-terminal sequence. The signal sequence is cleaved to expose the GPI attachment site (?-site). The first of several steps *(1)* in GPI biosynthesis attaches *N*-acetyl glucosamine (GlcNAc) to PI, by the enzyme GlcNAc transferase. The acetyl group is removed in the second step *(2)* by a deacetylase. Subsequently, three mannose (M) molecules are added by different mannose transferases *(3)* (attachment bonds differ), and, finally, the PEA molecule is attached by a PEA transferase. The attachment of the completed GPI to the protein is mediated by a transamidase complex. The first enzyme, GlcNAc transferase, is a complex of at least five gene products (see the chapter text for details). Phosphatidyl inositol glycan complementation class A (PIG-A) performs the catalytic function of the enzyme, and mutations in this gene result in paroxysmal nocturnal hemoglobinuria.

PIG-P is a small hydrophobic component, which interacts with PIG-A, therefore it is essential for GPI synthesis. Surprisingly, the PIG-P gene is located in the critical region of chromosome 21, which is involved in Down syndrome and is predicted to have a function that is related to malformations of the tongue. DPM-2 is the regulatory subunit of the DPM synthase (DPMS), which supplies mannose for GPI biosynthesis. DPM-2 therefore participates in two enzymatic complexes, the GlcNAc transferase and mannose synthase. The *second step* for GPI synthesis is catalyzed by PIG-L (GPI-12), which has GlcNAc-PI de- *N*-acetylase activity ([757]) and removes the acetyl group from GlcNAc. In the *third step*, PI is acylated and this is followed by flipping the intermediate structure to the luminal side of ER by an unknown lipase. In the *fourth step*, three mannose units are added by mannose transferases that are associated with the ER membrane. PIG-M adds the first mannose to the GlcNAc unit, and PIG-B–(GPI-10) attaches the third one. The *fifth step* in GPI synthesis is the addition of PEA by appropriate transferases, PIG-N, PIG-O, PIG-F, and GPI-7. In humans, there is only one PEA, which is added to the third mannose. PIG-O is responsible for such a reaction, and its function is stabilized by PIG-F. PIG-N is involved in the addition of PEA to the first mannose. Once the synthesis of GPI is complete, it is transferred to the protein by a transamidase complex. This complex consists of PIG-K (GPI-8), a small protein that is a protease, and PIG-T (GPI-16), PIG-S (GPI-17), and GPAA-1–GAA-1 proteins ([758]). These proteins interact physically with each other, but PIG-T is the most important for the stability of the complex. The protein to have the GPI attached is first processed by removing the N-terminal leader peptide. The protein bound on the lumenal side by a C-terminal peptide is translocated to the transamidase complex in the presence of the BiP chaperon. The C-terminal peptide of the protein is removed, and the transamidase complex attaches the GPI through the ethanolamine head to the newly exposed C-terminal (? site). This C-atom is linked to the amino group of PEA, which is attached to the third mannose by an amide bond.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA: IMMUNOPATHOLOGY The biochemical defect of PNH occurs in the first step of GPI synthesis and results from mutations in the PIG-A gene. Because PIG-A is on the X chromosome, one mutational event is sufficient to cause the disease ([759] , [760]). Cell proteins that are anchored by GPI are missing from PNH hematopoietic cells, and some of the clinical manifestations are due to loss of GPI-anchored proteins. Lack of CD55 alone is not responsible for the hemolytic component of the disease, because individuals with the Inab phenotype in which CD55 is absent have only slightly increased sensitivity. CD59, which binds to C3 and prevents binding and subsequent polymerization of C9, accounts for the intravascular hemolysis and, possibly, thrombosis in PNH ([761]). Diagnosis of PNH has improved with flow cytometry, which uses monoclonal antibodies to detect the proportion of granulocytes and monocytes that lack CD59. This proportion is larger than that of abnormal red cells. Appropriate combinations of CD14, CD16, CD64, and CD66 in a two-parameter analysis, such as CD64 versus CD14, can accurately detect the abnormal leukocytes. In addition to hemolysis, thrombosis is an important manifestation of PNH. The cause of thrombosis is probably due to the release of microparticles from platelets with procoagulant activity, such as particles that are rich in factor Va, factor Xa, and the prothrombinase complex. Endothelial cells are stimulated to express tissue factor and may contribute to thrombosis. Furthermore, the urokinase plasminogen activator receptor (uPAR CD87), a GPI-anchored protein, is absent. Normally, it binds urokinase on the surface of granulocytes and monocytes, converting plasminogen to plasmin-initiating fibrinolysis. Lack of uPAR may therefore promote thrombosis. An important, albeit still unanswered, question is the relationship of PNH to bone marrow aplasia or myelodysplasia and the development of acute myelogenous leukemia. Normal stem cells from patients with PNH show diminished proliferative potential *in vitro* as compared to mutant PNH $CD34^{+}$ stem cells ([762]). The PNH clone with a proliferative advantage expands and dominates over the normal cells. It has been suggested that PNH is expressed only when normal hematopoiesis is impaired and when the PNH clone dominates hematopoiesis. This is supported by some evidence that a tiny proportion of PIG-A^{-} progeny exists in normal individuals ([763]).

Deficiencies of Terminal Complement Components

Deficiencies of the terminal complement components, such as C7, have been detected in several countries, whereas C6 has been primarily detected in blacks in the United States and in South Africa, and the majority of C9 deficiencies have been found in Japan ([751] , [764] , [765] , [766] and [767]). C6 deficiency has been defined as *quantitatively zero C6* (C6Q0) or subtotal C6 (C6SD), when C6 is structurally abnormal but hemolytically active ([768]).

Deficiencies are due to single-base deletions or mutations that lead to premature stop codons. In C6 deficiency, there is a tendency for mutations in exon 6 ([767]) with defects in an area that is adjacent to a sequence that contains seven Gs and a string of six Ts ([769] and [770]). Carboxy terminally truncated C6, which results in a shorter dysmorphic, but functionally active, molecule, has been detected in South African families ([771]). Complement component C6 deficiency is associated with *Neisseria* infections (meningococci and gonococci) ([751]), with *N. meningitidis* infection often being recurrent ([772]).

Infections with serogroup B are the major problem with these patients; these infections limit the usefulness of the available vaccine, which is not directed against this group. Other infections have also been detected in homozygous C6 deficiency, such as SLE, Still disease, and glomerulosclerosis ([773]).

COMPLEMENT SYSTEM: FROM SEA URCHINS TO *HOMO SAPIENS SAPIENS*

The innate immune system antedates the appearance of the RAG genes, an evolutionary hallmark at the dawn of the adaptive immunity. The origins of the complement system can be traced as far back as the echinoderms, because C3 and a factor B–like protein have been identified in sea urchins ([680] , [774] , [775]). The ascidians (sea squirts), or tunicates, occupy a crucial intermediary position between invertebrates and vertebrates. Two lectins (that correspond to mammalian MBL), ficolins, two MASPs, a C3, a B factor, and a C3 receptor have been identified in ascidians. These findings indicate that a lectinlike pathway also precedes the development of the classical pathway, which seems to emerge only at the stage of cartilaginous fishes at the same time as the appearance of the adaptive immunity.

Megakaryocytes and Platelets

Kenneth Kaushansky and Gerald J. Roth

The role of platelets in humans is straightforward: “Platelets plug holes in blood vessels.” However, the development of platelets from megakaryocytes and the structure of platelets in the blood are far from simple. This chapter describes first the production of platelets from marrow megakaryocytes and second the anatomy and composition of these unique elements.

HISTORICAL PERSPECTIVE

Platelets were described by Addison in 1841 as “extremely minute…granules” in clotting blood ([1]) and were termed *platelets* (*blutplättchen*) by Bizzozero, who also observed their adhesive qualities as “increased stickiness…when a vascular wall is damaged” ([2], [3]). The same elements were identified by microscopic examination of blood smears by Osler and by Hayem in the late nineteenth century ([4], [5]).

Megakaryocytes have been recognized as rare marrow cells for nearly two centuries, but it was the elegant *camera lucida* studies of Howell in 1890 and his coining of the term *megakaryocyte* that led to their broader appreciation as distinct entities ([6]). In 1906, James Homer Wright put forth the hypothesis that blood platelets are derived from the cytoplasm of megakaryocytes ([7], [8]), and the basic elements of thrombopoiesis were established.

MEGAKARYOCYTES

Blood cell production is an enormous and complex task. Platelet production begins in the yolk sac ([9]) and, like the remainder of hematopoiesis, shifts to the fetal liver and then to the marrow at the time of gestation. Based on the adult blood volume (5 l), the number of platelets per µl of blood (~2 × 10^5), and their circulatory half-life (10 days), it can be calculated that each day an adult human produces 1 × 10^{11} platelets. The platelet count varies among the healthy population (1.5 to 3.5 × 10^5/µl) but remains within a fairly narrow range in any given individual. In times of increased demand, platelet production can rise tenfold or more. This chapter discusses the biochemical, cell physiologic, and molecular mechanisms underlying the development of megakaryocytes, the complex processes by which they generate thousands of platelets and then undergo programmed cell death (PCD), and the cell biology and biochemistry of platelet function in hemostasis. It is hoped that a thorough understanding of these processes will clarify the underlying mechanisms responsible for their pathologic disruption and aid in better devising strategies to intervene in those conditions associated with reduced, enhanced, or disordered megakaryocyte or platelet function, or both.

Cellular Basis of Megakaryopoiesis

The basic concepts of a hierarchic organization of stem and progenitor cells leading to mature blood cell production were formulated by Till and McCulloch in the early 1960s, although the concept of a common “mother cell” of all blood elements in the adult dates to Danchakoff in 1916 ([10]). The capacity to transplant marrow cells and reconstitute all of hematopoiesis in lethally irradiated recipients provided an *in vivo* assay for the hematopoietic stem cell (HSC), but it was not until the development of clonal *in vitro* assays of hematopoietic progenitors that a coherent model of blood cell production emerged. The pioneering work of Pluznik and Sachs ([11]) and of Bradley and Metcalf ([12]) provided a convenient method to enumerate and characterize marrow cells committed to various hematopoietic lineages. These investigators independently developed culture conditions that allowed colonies of cells to develop from single progenitors. However, the first hematopoietic colonies were composed of leukocytes; due to the more fastidious conditions required for megakaryopoiesis *in vitro*, the description of clonal megakaryocyte growth did not occur for another decade or more ([13], [14], [15] and [16]). Recent work using density fractionation, cell sorting, and fluorescent dye exclusion methods has yielded purified populations of stem cells ([17], [18], [19], [20] and [21]), common myeloid ([22]) and lymphoid ([23]) progenitors, and lineage-restricted hematopoietic progenitors ([24], [25]); these methods have greatly advanced understanding of the cell and the molecular biology of megakaryocyte development.

Culture conditions that support the proliferation of megakaryocytic progenitors have been described using methylcellulose, agar, or a plasma clot assay. Multiple investigators have demonstrated two colony morphologies that exclusively contain megakaryocytes. The colony-forming unit megakaryocyte (CFU-MK) is a cell that develops into a simple colony containing 3 to 50 mature megakaryocytes ([13], [14] and [15]). Larger, more complex colonies that include satellite collections of megakaryocytes and contain up to several hundred cells are derived from the burst-forming unit megakaryocyte (BFU-MK) ([16], [17]). Such lineage-restricted colonies have been described using marrow cells from both human and murine sources. Because of the difference in their proliferative potential and by analogy to erythroid progenitors, BFU-MK and CFU-MK are thought to represent primitive and mature progenitor cells restricted to the megakaryocyte lineage. Human marrow BFU-MKs are CD34 $^+$ and HLA-DR $^-$ and develop into multifocal collections of at least 100 megakaryocytes within approximately 21 days in culture ([16], [17], [26], [27]). CFU-MK–derived colonies are morphologically simpler, containing as few as three megakaryocytes and developing in 10 to 12 days; their progenitors are CD34 $^+$ but HLA-DR $^+$ and are rapidly cycling cells as determined by their sensitivity to 5-fluorouracil ([13], [14] and [15], [28], [29]). Recently, the close relationship of the erythroid and megakaryocyte lineages was reinforced by the identification of a mixed erythroid-megakaryocyte progenitor ([30], [31], [32], [33] and [34]). It is unlikely that all CFU-MK and BFU-MK arise from colony-forming unit erythroid-megakaryocytes, although definitive evidence has not yet been presented. More recently, fractionation methods have been devised that yield purified populations of CFU-MK for functional and biochemical analysis ([25]).

Extrinsic Regulation of Megakaryopoiesis

IDENTIFICATION AND PURIFICATION OF HUMORAL REGULATORS Perhaps the greatest debate surrounding the role of growth factors in hematopoiesis is whether they affect the differentiation of hematopoietic stem and progenitor cells or whether they merely allow for the survival of receptor-bearing cells by preventing PCD. Evidence for both views has been presented ([35], [36] and [37]), and it is fair to say that this controversy is far from resolved. Nevertheless, a great deal is now understood about the cyto-kines that affect megakaryocyte development. In the search to identify the primary humoral regulator of thrombopoiesis, several cytokines, first identified using alternate hematopoietic activity assays, were also found to affect megakaryo-cyte development. Interleukin (IL)-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and the c-kit ligand (KL) support the proliferation of megakaryocyte progenitors in plasma-containing cultures ([38], [39], [40], [41] and [42]). IL-3 is a 25- to 30-kd protein produced primarily by T lymphocytes ([43]). The mature human polypeptide contains 133 amino acids, but significant amounts of N-linked carbohydrate modification account for the larger-than-expected relative molecular mass (M_r) of the cyto-kine. GM-CSF is an 18- to 30-kd protein also produced by T lymphocytes, but endothelial cells, monocytes, and fibroblasts also produce the protein and, like IL-3, GM-CSF is highly modified with both N-linked and O-linked carbohydrate ([44]). Although the two polypeptides display essentially no primary sequence homology, their tertiary structures are highly related ([45], [46]), and the receptors for the two cytokines share a common subunit ([47]). However, the physiologic relevance of IL-3 and GM-CSF for thrombopoiesis is uncertain because their administration to mice or humans has only minimal effects on platelet production, and the genetic elimination of either cytokine has no impact on

megakaryopoiesis, even in combination with the elimination of other thrombopoietic cytokines ([48], [49]). In contrast to the hematopoietic cytokine family, KL is more closely related to other hematopoietic proteins that use protein tyrosine kinase receptors, such as macrophage colony-stimulating factor and the flt-3 ligand (FL) ([50]). Nevertheless, KL has been shown to stimulate megakaryocyte colony growth when used in combination with other cytokines ([42], [51], [52]). Moreover, genetic elimination of *c-kit* reduces megakaryocyte production ([53]) and the rebound thrombocytosis that occurs after immunosuppressive therapy ([54], [55]). Kit ligand was first identified using several different biologic assays (in addition to the term *KL*, the cytokine has been dubbed *stem cell factor*, *mast cell growth factor*, and *steel factor*) ([56], [57], [58] and [59]). Most recent studies indicate that the cytokine acts primarily on primitive cells of the hematopoietic, melanogenic, and germ cell systems ([60], [61], [62], [63], [64] and [65]). KL is a dimeric protein composed of two identical non–covalently linked polypeptides; the soluble form monomer contains 165 residues ([66]), derived by proteolytic cleavage of a membrane-bound form of the molecule ([67]). The membrane-bound form is actually more active than the soluble cytokine because cell survival and proliferation signals derived from the former are prolonged in receptor-bearing cells ([68]). Moreover, a naturally occurring mutant allele of the gene (Sl^d), which allows production of the soluble but not the membrane-bound form of KL, results in a phenotype nearly identical to deletion of the entire locus ([69]). The effects of FL on megakaryocyte formation have also been investigated. This growth factor was initially identified as a ligand for a novel member of the protein tyrosine kinase family of receptors ([50]). Similar to KL, to which it is most closely related, FL is found in both soluble and membrane-bound forms, is a non–covalently linked dimer, and affects primarily primitive hematopoietic cells ([50], [70], [71]). Although several studies have shown that when used alone FL does not support megakaryocyte colony formation, some studies suggest that it works in synergy with other megakaryocyte stimulatory agents to augment the proliferation of CFU-MK in culture ([72]). Moreover, the administration of FL to mice clearly expands the number of marrow and splenic progenitor cells that can give rise to megakaryocytes *in vitro* ([73]). However, genetic elimination of FL or its receptor has no platelet phenotype. In the late 1980s and early 1990s, three molecules related by use of a common receptor subunit were characterized that display effects on megakaryocyte production. IL-6, cloned by several groups using multiple assays [hepatocyte growth, myeloma cell growth, immunoglobulin (Ig) secretion, antiviral activity], was also found to enhance megakaryocyte maturation. IL-6 is a 26-kd polypeptide widely produced in response to inflammatory stimuli from T cells, fibroblasts, macrophages, and stromal cells ([74]). The mature protein is composed of 184 amino acids, contains two disulfide bonds, and displays both N-linked and O-linked carbohydrate modification. Although IL-6 alone does not affect *in vitro* megakaryopoiesis, it augments the number of megakaryocyte colonies obtained in the presence of IL-3 or KL ([75], [76]). In such culture systems, IL-6 exerts primarily a differentiating effect, as its levels correlate with megakaryocyte size and ploidy in long-term marrow cultures, and its neutralization reduces these parameters ([77], [78], [79] and [80]). The administration of IL-6 to mice, dogs, or humans results in a modest thrombocytosis ([75], [78], [81], [82], [83] and [84]). These findings suggest that IL-6 might contribute to megakaryopoiesis *in vivo*—a conclusion supported by its production by tumor cells in selected cases of paraneoplastic thrombocytosis ([85], [86], [87], [88] and [89]). However, genetic elimination of IL-6 does not significantly affect basal platelet production ([90]); recent evidence suggests that the cytokine affects platelet production indirectly ([91]). IL-11 and leukemia inhibitory factor (LIF) also act in synergy with IL-3 or KL to augment megakaryocyte formation. IL-11 is a 23-kd polypeptide initially cloned from a gibbon marrow stromal cell line as an activity that supported the proliferation of an IL-6 responsive myeloma cell line ([92], [93]). LIF was initially cloned as a *h*uman *i*nter *l*eukin that induced *DA*-1 cells to proliferate (hence its alternate name, *HILDA*) or induced leukemic M1 cells to differentiate ([94], [95]). LIF displays a wide range of activities ([96]) including effects on the liver (initiates the acute phase response), neurons (induces an adrenergic to cholinergic switch), adipocytes (inhibits lipoprotein lipase), and embryonic cells (maintains pluripotentiality). Like IL-6 and IL-11, LIF enhances megakaryocyte maturation *in vitro* ([80], [97]). Moreover, IL-6 and IL-11 were also found to augment the effects of IL-3 and KL on the proliferation of primitive hematopoietic cells, suggesting that these cytokines augment megakaryocyte development at multiple levels. Consistent with these *in vitro* findings, the administration of either recombinant IL-11 or LIF to rodents, nonhuman primates, or humans produces a modest thrombocytosis ([94], [98], [99], [100], [101] and [102]). Together, such findings suggested to many that these pleiotropic cytokines might provide the equivalent of the postulated primary regulator of platelet function, thrombopoietin (TPO). However, several investigators argued that neither IL-6 nor IL-11 was TPO ([103], [104], [105] and [106]). Consistent with this opposing view, only approximately 25% of thrombocytopenic children (amegakaryocytic thrombo-cytopenia, aplastic anemia, immune-mediated thrombocytopenia) displayed elevated levels of IL-11 ([107]), and IL-11 levels are, for the most part, normal in adult patients with thrombocytopenia secondary to liver failure or after myelosuppressive or myeloablative therapy ([88], [108], [109]). Moreover, genetic elimination of either LIF or the IL-11 receptor has no obvious effect on thrombopoiesis ([110], [111]). The term *thrombopoietin* was first coined in 1958 to describe the primary regulator of platelet production ([112]). Over the following four decades, evidence both for and against its existence as a distinct entity was presented ([113], [114]). Although not appreciated at the time, a major insight into megakaryocyte biology was provided in 1986 when Françoise Wendling and her colleagues described a murine retrovirus, myeloproliferative leukemia virus, which induced a vast expansion of hematopoietic cells ([115]). The responsible viral oncogene was characterized in 1990 ([116]), and its cellular homolog *c-mpl* was cloned in 1992 ([117]). Based on the presence of two copies of the hematopoietic cytokine receptor motif, it was immediately apparent that *c-mpl* encoded a growth factor receptor. However, its ligand was not known. Using three distinct strategies, four separate groups were able to clone the cDNA for the corresponding hormone and reported their results in 1994 ([118], [119], [120] and [121]). The gene for this c-mpl ligand was mapped to human chromosome 3q26-28, spans 6 to 8 kb, consists of seven exons, and encodes a predicted 36-kd polypeptide ([122], [123] and [124]). The recombinant and naturally occurring hormones migrate as 70-kd proteins, indicating substantial posttranslational modification, a conclusion verified by the finding of six sites of N-linked carbohydrate and many sites of O-linked carbohydrate ([125]). Based on its biologic activities, the c-mpl ligand was termed *thrombopoietin* ([126]). TPO bears striking homology to erythropoietin (EPO), the primary regulator of erythropoiesis, within the amino terminal half of the predicted polypeptide ([118], [119], [120] and [121]). The two proteins are more closely related than any other two cytokines within the hematopoietic cytokine family, sharing 20% identical amino acids, an additional 25% conservative substitutions, and identical positions of three of the four cysteine residues. However, unlike any of the other cytokines in the family, TPO contains a 181-residue carboxyl terminal extension, which bears homology to no known proteins. Two functions have been assigned to this region: It prolongs the circulatory half-life of the hormone ([127]), and it aids in secretion of the cytokine from cells that normally synthesize it ([128], [129]). The biologic activities of TPO are consistent with a primary role in megakaryopoiesis. Incubation of marrow cells from mice, rats, dogs, nonhuman primates, and humans with TPO leads to an impressive stimulation of megakaryocyte growth in both suspension and semisolid culture ([52], [118], [126], [130]). Compared to cultures initiated with IL-3 or KL, with or without IL-6, IL-11, or LIF, marrow cells grown in TPO contain greater numbers of megakaryocytes, and the cells are larger and more highly polyploid. When administered to animals or humans, TPO stimulates platelet production in a log-linear manner to levels tenfold higher than baseline ([120], [126], [127], [131], [132] and [133]) without affecting the peripheral blood red or white cell counts. However, perhaps unexpectedly, the number of erythroid and myeloid progenitors and mixed myeloid progenitors in marrow and spleen were also increased in some studies ([134], [135]), an effect that is especially impressive when the hormone is administered to animals after myelosuppressive therapy ([134], [136], [137]) and probably due to the synergy ([52]) between TPO and the other hematopoietic cytokines circulating at high levels in this condition. Clinically, the most important activity of TPO is likely to be its effects on megakaryopoiesis, potentially ameliorating the thrombocytopenia that occurs in natural and iatrogenic states of marrow failure. In this regard, a number of investigators have reported promising results in preclinical trials of the cytokine ([136], [137], [138], [139], [140] and [141]). More recently, a number of clinical trials have been conducted, with the hormone helpful in many ([132], [142], [143], [144] and [145]) but not all clinical situations ([146], [147] and [148]). The biologic effects of TPO *in vitro* and of its administration *in vivo* strongly suggest the hormone plays an important role in hematopoiesis. Based on genetic studies, it is now clear that TPO is the primary regulator of thrombopoiesis. Genetic elimination of *c-mpl* or *tpo* leads to profound thrombocytopenia in mice due to a greatly reduced number of megakaryocyte progenitors and mature megakaryocytes and the reduced polyploidy of the remaining megakaryocytes ([123], [149]). More recently, a human equivalent of mpl deficiency has been identified: congenital amegakaryocytic thrombocytopenia. In more than a dozen cases, the presence of nonsense or missense mutations has been identified that in homozygous or mixed heterozygous inheritance eliminates TPO responsiveness ([150], [151] and [152]). In addition to the critical roles for TPO revealed by these knock-out studies, the broader range of hematopoietic activities identified in *in vitro* studies of stem and primitive hematopoietic cells ([153], [154]) was confirmed in genetically engineered mice ([155], [156]) and in patients with congenital amegakaryocytic thrombocytopenia ([157]). By contrast, genetic elimination of IL-3, GM-CSF, IL-6, IL-11 receptor, or LIF produces other hematologic phenotypes but has no effect on thrombopoiesis ([111], [158], [159], [160] and [161]), and mutation of KL reduces platelet production only modestly ([51]). The TPO gene displays an unusual 5' untranslated region structure. Unlike the majority of genes that initiate translation of the encoded polypeptide from the first ATG codon present in the mRNA, TPO translation initiates at the eighth ATG codon located within the third exon of a full-length transcript [there are two transcription initiation sites that differ because of alternate splicing of the first exon ([122])]. Moreover, the eighth ATG is embedded in the short open reading frame (ORF) of the seventh ATG—a particularly inefficient circumstance for translation initiation ([162]). As such, little TPO protein is produced for any given amount of mRNA. Although it is not yet certain whether this molecular arrangement has physiologic consequences (i.e., it can be differentially regulated), it is clear that mutation of the TPO gene in noncoding sequences can lead to enhanced translation efficiency and thrombocytosis. Four cases of familial thrombocytosis have been linked to mutations in the region surrounding the initiation codon. In two families, a single mutation in different nucleotides of the intron 3 splice donor sequence results in alternate splicing of the primary TPO transcript, eliminating the seventh and eighth ATG codons, and in the creation of a new amino terminus by the fusing of the fifth ORF with the TPO coding sequence. This novel TPO mRNA is efficiently translated, resulting in supraphysiologic levels of hormone production and nonclonal expansion of thrombopoiesis ([163], [164]). In another mutant TPO allele, the deletion of a single nucleotide within the seventh ORF leads to its fusion with the TPO coding sequence and to now-enhanced translation of TPO from the seventh ATG codon ([165]). Finally, another mutation within the seventh ORF leads to its premature termination, preventing its interference with translation initiation from the usual eighth initiation codon ([166]) and again enhancing TPO production. These diseases of mRNA translation were recently summarized ([167]). The induction of acute immune-mediated thrombocytopenia results in a relatively rapid restoration of platelet levels followed by a brief period of rebound thrombocytosis ([114], [168], [169] and [170]). In most experimental and natural cases of thrombocytopenia, plasma concentrations of TPO vary inversely with platelet counts, rising to maximal levels within 24 hours of the onset of profound thrombocytopenia ([171], [172] and [173]). Two models have been

advanced to explain these findings. In the first, TPO production is constitutive, but its consumption (and, hence, the level remaining in the blood to affect megakaryopoiesis) is determined by the mass of mpl receptors (i.e., platelets and megakaryocytes) accessible to the plasma ([174], [175]). In this way, states of thrombocytosis result in increased TPO consumption (by the expanded platelet mass of mpl receptors), reducing megakaryopoiesis. Conversely, thrombocytopenia reduces peripheral blood TPO destruction, resulting in elevated blood levels of the hormone that drive megakaryopoiesis and platelet recovery. This model is based on one advanced for the regulation of macrophage colony-stimulating factor levels by monocyte uptake and destruction ([176]). The weight of current evidence supports an important role for this mechanism in the regulation of TPO production because the level of hepatic and renal TPO mRNA, the two most prominent tissue sources of specific transcripts, do not vary in states of profound thrombocytopenia or thrombocytosis ([173], [177]). Moreover, TPO knock-out mice display a gene dosage effect ([118]); platelet levels in heterozygous mice are intermediate between the wild-type and nullizygous animals, suggesting that active regulation of the remaining TPO locus does not compensate for the reduced level of mRNA derived from the remaining normal allele, at least for this minimal (60% of normal) thrombocytopenic stimulus. An alternative model suggests that TPO expression is a regulated event; very low platelet levels can induce enhanced mRNA production. Evidence for this model of regulation has been slower to develop. However, two studies argue that TPO mRNA levels are modulated in response to thrombocytopenia, at least in the marrow. By using a semiquantitative assay, McCarty and co-workers found increased TPO-specific mRNA in the marrow of mice made thrombocytopenic by both immune and myelosuppressive methods ([177]). These findings were confirmed in more recent studies; TPO was found in marrow stromal cells ([178], [179]), and, using *in situ* hybridization, marrow—but not liver or kidney—TPO mRNA signals were increased in patients with thrombocytopenia ([178]). In addition, a number of platelet proteins have been shown to modulate TPO production from marrow stromal cells [e.g., CD40 ligand, platelet-derived growth factor, fibroblast growth factor, transforming growth factor (TGF)-ß, platelet factor (PF) 4, and thrombospondin ([180], [181])], providing additional mechanisms for the regulation of thrombopoiesis. However, the relative importance of TPO gene regulation in the marrow is presently uncertain. The human TPO gene 5' flanking region lacks a TATA box or a CAAT motif and directs transcription initiation at multiple sites over a 50-nucleotide region ([182]). Reporter gene analysis in a hepatocyte cell line identified an Ets2 transcription factor–binding motif responsible for high-level expression of the gene. The 5' flanking region also includes specificity protein-1–, activator protein-2–, and nuclear factor-?B (NF-?B)–binding sites ([122]), although the contribution of these transcription factors to TPO gene expression, either under steady-state or stimulated conditions, has not yet been studied. In addition to the positive regulators of megakaryopoiesis, several substances have been shown to down-modulate megakaryocyte development. TGF-ß is a family of five isoforms, all disulfide-linked homodimers each containing 112 residues ([183]). TGF-ß $_1$ is the predominant type of TGF found in hematopoietic tissues; platelet a-granules are a particularly rich source of the cytokine. TGFs are, in general, inhibitors of hematopoiesis, particularly of megakaryocyte development ([184], [185], [186], [187] and [188]). The two best understood TGF-ß growth inhibitory effects are exerted on cell cycle progression. After binding to one of five TGF receptors, two pathways that block cell cycle progression are activated: pRb is hypophosphorylated ([189]), antagonizing the effects of G $_1$-phase cyclin-dependent kinases ([190]), and the cell cycle inhibitor p27 is up-regulated, again halting cell cycle progression at the level of S phase ([191]). It should be noted that TGF-ß is not inhibitory only for megakaryopoiesis; rather, the cytokine appears to reduce hematopoiesis at many levels ([192], [193] and [194]). In contrast to these effects of TGF-ß on cell proliferation, recent evidence has been presented that the cytokine might enhance megakaryocyte differentiation by enhancing expression of the cell cycle inhibitor p15 ^{Ink} ([195]), an effect that may be due to autocrine production of the cytokine. Additional platelet granule proteins found to inhibit megakaryocyte development include the chemokine PF4 ([196]) and ß-thromboglobulin ([197]). Whether these cytokines constitute a negative feedback regulatory system (i.e., high platelet counts lead to enhanced TGF-ß, ß-thromboglobulin, and PF4 release, resulting in inhibition of megakaryocyte development) is uncertain at present. Finally, interferon (IFN)-a inhibits megakaryopoiesis, and its use leads to modest to severe throm-bocytopenia in a significant number of patients undergoing therapy for chronic hepatitis ([198], [199]). The mechanisms responsible for the inhibitory effect of IFN-a are several. Some studies suggest a direct inhibitory effect of IFN-a on growth factor–induced proliferation pathways. For example, the cytokine augments double-stranded RNA–activated protein kinase activity, inhibiting translation initiation factor-2 and implicating reduction of the growth factor–induced protein synthesis necessary for cytokine response ([200]). Other investigators have reported that the functionally similar cytokine IFN-ß induces expression of the cell cycle inhibitor p27 ^{kip1}, arresting cells in G $_0$/G $_1$ ([201]). More recently, Wang and colleagues demonstrated that IFN-a induces a suppressor of cytokine signaling-1–based feedback mechanism that cross-reacts and depresses TPO signaling ([202]) (see the section Molecular Mechanisms That Translate Cytokine Signaling into Megakaryocyte Survival, Proliferation, and Differentiation). Thus, in addition to the multiple positive mediators of megakaryopoiesis, several cytokines block the process and can lead to thrombocytopenia.

COMPONENTS OF THE HEMATOPOIETIC MICROENVIRONMENT It has been estimated that the cellular concentration within the marrow is 10 ^{9} per ml; as such, cell–cell and cell–matrix interactions are certain to occur ([203]). Marrow stromal cells influence hematopoiesis in a number of ways. Marrow cells produce several cytokines that positively or negatively affect megakaryocyte growth ([179], [204], [205], [206], [207] and [208]) and some that are expressed on their cell surfaces ([68], [205]). Stromal cells are the origin of a number of extracellular matrix proteins and glycomucins that either directly affect hematopoietic cells or do so indirectly by binding growth factors and presenting them in a functional context ([209], [210]). They also bear ligands for Notch proteins, cell-surface receptors conserved from *Drosophila* to human, which are critical mediators of cell fate decisions ([211], [212]). Recent evidence has established important roles for Notch and its ligands Delta and Jagged as mitogenic regulators of primitive and mature hematopoietic progenitor cells ([213], [214] and [215]). Cell–cell interactions mediated by integrins present on hematopoietic cells and their counter-receptors on stromal cells are also very important for hematopoiesis ([216]); in addition to bringing hematopoietic cells into close proximity to cells producing soluble or cell-bound cytokines and, hence, raising the local concentration of these growth-promoting proteins, integrin engagement leads to intracellular signaling, usually promoting entry into the cell cycle and the prevention of PCD.

MOLECULAR MECHANISMS THAT TRANSLATE CYTOKINE SIGNALING INTO MEGAKARYOCYTE SURVIVAL, PROLIFERATION, AND DIFFERENTIATION Although each of the cytokines and cell-surface proteins that affect megakaryocyte growth and development use entirely distinct receptors, a remarkable overlap of biochemical consequences of receptor engagement has been identified in studies of cytokine signaling. As such, the molecular events triggered by cytokine action are discussed in general, with those that affect specific aspects of megakaryocyte development expanded on in the sections below. Several lines of evidence indicate that tyrosine phosphorylation is vital for cellular responses to hematopoietic growth factors ([217], [218] and [219]). Nevertheless, the receptors for most hematopoietic cytokines that affect megakaryocytes, including IL-3, IL-6, IL-11, LIF, and TPO, do not display any enzymatic activity. Instead, receptors of this class recruit cytoplasmic Janus kinase (JAK) family tyrosine kinases to a short motif (termed *box1*) adjacent to the transmembrane domain of the receptor ([220], [221]). Once the receptor is bound by ligand, a conformational change brings the tethered JAK kinases into close juxtaposition ([222]), resulting in their transphosphorylation (Fig. 19.1). Four JAK kinases have been identified in hematopoietic cells: JAK1, JAK2, JAK3, and TYK2 ([220]). Of the cytokines that affect megakaryopoiesis, IL-3 activates JAK2 ([223]); IL-6, IL-11, and LIF activate JAK1, JAK2, and TYK2 (although JAK1 is most important) ([224]); and TPO leads to JAK2 and TYK2 phosphorylation ([225], [226] and [227]) (although JAK2 is most important) ([228]). Moreover, even members of the receptor tyrosine kinase family that affect megakaryopoiesis, such as KL or FL, activate JAK kinases ([229], [230]).

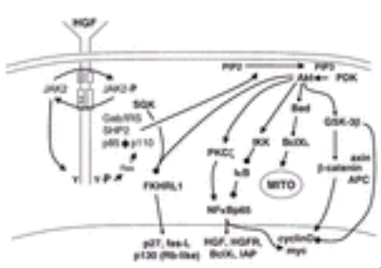

Figure 19.1. A model of growth factor–induced stimulation of cell cycling and cell survival. On binding to its cognate receptor, hematopoietic growth factor (HGF) induces a conformational change in a preexisting dimeric receptor. Such a change brings the cytoplasmic domains of the two receptors into close juxtaposition, allowing interaction of two Janus kinase (JAK) molecules normally tethered to the box 1 (and possibly) box 2 regions of the receptor. This event leads to mutual cross-tyrosine phosphorylation (indicated by -P), kinase activation, and subsequent phosphorylation of tyrosine (Y) residues in the cytoplasmic domain of the receptor. In this particular example, additional substrates for the activated JAK kinase include adapter proteins of the Gab and IRS families, the phosphatase SHP2, and the regulatory subunit (p85) of phosphoinositol 3-kinase (PI3K). Once this multimolecular complex forms, it recruits and activates the kinase domain of PI3K (p110), which then phosphorylates membrane-bound phosphoinositol 4,5 phosphate (PIP2) to form PI 3,4,5 phosphate (PIP3). Proteins containing pleckstrin homology domains including phosphoinositide-dependent kinase (PDK) and the serine/threonine kinase Akt (also termed *protein kinase B*) are then recruited to cell membranes bearing PIP3, thereby allowing PDK to phosphorylate Akt and activate it. The substrates of Akt include (a) Bad, inactivating the proapoptotic molecule [which would otherwise act to sequester and inactivate the mitochondrial (MITO) membrane antiapo-ptotic molecule BclX $_L$]; (b) glycogen synthase kinase (GSK)-3ß, which with axin and the product of the adenomatosis polyposis coli (APC) gene product, inhibits the nascent transcription factor ß-catenin; (c) inhibitor of ?B kinase (IKK), thereby activating it to phosphorylate inhibitor of ?B (I?B), thereby inactivating it, removing it from nuclear factor-?B (NF-?B), and allowing the latter to translocate to the nucleus and act as a transcription factor for prosurvival [inhibitor of apoptosis (IAP), BclX $_L$, and other HGFs and hematopoietic growth factor receptors (HGFRs)]; (d) protein kinase C (PKC) ?, which also helps to activate NF-?B; and (e) the forkhead transcription factor FKHRL1, inactivating it, which would otherwise stimulate transcription of cell cycle inhibitors such as p27 and the proapoptotic fas-ligand (fas-L). The serum and glucocorticoid responsive kinase (SGK) also helps to inactivate forkhead transcription factors, although the mechanism of its activation by growth factors is not certain. The activating (with respect to cell cycling and survival) events are depicted as solid arrows; the inhibitory actions as lines ending in solid circles.

Phosphorylation of JAKs leads to their activation, which, in turn, leads to phosphorylation of a number of substrates, including the receptors themselves and reversibly

tethered signaling molecules. One of the best studied families of secondary signaling molecules is the signal transducers and activators of transcription (STATs); these latent transcription factors dock at P-Tyr residues of cytokine receptors and are phosphorylated by JAKs, and, once so modified, P-STATs dimerize, translocate to the nucleus, and bind to specific genetic elements altering transcription. Both P-Tyr and P-Ser modifications are required to fully activate STATs ([231] and [232]). Of the cytokines affecting megakaryocyte development, IL-3 and GM-CSF activate STAT5 ([233]); IL-6, IL-11, and LIF activate STAT3 ([234], [235]); and TPO activates both STAT3 and STAT5 ([236], [237], [238] and [239]). Among the known targets of the STATs known to play an important role in cell survival and proliferation are BclX $_L$ and *c-myc* ([240], [241], [242] and [243]), with STAT1 displaying generally inhibitory effects on cell cycling and STAT3 and STAT5 displaying the opposite ([244]). Receptor P-Tyr motifs recruit additional signaling intermediates via SRC homology 2 domains, including the p85 regulatory subunit of phosphoino-sitol (PI) 3-kinase (PI3K), the guanine nucleotide exchange factor Vav, adapter proteins such as Shc and the Gabs, and the phosphatase SHP2, which, once modified by phosphorylation or docking-induced conformational change, induce activation of additional signaling pathways. The recruitment of pleckstrin homology (PH) domain–containing proteins to the inner cell membrane activates many signaling pathways and brings others into close juxtaposition to their substrates or activators, helping to orchestrate many of the biochemical responses to hematopoietic growth factors. PH domain–containing proteins dock to PI 4,5 phosphate (PIP2) and PI 3,4,5 phosphate (PIP3), which are generated in cell membranes by PI3K, a heterodimeric lipid kinase composed of a 110-kd kinase (p110) and an 85-kd (p85) regulatory subunit (Fig. 19.1). PI3K activity is initiated by the engagement of the two SRC homology 2 domains of p85, either by a phosphorylated cytokine receptor [usually in the context of YXXM or YVAC ([245], [246] and [247])] or an adapter molecule ([248], [249], [250], [251] and [252]), resulting in conformational changes allowing its recruitment and activation of p110 ([253]). Once engaged by membrane-bound receptor or adapter molecule, p110 is brought into proximity of its membrane lipid substrates and its coactivator, membrane-bound activated ras ([254]). The levels of membrane PI phosphorylation are also under negative regulation by the phosphatases SRC homology 2–containing inositol phosphatase ([255], [256] and [257]) and PTEN ([258], [259]). PI3K is activated in response to several cyto-kines that affect thrombopoiesis, including IL-3, GM-CSF, KL, IL-6, and TPO ([230], [251], [252], [260], [261], [262], [263], [264] and [265]), the blockade of which, in primary megakaryocytes, leads to reduced cell survival and DNA synthesis ([266]). Of the many proteins activated by PI3K, the Ser/Thr kinase Akt and its activating kinase phosphoinositide-dependent kinase (PDK)-1 ([267]) have received the most attention. PDK1 activity toward a specific substrate is dictated by the target protein conformation and by its juxtaposition to substrate. PDK1 contains a PH domain and is thus recruited to the cell membrane on PI3K-induced formation of PIP3, bringing PDK substrates with it ([268]). Once membrane PI phosphates engage the PH domain of a PDK1 substrate (e.g., Akt), a conformational change exposes a phosphorylation site, allowing its phosphorylation and activation by PDK1 ([263]). Additional substrates for this type of conformational change requirement are protein kinase C ? and p70S6K [which also requires mitogen-activated protein kinase (MAPK) phosphorylation of an autoinhibitory region]. Once Akt is phosphorylated by PDK1, then it likely autophosphorylates on Ser ^{473} (an activity previously attributed to a putative “PDK2”), leading to full activation of the kinase ([269]). Perhaps the best known function of Akt is to phosphorylate the proapoptotic protein Bad, resulting in its binding to protein 14-3-3 and destruction, removing its inhibitory effect on Bcl-X $_L$ (Fig. 19.1) ([270], [271] and [272]). However, other studies indicate that the phosphorylation of Bad does not always correlate with the prevention of PCD ([273], [274]), leading one to consider other Akt-mediated antiapoptotic pathways. Akt also affects the activity or abundance of a number of transcription factors linked to cell survival and cell cycling. One such pathway is the lymphocyte enhancer factor-1/ternary complex factor, initially identified downstream of Wnt, an evolutionary conserved signaling molecule involved in processes as diverse as segmentation, control of asymmetric cell divisions, and hematopoietic expansion ([275], [276]). In response to cytokine receptor signaling, Akt phosphorylates and thereby inactivates glycogen synthase kinase-3ß, which, if active, phosphorylates ß-catenin, leading to its proteasomal destruction ([277], [278]) (Fig. 19.1). The net effect of Akt activation is the accumulation of free ß-catenin, which translocates to the nucleus converting lymphocyte enhancer factor-1/ternary complex factor from a transcriptional repressor to an activator ([279], [280]). Among the known genetic targets of the ß-catenin/lymphocyte enhancer factor-1/ternary complex factor complex that mediate cell proliferation are *cyclin D*, *p27*, and *c-myc* ([281], [282] and [283]). Glycogen synthase kinase-3ß also has a second, more direct negative effect on the cell cycle: phosphorylating cyclin D1, forcing its association with the nuclear exportin CRM1, and leading to its destruction in the cytoplasm ([284]); Akt-mediated reduction in glycogen synthase kinase-3ß activity thus also enhances nuclear cyclin D levels, driving cell cycling. Another indirect Akt target is NF-?B, a family of dimeric transcription factors sequestered at baseline in the cytoplasm by inhibitor of ?B (I?B) proteins but released to the nucleus on ubiquitin-mediated destruction of the latter. The vital antiapoptotic targets of NF-?B are caspase inhibitors ([285], [286] and [287]) and members of the bcl family ([288], [289] and [290]). Akt activates I? B kinase (I?Ka), leading to I?B phosphorylation and destruction (Fig. 19.1). In addition, Akt activates ets2 ([291]), which induces transcription of *NF-? B* genes ([292]). The net effect is to increase nuclear NF-?B, leading to survival of hematopoietic cells ([293]). In addition, a number of stimulatory effects of NF-?B on the cell cycle have been identified, including transcription of *cyclin D* and *c-myc* ([294], [295], [296], [297], [298] and [299]). MAPKs are approximately 40-kd Ser/Thr kinases that are highly conserved in all eukaryotic cells from yeast to humans and play a major role in nearly every type of cell. At least six signaling cascades classified as MAPK pathways have been identified ([300], [301]) and have been found to mediate cell proliferation, survival, apoptosis, or differentiation. For instance, MAPK induces proliferation in NIH3T3 cells and differentiation in PC12 cells. At present, three classes of MAPKs have been identified in megakaryocytes: *e*xtracellular stimulus *r*esponse *k*inase (ERK) 1 and ERK2 (also termed *p44* and *p42*, respectively); c-jun *N*-terminal kinase; and p38 kinase ([302], [303] and [304]). Most receptors that activate MAPKs do so by activating ras. For the hematopoietic cytokine receptors, the adapter molecule Shc is recruited to the tyrosine-phosphorylated receptor cytoplasmic domain, which is then phosphorylated by JAK. P-Shc then recruits the adapter protein Grb2, which activates the guanine nucleotide exchange factor SOS, which then charges ras with guanosine triphosphate (GTP), thereby activating it. Active ras, in turn, leads to the activation of a MAPK kinase kinase, such as Raf-1, which phosphorylates a MAPK kinase, such as MEK1, which then phosphorylates a MAPK, such as ERK1 and ERK2. Because cells contain numerous MAPK kinase kinases and MAPK kinases, the potential for cross-talk between different MAPK pathways is large; this potential is reduced considerably through scaffolding proteins that sequester only the corresponding MAPK kinase kinase, MAPK kinase, and MAPK ([305], [306]). Virtually every cytokine affecting megakaryocytes activates ERK1 and ERK2 ([230], [261], [307], [308] and [309]). Alternate pathways to MAPK activation have also been described in platelets ([310]), and integrin engagement in fibroblasts affects the cellular localization of ERK1/2, exerting a profound effect on its capacity to signal ([311]). Blockade of ERK1 and ERK2 has been shown to reduce cell proliferation in c-mpl receptor–bearing cell lines and both cell proliferation and the generation of highly polyploid cells in megakaryocytic progenitors ([312]) but, curiously, to enhance proliferation of more primitive megakaryocytic progenitors from cord blood ([313]). The molecular targets of active MAPKs in megakaryocyte progenitors that mediate the effect of ERK1 and ERK2 on cell survival, proliferation, and differentiation are presently a topic of intense research; most studies in other cell systems suggest that ERK affects nuclear transcription factors, such as Elk-1 ([314], [315]), which then modulate activity of the cell cycle machinery. For example, stimulation of ERK1 and ERK2 leads to increased levels of cyclin D in fibroblasts ([316]), forced overexpression of cyclin D1 increases megakaryocyte polyploidy ([317]), and blockade of cyclin D3 in megakaryocytes reduces endomitosis ([318]). MAPKs also act on additional kinases; for example, the serum- and glucocorticoid-responsive kinase is also activated in a MAPK-dependent fashion in response to growth factors ([319]). Finally, although TPO activates JNK and p38 in mpl-bearing cells, primary megakaryocytes, and platelets ([320], [321]), less is known of their effects on megakaryocyte development. The development of blood cells is dependent on both soluble cytokines and the hematopoietic microenvironment; interaction between hematopoietic cells and their surroundings is dependent on cell-surface ß $_1$ integrins. Numerous cytokines have been shown to affect integrin affinity ([322], [323], [324], [325], [326], [327], [328] and [329]). Recent studies have elucidated at least one of the pathways initiated by cyto-kine binding that affects hematopoietic ß $_1$ integrins. On ligand binding, cytokine receptors trigger JAK and STAT activation; one target of the former is the adapter protein CrkL ([330], [331] and [332]). One of the targets of CrkL is C3G, a guanine nucleotide exchange factor that activates Rap1, a small G protein known to enhance cell adhesion through ß $_1$ integrins ([333]). As should be clear from the previous discussion, the megakaryocyte and probably all hematopoietic cells use multiple molecular pathways to effect cell survival and proliferation and, although not as well understood, probably also display this seemingly redundant approach to support cellular differentiation. Recent work with the TPO receptor has helped to clarify the nature and teleology behind this seeming redundancy. Phosphorylation of the penultimate tyrosine residue in the cytoplasmic domain of c-Mpl leads to Shc, STAT3, and STAT5 activation ([154], [239]). Moreover, MAPK activation is also thought to emanate from the distal half of the receptor ([309]). Nevertheless, a truncated form of c-Mpl bearing neither of these regions continues to activate STAT5, MAPK, and PI3K in a TPO-dependent manner ([239]), and introduction of a similarly truncated receptor into the germ line in place of the full-length receptor affords the resultant mice a normal steady-state platelet count throughout life ([334]). However, these mice do not respond properly to stress; compared to normal mice, platelet recovery after immune-mediated or chemotherapy-induced thrombocytopenia is substantially delayed. Thus, the seeming redundancy in cytokine signaling appears to reflect a capacity of the cell to grade the TPO response into steady-state and emergency thrombopoiesis. A similar conclusion regarding signaling via STAT5 in erythropoiesis has been presented ([242]). The signaling cascades initiated by IL-3, IL-6, IL-11, and TPO are of limited duration. Multiple mechanisms exist to govern this process. One such mechanism depends on dephosphorylation of cytokine receptors. For example, after IL-3–induced receptor phosphorylation, hematopoietic cell phosphatase (also termed *SHPTP1* or *SHP1*) binds to the ß $_C$ subunit and dephosphorylates the IL-3 receptor. Overexpression of the phosphatase is associated with diminished IL-3–induced proliferation ([335]), strongly suggesting that this mechanism serves to limit ligand-induced signaling. A similar mechanism has been shown to limit EPO-induced signaling; genetic elimination of the region of phosphatase binding leads to congenital erythrocytosis ([336]). Another mechanism of feedback inhibition of cytokine receptor signaling is mediated by the suppressor of cytokine signaling (SOCS) proteins ([337]). At present, five members of this STAT-induced family of signaling proteins have been found to inhibit signaling, either by directly blocking JAK kinase function or by competing for binding to phosphotyrosine receptor–signaling sites with secondary signaling mediators. Hence, when a cytokine such as IL-3, IFN, or TPO induces STAT activation, it activates a delayed mechanism that shuts down signaling. This mechanism can also account for receptor cross-talk (i.e., the ability of one cytokine signal to negatively impact another) ([201], [338]).

Megakaryocyte Cellular Development

HEMATOPOIETIC STEM AND COMMON MYELOID PROGENITOR CELLS The HSC is capable of giving rise to all blood cell lineages. Operationally, the cell is recognized retrospectively by its ability to repopulate all aspects of hematopoiesis after transplantation into myeloablated recipients. Although morphologically indistinguishable from small lymphocytes, hematopoietic stem and primitive progenitor cells express several cell-surface proteins that distinguish them from nonhematopoietic and more mature hematopoietic cells. As thrombopoiesis begins with the HSC, the following section on megakaryocyte development also includes a brief discussion of this cell with an emphasis on those aspects most important for platelet production. Numerous investigators have used monoclonal antibodies to hematopoietic cell-surface proteins to negatively or positively (or both) enrich bone marrow and blood for stem and primitive progenitor cells. However, the function of only a few of the stem cell-surface proteins recognized by these antibodies is known. Others have taken advantage of the capacity of primitive hematopoietic cells to extrude fluorescent organic chemicals or of their buoyant density to obtain purified populations of these scarce marrow cells; most successful stem cell purification strategies use two or three such techniques. The antigenic proteins and glycoproteins (gps) exclusively or predominantly present on mammalian stem cells include (a) CD34, a 90- to 110-kd type I gp that has been postulated to mediate cell adhesion, cell cycle arrest, or both ([19], [339], [340]); (b) Thy1, also termed *CD90* ([341], [342]), a heavily glycosylated glycophosphoinositol-linked protein that participates in T-cell adhesion to stromal cells ([343]), the cross-linking of which affects T-cell proliferation and survival ([344], [345]), although it is uncertain if this also occurs in HSCs; (c) the c-kit receptor, also termed *CD117* ([346]), which supports primitive hematopoietic cell survival and proliferation; (d) murine AA4 ([20]), a molecule homologous to the human phagocyte C1q complement receptor ([347]); (e) murine Sca1 ([341]), the cross-linking of which coactivates T cells in the presence of other mitogens (but there is no evidence that this occurs with HSCs); (f) AC133 ([348]), a protein of unknown function ([349]); (g) CD164 ([350]), a cell-surface sialomucin that is present in several alternately spliced isoforms, which is possibly involved in blood cell homing, trafficking, and recirculation ([351]); and (h) the TPO receptor c-Mpl ([130], [352]), which is in many ways the most unexpected stem cell-surface molecule because TPO was postulated to be a lineage-specific growth and differentiation factor. Nevertheless, several groups have shown that (a) TPO affects the survival and proliferation of purified HSCs *in vitro* ([152], [153]), (b) essentially all of the repopulating capacity of murine marrow resides in the mpl $^{+}$ fraction of cells ([155]), and (c) genetic elimination of c-mpl leads to an 85% reduction in the number of repopulating stem cells in mice ([155]) and to aplastic anemia in humans ([150], [151]). Many or most of the surface membrane proteins found on HSCs are also present on cells that have begun to differentiate toward specific lineages, but also present on the latter cells—but not on stem cells—are CD38 and HLA-DR and other markers of lineage-specific maturation, including CD3, CD4, CD5 or CD8 (T cells), CD11b, CD14 or Gr-1 (macrophages and granulocytes), CD10, CD19, CD20 or B220 (B cells), and glycophorin A or Ter119 (erythroid), allowing separation of stem and more mature cells from marrow cells. Because stem cells have active small molecule exporters, manifest clinically as the multidrug resistance phenotype, they actively eliminate many fluorescent molecules such as rhodamine 123 or Hoechst 33342 dyes, allowing selection of stem cells based on the lowest retention of these substances ([21], [353], [354], [355] and [356]). Recent studies have clearly indicated the existence of distinct progenitor cells committed to either the lymphoid lineage [the common lymphoid progenitor is Lin $^{-}$/IL-7R $^{+}$/Thy1 $^{-}$/Sca-1 ^{low}/c-kit ^{low} ([23])] or the myeloid lineage [the common myeloid progenitor (CMP) is IL-7Ra $^{-}$/Lin $^{-}$/c-kit $^{+}$/Sca-1 $^{-}$ ([22])]. One of the primary goals of modern physiology is to provide a molecular understanding of the gene or sets of genes required to orchestrate specific developmental events. Fundamental to this process is an understanding of the proteins present in cells that regulate gene transcription in a lineage-, ontogenic stage–, and maturation phase–specific manner. Several transcription factors have been identified in stem cell populations or have been shown to affect stem cell differentiation into the lymphoid and myeloid lineages. Members of the Hox family of transcription factors likely serve as master regulators of hematopoietic cell fate decisions, based on (a) a similar role in multiple organ systems ([357]); (b) their lineage- and differentiation-stage–specific expression pattern in hematopoietic cells ([358], [359] and [360]); (c) the disruption of their usual level or pattern of expression leads to hematologic expansion or malignancies ([361], [362]); and (d) their elimination ([363], [364] and [365]), or elimination of the gene(s) that regulate them ([366], [367]), leads to hematopoietic defects. In addition, members of the extradenticle family of homeodomain-containing proteins have been found to serve as cofactors for Hox proteins, altering their DNA-binding affinities and specificities. Like Hox genes, genetic elimination of some of these cofactor proteins can lead to HSC defects; for example, *Pbx1* null mice display a prominent defect in the generation of CMPs from HSCs ([368]). The *Ikaros* gene encodes a family of lymphoid-restricted zinc-finger transcription factors related to the *Drosophila hunchback* gene ([369]). All isoforms of Ikaros contain an identical *C*-terminal activation domain and two zinc-finger dimerization domains. However, only isoforms 1 to 3 of the six known alternately spliced forms contain at least three of the four *N*-terminal zinc fingers required for DNA to bind to the consensus DNA core motif GGGA ([370]). The PU.1 gene is one of approximately 30 members of the Ets family of transcription factors ([369]) that binds to the purine-rich PU box sequence (5'-GGAA-3'). Genetic inactivation studies of the *Ikaros* and *PU.1* genes have shown that their encoded transcription factors are involved in commitment to the lymphoid lineage; fetal stem cells in *Ikaros* -/- mice do not generate any definitive T- or B-lymphocyte precursors ([371]). However, stem cells can give rise to thymocyte precursors postnatally, but cells that undergo aberrant differentiation into the CD4 lineage and all natural killer cells, most thymic dendritic cells, and some ?dT-cell subsets do not develop in adult mice. Thus, *Ikaros* is essential for all of lymphopoiesis early during ontogeny and for several subsets later in life. In a similar fashion, *PU.1*-deficient mice also lack any definitive T- and B-cell precursors in their lymphoid organs at birth ([372], [373]). However, knock-out mice maintained on antibiotics survived the first 48 hours of life and began to develop normal-appearing T cells 3 to 5 days later. In contrast, mature B cells and macro-phages remained undetectable in these older mice, indicating absolute tissue dependence for this lineage. Transcription factors that may be responsible for myeloid commitment include SCL (stem cell leukemia) and GATA-2. The *SCL* gene was first identified at the site of chromosomal rearrangement in a patient with stem cell leukemia and encodes a helix-loop-helix transcription factor that pairs with one of two nuclear partners: LMO1 or LMO2 ([374]). The protein is present in HSCs, CMPs, and CFU-EMK progenitors ([22]). Previous studies have shown that SCL is down-regulated in differentiating granulocytic and monocytic progenitor cells ([375], [376] and [377]) and that forced expression of the gene in three hematopoietic cell lines inhibits cytokine-induced granulocytic and monocytic differentiation ([377], [378] and [379]). Together, these results suggest that down-modulation of *SCL* expression is required for HSC differentiation. Moreover, KL has been shown to sustain *SCL* expression in primary CD34 $^{+}$ cells, maintaining them in an undifferentiated state, whereas GM-CSF down-regulates SCL levels and favors granulocyte and monocyte differentiation ([380]). These studies provide further insights into the vital question of the permissive versus directive role of growth factors in hematopoiesis. The GATA family of transcription factors contains six members that have a highly related DNA-binding domain composed of two evolutionarily conserved zinc fingers ([381]). GATA-1 and GATA-2 are present in hematopoietic cells; GATA-2 is found in the same cells as SCL, with GATA-1 expression restricted to the latter stages of hematopoietic differentiation. Because genetic elimination of GATA-2 is lethal due to numerous nonhematopoietic defects, and lineage-specific knock-outs have not yet been engineered, the role of GATA-2 in early hematopoiesis is not yet certain. However, like *SCL*, it appears that elimination of *GATA-2* expression is required for hematopoietic cell maturation because its forced expression in primitive cells blocks both their amplification and differentiation ([382]). As noted above, numerous lines of evidence indicate that HSCs express the c-Mpl receptor; this is most convincingly demonstrated by the ability to sort all repopulating stem cells into the mpl $^{+}$ fraction of AA4 $^{+}$/Sca $^{+}$ cells ([155]). Several investigators have also shown that the 5' flanking region of the *c-mpl* gene contains a GATA site, that deletion of this site reduces expression of an mpl-reporter construct, and that GATA-1 transactivates the gene in two hematopoietic cell lines ([383], [384]). However, GATA-1 is not likely to be responsible for expression of *c-mpl* in stem cells because the transcription factor does not appear in hematopoietic cells until they have become DR $^{+}$—an event that occurs after the cells lose their repopulating capacity ([385]). Instead, it is possible that GATA-2 fulfills this role in stem cells, although there is no evidence yet available establishing that this protein can transactivate the mpl GATA site, which is an important caveat because not all genes regulated by GATA-1 can be activated by GATA-2 ([386]). It is thus also possible that other regulatory elements drive *c-mpl* expression in stem cells. Along these lines, it has been shown that an ets site is also present in the proximal regulatory region of the *c-mpl* gene, that its alteration reduces expression of a linked reporter gene, and that forced expression of the two ets proteins Ets-1 and Fli-1 leads to enhanced *c-mpl* promoter activity in human erythroleukemia (HEL) line cells ([383]). The regulation of stem cell survival, proliferation, and differentiation has been difficult to address due to their rarity and the requirement that they be assessed retrospectively using cumbersome transplantation assays. Nevertheless, it is clear that several cytokines exert important effects on HSCs. The pursuit of the cytokines that affect HSCs is of more than pure physiologic interest, as the availability of the right combination of such proteins could allow expansion of the cells for therapeutic use without sacrificing their pluripotent and self-renewal capacities. Three proteins, KL, FL, and TPO, exert important effects on the number and growth of HSCs both *in vitro* and *in vivo*. The importance of KL to hematopoiesis is easily demonstrated; although nullizygous mice (*Sl*/ *Sl*) are embryonic lethal due to a number of developmental defects, the presence of a partially functional allele (Sl^{d}) allows compound heterozygotes (*Sl*/Sl^{d}) to survive gestation. However, the resultant mice are severely anemic ([387]) because of diminished numbers of primitive and lineage-committed hematopoietic progenitors in the marrow and spleen ([388], [389]), best demonstrated by the diminished capacity of marrow cells from mice deficient in *KL* or of the gene for the corresponding *c-kit* receptor to compete with wild-type cells in competitive repopulation transplantation assays ([390], [391]). In addition to its critical role in hematopoietic ontogeny, treatment of adult mice with a neutralizing c-kit receptor monoclonal antibody also results in severe pancytopenia ([392]), indicating an important hematopoietic role for the receptor-ligand pair throughout life. By itself, KL is only a weak stimulator of hematopoiesis, primarily inducing the development of mast cells both *in vitro* and *in vivo*. However, in the presence of IL-3, IL-6, IL-11, granulocyte colony-stimulating factor, or TPO, KL exerts profound effects on the generation of hematopoietic progenitor cells of all lineages ([151], [152], [393], [394], [395] and [396]), pointing to primitive hematopoietic cells as critical targets. The molecular mechanisms of such synergy are beginning to emerge. Recently, a physical association of the c-kit and EPO receptors has been detected after KL stimulation of cells bearing both receptors, an event that is essential for their functional synergy ([397], [398]). However, despite much progress in understanding the basis for the effects of KL on hematopoietic progenitor cells, the physiologic role of KL on HSC survival and expansion has been more difficult to document. For example, although KL can expand CFU-S manyfold ([399]) and support the survival of highly enriched populations of stem cells ([400]), other factors produced by marrow

stromal cells can support HSC survival when KL function is eliminated ([401]). Flt ligand was cloned as the binding partner for a recently identified novel orphan receptor ([70]), a protein closely related to the receptor for M-CSF (termed *c-fms*) (hence, the term *flt* stands for *f*ms *l*ike *t*yrosine kinase). FL was initially derived from T cells ([49] , [70]); subsequent studies indicate that the cyto-kine is also produced by marrow stromal cells ([178] , [402]). Blood levels of FL are approximately 15 pg/ml in normal animals and humans, levels of which can rise to 2500 pg/ml in response to pancytopenia ([403]). Interestingly, only pancytopenia, as seen in patients with Fanconi anemia or acquired aplastic anemia, and not individual lineage deficiencies causes an increase in blood FL concentrations, suggesting that the cytokine is a bona fide regulator of stem or primitive hematopoietic cells. Consistent with this hypothesis is competitive repopulation data indicating that stem cells from flt3/flk2 receptor–deficient mice do not effectively reconstitute the hematopoietic system ([404]). Like KL, FL appears to act on hematopoietic cells only in synergy with other hematopoietic cytokines or hormones ([405] , [406]). Administration of the recombinant protein to animals and humans results in a modest rise in lymphocyte levels, a moderate increase in neutrophils, and a marked increase in monocytes, natural killer cells, and dendritic cells ([407] , [408]). In particular, these antigen-presenting cells seem particularly dependent on FL, as the combination of FL and TGF-ß $_1$ can generate dendritic cells from CD34-selected marrow cells in serum-free culture ([409]). However, it is in combination with TPO that the FL effects on stem cells have been most dramatic; long-term culture-initiating cells, a surrogate marker for the HSC, were reported to expand 10^5-fold from cord blood $CD34^+$ cells cultured for 20 weeks in the presence of FL and TPO ([410]). Multiple lines of evidence indicate that TPO can exert profound effects on the HSC. TPO has been shown to support the survival of candidate HSC populations and acts in synergy with IL-3 and KL to induce these cells into the cell cycle and increase their output of both primitive and committed hematopoietic progenitor cells of all lineages ([151] , [152] , [411]). Moreover, these *in vitro* effects are reflective of *in vivo* events; administration of TPO to myelosuppressed animals leads to more rapid recovery of all hematopoietic lineages, including primitive cells ([131] , [135] , [139] , [412] , [413]), and genetic elimination of TPO or its receptor is associated with reduction of the numbers of marrow hematopoietic stem and progenitor cells of all lineages to 15 to 25% of normal values ([154] , [414] , [415]). In addition, as noted above, TPO acts in synergy with FL to expand primitive hematopoietic cells in suspension culture and, more recently, when used to supplement long-term marrow cultures, the hormone was found to maintain hematopoietic repopulating stem cells for up to 2 months without loss ([416]), compared to standard long-term cultures in which stem cells are no longer detectable at this time. One of the major advances in experimental hematology has been the capacity to grow hematopoietic cells in long-term culture ([417]). By allowing a stromal cell and extracellular proteinaceous matrix to form over several weeks in the presence of serum, these long-term cultures are capable of supporting hematopoiesis for months when subsequently recharged with fresh marrow cells. It is presumed that the cell–cell and cell–matrix interactions that develop in such cultures more closely resemble those found *in vivo*, helping to explain the longevity of such cultures and their capacity to maintain the numbers of hematopoietic stem and primitive progenitor cells far longer *ex vivo* than do nonstromal-based cultures. The molecular basis for the improved hematopoietic environment of long-term cultures is thought to rely on stromal cell-surface molecules that promote cell–cell contact, prevent PCD, and regulate growth. *Integrins* are a family of heterodimeric single-pass transmembrane proteins (19 a and 8 ß subunits form 25 different cell-surface adhesion receptors) characterized by multiple Ig-like extracellular domains that allow two-way communication between a cell and its environment ([215] , [418] , [419]). A large number of cell types require contact for survival; *in vitro*, this is usually manifest as integrin-dependent cell adhesion, either to extracellular matrix protein(s), often through an “RGD” (Arg-Gly-Asp) recognition sequence, or to other cells. In such cultures, disruption of adherence causes a type of apoptosis termed *anoikis*; for example, endothelial cells undergo anoikis on forced detachment *in vitro* due to disruption of multiple integrins ([420] , [421]). Integrins can also influence the proliferation of cells by affecting the G_1 to S phase transition of the cell cycle ([422]). These effects also operate *in vivo*; mice nullizygous for a $_1$ integrin (a component of the $a_1ß_1$ collagen receptor) have a hypoplastic dermis, and the growth of a_1 -/- fibroblasts on collagen is substantially reduced ([423]). Hematopoietic stem and progenitor cells express multiple integrins, including $a_4ß_1$ [also termed *very late antigen* (VLA) 4], which binds to either vascular cell adhesion molecule-1 (VCAM-1) or fibronectin, and $a_5ß_1$ (VLA5), which binds to distinct regions of fibronectin. The avidity of progenitor cell–integrin interaction can be altered by external effectors; numerous cytokines and chemokines, including KL, IL-1, IL-3, IL-6, GM-CSF, granulocyte colony-stimulating factor, TPO, and stromal cell–derived factor-1, have been shown to enhance integrin-mediated binding ([322] , [323] , [324] , [325] , [326] , [327] , [328] and [329]). Counter-receptors for both integrins, such as VCAM-1 and fibronectin, are highly expressed in the marrow matrix and on marrow stromal cells. It is also clear that integrin-based interactions with the stroma are responsible for homing and retention of stem and primitive progenitor cells in the marrow, as antibodies that interfere with the interaction can mobilize stem and progenitor cells into the peripheral blood ([424]). However, it is not yet certain whether integrins can influence the survival or growth of stem cells or influence their ultimate developmental fate.

ERYTHROID-MEGAKARYOCYTIC PROGENITORS Progenitors for megakaryocytes and erythroid cells display many common features. They share a number of transcription factors [SCL, GATA-1, GATA-2, and nuclear factor-erythroid 2 (NF-E2)], cell-surface molecules (Ter119), and cytokine receptors (for IL-3, KL, EPO, and TPO), and most erythroid and megakaryocytic leukemia cell lines display, or can be induced to display, features of the alternate lineage ([425]). Moreover, the cytokines most responsible for erythropoiesis and megakaryo-poiesis, EPO and TPO, are the two most closely related proteins in the hematopoietic cytokine family ([117] , [118] and [119]) and display synergy in stimulating the growth of progenitors of both lineages ([51] , [133] , [426] , [427]). For these and other reasons, it has been postulated that erythropoiesis and megakaryopoiesis might share a common progenitor cell ([30] , [31])—a hypothesis that is now established ([22] , [428] , [429]). Like other primitive hematopoietic cells, bipotent erythroid/megakaryocytic progenitors resemble small lymphocytes but can be distinguished by a specific pattern of cell-surface protein display. Akashi and co-workers have shown that a population of Lin^-/IL-7Ra $^-$/c-kit $^+$/Sca-1 $^-$ CMP cells can be further fractionated into $CD34^+$/Fc?R $^+$ cells that are committed to the neutrophilic and monocytic lineages and $CD34^-$/Fc?R $^-$ cells that give rise only to erythroid and megakaryocytic cells. Cells committed to the megakaryocyte lineage then begin to express CD41 and CD61 (integrins a_{IIb} and $ß_3$), CD42 (gpIb), and gpV. These and other cell-surface markers provide experimental hematologists several strategies to purify committed megakaryocytic progenitors ([25] , [430]). Another useful method to identify megakaryoblasts, at least in studies of rodent megakaryopoiesis, is histochemical staining for acetylcholinesterase ([431]) and von Willebrand's factor (vWF) ([432] , [433] and [434]). The antigenic profile of megakaryocyte development is illustrated in Table 19.1.

TABLE 19.1. Antigenic Profile of Developing Megakaryocytes

	Hematopoietic Stem Cell	Common Myeloid Progenitor	Colony-Forming Unit Erythroid-Megakaryocyte	Burst-Forming Unit Megakaryocyte	Colony-Forming Unit Megakaryocyte	Megakaryoblast (Stage I)	Megakaryocyte (Stage II/III/IV)	Platelet

The molecular basis by which primitive hematopoietic cells give rise to bipotent erythroid/megakaryocytic progenitors or to bipotent granulocyte/monocyte progenitors is a topic of much investigation, as is the question of how these bipotent cells “select” a lineage. Many investigators believe that the stochastic emergence of one or a small set of lineage-specific transcription factors in a cell determines its developmental fate; thus, the molecular mechanisms that lead to the expression of a $_{IIb}$ integrin (gpIIb or CD41), the platelet fibrinogen receptor, become critical for the lineage and illustrate the concept. The transcription factors expressed during megakaryocyte development are shown in Table 19.2 ([435]).

NOTE: + to +++ indicate relative levels of antigen expression.

In elegant studies using a toxic transgene controlled by its promoter, erythroid and megakaryocytic progenitor cells were shown to express a $_{IIb}$ integrin ([436]). Using mixed erythroid/megakaryocytic cell lines, several *cis*-acting sequences that affect expression of a $_{IIb}$ integrin have been identified and include functionally important binding sites for GATA-1, Ets, and SP1 ([437], [438] and [439]). A very similar profile of *cis*-regulatory elements is found in the promoters for gpIb, gpV, and gpIX, components of the platelet vWF receptor ([440], [441] and [442]). GATA-1 is present in all erythroid and megakaryocytic cells; SP1 is ubiquitous; and the Ets family transcription factor PU.1 is expressed in erythroid and megakaryocytic cell lines and, at least in one mpl-bearing cell line, is responsive to TPO ([443]). GATA-1 is an X-linked gene encoding a 50-kd polypeptide that contains two zinc fingers required for DNA binding ([444]). The importance of GATA-1 for erythroid and megakaryocytic development comes from genetic elimination of the transcription factor; *GATA-1* -/- mice are embryonic lethal due to a failure of erythropoiesis ([445]), and megakaryocyte-specific elimination of GATA-1 leads to severe thrombocytopenia due to dysmegakaryo-poiesis ([446]). GATA-1 acts with another protein that affects transcription without binding to DNA: Friend of GATA (FOG) ([447]). The importance of this interaction to megakaryopoiesis is clear; several different mutations of the site on GATA-1 responsible for FOG binding lead to congenital thrombocytopenia ([448], [449] and [450]). As noted above, the ets family of transcription factors includes approximately 30 members that bind to a purine box sequence, proteins that interact in both positive and antagonistic ways. For example, PU.1, initially termed *Spi-1* based on its association with spleen focus-forming virus-induced erythroleukemias, blocks erythroid differentiation, although it appears important for megakaryocyte development ([443]). An important concept developed in recent years may help to explain how transcription factors contribute to lineage commitment; once a lineage-specific transcription factor level rises, positive feedback loops are activated that consolidate the event. For example, should a multipotent hematopoietic progenitor express CCAAT/enhancer-binding protein ß, it will differentiate along the eosinophilic lineage, with the transcription factor acting to induce eosinophil-specific markers (e.g., major basic protein) and to down-modulate FOG ([451], [452]). This latter event is crucial, as forced expression of FOG dedifferentiates cells committed to the eosinophilic lineage into multipotent progenitors ([453]). A similar paradigm appears to contribute to the erythroid/megakaryocytic versus neutrophilic/monocytic dichotomy; GATA-1 appears to be the integral trigger for the entire erythroid and megakaryocytic developmental program. Like commitment to the eosinophilic lineage, GATA-1 appears to exert a reciprocal feedback inhibition on transcription factors that induce neutrophilic/monocytic differentiation. Once GATA-1 is expressed in stem cell progeny, the EMk differentiation pathway is locked into place as the transcription factor inhibits binding of the primary transcriptional regulator of myeloid differentiation, PU.1, to its myeloid promoter targets ([454]). In contrast, because PU.1 needs to be down-regulated during erythropoiesis ([455]), if this transcription factor first predominates in the multipotent progenitor, then its inhibition of GATA-1 *trans*-activator function on erythroid and megakaryocyte-specific genes ([456]) might commit the cell to the neutrophilic or monocytic lineages. Several investigators have shown that components of the extracellular matrix can affect platelet formation *in vitro* and platelet function *in vivo*. However, despite an impressive array of evidence that integrins can affect cell survival and proliferation in adherent cells, few have tried to extrapolate these conclusions to hematopoietic cells. Although hematopoietic progenitors are not typically thought of as adherent cells, the high cell density in the marrow and the presence of multiple integrins on the surface of hematopoietic cells, including megakaryocytic progenitors ([324], [457], [458], [459] and [460]), argue that integrin engagement might affect thrombopoiesis. In recent studies, the role of integrins a $_4$ß $_1$ and a $_5$ß $_1$ in erythropoiesis has been deciphered ([461]). In a similar fashion, Fox and colleagues have determined that fibronectin engagement of a $_5$ß $_1$ integrin augments megakaryocytic progenitor cell proliferation, whereas binding of a $_4$ß $_1$ reduces it ([462]). These two findings not only open a window on the contribution of the marrow microenvironment to hematopoiesis, but also begin to provide a molecular understanding of commitment in the bipotent EMk lineage. The biochemical mechanisms that might mediate direct integrin signaling have been recently reviewed ([463], [464]).

PROGENITORS COMMITTED TO THE MEGAKARYOCYTIC LINEAGE Megakaryocytic progenitors are CD34 $^+$, c-kit $^+$, mpl $^+$, HLA-DR $^+$, and CD41/61 $^+$. Several cytokines stimulate the proliferation and survival of megakaryocytic progenitor cells, first identified as megakaryocyte colony-stimulating factors. Initial studies of megakaryocyte colony formation used plasma as a source of megakaryocyte colony-stimulating factor. With the cloning of IL-3 in the mid-1980s, the cytokine was shown to stimulate megakaryocyte colony formation ([37], [79]). Likewise, GM-CSF was shown to have similar but less potent effects ([39], [465]). The availability of recombinant KL in the early 1990s revealed that it also stimulated megakaryocyte colony formation when used in conjunction with plasma ([50], [79]). In the 1990s, it was also determined that although incapable of stimulating the growth of megakaryocyte progenitor cells alone, cytokines that function by stimulating the gp130 co-receptor (IL-6, IL-11, LIF) acted in synergy with these other cytokines (IL-3, KL) to augment the number and size of megakaryocyte colonies ([75], [79], [91], [466], [467] and [468]). More recently, TPO has been shown to be a potent megakaryocyte colony-stimulating factor, both alone and in synergy with KL, IL-3, and IL-11 and, surprisingly, in synergy with EPO ([51], [125], [129]). With the exception of IL-3 and GM-CSF, administration of each of these cytokines has also been shown to promote platelet production *in vivo* ([81], [97], [133]). Despite this plethora of cytokines shown to affect megakaryocyte progenitor cells *in vitro* and *in vivo*, genetic elimination of the majority of these molecules does not affect resting or stimulated platelet production; only deficiencies in KL or c-kit [50% reduction ([48]), which may be due to stem cell and not megakaryocyte progenitor cell deficiency] and TPO and c-Mpl [reduction to 10% of normal ([469])] lead to thrombocytopenia. The cause of the remaining thrombopoiesis in *tpo* or *c-mpl* nullizygous mice has been searched for but not yet determined ([48], [110], [470], [471]). In addition to these studies of the growth factors required for the process, important new insights into the transcription factors that drive megakaryopoiesis have been reported. The ets protein Fli-1 is present in megakaryocytic progenitors ([472]) and seems to play a particularly important role in megakaryocyte development. For example, Fli-1 promotes a megakaryocytic developmental program in the mixed erythroid/megakaryocytic cell line K562 ([473]); it drives expression of megakaryocyte-specific genes ([474]); dysmegakaryopoiesis occurs in Fli-1 null embryos ([472]); patients with thrombocytopenia associated with Jacobsen or Paris-Trousseau syndrome have terminal deletions of 11q, the site of *Fli-1* in humans ([475]); and forced expression of Fli-1 in pluripotent human hematopoietic cells leads to megakaryocytic differentiation ([476]) and down-modulation of erythropoiesis via reduction in GATA-1 expression ([477]). Thus, a basic outline of the genetic details for a stem cell to ultimately commit to the megakaryocytic lineage has emerged. Although future work will undoubtedly fill in many details, it appears that the development of CFU-MK requires a pluripotent stem cell to express *SCL* and *GATA-2* and to avoid *Ikaros* allowing (directing) its development into a CMP; then, it must express *GATA-1* and turn off *PU.1* to become a CFU-EMK; finally, it must turn on *Fli-1* and turn down (but not turn off) *GATA-1* to emerge as a CFU-MK. Whether TPO or other megakaryopoietic cytokines or components of the marrow microenvironment can influence these events remains an intriguing and critical question for experimental hematologists.

MEGAKARYOBLAST/STAGE I MEGAKARYOCYTES A generally accepted terminology has been developed to describe the developmental stages of megakaryocytes, the major criteria being the quality and quantity of the cytoplasm and the size, lobulation, and chromatin pattern of the nucleus. Stage I megakaryocytes account for approximately 20% of all megakaryocyte lineage cells in a normal marrow. They are 6 to 24 µm in diameter and contain a relatively large, minimally indented nucleus with loosely organized chromatin and multiple nucleoli and scant basophilic cytoplasm containing a small Golgi complex, a few mitochondria and a-granules, and abundant free ribosomes. This early phase of megakaryocyte development is also sometimes termed a *megakaryoblast* and, in rodent megakaryocytes, is characterized by intense staining for acetylcholinesterase. Although the elegant toxigene experiments of Marguerie and colleagues clearly demonstrated that the a $_{IIb}$ß $_3$ integrin gene must be expressed as early as the EMk progenitor stage ([436]) and possibly in the CMP, it is not until early stages of megakaryocyte development that the cell-surface protein becomes functionally important. a $_{IIb}$ß $_3$ integrin is an integral transmembrane protein of two subunits. The a subunit contains several divalent cation-binding sites and is dependent on µmol levels of Ca $^{2+}$ for proper conformation and dimer formation. Of the two subunits, only the a subunit is megakaryocyte lineage specific; loss of a $_{IIb}$ß $_3$ integrin leads to Glanzmann's thrombasthenia due to failure of the defective platelets to engage fibrinogen during aggregation. The two subunits of a $_{IIb}$ß $_3$ integrin are synthesized in the endoplasmic reticulum and form a Ca $^{2+}$-dependent complex immediately on translation—a step necessary for membrane expression. Subsequently, the a subunit is cleaved into heavy and light chains and modified with carbohydrate before transfer to the cell-surface, demarcation, and a-granule membranes ([478], [479]). Megakaryocytes and platelets contain approximately twice the amount of a $_{IIb}$ß $_3$ integrin as is present on the cell surface, the granule compartment serving as a mobilizable pool that is exteriorized on platelet activation. The role of the integrin in platelet function is discussed in the section Major Surface Adhesive Glycoproteins: Glycoprotein Ib and Glycoprotein IIb-IIa, but because megakaryocytes do not synthesize but contain fibrinogen in their a-granules and megakaryocytes from patients with Glanzmann's thrombasthenia do not, it is clear that a $_{IIb}$ß $_3$ integrin begins to function, at least at the level of fibrinogen binding and uptake, long before platelet formation. The gpIb/IX complex is developmentally expressed only slightly after the appearance of a $_{IIb}$ß $_3$ integrin ([480]). Although endothelial cells have been reported to express gpIb ([481]), its levels are very low; otherwise, gpIb is a megakaryocyte-specific protein that is expressed in the same distribution as a $_{IIb}$ß $_3$ integrin. gpV is also expressed in complex with gpIb and IX in a 2:2:1 (Ib:IX:V) stoichiometric ratio ([482], [483]). Because its genetic elimination has little effect on platelet adhesion ([484]) and, unlike gpIb and gpIX, no mutations of gpV have been associated with Bernard-Soulier syndrome ([485]), gpV is not required for function of the gpIb/V/IX complex as a vWF receptor. Rather, gpV appears to function as a target of thrombin, possibly playing a role in platelet activation ([486], [487]). Another feature of stage I megakaryocytes is the initial development of demarcation membranes. Initially described more than 30 years ago ([488]), what begins as invaginations of the plasma membrane ultimately develops into a highly branched interconnected system of channels that course through the cytoplasm. The use of electron-dense tracers indicated that the demarcation membrane system is in open communication with the extracellular space ([488], [489] and [490]), and biochemical analysis indicates that the composition of these membranes is very similar to the plasma membrane at each stage of megakaryocyte development. Over the 72 hours it takes for stage III and stage IV cells to develop from stage I megakaryocytes, the demarcation membrane system grows by approximately 25-fold. The purpose of the demarcation membrane system has been disputed for nearly 20 years ([491]); initially, it was thought to compartmentalize the cytoplasm of the mature megakaryocyte into platelet territories, which ultimately fragment into mature platelets along the cleavage planes so formed, but others believe the demarcation membranes provide the necessary surface membrane required for the exvaginations of

megakaryocytes known as *proplatelet processes* that form in stage IV megakaryocytes and give rise on fragmentation to mature platelets. Much work is presently focused on this question ([492]). One of the most characteristic features of megakaryocyte development is endomitosis, DNA replication in the absence of nuclear or cytoplasmic division, which results in megakaryocyte poly-ploidy. Endomitosis begins in megakaryoblasts after the standard cell divisions required to expand the number of immediate megakaryocytic precursor cells and is completed by the end of stage II megakaryocyte development ([493] , [494]). This carefully controlled process (i.e., each cycle of DNA synthesis produces an exact doubling of all the chromosomes) results in cells containing DNA content from 8 to 128 times the normal chromosomal complement in a single, highly lobated nucleus. Although poorly understood for many years, the recent ability to produce a large number of normal megakaryocytes in culture has begun to shed light on this enigmatic process. Endomitosis is not simply the absence of mitosis but rather an aborted mitosis ([495]). The cell cycle kinetics of endomitotic cells is also unusual, characterized by a short G_1 phase, a normal or modestly prolonged DNA synthesis phase, a short G_2 phase, and a very short endomitosis phase ([496]). During the latter, megakaryocytic chromosomes condense, the nuclear membrane breaks down, and centromeres form mitotic spindles on which the replicated chromosomes assemble. However, after initial chromosomal separation, individual chromatids fail to complete their normal migration to opposite poles of the cell, the spindle dissociates, and the cell once again enters G_1 phase ([495] , [497]). Attempts at biochemical analysis of this process have come from leukemic cell lines and normal cultured megakaryocytes. The cell cycle is driven in all cells by the progressive activation of a series of serine/threonine kinases, all of which are dependent on cell cycle phase–restricted activating subunits, termed *cyclins* ([498] , [499]). In addition, cell cycle kinase inhibitors, such as p21, p27, and the Ink proteins, or inhibitory phosphorylation of the cyclin-dependent kinases must be overcome. As the major departure from normal cell cycle behavior in megakaryocytes occurs during M phase, an attractive hypothesis to explain endomitosis is a failure to form or activate the M phase cyclin-dependent kinase cyclin B–cdc2 ([500]). Also termed *mitosis-promoting factor*, cyclin B–cdc2 participates in several aspects of mitosis, including chromosomal condensation, nuclear membrane breakdown, and inhibition of previous phases of the cell cycle. Of some interest, yeast, which carry temperature-sensitive mutations of either cyclin B or cdc2 homologs, undergo an extra round of DNA synthesis when grown at the nonpermissive temperature and then returned to the permissive temperature ([501] , [502]). Working with the bipotent erythroid/megakaryocytic cell line HEL, Long and colleagues found that endomitotic cells contain high levels of cyclin B but lack cdc2 ([503]). In contrast, MegT cells, derived from the transformation of murine marrow with a temperature-sensitive SV40 large T antigen driven by a megakaryocyte-specific promoter, fail to produce cyclin B during their mitotic phase ([504]). Additionally, the overexpression of cyclin D coupled with the elimination of cdc2 in F36 cells engineered to express c-mpl leads to polyploidy ([505]). Thus, each of these cell lines became polyploid by failing to express a functional mitotic kinase during endomitotic development but by different mechanisms. In contrast to these findings, results from normal murine and human megakaryocytes argue for normal mitotic kinase activity during endomitosis. Using TPO to expand marrow cell cultures *in vitro*, two groups have demonstrated the presence of both cyclin B and cdc2 in endomitotic megakaryocytes and their associated kinase activity ([495] , [506]) as well as a normal metaphase checkpoint mechanism ([507]). Thus, although probably etiologic for polyploidy in leukemic cell lines, studies in normal murine and human marrow cells call into question whether decreased mitosis-promoting factor (cyclin B–cdc2) is responsible for normal megakaryocyte endomitosis. Rather, recent attention has focused on two aspects of the process: the multipolar spindle that forms in polyploid megakaryocytes and the anaphase/telophase process termed *exit from mitosis*. This latter event encompasses a late anaphase checkpoint, in which a sequestered nucleolar phosphatase, cdc14, must be released to initiate the final stages of anaphase by activating Cdh1, a proteasome activator that triggers the destruction of cyclin B and other proteins required for exit from mitosis ([508] , [509] , [510] and [511]). Part of this process is the proper localization of survivin, INCENP (inner centromere protein), and the Aurora kinases at the centromere and midbody of the spindle ([512]). Of interest, elimination of survivin or INCENP in organisms as diverse as Drosophila and mammals leads to the abrogation of proper cell division and the formation of a cellular syncytium containing a large nuclear mass ([513] , [514] and [515]). Of further interest, a megakaryocytic cell line and normal murine megakaryocytes appear to be deficient in one of the Aurora kinases ([516] , [517] and [518]). Although such studies are only in their infancy, it appears that the elimination of mechanisms that are normally required to couple DNA synthesis and nuclear and cytoplasmic division can be down-modulated during megakaryocyte development. The promoters for a $_{IIb}$ integrin, gpIb, gpIX, and PF4 genes have been the focus of several recent studies and are active at the megakaryoblast stage of development. Most investigators have identified consensus sequences for both GATA-1 and members of the Ets family of transcription factors in the 5' flanking regions of these genes, the deletion of which reduces or eliminates reporter gene expression ([437] , [474] , [519] , [520]), at least in mature hematopoietic cells. Another important target of GATA-1 in megakaryocytes appears to be polyphosphate 4-phosphatase (P4P). By subtracting cDNA obtained from GATA-1 knock-down megakaryocytes from that generated from wild-type cells, a clone for P4P was obtained ([521]). One of the unexplained features of megakaryocytes in GATA-1 knock-down mice is that instead of the massive cell death seen in GATA-1–deficient erythroid progenitors ([445]), the aberrantly developing megakaryocytes in GATA-1 knock-down marrow are highly abundant and proliferate *in vitro* far greater than control cells ([446]). P4P catalyzes the hydrolysis of the D-4 position phosphate of PIP2 and PIP3. As these membrane phospholipids are products of PI3K, they play an important role in the proliferative and survival response to megakaryocyte growth factors. When reintroduced into the knock-down mice, P4P diminishes the exuberant growth characteristic of the knock-down cells ([521]). These findings are very much akin to the phenotype of cells from PTEN or src homology 2–containing inositol phosphatase (enzymes that hydrolyze the D-3 and D-5 positions of PIP3) knock-out mice. Although potentially a mechanism of proliferative control in megakaryocytes, the precise role of P4P in thrombopoiesis awaits further study. The cytokines responsible for survival and proliferation of megakaryoblasts are thought to include TPO, IL-3, and KL, with the first being the most critical. The proliferation of megakaryocytes is dependent on at least two signaling pathways, PI3K and MAPK, with the latter being particularly important for the generation of polyploid cells ([522]), a critical aspect of cells at this stage of development.

STAGE II MEGAKARYOCYTES Stage II megakaryocytes contain a lobulated nucleus and more abundant, but less intensely basophilic, cytoplasm. Ultrastructurally, the cytoplasm contains more abundant a-granules and organelles, and the demarcation membrane system begins to expand at this stage of development. Stage II megakaryocytes measure 14 to 30 µm in diameter, comprise approximately 25% of marrow megakaryocytes, and display ploidy values of 8 to 64 N. Early in megakaryocyte development, the cytoplasm acquires a rich network of microfilaments and microtubules. Toward stage III and IV, these proteins accumulate in the cell periphery, creating an organelle-poor peripheral zone. Biochemically, the megakaryocyte cytoskeleton is composed of actin, a-actinin, filamin, nonmuscle myosin [including the product of the *MYH9* gene, mutated in several giant platelet thrombocytopenic syndromes ([523] , [524])], ß1 tubulin, talin, and several other actin-binding proteins. Like platelets, megakaryocytes can respond to external stimuli by changing shape, transporting organelles around the cytoplasm, and secreting granules. These functions are dependent on the microfilament and microtubule systems of the cell. In addition, microtubules are believed to be a measuring stick for platelet formation during proplatelet generation in stage IV cells ([492]). As discussed in the section Erythroid-Megakaryocytic Progenitors, GATA-1 is vital for committing primitive multipotent progenitors into the erythroid/megakaryocyte pathway. However, the transcription factor is also critical later in megakaryopoiesis for cytoplasmic development. The first convincing evidence that GATA proteins are essential for megakaryocyte development came from studies of the myeloid leukemia cell line 416B. The forced overexpression of *GATA-1*, but not *SCL*, led to partial megakaryocytic differentiation of these cells ([525]). More recently, analysis of *GATA-1* knock-down mice revealed that megakaryocytes undergo endomitosis, but cytoplasmic development is severely altered; the scant cytoplasm was deficient in demarcation membranes and platelet-specific granules and contained excess rough endoplasmic reticulum and peripheral clear zones ([446]). Thus, although identification of the target genes responsible for this phenotype requires additional study, GATA-1 appears essential for postendomitotic megakaryocyte cytoplasmic maturation. Although more prominent in later stages of megakaryocyte differentiation, platelet-specific a-granules first begin to form adjacent to the Golgi apparatus as 300- to 500-nm round or oval organelles in stage I and II cells. Three distinct compartments are recognized in a-granules: (a) a central electron-dense nucleoid containing fibrinogen, PF4, ß-thromboglobulin, TGF-ß $_1$, vitronectin, multimerin, and tissue-type plasminogen activator; (b) a relatively lucent peripheral zone containing tubules and vWF (an arrangement akin to Weibel-Palade bodies found in endothelial cells); and (c) the granule membrane containing many of the critical platelet receptors for cell rolling (P-selectin, also termed *CD62p*), firm adhesion (gpIb/V/IX), and aggregation (a $_{IIb}$ß $_3$ integrin). Proteins present in a-granules arise from *de novo* megakaryocyte synthesis (e.g., gpIb/V/IX, gpIV, a $_{IIb}$ß $_3$ integrin, vWF, P-selectin, ß-thromboglobulin, platelet-derived growth factor), nonspecific pinocytosis of environmental proteins (e.g., albumin and IgG), or cell-surface membrane receptor–mediated uptake from the environment [e.g., fibrinogen ([526]), fibronectin, and factor V ([527])].

STAGE III/IV MEGAKARYOCYTES Continued cytoplasmic maturation characterizes stage III/IV megakaryocyte development—cells that comprise almost one-half of all recognizable members of this lineage in normal marrow. Stage III/IV megakaryocytes are extremely large (40 to 60 µm in diameter) and display a low nuclear to cytoplasmic ratio. Cytoplasmic basophilia wanes with development during stage III, the demarcation membrane system is prominent, and the endoplasmic reticulum and Golgi apparatus are disappearing during these final stages of maturation. The nucleus is usually eccentrically placed, and although sometimes appearing as several distinct nuclei in biopsy sections, it remains highly lobulated but single in all stages of megakaryocyte development. Most of the specific characteristics of megakaryocyte membranes have been achieved at this stage of development. Megakaryocyte membrane lipid composition progressively changes through development, achieving approximately four times the content of phospholipids and cholesterol found in immature cells; megakaryocytes contain approximately the same amounts of membrane-neutral lipid and phospholipid as platelets, but relatively more phosphatidylinositol and less phosphatidylserine (PS) and arachidonic acid. One transcription factor that plays an important role in the final stages of megakaryocyte maturation is NF-E2. Initially described as an erythroid-specific, heterodimeric protein belonging to the basic leucine zipper family of transcription factors, NF-E2 is composed of a ubiquitously expressed p18 subunit and a p45 protein present also in megakaryocytes ([528] , [529]). NF-E2 binds to tandem activator protein-1–like motifs, like that seen in the second DNAse hypersensitive site of the ß-globin locus control region ([528]), and is required for ß-globin expression ([530] , [531]). However, the genetic elimination of p45 failed to significantly affect erythropoiesis; rather, p45-deficient mice displayed prominent alterations in megakaryocyte development and severe thrombocytopenia ([532]). Although interbreeding of heterozygous p45 mice results in live births with the expected mendelian ratios, nullizygous mice die soon after birth of widespread hemorrhage. Examination of the animals reveals a modest expansion of marrow megakaryocytes but a failure of the cells to produce platelets. Additional studies localized the NF-E2 defect to cytoplasmic maturation. Megakaryocytes from knock-out mice proliferate normally in response to TPO; they become polyploid and express mpl, acetylcholines-terase, the megakaryocyte-specific marker 4A5 (thought to be gpV), PF4, and a $_{IIb}$ß $_3$ integrin. However, megakaryocytes from the knock-out animals are deficient in platelet

granules and demarcation membranes, the regions of megakaryocyte cytoplasm required for platelet formation. Thus, the loss of either GATA-1 or NF-E2 results in a failure of the late aspects of cellular maturation. Of interest, p45 NF-E2 is induced by GATA-1/FOG ([453]), potentially providing an explanation for the lack of cytoplasmic development in GATA knock-down mice. Nevertheless, identification of the target genes on which these two transcription factors exert their effects on cellular maturation is just now beginning ([533]). Platelets form by fragmentation of megakaryocyte cytoplasm. It has been estimated that each megakaryocyte gives rise to 1000 to 5000 platelets ([534], [535] and [536]) before the residual nuclear material is engulfed and eliminated by marrow macrophages ([537]). Stage IV megakaryocytes are wholly engaged in platelet formation. Careful microscopic studies have localized marrow megakaryocytes to the abluminal surface of sinusoidal endothelial cells. Fully mature megakaryocytes develop cytoplasmic processes constricted at platelet-sized intervals that extend through the endothelial barrier into the sinusoidal lumen, where platelets are released ([538]). It is likely that both integrin-mediated cell–cell interactions and extracellular matrix degradation are required for this process ([539], [540] and [541]). It is also possible that the final stages of megakaryocyte fragmentation occur in the lung, at least for some megakaryocytes. Howell and Donahue reported in 1939 that platelet levels in pulmonary venous blood exceed those found in the pulmonary artery, suggesting platelet production in the lung ([542]). Whether this represents the migration and fragmentation of intact megakaryocytes in the lung or merely the final size reduction of large fragments of megakaryocyte cytoplasm that are also released into the blood ([543]) is not clear. Lung megakaryocytes have been characterized by Slater and co-workers, who believe they contribute substantially to blood platelet production ([544]). However, in our recent preclinical studies of TPO in mice ([126]), we did not detect any denuded megakaryocyte nuclei in the lungs of mice sacrificed with platelet counts as high as 4 million per mm ^{3}. Moreover, cultured megakaryocytes can form functional platelets *in vitro* by generating proplatelets in the absence of endothelial surfaces or the pulmonary circulation (see below). Thus, the role of pulmonary bed platelet production remains controversial. One study found that dog lungs contain 2.5 megakaryocytes per cm ^{2} ([545]); extrapolation of these data would suggest that human lungs contain approximately 6000 megakaryocytes—only enough to account for a small proportion (<0.1%) of daily platelet production. More than 25 years ago, careful marrow morphologic studies demonstrated that marrow megakaryocytes issue long, thin, beaded extensions through the sinusoidal endothelial cells and into the vascular lumen ([546]). These proplatelet processes are thought to ultimately fragment into platelets, which are then free to leave the marrow space and circulate. Support for this mechanism of platelet formation was bolstered by the development of *in vitro* conditions in which similar structures could form ([540], [541], [547], [548]). Subsequent studies revealed that integrin and subcellular matrix engagement was required for this process ([549], [550]) and that the platelets derived from such cultures were functional ([548]). More recent studies have begun to delve into the molecular basis of proplatelet formation. Although only limited insights have been gained thus far, it is clear that (a) despite the importance of TPO for the generation of fully mature megakaryocytes from which proplatelets arise, elimination of the cytokine during the final stages of platelet formation is not detrimental; (b) external signals for proplatelet formation are probably required for the process to proceed efficiently, a conclusion based on most investigators finding that although proplatelet formation is possible under serum-free conditions, plasma and an integrin ligand-containing substratum (e.g., fibronectin, vitronectin) stimulate the process substantially ([312], [548]); (c) proplatelet formation involves massive reorganization of megakaryo-cyte cytoskeletal components including actin and tubulin; (d) proplatelet generation is an active, motile process in which the termini of the process branch and issue platelets ([492]); and (e) activation of protein kinase C is necessary for the process to proceed ([312]). One report suggests that thrombin/antithrombin III complex with or without high-density lipoprotein particles mediates the favorable effect of plasma on proplatelet formation ([551]), although older data suggest that prothromobin and its conversion to thrombin by megakaryocytes inhibit the process ([552]). The size of the individual platelets formed is also of interest; however, little is known about this aspect of platelet formation except that it has been proposed that tubulin acts as a measuring device for the proper site to pinch off platelets from proplatelet processes. It is also clear that the mechanism of platelet formation must be affected in some way by the transcription factor GATA-1, the gpIb/IX complex, the Wiskott-Aldrich syndrome protein, and platelet myosin, as defects in each of these genes lead to unusually large or small platelets ([448], [449], [485], [524], [553]).

PLATELETS

Megakaryocytes and megakaryocytopoiesis, described in the section Megakaryocytes, produce the circulating platelet of the blood that is comprised of fragments of megakaryocyte cytoplasm and functions in both normal hemostasis and abnormal thrombosis. This section, Platelets, describes normal platelet structure and function.

Structural and Functional Anatomy

LIGHT MICROSCOPY Light microscopy of Wright-stained smears (Fig. 19.2) reveals platelets as small, anucleate (i.e., lacking a nucleus) fragments with occasional reddish granules, measuring approximately 2 µm in diameter with a volume of approximately 8 fl ([554], [555]) and exhibiting considerable variation in size and shape. Platelets released from the marrow under “conditions of stress” such as thrombocytopenia and termed *stress platelets* are large and often beaded in shape ([543]), whereas young platelets, recently released from the marrow, are termed *reticulated* in reference to their RNA content and in analogy to young red cell reticulocytes ([556]).

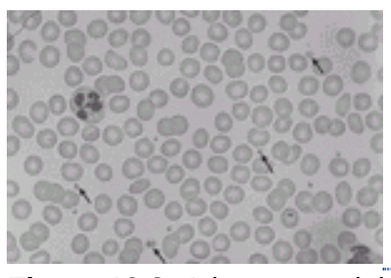

Figure 19.2. A human peripheral blood smear stained with Wright-Giemsa. Platelets, indicated by arrows, are interspersed between erythrocytes and a few leukocytes. The pale, grayish-blue cytoplasm contains purple-red granules. Original magnification of 35-mm slide = ×100. See Color Plate.

ELECTRON MICROSCOPY AND SUBCELLULAR FEATURES Platelets exist in two distinct forms, resting and activated, with the resting state marked by baseline metabolic activity and the activated form resulting from agonist stimulation (i.e., response to thrombin). Because platelets change their structure during the “resting-to-activated” transition, some description of these changes is provided here, and additional information on platelet function and the physiology of activated platelets is given in Chapter 20. By scanning electron microscopy, circulating resting blood platelets appear as flat discs with smooth contours, rare spiny filopodia (Fig. 19.3), and random openings of a channel system, the surface-connected canalicular system (SCCS), which invaginates throughout the platelet and is the conduit by which granule contents exocytose after stimulation ([557], [558]). Although the platelet is anucleate, transmission electron microscopy reveals a complex surface and a cytoplasm packed with a number of different subplatelet structures and organelles that are essential to the maintenance of normal hemostasis (Fig. 19.4 and Fig. 19.5). In describing detailed platelet anatomy, most information is derived from transmission electron microscopy, and platelet structure is classified into four general areas: the platelet surface, membranous structures, cytoskeleton (sol-gel zone), and granules. This classification is followed here.

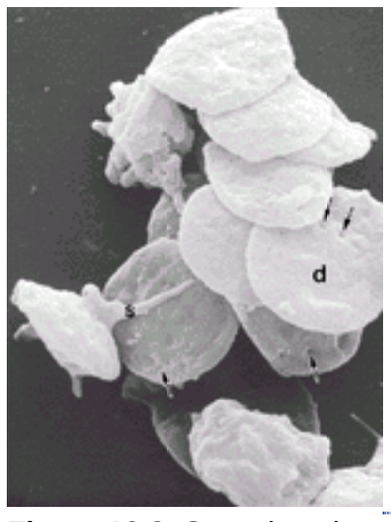

Figure 19.3. Scanning electron micrograph of unstimulated human platelets. Most are discoid (d) in shape. Many surface indentations, indicated by arrows, are present; these correspond to openings of the surface-connected canalicular system to the external milieu. Magnification = ×15,000. (Data from Stenberg PE, Shuman MA, Levine SP, Bainton DF. Optimal techniques for the immunocytochemical demonstration of ß-thromboglobulin, platelet factor 4, and fibrinogen in the alpha granules of unstimulated platelets. Histochem J 1984;16:983–1001.)

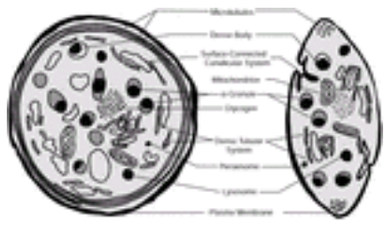

Figure 19.4. Diagram of a human platelet displaying components visible by electron microscopy and cytochemistry. In addition to membranous components (plasma membrane, surface-connected canalicular system, and dense tubular system), mitochondria, microtubules, and glycogen, four types of storage organelles are identified: a-granules, dense bodies, lysosomes, and microperoxisomes. Whereas the first two can be identified morphologically, microperoxisomes and lysosomes are recognizable only by cytochemical stains. (From Bentfeld-Barker ME, Bainton DF. Identification of primary lysosomes in human megakaryocytes and platelets. Blood 1982;59:472–481, with permission.)

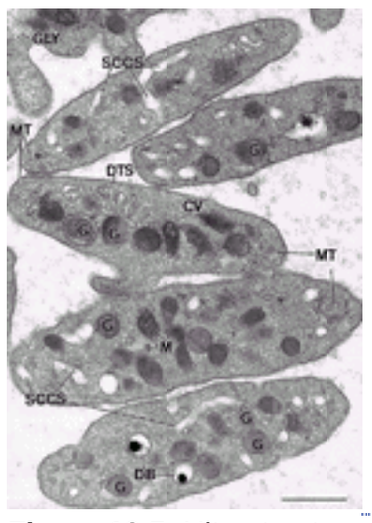

Figure 19.5. Ultrastructure of unstimulated human platelets. Membranous organelles, including the surface-connected canalicular system (SCCS) and dense tubular system (DTS), and cytoplasmic organelles, including mitochondria (M), a-granules (G), dense bodies (DB), coated vesicles (CV), and glycogen (GLY), are visualized at the ultrastructural level. Microtubules (MT) are present as cross-sectional and longitudinal profiles at the poles of the discoid platelets. Magnification = ×46,000. Bar = 0.5 µm.

PLATELET SURFACE

Plasma Membrane The platelet plasma membrane separates intra- from extracellular regions and, in thin sections, exhibits a typical 20-nm thick trilaminar structure ([559]) whose overall appearance does not differ from that of other blood cells ([560]). However, this “unit membrane” of platelets is exceptionally complex in composition, distribution, and function, incorporating a number of gps and lipids into its phospholipid bilayer and integrating a variety of extra- and intraplatelet events such as permeability, agonist stimulation, and platelet adhesion, activation/secretion, and aggregation. In terms of the fine structure of the membrane, freeze-fracture techniques show that intramembranous particles in platelets are concentrated on the outer (external face) leaflet ([561] , [562]), where numerous receptors are located, suggesting that these intramembranous particles might be related to prominent platelet surface receptors such as gpIIb-IIIa ([562]). The lipid composition of the membrane also warrants comment; it contains a large proportion of total platelet phospholipid, approximately 60% ([563]), and distributes it in an asymmetric manner, with neutral species located mainly in the outer layer and anionic forms, such as PS, concentrated on the inner side ([564]). This sequestration of PS, which promotes plasma coagulation by contributing to the prothrombinase complex ([565]), on the inner side of the membrane may account for the fact that resting platelets are essentially nonreactive in terms of thrombin generation ([566]). On the other hand, activated platelets make a major contribution to thrombin formation through the interactions of factors Xa and Va and prothrombin—an activity referred to originally as *platelet factor 3*—on their surface ([566] , [567] and [568]). Finally, the plasma membrane contains sodium and calcium aden-osine triphosphatase (ATPase) pumps, which are important for maintaining ionic homeostasis ([569]).

Glycocalyx A fuzzy layer of lipids, sugars, and proteins, 15 to 20 nm thick, coats the outside surface of the platelet plasma membrane, including the SCCS, and interacts with both the plasma and the cellular components of the blood and blood vessels. Termed the *platelet glycocalyx* ([488]), the layer provides a transfer point for plasma proteins such as fibrinogen as they are taken up into secretory granules by endocytosis ([570]). The glycocalyx contains gps, glycolipids, mucopolysaccharides, and adsorbed plasma proteins ([557] , [559]) and produces a net negative surface charge mainly due to sialic acid residues on certain proteins such as gpIb ([571]). This charge is thought to minimize attachment of circulating platelets to each other and to vessels ([572]). Being rich in the extracellular regions of both adhesive gps and agonist receptors, the glycocalyx is a fundamental participant in all aspects of platelet function.

PLATELET MEMBRANOUS SYSTEMS Platelets have features of muscle-related cells in terms of their high content of actin and their contractile response during activation. Similar musclelike qualities are found in the two membranous systems of platelets, the SCCS and the dense tubular system, which resemble transverse tubules and sarcotubules, respectively ([560] , [573]).

Surface-Connected Canalicular System The surface-connected canalicular system, also called the *open canalicular system*, is fenestrated and contiguous with the surface plasma membrane ([557] , [574] , [575] and [576]), weaving through the entire platelet cytoplasm in a tortuous fashion. The glycocalyx is less prominent in the SCCS as is one major surface gp, the gpIb-IX-V complex, whereas the other major receptor, gpIIb-IIIa, is distributed homogeneously through both the surface and the SCCS ([577]). The SCCS has several prominent functional roles: first, as an internal reservoir of membrane to facilitate platelet spreading and filopodia formation after adhesion ([577]); and second, as a storage reservoir for membrane gps, such as gpIIb-IIIa, that increase on the platelet surface after activation ([578]). The system also provides a route for granule release during the secretory phase of platelet activation ([558]) and serves as a route of ingress and egress for molecules as they translocate between the plasma and the platelet ([574]).

Dense Tubules Unlike the SCCS, the *dense tubular system* is a closed-channel system consisting of narrow, membrane-limited tubules, approximately 40 to 60 nm in diameter ([579]). Characteristically, it contains amorphous, moderately electron-dense material resembling cytoplasm within its lumina ([579]). It is, in fact, residual smooth endoplasmic reticulum from the megakaryocyte ([580] , [581]). Peroxidase ([582] , [583] and [584]), glucose-6-phosphatase ([585]), acetylcholinesterase (in cat, rat, and mouse but not human platelets or megakaryocytes) ([586]), adenylate cyclase, and Ca^{2+}- and Mg^{2+}-activated ATPases ([587]) have been cytochemically demonstrated in the dense tubular system. This channel system is involved in the regulation of intracellular calcium transport because it has been reported to selectively bind, sequester, and release divalent cations after activation ([587]). The dense tubular system is also the site of prostaglandin (PG) synthesis in platelets ([588] , [589]).

PLATELET CYTOSKELETON Both the shape of platelets and their ability to contract and spread depend on a cytoplasmic framework of monomers, filaments, and tubules that constitute the cytoskeleton ([590]). The cytoskeleton can direct platelet shape change, send out extracellular extensions, collect and then extrude secretory granules, and affect surface reactivity (Fig. 19.6). These varied functions are performed by three distinct structures: first, the membrane skeleton, which buttresses the inner side of the plasma membrane; second, the mass of actin and intermediate filaments, which fills the cytoplasm (cytoplasmic actin filaments; also termed the *sol-gel zone*); and third, the circumferential microtubule band, which encircles the substance of the platelet to produce the resting disclike form ([577] , [590]). Three different protein filaments/tubules contribute to the overall network: namely, 5- to 6-nm–diameter microfilaments of actin ([591] , [592]), 10- to 12-nm intermediate filaments of desmin and vimentin ([593] , [594]), and 25-nm microtubules composed mainly of tubulin ([595] , [596] and [597]). Together, these filaments, depending on the activation state of the platelet, comprise 30 to 50% of total platelet protein.

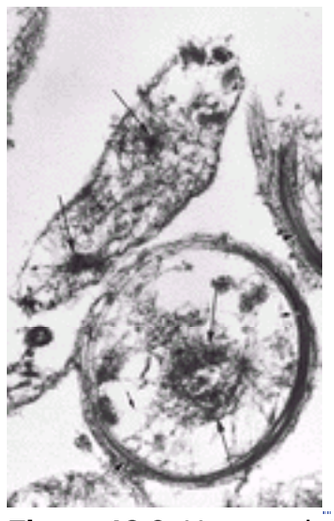

Figure 19.6. Human platelet cytoskeletons prepared by simultaneous fixation and lysis in Triton X-100 detergent. Single actin filaments, indicated by short arrows, course throughout the platelet cytoplasm. Clusters of filaments, indicated by long arrows, also are present. Note the microtubule coils at the platelet peripheries (*arrowheads*). Magnification = ×30,000. (From Boyles J, Fox JEB, Phillips DR, Stenberg PE. Organization of the cytoskeleton in resting, discoid platelets: preservation of actin filaments by a modified fixation that prevents osmium damage. J Cell Biol 1985;101:1463–1472, with permission.)

In addition to well-established electron microscopic technologies (quick freeze and deep etch; negative staining) ([598]), a more recent detergent extraction technique has been widely applied to understand the composition and function of the platelet cytoskeleton ([599]). Under defined conditions, the nonionic detergent Triton X-100 is added to resting or activated platelets, and the insoluble proteins, sedimenting at 15,600 × g for 15 minutes, are operationally defined as the *platelet cytoskeleton* or *cytoplasmic actin filaments* ([590]). The remaining supernate is recentrifuged at 100 K × g for 1 hour, and the pelleted proteins are termed the *membrane cytoskeleton* because they prove to contain surface-associated molecules such as gpIb ([600]). Such work has permitted the analysis of a number of physically linked proteins, including structural, signaling, and receptor elements, as they associate with or dissociate from the two cytoskeletal preparations (membrane and cytoplasmic) under varying conditions and with different time courses ([601] , [602]). The literature on the third cytoskeletal structure, the microtubules, has generally remained outside these studies that use Triton X-100 and is discussed later.

Membrane Skeleton This structure was first described more than 30 years ago by electron microscopy ([603] , [604]) and then analyzed biochemically through the detergent lysis approach noted in the section Platelet Cytoskeleton ([599]). Also termed the *submembrane region*/ *skeleton*/ *cytoskeleton*, this is basically a collection of short actin filaments that underpin the plasma membrane and connect surface receptors with the bulk of cytoplasmic actin filaments ([591]). For example, the membrane skeleton associates with the cytoplasmic domain of the transmembrane gpIb through actin-binding protein (filamin 1) and appears to attach to gpIIb-IIIa also, although the precise linkage to this second major surface gp is not well defined ([590]). A number of additional associated proteins with a variety of linking and signaling properties, such as spectrin, talin, pp60c-src, and Rho, have been identified (Table 19.3) ([577] , [590]). Such a convergence of interesting molecules makes this structure a focus for studies that seek to understand the role of signal transduction in platelet activation. In addition, the membrane skeleton appears to play a role in platelet spreading after adhesion and in regulating the surface mobility of receptors such as gps Ib and IIb-IIIa ([577]). Various cytoskeletal molecules are listed in Table 19.3, divided according to their presence in high- or low-speed fractions of the detergent-extracted skeleton. A brief summary of the properties of the individual proteins is presented along with pertinent references.

TABLE 19.3. Major Platelet Cytoskeletal Proteins

Protein	Molecular Weight	Principal Known Function	References
Actin	42,000	Major protein constituent of microfilaments; 30% of platelet protein; F-actin binds myosin.	590, 623
Myosin II	500,000	Binds actin; phosphorylation of light chains contracts microfilaments; 4% of platelet protein.	590, 606, 621
Talin	235,000	Interacts with a-actinin, vinculin; 2% of platelet protein.	607
Vinculin	130,000	Interacts with talin; links to actin.	608
a-Actinin	102,000	Dimer forms a gel with F-actin; promotes actin polymerization.	590
Actin-binding protein (filamin 1)	260,000	Cross-links actin filaments; links membrane skeleton with glycoprotein Ib-IX complex.	601, 609
Gelsolin	91,000	Caps and severs actin filaments.	613
Thymosin ß $_4$	5000	Binds 1:1 with G-actin monomers and inhibits its polymerization.	614
Profilin	15,200	Binds 1:1 with G-actin and inhibits its polymerization; adds adenosine triphosphate.	615
Tropomyosin	28,000	Binds groove on certain F-actins.	590
Caldesmon	80,000	Regulates actomyosin ATPase and actin bundling.	616
Myosin light chain kinase	105,000	Phosphorylates myosin, activates its ATPase, and causes contraction.	622
Calmodulin	17,000	Binds four Ca^{2+}; activates myosin light chain kinase.	590, 622

ATPase, adenosine triphosphatase.

Cytoplasmic Actin and Intermediate Filaments (The Sol-Gel Zone) The bulk of the platelet cytoskeleton consists of a large amount of actin (M_r = 42,000) that comprises approximately 25% of total platelet protein ([605]). Other platelet cytoskeletal proteins, such as tropomyosin and a-actinin, are present in lower amounts (2 to 5% of total platelet protein) ([606] , [607] , [608] and [609]). The actin exists in soluble, monomeric (G-actin), and filamentous (F-actin) forms and connects to both the membrane skeleton and the microtubules ([577]). In resting platelets, approximately 40% of actin is in microfilaments, which are dispersed throughout the cytoplasm and obscured by their small size and the many other subplatelet structures present, such as granules ([610]). The intermediate filaments are more stable, resistant structures, rich in vimentin, that appear to bear tension within the cytoplasm ([594]). Platelet stimulation results in profound changes in cytoskeletal organization. Morphologically, platelets rapidly lose their discoid shape, become rounded, and extend filopodia ([611] , [612]). With the rise in intracellular calcium, the proportion of F-actin increases rapidly to 60 or 70%; the transition is governed by the actions of gelsolin and the dissociation of the filament-capping protein capZ, coupled with the subsequent interactions of thymosin ß $_4$, polyphosphoinositides, profilin, and the actin-related protein 2/3 complex ([612] , [613] , [614] and [615]). Actin monomers polymerize onto filaments at platelet peripheries ([611] , [616]), and bundles of new filaments form to fill developing filopodia ([617] , [618] and [619]). Phosphorylation of myosin light chain results in binding of myosin to actin ([620] , [621] and [622]), providing the tension required for granule centralization and retraction of filopodia ([623]). Additional proteins, such as talin and surface gpIIb-IIIa, join the developing electron-dense actin filaments, and the structure is remodeled through the action of an associated calcium-dependent protease, calpain ([624]). Added to these multiple events is the activation of several Rho family GTPases that mediate different aspects of platelet spreading ([625]). The sum of these events in platelet function is critical because the combination of various additions, rearrangements, and remodeling steps underpins shape change and spreading (filopodia and lamellipodia formation) along with platelet secretion and clot retraction ([590]).

Microtubules A circumferential microtubule band that supports the discoid form of the platelet ([595] , [596]) is made of two nonidentical subunit proteins (a and ß tubulin) ([626]), associated with microtubule-associated proteins ([627] , [628]). The 25-nm–diameter microtubule coil lies adjacent to, but does not touch, the plasma membrane ([629]). By electron microscopy of sectioned platelets, microtubules appear as 8 to 24 tubular profiles at the poles of discoid platelets. Microtubules are present primarily in their polymerized form in unstimulated platelets. Platelet activation results in microtubule disassembly and then reassembly; such alterations in the marginal microtubule bundle result in platelet shape changes ([629] , [630]). Microtubules may be disorganized in giant platelet disorders ([626]).

PLATELET GRANULES AND ORGANELLES Normal platelet function appears to require some amplification or accentuation of any given stimulus to obtain an appropriate response. Accordingly, platelets possess secretory granules and mechanisms that serve this purpose by releasing additional stimulatory materials, previously sequestered within the resting platelet, into the environment of a developing hemostatic or thrombotic mass. Two main secretory granules, the a-granules and the dense bodies, appear to be the main effectors with their highly reactive and readily available contents [i.e., adenosine diphosphate (ADP) and fibrinogen] ([631]). Platelet granule secretion begins with a dramatic increase in platelet metabolic activity, set off by a wave of calcium release and marked by increased adenosine triphosphate (ATP) production ([632] , [633]). ATP generation proceeds with rapid changes in the cytoskeleton with the “bundling” of actin filaments and the development of the “contractile ring” around centralized granules before their extrusion ([559] , [560]). After platelet stimulation by agonists, granules fuse with the surface membranes and extrude their contents ([634]). The actual site of granule membrane fusion, in the SCCS or plasma membrane or both, remains unclear ([558] , [635]). Internal contraction is required for this extrusion and ultimate discharge into the surrounding medium. Some of the molecular events that govern platelet granule release

appear to involve many of the same proteins and processes observed in other systems of membrane docking, fusion, and extrusion ([636], [637] and [638]). Furthermore, granule secretion in platelets is a graded process that depends on the number, concentration, and nature of the original stimulus/stimuli, either strong (i.e., thrombin and collagen) or weak (i.e., ADP and epinephrine) ([639]). a-Granules and dense bodies are distinguished morphologically from one another by their electron density as revealed by electron microscopy, whereas lysosomes and microperoxisomes require enzyme cytochemical stains to be visualized ([640], [641]). The role of these other platelet granules (lysosomes, peroxisomes) and organelles, such as mitochondria, is less dramatic than those of the a-granules and dense bodies and is discussed later.

a-Granules a-Granules, numbering approximately 50 per platelet, are the predominant platelet granules with a cross-sectional diameter of approximately 300 nm ([642]). They are approximately spherical in shape with an outer membrane enclosing two distinct intragranular zones that vary in electron density. The larger, electron-dense region is often eccentrically placed and consists of a nucleoid material that is rich in platelet-specific proteins such as ß-thromboglobulin ([643]). The second zone of lower electron density lies in the periphery adjacent to the granule membrane and contains tubular structures with adhesive gps such as vWF and multimerin along with factor V ([644], [645] and [646]). It has been known for many years that platelets take up material into their cytoplasm from the external milieu ([647]), and recent work demonstrates that they can incorporate specific plasma proteins into their a-granules ([648], [649]). At this point, one can categorize the various a-granule proteins into different aspects such as origin (megakaryocyte or nonmegakaryocyte), location within the granule, and function (adhesive or mitogenic). The proteins are discussed below in that order and listed in Table 19.4 with references.

TABLE 19.4. Major Platelet Granular Constituents Secreted with Activation

a-Granules				
Protein	**Comments**	**Amount/10^9 Platelets**	**Concentration in Platelets >Plasma**	**Reference**
Coagulant proteins				
Fibrinogen	Critical ligand for aggregation	140 µg/10^9 platelets	3× conc. platelets >plasma	631
Factor V	Critical cofactor for coagulation	4 µg/10^9 platelets	30× conc. platelets >plasma	663
Platelet-specific proteins				
Platelet factor 4	Marker for platelet activation	12 µg/10^9 platelets	20 K conc. platelets >plasma	654
ß-Thromboglobulin	Marker for activation	10–20 µg/10^9 platelets	20 K conc. platelets >plasma	655
Mitogenic and angiogenic factors				
Platelet-derived growth factor	Smooth muscle mitogen	30–100 ng/10^9 platelets		680, 683
Transforming growth factor-ß	Complex activation pathway; binds thrombospondin			681
Vascular endothelial growth factor	Relatively high concentrations in platelets			682
Adhesive glycoproteins and a-granule membrane-specific proteins				
Thrombospondin	Multiple complexes	40 µg/10^9 platelets	20 K conc. platelets >plasma	656, 657, 658 and 659
von Willebrand factor (vWF)	Role in adhesion	0.3 µg/10^9 platelets	100× conc. platelets >plasma	1030, 1031
Multimerin	Binds factor V; resembles vWF binding factor VIII; has RDG sequence			646
P-selectin	Mediates platelet-leukocyte binding	20,000 copies on activated platelets		672

Dense Granules				
Constituent	**Comments**	**Concentration in Granules (nmol/mg Dense Granule Protein)**	**Percent (%) Secreted**	**Reference**
Adenosine diphosphate	Highly concentrated; a critical mediator of aggregation	630	95 secreted with platelet activation	631
Adenosine triphosphate		440	40 released with activation	688
Calcium		2630	70 secreted with activation	
Serotonin		100	95 released with activation	

conc., concentration.
NOTE: A number of additional elements are released or secreted from within the platelet. For example, a-granules also contain the major platelet surface glycoproteins (gps) gpIIb-IIIa and gpIb-IX along with albumin and immunoglobulin G, adhesive glycoproteins (fibronectin, vitronectin), fibrinolytic components (a $_2$-antiplasmin, plasminogen activator), and coagulation-related proteins (high-molecular-weight kininogen, a $_2$-macroglobulin). In addition, dense granules contain guanosine triphosphate/guanosine diphosphate and high concentrations of pyrophosphate, phosphate, and magnesium, much of which is secreted with activation ([631]). A number of additional proteins are present, some released and some retained in the platelet cytosol, such as a subunit of factor XIII, amyloid ß-protein precursor, protease nexin I, and tissue factor pathway inhibitor.

Three proteins, ß-thromboglobulin, PF4, and thrombospondin, are highly concentrated in a-granules and are synthesized in megakaryocytes. The first two, ß-thromboglobulin and PF4, show homology in amino acid sequence and share the additional features of localization in the dense nucleoid of a-granules, heparin-binding properties, and membership in the CXC family of chemokines ([526], [576], [650], [651], [652] and [653]). Together, they constitute approximately 5% of total platelet protein, and because of their platelet specificity (produced solely in megakaryocytes), they can serve as useful markers for platelets in serum or plasma ([654], [655]). The origins, neutrophil-activating properties, heparin-binding features, structures, and antiangiogenic effects of these small (M_r = ~10,000) but complex proteins and their relatives have been described ([631]). The third member of this group, thrombospondin, first described as thrombin-sensitive protein/endogenous platelet lectin ([656], [657] and [658]), is part of the thrombospondin family of proteins, comprises 20% of the total platelet protein released in response to thrombin, and participates in platelet plug formation ([656], [659], [660]). vWF is synthesized by megakaryocytes and is present in the tubular structures of the a-granule peripheral zone, similar to its localization within Weibel-Palade bodies of vascular endo-thelial cells ([645], [661]). Factor V and multimerin, a factor V/Va–binding protein ([646], [662], [663]), co-localize with vWF in platelets but not in endothelial cells. Additional coagulant proteins in the a-granule include fibrinogen, which is incorporated actively from plasma but apparently is not synthesized by megakaryocytes ([648], [664]), and a plasminogen activator similar to tissue plasminogen activator ([665]). *In vitro* studies demonstrate that antibodies to gpIIb-IIIa are transported from the plasma membrane into a-granules ([666]), and cycling of gpIIb-IIIa between granules and the platelet surface has been described ([667]). Some data suggest that these movements of the gpIIb-IIIa complex could affect fibrinogen transport into granules ([668]). The reservoir of gpIIb-IIIa present in a-granule membranes may contribute significantly to the surface fibrinogen receptors present on activated platelets ([669], [670] and [671]). Two distinct granule membrane proteins, P-selectin (granule membrane protein-140) and granule membrane protein-33, have been shown to be translocated from the granule membrane to the plasma membrane after platelet activation ([672], [673]). Finally, a number of additional proteins have been located to the surface of a-granules alone, including CD9, platelet-endothelial cell adhesion molecule-1 (PECAM-1), Rap 1b, gpIb-IX-V, and osteonectin ([674], [675] and [676]) (Table 19.4). Small amounts of virtually all plasma proteins, such as albumin, IgG, fibronectin, and ß-amyloid protein precursor, may be taken up into the platelet a-granules ([661], [677], [678] and [679]). In addition, the presence of several growth factors, including platelet-derived growth factor, TGF-ß $_1$, and vascular endothelial growth factor, in these granules has important implications for the potential mitogenic activity of platelets ([680], [681] and [682]). For example, activated and aggregating platelets can potentially release these growth

stimulants directly onto responsive vascular cells, such as smooth muscle cells, and induce proliferation that can relate to the progression of atherosclerotic vascular lesions ([683], [684]). The platelets and megakaryocytes of patients with gray platelet syndrome have decreased numbers of a-granules and reduced levels of some proteins. It is proposed that there is incorrect targeting of a-granule proteins to the a-granule in the megakaryocyte in this disease ([685], [686]).

Dense Bodies Dense bodies, numbering approximately five per platelet, are exceptionally electron dense and easily appreciated by electron microscopy due to their distinctive “bull's eye” appearance ([687]). With an approximate diameter of 250 nm, these granules contain a large reservoir of ADP, a critical agonist for platelet activation that amplifies the effect of other stimuli ([688]). In addition to this nonmetabolic pool of ADP, the dense bodies are rich in ATP, pyrophosphate, calcium, and serotonin (5-hydroxytryptamine) with lesser amounts of GTP, guanosine diphosphate, and magnesium ([631]). The adenine nucleotides are synthesized and segregated by megakaryocytes, whereas serotonin is incorporated into dense granules from the plasma by circulating platelets ([689], [690] and [691]). There is more ADP than ATP in dense bodies, and both can lead to adenosine monophosphate (AMP). In turn, AMP can be dephosphorylated to aden-osine or cyclized to produce cyclic AMP, an inhibitor of the platelet stimulatory response. The dense granule membrane contains P-selectin and granulophysin ([692]).

Lysosomes *Lysosomes* are small, acidified vesicles, approximately 200 nm in diameter, that are identifiable only with specific cytochemical stains for acid phosphatase and aryl sulfatase ([640]) or through immunocytochemistry for cathepsin D and lysosome-associated membrane proteins (LAMP-1/LAMP-2; these are expressed on the plasma membrane after activation) ([693], [694] and [695]). The exact identification of the CD63 antigen and its relationship to the integral lysosomal membrane proteins have proved controversial ([696], [697]). Lysosomes are the only platelet granules that contain acid hydrolases with pH optima of 3.5 to 5.5, including ß-glucuronidase, cathepsins, aryl sulfatase, ß-hexosaminidase, ß-galactosidase, heparitinase, and ß-glycerophosphatase ([631]). Lysosomal constituents are released more slowly and incompletely (maximally, 60% of the granules) than a-granule or dense body components after platelet stimulation, and their release also requires stronger agonists such as thrombin or collagen, suggesting that they may have a greater role in lysis of thrombi than in the immediate hemostatic response ([698], [699]).

Organelles: Microperoxisomes, Coated Vesicles, Mitochondria, and Glycogen *Microperoxisomes* are rare, small (90 nm in diameter) granules, demonstrable with alkaline diaminobenzidine due to their catalase activity ([700]). The structure may participate in the synthesis of platelet-activating factor, but its ultimate fate within the platelet cytoplasm is unknown ([701]). *Coated vesicles* are 70- to 90-nm–diameter platelet organelles, distinguished by their electron-dense bristle coat ([702]). The polyhedral surface coat is composed of clathrin, and special staining reveals that the same coat that is in the plasma and SCCS membranes is found on the coated pits and vesicles themselves ([703]). Coated pits and vesicles transfer plasma components to platelet granules, and the number of coated vesicles in platelets increases after stimulation with ADP ([704]). Mitochondria in platelets are similar, with the exception of their smaller size, to those in other cell types. There are approximately seven per human platelet, and they serve as the site for the actions of the respiratory chain and the citric acid cycle ([705]). Glycogen is found in small particles or in masses of closely associated particles, playing an essential role in platelet metabolism ([706]).

Platelet Physiology

The physiologic challenge to platelets remains simple: “Plug holes in blood vessels”; this stands in contrast to the complex information on platelet anatomy noted in the section Structural and Functional Anatomy.

A GLOBAL VIEW The point of this “global view” is to emphasize a limited number of major current features of platelet physiology. To begin, it is fair to say that the platelet has come a long way from its past as an “inert particle” or possible artifact ([4], [707]) to its present recognition as a remarkable fragment of megakaryocyte cytoplasm, capable of intense, focused activity that produces a tenacious mass at a site of vessel damage or disease ([708], [709]). The clinical relevance of platelets is well illustrated by the widespread use of platelet gpIIb-IIIa antagonists (e.g., abciximab, eptifibatide) during angioplasty ([710], [711]) and by the general acceptance of aspirin as an antiplatelet agent to prevent heart attack and stroke ([712], [713]).

Inert but Poised Monitor of Vascular Lumen A new platelet, emerging from the bone marrow, survives for 10 days in the blood; during this time, it makes innumerable circuits through the vasculature and is continually pushed outward by rheologic forces to the interface between moving blood and the immobile vessel wall ([714], [715]). In the absence of agonists, the platelet remains unactivated for its entire lifespan; its surface receptors, signaling pathways, and contractile elements appear unresponsive—perhaps due, in part, to its negative surface charge and exposure to prostacyclin (PGI2) in the microvasculature ([716]). Similarly, the major intraplatelet metabolic systems are minimally active in such resting platelets: ATP generation, lipid metabolism to generate ATP, and lipid transformations to PGs are absent or minimal. However, to the best of our knowledge, if this same resting platelet encounters a severed blood vessel (i.e., a bleeding time wound) or an atheromatous plaque ([717]), it can immediately stop (adhere) at the site and begin to generate a platelet hemostatic or thrombotic mass (plug). The emphasis here is on the dramatic difference between the resting and activated forms of the platelet and the fact that the inert form can circulate for days in the absence of agonists. Conversely, a vessel abnormality or other agonist can set off activation almost instantaneously at essentially any place within the circulation at any time.

Greater Role in Arteries Than in Veins Thrombocytopenic patients exhibit mucocutaneous bleeding (skin and mucous membranes), whereas hemophilia patients experience deep visceral bleeding (joints, muscle masses) ([718]). The distinction is by no means perfect, but it is clinically relevant. Physicians use the difference as a rough, initial approach to understanding causation in a bleeding patient ([719]). Platelet deposition (primary hemostasis) is more important than fibrin deposition (secondary hemostasis) in stopping bleeding from the small exposed vessels of the skin (petechiae) and mucous membranes (epistaxis, menorrhagia). Apparently, these vessels have an arteriolar or arterial nature. The converse is true in joints (knee, elbow) and muscles (psoas muscle) in which fibrin deposition is more critical, and the bleeding vessels appear to be venous in terms of the hemostatic pathway involved. The same pattern emerges in treating arterial versus venous thrombosis, with antiplatelet agents (aspirin, clopidogrel) being used to prevent coronary and cerebral vascular events (arterial) and anticoagulants (warfarin, heparin) used in deep venous thrombosis (venous) ([720], [721]). The point emerges that the platelet system has an efficient means (gpIb and vWF) to manage the flow conditions of the arterial circulation, whereas the fibrin system of plasma coagulation does not. As a result, platelets function successfully in arteries and arterioles, whereas fibrin deposition functions less well. Conversely, in the venous system with minimal blood flow, thrombin and fibrin act appropriately under static or low-flow conditions, and platelets have a lesser role.

Initial, Basic Challenge: Arrest and Anchor a Moving Platelet Moving platelets in the arterial circulation use their movement to stop their movement ([709]). This puzzling and unique functional mechanism, termed *shear-dependent platelet adhesion*, is not understood presently at a molecular level, although the structures of the relevant receptor-ligand pair, platelet gpIb-IX-V and plasma vWF, are known in detail ([722], [723]). Under resting, static conditions, the two components display no affinity for one another, and exogenous stimuli such as ristocetin are required to induce their interaction ([724]). However, in the presence of rather modest shear forces (>6 dyne per cm ^{2}), the two proteins develop a sufficient binding affinity to arrest and anchor platelets at the lip of a severed blood vessel or to a vascular surface in the high-flow environment of a coronary artery plaque ([725]). The fundamental question is how shear force, generated by moving blood, affects the receptor or the ligand, or both. To date, a number of possible explanations have been advanced ([726]). The most often-stated theory is that shear force alters the conformation of vWF once it is bound to the exposed subendothelium of a damaged artery. However, shear could also affect the receptor alone ([708]).

Emerging Concept: Surface versus Core of a Platelet Deposit In 1999, a major insight altered the thinking about arterial platelet adhesion by demonstrating that the addition of platelets to the surface of a growing platelet deposit/thrombus requires the binding of circulating vWF to the gpIb receptor exposed on the surface of immobilized aggregating platelets ([727]). This sequence of events is markedly different from the older concept that vWF served only to adhere platelets to a nonplatelet surface such as the subendothelium and that thrombus growth was entirely dependent on the fibrinogen-to-integrin (gpIIb-IIIa) linkage, known earlier to be a major mechanism for platelet aggregation in suspended systems ([728]). The new concept of vWF-to-gpIb interactions as part of thrombus growth has led to current work on the overall structure of a platelet plug in an arterial flow environment ([729]). The “thrombus surface” differs dramatically from the “thrombus core,” with vWF-gpIb being the dominant surface system and fibrinogen (particularly platelet a-granule fibrinogen)–gpIIb-IIIa probably being the required intrathrombus strengthening system needed to produce a resilient platelet mass ([730]).

Bedrock of Platelet Function: Glycoprotein Ib to Glycoprotein IIb-IIIa Axis The list of platelet surface receptors, signaling molecules, and secreted granular contents is long. However, the number of critical molecules is much smaller if one focuses on the activities of two platelet-specific genes with unique, specific, and dominant roles: gpIb and gpIIb ([731], [732]). For example, gpIb and the gpIIb-IIIa receptor are present in high number (i.e., ~50,000 receptors per platelet), and deficiencies in either one cause severe clinical bleeding syndromes (Bernard-Soulier syndrome and Glanz-mann thrombasthenia) ([733], [734], [735], [736] and [737]). Therefore, these two receptors are central to platelet function and play central roles. Each receptor-ligand pair has a distinct role, separated in time. For example, the gpIb–vWF interactions subserve shear-dependent adhesion, but once the platelet has stopped and anchored itself to the vessel wall or to the platelet deposit, the receptor–ligand interaction switches to an “off” configuration or mode, and if the gpIIb-IIIa–fibrinogen receptor-ligand pair does not act, then the anchored platelet is likely to release and disengage ([738], [739]).

Other Essential Elements: One Plasma and One Granule Ligand Plasma vWF is composed of approximately 100 subunits that form elongated multimers up to 1.0 µm in length, a distance that approaches one-half of the platelet diameter ([740], [741]). This huge strand of protein has a highly specific and unique role to mediate platelet adhesion to vascular subendo-thelium under the flow conditions of the arterial circulation ([742]). Apparently, the extreme length of vWF is needed for arterial platelet adhesion, but an outer limit to vWF length must exist because if it is longer, then thrombotic thrombocytopenic purpura ensues ([743], [744]). Thrombotic thrombocytopenic purpura results from the absence of the metalloprotease that normally cleaves vWF to an effective but not pathologic length ([745]). In addition to vWF, a-granule fibrinogen, probably with plasma fibrinogen, is required to link aggregating platelets into a permanent and resilient mass once platelet function is

initiated by gpIb and vWF. Plasma fibrinogen alone appears insufficient to give optimal function, so signal transduction is needed within the platelet to activate gpIIb-IIIa once shear-dependent adhesion has occurred. Consequently, a-granule secretion of fibrinogen into the deposit is also exceptionally important for normal platelet mass development ([730]).

Summary The essence of platelet physiology is constant surveillance of the lumens of the arterial circulation, followed by rapid deposition at sites of damage. The initial step of adhesion depends on platelet gpIb and plasma vWF, whose affinity requires shear forces generated by blood flow. The binding of gpIb-vWF is followed by aggregation through the gpIIb-IIIa–fibrinogen system as amplified and reinforced by signal transduction and secretion events that activate gpIIb-IIIa and release a-granule fibrinogen.

A MOLECULAR PERSPECTIVE This section classifies the major molecular systems in platelets as (a) surface receptors, (b) signaling elements, (c) molecules that govern shape change and motility, (d) selected granule constituents and members of the membrane fusion system for granule secretion, and (e) inhibitors.

Surface Membrane Receptors The surface membrane receptors of platelets are broadly classified here as *adhesive* or *agonist*; in turn, they are somewhat arbitrarily ordered as to potential importance, depending on current knowledge of their number on the platelet surface, the extent of their activity, and their known clinical relevance. They mediate a wide variety of adhesive cellular interactions, often through specific ligand binding, and they function as receptors that can receive signals from outside the platelet, resulting in distinct platelet responses to the external environment. Table 19.5 provides a current summary of these receptors.

TABLE 19.5. Platelet Surface Glycoprotein (gp) Receptors for Adhesion/Aggregation

Receptor	Family Group and/or Name	Ligand	Comment	Molecules/Platelet
Fundamental pairing (many copies; clear role; lack leads to clinical bleeding)				
gpIb-IX-V	Leucine rich gp	vWF	Lack: Bernard-Soulier syndrome	25,000
gpIIb-IIIa	$a_{IIb}ß_3$ Integrin	Fibrinogen and vWF	Lack: Glanzmann thrombasthenia	50–80,000
Collagen receptors (confusing bleeding, no bleeding, or mild bleeding)				
gpIa-IIa	$a_2ß_1$ Integrin	Collagen	Variable reports of bleeding with deficit	1000
gpIV	No family known, CD36	Collagen/thrombospondin	No bleeding with deficit	20,000
gpVI	Ig family	Collagen	Role in activation; mild bleeding with deficit	2000
Extracellular matrix receptors (few copies and no known platelet deficiency states)				
gpIc-IIa	$a_5ß_1$ Integrin	Fibronectin	a-Chain differs from a6	1000
gpIc-IIa	$a_6ß_1$ Integrin	Laminin	a-Chain migrates with a5 on PAGE	1000
a_v-gpIIIa	$a_vß_3$ Integrin	Vitronectin	Same ß-chain as gpIIb-IIIa, different as	100
Additional surface elements of uncertain significance in hemostasis				
PECAM-1	Ig family, CD31	Heparin	Uncertain function, perhaps adhesion	8000
Fc?RII	Ig family, CD32		Immune complexes; role in immune complex deposits	1000
CD9	Tetraspanin, p24		Unknown role, but abundant surface copies	40,000

Ig, immunoglobulin; PAGE, polyacrylamide gel electrophoresis; PECAM-1, platelet-endothelial cell adhesion molecule-1; vWF, von Willebrand factor.
NOTE: The group of surface receptors noted above functions in interactions between cells or between cells and immobilized surfaces, and the group differs markedly from the other major class of platelet surface receptors that mediate specific responses to soluble agonists. These latter “agonist receptors” include those for thrombin, adenosine diphosphate, and thromboxane A_2 and, as discussed in the text, generally prove to be G protein–coupled receptors with seven-transmembrane domains.

Major Surface Adhesive Glycoproteins: Glycoprotein Ib and Glycoprotein IIb-IIIa The *gpIb-IX-V complex* is a set of four distinct polypeptide chains, although the group is often referred to as simply *gpIb* ([722] , [746] , [747] and [748]). Produced from four discrete genes on four different chromosomal sites ([749] , [750] , [751] and [752]), the different peptide chains share structural features (e.g., leucine-rich repeats, specific interactions within the surface-expressed complex/system, and common absence in the deficiency state, Bernard-Soulier syndrome) ([735] , [753] , [754]) and form the receptor that mediates the shear-dependent interaction of platelets with vWF ([755] , [756] , [757] and [758]). The active site within gpIba binds the vWF ligand within a discrete region, termed the *A1 domain*, a structure that is distinct from the RGD-containing sequence in vWF that interacts with gpIIb-IIIa ([758] , [759]). Platelet gpIb-IX-V also binds thrombin in the same charged region of gpIba located to the COOH-terminal side of the seven leucine-rich repeats ([760]). The complex also serves as a thrombin receptor (in addition to its thrombin-binding quality) after the cleavage and removal of the gpV chain through proteolysis ([761] , [762]). Each chain has distinctive features: gpIba, with a large amount of sialic acid–rich O-linked carbohydrate in its macroglycopeptide region, contributes to the negative charge of the plasma membrane ([571] , [763]). gpIbß has a phosphorylation site and is disulfide bonded to the a-chain. gpIX has a single leucine-rich repeat, as does the ß-chain, whereas gpV has 15 tandem repeats ([747] , [748] , [764]). gpIba extends into the shear field of the extracellular environment through a variable number of 13–amino acid repeats ([765]) and also is connected to the platelet cytoskeleton by the interaction of its cytoplasmic domain with actin-binding protein ([766]). Both the a- and ß-chains interact with a potential signaling element termed ?14-3-3 ([767] , [768]). gpIb is present on platelet surfaces in a 2:2:1 ratio with gpIX and gpV, respectively ([769]), and patients with Bernard-Soulier syndrome who lack or have deficient levels of gpIb and gpIX ([735]) exhibit a bleeding diathesis. *gpIIb-IIIa* is the platelet fibrinogen receptor for aggregation and one of the major surface structures and is present in 50 to 100,000 copies distributed on the surface itself, the SCCS, and the a-granules ([732]). As a member of the integrin family of proteins, gpIIb-IIIa is a transmembrane heterodimer made up of a two-chain disulfide-linked a subunit with four divalent cation–binding domains and a disulfide bond–rich ß subunit ([736] , [737] , [770] , [771]). gpIIb and gpIIIa require Ca^{2+} to maintain their heterodimeric complex ([772]) and undergo a Ca^{2+}-dependent conformational change after platelet agonist–induced stimulation that facilitates strong binding to fibrinogen and vWF ([773] , [774]). This results in the cross-linking of gpIIb-IIIa molecules on adjacent platelets and subsequent platelet aggregation ([775] , [776] , [777] and [778]). As an integrin, gpIIb-IIIa recognizes the RGD sequence and binds to a variety of related adhesive, RGD-containing ligands, including fibrinogen, fibronectin, vWF, vitronectin, and thrombospondin ([779]). However, binding affinities vary between ligands, either soluble or immobilized, and the major ligand site on the C-terminus of the fibrinogen ?-chain lacks the RGD sequence ([777] , [778] , [779] , [780] and [781]). Platelets exhibit both inside-out (response to surface agonist) and outside-in (response to ligand binding of IIb-IIIa) signaling that regulates and responds to this dominant receptor activity ([777] , [778] , [779] , [780] , [781] and [782]). The precise molecular basis for the dramatic variations in ligand affinity and the pathways that signal to or from the receptor have been difficult to define. However, point mutations, detected in Glanzmann's thrombasthenia kindreds, have indicated various functional sites, and progress has been made in identifying activating elements ([783] , [784] , [785] , [786] , [787] , [788] and [789]). Recent progress suggests that calcium integrin–binding protein activates the receptor by binding to the cytoplasmic domain of IIb and that the Wiskott-Aldrich syndrome protein may play a role in this stimulatory process ([790] , [791] and [792]).

Other Surface Membrane Adhesive Receptors The *collagen receptors* are a set of three membrane proteins (gpIa-IIa, IV, and VI) that mediate collagen interactions. Early studies suggested a significant functional role for these proteins because suspended collagen is a powerful platelet agonist and activator *in vitro* ([793] , [794] , [795] and [796]). However, several issues arise when assessing the importance of these receptors. First, they tend to be present in relatively low density [<5000 per platelet ([797])]; second, their congenital deficiency states are either rare and found to diminish with age [gpIa-IIa deficiency ([796] , [798])] or common and of no clinical significance [i.e., approximately 5% of individuals in some populations lack gpIV and do not bleed ([799])]; third, they do not function under arterial flow conditions, during which the platelet contribution to hemostasis and thrombosis is most important ([800]). The proteins themselves are well characterized: gpIa-IIa ($a_2ß_1$ integrin, VLA-2) is an adhesion receptor for collagen whose degree of conformational change with platelet activation is debated ([796] , [801] , [802]); gpIV (CD36, gpIIIb, thrombospondin receptor) binds collagen in addition to other surface elements, such as red blood cells containing malarial parasites, but the significance of its contribution to platelet reactivity with collagen remains unclear ([803] , [804]); gpVI (member of the Ig superfamily) appears to play a role in signal transduction through *src* family kinases and may act in concert with the Fc? and gpIa-IIb receptors ([805] , [806]). To summarize, available knowledge suggests that these platelet collagen receptors have a modest, perhaps redundant, functional role.

Caveat Although not included here, vWF can be classified as part of the collagen and extracellular matrix receptor systems, because vWF binds to collagen and related molecules and, in turn, interacts with platelet gpIb. However, descriptions of the vWF–collagen interaction indicate that vWF is not activated by collagen or other subendothelial/extracellular matrix components ([807], [808]). In the absence of shear force, vWF bound to collagenlike materials does not differ from vWF bound to plastic or other inert surfaces ([708], [807], [809]). In the absence of stimulants (shear, ristocetin), no affinity exists between platelet gpIb and these soluble or immobilized forms of vWF. The conformational effect of shear on collagen-bound vWF is debated ([810], [811]). The integrin receptors for specific extracellular matrix components include gpIa-IIa for collagen, as noted above, and additional entities for fibronectin, laminin, and vitronectin. All four are trace integrin surface receptors that are found on a variety of cells, present in 1000 copies per platelet or less, whose contribution to platelet function is uncertain. The fibronectin receptor (gpIc-IIa, a $_5$ß $_1$, VLA-5, CD29) appears to function in resting platelets ([812]). A second, distinct platelet gpIc-IIa receptor (a $_6$ß $_1$, VLA-6, CD29) binds laminin in a cation-specific manner (Mg/Mn dependent, Ca independent) ([813]), whereas the last member of this group (a $_v$ß $_3$, CD51/61), present in 100 copies per platelet, uses a ß-chain identical to that of the IIb-IIIa receptor but binds selectively to vitronectin ([814]).

Additional Receptors Related to Adhesion PECAM-1 binds to heparinlike molecules and may contribute to platelet–heparin interactions and the interactions of platelets with other cells ([815]). P-selectin [platelet activation–dependent granule-external membrane protein (PADGEM); granule membrane protein-140] is present on a-granule membranes, as well as the Weibel-Palade body membranes of endothelial cells ([816]). Because it is translocated to the platelet plasma membrane after activation, its expression on the platelet surface has been used as an indicator of platelet activation *in vivo*. P-selectin mediates the adhesion of neutrophils and monocytes to activated platelets and endothelial cells and, thus, may serve to localize these cells to sites of injury ([816], [817]). A quadraspanin of uncertain function, *p24/CD9*, is abundant on platelet membranes and is found on a variety of other cell types as well ([818]). Other surface receptors found in platelets include the Fc?RIIA, with its capacity to bind immune complexes ([819]); intercellular adhesion molecule-2, capable of mediating platelet–leukocyte interaction ([820]); platelet-endothelial cell tetraspan antigen-3 ([821]) of uncertain function; several C1q complement receptors, potentially involved in platelet activation through the contact system ([822]); and a second nonintegrin receptor for laminin ([823]).

Surface Membrane Agonist Receptors for Thrombin, Adeno-sine Diphosphate, and Thromboxane A $_2$ A broad distinction is drawn between the *adhesive* receptors discussed above and the *agonist* receptors noted here. Three main agonist receptors are emphasized because of two attributes: first, their exceptional ability to activate platelets and their clear connection to plasma coagulation (thrombin receptors); second, their obvious clinical relevance as drug targets with clopidogrel acting upon an ADP receptor and aspirin through the thromboxane A $_2$ pathway. Most of these receptors prove to be seven-transmembrane, G protein–coupled *r*eceptors (GPCRs).

Platelet Thrombin Receptors: Protease-Activated Forms Platelets have two general forms of thrombin receptors: the well-known *p*rotease- *a*ctivated *r*eceptors (PARs) ([824]) and the recently reported form that arises when gpV is cleaved from the gpIb-IX-V complex (discussed above) ([761]). In human platelets, the major PAR for thrombin is the one first described in 1991 and now known as *PAR-1* ([825]), whereas the functional contribution of the second, PAR-4, remains unclear ([826]). In the mouse, knock-out technology has shown that more than one platelet PAR can be required for normal responsiveness to thrombin ([827]). The basic physiology of thrombin-mediated cleavage of an *N*-terminal peptide from the extracellular portion of any individual PAR remains applicable to all of the isoforms, with the newly exposed N-terminus then acting as a “tethered ligand” to activate the system through one of at least three G protein a subunits: Gaq, Ga12/13, and Gai ([828], [829] and [830]). The irreversible nature of the thrombin cleavage of the PARs is followed by subsequent uncoupling, internalization, and degradation of the receptor within lysosomes ([831]). One of the remarkable aspects of the platelet PAR system is its exceptional “strong agonist” quality that rapidly sets off irreversible platelet activation and aggregation despite the presence of only 2000 PAR molecules per platelet ([832], [833]). Also, the PARs appear to be a critical link between the plasma coagulation system of secondary hemostasis that produces thrombin and the platelet arm of hemostasis that depends on the “resting to activated” process induced by agonists ([834]).
