MCL is considered a part of the spectrum of diffuse small B-cell lymphomas. They usually express CD5 (pan T marker) and are negative for CD10 (follicular center B cells). The classic cytogenetic marker, t(11;14)(q13;q32), is detected in 50 to 70% of cases by conventional chromosome analysis or fluorescence *in situ* hybridization, or both ([424], [425]). Overexpression of cyclin D1 RNA or protein, or both, is found in more than 90% of cases and is considered the most reliable pathologic marker in the diagnosis of MCL ([426]). Recent identification of a minimally deleted segment of 11q22-q23 that affects the *ATM* gene in 50% of MCL suggests that this could be the initial genetic event before the *BCL1* translocation to chromosome 14 ([427]). Loss of tumor suppressor genes, including *p53* and *CDKN2/p16*, is an ongoing genetic change that is associated with an aggressive course in MCL ([299], [300], [428], [429]).

MCL has features of an indolent NHL, because of the absence of a plateau on the survival curve, and aggressive NHL, because of short median survivals of 2.5 to 4.0 years (Fig. 90.11) ([345], [420], [421] and [422]). Although response rates are 50 to 90%, CRs are usually less than 50%, and median time to treatment failure is usually less than 18 months ([330], [430]). Although some investigators have recommended using anthracyclines in therapy ([431]), there is no randomized trial that proves the efficacy of anthracycline-based therapy over other regimens ([432], [433]). Similarly, there was no advantage to fludarabine plus idarubicin compared to fludarabine alone in a randomized trial that involved MCL patients ([434]). Cyclophosphamide and fludarabine and cladribine and mitoxantrone are other effective combinations for MCL in phase II trials ([435], [436]). Responses with rituximab have been in a range from 20 to 38% in relapsed MCL, and it is now being added to chemotherapy regimens ([430], [437]). CHOP plus rituximab resulted in a high response rate (96%: 48% CR and unconfirmed complete response and 48% PR) in 40 newly diagnosed MCL patients, but 28 (70%) relapsed or developed progressive disease with a median PFS of 16.6 months ([438]). Even patients who had achieved a molecular CR had no improvement in PFS ([438]).

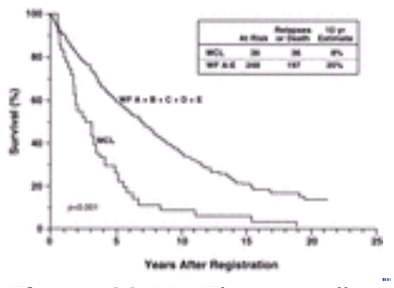

Figure 90.11. The overall survival of 36 patients with mantle cell lymphoma (MCL) is significantly worse when compared to 248 patients with indolent lymphomas that are recognized by the Working Formulation (WF) as types A through E. [From Fisher RI, Dahlberg S, Nathwani BN, et al. A clinical analysis of two indolent lymphoma entities: mantle cell and marginal zone lymphoma (including the mucosa-associated lymphoid tissue and monocytoid B-cell subcategories): a Southwest Oncology Group Study. Blood 1995;85:1075–1082, with permission.]

More intensive regimens, often using stem cell transplantation (SCT), have had mixed results in MCL. The best published results are by Khouri et al. ([439]) from MDACC, who used hyper CVAD (cyclophosphamide, vincristine, doxorubicin, and dexamethasone) followed by autologous or allogeneic transplantation. For previously untreated patients, the 3-year event-free survival (EFS) and OS were 72% and 92%, respectively, compared to 17% ($p = .007$) and 25% ($p = .005$) in previously treated patients. Other autologous transplant series for MCL have not seen plateaus on survival curves even in first CR, and results approach zero survival in heavily treated patients ([440] , [441]). Myeloablative radioimmunotherapy or allogeneic transplantation have been successful in resistant MCL ([442] , [443]). The optimal chemotherapy and use of SCT have yet to be determined in MCL.

AGGRESSIVE LYMPHOMAS

Diffuse Large B-Cell Lymphomas

One of the problems of the WF was the heterogeneity of the neoplasms that were called *intermediate grade*. Subsets of intermediate-grade lymphomas, such as diffuse small cleaved, many of which are MCLs, behave clinically as low-grade neoplasms; that is, they have high relapse rates and have been difficult to cure. Intermediate-grade lymphomas that are curable with chemotherapy include DLBCL, B-cell immunoblastic lymphoma, and Ki-1+ ALCL (predominantly T cell in origin). Another subset of intermediate-grade lymphoma within the WF was diffuse mixed lymphoma (DML), which is also heterogeneous and generally has had a higher relapse rate than DLCL ([444]). The higher relapse rate in DML might be accounted for by the inclusion of low-grade lymphomas and some PTCL, which have generally been harder to cure than DLBCL ([269] , [270] and [271] , [445]).

Despite the recognition of DLBCL as a pathologic category within the WHO classification, it is heterogeneous. DLBCL constitutes as much as 20 to 25% of NHL in many series, and 40 to 50% of cases are curable in adults. Differences within the category of DLBCL include pathology and molecular genetics. Although B-cell immunoblastic lymphoma was categorized as high grade in the WF, it is generally regarded as intermediate grade in that no apparent differences in survival exist between it and other DLBCL in some series ([446] , [447]). T-cell–rich B-cell lymphomas, many of which were previously within the DML category, are believed to represent a subset of large B-cell lymphoma in which the malignant large B cell is the minority cell ([448]). $CD5^+$ DLBCL is associated with a higher IPI than the more common $CD5^-$ DLBCL and has a correspondingly worse survival ([449]). Within the category of DLBCL, there are molecular genetic differences that are associated with survival differences and probably are important in developing therapeutic strategies (see the section Prognostic Factors) ([301] , [302]).

Although studies are ongoing to identify different subgroups within DLBCL, therapy is directed at clinical features, pathology, and stage of disease (see the section Therapeutic Principles). Because DLBCL represents a group of potentially curable neoplasms, prognostic factors are important to recognize and can influence the type, intensity, and duration of therapy. Selecting the intensity of therapy based on prognostic factors is referred to as *risk stratification* and has been applied successfully in pediatrics in which the curability of all types and stages of NHL approaches 80% (Chapter 91).

Unique clinical presentations of DLBCL include large B-cell lymphoma of the leg, intravascular B-cell lymphoma, and mediastinal large B-cell lymphoma, the latter of which is recognized by the WHO classification. Large B-cell lymphoma of the leg is seen in the elderly and has a poorer prognosis than other cutaneous B-cell lymphomas ([450]). Intravascular B-cell lymphoma was recognized in 1959 and was known as *malignant angioendotheliomatosis* ([451] , [452]). It occurs in the elderly (median age, 65 to 70 years) and most commonly affects the skin and CNS. Symptoms are usually related to ischemia secondary to occlusion of blood vessels, and approximately one-half of cases are first detected at autopsy ([452]).

MEDIASTINAL LARGE B-CELL LYMPHOMA The WHO classification recognizes a distinct large B-cell lymphoma that probably arises from the thymus and that can be confused with LL, HD, thymomas, and extragonadal germ cell neoplasms ([453] , [454] , [455] , [456] , [457] and [458]). Primary mediastinal B-cell lymphomas (PMBL) constitute 2 to 3% of NHL and occur predominantly in women (female to male ratio is approximately 2:1) and young adults; three-fourths of patients are younger than 35 years of age ([453]). Gains in chromosome 9p have been recognized in as much as 50% of patients ([459]). *BCL2* and *BCL6* gene rearrangements rarely occur; overexpression of the *MAL* gene is common ([460]). Presenting features are usually of short duration, varying from a few weeks to several months, and include chest pain (73%), cough (60%), dyspnea (46%), and superior vena cava obstruction (30 to 57%) ([454] , [457]). More than two-thirds of patients have large masses (=10 cm). Local extension of the mass into the pericardium, chest wall, or lung is common, whereas distant involvement of peripheral nodes, marrow, or CNS is infrequent ([453] , [454] , [458]). Unusual extranodal sites of involvement include kidney, ovaries, and adrenal glands. Although early reports indicated a poor prognosis despite combination chemotherapy, more recent studies have had a good prognosis similar to other DLBCL ([454] , [456] , [457]). Some of the best results have added involved field radiation therapy ([454] , [457]), but some series have had equally good results without radiation; thus, the role of radiation remains controversial ([456]). As much as one-third of patients fail induction therapy, but the 3-year FFS ranges from 38 to 88% ([458]). Poor prognostic factors in PMBL have been the presence of pleural or pericardial effusion, multiple extranodal sites (=2) of disease, bulk (=10 cm), high LDH (more than three times the normal level), and a persistently positive gallium or PET scan posttherapy ([453] , [457] , [458]). Because the disease is usually localized and occurs in young people, the IPI may have limited value ([453] , [457]). SCT has been used in PMBL, and results vary according to remission status and chemosensitivity ([461] , [462]).

Peripheral T-Cell and Natural Killer–Cell Lymphomas

The clinical significance and the management of PTCL are areas of controversy in part because of the relative infrequency as compared to B-cell lymphomas and the lack of controlled trials that evaluate the impact of immunophenotype on prognosis ([270] , [463] , [464]). PTCL and NK-cell neoplasms represent less than 15% of NHL in the West, and there are multiple subtypes, so that most represent less than 1% of NHL ([465]). PTCL often is associated with paraneoplastic phenomena, including skin rashes, autoimmune hemolytic anemia, hypergammaglobulinemia, eosinophilia, hypercalcemia, vasculitis, and hemophagocytosis, which may obscure the initial diagnosis ([466]).

Attempts have been made to separate postthymic T-cell neoplasms into low-grade and intermediate- to high-grade subcategories; however, the so-called low-grade T-cell lymphomas may have an aggressive course and can undergo histologic transformation similar to that seen in low-grade B-cell lymphomas ([467]). Cytogenetic differences have been used in an attempt to separate PTCL into low- and high-grade categories ([298]). PTCLs that have been described with an indolent course include angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) (AILD-like T-cell lymphoma), T-zone lymphoma, and lymphoepithelioid lymphoma (Lennert lymphoma) ([467] , [468] and [469]); only AILD is described in the WHO classification as a distinct entity (angioimmunoblastic T-cell lymphoma), whereas the latter two entities would be referred to as *PTCL, not otherwise specified*. Lennert lymphoma typically occurs in older patients, often with diffuse adenopathy and involvement of Waldeyer ring, and has a clinical course that is characterized by recurrent relapses ([468] , [469]).

The WHO classification separates the mature T- and NK-cell neoplasms by site of involvement: nodal, extranodal, leukemic, and cutaneous. In the subsequent section, the focus is primarily on nodal and extranodal diseases, followed by a brief description of the leukemias. CTCLs are reviewed in Chapter 94.

KI-1+ ANAPLASTIC LARGE CELL LYMPHOMA Since the original description of Ki-1+ (CD30) ALCL by Stein et al. in 1985, a type of ALCL has become a paradigm for the WHO classification for NHL ([220] , [470]). In the past two decades, the clinical, morphologic, immunophenotypic, and genetic spectrum of ALK-positive ALCL has

been defined. The first clinical description of ALCL was in a series by Kadin et al. (471) in six children, all of whom had skin lesions. Subsequent studies that included adults recognized a common lymphoma (2 to 8% of NHL) with a wide morphologic spectrum, young median age, peripheral adenopathy with relative sparing of the mediastinum, frequent extranodal disease, and a good prognosis (220 , 472 , 473). In 1989, a proportion of ALCLs were associated with a specific chromosomal translocation (474 , 475), and, in 1994, Morris et al. (476) identified the genes that are involved in the t(2;5) (Chapter 89). *ALK* rearrangements are present in 50 to 70% of CD30 $^{+}$ ALCL, and the t(2;5) occurs in approximately three-fourths of these patients (220 , 477). Cytogenetic variants have been described, with t(1;2)(q25;p23) as the most common (477). Immunocytochemical stain for the ALK protein is usually present in cytoplasm and nuclei of the classic t(2;5)(p23;q35), whereas it is present only in the cytoplasm of the variants (220 , 244). Because the variants are of T- or null-cell origin and occur in a similar age group as the t(2;5), Falini et al. (244) proposed the term *ALKoma* for all patients expressing the ALK protein. ALK expression subdivides ALCL into at least three clinical subtypes of ALCL: (a) ALK-positive systemic ALCL, (b) ALK-negative systemic ALCL, and (c) primary cutaneous ALCL (also ALK negative). ALK-positive ALCL occurs at a younger median age (15 to 30 years) than ALK negative (45 to 65 years), has a male predominance (male to female ratio is 2 to 6:1), and usually has advanced-stage disease with frequent B symptoms (40 to 75%) and extranodal involvement (50 to 80%) (220 , 244 , 478). Skin (21 to 35%), soft tissue (17%), and bone (8 to 17%) are common extranodal sites, whereas the gastrointestinal tract and CNS are rarely involved (220). Bone marrow involvement in ALK-positive ALCL is identified in 10 to 15% with hematoxylin and eosin stains but in as much as 30% if immunohistochemistry stains are used to identify isolated ALCL cells (220 , 479). Limited data indicate that ALK-positive ALCL is more chemosensitive than ALK-negative ALCL, with CR rates being greater than 75% for ALK-positive ALCL and 50 to 75% in ALK-negative ALCL (244 , 478). Better responses have resulted in a twofold or higher increase in survival for ALK-positive ALCL (71 to 93% at 5 years), compared to ALK-negative ALCL (15 to 46%) in retrospective series (244 , 478 , 480); however, not all series have confirmed an improved survival for ALK-positive ALCL (481). Differences among studies could be due in part to the favorable younger age of ALK-positive ALCL, but an improved survival has been reported for ALK-positive ALCL over ALK-negative ALCL in patients who are younger than 30 years of age (480). Another problem with comparing ALK-positive ALCL to ALK-negative ALCL is the fact that the latter represents a het-erogeneous group of diseases. ALK-negative ALCL may be considered as secondary ALCL when it follows mycosis fungoides, lymphomatoid papulosis, or HD (220). Hodgkin-like ALCL is formerly a provisional diagnosis of the WHO classification but is probably a variant of HD (482). ALK-negative ALCL can rarely be of B-cell origin either with an aggressive course or in the setting of AIDS (220 , 483). Primary cutaneous ALCL is another ALK-negative ALCL, is part of the spectrum of CD30 $^{+}$ cutaneous lymphoproliferative disease, and clinically overlaps with lymphomatoid papulosis (Chapter 94) (471 , 484). It usually arises in the skin in an older patient (median age is approximately 60 years) as an isolated reddish-violet tumor, which may be ulcerated. Less commonly, it may present as multiple nodules in a circumscribed area or, rarely, with disseminated skin lesions. Treatment of localized lesions may include watchful waiting, because approximately one-fourth of patients regress, as well as local excision with or without radiation or radiation alone (220). Combination chemotherapy may be warranted with widespread skin disease or localized skin disease with adjacent nodal involvement, but these patients tend to relapse (485). Although therapy for adults has not been stratified according to prognostic factors in ALCL, pediatric groups have stratified therapy according to risk factors and have a 5-year EFS that is greater than 70% even for the ALCL patients with multiple adverse features (486). Some investigators have advocated a role of autologous transplant in first CR for adults with ALCL and report a greater than 90% DFS (487). They justified SCT based on the early data that the IPI did not correlate with prognosis in ALCL (488). Because prognosis does correlate with IPI and ALCL has a good response to chemotherapy, a policy of transplantation in first CR cannot be supported in most patients (244). In addition, preliminary data indicate that ALK-positive ALCL has a high salvage rate with SCT in chemosensitive relapse (489).

NODAL PERIPHERAL T-CELL LYMPHOMA The distribution of PTCL varies according to geography, viral associations, and referral patterns (270 , 316 , 490 , 491 , 492 , 493 , 494 , 495 and 496). In the West, nodal disease predominates with PTCL, not otherwise specified; ALCL and AILD represent the largest groups, whereas in the Far East, there are increased numbers of extranodal disease, often of nasal origin with angiocentric features and an association with EBV (492). In HTLV-1 endemic areas, as much as one-half of the T- and NK-cell neoplasms are ATLL (493). Problems in management of PTCL include the fact that, unlike B-cell NHL, cell size does not correlate with prognosis, and there are sparse data regarding the impact of cytogenetics on diagnosis other than ALK expression in ALCL. The IPI does correlate with prognosis in PTCL, but only the low risk (0, 1) has prolonged survival that is greater than 50% (316 , 494). Expression of chemokine receptors differs among PTCL and could contribute to biologic differences (497). Genomic profiling is likely to identify different prognostic subsets among PTCL, as has been done in DLBCL (301 , 302). AILD-like T-cell lymphoma serves as a model for the problems with assigning grade and therapy to some PTCL. AILD usually occurs in older patients with a median age between 57 and 68 years of age; they frequently have B symptoms, generalized adenopathy, skin rash, organomegaly, anemia, and polyclonal hypergammaglobulinemia (498). The clinical course of AILD is variable, with spontaneous remissions occurring in as much as 10% of patients. Single agents, primarily steroids, but also alkylating agents, methotrexate, IFN, and cyclosporine can achieve responses, but many patients develop a progressive lymphoma. Although AILD can respond to single agents, combination chemotherapy is usually recommended once a diagnosis is confirmed. The CR rate with anthracycline-based regimens is in the range from 50 to 70%, but patients have frequent relapses or death due to infection, so that median survivals are short (11 to 30 months) (498 , 499). There is clonal evolution over time in AILD (500), and EBV may participate in lymphomagenesis (501). TCR gene rearrangements occur early in the course of AILD, thus indicating a clonal T-cell population; some patients have also had Ig gene rearrangements. Similar to posttransplant lymphoproliferation but unlike other NHL, unrelated or oligoclonal clones are commonly found in AILD (500). The most common cytogenetic abnormalities are trisomy 3, trisomy 5, and an additional X chromosome, but patients who develop complex aberrant clones and structural abnormalities in the short arm of chromosome 1 progress rapidly (500 , 502). EBV can be identified in B and T cells of AILD, and it may participate in the occasional B-cell immunoblastic lymphoma as well as the more common PTCL (503). Cytokines, particularly lymphotoxin and tumor necrosis factor-a, are primarily found in B cells and probably contribute to the clinicopathologic course of AILD (504). Because the clinical course is variable, and no single therapy has been shown to be better, optimal treatment for AILD-like T-cell lymphoma remains to be defined.

EXTRANODAL T-CELL AND NATURAL KILLER–CELL LYMPHOMAS Hepatosplenic ?d T-cell lymphoma was first described in 1990 as an aggressive illness with B symptoms and organomegaly in young adult men (505). The median age is 29 years of age, and patients have splenomegaly (98%), hepatomegaly (80%), minimal to no lymphadenopathy, anemia (84%), and severe thrombocytopenia (85%) (506). The bone marrow is involved in 72% of patients, and erythrophagocytosis may occur (506). Isochromosone 7q, which is often associated with trisomy 8, is a common cytogenetic abnormality (507). Most patients are refractory to anthracycline-based therapy, with CR rates that are less than 15% and median survival of 8 months (506). Because of the poor prognosis, there may be a role for allogeneic SCT (506). There is an aß variant with similar features and prognosis (508). Subcutaneous panniculitis-like T-cell lymphoma presents with subcutaneous nodules, usually on the extremities, and is often associated with systemic symptoms and erythrophagocytosis (509 , 510 and 511). Median age is 43 years of age, and women predominate. There can be nodal dissemination, but a poor prognosis is usually due to fulminant hemophagocytosis. Median survival is usually less than 2 years, but occasional patients without hemophagocytosis have an indolent course, and some patients have had prolonged remissions after chemotherapy (509 , 510 and 511). EATL has an association with celiac disease but has occurred without it as well (512 , 513 and 514). The median age is 50 years of age, and men predominate (514). Abdominal pain and weight loss occur in more than four-fifths of patients at presentation, followed by diarrhea or vomiting in one-third of patients (514). Small bowel obstruction or perforation is common, and the diagnosis of EATL is usually made at laparotomy. Prognosis is poor, with a median survival of 7.5 months and a 1-year FFS of less than 20% (514). Nasal and nasal-type NK- and T-cell lymphomas are characterized by angiocentric and angiodestructive proliferation; LGL morphology; CD2 $^{+}$, CD3 $^{-}$, CD16 $^{-/+}$, CD56 $^{+}$, CD57 $^{-}$ phenotype; and an aggressive course (93 , 515 , 516). Only 10% express surface CD3 $^{+}$, have clonal TCR rearrangement, and have a similar course (517). Nasal NK- and T-cell lymphomas may present with facial swelling or mid-facial destruction and was formerly called *lethal midline granuloma* or *polymorphic reticulosis*. The disease occurs more commonly in men with a median age of 50 to 55 years of age (515 , 516). Nasal NK- and T-cell lymphoma is localized stages I and II in 80% of patients at diagnosis but can disseminate early to skin, gastrointestinal tract, testis, orbit, and CNS. Although radiation alone can achieve CR in two-thirds of localized disease, local relapse occurs in one-half of patients, and disseminated disease develops in one-fourth of patients (515). Combined modality therapy and CNS prophylaxis are recommended. Prognosis is variable, with a long-term survival of 20 to 80%, usually only in the patients with stage I, nonbulky disease (515 , 516 and 517). Nasal-type NK- and T-cell lymphoma is essentially disseminated nasal disease without obvious nasal involvement (518). Only one-fifth of patients have stage I disease (518). Despite anthracycline therapy, median survival is less than 1 year (518). Patients with cutaneous-only involvement have a better survival (519). A disseminated, leukemic form is usually fatal within weeks (520). Because of poor prognosis, there may be a role for transplant in some patients with nasal-type NK- and T-cell lymphomas (521).

Mature T-Cell and Natural Killer–Cell Leukemias

The differential diagnosis of CLL in Chapter 92 includes the mature T- and NK-cell leukemias. LGL leukemia was associated with chronic neutropenia in 1977, was recognized as a clonal disorder in 1985, and was classified into T-cell (CD3 $^{+}$) and NK-cell (CD3 $^{-}$) types in 1993 (Fig. 90.12A) (180 , 522 , 523). The median age is 55 years of age, and there is an association with rheumatoid arthritis and autoimmune features (180 , 524). Lymphocytosis is usually between 2 to 20 × 10 ^{9} per L, and mild splenomegaly may be present, but the usual clinical presentation and problem is neutropenia or anemia (180). Pure red cell aplasia, autoimmune hemolytic anemia, aplastic anemia, idiopathic thrombocytopenic purpura, and myelodysplastic syndrome (MDS) may occur in LGL leukemia (180). Leukemic LGL cells express high levels of Fas and Fas ligand, but the cells are resistant to Fas-mediated death due to signal transducer and activator of transcription type 3 activation, which up-regulates an antiapoptotic protein (525 , 526). LGL leukemia is an indolent disease, with a median survival of longer than 10 years in a series of 68 patients (527).

Immunosuppressant drugs, which have been used in LGL leukemia, include methotrexate, cyclosporine, prednisone, and cyclophosphamide ([527], [528] and [529]). Prolonged treatment with methotrexate of 1 to 2 years has resulted in CR in as much as 50% of patients ([528]).

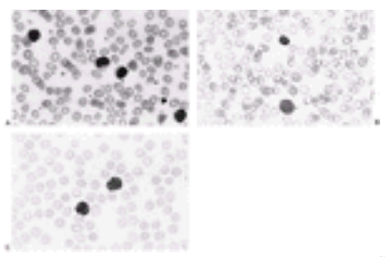

Figure 90.12. Mature T-cell and natural killer–cell leukemias. **A:** Peripheral blood, T-cell granular lymphocytic leukemia. Two lymphocytes that have oval-shaped nuclei, condensed chromatin, inconspicuous nucleoli, and abundant pale cytoplasm that contains azurophilic granules are in the center of the field. These lymphocytes have the characteristic morphology of large granulocytes that are normal constituents of the peripheral blood or that can be seen in large granular lymphocytic leukemia or in some reactive states. **B:** Peripheral blood, peripheral T-cell lymphoma of cytotoxic (natural killer–like) T-cell phenotype. A neoplastic large lymphocyte that has clumpy chromatin, a discernible nucleolus, and a modest amount of basophilic cytoplasm that contains a few azurophilic granules is associated with a smaller peripheral blood lymphocyte. The lymphoma had a $CD56^{+}$ and perforin+ T-cell phenotype. **C:** Peripheral blood, T-cell prolymphocytic leukemia, small ("knobby") cell variant. Small lymphocytes with markedly irregular ("knobby") nuclear profiles, coarse chromatin, variably discernible nucleoli, and scant agranular cytoplasm are characteristic of the small cell variant of T-cell prolymphocytic leukemia ("T-cell chronic lymphocytic leukemia"). See Color Plate. (Courtesy of William Macon, Mayo Clinic, Rochester, MN.)

Aggressive NK- and T-cell leukemia is a rare disorder more common in Asia and often is associated with EBV, and some cases may represent the leukemic phase of nasal-type NK-cell lymphoma (Fig. 90.12B) ([530], [531] and [532]). Patients are usually teenagers to young adults, with slight male predominance, and present with a fulminant illness that is characterized by diffuse adenopathy, organomegaly, and circulating LGL cells that can have a blastic appearance ([531], [532]). Patients are usually chemoresistant and have median survivals of less than 3 months ([531], [532]). Rare NK-cell–like T-cell lymphomas present with B symptoms and organomegaly, have occurred in immunosuppressed hosts, and usually have a similar fatal course, which can include a leukemic phase ([203], [533]). Immature NK-cell neoplasms include myeloid and NK-cell precursor acute leukemia and blastic NK-cell lymphoma/leukemia ([534]).

T-prolymphocytic leukemia (T-PLL) represents approximately 2% of small lymphocytic leukemia in adults (Fig. 90.12C) ([535]). The median age is 57 to 69 years of age, and the male to female ratio is 1.5:1.0 ([536], [537]). Patients usually have a marked lymphocytosis (>100 × 10^{9} per L in 75% of patients), splenomegaly (73%), and lymphadenopathy (53%), and approximately 20% of patients have skin infiltration ([535], [536]). Cell morphology is variable; the nuclei are irregular, include a "knobby" variant, and usually have prominent nucleoli; cytoplasmic protrusions are characteristic. Sixty percent of patients are $CD4^{+}$ and $CD8^{-}$; 25% coexpress $CD4^{+}$ and $CD8^{+}$; and 15% are $CD4^{-}$ and $CD8^{+}$ ([535], [536]). The most common cytogenetic abnormality, occurring in 80% of patients, is an inversion of chromosome 14 with breakpoints in q11 and q32; 10% have a reciprocal translocation t(14;14)(q11;132) ([535], [538]). These translocations juxtapose the locus of the *TCR* aß gene with the *TCL1* and *TCL1b* genes at 14q32 ([539]). Deletions at 11q23, the locus for the *ATM* gene, and 12p13 and abnormalities of chromosome 8 are other common cytogenetic findings in T-PLL ([535], [540]). Response rates in T-PLL are 10 to 48%, with few CRs using chemotherapy, including CHOP or nucleoside analogs ([536], [537]). Median survival is usually 1 year, although as much as one-third of patients can have an indolent phase ([536], [537], [541]). The best responses have been reported with alemtuzumab (Campath 1H), and preliminary data recommend proceeding to an allogeneic transplant if a donor is available ([542], [543]).

The clinical course of ATLL is variable and takes four basic forms: (a) acute, (b) lymphoma, (c) chronic, and (d) smoldering. The male to female ratio is 1.3 to 2.2:1, and the median age is 47 to 65 years of age ([544], [545] and [546]). Between 55 and 65% of patients have the acute form, which is characterized by lymphadenopathy; organomegaly; skin lesions; elevated white count with multilobed lymphocytes, often referred to as *cloverleaf* or *flower* cells (Fig. 90.2A); hypercalcemia; elevated LDH level; and, usually, a rapidly fatal course ([545], [546], [547] and [548]). The cutaneous lesions have a diverse appearance, including papules, nodules, plaques, tumors, and ulcers. Histologically, dermal invasion predominates, although the lesions of ATLL may resemble primary CTCL with epidermotropism and Pautrier microabscesses. Anemia and thrombocytopenia are infrequent findings because of a low degree of marrow infiltration. CNS involvement may develop in as many as 10% of patients with ATLL ([549]).

Lymphoma is the second most common form of ATLL, represents 20 to 25% of cases, and is distinguished by prominent adenopathy without significant peripheral blood involvement. Primary extranodal lymphoma occurs in approximately 5% of lymphomatous presentations and has involved skin, Waldeyer ring, gastrointestinal tract, sinuses, and pleura ([550]). The chronic type is associated with an increased white blood cell count and occasionally with slight adenopathy and organomegaly. Patients with smoldering ATLL have few ATLL cells (0.5 to 3.0%) in the peripheral blood and may have skin lesions, as well as slight adenopathy, organomegaly, and marrow infiltration ([551]). Chronic or smoldering ATLL, or both, may evolve into an acute form after many years of indolent disease ([552], [553]).

No consistent cytogenetic abnormality has been identified in ATLL, but the most common abnormalities are trisomy 7,6q–, and 14q+ ([25], [554], [555]). Aneuploidy, multiple chromosomal breaks, and loss of tumor suppressor genes are associated with an aggressive course ([556]).

Despite combination chemotherapy, which can yield brief responses, median survivals in the acute and lymphomatous forms of ATLL are less than 10 months ([235], [557]). Poor performance status, high LDH, age older than 40 years, tumor bulk, and hypercalcemia are adverse prognostic factors ([235], [557]). The chronic and smoldering forms have a longer survival rate regardless of therapy ([552], [558]). The major causes of death in ATLL are opportunistic pulmonary infections and progressive disease, often in association with hypercalcemia ([547], [559]). New chemotherapy agents have included nucleoside analogs and topoisomerase inhibitors, but response rates are 10 to 40% and are brief in duration ([560], [561] and [562]). Conjugated and unconjugated monoclonal antibodies directed at the IL-2 receptor have activity in ATLL and remain under investigation ([563]). There are data that indicate improved responses to a combination of IFN-a and zidovudine ([564], [565]). Because of the poor prognosis, there may be a role for early allogeneic transplantation.

THERAPY FOR LOCALIZED LARGE CELL LYMPHOMA

Localized disease is defined by stage I or II disease that is nonbulky (no tumor mass =10 cm; no mediastinal mass greater than one-third of the chest diameter) ([566]). Radiation therapy alone has resulted in 20 to 85% cure rates for limited-stage large cell lymphomas, with the best results in patients who have stage I disease after undergoing pathologic staging ([567], [568]). With clinical staging, cure rates with radiation alone have usually been less than 50%; therefore, most investigators are advocating chemotherapy, usually CHOP-type regimens, often followed by radiation, with cure rates of 70 to 90% ([569], [570] and [571]). Patients with stage I disease have generally done better than stage II patients, with cure rates greater than 90% in some series ([571]).

Recent clinical trials have addressed the issue of chemotherapy versus combined modality therapy in limited-stage large cell lymphoma and have favored combined modality for adults ([572], [573]). In a SWOG study, patients with localized intermediate- or high-grade NHL were randomized to three cycles of CHOP followed by involved field radiation therapy (4000 to 5500 cGy) versus eight cycles of CHOP ([573]). Better PFSs (77% vs. 64%; $p = .03$) and OS (82% vs. 72%; $p = .02$) were observed in the combined modality arm, and there was a trend toward increased toxicity, particularly cardiac, in the chemotherapy-only arm ([573]). A subsequent follow-up report, however, indicates no difference in survival between the two arms ([574]). Similar randomized trials in children, as well as adults, have not shown a benefit to chemotherapy plus radiation over chemotherapy alone in limited-stage patients ([575]). Other concerns of the SWOG study are that eight cycles of CHOP are probably excessive for localized disease and that radiation contributes to the risk of long-term toxicities. Thus, although short-course chemotherapy (three to four cycles) followed by radiation is an accepted treatment for adults for localized large cell NHL, ongoing trials are still warranted to identify patients who can do well with chemotherapy alone.

CHEMOTHERAPY

In the early 1970s, DeVita et al. at the NCI introduced a combination chemotherapy regimen, C-MOPP (cyclophosphamide replacing mechlorethamine, vincristine, procarbazine, and prednisone), which produced a CR rate in excess of 40% in patients with diffuse “histiocytic” lymphoma, a neoplasm that is generally equivalent to DLCL; approximately one-third of these patients were cured ([566], [576]) (Table 90.10). By the middle 1970s, doxorubicin had been added to cyclophosphamide, vincristine, and prednisone to produce the CHOP regimen, which produced CR rates of 50 to 60% and a DFS of 30 to 40% ([381], [577]). CHOP remains the most extensively studied and used regimen in the therapy of large cell lymphoma. Other first generation regimens with similar cure rates include BACOP (bleomycin, doxorubicin, cyclophosphamide, vincristine, and prednisone) ([578]) and COMLA (cyclophosphamide, vincristine, methotrexate, leucovorin, and arabinosylcytosine) ([579], [580]). Important clinical observations were that rapid achievement of a CR was associated with a good prognosis ([306], [577]) and that relapses after 2 years of DFS were rare. Further follow-up for large cell lymphoma, however, has recorded relapses in 6 to 22% of patients after 2 years of CR ([306], [581]).

TABLE 90.10. Chemotherapy Programs for Non-Hodgkin Lymphoma, Predominantly Large Cell Lymphoma

Regimen	Institution (Reference)	Number of Patients	Complete Remission (%)	Disease-Free Survival (%)	Comments
First generation					
C-MOPP	National Cancer Institute (576)	27	45	37	Initial report of curative therapy.
CHOP	Southwest Oncology Group (381)	250	58	34	Introduced anthracyclines; still the most commonly used therapy.
BACOP	National Cancer Institute and Dana Farber Cancer Institute (590)	99	48	34	Introduced bleomycin.
COMLA	Yale University and University of Chicago (579, 580)	54	44	32	Introduced methotrexate and cytarabine.
Second generation					
M-BACOD	Dana Farber Cancer Institute (585)	81	72	41	High-dose methotrexate used; includes late relapses with 8-yr median follow-up.
m-BACOD	Dana Farber Cancer Institute (584)	131	61	47	Lower-dose methotrexate had similar results to high dose; identified prognostic categories.
ProMACE-MOPP	National Cancer Institute (586)	79	74	47	Introduced flexible therapy concept; 10% mortality.
COPBLAM	New York Hospital, Cornell Medical Center (583)	48	73	55	Introduced continuous infusions of vincristine and bleomycin.
CAP-BOP	University of Nebraska (310)	51	73	54	Continuous infusions of vincristine and bleomycin along with higher doses of cyclophosphamide and doxorubicin.
Third generation and newer					
MACOP-B	Cancer Control Agency, British Columbia (589)	126	86	58	Short (12-wk) therapy with antibiotic prophylaxis; new regimen (VACOP-B) replaces methotrexate with etoposide and has equivalent results with less toxicity.
COPBLAM-III	New York Hospital, Cornell Medical Center (587)	51	84	65	Introduced continuous infusions into therapy.
CODBLAM-IV	New York Hospital, Cornell Medical Center (583)	61	88	64	Introduced higher doses of cyclophosphamide and doxorubicin as consolidation.
ProMACE-CytaBOM	National Cancer Institute (590)	94	86	69	Better results than ProMACE-MOPP when compared in randomized trials.
LNH regimens	Groupe Francais d'Etude des Lymphomes Agressifs (GELA Group), France (445, 588, 612, 613)				Dose-intensive regimen; T immunophenotype had inferior survival to B immunophenotype. Randomized arm to intensification and transplantation in LNH-84, LNH-87, and LNH-93 did not improve survival. LNH-93 stratifies patients according to age, IPI, and ß$_2$-microglobulin.
LNH-80		100	84	59	
LNH-84		737	75	48	
LNH-87		273	61	54	
LNH-93		181	64	52	
MEGA-III	Vanderbilt University Medical Center (609)	36	75	58	Phase II, short, dose-intensive therapy in poor prognosis patients.
CHOP-B/CMED	M. D. Anderson Cancer Center (591)	138	78	58	Alternating non–cross-resistant regimens included involved field radiation in stage II and III patients and had better 5-yr survival than historic control of CHOP-B alone.
High-dose CHOP	Dana Farber Cancer Institute (608)	22	86	69	Phase II study to determine maximum tolerated dose of CHOP (plus G-CSF) with short follow-up.
200% ProMACE-CytaBOM	Eastern Cooperative Oncology Group (610)	74	69	71	Phase II trial of dose intensity plus G/GM-CSF.
EPOCH	National Cancer Institute (604)	50	92	70	Dose-adjusted phase II trial; 70% is progression-free survival.

BACOP, bleomycin, doxorubicin, cyclophosphamide, vincristine, prednisone; CAP-BOP, cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, prednisone; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; CMED, cyclophosphamide, methotrexate, etoposide, dexamethasone; C-MOPP, cyclophosphamide, vincristine, procarbazine, prednisone; COMLA, cyclophosphamide, vincristine, methotrexate, leucovorin, cytarabine; COP(D)/BLAM, cyclophosphamide, vincristine, prednisone (dexamethasone)/bleomycin, doxorubicin, procarbazine; CytaBOM, cytarabine, bleomycin, vincristine, methotrexate; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; MACOP-B, methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin; M/m-BACOD, high dose (M) or low dose (m) methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, dexamethasone; ProMACE-MOPP, prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide/mechlorethamine, vincristine, procarbazine, prednisone.

Subsequent regimens were developed in part on the concepts of Goldie and Coldman, who proposed that tumors develop drug resistance by spontaneous mutation soon after exposure to chemotherapy, and of Hryniuk and Bush, who proposed that increasing dose intensity could overcome drug resistance ([582]). Thus, new regimens introduced as many non–cross-resistant chemotherapeutic agents as early as possible and at the highest doses that were tolerable. Some of the regimens, such as Pro-MACE-MOPP, used a non–cross-resistant regimen after a patient achieved a maximum response with the initial regimen. Second-generation regimens

included COPBLAM (cyclophosphamide, vincristine, prednisone, bleomycin, doxorubicin, and procarbazine) ([583]); m/M-BACOD [regular and moderate-dose methotrexate, bleomycin, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), and dexamethasone] ([314], [584], [585]); and ProMACE-MOPP ([586]), which produced CR rates of 70 to 76% and a DFS of 40 to 55% in patients with predominantly large cell lymphomas ([582]).

Third-generation regimens, which included variations of COPBLAM ([583], [587]); LNH 80/84 ([445], [588]); MACOP-B [methotrexate-leucovorin, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), prednisone, and bleomycin] ([589]); and ProMACE/CytaBOM [cytarabine, bleomycin, Oncovin (vincristine), methotrexate] ([590]) were designed to further shorten and intensify therapy along with modifying delivery and schedules of drug. The CR rates of these regimens were 75 to 88% with a DFS of 50 to 65% in studies primarily at single institutions. Alternating regimens between different combinations compared favorably with the third-generation regimens ([591], [592]). Many of these newer regimens had considerable toxicity, when they were used initially, and were associated with mortality rates of 5 to 10%; however, the rate of toxic deaths decreased over time with more experience and perhaps with better patient selection ([581]). Many of the series in which these regimens were used involved favorable prognostic groups, including patients with limited-stage disease and patients with a relatively young median age. Cooperative groups generally were not able to reproduce the results that were obtained at single institutions ([593], [594] and [595]).

One of the most important clinical trials for lymphoma was performed by an intergroup (SWOG and ECOG) study that compared CHOP with three of the newer and reportedly more intensive regimens, m-BACOD, MACOP-B, and ProMACE-CytaBOM ([596]). There were no differences in CR, PFS, or OS. The percentage of patients alive without progression at 3 years was 41% in the CHOP and MACOP-B groups and 46% in the m-BACOD and ProMACE-CytaBOM groups (Fig. 90.13). The estimated OS was 52% of the entire group, 50% for ProMACE-CytaBOM and MACOP-B, 52% for m-BACOD, and 54% for CHOP ($p = .90$). There were also no differences in fatal toxicities among the regimens: CHOP (1%), ProMACE-CytaBOM (3%), m-BACOD (5%), and MACOP-B (6%) ($p = .09$). Similar cooperative group comparisons found no differences among these regimens ([597], [598] and [599]).

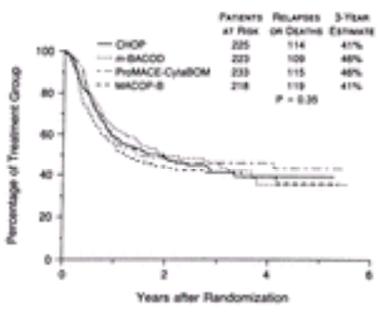

Figure 90.13. Intergroup study that compares CHOP, m-BACOD, MACOP-B, and ProMACE-CytaBOM in predominantly intermediate-grade working formulation lymphomas. There were no differences observed in time-to-treatment failure in the four groups. [From Fisher RI, Gaynor ER, Dahlberg S, et al. Comparison of a standard regimen (CHOP) with three intensive chemotherapy regimens for advanced non-Hodgkin's lymphoma. N Engl J Med 1993;328:1002–1006, with permission.]

Although the intergroup study reestablished CHOP as standard therapy for large cell lymphoma, it did not address the issue of dose intensity, and it did not emphasize how poorly these regimens do in patients with adverse prognostic factors. Although the newer regimens supposedly were more dose intensive than CHOP, there are little differences among the regimens with respect to the most active agents that were used (i.e., cyclophosphamide and doxorubicin). Although no differences were identified among the regimens in patients with adverse prognostic factors, none of them produced good results. Using these conventional regimens, CR rates of 55% and 44% and 5-year survivals of 43% and 26% were observed in the high-intermediate and high risk groups, respectively, in the IPI (see the section Prognostic Factors) ([241], [600]).

The intergroup trial was met with praise, as well as disappointment, because it indicated no improvement in survival for nearly two decades after the establishment of CHOP as an effective regimen. The first study to show an improvement in survival was a randomized comparison of CHOP to CHOP plus rituximab in elderly patients (60 to 80 years of age) with DLBCL (Fig. 90.14) ([273]). The rate of CR was higher for CHOP plus rituximab, compared to CHOP alone (76% vs. 63%; $p = .005$). The EFS and OS were significantly higher in the CHOP-plus-rituximab arm: 57% versus 38% ($p < .001$) and 70% versus 57% ($p = .007$) ([273]). Potential concerns regarding the trial included the fact that 12.5% of patients had their diagnoses changed after central pathology review, the inclusion of stage II patients who could have received combined modality, and the use of eight cycles of CHOP, which could be excessive in an elderly population. Phase II trials have confirmed the efficacy of CHOP plus rituximab in a diverse group of B-cell lymphomas, and a similar intergroup phase III trial in the elderly in the United States has been completed but not reported ([601]). Despite these concerns, CHOP plus rituximab has become standard therapy for DLBCL in the elderly, and its use has been extended to most patients with DLBCL, as well as to other CD20 $^{+}$ NHLs.

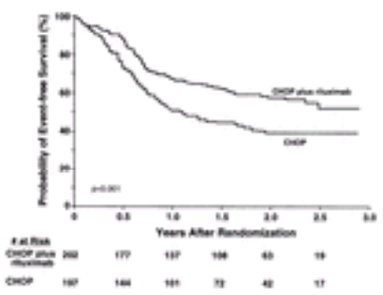

Figure 90.14. Event-free survival among 399 elderly patients who were randomized between CHOP plus rituximab (57% 2-year event-free survival) and CHOP (38% 2-year event-free survival). (From Coiffier B, Lepage E, Briere J, et al. CHOP chemotherapy plus rituximab compared with CHOP alone in elderly patients with diffuse large-B-cell lymphoma. N Engl J Med 2002;346:235–242, with permission.)

Although there is agreement about which clinical factors adversely affect prognosis, there is no consensus about how to improve CHOP-based therapy, except for the addition of rituximab for B-cell NHL. Strategies to improve response and survival in aggressive lymphomas have included using alternating non–cross-resistant regimens, infusion therapy, modifiers of multidrug resistance (MDR) genes, and dose intensification, including SCT. Phase II trials of non–cross-resistant regimens, such as ATT from the MDACC, appear to overcome adverse prognostic factors, but they have not been rigorously compared to CHOP in phase III trials ([602], [603]). Similarly, a continuous infusion regimen, EPOCH (etoposide, prednisone, Oncovin, Cytoxan, Adriamycin) with dose adjustments based on an individual's drug clearance, had a CR rate in large B-cell NHL of 92% and a 5-year PFS and OS of 70% and 73%, respectively; it overcame the IPI, but it has not been compared to CHOP ([604]). A phase II ECOG trial of infusion cyclophosphamide, doxorubicin, and etoposide in predominantly intermediate-grade NHL had a 2-year FFS of 50%, which was not significantly improved over historically IPI-matched controls ([605]). Phase II SWOG trials that evaluated infusion cyclophosphamide, vincristine, doxorubicin, and dexamethasone with or without modifiers of MDR (verapamil and quinine) also showed no advantage over historic trials that used CHOP therapy ([606]).

Dose escalation has been advocated as a means to improve response and survival in aggressive lymphomas, but phase III clinical trials have yet to prove the efficacy of dose intensity. Increased doses of doxorubicin in the regimen of bleomycin, doxorubicin, cyclophosphamide, vincristine, and prednisone failed to show improvement in response or survival when compared in a randomized trial to the standard dose ([607]). In a small trial of 22 patients who were treated with high-dose CHOP, the CR rate was 86% with a 69% PFS but a short follow-up (median of 20 months) ([608]). In a trial of 70 patients with intermediate- to high-grade lymphoma, short-course (8 weeks), dose-intensive therapy, which is referred to as *MEGA*, produced an 81% CR rate and a 52% 5-year FFS ([609]). Another phase II trial that evaluated double-dose ProMACE-CytaBOM with growth factor support reported a CR of 69%, a PFS of 58%, and an OS at 73% at 4 years ([610]).

In one of the few phase III trials (LNH87-1) that compared a more intensive regimen—ACVBP [Adriamycin (doxorubicin), cyclophosphamide, vindesine, bleomycin, and prednisone] to a standard regimen (m-BACOD)—in a group of low-risk aggressive-lymphoma patients, there were no differences in FFS and OS (65% and 75% in ACVBP and 61% and 73% in m-BACOD) ([611]). In a multivariate analysis, ACVBP was associated with a better FFS in the patients with two or three age-adjusted IPI

risk factors (611).

Some investigators advocate early SCT for selected patients with poor prognostic factors, but large randomized trials have failed to show a benefit for early transplantation (see the section Role of Stem Cell Transplantation) (308 , 612 , 613). CHOP with or without rituximab is the standard regimen for aggressive lymphomas for adults in the United States. European trials and pediatric studies, however, have indicated a role for more intensive therapy based on an increasing number of adverse features (611). It is likely that there are patients with such poor survival at diagnosis who still should be considered for early transplantation. Ongoing trials continue to address the issues of dose intensity and transplantation as front-line therapy for aggressive NHL.

SALVAGE CHEMOTHERAPY

Although the role of transplantation in first remission remains uncertain, there is general agreement that transplantation can improve survival predominantly in patients with intermediate-grade NHL that responds to salvage chemotherapy (see the section Role of Stem Cell Transplantation). Chemotherapy regimens at relapse usually involve agents that are non–cross-resistant with, or at least different from, drugs that are used in initial therapy. Investigators at MDACC have developed multiple effective protocols: MIME [methylguazone, ifosfamide, methotrexate, and etoposide (VP-16)] (614); DHAP [dexamethasone, high-dose cytarabine (ara-C), and cisplatin (Platinol)] (615); ESHAP [etoposide, solumedrol (methylprednisolone), high-dose cytarabine (ara-C), and Platinol (cisplatin)] (616); MINE [mesna, ifosfamide, Novantrone (mitoxantrone), and etoposide] (617); and MINT [mesna, ifosfamide, Novantrone (mitoxantrone), and Taxol (paclitaxel)] (618). Various doses and schedules of ICE (ifosfamide, carboplatin, and etoposide) have been used in relapsed NHL and to mobilize peripheral blood stem cells before transplant (619 , 620).

The CR and PR rates for a variety of histologic types were 24 and 36% for MIME; 31 and 24% for DHAP; 37 and 27% for etoposide, solumedrol (methylprednisolone), and high-dose cytarabine (ara-C) with or without cisplatin; and 26 and 20% for MINT, but most of the responses were of short duration, with the median times to treatment failure usually being less than 1 year, particularly in the intermediate- to high-grade histologies. The response rate to an ICE regimen that was developed at Memorial Sloan-Kettering Cancer Center was 66%, with 89% of these patients going on to transplantation (619). Patients who achieved a CR to ICE before transplantation had a superior OS to patients who had a PR (65% vs. 30%; $p = .003$) (619).

Based on the premise that prolonged exposure to therapy may be more effective than bolus, a continuous infusion regimen, EPOCH, was developed at the NCI and produced a 24% CR and a 50% PR in relapsed and refractory NHL (621). With a median follow-up of 76 months, the OS and EFS were 17.5 and 7 months, respectively. In patients with chemosensitive disease with aggressive histologies, the EFS was 19% at 3 years (621). Investigators at Stanford University developed a regimen of cyclophosphamide, etoposide, procarbazine, and prednisone with or without bleomycin, which produced a 34% CR and a 22% PR in previously treated patients with intermediate- or high-grade histologies (622).

Combinations of regimens, such as MINT-ESHAP or MINE-ESHAP, have yielded response rates in a range from 49 to 69%, but there are no obvious differences in outcome among the combinations (623 , 624). In general, salvage chemotherapy regimens in aggressive lymphomas are used as a bridge to transplantations, because prolonged survivals without transplant are less than 15%. Single-agent therapy is rarely used in intermediate- to high-grade lymphoma, except in phase I and II studies or as palliation. Because of significant activity in relapsed disease, some of the agents are being used in combination with other drugs earlier in the course of NHL.

Doxorubicin-related compounds that are used as single agents and in combination chemotherapy for relapsed NHL include mitoxantrone (624), amsacrine (625), idarubicin (626), epirubicin (627), aclacinomycin (628), and esorubicin (629). No drug has had an advantage over doxorubicin, although mitoxantrone produces less alopecia, mucositis, nausea, vomiting, and cardiotoxicity. CHOP has been shown to be superior to a regimen of CNOP (cyclophosphamide, mitoxantrone, vincristine, and prednisone) in a randomized trial in elderly patients (630); however, an argument has been made that the study did not compare equivalent doses of doxorubicin and mitoxantrone (624). Ifosfamide, an alkylating agent analog, produced a 29% response in phase II trials (631) and is used in salvage combination chemotherapy (619 , 620).

Taxanes and camptothecins are agents with considerable activity in solid tumors and are being evaluated in the therapy of NHL. Paclitaxel (Taxol) and docetaxel (Taxotere) are tubulin-binding taxanes that have produced responses in 13 to 23% of heavily treated patients (632 , 633 , 634 and 635). Camptothecins and type I topoisomerase inhibitors, including hycamptamine (Topotecan), irinotecan (CPT-11, Camptosar), and 9-aminocamptothecin (9-AC) have had responses of 25 to 35% (636 , 637). Combinations of paclitaxel plus hycamptamine appear to be synergistic, with a response rate of 48% and a median duration of 6 months (638).

Nucleoside analogs have primarily been used in indolent lymphomas, but gemcitabine, a pyrimidine antimetabolite, has had activity in relapsed intermediate-grade lymphomas. A response rate of 20% was observed in predominantly large B-cell NHL, and higher responses have been observed in PTCL (639 , 640). Combining gemcitabine with irinotecan in a phase I trial led to a 33% response for patients with NHL (641).

Vinca alkaloids with less neurotoxicity than vincristine have also been evaluated in NHL. Liposomal vincristine resulted in 41% response, with a median PFS of 5.5 months in responders (642). Infusion vinorelbine resulted in a 25% response, with a median PFS of 6 months in responders (643). Novel methods of drug delivery, including liposomal formulations, pegylation, different schedules of infusions, and oral formulations, may also obtain responses in relapsed NHL (641 , 644 , 645). Incorporation of these and other new agents into combination regimens is an ongoing area of investigation.

Understanding mechanisms of drug resistance is also an area of investigation for the development of salvage regimens. Although the *MDR* gene and its gene product, P-glycoprotein, are expressed rarely in lymphomas at diagnosis, *MDR* expression often is detected in lymphoma cells at relapse. The *MDR*-inhibiting agents include verapamil and cyclosporine and its analog, PSC-833, and their use in conjunction with chemotherapy has been inconsistent in patients with relapsed lymphomas. (309 , 646).

HIGHLY AGGRESSIVE LYMPHOMAS

SNC lymphoma (Burkitt and Burkitt-like NHL) and LL, usually of T-cell origin, are rare NHLs in adults, each representing less than 3% of NHL. Because they are more common lymphomas in children, most of the advancement in therapy has evolved through phase III trials in pediatrics (Chapter 91) (272). The basic principles that are learned from pediatrics apply to the therapy of highly aggressive lymphoma in adults. In brief, short-course, dose-intensive cyclophosphamide therapy is used in SNC lymphoma, whereas therapy for ALL is the main approach to LL. Both types of highly aggressive NHL require CNS prophylaxis and have clinical overlap with adult ALL (Chapter 78).

Small Noncleaved Cell Lymphoma

SNC lymphoma can be subdivided pathologically into Burkitt and Burkitt-like lymphoma (BLL), with the latter having more nuclear irregularity and also occurring more commonly in adults; however, they behave similarly clinically (647). Some have suggested combining BLL into DLBCL; however, the SWOG group delineated biologic and genetic differences between BLL and DLBCL (648). BLL had a higher proliferative rate, a greater expression of CD10, and a decreased expression of *BCL2*. Additionally, BLL had low cytotoxic T cells, an absence of one or more adhesion molecules, and an absence of the CD44 homing receptor (648). BLL had the t(8;14) translocation in 80% of patients and, most important, had a median survival of 1.2 years compared to 2.5 years for DLBCL (648).

In the United States, the Burkitt type of lymphoma tends to occur in younger adults, with more gastrointestinal presentations and less marrow involvement than BLL, but Burkitt lymphoma and BLL clinically overlap, have a risk for tumor lysis, and have been difficult to cure with conventional chemotherapy for adults. Two early reports in 1983 by Levine et al. (649) and Oviatt et al. (650) had CR rates of 29 to 40%, a continuous CR of 20 to 26%, and median survivals of 6 to 10 months (649 , 650). With combination chemotherapy that was effective in large cell lymphoma, the Vancouver group reported only a 40% CR rate in SNC lymphoma that was treated with MACOP-B and no long-term survivors (651); however, the NCI reported a 61% DFS and a 35% OS with a ProMACE-based regimen (652).

More intensive regimens have improved results in SNC NHL and mature B-cell ALL (653 , 654 , 655 , 656 , 657 , 658 , 659 and 660). Results vary in part owing to differences in age, stage, number of HIV-positive patients, and intensity of therapy (Table 90.11). In general, the CR rates are in the range of greater than 80%, and survival is

approximately 50% for the older adult and in the range from 60 to 80% for young adults. Relapses are usually confined to the first year after stopping therapy; there is no role for maintenance. Previously, intensity of therapy in HIV patients with NHL was reduced owing to risk of infections and poor survival; however, in the era of HAART and growth factor support, the CR rate with hyper CVAD in HIV patients with Burkitt lymphoma/leukemia has reached 92% with a 2-year survival of 48% (Chapter 69) ([661]). In pediatric trials, there is usually a prephase with low-dose cyclophosphamide steroids to debulk and to lessen tumor lysis, followed by intensive therapy that is stratified according to prognostic factors ([655]). Previously, subsets of advanced-stage patients with CNS or marrow involvement had a survival of less than 30% and were considered candidates for early transplantation ([662]); however, with the present day regimens, DFS is in a range from 50 to 80% for advanced SNC lymphoma and Burkitt leukemia, thus obviating the need for early transplantation in most adult patients ([663]).

TABLE 90.11. Chemotherapy in Adults with Small Noncleaved Cell Lymphoma

Author, Year (Reference)	Number of Patients	Median Age (Yr)	HIV (%)	Bone Marrow (%)	Therapy	CR (%)	Survival			Comments
							Overall (%)	Limited (%)	Advanced (%)	
Lopez, 1990 (653)	44	32	27	16	Variable, three rotating regimens	80	63	95	29	83% CR and 36% overall survival in HIV.
McMaster, 1991 (654)	26	45	23	35	MEGA	81	55	88	40	<30% DFS in patients older than 60 yr of age; lactate dehydrogenase >900 IU/L; marrow involvement; 33% DFS in HIV.
Soussain, 1995 (655)	65	26	0	43	LMB regimens	89	71	92	76 (stage III) 57 (stage IV)	Pediatric protocol; includes 13 patients who were transplanted in first CR; 7 out of 12 patients with central nervous system disease have long DFS.
Magrath, 1996 (656)	39	24	0	28	77-04	82	56	66 (stages I through III)	19 (stage IV)	DFS includes children; there was no difference with adults. New regimen (89-C-41) added IVAC; no benefit to granulocyte- macrophage colony-stimulating factor.
	20	25	0	15	89-C-41	100	92	97 (stages I through III)	80 (stage IV)	
Hoelzer, 1996 (657)	35	36	0	100	B-NHL86	74	51	—	51	All patients had B-cell acute lymphocytic leukemia; 17% central nervous system relapses; 9% early deaths.
Thomas, 1999 (658)	26	58	0	100	Hyper CVAD	81	49	—	49	77% overall survival for patients younger than 60 yr of age compared to 17% for patients equal to or older than 60 yr of age (p <.01).
Lee, 2001 (659)	54	44	0	80	CALGB 9251	80	52	Not available	46	Median follow-up 5.1 yr; 19 patients excluded by path review.
Mead, 2002 (660)	52	35	0	48	United Kingdom LY06	77	73	82	70	Uses Magrath regimen 89-C-41.

CR, complete remission; CVAD, cyclophosphamide, vincristine, Adriamycin (doxorubicin), dexamethasone; DFS, disease-free survival; HIV, human immunodeficiency virus; IVAC, ifosfamide, VP-16 (etoposide), Ara-C (cytarabine).

Lymphoblastic Lymphoma

The immature T-cell origin of LL was confirmed by the presence of the intranuclear enzyme, terminal deoxynucleotidyl transferase, which is not detected in the mature or peripheral T-cell neoplasms. Although LL expresses less terminal deoxynucleotidyl transferase and tends to have a more mature phenotype than T-cell ALL, considerable overlap exists biologically and clinically between these entities ([664]). In the past decade, multiple oncogenes have been identified in the translocations that are associated with T-cell LL and ALL (Chapter 89). Rarely, T-cell LL is associated with eosinophilia, acute myelogenous leukemia (AML), and a specific cytogenetic abnormality, t(8;13) (p11;q11) ([665]), and it has been associated with prior epipodophyllotoxin chemotherapy and a cytogenetic translocation that involves the *MLL* gene, t(11;19)(q23;p23) ([666]). LL is occasionally of B-cell origin, which has different clinical features from T-cell disease, including cutaneous and bone involvement and less mediastinal disease ([667]).

Because LL is rare in adults, only a few series have addressed therapy, and some patients have received early transplantation, which compromises the assessment of the impact of chemotherapy. In 1978, Rosen et al. ([668]) described 12 adult patients with a median survival of 13 months and less than 20% DFS. Studies in the 1980s indicated a CR rate of 53 to 95% when using CHOP-like induction regimens, and a high CNS relapse (approximately 40%), if CNS prophylaxis was not given ([669], [670] and [671]). ALL-like regimens with a maintenance phase that lasted 12 to 36 months resulted in 3- to 5-year survivals of 30 to 56% ([669], [670] and [671]). Poor prognostic features included age (older than 30 years), bone marrow involvement, elevated white cell count (>50 × 10^9 per L), CNS disease, elevated LDH, and slow response ([670], [671]). Coleman et al. ([671]) reported a 5-year survival of 94% in low-risk patients, compared to 19% (p <.001), with high-risk features defined by bone marrow or CNS disease or elevated LDH (>1.5 times normal). Short-course, dose-intensive regimens without maintenance have been tried in LL, but the relapses appear excessive, and the numbers are too small to use this approach ([672]).

Controversial management issues for LL include the optimal type of CNS prophylaxis, the role of radiation to the mediastinum, the type of maintenance therapy, and the role of transplantation. With present-day ALL regimens, the CR rates are 75 to 90%, with a prolonged DFS of 40 to 60% of responders (Table 90.12) ([673], [674], [675], [676], [677] and [678]). An option to consider for young adults is to use pediatric-based protocols, which have had better EFS when compared to adult ALL protocols ([679]). Because of poor survival with chemotherapy, high-risk patients may be candidates for early transplantation.

TABLE 90.12. Chemotherapy in Adults with Lymphoblastic Lymphoma

The most significant predictor of survival for patients who undergo SCT is the status of the disease at the time of transplant ([680], [681], [682], [683], [684] and [685]). The European Bone Marrow Transplantation Group retrospectively reviewed their experience in 214 patients with LL who underwent autologous transplantation; the 6-year DFS varied according to disease status: 63% in first CR, 31% in second CR, and 15% with resistant disease ([682]). In a randomized trial that compared early autologous SCT to conventional chemotherapy, Sweetenham et al. ([684]) reported a trend that favored autologous SCT (55% vs. 24%; p = .065), but there was no improvement in OS. The role of allogeneic transplant in LL in first CR is even more controversial. In an International Bone Marrow Transplant Registry retrospective review of transplants for LL, there were fewer relapses with allogeneic SCT, compared to autologous SCT, but there was no survival advantage owing to higher

treatment-related mortality ([685]). Recent randomized trials in adult ALL, which include LL, however, are favoring the allogeneic arm ([686] , [687]).

MANAGEMENT OF EXTRANODAL LYMPHOMAS

Sites of involvement and histologic type are important factors in the management of extranodal lymphomas. The Ann Arbor staging system has been used: Stage I_E represents localized extranodal lymphoma; stage II_E represents extranodal lymphoma with involvement of adjacent lymph nodes; subclassifications of stage II_E separate involvement into contiguous nodes (stage II_{1E}) and noncontiguous nodes (stage II_{2E}) and have been used in gastric lymphomas; stages III and IV in extranodal lymphomas represent disseminated disease with little advantage in distinguishing the two stages. Extranodal lymphomas of the gastrointestinal tract, the nasopharynx, and the testes are generally more aggressive than those of the lung, the orbit, or the salivary gland. Therapy, however, depends not only on the site, but also on the histologic characteristics, immunophenotype, and stage of the lymphoma (Table 90.13).

TABLE 90.13. Management Issues for Extranodal Lymphomas

Site	Usual Pathology	Clinical Associations	Suggested Therapy [a]
Stomach	B-cell MALToma	*Helicobacter pylori*	Antibiotic trial, serial endoscopy; other therapy if t(11;18) or progressive disease
Intestine			
Ileum	Small noncleaved B cell	Obstruction	High-dose cyclophosphamide combination chemotherapy with or without surgery
Immunoproliferative small intestinal disease	B cell MALToma	Malabsorption, immunoglobulin A heavy chain, Middle East	Antibiotics, steroids, with or without combination chemotherapy
Enteropathy associated T-cell lymphoma	Peripheral T-cell lymphoma	Celiac disease, West, obstruction	Combination chemotherapy with or without surgery
Waldeyer ring	Large B cell	Other gastrointestinal disease	Combined modality
Paranasal	Large B cell	CNS disease	Combined modality, CNS prophylaxis
Nasal	Natural killer–cell and peripheral T-cell lymphoma	Epstein-Barr virus, angiocentric features, CNS disease, Far East	Combined modality, CNS prophylaxis
Salivary gland	B-cell MALToma	Sjögren syndrome	Single agent or radiation, or both
Thyroid	B cell	Hashimoto thyroiditis	Radiation or combined modality, depending on histology and stage
Lung	Small B cell, B-cell MALToma	—	Single agent, surgery, or radiation
Orbital	Small B cell, B-cell MALToma	—	Radiation
Primary CNS	Large B cell	Ocular involvement, leptomeningeal disease, acquired immunodeficiency syndrome	Steroids, high-dose methotrexate with or without radiation
Testis	Large B cell	Contralateral testicular disease, CNS disease, retroperitoneal spread	Orchiectomy, combination chemotherapy, radiation to contralateral testis, CNS prophylaxis
Breast	Large B cell	Pregnancy	Combination chemotherapy with or without radiation
Ovary	Burkitt, large B cell	Bilateral disease	Combination chemotherapy
Bone	Large B cell	—	Combination chemotherapy with or without radiation
Cutaneous	Mycosis fungoides	—	Skin-directed
	B-cell MALToma, primary cutaneous follicular lymphoma		Radiation if stage I_E
	Primary cutaneous B-cell lymphoma		Combined modality

CNS, central nervous system; MALToma, lymphoma of mucosa-associated lymphoid tissue.

[a] Combined modality refers to combination chemotherapy and radiation. Combination chemotherapy refers to doxorubicin-based therapy. Rituximab can be added to therapy of most B-cell ($CD20^+$) lymphomas.

The recognition of MALTomas has led to unique therapeutic options. MALTomas were previously called *pseudolymphomas*, but the latter term is probably no longer valid because MALTomas are monoclonal, can be associated with a higher-grade histology, and have cytogenetic abnormalities ([688]). Clinically, MALT-omas are different from other low-grade lymphomas in that they tend to remain localized, rarely disseminate, and respond favorably to local therapy (Fig. 90.15) ([688] , [689]).

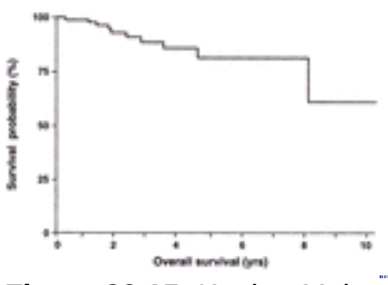

Figure 90.15. Kaplan-Meier survival curve of overall survival for mucosa-associated lymphoid tissue lymphoma of the stomach in 93 patients who were diagnosed from 1986 to 1995 in northern Italy. Most patients presented with localized disease (82 stage I, four stage II, and seven stage IV). The 5-year projected overall survival was 82% (95% confidence interval, 76 to 91%) without any apparent differences from different therapies [antibiotics ([49]), gastrectomy plus other therapy ([24]), chemotherapy ([12]), radiotherapy ([10]), and none ([7])]. (From Pinotti G, Zucca E, Roggero E, et al. Clinical features, treatment and outcome in a series of 93 patients with low grade gastric MALT lymphoma. Leuk Lymphoma 1997;26:527–537, with permission.)

Management of gastric MALToma changed when antibiotic therapy for *H. pylori* resulted in regression of lymphoma ([690] , [691] , [692] and [693]). Ultrasound endoscopy and biopsies assist in the determination of the extent of disease and the depth of invasion, which correlate with spread to regional lymph nodes and response to antibiotics ([694]). CR rates to antibiotics are greater than 70% when the disease is confined to the mucosa and submucosa ([693]). Infiltration of the muscularis mucosa or nodal extension and the presence of t(11;18) do not respond well to antibiotics ([692] , [693] , [695]). Serial endoscopies are warranted to ensure eradication of *H. pylori* and gradual disappearance of the lymphoma over many months ([690] , [691] , [692] and [693]). Follow-up endoscopy is recommended 2 months after antibiotic therapy and, subsequently, at least twice a year for 2 years ([694]). B-cell clonality, as detected by PCR, may persist after histologic regression but is of uncertain clinical significance ([150] , [696]). If there is evidence of a high-grade component or progressive disease, alternative therapies are usually warranted. Surgery can be curative in gastric lymphoma, particularly in stage I_E, with cure rates greater than 80% ([697] , [698]); however, radiation therapy or single-agent chemotherapy is also effective in

low-grade MALToma and may prevent the morbidity of total gastrectomy ([689], [699], [700]). Preliminary data also indicate that MALToma can respond to rituximab ([701]).

With the recognition of MALToma and the effectiveness of other therapies, the role of surgery has become an area of controversy in the management of gastrointestinal lymphoma. Although many investigators advocate surgical resection in gastric and other intestinal lymphomas to debulk, to stage accurately, and to prevent perforation ([214], [697], [698], [702], [703]), some investigators have achieved good results with combination chemotherapy or combined modality without surgery, particularly for the higher-grade lesions ([704], [705]). Although a partial or subtotal gastrectomy may be justified in some cases, more extensive surgery, such as total gastrectomy, should not be routinely performed because of the increased morbidity and the curability with alternative therapies ([703], [706], [707]). Surgery was avoided in two series of patients with intermediate- to high-grade gastrointestinal lymphoma who achieved a 61% 4-year DFS and a 76% 6-year survival with combination chemotherapy alone ([704], [708]).

Similar surgical issues pertain to intestinal lymphomas as in gastric lymphomas, particularly if they present with obstruction; however, they usually are less amenable to total resection ([709]). Other B-cell tumors that have relatively unique presentations are SNC (Burkitt or Burkitt-like) in the ileocecal region, which is particularly common in the Middle East ([710]), and MCL, which can present with lymphomatous polyposis ([216]). IPSID can be considered a subtype of B-cell MALToma and is distinguished by its occurrence in young adults from low socioeconomic groups in the Middle East and North Africa and its association with the synthesis of an IgA heavy chain ([711], [712]). Although the prognosis is usually considered poor in IPSID, a combination of antibiotics (tetracycline), steroids, and anthracycline-based chemotherapy, along with aggressive supportive care with hyperalimentation, can achieve CRs in two-thirds of patients with survivals in more than one-half of the patients at 3.5 years ([713]). The only unique T-cell lymphoma of the gut is the EATL, which may require emergent surgery and responds poorly to chemotherapy (see the section Extranodal T-Cell and Natural Killer–Cell Lymphomas) ([512], [513] and [514]).

Lymphomas that involve Waldeyer ring account for as much as one-third of extranodal lymphomas and are second to gastric lymphoma as the most common extranodal site ([52], [53]). Prognosis depends on histologic findings, which are usually a large B-cell lymphoma, the size of the tonsillar mass, and the stage ([714], [715]). As much as one-half of patients have advanced disease, and simultaneous involvement of the gastrointestinal tract is detected in 10 to 15% of patients with Waldeyer ring lymphoma ([716], [717]). Because of the intermediate histologic grade and the advanced stage of many patients, chemotherapy, often in combination with radiation, is usually considered the therapy of choice ([718]). With combined modality therapy, 70 to 90% of clinical stage I_E patients survive 5 years, along with 40 to 60% of patients with stage II_E ([719], [720]).

Lymphomas of the nasal cavity and paranasal sinuses often are evaluated in series that include Waldeyer ring lymphomas, despite differences in presentation, diagnosis, and therapy. The primary lymphoma often is more advanced in nasal lymphomas with invasion of adjacent bones and an increased risk for CNS involvement. Although uncommon, cervical node involvement in nasal lymphomas is associated with a poor prognosis ([719]). Large B-cell lymphoma is the most common histology; but, in series from the Far East, NK and PTCL frequently originate from the nasal area, have angiocentric and angiodestructive features, and are associated with EBV (see the section Extranodal T-Cell and Natural Killer–Cell Lymphomas) ([93], [515], [516] and [517]). Some investigators advocate using the American Joint Committee TNM staging for carcinoma of the paranasal sinuses. In a series from MDACC, patients with T1 and T2 lesions had an 89% 5-year DFS compared to 25% for patients with T3 and T4 lesions ([719]). Patients with Ann Arbor stage III and IV disease usually die, despite chemotherapy ([516]). The best therapeutic results have tended to be in those series with combined modality therapy ([516], [517], [719], [721]).

Other rare extranodal lymphomas include salivary gland, thyroid, pulmonary, and orbital lymphomas; all have unique presentations and histopathologic features and may be associated with autoimmune disorders. Although somewhat variable according to series, the majority of salivary gland lymphomas are indolent and localized, have been treated with radiation, and have survivals of 70 to 80% at 5 years and 40 to 50% at 10 years ([722], [723]). Most patients with thyroid lymphomas have localized stage I_E or II_E disease and have been treated with radiation, with a 5-year DFS of 40 to 70% ([724], [725] and [726]). A worse prognosis occurs with penetration of the thyroid capsule, tumor bulk, advanced stage, and intermediate- to high-grade histologic types. Because of the frequency of these factors, many have advocated combined modality therapy for thyroid lymphoma, except in the patient with small stage I disease ([725], [726]).

Most primary pulmonary lymphomas are small B lymphocytic, with or without plasmacytic differentiation, and are considered a part of the spectrum of MALTomas. Therapy options include chemotherapy, single agent or a nonanthracycline combination; surgical resection; radiation; or rituximab, or a combination of these. The prognosis is good, with a 94% OS at 5 years without reaching a median survival at 10 years, and there is no advantage for a specific type of therapy ([231], [727], [728]). Other pulmonary lymphomas are heterogeneous but generally have a poor prognosis and include disseminated large B-cell lymphoma and lymphomatoid granulomatosis, which can be associated with PTCL ([231], [729]).

Orbital lymphomas, like the bronchus-associated lymphoid tissue lymphomas, usually involve small B lymphocytes, with or without plasmacytic differentiation, and need to be distinguished from benign lymphoid hyperplasia. They tend to be localized, and 10 to 15% are bilateral. They respond to radiation, with a survival of 75 to 92% at 5 years and 70 to 80% at 10 years ([227], [730], [731]). Large B-cell lymphomas are less common, tend to involve the lacrimal gland or retroorbital area, and have a worse prognosis despite the recommended use of combined modality therapy ([227]).

CNS lymphomas are responsive to steroids, radiation, intrathecal or Ommaya reservoir therapy, and systemic chemotherapy, which crosses the blood–brain barrier. Standard treatment for PCNSL historically was whole-brain radiation therapy alone; the prognosis was poor, with a survival less than 6 months in AIDS patients and 1 to 2 years in immunocompetent hosts ([732], [733]). However, recent data that use early chemotherapy, particularly high-dose methotrexate or cytosine arabinoside, usually followed by whole-brain radiation therapy, have improved results in PCNSL, with median survivals from 30 to 60 months ([221], [734], [735] and [736]). Severe neurologic toxicity that is manifested as leukoencephalopathy secondary to radiation is common, particularly in the patient who is older than 60 years of age, and trials with chemotherapy alone and deferred radiation are being conducted ([737], [738] and [739]).

Testicular lymphoma, which represents approximately 5% of testicular neoplasms, is the most common testicular tumor in patients who are older than 60 years of age and is the most common bilateral testicular tumor ([740], [741]). It is associated with involvement of the contralateral testis in 20% of patients and involvement of the skin, Waldeyer ring, and CNS, each in approximately 10% of patients. The predominant histologic type is a DLCL, usually of B-cell origin. In most series, median survivals have been 1 to 2 years, and 5-year survivals have varied from 12 to 48%, depending in part on the extent of disease ([740], [741], [742] and [743]). Because of the poor prognosis and early systemic spread, anthracycline-based chemotherapy is warranted, usually with radiation to the involved testis, if unresected, as well as to the contralateral testis. Because of the CNS relapse rate of 15 to 31%, CNS prophylaxis should also be considered ([740], [744]).

Breast lymphomas usually manifest as a rapidly enlarging mass, may be multiple, and involve the opposite breast in 10 to 20% of patients ([227], [230], [745], [746] and [747]). The histologic type is variable, but it is more often a large B-cell lymphoma; low-grade lesions with MALToma features and an association with lymphocytic lobulitis have also been described ([748]). Massive bilateral breast involvement with SNC lymphoma has been described in pregnant or lactating women, predominantly those from Africa, and is characterized by rapid dissemination with ovarian and CNS disease ([230]). After simple biopsy and staging, radiation therapy can be considered for local control of low-grade lesions, but combination chemotherapy is warranted for aggressive histologies.

Primary ovarian lymphomas are rare, except in countries in which Burkitt lymphoma is endemic; however, the ovary is the most common site of female genital tract involvement by lymphoma at autopsy ([749]). Ovarian lymphomas may be associated with bilateral involvement in more than one-half of patients and have had a poor prognosis, with a 5-year survival of less than 25% ([750]). Prognosis depends on the extent of disease and the histologic type. Combination chemotherapy is warranted in most patients owing to aggressive histologies.

Primary bone lymphomas are usually intermediate- or high-grade B-cell NHL, and approximately one-third of cases have more than one bone involved ([53], [227], [228]). Prognosis depends on the bones that are involved, with the femur having the best prognosis and the spine having the worst prognosis; histologic type; stage; and the presence of soft-tissue involvement ([228], [751]). Local radiation is usually given to the entire bone, with a boost to the tumor bed. Although combined modality has been recommended for aggressive histologies ([752], [753]), chemotherapy alone has been successful, particularly in children ([754]). For localized bone lymphoma, RFS exceeds 70% at 5 years ([227]).

Therapy of CTCL and the differential diagnosis of cutaneous lymphomas are addressed in Chapter 94. Local radiation therapy is often adequate for localized (stage I

$_E$) cutaneous MALT-oma or PCFL, whereas multiple therapeutic options can be considered for advanced disease that is similar to other indolent lymphomas. Combined modality therapy is usually recommended for localized PCBCL. The majority of PCFL lack *BCL2* expression and the *BCL2* gene rearrangement and have a good prognosis ([755]). Alternatively, *BCL2* expression is often present in PCBCL of the leg, as opposed to other sites; is primarily seen in the elderly; and has a poor prognosis ([756]).

ROLE OF STEM CELL TRANSPLANTATION

Transplantation is addressed in Chapter 25 and has taken an expanded role in the therapy of NHL; its use has been noted in the preceding sections on individual diseases. In 1978, Appelbaum et al. ([757]) reported long-term DFS in three of nine patients with relapsed Burkitt lymphoma who underwent high-dose chemotherapy and autologous marrow transplantation. In subsequent series using autologous transplants, the OS rate has usually been 20 to 40% in relapsed NHL ([758], [759], [760], [761] and [762]). Patients who are in a sensitive relapse—that is, they are responding to additional chemotherapy—have 30 to 50% salvage rates with transplantation, compared to 0 to 15% in patients who are in a resistant relapse. Patient selection influences outcome, with the best results achieved in patients in first CR or who had minimal disease before the transplant ([759], [763]). Histologic grade and preparative regimen have not consistently influenced outcome. Mortality has been in the range from 5 to 25% but has decreased with the use of peripheral blood stem cells and improved supportive care. Relapse is the main reason for failure after autologous transplants. Hematopoietic growth factors lessen the length of neutropenia and hospitalization with autologous marrow transplantation and may decrease morbidity and mortality rates ([764], [765]).

An unresolved issue of SCT for NHL is the optimal timing of transplant. There is agreement that SCT is warranted in relapsed patients with intermediate- to high-grade histology based on the PARMA trial, which randomized patients to transplantation versus chemotherapy (Fig. 90.16) ([766]). Much disagreement surrounds which, if any, poor prognostic factors could be used to select patients with NHL for early SCT. Although several small series have had a DFS of greater than 75% in selected patients who were transplanted in good PR or first CR with intermediate- to high-grade histology ([767], [768] and [769]), most studies that have compared SCT to chemotherapy in first CR or in slow responders have shown no advantage to early transplantation (Table 90.14) ([308], [612], [613], [770], [771], [772] and [773]). Retrospective analysis of trials indicated a survival advantage for SCT in patients with an age-adjusted IPI that was greater than or equal to 2 ([612]); however, prospective randomized trials have not supported early transplantation over chemotherapy in first CR ([774]).

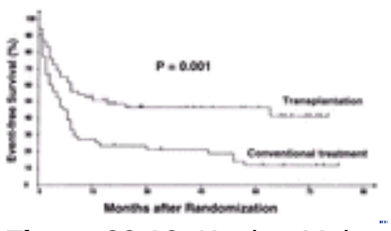

Figure 90.16. Kaplan-Meier survival curves for event-free survival of patients with relapsed intermediate- to high-grade lymphomas in the transplantation and conventional treatment groups. Data are based on an intention-to-treat analysis. The tick marks represent censored data. (From Philip T, Guglielmi C, Hagen Beck A, et al. Autologous bone marrow transplantation as compared with salvage chemotherapy in relapses of chemotherapy-sensitive non-Hodgkin's lymphoma. N Engl J Med 1995;333:1540–1545, with permission.)

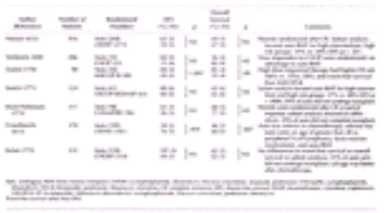

TABLE 90.14. Randomized Trials: Chemotherapy versus Autologous Transplant for Aggressive Non-Hodgkin Lymphoma as Front-Line Therapy

The use and timing of SCT and the role of purging are controversial in indolent lymphomas. Various techniques have been used for removal of tumor cells and include *in vivo* and *in vitro* monoclonal antibodies, metabolites of cytotoxic agents, and physical methods ([775]). Prognostic models have been developed to select patients with indolent lymphomas for early SCT and include progressive disease within 1 year of initial therapy, extensive marrow involvement, multiple extranodal sites of disease, tumor bulk, transformation, and a high IPI ([379], [776], [777] and [778]). Although some patients with low-grade lymphomas, particularly those of follicular center cell origin, are transplanted with disease progression after one or more therapies, there are trials that evaluate early transplantation ([776]). There is also evidence that indicates an advantage for successfully purging the *BCL2* oncogene ([779]). Long-term follow-up and randomized trials are required to determine the role of transplantation and purging in indolent lymphomas ([775], [776]).

The optimal stem cell source is also controversial, and the choices are expanding. Peripheral blood stem cells have replaced bone marrow for autografting owing to quicker engraftment but have not consistently improved survival compared to marrow ([780]). As much as one-half of patients mobilize malignant cells ([780], [781]). MDS and secondary AML are an increasingly recognized problem after autografts ([763], [782]). Some investigators have favored allografts because of fewer relapses, a graft-versus-lymphoma effect, a tumor-free stem cell source, and less MDS and AML ([783], [784] and [785]). The lack of an available donor and the toxicity of allograft transplantation keep the issue of optimal stem cell source unresolved. Recent studies have shown that nonmyeloablative allogeneic SCT has less early mortality than standard myeloablative transplants, and preliminary data indicate a role for its use in indolent and chemosensitive disease ([786], [787]). Because of higher relapse rates in autografts, trials are evaluating pre- and posttransplant immunotherapy to eradicate minimal residual disease ([788], [789] and [790]).

SPECIAL AREAS

Therapy in the Elderly

Although lymphomas steadily increase in number with aging, and the prognosis tends to be poor in the older patient, the management of lymphomas, primarily intermediate- to high-grade types, in the elderly is controversial. Possible factors that contribute to poor prognosis in this group include poor performance status, reduced vital organ reserve, comorbid diseases, and biologic features of the lymphoma; however, physician biases and reduction of chemotherapy doses may also contribute to an inferior prognosis ([791], [792]). In a SWOG study with CHOP chemotherapy in which the dosage was reduced by 50% in patients who were older than 65 years of age, CR rates declined with advancing age; however, in a small subset of patients who were older than 65 years of age who did receive full doses, the CR rate approximated that of younger patients ([793]). Randomized clinical trials that have compared different regimens to doxorubicin-based therapy have usually shown equivalent or inferior results ([630], [794], [795], [796] and [797]). The randomized trial that favored CHOP plus rituximab over CHOP established a new standard for therapy of large B-cell lymphoma in the elderly ([273]). Despite anthracyclines being recommended in the elderly, close monitoring of cardiac function is essential, and a decline in ejection fraction requires substitution of another drug.

Although some studies have excluded older patients, as evidenced by a median age of younger than 52 years ([585], [586]), others have had unacceptable toxicity in the elderly population, with as high as a 23% mortality in patients who were older than 60 years of age who were treated with MACOP-B ([589]). In a University of Nebraska study of the chemotherapy regimen of CAP-BOP (cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, and prednisone), Vose et al. ([310]) noted that the CR rate for patients who were older than 60 years of age (61%) was not statistically different from the CR rate for patients who were younger than 60 years of age (76%; $p = .18$). Moreover, although the overall 5-year survival rate was 34% in the elderly, compared to 62% in younger patients ($p = .01$), no difference in survival by age was noted when elderly patients who died of unrelated causes (22%) were censored. Novel regimens have been developed for the elderly patient, not only to lessen toxicity, but also to maintain a high curability ([798], [799], [800], [801] and [802]). CR rates are usually 45 to 60%, and OS at 3 years is 25 to 42%, but most have not been compared to CHOP. Growth factors lessen the neutropenia of various regimens and allow the delivery of adequate doses on schedule ([803]). Age is a

continuum, with tolerance to therapy and survival worsening in patients older than 70 years of age; however, performance status is the best predictor of treatment-related death ([804]). Autologous transplantation in the elderly can result in similar outcomes to those observed in younger patients ([805]). Elderly patients should not be excluded from clinical trials or curative therapy solely on the basis of age.

Therapy in Pregnancy

The coincidence of NHL in pregnancy is unknown ([806]). More than 100 cases of NHL in pregnancy have been reported ([806]); therapy is based on the histologic type and the point of gestation at diagnosis. Staging studies are limited owing to concern for radiation exposure to the fetus. Most women who develop NHL during pregnancy have intermediate- to high-grade histologies and advanced-stage disease ([806]). There is an unusually high incidence of breast, ovarian, uterine, and cervix involvement that is attributed to hormonal influences and increased blood flow to these organs ([806]). Placental involvement is rare, and transmission to the fetus is so uncommon that it is reportable ([807]).

Patients with aggressive lymphomas who present in the first trimester should be considered for a therapeutic abortion, unless the lymphoma is localized above the diaphragm and could be treated with involved field radiation plus abdominal shielding ([808]). As a rule, radiation should be avoided until the third trimester, whereas combination chemotherapy can be given successfully in the second or third trimester. Early delivery (by induction or cesarean section) can be considered to avoid myelosuppression of mother and fetus or to initiate intensive chemotherapy. Staging should be completed after delivery. Prognosis for mothers has been relatively poor, with a DFS of only 40 to 45%, probably owing to the aggressive histologies and the advanced stage ([806] , [807] , [808] and [809]). Although low-grade lymphomas constitute a minority of NHL in pregnancy, they generally can be observed until after delivery. If necessary, IFN can be used throughout pregnancy to control indolent hematologic disorders ([810]). Offspring who, as fetuses, received chemotherapy, even in the first trimester, have had normal growth and development and no increased risk of cancer ([811]).

Long-Term Sequelae

The long-term complications of therapy in NHL are not as well described as those in HD, but they appear to be similar and depend on the therapy that is used, the age of the patient, and the comorbid illnesses. These problems include endocrine disorders (infertility, hypothyroidism, panhypopituitarism, growth retardation), vital organ toxicity, psychosocial issues, transfusion-induced viral infections, and second neoplasms (Chapter 95) ([812] , [813]). Radiation is the main cause of endocrine and neurologic toxicities ([812]). Cardiotoxicity from anthracyclines is the most common chemotherapy-related toxicity ([814]). Although previous studies have suggested no increase in second neoplasms after therapy for NHL, the NCI's Surveillance, Epidemiology, and End Results Program identified an increased risk over time for AML; cancers of the bladder, kidney, and lung; malignant melanoma; and HD ([812] , [813]). As much as 10% of NHL patients who are treated with standard chemotherapy regimens or autologous transplantation, particularly in regimens that use total body irradiation, may develop MDS or AML within 10 years of their initial therapy ([782]).

FUTURE DEVELOPMENTS AND SUMMARY

New drugs with unique activity are in phase I and II trials ([815]). Depsipeptide is a histone deacetylase inhibitor that causes cell cycle arrest at G_0 and G_1 and has activity in PTCL and CTCL ([816]). Other drugs that are directed at the cell cycle are flavopiridol, which inhibits cyclins and cyclin-dependent kinases, and UCN-01, which inhibits serine and threonine kinases and leads to the arrest of cells in G_1 ([815]). Bortezomib (Velcade, Millenium Pharmaceuticals, Inc., Cambridge, MA) is the first proteasome inhibitor in trials and has been approved for use in relapsed myeloma ([817]). G 3139 (oblimersen sodium, Genta Incorporated, Berkely Heights, NJ), the first antisense molecule in trials, targets *BCL2* messenger RNA and causes BCL2 protein expression reduction, which correlates with response in NHL ([818]). These and other new agents are synergistic with other chemotherapy and monoclonal antibodies and require phase III trials to establish their place in the expanding list of treatments for NHL.

Advances in NHL will involve molecular techniques to refine diagnosis, classification, and therapy. The classification of lymphoma will improve with genomic profiling in conjunction with clinical and pathologic factors. The application of PCR to detect minimal residual disease may identify patients who should be followed more closely or should receive additional therapy. The success of monoclonal antibody therapy in NHL has been remarkable, and the development of vaccines may be the ultimate goal of immunotherapy (Chapter 74). Continued trials that evaluate the role of dose intensification and the use of different types of transplantation are still warranted in NHL.

Non-Hodgkin Lymphomas in Children

There have been significant clinical and laboratory advances over the last decade that add to our understanding of the non-Hodgkin lymphomas (NHLs) of childhood. These include the refinement of diagnosis and classification of clinically relevant histologic subtypes, the elucidation of various pathogenic mechanisms, and most importantly, improvements in therapy and supportive care, which have resulted in improved event-free and overall survival rates. Increased attention toward the reduction and elimination of concerning late effects of therapy, such as infertility, cardiotoxicity, and second cancers, is another important hallmark of clinical research in recent years. These advances and future directions are discussed in this chapter.

Malignant lymphomas, which comprise both Hodgkin disease and NHL, are the third most common type of childhood cancer, after acute lymphoblastic leukemia (ALL) and brain tumors ([1], [2], [3], [4], [5], [6], [7] and [8]). Among children between the ages of 15 and 18, there is a slight predominance of Hodgkin disease, whereas NHL is more common among those younger than 15 years of age ([4], [5], [8]).

It is important to note the distinction between the NHLs of adults and those of children ([9]). Children typically present with diffuse extranodal disease, in contrast to adults, among whom primary nodal disease is more common. Additionally, the pediatric NHLs are typically high-grade tumors as defined by the National Cancer Institute Working Formulation ([10]), in contrast to the low- and intermediate-grade tumors that are predominant among adults. Age-related differences in the immune system and associated susceptibility to malignant transformation are factors that likely contribute to these observed differences in histologic subtype ([2]).

EPIDEMIOLOGY

There are approximately 500 cases of newly diagnosed pediatric NHL in the United States each year ([5], [6], [7] and [8]). Although there is no clear peak age, the median age in one single-institution review was 10 years (range, 7 months to 19 years) ([3]). This disease is uncommon in very young children (i.e., younger than 3 years of age) ([3], [11]). NHL is two to three times more common in boys than in girls and is more common in black children than in white children ([2], [3]). The reasons for these differences have yet to be elucidated.

There are geographic differences with respect to frequency and distribution of histologic subtypes of NHL in children ([4], [12], [13], [14], [15] and [16]). For example, although NHL is very common in equatorial Africa, it is very rare in Japan ([15]). Among the NHL cases observed in equatorial Africa, Burkitt lymphoma is the most common type observed. Burkitt lymphoma is also the most frequent histologic subtype encountered in northeastern Brazil and in some areas of the Middle East ([14]). In contrast, lymphoblastic lymphoma is the predominant histologic subtype in southern India ([14]).

Burkitt lymphoma is also of interest with respect to the geographic variances (i.e., endemic vs. sporadic) in both clinical and biologic features ([15]). Those tumors that arise in children from equatorial Africa (*endemic subtype*) are characterized clinically by frequent involvement of jaw, abdomen, paraspinal area, and orbit and by a younger age at diagnosis ([14], [15] and [16]). Those Burkitt tumors that arise in children from Western Europe and the United States (*sporadic subtype*) are, in contrast, characterized by frequent involvement of the abdomen, nasopharynx, and bone marrow and by an older age at diagnosis ([14], [15] and [16]). The breakpoint in the c-myc protooncogene in Burkitt lymphomas has also been reported to vary with respect to geography; in sporadic cases, the breakpoint tends to occur within the c-myc gene, as compared to upstream of c-myc as tends to be the case in endemic cases ([15]).

An infectious agent was suspected to play a role in the pathogenesis of Burkitt lymphoma in equatorial Africa after it was noticed that the malaria belt overlapped with the lymphoma belt. Subsequently, Epstein-Barr virus (EBV) was shown to be associated with Burkitt lymphoma in equatorial Africa ([15], [16]). However, the association of EBV with Burkitt lymphoma has been shown to vary with geography. EBV association occurs in approximately 85% of endemic cases, in contrast to the 15% association in Western Europe and the United States ([15], [16]). An intermediate degree of EBV association has been observed in other parts of the world, such as northeastern Brazil ([12]). Although the evidence for a direct role for EBV in Burkitt lymphoma pathogenesis is relatively lacking, the circumstantial evidence is compelling. It was initially hypothesized that EBV, a B-cell mitogen, increases the target pool of cells that would be susceptible to a malignant transformation ([15]). This hypothesis is supported by the observation that the expression of the recombination activating gene can be induced by EBV and therefore potentially increases the chance that a chromosomal translocation may occur during immunoglobulin (Ig) gene rearrangement ([17]). That transgenic mice expressing Epstein-Barr nuclear antigen-1 develop lymphomas is also provocative ([18]). The observation that the EBV-positive cell line Akata loses its malignant phenotype with spontaneous loss of EBV, yet maintains the ability to regain its malignant phenotype with EBV reinfection, is suggestive of a more direct role for EBV in pathogenesis ([19]).

Children with certain immunodeficiency conditions are at increased risk for the development of NHL ([1], [2] and [3]). Examples of specific populations at risk include those with congenital immunodeficiency disorders such as ataxia-telangiectasia ([20]), X-linked lymphoproliferative syndrome, and Wiskott-Aldrich syndrome. It is important that these underlying conditions be recognized in children who present with NHL, so that appropriately designed therapy can be delivered. For example, in children with ataxia-telangiectasia, involved field irradiation and the use of radiomimetics such as bleomycin should be avoided, and the judicious use of x-rays is advised. Children with ataxia-telangiectasia are also at increased risk for the development of severe hemorrhagic cystitis after the administration of alkylating agents such as cyclophosphamide and ifosfamide; therefore, vigorous hydration and administration of the uroprotectant mesna are recommended whenever these agents are delivered. Boys with X-linked lymphoproliferative syndrome are at increased risk for the development of both B-cell lymphomas and fatal infectious mononucleosis and are potential candidates for matched sibling allogeneic bone marrow transplantation. Therefore, the diagnosis of X-linked lymphoproliferative syndrome should be considered in (a) any boy who presents with a B-cell lymphoma and whose brother has had either B-cell lymphoma or fatal infectious mononucleosis, and (b) in any male who has had two primary B-cell lymphomas. There is also an increased risk for the development of NHL among children with acquired immunodeficiency conditions ([20], [21], [22], [23], [24], [25] and [26]). Specific populations at risk include those with the acquired immunodeficiency syndrome and those on immunosuppressive therapy after bone marrow or organ transplantation.

PATHOLOGIC SPECIMEN EVALUATION

The NHLs of childhood are very rapidly growing neoplasms. It is therefore imperative that the diagnosis be established as soon as possible so that appropriate therapy can be started. The diagnosis can be established after a comprehensive characterization of the biologic features of the tumor. Optimally, sufficient tissue should be obtained to permit histologic, cytochemical, flow cytometric, cytogenetic, and molecular pathologic studies. Sufficient tissue for these studies is most readily obtained by open biopsy of an involved site. Bilateral bone marrow aspirates and biopsies should be performed before open biopsy, because the diagnosis may be

established with these required staging examinations, thereby negating the need for a more invasive procedure such as an open biopsy. There may be some patients, such as those with a large anterior mediastinal mass, who are not candidates for general anesthesia. In these cases, the diagnosis may be established by examination of pleural fluid obtained by thoracentesis; alternatively, tissue may be obtained by parasternal core biopsy of the mass using local anesthesia with an anesthesiologist in attendance ([27]).

CLASSIFICATION

The National Cancer Institute (NCI) Working Formulation, the Revised European-American Lymphoma (REAL) Classification, and the World Health Organization (WHO) Classification of Tumors of Haematopoietic and Lymphoid Tissues all recognize the three major subtypes of NHL in children: Burkitt, lymphoblastic, and large cell lymphoma. The more recent REAL and WHO systems incorporate genetic abnormalities and additional histopathologic features. Among the pediatric NHLs, these refinements have primarily influenced the classifications of the large cell lymphomas by designating anaplastic large cell lymphoma (ALCL) and mediastinal large B-cell lymphoma, which were not featured in the NCI Working Formulation. Table 91.1 summarizes the pediatric NHLs according to the WHO system.

TABLE 91.1. World Health Organization Classification of Pediatric Non-Hodgkin Lymphomas

Common pediatric lymphomas
B-cell lymphomas
Precursor B-lymphoblastic lymphoma/leukemia
Burkitt lymphoma
Diffuse large B-cell lymphoma
Mediastinal (thymic) large B-cell lymphoma
T-cell lymphomas
Precursor T-lymphoblastic lymphoma/leukemia
Anaplastic large cell lymphoma
Peripheral T-cell lymphoma, unspecified
Uncommon pediatric lymphomas
Follicular lymphoma (grade 1, 2, or 3)
Hepatosplenic T-cell lymphoma
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Rare pediatric lymphomas
Mycosis fungoides
Subcutaneous panniculitis-like T-cell lymphoma
Adult T-cell leukemia/lymphoma (human T-cell leukemia virus type 1–associated leukemia/lymphoma)
Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
Extranodal natural killer cell/T-cell lymphoma

Lymphoblastic Lymphoma

ALL and lymphoblastic lymphoma (precursor B- and T-lymphoblastic lymphoma/leukemia) have overlapping morphologic, immunophenotypic, and cytogenetic features; thus, the distinction between these two processes is considered by many to be largely arbitrary ([28], [29] and [30]). In keeping with this concept, the International Lymphoma Study Group and the WHO designate these malignancies *precursor B-* and *T-lymphoblastic leukemia/lymphoma* in the updated REAL and WHO classifications, respectively ([31], [32]). However, less obvious etiologic or molecular genetic differences must exist to explain why some lymphoblastic processes remain relatively localized and others rapidly expand to involve distant sites. Future immunologic and molecular genetic investigations may reveal the underlying differences and possibly provide insight to new therapeutic approaches. The distinction between a leukemic phase of lymphoblastic lymphoma and extramedullary involvement of ALL is arbitrary. Lymphoblastic malignancy confined to an extramedullary site is considered lymphoblastic lymphoma. Regardless of the extent of extramedullary disease, the St. Jude criteria define *ALL* as greater than 25% lymphoblasts in the bone marrow or blood, whereas other criteria require only 10% lymphoblasts in the marrow ([9], [33], [34]).

Common presenting sites of precursor T-lymphoblastic lymphoma are mediastinum, lymph nodes, skin, bone, and soft tissues. Rarely, the presentation may be in kidney, lung, or orbit. By contrast, precursor B-lymphoblastic lymphoma more often presents in the lymph nodes, skin, bone, soft tissues, or breast, with mediastinal presentation being very uncommon ([35], [36], [37], [38] and [39]). The most frequent location of skin lesions in children is the head ([38], [39]). Patients with precursor B-lymphoblastic lymphoma may fare better than those with T-lymphoblastic lymphoma, but this impression is tempered by the relative infrequency of the precursor B-lymphoblastic lymphoma ([35], [36] and [37]).

Although some patients with lymphoblastic lymphoma may appear to have localized disease by morphologic and clinical evaluations, sensitive flow cytometric and molecular studies frequently reveal submicroscopic involvement of bone marrow or blood. Precursor B- and T-lymphoblastic lymphomas show a diffuse pattern of tissue involvement by a uniform population of small to medium-sized blastic cells. Partially involved lymphoid tissues may show residual normal follicles and germinal centers. The malignant lymphoblasts characteristically have scant to moderate amounts of basophilic cytoplasm and finely dispersed chromatin with small indistinct nucleoli. The nuclei of B or T types may be markedly irregular or convoluted, although this is more commonly a feature of T-lymphoblastic lymphomas. Mitotic figures may be numerous and correspond to the rapid growth potential of these lymphomas. Large, actively phagocytosing histiocytes interspersed among the malignant lymphoblasts may impart a microscopic “starry-sky” appearance in some cases. A high mitotic rate and starry-sky pattern are characteristics of Burkitt lymphoma and, when present in lymphoblastic lymphoma, may make the morphologic distinction between these lymphomas very difficult. However, immunologic and genetic studies readily distinguish between these entities.

Immunophenotypic studies have revealed only minor antigen-expression differences between B- or T-lymphoblastic lymphomas and their ALL counterparts. Approximately 90% of lymphoblastic lymphomas are of T lineage, and the remaining 10% is of B lineage ([40], [41], [42], [43] and [44]). Rarely, one might encounter a case of lymphoblastic lymphoma derived from a natural killer (NK) cell of origin ([43], [45], [46]). Lymphoblastic lymphomas are usually Tdt (*t*erminal *d*eoxynucleotidyl *t*ransferase)-positive, a marker that distinguishes this neoplastic process from all other types of lymphoma ([47], [48], [49], [50] and [51]). Previously, Tdt-positive cells were believed to be confined to the bone marrow and thymus, sites of normal B- and T-cell development, respectively. The presence of Tdt-positive cells in the peripheral blood or lymph nodes was considered to be evidence of lymphoblastic malignancy in these tissues. However, improved immunohistochemical and flow cytometric methodologies have allowed for the detection of small numbers of benign immature Tdt-positive lymphocytes in blood and lymph nodes ([52]). CD34 is expressed by the many lymphoblastic lymphomas and is also useful in distinguishing these malignancies from Burkitt lymphoma. Expression of Tdt and CD34 can be performed by flow cytometry of lymphoma cell suspensions or by immunohistochemical studies of fixed and paraffin-embedded tumor biopsies ([53]). Precursor B- and T-lymphoblastic lymphomas may express CD10 or the common ALL antigen. A favorable clinical outcome is associated with $CD10^+$ T-ALLs, but a similar association of CD10 expression with T-lymphoblastic lymphoma has not been described ([43], [54]).

The lymphoblastic lymphomas may be further subclassified by their apparent stage of bone marrow or intrathymic maturation in a manner analogous to ALL (Table 91.2) ([55], [56], [57] and [58]). Attempts at separating lymphoblastic lymphoma from ALL by immunophenotypic features and the identification of clinically significant immunologic subtypes have been largely unsuccessful. In our and others' experience, B-lymphoblastic lymphomas may correspond to any of the four subtypes listed in Table 91.2. As compared to B-precursor ALL, a pre-B stage of maturation (i.e., cytoplasmic µ–heavy chain expression without detectable ?- or ?-Ig light chains)

appears to be more frequent ([42], [59], [60]). Rare cases of B-lymphoblastic lymphoma may express surface Ig without detectable Tdt and should not be confused with Burkitt lymphoma ([43], [61]). T-lymphoblastic malignancies can also be subdivided according to the corresponding stages of normal intrathymic T-cell maturation: early thymic stage (CD7 $^{+}$, cytoplasmic CD3 $^{+}$, CD5 $^{\pm}$, CD2 $^{\pm}$, CD1a $^{-}$, CD4 $^{-}$, CD8 $^{-}$), mid–thymic stage (CD7 $^{+}$, CD5 $^{+}$, CD2 $^{+}$, cytoplasmic CD3 $^{+}$, surface CD3 $^{\pm}$, CD1a $^{\pm}$, CD4 $^{\pm}$, CD8 $^{\pm}$), and late thymic stage (CD7 $^{+}$, CD5 $^{+}$, CD2 $^{+}$, surface CD3 $^{+}$, CD1a $^{-}$, CD4 $^{+}$ or CD8 $^{+}$). The majority of T-lymphoblastic lymphomas correspond to the late stage of intrathymic T-cell maturation ([56], [57] and [58]). Most lymphoblastic lymphomas retain the expression of pan–T-cell antigens (e.g., CD7, CD2, CD5, and CD6), whereas one or more of these are often undetectable in large T-cell lymphomas. A more frequent expression of T-cell receptor (TCR) a-ß than ?-d has been reported in T-lymphoblastic lymphoma as compared to T-precursor ALL ([62]). Some lymphoblastic lymphomas may aberrantly express myeloid-associated antigens ([41], [63], [64]). CD56, a marker of NK cells and cytotoxic T cells, is occasionally expressed by blasts of T-lymphoblastic lymphoma but does not appear to be of clinical significance. All relapses of T-lymphoblastic lymphomas should be restudied immunologically, as a small number of cases can undergo a phenotypic switch to acute myeloid leukemia ([65], [66]).

TABLE 91.2. Immunophenotypic Features of Precursor B- and T-Lymphoblastic Lymphomas

Subtype	CD45	CD34	Tdt	CD3 [a]	CD5	CD7	CD19	CD20	CD22	CD79a [a]	CD10	Immunoglobulin Expression
Early pre-B	+ [b]	+	+	-	-	-	+	±	+	+	+	cIgμ $^{-}$, sIgμ $^{-}$, ? $^{-}$, ? $^{-}$
Pre-B	+	±	+	-	-	-	+	±	+	+	+	cIgμ $^{+}$, sIgμ $^{-}$, ? $^{-}$, ? $^{-}$
Late pre-B [c]	+	±	±	-	-	-	+	±	+	+	+	cIgμ $^{+}$, sIgμ $^{+}$, ? $^{-}$, ? $^{-}$
Mature B [d]	+	±	±	-	-	-	+	±	+	+	+	cIgμ $^{+}$, sIgμ $^{+}$, ? $^{\pm}$, ? $^{\pm}$
T [e]	+	±	±	+	±	+	-	-	-	±	-	—

cIgμ, cytoplasmic immunoglobulin μ; ?, immunoglobulin light chain ?; ?, immunoglobulin light chain ?; sIgμ, surface immunoglobulin μ; Tdt, terminal deoxynucleotidyl transferase.

[a] Cytoplasmic antigen expression.

[b] 10% of cases may have very weak to no detectable CD45 antigen.

[c] Also termed *transitional pre-B*.

[d] Rare subtype not to be confused with Burkitt lymphoma.

[e] May be subclassified into early thymic stage (CD7 $^{+}$, cytoplasmic CD3 $^{+}$, CD5 $^{\pm}$, CD2 $^{\pm}$, CD1a $^{-}$, CD4 $^{-}$, CD8 $^{-}$), mid-thymic stage (CD7 $^{+}$, CD5 $^{+}$, CD2 $^{+}$, cytoplasmic CD3 $^{+}$, surface CD3 $^{\pm}$, CD1a $^{\pm}$, CD4 $^{\pm}$, CD8 $^{\pm}$), and late thymic stage (CD7 $^{+}$, CD5 $^{+}$, CD2 $^{+}$, surface CD3 $^{+}$, CD1a $^{-}$, CD4 $^{+}$ or CD8 $^{+}$).

Cytogenetic studies of pediatric lymphoblastic lymphomas are few and include small numbers of patients ([67], [68], [69] and [70]). Additionally, some reports of the cytogenetics or molecular genetics of lymphoblastic lymphoma include cases of ALL with extramedullary spread. T-lymphoblastic lymphoma and T-precursor ALL share similar chromosomal abnormalities. Chromosome abnormalities of the TCR are relatively common and include chromosome abnormalities at 7q34-36, 7p15, and 14q11 ([68], [69]). The t(9;17) translocation is more common in T-lymphoblastic lymphoma than in T-precursor ALL ([68]). These patients often present with a mediastinal mass and have an aggressive disease course. The t(8;13)(p11;q11-14) has been described in rare cases of T-lymphoblastic lymphoma that present with myeloid hyperplasia and eosinophilia ([71], [72] and [73]). The t(10;11)(p13-14;q14-21) is an uncommon but recurring translocation associated with ALL, AML, and lymphoblastic lymphoma ([74], [75]). Cytogenetic abnormalities have not been shown to be of prognostic significance in lymphoblastic lymphoma. Gene expression profile (microarray) studies of lymphoblastic lymphoma may unveil clinically relevant subgroups similar to those reported for T-ALL ([76], [77]).

Burkitt Lymphoma

The updated REAL and the WHO classifications replace the “small noncleaved cell lymphoma” of the Lukes-Collins and NCI Working Formulations with *Burkitt lymphoma* (Table 91.1) ([10], [31], [32], [78]). The REAL and WHO classifications also combine the L3-ALL of the French-American-British classification with Burkitt lymphoma. Indeed, most but not all L3-ALLs appear to be the leukemic phase of Burkitt lymphoma ([79]). Biologic and genetic differences between Burkitt lymphoma and primary Burkitt leukemia have not been reported.

Classic Burkitt lymphoma consists of a diffuse infiltrative pattern of uniform small to medium-sized cells with moderate amounts of basophilic cytoplasm ([31], [32]). The cells have round nuclei, clumped or condensed chromatin with clear parachromatin, and one to three nucleoli. Lukes and Collins called these cells “small noncleaved cells” because of their morphologic resemblance to cells in the reactive germinal center of normal lymph nodes. But unlike normal germinal center cells, Burkitt lymphoma cells characteristically have multiple small, clear, cytoplasm vacuoles. Frequent mitotic and apoptotic cells are present and reflect this lymphoma's high proliferative rate and apoptotic index, respectively. Tingible body macrophages interspersed among the neoplastic cells impart a low-power microscopic starry-sky appearance. Burkitt lymphoma cells in malignant pleural effusions often are larger and more pleomorphic than their tissue or blood counterparts and may be confused with large cell lymphoma.

The WHO classification recognizes two morphologic variants of Burkitt lymphoma: Burkitt lymphoma with plasmacytoid differentiation and atypical Burkitt or Burkittlike lymphoma ([32]). The plasmacytoid variant contains many tumor cells with eccentrically placed nuclei and a single, central nucleolus—features of plasma cells ([31], [32]). This variant is more frequently found in immunodeficiency-related Burkitt lymphomas ([80]). No prognostic significance in children has been described for this variant.

The neoplastic cells of atypical Burkitt or Burkittlike lymphoma show a wider range of nuclear size and shape plus fewer and larger nucleoli ([32], [81]). These cellular features may lead to difficulties in differentiating this variant from large B-cell lymphoma. To be considered part of the Burkitt lymphoma family, these lymphomas must have evidence of a c- *MYC* translocation. However, c- *MYC* translocations may also be present in some large B-cell lymphomas. In classic Burkitt lymphoma, c- *MYC* deregulation results in almost 100% of the tumor cells being in cell cycle. This proliferative activity can be detected with Ki-67 antibodies, such that almost all of the Burkitt lymphoma cells show positive nuclear reactivity with this antibody. The WHO committee suggests that a Burkittlike lymphoma diagnosis should be made for tumors with morphologic features intermediate between Burkitt lymphoma and diffuse large B-cell lymphoma (DLBCL) in which the Ki-67 fraction of viable cells is at least 99% or a *c-MYC* translocation is present ([32], [82]). Lymphomas with typical features of large cell lymphoma plus a *c-MYC* translocation or a very high Ki-67–positive fraction and Burkittlike lymphomas with a low Ki-67 index should be classified as *DLBCLs* ([32], [82]). Whether large cell lymphomas with a *c-MYC* translocation and high proliferative rate respond to the same therapy as that for Burkitt lymphoma is not known. The atypical Burkitt variant is more common in adults than in children, and controversy continues as to its clinical significance in children ([83]).

Burkitt lymphomas display a characteristic but not unique immunophenotype expression profile: CD19 $^{+}$, strong CD20 $^{+}$, CD22 $^{+}$, and CD79a $^{+}$, and moderately strong expression of surface IgM or, less commonly, IgA or IgG with light chain ? or ? restriction (Table 91.3) ([84]). Nuclear Bcl-6 is present without evidence of *BCL6* rearrangement ([85]). Markers CD5, CD34, BCL2, and Tdt are negative. CD10 is expressed by over half of cases and is often cited as evidence of a germinal center of origin. CD21, the receptor for complement fragment Cd3 and EBV, is more frequently detected in the endemic than in the sporadic form. A small percentage of Burkitt lymphomas have cytoplasmic Ig-μ with no detectable surface Ig, and a rare case may have neither ([86], [87]). Cases with double ?- plus ?–Ig light chain expression may be encountered but are very rare. In contrast to B-lymphoblastic lymphomas, Burkitt lymphomas do not express CD34 or Tdt.

TABLE 91.3. Immunohistochemical Markers of Lymphomas of Children

	Tdt	CD20	CD79a	Ig	CD5	CD3	CD30	CD15	ALK	CTA	MUM1	BCL2	BCL6
T-lymphoblastic lymphoma	+(-)	-	-(+)	-	+/-	+[a]	-	-	-	-	-/+	-	+/-
Burkitt lymphoma	-	+	+	+	-	-	-	-	-	-	-	-	+

Hepatosplenic lymphoma	-	-	-	-	-	+	-	-	-	+	-/+	-	+

+, positive; -, negative; (+), less than 15% of cases positive; +/-, commonly positive but may be negative; -/+, commonly negative but may be positive; (-), less than 15% of cases negative; ALK, anaplastic lymphoma kinase; CTA, cytotoxic antigen (e.g., TIA-1, perforin); Ig, immunoglobulin; MUM1, interferon regulatory factor-4; Tdt, terminal deoxynucleotidyl transferase.

[a] Cytoplasmic CD3.

[b] Marker features are for T-lineage anaplastic large cell lymphomas with ALK gene rearrangements. Rare ALK-positive cases may be B-lineage with CD20 $^{+}$/CD79a $^{+}$/CD3 $^{-}$ profile; anaplastic large cell lymphomas without ALK rearrangements are ALK-1-negative and may express BCL2 protein.

Data from Falini B, Mason DY. Proteins encoded by genes involved in chromosomal alterations in lymphoma and leukemia: clinical value of their detection by immunocytochemistry. Blood 2002;99:409–426.

All cases of Burkitt lymphoma have a chromosomal translocation t(8;14), t(2;8), or t(8;22) involving the *MYC* locus on chromosome 8 at band q24. The partner genes of these translocations involve the Ig heavy chain gene on chromosome 14 at band q32, ?–Ig light chain loci at 2q11, or the ?–Ig light loci at 22q11. Approximately 80% of Burkitt lymphomas have a t(8;14)(q24;q32) translocation ([88]). The breakpoint on chromosome 14 in endemic Burkitt lymphoma involves the heavy-chain joining region, whereas sporadic cases usually show translocation of *MYC* to the Ig gene switch region. As a result of these translocations, *MYC* comes under the influence of the promoter region of the Ig gene, resulting in constitutive expression of *MYC* ([89]). The deregulation of *MYC* drives cells through the cell cycle and activates genes involved in apoptosis. *MYC* translocations are not entirely specific for Burkitt lymphoma, having been reported in large B-cell lymphomas, follicular lymphomas, and precursor B-lymphoblastic transformation of follicular lymphoma. The translocations associated with Burkitt lymphoma are relatively easily detected by classical cytogenetic methods and, more recently, by fluorescence *in situ* hybridization of interphase nuclei ([90]).

Large Cell Lymphoma

Large cell lymphomas are composed of lymphoid cells that are larger than the diameter of a histiocytic nucleus or two to three times the width of small, inactive-appearing lymphocytes. These lymphomas are of B-, T- or, rarely, NK-cell origin. The term *non-B*, *non-T*, or *null-cell large cell lymphoma* usually indicates incomplete laboratory characterization of the cell origin and should not be regarded as a lymphoma without lineage commitment. Large cell neoplasms of true monocytic/histiocytic or dendritic phenotype should not be considered lymphomas, as their clinical course and treatment differ. The revised REAL and recent WHO classifications recognize several types of large cell lymphoma, including diffuse large B-cell, mediastinal (thymic) B-cell, intravascular large B-cell, peripheral T-cell–unspecified, angioimmunoblastic T-cell, and ALCL ([32]). Other lymphomas, including adult T-cell leukemia/lymphoma, extranodal nasal NK/T-cell lymphoma, enteropathy-type T-cell lymphoma, subcutaneous panniculitis-like T-cell lymphoma, and primary cutaneous CD30 $^{+}$ T-cell disorders, may have prominent large cell components but are defined by other biologic or clinical features ([32]). ALCL of T/null type, DLBCL, and peripheral T-cell lymphoma (PTCL) comprise the majority of pediatric large cell lymphomas, although rare examples of other types of large cell lymphomas in this age group have been described. ALCLs account for 40 to 50% of pediatric large cell lymphomas, and DLBCLs comprise another 30 to 40%, with the remainder consisting of PTCL ([91] , [92]). Although the morphologic and immunophenotypic features of large cell lymphomas of adults and children are for the most part identical, very few investigations of the laboratory and biologic features of pediatric large cell lymphomas other than the anaplastic large cell–type have been reported.

ANAPLASTIC LARGE CELL LYMPHOMA ALCL is rare in very young children and has a peak incidence in adolescence ([93]). In children, ALCL tends to involve lymph nodes and extranodal sites, including skin, soft tissues, lungs, and bones ([93] , [94]). Approximately 20 to 25% of patients have bone marrow involvement at diagnosis that may not be obvious without special studies ([95]). The architecture of involved lymph nodes may be partially or totally effaced by malignant cells. A frequent pattern of early lymph node involvement consists of proliferation of lymphoma cells within the lymphoid sinuses, resulting in a cohesive appearance that mimics metastatic tumor. ALCL is typically comprised of variable numbers of small, medium-sized, and large neoplastic cells. The hallmark cells of ALCL are large cells with eccentrically placed, monocytoid or horseshoe-shaped nuclei with an eosinophilic Golgi region near the nucleus. Gigantic large cells with multiple nuclei forming a wreathlike appearance are common. The large cells often resemble Reed-Sternberg cells and their variant forms. The smaller cells usually have smaller amounts of cytoplasm and lack the nuclear characteristics of the large cells. ALCL includes several morphologic forms or variants, including the common, lymphohistiocytic, and small cell variants ([32] , [96]). The *common variant* accounts for over 70% of cases and features the hallmark large anaplastic tumor cells described above ([97]). Varying numbers of small and medium-sized lymphoid cells are also commonly present. Histiocytic erythrophagocytosis is a prominent feature in some cases. The *lymphohistiocytic variant* accounts for less than 20% of ALCL in children and consists of a mixture of small and larger lymphoid cells and many histiocytes ([98] , [99]). The histiocytes may be so numerous as to partially obscure the lymphoid cells. Not infrequently, there is evidence of active histiocytic erythrophagocytosis, simulating a hemophagocytic syndrome ([100] , [101]). Neutrophils and sometimes eosinophils can also be present. The *small cell variant* accounts for less than 10% of cases and may not be recognized if the hallmark large cells are scarce and immunophenotyping and cytogenetic studies are not performed ([102]). In the past, this variant in children and adults was often called *PTCL*. A neutrophil-rich form of ALCL has also been described but is not recognized as a variant form by the WHO classification ([103] , [104] , [105] and [106]). Other rare forms of ALCL include sarcomatoid, signet ring, and granulomatous forms ([107] , [108] and [109]). Most ALCLs express one or more T-cell–associated antigens, including CD2, CD3, CD4, CD7, and CD45RO (Table 91.3) ([32] , [110]). T-cell antigens CD5 and CD8 are usually negative. Some cases lack demonstrable T-cell antigens but have evidence of TCR gene rearrangements. These cases are similar to T-cell antigen–positive cases in every other way and may be referred to as *null/T ALCL* ([32]). Most ALCLs express cytoplasmic cytotoxic cell–associated proteins TIA-1, granzyme B, or perforin. A membranous plus Golgi pattern of CD30 expression is characteristic of the neoplastic cells of ALCL ([111]). The most intense reactivity to CD30 antibodies is seen in the large cells, whereas the smaller cells are weakly positive or, more often, negative. Most ALCLs are positive for the EMA (*e*pithelial *m*embrane *a*ntigen) in a manner analogous to CD30 ([112]). Myeloid-associated CD15 may be weakly expressed by some neoplastic cells in a minority of cases. Gene expression profiling studies show that clusterin is aberrantly expressed in systemic but not primary cutaneous anaplastic lymphoma kinase (ALK)–negative ALCL ([113]). B-cell–associated antigens CD19, CD20, CD22, and CD79a are not expressed by the ALCLs except for rare, controversial cases of B-cell ALCL. A t(2;5)(p23;q35) translocation is demonstrable in over 75% of ALCLs ([114] , [115]). Several other translocations of ALK have been described, including t(1;2)(q25;p23), t(2;3)(p23;q21), inv(2)(p23q35), t(2;22), t(2;17)(p23;q11), and t(2;19)(p23;p13) ([116] , [117] , [118] and [119]). With the t(2;5), *NPM* (nucleophosmin) on chromosome 5q35 is fused with *ALK* on chromosome 2p23, resulting in expression of a chimeric NPM-ALK protein ([120]). ALK protein is a transmembrane protein normally expressed by some cells of the brain but not by lymphoid or hematopoietic elements. The result of *ALK* translocations is up-regulation of ALK with resultant aberrant expression of a chimeric ALK protein in the lymphoma cells. ALCLs with the t(2;5) display a cytoplasmic plus nuclear ALK expression pattern, whereas those with other *ALK* translocations display a cytoplasmic-only pattern ([110] , [111]). Rare cases of ALCL with the t(2;17)(q23;q11) display granular cytoplasmic staining with ALK antibodies ([121]). Approximately 10% of ALCL cases do not have a detectable *ALK* translocation or express ALK ([99]). Conversely, rare lymphomas with a t(2;5) do not have the morphologic features of ALCL ([93]). The lymphoma cells of over 85% of ALCL cases express ALK proteins detectable with the p80 or ALK1 antibodies ([120] , [122] , [123]). Thus, tumor cell expression of ALK is a highly sensitive marker for ALCL and its variants having a translocation of *ALK*. Lymphomas with ALCL morphology and immunophenotype but no detectable *ALK* translocation or expression should be regarded as phenotypic variants of ALCL or as a different entity, because ALK positivity appears to have prognostic significance ([32]). Some mesenchymal tumors in children and adults can also express ALK, including neuroblastoma, inflammatory myofibroblastic tumor, rhabdomyosarcoma, and malignant peripheral nerve sheath tumor ([124] , [125] and [126]). ALK expression in these tumors may be due to rearrangement of an *ALK* loci or other mechanisms that up-regulate ALK expression. Thus, ALK expression alone should not be used to distinguish between lymphoma and other tumors. ALCL can present as a leukemic process, or a leukemic phase may develop during the disease course ([119] , [127] , [128] , [129] , [130] and [131]). Lymphadenopathy or extranodal masses may not be present in patients presenting with a leukemic process. The circulating lymphoma cells are usually small to medium-sized with atypical nuclear features.

White blood cell counts can be over 100 × 10^9 per L. Tissue masses, when present, can show the typical histopathologic features of common ALCL, but most cases reported to date resemble the small cell variant. The bone marrow may contain lymphoma cells resembling those in the peripheral blood or may be comprised in part or largely of large anaplastic cells. The circulating cells have a T-cell phenotype profile. In contrast to precursor T-ALL, CD1a, CD34, and Tdt are negative. ALK- and EMA-expressing cells are usually demonstrated in the bone marrow. Cytogenetic or molecular studies for *ALK* translocations are necessary to confirm a primary diagnosis. A t(2;5)(p23;q35) is demonstrable in most cases. A novel t(2;19)(p23;p13) was found in an 18-month-old boy who presented with a leukemia process and hepatosplenomegaly but no overt bone marrow involvement, adenopathy, or other extranodal masses ([119]). Studies revealed an unusual immunophenotype: positive for CD45, CD13, CD30, CD33, CD16/56, ALK, perforin, and granzyme B and negative for CD3, CD34, Tdt, and myeloperoxidase. The phenotype of this leukemia was suggestive of a NK-cell origin and raises the possibility that some cases of null-ALCL may likewise arise from this cell lineage. In adults, ALK protein expression in ALCL is a favorable prognostic factor ([132], [133] and [134]). Treatment responses in adults are similar for patients with the t(2;5) or its variant translocations ([110]). A similar favorable outcome is found in children with immunohistochemically documented ALK-positive ALCL ([93], [99], [135], [136]). In multivariant analyses of childhood ALCL, mediastinal, visceral (lung, liver, spleen), and skin involvement are poor prognostic factors ([137], [138]).

Diffuse Large Cell Lymphomas of B-Cell Lineage The WHO classification recognizes four types of large cell lymphoma of B-cell lineage based on laboratory and clinical features: (a) DLBCL, (b) mediastinal large B-cell lymphoma (MLBCL), (c) intravascular large B-cell lymphoma, and (d) primary effusion lymphoma ([32]). The last two large cell lymphomas are very rare in adults and are very uncommon or have not been reported in the pediatric age group.

Diffuse Large B-Cell Lymphoma DLBCL includes four morphologic variants, including centroblastic, immunoblastic, T-cell/histiocyte–rich, and anaplastic variants ([32]). The variants are not recognized as clinical/pathologic entities in the WHO classification, in part because of difficulties with morphologic reproducibility among different observers and controversy over the clinical relevance of separating these lymphomas. Another not infrequently encountered problem is distinguishing among Burkitt, Burkittlike, and DLBCLs. In a recent study, the consensus for identifying Burkitt and DLBCL was 88% and 80%, respectively, and 42% for Burkittlike lymphoma ([139]). In many cases, the difficulty is a direct result of limited size or quality of the tissue obtained for examination. Additional biopsy tissue, if available, often results in recognition of the patient's lymphoma type. DLBCLs express one or more pan–B-associated markers, CD19, CD20, CD22, and CD79a. Surface or cytoplasmic Igs are expressed by 50% or more cases. Some cases may express CD5, CD10, BCL2, or BCL6 (Table 91.3). The proliferative index, as measured by nuclear Ki-67 expression, may be high in some DLBCLs but is less than in Burkitt lymphoma. Centroblastic lymphoma may be more common than the other DLBCL variants in children. These lymphomas are believed to arise from germinal center cells and express CD20, CD79a, CD10, and BCL6 but not MUM-1(interferon regulatory factor-4) and CD138. The immunoblastic variant is rare and consists of over 90% immunoblasts with single, large, centrally placed nucleoli, sometimes with a plasmacytoid appearance. Immunoblastic lymphomas express CD20 and CD79a, and, in some instances, CD30, MUM-1, or CD138. In adults, controversy exists as to whether patients with the immunoblastic variant fare less well than those with the centroblastic variant ([140]). The rarely encountered B-cell ALCL is characterized by cohesive large pleomorphic cells that initially occupy the sinuses of involved lymph nodes. These lymphomas can express CD30 but not ALK. In adults, full-length ALK protein is detected in a rare subtype of DLBCL that has plasmacytoid features but no rearrangement of the ALK gene ([141]). Rare cases of t(2;5) and ALK expressing DLBCL with plasmacytoid features can be found among DLBCLs of children ([142]). T-cell/histiocyte–rich large B-cell lymphomas are rare in children and may be confused with Hodgkin lymphoma or reactive processes ([143]). The large cells express CD20, CD79a, BCL-6, and sometimes CD30 and EMA but not CD15 or ALK ([139], [144]). Information on the genetic lesions in childhood DLBCL is scanty. In a recent small study of pediatric DLBCL, expression of Bcl-6, c-myc, and Bcl-2 was detected in 66%, 100%, and 50% of cases, respectively ([145]). Approximately 30% of adult DLCLs express BLC2 or have a t(14;18) translocation, indicative of germinal center origin. Another 30% of cases may have abnormalities of the chromosome 3 band q27, the locus of *BCL6*. A small number of cases may have a t(8;14) translocation. Recent gene expression profiling studies reveal that adult DLBCL consists of three subgroups: germinal center B-cell–like, activated B-cell–like, and a third type not corresponding clearly to a stage of recognized B-cell differentiation ([146], [147] and [148]). Another DNA-based gene expression profile study of adults with DLBCL delineated patients within International Prognostic Index risk categories who were likely to be cured or to die of their disease ([149]). Gene profiling studies of pediatric large cell lymphomas have not been reported.

Mediastinal Large B-Cell Lymphoma MLBCL is an uncommon subtype of DLBCL ([32], [150], [151], [152], [153], [154] and [155]). Other names for this lymphoma include *mediastinal diffuse large cell lymphoma with sclerosis* and *mediastinal clear cell lymphoma of B-cell type*. MLBCLs comprise less than 10% of all large cell lymphomas in children. In contrast to a female prevalence in adults, this lymphoma may occur slightly more frequently in male children and adolescents. These neoplasms appear analogous to noncirculating thymic medullary B cells. Patients present with signs and symptoms of a large mediastinal mass, frequently with extension into adjacent structures, including lung, pericardium, chest wall, and superior vena cava. Extrathoracic extension at diagnosis is uncommon but, with disease progression, can involve kidneys, brain, soft tissue, skin, and adrenal glands. Previously, MLBCL was considered an aggressive neoplasm, but current chemotherapy treatments of children and adults with localized disease have resulted in greater than 80% overall survival ([151], [153]). Pediatric patients presenting with extrathoracic disease fare less well ([153]). Under the microscope, MLBCLs typically show small clusters of large lymphoid cells surrounded by thin to thick dense fibrotic bands. The clusters of neoplastic cells can mimic the metastatic undifferentiated carcinoma. Remnant thymic epithelial cells expressing cytokeratin may also be present and may be confused with an epithelial tumor or thymoma in small biopsies. Not infrequently, intense fibrosis can obscure the neoplastic lymphocytes. The lymphoma may be comprised of a mixture of small, medium, or large lymphoid cells or may consist primarily of large cells with ample amounts of clear and, less commonly, acidophilic or weakly basophilic cytoplasm ([156]). Small benign-appearing lymphocytes and eosinophils may be present and may create problems initially in differentiating MLBCL from Hodgkin lymphoma. Unlike classical Hodgkin lymphoma, the neoplastic cells of MLBCL express CD45 and B-cell–associated antigens CD19, CD20, CD22, and CD79a (Table 91.3). Expression of BCL-6 and CD10 by these lymphomas suggests a possible derivation from germinal center B cells ([157]). Ig expression may be weak but often is not detectable ([158], [159]). In contrast to lymphoblastic lymphoma, these tumors do not express Tdt or CD34. The CD30 antigen, a marker common to ALCL and classical Hodgkin disease, may be weakly to strongly expressed by a few or sometimes the majority of lymphoma cells ([160]). Molecular studies uniformly reveal clonal Ig gene rearrangements even when Igs are not demonstrable by immunologic techniques. The lymphoma cells show mutated Ig V region genes consistent with antigen-experienced or post–germinal center B cells ([161]). It is uncommon for evidence of clonal EBV genome to be present in the tumor cells. Relatively few cytogenetic studies have been reported, but those available show aneu-ploid tumor cells, often with gains of chromosome 9p or Xq ([162], [163]). The t(14;18) chromosomal translocation and its variants, common to adult large cell follicular lymphomas, are rare ([163]). The tumor cells may overexpress *REL* or *MAL* in a minority of cases ([164]). *BCL6*, p53, p16INK4 alterations, and *c-MYC* rearrangements may be present ([162], [163], [164], [165] and [166]).

Uncommon Pediatric Lymphomas

FOLLICULAR LYMPHOMA *Follicular lymphoma* is a neoplasm of follicular center B cells that retains a follicular or nodular growth pattern. The WHO classification recognizes three morphologic grades of follicular lymphoma based on ratios of centroblasts or centrocytes (noncleaved and cleaved follicular center cells, respectively) ([32]). Follicular lymphomas comprise approximately 35% of adult NHLs and, in this age group, usually present in lymph nodes, spleen, and bone marrow ([32]). More than two-thirds of adult patients have disseminated disease at diagnosis and are not cured with chemotherapy. In contrast, follicular lymphoma comprises less than 3% of all pediatric lymphomas ([167], [168], [169], [170], [171] and [172]). Furthermore, in children, these lymphomas usually present with disease localized to tonsillar, cervical, and inguinal lymphoid tissues. Examples of localized testicular follicular large cell lymphomas in the pediatric age group have also been reported ([172], [173], [174], [175] and [176]). In striking contrast to adults, transformation to higher grade, diffuse lymphoma or leukemic phase is distinctly uncommon, and most children have prolonged remissions with or without therapy. The actuarial 5-year event-free survival was 94% in a series reported by Ribeiro ([170]). In another study, six of seven children were in complete remission, including three who had no chemotherapy ([171]). In a recent study of 23 pediatric patients, 15 of 19 patients had stage I disease, and 11 of 13 with sufficient follow-up achieved a durable clinical remission ([172]). Despite good morphologic criteria for follicular lymphoma, the rarity of this disease in children requires additional immunophenotypic and molecular studies to confirm a lymphoma diagnosis and to clearly separate it from the more frequent occurrence of benign follicular hyperplasia. Adult and pediatric follicular lymphomas do not differ morphologically, but recent studies reveal biologic differences in the lymphomas of these two age groups. Pediatric testicular follicular lymphomas express bcl-6 or have *BCL6* rearrangements but lack t(14;18)(q32;q21) chromosomal translocations and *bcl-2* and *p53* abnormalities (Table 91.3) ([173], [174], [175] and [176]). By contrast, the majority of adult follicular lymphomas express bcl-2, have a t(14;18) that involves rearrangement of *BCL2*, and progress despite chemotherapy ([32]). Bcl-2 is a mitochondrial protein that plays a central role in resistance to apoptosis. Bcl-2 is normally expressed by T cells and mantle zone B cells but not by germinal center cells. Aberrant expression of bcl-2 by follicular lymphomas may influence the therapeutic response of the lymphomas. In two separate investigations of pediatric nontesticular follicular lymphomas, bcl-2 expression was detected in only 6 of 20 patients and BCL2 rearrangements by polymerase chain reaction in 2 of 16 patients ([171], [172]). In one of the latter studies, all four patients with lymphomas expressing bcl-2 presented with advanced disease stage or had disease refractory to therapy, whereas children with bcl-2–negative tumors had stage I disease, achieved complete remission, and had no relapses ([172]). Thus, bcl-2 expression does not appear to contribute to the pathogenesis of most pediatric follicular lymphomas. However, bcl-2 expression appears to identify a subset of pediatric patients in whom the lymphoma is often disseminated and more refractory to chemotherapy.

HEPATOSPLENIC T-CELL LYMPHOMA *Hepatosplenic T-cell lymphoma* is an aggressive extranodal malignancy of cytotoxic T cells usually of ?d and, less commonly, aß TCR type ([32], [177], [178], [179], [180], [181] and [182]). Children and adults are rare victims of this systemic lymphoma, which has its peak incidence in adolescents and young adults ([32], [178]). Males are more frequently affected than females, although a female predisposition is reported for aß hepatosplenic lymphomas ([180], [181]). Patients typically present with enlarged spleens and livers with no appreciable lymphadenopathy. Thrombocytopenia is common as is anemia. Circulating lymphoma cells are commonly present at diagnosis but may be difficult to distinguish from atypical lymphocytes. A more obvious leukemic phase may develop as the disease

progresses ([180] , [181]). Cases of aß hepatosplenic lymphoma are histologically, cytogenetically, and clinically similar to the ?d form ([181]). A relatively high percentage of cases follow solid organ transplant, suggesting that an underlying immune problem predisposes to this neoplasm ([183] , [184] , [185] and [186]). The neoplastic cells are medium sized with scant to moderate amounts of cytoplasm. Azurophilic cytoplasmic granules have been described in a minority of cases. The nuclei may be round or convoluted with condensed chromatin and inconspicuous nucleoli. Mitotic cells are infrequent. With disease progression, a blast cell transformation with cells having prominent nucleoli may occur ([183] , [187] , [188]). The lymphoma cells may be difficult to appreciate in bone marrow aspirates, but bone marrow needle biopsies frequently show the presence of a characteristic sinusoidal infiltrate ([181] , [182] , [188]). The spleen and liver also show marked sinusoidal infiltrations by the neoplastic cells ([181] , [182]). Erythrophagocytosis may be evident in splenic and bone marrow sinusoids ([181] , [182] , [189] , [190]). The lymphoma cells have a fairly consistent immunophenotypic expression pattern of CD2 $^{+}$, CD3 $^{+}$, CD4 $^{-}$, CD8 $^{\pm}$, CD5 $^{-}$, CD7 $^{+}$, CD16 $^{+}$, and CD56 $^{\pm}$ (Table 91.3) ([32] , [180]), although exceptions to this phenotype are not uncommon. The aß hepatosplenic lymphomas have a similar immunophenotype except for a slightly more frequent expression of CD57 ([181]). TCR-?d or less common TCR-aß proteins can be detected by flow cytometric analyses ([177] , [182]). Cytotoxic granular protein TIA-1 is detected in most cases, whereas granzyme B or perforin are detected in only a minority of cases ([180] , [181] , [189] , [191] , [192]). An isochrome 7q, often with trisomy 8 and other random chromosomal abnormalities, is found in the majority of reported cases ([181] , [185] , [187] , [188] , [193] , [194] , [195] and [196]). TCR ?- and ß-chain gene rearrangement studies show reciprocal findings between aß and ?d types of hepatosplenic lymphomas and should not be used as a distinguishing test ([180] , [181]). The majority of ?d cytotoxic T cells in the sinuses of normal spleens utilize Vd 1. This splenic cell is cited as being the origin of ?d hepatosplenic T-cell lymphoma, because the majority of these lymphomas preferentially express Vd 1 ([180] , [197]). EBV genome may be present in the neoplastic cells of some patients, but there does not appear to be any causative relationship ([181] , [198]). Hepatosplenic T-cell lymphoma in children may have been previously confused with a T-cell lymphoblastic malignancy or other forms of peripheral T-cell lymphomas. Reports of pediatric cases are limited to case discussions or are included in reports of adult investigations ([177] , [180] , [181] , [194] , [196] , [198]). Children with aß hepatosplenic lymphoma tend to be younger than those with the ?d form of lymphoma ([181] , [199]). As in adults, the clinical course in children is aggressive. Initial responses to chemotherapy are followed shortly thereafter by relapse and death in the majority of patients. Bone marrow transplant with subsequent relapse has been mentioned in one report ([181]).

RARE PEDIATRIC LYMPHOMAS Rare lymphomas of children and adolescents include mycosis fungoides ([200] , [201] , [202] , [203] , [204] , [205] , [206] and [207]), mucosa-associated lymphoid tissue lymphoma ([208]), panniculitis-like T-cell lymphoma ([209] , [210]), human T-cell leukemia virus type 1–associated leukemia/lymphoma ([211] , [212] and [213]), and NK lymphoma ([214] , [215] and [216]). For the most part, the clinical and biologic features of these lymphomas in children resemble their adult counterparts. However, because of their rarity in children, clinical and biologic features of these lymphomas can only be gleaned from compilations of case reports. The diagnosis of these rare lymphomas in children is often delayed or initially interpreted as a reactive process or as one of the more common pediatric lymphomas.

CLINICAL FEATURES

The clinical presentation for children with NHL is quite varied (Table 91.4) ([1] , [2] and [3]). The primary sites of disease, which vary according to histologic subtype, are the primary determinants for the signs and symptoms observed. Children with lymphoblastic lymphoma typically present with a mediastinal mass, whereas children with Burkitt lymphoma typically present with abdominal disease (usually arising from the terminal ileum and often serving as a trigger point for an intussusception). By way of contrast, children with large cell lymphoma may present with primary involvement of either mediastinum or abdomen.

TABLE 91.4. Clinical and Biologic Characteristics of Non-Hodgkin Lymphoma in Children

Subtype	Proportion of Cases (%) [a]	Phenotype	Primary Site	Translocation	Affected Genes
Burkitt	39	B cell	Abdomen or head and neck	t(8;14)(q24;q32)	IgH-c *MYC*
				t(2;8)(p11;q24)	Ig?-c *MYC*
				t(8;22)(q24;q11)	*Ig? -cMYC*
Lymphoblastic	28	T cell [b]	Mediastinum or head and neck	t(1;14)(p32;q11)	TCRad- *TAL*1
				t(11;14)(p13;q11)	TCRad- *RHOMB2*
				t(11;14)(p15;q11)	TCRad- *RHOMB1*
				t(10;14)(q24;q11)	TCRad- *HOX11*
				t(7;19)(q35;p13)	TCRß- *LYL1*
				t(8;14)(q24;q11)	TCRad- *MYC*
				t(1;7)(p34;q34)	TCRß- *LCK*
Large cell	26	B cell, T cell, [c] indeterminate [c]	Mediastinum, abdomen, head and neck, or skin [c]	t(2;5)(p23;q35)	*NPM-ALK*

Ig, immunoglobulin; TCR, T-cell receptor.

[a] Proportion at St. Jude Children's Research Hospital; other histotypes account for approximately 7%.

[b] B-cell progenitor variants have also been described.

[c] Associated with the anaplastic large cell lymphoma subtype (approximately 10% of childhood non-Hodgkin lymphoma).

Children presenting with an abdominal mass may have associated nausea, vomiting, and abdominal pain. Abdominal distention secondary to obstruction and associated ascites may be present on physical examination. Extension of the mass into the pelvis may result in ureteral compression and hydronephrosis. The presence of an anterior mediastinal mass may result in some degree of respiratory distress, ranging from slight cough to severe respiratory compromise including arrest ([2]). The respiratory status may also be compromised by the presence of a pleural effusion. A mediastinal mass may obstruct venous return to the heart, resulting in a superior vena cava syndrome ([2]). This syndrome is characterized by swelling in the neck and shoulder region and prominent venous vasculature, a condition that may predispose the patient to the development of a deep venous thrombosis.

The degree of tumor burden at the time of diagnosis is quite variable. Some children present with isolated lymph node involvement, whereas others may present with more widespread disease. Involvement of the bone marrow may be associated with pancytopenia, pallor, and bruising. Blurred vision, headache, or the presence of a cranial nerve palsy on physical examination may be present when the central nervous system is involved. Skin lesions may be present at the time of diagnosis in approximately 4% of children; however, this is usually associated with the CD30 $^{+}$, ALK $^{+}$, anaplastic subtype of large cell lymphoma ([217] , [218]). Involvement of bone may be associated with local swelling, pain, or limp. Boys may present with testicular enlargement secondary to tumor infiltration. Involvement of the ovary may be identified on diagnostic imaging studies.

MANAGEMENT

Initial Workup and Staging

Modern therapy for the NHLs of childhood is determined by both the histologic diagnosis and the disease stage. It is therefore imperative that an expeditious and comprehensive staging workup be performed after the diagnosis is established. This generally includes (a) computed tomography of the neck, chest, abdomen, and pelvis; (b) nuclear scans (e.g., bone scan, gallium scan); (c) bilateral bone marrow aspirates and biopsies for cell count and differential, flow cytometry if marrow overtly involved, cytogenetics, and molecular pathology; and (d) lumbar puncture for cerebrospinal fluid cytology ([1] , [2] and [3]). Positron emission tomography is commonly used among adults with either Hodgkin disease or NHL; however, it is not currently a standard staging modality for children with NHL ([219]). Further data on how positron emission tomography compares to conventional gallium and bone scanning are needed. A complete blood count with differential and chemistry panel, including serum lactate dehydrogenase, should also be obtained. On completion of the workup described above, patients are designated with a disease stage, usually according to the St. Jude system described by Murphy (Table 91.5) ([9]). Those in stage I or II are considered to have limited stage disease, whereas those in stage III

or IV are considered to have advanced stage disease.

TABLE 91.5. Stages of Non-Hodgkin Lymphoma

Stage I
A single tumor (extranodal) or involvement of a single anatomic area (nodal), with the exclusion of the mediastinum and abdomen.
Stage II
A single tumor (extranodal) with regional node involvement.
Two or more nodal areas on the same side of the diaphragm.
Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm.
A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable.
Stage III
Two single tumors (extranodal) on opposite sides of the diaphragm.
Two or more nodal areas above and below the diaphragm.
Any primary intrathoracic tumor (mediastinal, pleural, or thymic).
Extensive primary intraabdominal disease.
Any paraspinal or epidural tumor, whether or not other sites are involved.
Stage IV
Any of the above findings with initial involvement of the central nevous system, bone marrow, or both.

Adapted from Murphy SB. Classification, staging and end results of treatment of childhood non-Hodgkin's lymphomas: dissimilarities from lymphoma in adults. Semin Oncol 1980;7:332–339.

Initial Management

On expeditious completion of the diagnostic and staging workup, appropriate therapeutic options can be considered. Before chemotherapy is started, however, a number of issues must be considered. Some children are at high risk for tumor lysis syndrome. This primarily includes children with advanced stage Burkitt lymphoma and some children with lymphoblastic lymphoma who have a large tumor burden at diagnosis, which may be reflected by an elevated serum lactate dehydrogenase. Some of these children have metabolic abnormalities with some degree of renal dysfunction at diagnosis, which only worsen once chemotherapy is started (e.g., hyperkalemia, hyperuricemia, hyperphosphatemia, and so forth). Therefore, these children should have excellent intravenous access and vigorous hydration before starting chemotherapy. Hyperuricemia has historically been managed using hyperhydration coupled with allopurinol, a xanthine oxidase inhibitor. Uricolytics, such as uricozyme, which cleaves uric acid to the more soluble and readily cleared allantoin, have been used in France for decades. More recently, a recombinant form of this drug, rasburicase (SR29142), has become available and has been shown to be very effective and well tolerated with a reduced risk of associated allergic reaction ([220]). The advantage of these agents is that they cause a precipitous drop in serum uric acid, which negates the need for alkalinization, thus facilitating phosphorus excretion. It is of note that a recent study of rasburicase in children at high risk for tumor lysis syndrome demonstrated preservation of renal function with no significant associated hyperphosphatemia or hyperkalemia ([220]).

Therapy

There have been significant improvements in treatment outcome for children with newly diagnosed NHL over the past 20 years ([1]). This has been accomplished largely through incremental refinements in sequential multicenter trials that feature a stage and histology–directed or an immunophenotype-directed approach to treatment assignment. Two of the initial successful regimens for children with NHL were the multiagent LSA $_2$L $_2$ regimen ([221] , [222] and [223]) designed for children with ALL and the COMP regimen (cyclophosphamide, vincristine, methotrexate, and prednisone) ([221]). A randomized trial by the Children's Cancer Group (CCG) comparing these two approaches validated a stage and histology–directed therapeutic approach to pediatric NHL ([221]). Specifically, children with limited stage disease did well regardless of treatment arm. In contrast, among those with advanced stage disease, those with Burkitt lymphoma had a better outcome with COMP, and those with lymphoblastic lymphoma had a better outcome with LSA $_2$L $_2$; there was no clear therapeutic advantage with either approach for children with advanced stage large cell lymphoma. Other trials validated and built on these observations ([224] , [225] , [226] , [227] , [228] , [229] , [230] , [231] , [232] , [233] , [234] , [235] , [236] , [237] , [238] , [239] , [240] , [241] , [242] , [243] , [244] , [245] , [246] , [247] , [248] , [249] , [250] , [251] , [252] , [253] , [254] , [255] , [256] , [257] , [258] , [259] , [260] , [261] , [262] , [263] , [264] , [265] , [266] , [267] and [268]).

Subsequent to the CCG trial comparing LSA $_2$L $_2$ and COMP, the dominant theme of most trials for children with limited stage disease has been the reduction of treatment-related acute and late effects without compromising treatment outcome ([226] , [228] , [229] , [247] , [250] , [251]). This has been attempted by shortening the duration of therapy, reducing the dose of certain agents, and eliminating involved field irradiation. In the first of two sequential trials performed by the Pediatric Oncology Group (POG) ([229]), it was demonstrated that involved field irradiation could safely be eliminated from a 33-week treatment plan that featured three courses of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) followed by a 24-week maintenance phase of 6-mercaptopurine and low-dose methotrexate. In the subsequent trial, it was shown that the 24-week maintenance phase could be safely eliminated for children with Burkitt or large cell lymphoma; however, the result was inferior for children with lymphoblastic lymphoma ([229]). Even with the 24-week maintenance phase, one-third of children with lymphoblastic lymphoma experience a recurrence; however, the majority is successfully salvaged, resulting in an overall survival similar to other histologic subtypes. Other groups have approached limited stage lymphoblastic lymphoma with a more intensive initial treatment regimen ([246]). For example, the French Pediatric Oncology Society (SFOP) cooperative group trial treats children with lymphoblastic lymphoma with the same regimen used for those with advanced stage disease ([246]). A somewhat intermediate-intensity approach is currently being studied by the Children's Oncology Group, in which patients with limited stage lymphoblastic lymphoma are receiving a regimen modeled after approaches used for low-risk ALL.

Treatment advances for children with advanced stage disease have primarily focused on improving histology- and immunophenotype-directed treatment strategies (United States and Europe, respectively) ([224] , [225] , [226] and [227] , [230] , [231] , [232] , [233] , [234] , [235] , [236] , [237] , [238] , [239] , [240] , [241] , [242] , [243] , [244] , [245] , [246] , [247] , [248] , [249] , [250] , [251] , [252] , [253] , [254] , [255] , [256] , [257] , [258] , [259] and [260]). Intensification of therapy, addition of new active agents, and refinement in risk-adapted therapy have all been credited with improvement in outcome.

For children with advanced stage Burkitt lymphoma, initial improvements in treatment outcome beyond those achieved with COMP were attained by the incorporation of high-dose methotrexate and cytarabine (Table 91.6). Two-year event-free survival rates of approximately 80% for children with stage III Burkitt lymphoma were reported with the Total B regimen, which featured 1 g/m ^{2} methotrexate and sequentially escalating doses of continuous-infusion cytarabine; for those with bone marrow involvement, however, the outcome was inferior (approximately 20%) ([227]). The POG modified the Total B approach in the PG8617 protocol by incorporating high-dose pulses of cytarabine and intensified intrathecal therapy. This resulted in an improved treatment outcome for children with stage IV disease ([231]).

TABLE 91.6. Treatment Outcome for Advanced Stage Burkitt Lymphoma

Protocol	Stage	Patients (No.)	EFS Rate	Reference
POG 8617	IV	34	4-yr EFS = 79% ± 9%	231
	B-ALL	47	4-yr EFS = 65% ± 8%	
LMB 89 [a]	III	278	5-yr EFS = 91% (CI, 95%; range, 87–94%)	226
	IV	62	5-yr EFS = 87% (CI, 95%; range, 77–93%)	

	B-ALL	102	5-yr EFS = 87% (CI, 95%; range, 79–92%)	
BFM 90	III	169	6-yr EFS = 86% ± 3%	251
	IV	24	6-yr EFS = 73% ± 10%	
	B-ALL	56	6-yr EFS = 74% ± 6%	
CCG [a] Orange *vs.*	III/IV/B-ALL	43	12-mo EFS = 83%	236
LMB 86	III/IV/B-ALL	42	12-mo EFS = 84%	

B-ALL, B-cell acute lymphoblastic leukemia; CI, confidence interval; EFS, event-free survival.

[a] Includes patients with B-cell large cell non-Hodgkin lymphoma.

The optimal duration of therapy was examined in other trials. For example, the French SFOP (232) demonstrated that the duration of therapy could be reduced to 4 months; Schwenn et al. (238) reported an excellent result with a 2-month regimen for those with stage III disease. Further advances in therapy have been achieved over the last 10 years by dose intensification of cyclophosphamide, methotrexate, and cytarabine and by the incorporation of new active agents (e.g., etoposide). The German Berlin-Frankfurt-Munster (BFM) (264) and French SFOP (226) cooperative groups have reported among the best results, using risk-directed treatment assignment based on clinical features such as stage, degree of surgical resection, tumor burden, degree of bone marrow involvement, and disease sites. For example, in the SFOP LMB-89 regimen (226), Group A treatment is restricted to those who have completely resected limited stage disease, whereas Group C, which is the most intensive arm, comprises those who have greater than 70% marrow blasts or central nervous system disease. Group B treatment is intermediate in intensity and is given to those with incompletely resected limited stage disease, stage III, and those with less than 70% bone marrow replacement. Approximately 85% of children with advanced stage B-cell lymphoma are cured with this approach.

Strategies to improve the outcome for children with lymphoblastic lymphoma have generally built on the results of the CCG trial, which demonstrated a superior result with an ALL-like treatment approach (i.e., LSA $_2$L $_2$). The incorporation of high-dose methotrexate has been featured in a number of successful treatment regimens (Table 91.7) (246 , 255 , 260). For example, the SFOP modified the LSA $_2$L $_2$ regimen by incorporating courses of high-dose methotrexate throughout the maintenance phase of therapy with an excellent treatment result (246). The BFM cooperative group achieved an outstanding result (i.e., 5-year event-free survival of 90%) with an approach that featured a high-dose methotrexate consolidation phase (5 g/m ^{2} every other week for a total of four courses) (255). The improved outcome with higher doses of methotrexate may be the result of higher levels of intracellular methotrexate polyglutamates achieved with dose escalation (269). The necessity of methotrexate in the treatment regimen has been questioned (260). In a randomized trial performed by the POG, it did not appear that high-dose methotrexate added to the treatment result for children with lymphoblastic lymphoma in the setting of an anthracycline- and asparaginase-rich backbone (260); however, the result for children with T-cell ALL entered on this trial was inferior in the arm without high-dose methotrexate. In light of the results of the POG trial, which questioned the need for high-dose methotrexate in children with lymphoblastic lymphoma, the Children's Oncology Group is currently performing another randomized trial to address this issue. Improvements in treatment outcome have also been attributed to other interventions, such as the incorporation of a delayed intensification phase (i.e., reinduction phase) (255), L-asparaginase (265), and new active agents (240).

TABLE 91.7. Treatment Outcome for Advanced Stage Lymphoblastic Non-Hodgkin Lymphoma

Protocol	Stage	Patients (No.)	EFS Rate	Reference
LSA $_2$L $_2$ (modified); CCG-551	III/IV	124	5-yr EFS = 64%	221
BFM 90	III	82	5-yr EFS = 90% ± 3%	255
	IV	19	5-yr EFS = 95% ± 5%	
X-H SJCRH	III/IV	22	4-yr DFS = 73%	240
APO (Dana Farber)	III/IV	21	3-yr DFS = 58% ± 23%	34
A-COP + (POG)	III	33	3-yr DFS = 54% ± 9%	241
SFOP LMT81	III	33	57-mo EFS = 79% (SE, 4%)	246
	IV/acute lymphoblastic leukemia	43	57-mo EFS = 72% (SE, 4%)	
CCG: LSA $_2$L $_2$ (modified) *vs.*	I–IV	243	5-yr EFS = 74%	249
ADCOMP	I–IV	138	5-yr EFS = 64%	
POG8704: no extra Asp *vs.*	III/IV	83	4-yr CCR = 64% (SE, 6%)	265
Extra Asp	III/IV	84	4-yr CCR = 78% (SE, 5%)	

Asp, asparaginase; CCR, continuous complete remission; DFS, disease-free survival; EFS, event-free survival.

Determining the optimal treatment approach for children with advanced stage large cell lymphoma has been more of a challenge for various reasons. The CCG randomized trial comparing COMP and LSA $_2$L $_2$ did not show an advantage to either approach for children with advanced stage large cell lymphoma. Further complicating the picture is the fact that, historically, children with large cell lymphoma in the United States were treated on the basis of the histologic diagnosis (i.e., uniform therapy for all immunophenotypic subtypes), whereas in Europe, children with large cell lymphoma have been treated primarily according to immunophenotype (e.g., T-cell, B-cell, or CD30 $^+$ ALCL) (99 , 135 , 136 , 261). With histology-directed therapy, the 5-year event-free survival rates for children with advanced stage disease have generally been in the range of 60 to 75% (221 , 224 , 244 , 225 , 235 , 261 , 262 and 263) (Table 91.8). These results have been achieved largely by using CHOP-based therapy (cyclophosphamide, doxorubicin, vincristine, and prednisone). There is a general trend in the United States to move toward an immunophenotype-directed approach for children with large cell lymphoma, in part because of the excellent result achieved in Europe using this strategy. For example, in France (SFOP), children with advanced stage B-cell large cell lymphoma are treated according to the Burkitt lymphoma regimen (LMB89) with an excellent result (3-year event-free survival, >80%) (256). Most groups are now treating Burkitt lymphoma and B-cell large cell lymphoma similarly.

TABLE 91.8. Treatment Outcome for Advanced Stage Large Cell Non-Hodgkin Lymphoma

Protocol	Stage	Patients (No.)	EFS Rate	Reference
CHOP	III and IV	21	3-yr EFS = 62% ± 11%	224
MACOP-B	III and IV	11	3-yr EFS = 55% ± 16%	244
COMP *vs.*	III and IV	42	5-yr EFS = 52%	221
LSA $_2$L $_2$	III and IV	18	5-yr EFS = 43%	
APO *vs.*	III and IV	62	3-yr EFS = 72% ± 6%	263
ACOP+	III and IV	58	4-yr EFS = 62% ± 7%	

EFS, event-free survival.

Quite varied approaches are still used for children with CD30 $^{+}$ ALCL ([99], [135], [136], [263]). In SFOP trials, children with CD30 $^{+}$ ALCL have been entered on regimens specific for that subtype ([99]). In the German BFM trials, children with CD30 $^{+}$ ALCL have been treated with a B-cell approach (Burkitt lymphoma–like) with an outstanding result (3-year event-free survival of approximately 80%) ([135], [136]). In the United States, a comparable result was achieved using the APO regimen (doxorubicin, prednisone, and vincristine) ([225]). Current cooperative group trials in Europe and the United States are building on the BFM B-cell and APO strategies, respectively. Both studies are examining the benefit of adding vinblastine, an agent that has activity as a single agent in multiply relapsed ALCL patients ([268]).

RELAPSE

Approximately 20 to 30% of children with NHL have a treatment failure with frontline therapy as manifested by either recurrent or, less commonly, refractory disease ([1]). The prognosis for children with recurrent or refractory NHL has generally been believed to be quite poor. Therefore, most oncologists consider either intensive or novel salvage chemotherapy regimens followed by an intensification phase including either autologous or allogeneic hematopoietic stem cell transplantation (HSCT) in the majority of cases. However, the role of HSCT in this setting is somewhat controversial, with a recent publication questioning the benefit of this salvage strategy ([270]).

There are a number of studies that feature HSCT ([264], [271], [272], [273], [274], [275], [276], [277], [278], [279] and [280]). For example, some children with Burkitt lymphoma who had a poor early response to therapy were successfully salvaged with high-dose intensive chemotherapy followed by autologous HSCT in European cooperative group trials ([264], [273], [275], [276], [278]). The Spanish Working Party for Bone Marrow Transplantation reported that 58% of the children who had either refractory/recurrent NHL or high risk disease in first complete remission were event-free survivors after HSCT ([275]). The French cooperative group SFOP reported that 8 of 24 children with refractory or recurrent NHL were long-term disease-free survivors using HSCT ([276]). In a St. Jude single-institution review of 20 children with recurrent or refractory NHL, approximately 45% were survivors after HSCT ([280]). Published studies featuring HSCT for pediatric NHL are relatively small in number and vary with respect to the type of HSCT (autologous vs. allogeneic), salvage therapy, preparative regimen, and histologic subtype, making direct comparisons difficult.

Histologic subtype of NHL should be considered in determining the appropriate type of HSCT (i.e., allogeneic vs. autologous) for those children who experience a failure after primary therapy. A number of studies have suggested that autologous HSCT is beneficial in the management of children with Burkitt lymphoma who have a poor early response to initial therapy ([264], [271], [276]). It is less clear which approach is optimal for those children with Burkitt lymphoma who relapse in the bone marrow, although many favor an allogeneic approach if a suitable donor is available. Autologous HSCT strategies have been shown to be efficacious in children with recurrent large cell lymphoma ([274], [280]), whereas the results of an autologous approach for those with recurrent lymphoblastic lymphoma have been generally less encouraging ([270]).

There is a spectrum of preparative regimens that have been studied in children with recurrent or refractory NHL ([264], [271], [272], [273], [274], [275], [276], [277], [278], [279] and [280]). Carmustine, etoposide, cytarabine, and melphalan (BEAM) and carmustine, cytarabine, cyclophosphamide, and thioguanine (BACT) are two of the earliest drug combinations used successfully ([271], [272], [279]). The SFOP credited their excellent salvage rate in part to the inclusion of high-dose busulfan in the preparative regimen ([276]). Gordon et al. ([274]) reported excellent results for children with recurrent PTCL using a regimen that featured thiotepa.

At present, most would consider an autologous HSCT for children with Burkitt lymphoma who have a poor early response and for those with chemosensitive recurrent large cell lymphoma. An allogeneic HSCT is generally considered for children with lymphoblastic or Burkitt lymphoma that recurs in the bone marrow and is shown to be chemosensitive. Additional prospective clinical trials that examine HSCT strategies in children with recurrent or refractory NHL are clearly needed; it has been suggested by one group that the potential graft-versus-lymphoma effect of the allogeneic HSCT approach be studied ([278]).

LONG-TERM SEQUELAE

Improvements in the cure rate for children with NHL have prompted investigators to more closely examine long-term treatment-related late effects. Areas of concern include second malignancies, second cancers, and effects on fertility. Attempts to reduce these unwanted sequelae include trials that have eliminated or reduced the doses of certain chemotherapeutic agents or involved field irradiation.

In the first of two sequential randomized trials for limited stage NHL, the POG demonstrated that involved field irradiation could be safely eliminated without compromising the excellent treatment outcome ([229]). The elimination of involved field irradiation was also shown to be possible without compromising outcome in a St. Jude study of patients with advanced stage disease ([281]). Involved field irradiation of primary tumor masses is not used in most current NHL trials. Cranial irradiation is considered in the management of children with lymphoblastic lymphoma who present with overt involvement of the central nervous system; however, its use for central nervous system prophylaxis in these children is controversial.

Alkylating agents, such as cyclophosphamide and ifosfamide, cause a dose-related depletion of germinal cells and tend to be more gonadotoxic in males. Studies suggest that fertility is generally maintained at a cumulative cyclophosphamide dose of less than 4 g/m ^{2}, whereas sterility is likely at doses greater than 7.5 g/m ^{2} ([282]). In this regard, various clinical trials have examined the possibility of eliminating or reducing the dose of cyclophosphamide in the treatment of certain NHL subtypes ([263]).

Pediatric NHL trials have also been influenced by the desire to avoid or limit anthracycline-related cardiac toxicity. Although adults have been shown to tolerate cumulative doxorubicin doses of 550 mg/m ^{2}, children treated with lower cumulative doses have been shown to have clinically significant abnormalities in ventricular contractility ([283]). Factors that have been shown to be predictive of cardiac dysfunction include higher anthracycline dose intensity, cumulative anthracycline dose, female sex, younger age at time of treatment, combined modality therapy that includes mediastinal irradiation, and time interval since completion of therapy ([284], [285]). In addition to trials that attempt to reduce the cumulative dose of anthracyclines ([235]), the study of cardioprotectants is also indicated.

FUTURE DIRECTIONS

Although significant progress has been made in the treatment of children with NHL, 25 to 30% continue to have refractory or recurrent disease. Treatment-related late effects are of additional concern. Thus, the continued goal and challenge for the pediatric oncologist are to develop more effective treatment approaches that are not associated with significant late effects. This will require further refinement in risk-adapted treatment planning, which will be made possible by the identification of additional prognostic biologic and clinical factors.

Various strategies may contribute to further improvement in treatment outcome, such as the development of new active agents or new schedules for the delivery of current agents. One of the most promising novel approaches is the use of immunotherapeutic agents, such as the use of rituximab for adults with CD20 $^{+}$ B-cell lymphomas ([286], [287]). Pediatric trials are currently under way. Small molecule inhibitors, which have been shown to be active in adults with chronic myelogenous leukemia, may have a role in some types of childhood NHL.

The continued molecular characterization of chromosomal abnormalities associated with pediatric NHL may prove helpful in refining the classification of clinically relevant histologic subtypes, evaluating response to therapy, and developing novel therapeutic approaches that target the molecular lesion directly.

James B. Johnston

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is characterized by the accumulation of nonproliferating mature-appearing lymphocytes in the blood, marrow, lymph nodes, and spleen. The CLL cells are monoclonal B lymphocytes and are unique in being $CD5^+$ and $CD23^+$ ([1], [2] and [3]). Recent evidence suggests that these tumor cells are derived from memory B cells, and there is considerable heterogeneity in CLL in terms of cellular morphology, phenotype, biology, molecular genetics, and prognosis ([4], [5] and [6]). The incidence of CLL varies throughout the world, being highest in North America and rare in the Far East. In North America, CLL accounts for 22.6% of all leukemias, and the incidence is 3.35 to 3.69 per 100,000 per year for men and 1.61 to 1.92 per 100,000 per year for women ([7], [8]). Indeed, it has recently been suggested that the incidence of CLL is much higher than reported, as many patients are diagnosed by flow cytometry and do not require referral for treatment ([9]). The disease is rare in young people, but the incidence rises in the fourth decade and continues to rise exponentially, with the mean age at diagnosis being 69.6 years and greater than 80% of patients being older than 60 years ([7]) (Fig. 92.1). However, in contrast with the non-Hodgkin lymphomas, the incidence of CLL has not increased over the past 30 years.

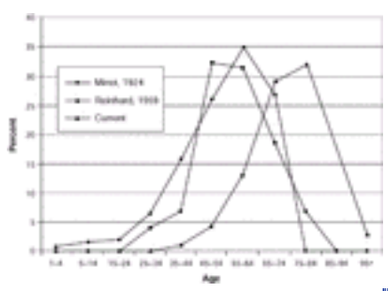

Figure 92.1. Age distribution in chronic lymphocytic leukemia. (From Diehl LF, Karnell LH, Menck HR. The National Cancer Data Base report on age, gender, treatment, and outcomes of patients with chronic lymphocytic leukemia. Cancer 1999;86:2684–2692, with permission.)

PATHOPHYSIOLOGY

Predisposing Factors

Unlike other leukemias, there is no firm evidence linking an environmental or occupational exposure with an increased incidence of CLL ([8]). However, a family history of CLL or another lymphoproliferative disorder is a strong risk factor for CLL, and it is estimated that one in ten patients with CLL has a family history of CLL or another lymphoproliferative disorder ([10]). There is a 30-fold increase in the risk of CLL in first-degree relatives of patients with CLL ([8], [10], [11] and [12]), and 13.5% of first-degree relatives have peripheral blood lymphocytes with the typical CLL immunophenotype ([13]). However, whether individuals with these abnormal cells will eventually develop CLL is presently unknown ([13]). Patients with familial CLL are approximately 10 years younger than those with sporadic CLL ([11]), and anticipation occurs in familial CLL, with affected children being 15 to 20 years younger than their parents at diagnosis ([14], [15], [16] and [17]). The pattern of inheritance in this condition is unknown, but there is no linkage to HLA type ([18]). As discussed in the section Cell of Origin, there are two forms of sporadic CLL: those with somatic hypermutations of the variable region of the immunoglobulin (*IgV*) gene and those without. At the present time, there is controversy as to whether familial CLL differs from sporadic CLL with regard to the incidence of *IgV* gene mutations ([19], [20]).

The *ataxia telangiectasia mutation* (*ATM*) gene may induce DNA repair or apoptosis in response to the induction of DNA double-strand breaks, and at least part of these effects is mediated through p53, which is phosphorylated by ATM ([21]). The *ATM* gene is particularly important in lymphocyte development, and patients with ataxia telangiectasia are predisposed to T-cell lymphoid malignancies ([21], [22], [23] and [24]). It has recently been demonstrated that up to one-third of CLL patients have mutations or deletions of the *ATM* gene in the leukemic cells ([22], [23]), and these cases do not have *IgV* gene mutations and are thus of pregerminal cell origin ([24]). As *ATM* mutations are also observed in the germ-line of these patients, it has been suggested that heterozygosity of the *ATM* gene may predispose an individual to CLL

and explain the familial clustering seen in this disease ([22], [23] and [24]). However, more recent evidence indicates that this is unlikely ([25]).

Cell of Origin

There has been controversy as to the normal counterpart of the CLL cell ([26]). As the CLL cell is CD5 $^{+}$, it was previously believed that the normal counterpart was the CD5 $^{+}$ B lymphocyte, which is present in the mantle zone of lymph nodes and in small numbers in the peripheral blood ([1], [26], [27]). However, the CD5 $^{+}$ B lymphocyte lacks mutations of the *IgV* gene ([28]), whereas the CLL cell has undergone mutations in approximately 50% of cases ([29], [30] and [31]). These data indicate that there are two forms of CLL, one arising from the pregerminal lymphocyte and lacking mutations of the *IgV* gene and the other having traversed the germinal center and containing mutations ([32]). It is interesting that these two forms of CLL have different genetic abnormalities (see Genomic Abnormalities) and prognoses ([29], [30] and [31]). Those with mutations are more likely to have deletions of 13q14 and a good prognosis, whereas those without mutations more frequently express trisomy 12 and have a poor prognosis (Fig. 92.2) ([29], [31]).

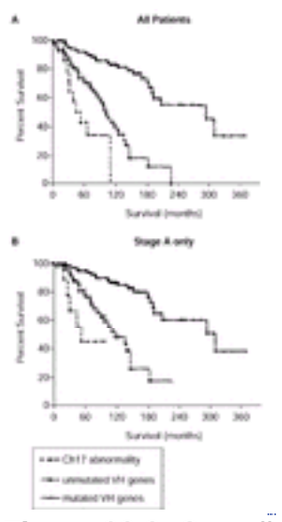

Figure 92.2. Overall survival of patients with loss or mutation of p53 regardless of *IgVH* gene status compared to patients with mutated or unmutated *IgVH* genes with no p53 abnormality. **A:** All patients. **B:** Stage A patients. The median survival of patients with mutated or unmutated *IgVH* genes or a p53 abnormality was 310, 119, and 47 months, respectively, for all patients, and 327, 115, and 54 months, respectively, for stage A patients. (From Oscier DG, Gardiner AC, Mould SJ, et al. Multivariate analysis of prognostic factors in CLL: clinical stage, IGVH gene mutational status, and loss or mutation of the p53 gene are independent prognostic factors. Blood 2002;100:1177–1184, with permission.)

More recently, the gene expression profile in CLL has been studied by DNA chip microarrays ([5], [6]). Twelve thousand genes were analyzed by Klein et al. ([5]), and there was a common pattern of expression for most genes in the 16 mutated and 18 unmutated cases. However, there was a differential expression of 23 genes between the two groups. When compared to normal naïve B cells, germinal cells, CD5 $^{+}$ cells, and memory cells, both mutated and unmutated CLL cells were most similar to the memory cell ([5]). Using Lymphochip complementary DNA microarrays, Rosenwald et al. ([6]) have reached similar conclusions in 37 CLL patients. In that study, *IgV* gene–mutated CLL cells could be differentiated from unmutated cells by the expressions of approximately 175 genes (Fig. 92.3). Using 56 differentially expressed genes, they were able to accurately assign nine of ten patients to the mutated or unmutated group. The gene that could most accurately differentiate the two groups was ZAP-70, a kinase that is primarily expressed in T cells and is responsible for the transduction of signals from the T-cell receptor. Using reverse transcriptase–polymerase chain reaction, it was confirmed that cells without mutations had higher levels of ZAP-70 messenger RNA than cells with mutations.

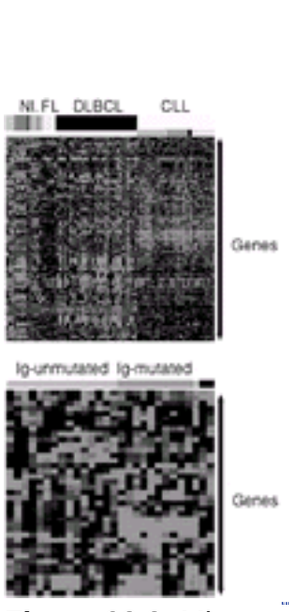

Figure 92.3. Microarray analysis in chronic lymphocytic leukemia (CLL). **A:** The expression of Ç 247 “signature” genes differentiates CLL cells from diffuse large B-cell lymphoma (DLBCL), follicular lymphomas (FL), and most normal lymphocytes (NI). The “signature” genes are expressed by CLL cases with or without *IgV* gene mutations. **B:** CLL patients can be differentiated into those with or without mutations of the *IgV* gene by the expressions of 56 genes ([6]). Ig, immunoglobulin. See Color Plate. (From Staudt LM. Gene expression profiling of lymphoid malignancies. Annu Rev Med 2002;53:303–318, with permission.)

The results of these studies indicate that the CLL cell is not derived from the CD5 $^{+}$ cell, a naïve B cell, or a follicle center cell, suggesting that the expressions of CD5 and CD23 on these cells are secondary changes, perhaps representing cell activation or nonspecific changes secondary to the malignancy. The cell of origin of the CLL cell appears to be the memory B cell, regardless of whether or not there are mutations of the *IgV* gene. This would explain why all CLL cells are CD27 $^{+}$, which is typically a marker of the memory B cell ([33], [34] and [35]). Although most normal CD27 $^{+}$ B cells have *IgV* gene mutations, a small fraction does not ([36], [37]). It is thus possible that the CLL cell evolves from the two types of CD27 $^{+}$ cell: one group with *IgV* gene mutations and the other without.

Abnormalities in Apoptosis

Galton ([38]) and Dameshek ([39]) made the astute observation 35 years ago that the basic defect in CLL is one of cellular accumulation rather than proliferation. Since then, it has become clear that a defect in apoptosis typifies CLL, with the majority of cells being long-lived, noncycling, and in G $_{0}$, with a small fraction of cells replicating and being responsible for the gradual increase in cell number. Chemotherapeutic agents induce apoptosis, and defects in apoptosis may also be responsible for drug resistance ([40], [41] and [42]). Considerable knowledge has been obtained regarding the apoptotic pathways, and the major steps are shown in Figure 92.4 (reviewed in references 40–42). Apoptosis occurs through the activation of caspases, which are cysteine proteases that cleave other caspases at aspartate acid residues, converting the inactive proforms to active enzymes. The downstream caspases, caspases 3, 6, and 7, cleave specific proteins leading to the typical morphologic changes of apoptosis. Apoptosis can be initiated through two main pathways, which interact and subsequently activate the same downstream caspases.

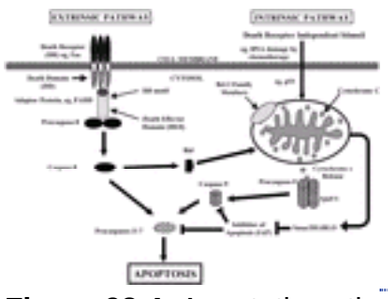

Figure 92.4. Apoptotic pathway in chronic lymphocytic leukemia.

TWO MAJOR APOPTOTIC PATHWAYS The *mitochondria/cytochrome* c *(intrinsic) pathway* is typically initiated by DNA damage, which causes the up-regulation of p53, an increase in the bax:bc-2 ratio, and the release of cytochrome *c* from between the inner and outer mitochondrial membranes into the cytosol. Cytochrome *c* binds to and activates apoptosis-activating factor-1 (Apaf-1) in the cytosol in a process that requires deoxyadenosine triphosphate (dATP). The *N*-terminal of Apaf-1 binds to and causes the autoactivation of procaspase 9 and, subsequently, caspase 3 ([43]). The cytochrome *c*/mitochondrial system is important for the activity of chemotherapy, and a deficiency in Apaf-1 can cause drug resistance ([44]), although whether the variable levels of Apaf-1 in CLL influence sensitivity to chemotherapy is unknown ([45]). As discussed later, the triphosphate derivatives of fludarabine and 2-chlorodeoxyadenosine (CdA) can substitute for dATP, and part of their cytotoxic activities is related to the binding of Apaf-1 and direct activation of caspases 9 and 3 ([46] , [47]). Smac/DIABLO is also released from the mitochondria along with cytochrome *c* and induces apoptosis by binding to the inhibitor of apoptosis family of proteins, which normally inactivate a number of caspases, including caspase 3. The *tumor necrosis factor (TNF) death receptor (DR) (extrinsic) pathway* also plays a major role in apoptosis. There are presently six known DRs, and these include TNF, Fas (APO-1 or CD95) and DR4/DR5 [receptors for TNF-related apoptosis-inducing ligand (TRAIL)]. These receptors contain a cytosolic domain called the *death domain*, which recruits adaptor proteins such as Fadd/Mort-1 to the receptor complex after binding to ligand. The recruiter adaptor protein has a death domain end and a death effector domain (DED). Once bound to the TNF receptor, the DED binds to caspases 8 and 10, which then become activated by autoactivation ([43]). Apoptosis through this pathway is controlled by the presence of the receptor and a variety of inhibitors that can bind to the DED in place of the caspases. One of these is FLICE inhibitory protein, which is a homolog of procaspase 8 and contains two DED domains but lacks proteolytic activity ([48]). There is cross-talk between the intrinsic and extrinsic pathways. Thus, caspase 8 can activate Bid, which causes the release of cytochrome *c* from the mitochondria ([42] , [49]). Alternatively, activation of the intrinsic pathway in CLL cells by chemotherapy or irradiation also activates caspase 8 ([50]), possibly by activation of caspase 3 ([51]). Apoptosis through the TNF receptors plays an important role in controlling lymphoid cell populations, and defects either in Fas ligand or the receptor result in the autoimmune lymphoproliferative syndrome with lymphadenopathy, splenomegaly, and an increase in the risk of subsequent autoimmune diseases and lymphomas. Fas is normally up-regulated in activated lymphocytes, and CLL cells are not sensitive to Fas ligand, even if Fas (CD95) is increased through the use of *Staphylococcus aureus* protein A from Cowan I plus interleukin (IL)-2, CD40 ligation, or through a- or ?-interferon ([50] , [51] , [52] and [53]). DR4 and DR5 receptors are present on CLL cells, but the extent of sensitivity of these cells to TRAIL is controversial ([54] , [55]). CLL cells secrete both TRAIL ([56]) and Fas ligand ([50] , [56]), which may suppress normal T cells and contribute to the immunosuppression seen with this disease. Apart from the direct induction of apoptosis through the interaction with TNF ligands, the TNF receptors may play a role in the activity of chemotherapeutic agents. Chemotherapeutic agents may up-regulate receptors for Fas ([57] , [58]) or DR4/DR5 ([59] , [60]), which could prime the cells to physiologic levels of Fas ligand or TRAIL. However, although fludarabine and chlorambucil increase Fas messenger RNA levels in CLL cells *in vitro*, they do not affect the levels of Fas protein ([50]). In contrast, irradiation does increase Fas protein levels, but none of these agents sensitizes CLL cells to Fas ligand ([50]). Fludarabine and chlorambucil increase the messenger RNA and cell-surface expression levels of DR4/DR5 in CLL cells, but it is not yet known whether this sensitizes the cells to TRAIL ([55]).

MODULATORS OF THE APOPTOTIC PATHWAYS The above pathways are modulated by a variety of proteins, which may be altered in CLL. The *bcl-2 family* consists of approximately 20 members that can either promote or inhibit apoptosis. These proteins are located in the cell membrane, nuclear membrane, and mitochondrial membrane and function by binding to other proteins or influencing cell permeability and the release of cytochrome *c* from the mitochondria. Some bcl-2 family members (e.g., bax, bcl-x $_S$, bak, and bad) promote apoptosis, whereas others (e.g., bcl-2, bcl-x $_L$, and mcl-1) inhibit apoptosis ([61] , [62] , [63] , [64] , [65] , [66] and [67]). In addition, another group (e.g., bag-1) can influence the activities of the other family members ([61] , [62] , [63] , [64] , [65] , [66] and [67]). CLL cells have high bcl-2, bax, and bak levels but have low levels of bcl-x $_L$ and bad ([61] , [62] , [63] , [64] , [65] , [66] and [67]). The bcl-2 overexpression is related to hypomethylation of DNA, rather than to a translocation, and may contribute to the longevity of the CLL cell ([61]). CLL cells with high bcl-2 levels have more prolonged *in vitro* survival than those with low levels, and decreasing bcl-2 expression by antisense oligonucleotides can induce apoptosis ([66]). Whether the bax and bcl-2 levels or the bax:bcl-2 ratios are predictive of drug sensitivity in CLL is controversial ([62] , [63] , [64] , [65] , [66] and [67]). Mcl-1 protein levels are variable in CLL, and it has been suggested that patients with high levels are more resistant to chemotherapy ([65]). The transcription factor nuclear factor-?B (NF-?B) plays an important role in suppressing apoptosis by inducing the expression of a variety of antiapoptotic genes ([68] , [69]). NF-?B is inactivated by I?B, which binds NF-?B and prevents its access to the nucleus; activation of NF-?B occurs by the phosphorylation of I?B, which leads to the coupling of I?B with ubiquitin. This complex is degraded by a protease called the *proteasome*. The levels of NF-?B are high in CLL and are increased further by stimulation with CD40 ligand, which, as discussed in the Cytokines section, plays an important role in preventing apo-ptosis and prolonging cell survival in CLL ([70]). In addition, inactivation of the proteasome by inhibitors such as lactacystin, MG132, and PS-341 can induce death of CLL cells but not normal lymphocytes ([71] , [72] and [73]). Cell death is mediated through the cytochrome *c*/mitochondrial pathway, and these agents may be useful in drug-resistant disease ([71] , [72] and [73]). The protein kinase *Akt* is activated through phosphatidyl-inositol 3'-hydroxykinase and can suppress apoptosis by phosphorylating bad, caspase 9, and other proteins involved in apoptosis ([74] , [75]). This pathway is activated by autologous plasma in CLL, which may explain the relative resistance of these cells to spontaneous apoptosis and chemotherapy when they are grown in autologous plasma ([75]). A number of other proteins play a key role in apoptosis, and their expressions can be affected by the chromosomal changes that occur in CLL (discussed further in Genomic Abnormalities). The tumor-suppressor gene, *p53*, is a transcriptional activator and is located on chromosome 17p13 ([42] , [76]). p53 protein is phosphorylated and stabilized after DNA damage, such as that produced by radiation or alkylating agents, through activation of ATM kinase and DNA-dependent kinase ([76]). Cell cycle blockage at G $_1$ or G $_2$ may occur, allowing the cell to repair the damage before entering S- or M-phase ([76]). However, p53 may also induce apoptosis, and this occurs preferentially in tumor cells, a feature that may explain the relative tumor specificity of anticancer agents ([77]). p53 mutations are typically associated with deletions of the second allele (deletion 17p13), and mutations or p53 gene deletions are observed in 10 to 15% of CLL patients (see section Genomic Abnormalities); these abnormalities are associated with high lymphocyte counts, drug resistance to anticancer agents *in vitro* and *in vivo*, and poor patient survival (Fig. 92.2 and Fig. 92.5) ([63] , [64] , [78] , [79]). In a longitudinal study of 181 patients, the percentage of leukemia cells with a p53 mutation increased during the course of the disease, indicating that the mutation provided a survival advantage for the tumor cells ([78]).

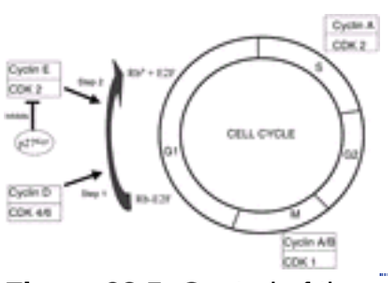

Figure 92.5. Control of the cell cycle. Chronic lymphocytic leukemia cells are quiescent and in G $_0$/G $_1$. Both cyclins D2 and D3 are overexpressed in chronic lymphocytic leukemia cells, but the retinoblastoma (Rb) protein is not phosphorylated, perhaps related to overexpression of p27 ^{Kip1}. CDK, cyclin-dependent kinase.

The *murine double minute-2* (*mdm-2*) gene is located on chromosome 12 and is transactivated by p53 ([76]). The mdm-2 protein enhances the binding of p53 to ubiquitin, and p53 is subsequently degraded ([76]). Thus, overexpression of mdm-2 in cell lines reduces the capacity of p53 to block the cell cycle in G $_1$ after irradiation and speculatively could also decrease p53-induced apoptosis and produce drug resistance ([63]). However, although the mdm-2 protein has been found to be overexpressed in two-thirds of CLL cases, this does not correlate with disease stage, aggressiveness, or drug resistance ([80]). The *ATM gene* is located on chromosome 11q22-23 and is responsible for phosphorylation and activation of p53 after DNA damage ([21] , [76]). Approximately 30% of CLL patients have a mutation of ATM, and these patients have a defect in cellular response to irradiation similar to that observed in patients with a p53 mutation ([21] , [81]). This would explain the drug resistance and poor clinical outcome in patients with an ATM mutation ([82] , [83]). It is interesting that ATM mutations are seen in patients with an unmutated *IgV* gene, and these patients are known to have a poor prognosis ([24] , [29] , [30] and [31]).

Abnormalities in Cell Division

Passage through the cell cycle is controlled by the interaction of the cyclins and the cyclin-dependent kinases (CDKs); the levels of the CDK remain constant, whereas the levels of the five different cyclins fluctuate and activate the appropriate CDK, leading the cell through the cycle (Fig. 92.5) ([84]). In addition, two classes of CDK inhibitors, the INK4 proteins and the Cip/Kip proteins, control the activity of the CDKs ([85]). Normally, when quiescent cells enter the cell cycle, the D cyclins (D1, D2, and D3) in conjunction with CDKs 4 and 6 bring the cell into the S-phase. The D cyclin/CDK4/6 initiates phosphorylation of the retinoblastoma (Rb) protein, which is then further phosphorylated by cyclin E/CDK2. Another function of the D cyclins/CDK4 is the sequestration of the Cip/Kip inhibitors $p27^{Kip1}$ and $p21^{Cip1}$, which normally inhibit the activity of cyclin E/CDK2. Although the CLL cell is quiescent and in G_0/G_1, the expression of cyclins D2 and D3 is increased in these cells ([86] , [87] and [88]). In addition, cyclin D1 is also detectable and increased in 25% of patients, although the levels are not as high as seen in mantle cell lymphoma ([89]). Despite these findings, the Rb protein is not phosphorylated in unstimulated CLL cells ([90]); this may be related to overexpression of $p27^{Kip1}$, in which high levels are associated with high lymphocyte counts and poor patient survival ([91]).

Genomic Abnormalities

Conventional cytogenetic studies were initially carried out in CLL in the 1980s, and these proved difficult as CLL cells have a very low proliferative index, and even with mitogens, metaphases are difficult to obtain ([79] , [92]). When analysis is possible, clonal chromosomal abnormalities are detected in approximately 50% of cases ([79] , [92] , [93] , [94] , [95] , [96] , [97] , [98] , [99] , [100] , [101] , [102] , [103] , [104] and [105]), and it is likely that the normal karyotyping in the remaining cases is due to analysis of contaminating normal T cells ([79]). Of the 50% of cases with clonal abnormalities, one-half have one clonal abnormality, and the remainder have two or three clones ([94]). With newer techniques, such as fluorescence *in situ* hybridization (FISH) and comparative genomic hybridization, which allow analysis of interphase cells (FISH) or isolated DNA (comparative genomic hybridization), respectively, abnormalities may be detected in over 80% of cases ([79] , [92]). Most commonly, these abnormalities are deletions or aneuploidy, and in contrast to other low-grade lymphoid malignancies, translocations are infrequent. FISH is highly sensitive, but the specific abnormality to be studied needs to be known in advance, and this is therefore not a good technique to screen for new abnormalities. In contrast, comparative genomic hybridization has been used to screen for chromosome gain or loss (i.e., aneuploidy, gene amplification, or deletions not detected by conventional cytogenetics) ([92]). As more sophisticated techniques are being developed, such as allelotyping with microsatellite markers spaced throughout the genome, multiple new abnormalities are being detected and will hopefully provide insight into the pathogenesis of this disease ([93]).

ANALYSIS BY CONVENTIONAL CYTOGENETICS Using conventional cytogenetics, the International Working Party on Chromosomes in CLL reported in 1990 that clonal chromosomal abnormalities were obtained in 311 patients (51%) out of a total of 604 cytogenetically evaluable cases (Table 92.1) ([98] , [99]). The most common clonal abnormality was trisomy 12 (36%, or 19% of all evaluable cases), either by itself or in combination with other cytogenetic changes. Other frequently observed alterations included structural abnormalities of chromosome 13 (20%, or 10% of all cases) and of chromosome 14 (16%, or 8% of all cases) ([98] , [99]). The 13q abnormalities usually involved a 13q14 deletion (site of the *Rb* gene) or translocations with a breakpoint at chromosome 13q14. The 14q abnormalities included translocations from a variety of chromosomes, usually involving chromosome 11. As t(11;14)(q13;q32) is classically seen in mantle cell lymphoma and rarely in CLL (see below), it is likely that these patients had mantle cell lymphoma and not CLL ([106]). Less than 5% of patients had an 11q deletion. The abnormalities of chromosomes 12 and 13 occurred with equal frequency in cases with a single clonal abnormality and in patients having more than one clonal abnormality ([94] , [98]). In contrast, abnormalities of chromosome 14 occurred primarily in patients having more than one clonal abnormality ([94] , [98]).

TABLE 92.1. Incidence of Genomic Abnormalities and the Associated Clinical Features in Chronic Lymphocytic Leukemia

Genomic Abnormality	Incidence (%)		Affected Genes	Clinical Features
	Classical Cytogenetics [a]	Fluorescence *In Situ* Hybridization [b]		
Normal	50 [c]	20	—	—
13q deletion	10	55	*Rb*	*IgV* gene mutations; good prognosis
Alone	5	36		
Combined with other abnormalities	5	19		
11q deletion	8	18	*ATM*	No *IgV* gene mutations; bulky lymphadenopathy
12q trisomy	13	16	*mdm2*	No *IgV* gene mutations; “atypical” morphology; end-stage disease
17p deletion	4	17	*p53*	No *IgV* gene mutations; chronic lymphocytic leukemia/prolymphocytic leukemia morphology
6q deletion	4	6	—	—

Prognostic subgroups in B-cell-chronic lymphocytic leukemia defined by specific chromosome abnormalities. N Engl J Med 1990;323:720–724; and Juliusson G, Oscier D, Gahrton G, et al. Cytogenetic findings and survival in B-cell chronic lymphocytic leukemia. Second IWCCLL compilation of data on 662 patients. Leuk Lymphoma 1991;5:21–25. Percentages refer to the number of cases with the abnormality compared with the total number of cases in which cytogenetic analysis was possible.

[b] From Döhner H, Stilgenbauer S, Benner A, et al. Genomic aberrations and survival in chronic lymphocytic leukemia. N Engl J Med 2000;343:1910–1916.

[c] In 50% of cases, clonal abnormalities were not obtained. As these studies were not carried out on purified chronic lymphocytic leukemia cells, some of the cases with normal cytogenetics reflect analysis of normal T cells.

In general, patients with abnormal karyotyping had a worse prognosis than those with normal cytogenetics, and the outlook was poorest for those with multiple clonal abnormalities ([95] , [96] , [97] , [98] , [99] , [100] and [101]). In addition, the higher the percentage of cells at metaphase with a clonal chromosomal abnormality, the worse the prognosis. Of patients with a single clonal abnormality, those with trisomy 12 had the worst prognosis, and those with $13q^{+}$ had a similar survival as cases with normal karyotyping ([98] , [99]). It is interesting that trisomy 12 was usually seen in those 15% of cases with CLL variants, either CLL/prolymphocytic leukemia (CLL/PL) or “atypical” CLL (see Laboratory Findings for details of these variants), and this may explain the poor prognosis associated with these morphologic variants ([101] , [102] and [103]). When all patients were considered, regardless of the number of clones, those with chromosome 14 abnormalities had the worst prognosis ([98]). As most of the chromosome 14 abnormality group had a t(11;14)(q13;q32), in retrospect, they likely had mantle cell lymphoma and not CLL. More recently, 11q deletions have been detected in 13% of patients by karyotyping, and these patients had disease progression and poor survival ([104]). The chromosome abnormalities identified in CLL occur early, and it is disputed as to whether additional chromosomal abnormalities develop with disease progression ([98] , [107] , [108]). Although Juliusson et al. ([98]) found little evidence for clonal evolution, others have noted a 16 to 39% incidence of new or additional chromosomal abnormalities, which develop over several years from initial diagnosis ([107] , [108]). The acquisition of deletions of 11q or 6q is associated with disease progression ([109] , [110]). The presence of multiple clones and subclones and the development of new clonal abnormalities have been taken as evidence that clonal evolution may be a common event in CLL ([107] , [108]).

ANALYSIS BY FLUORESCENCE *IN SITU* HYBRIDIZATION Because of the limitations of conventional cytogenetics in CLL, most present day studies use FISH to identify and quantify the genetic defects in CLL. In a recent major study using FISH, Döhner et al. ([79]) evaluated 325 CLL patients for deletions of 6q21, 11q22-q23, 13q14, and 17p13; for trisomies of bands 3q26, 8q24, and 12q13; and for translocations involving the Ig heavy chain locus on 14q32. In these patients, 268 (82%) had abnormalities, with deletion 13q14 being most frequent (55%), followed by deletion 11q22-q23 (18%), trisomy 12q13 (16%), deletion 17p13 (7%), and deletion 6q21 (7%) ([79]). The frequency of the different abnormalities differed from the studies using conventional cytogenetics, presumably because classical cytogenetics only detect abnormalities in replicating cells, whereas interphase FISH detects abnormalities in the entire cell population. A comparison of the incidence of the different abnormalities, as detected by FISH and cytogenetics, is shown in Table 92.1. In this FISH study, there was one abnormality in 175 patients, 67 patients had two aberrations, and 26 patients had more than two chromosomal changes. As shown in Figure 92.6, there was a very good correlation between the presence of these abnormalities and survival: Patients with deletion 13q had a similar survival to those with normal chromosomes, and only one-third required therapy. Patients with 17p or 11q deletions had the poorest survival, had more marked lymphadenopathy and splenomegaly, and were more likely to be symptomatic with night sweats and weight loss.

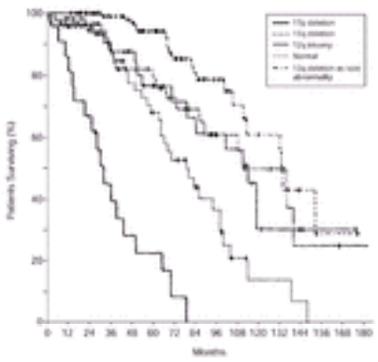

Figure 92.6. Survival according to molecular genetic changes in chronic lymphocytic leukemia. (From Döhner H, Stilgenbauer S, Benner A, et al. Genomic aberrations and survival in chronic lymphocytic leukemia. N Engl J Med 2000;343:1910–1916, with permission.)

In addition to a correlation between genomic abnormalities and prognosis, FISH studies have also demonstrated a correlation between these abnormalities and the presence or absence of *IgV* gene mutations ([29], [30] and [31]) and alterations in cell morphology ([29], [102], [103]). Cases with trisomy 12 or deletions of 17p13 or 11q22-11q23 typically do not have mutations of the *IgV* gene, whereas those with deletions of 13q14 do have *IgV* gene mutations ([29], [30] and [31]). Trisomy 12 frequently occurs in “atypical” CLL or CLL/PL ([102]). However, not all the “atypical” cells in an individual patient contain trisomy 12, indicating that the chromosomal abnormality is not responsible for the atypical morphology ([110], [111]). In addition, although trisomy 12 connotes aggressive disease, it is unclear whether the proportion of cells with trisomy 12 increases over time ([112], [113]). Half the patients with CLL/PL have a p53 mutation, suggesting a role for the gene in the pathogenesis of this variant ([114]).

EFFECTS OF CHROMOSOME CHANGES ON GENE EXPRESSION The most frequent structural abnormality in CLL is a deletion at 13q14 ([79], [92], [96], [98], [99] and [100]). Cases with this abnormality usually have mutations of the *IgV* gene, classic CLL cell morphology, and good prognosis ([29], [79]). Approximately one-half of the abnormalities involve an interstitial deletion and almost invariably are associated with loss of the *Rb* gene ([94], [98]). Translocations involving 13q are found in the remaining one-half of cases, and most of these involve a breakpoint at 13q14, which is the site of the *Rb* gene, with translocations from a variety of other chromosomes ([94], [98]). Usually, the translocations are accompanied by submicroscopic deletions at 13q14 ([100]). The *Rb* gene plays a key role in controlling cellular proliferation (Fig. 92.5), and loss of *Rb* may lead to cell cycle progression and tumor development ([90], [116]). Inactivation of both *Rb* alleles is required for this effect, and this contrasts with p53 mutations, in which a mutation affecting one allele leads to a mutant protein that has a dominant effect ([115], [116]). Using conventional cytogenetic techniques, deletions of 13q14 are found to occur in 15 to 30% of CLL patients ([98], [99] and [100]), whereas monoallelic deletions of the *Rb* gene may be detected by FISH in approximately one-half of patients ([79], [104]). However, mutations of the remaining allele are uncommon ([79], [104]). The D13S25 probe, which identifies a region telomeric to the *Rb* gene on chromosome 13q, has been shown to be more frequently deleted than the *Rb* gene ([99], [117], [118]). Mapping of this region (reviewed in references 100 and 119) has been carried out by a number of groups to identify a putative tumor-suppressor gene, and three candidate genes include *Leu1*, *Leu2*, and *Leu5* ([119], [120] and [121]). However, whether they have a role in the pathogenesis of this disease is still unclear ([119], [120] and [121]). Garcia-Marco et al. ([100]) have provided evidence for a new tumor-suppressor locus at 13q12.3, which is more centromeric than the *Rb* locus. This area encompasses the breast cancer susceptibility gene, *BRCA2*, and using FISH, 80% of patients had either homozygous or heterozygous deletions of the gene; in most cases, there were two cell populations, one containing a heterozygous deletion and one a homozygous deletion ([99]). However, these findings have been disputed ([122]). A deletion of 11q22-q23 occurs in approximately 20% of cases, is seen in younger patients, and is associated with marked lymphadenopathy, rapid disease progression, and poor survival ([79], [123], [124] and [125]). The critical region for the deletion is a 3-Mb segment at 11q22.3-q23.1, and candidate genes in this region include radixin (RDX), which has homology to the neurofibromatosis-type 2 (NF2) tumor-suppressor gene and the ATM gene ([124]). However, mutations of the remaining *ATM* allele only occur in 20% of patients with a deletion ([22]). Although CLL cells with a deletion of 11q22-q23 do not differ from other CLL cells in growth fraction, NF-?B expression, or response to mitogenic stimuli, they have reduced levels of a number of adhesion proteins, which may explain the marked lymphadenopathy observed in these cases ([124]). Complementary DNA microarray analysis has demonstrated that patients with a deletion of 11q22-11q23 have a distinct expression pattern, and the expressions of 16 genes could separate these patients from those without the deletion ([125]). Trisomy 12q13 occurs as a result of duplication of one homolog and is seen in 10 to 20% of CLL patients. Trisomy 12 is frequently associated with “atypical” CLL and CLL/PL. Patient survival is only minimally affected when trisomy 12 is detected by FISH, whereas survival is shortened if trisomy 12 is detected by classical cytogenetics ([79], [98], [99]). 12q13-15 contains the *mdm-2* gene, and overexpression of mdm-2 could simulate a p53 mutation, as mdm-2 binds and inactivates p53 ([122]). However, although mdm-2 is overexpressed in two-thirds of patients, the increase does not correlate with disease stage, aggressiveness, or drug resistance ([80]). 14q32 is the site of the Ig heavy chain gene, and the most common translocation is with chromosome 11, but others have also been reported ([93]). The t(11;14) (q13;q32) occurs more typically in mantle cell lymphoma, and the rearrangement on chromosome 11 involves the *bcl-1* (*B-cell leukemia/lymphoma-1*) gene, a G_1 cyclin also called *CCND1* or *cyclin D1* ([106]). A t(14;18) (q32;q21) translocation is seen commonly in follicular lymphomas, and this rearrangement juxtaposes the Ig heavy chain locus on chromosome 14 to the 3' end of *bcl-2* on chromosome 18 ([32]). This rearrangement causes overexpression of bcl-2 in the follicular lymphomas with inhibition of apoptosis; although the levels of bcl-2 in CLL are equivalent to those in follicular lymphomas, the overexpression in CLL is related to *bcl-2* gene hypomethylation ([61], [63]). The t(14;19) (q32;q13.1) is a rare event and involves the juxtapositioning of *bcl-3* on chromosome 19 with the Ig gene on chromosome 14. The candidate oncogene *bcl-3* is a member of the I?B family, and patients with this translocation have atypical morphology and progressive disease ([126]).

Cytokines

As lymphocyte survival and growth are intimately related to growth factors, it has been suggested that alterations in the production of and response to cytokines may play major roles in the pathogenesis of CLL ([127], [128]). Speculatively, these cytokines may decrease apoptosis or stimulate proliferation of CLL cells but inhibit survival of normal lymphoid and marrow cells, leading to the immunosuppression and myelosuppression seen in this disease.

CLL cells produce TNF-a *in vitro* ([129], [130]), and TNF-a decreases apoptosis in these cells through the induction of bcl-2 ([129], [131], [132] and [133]). In addition, TNF-a may induce the proliferation of CLL cells while suppressing the growth of normal lymphocytes and marrow cells ([129], [131], [132] and [133]). The serum level of TNF-a is increased in most patients with CLL, and the highest levels are observed in those with advanced disease ([132]). An increase in the serum levels of the soluble receptors for TNF-a has also been observed in CLL ([134]).

Transforming growth factor-ß is secreted by CLL cells ([135]) and marrow stromal cells in CLL ([136]). Transforming growth factor-ß inhibits DNA synthesis in both CLL and normal B cells, although the degree of inhibition can be quite low in CLL as a result of the loss of TGF-ß receptors ([137], [138]). In contrast to normal B cells, CLL cells are consistently resistant to apoptosis induced by TGF-ß ([139]).

CLL cells differ from normal $CD19^+$ B cells in producing the lymphoid stem cell growth factor IL-7, suggesting that this cytokine might also be important in disease pathogenesis ([140]). IL-7 does not itself induce proliferation or prevent apoptosis of CLL cells *in vitro* ([140]). However, the prevention of apoptosis of CLL cells by co-culturing with endothelial cells appears to be related to the maintenance of intracellular IL-7 levels, which occurs by signaling through the cell-surface ß2-integrin ([140]). Both IL-2 and IL-15 stimulate the proliferation of CLL but not normal B cells ([141]). Moreover, IL-2 is sequestered by the CLL cells and by the increased serum levels of the IL-2 receptor (TAC receptor) seen in this disease, preventing its interaction with normal lymphocytes ([142], [143]). This may partly explain the immune dysfunction seen in CLL ([143]). A number of other cytokines (e.g., a- and ?-interferon, IL-1, IL-2, IL-4, IL-6, and IL-8) can prevent CLL cells from undergoing spontaneous apoptosis ([144]); these ILs may be derived from the CLL cells (IL-1, -6, and -8) or from T cells (IL-2 and -4) ([144]).

CD40 is a glycoprotein of the TNF superfamily that is expressed on B-cell surfaces and is important for B-cell differentiation and function, whereas the CD40 ligand (CD40L) is expressed on activated T-cell surfaces. Stimulation of CD40 on CLL cells induces proliferation and the release of cytokines ([145]) and also prevents apoptosis induced by chemotherapy ([146]). In addition, CLL cells release CD40L, and the level of ligand is high in the plasma of CLL patients ([147]). As CLL cells have both CD40 and CD40L, it has been suggested that the cell may stimulate its own growth and survival ([148]). Moreover, the CD40L released by CLL cells may stimulate nonmalignant B cells to produce autoantibodies, and this may be a mechanism for the autoimmune phenomena in CLL ([128]). Finally, the CD40 on CLL cells can down-regulate the CD40L on activated T cells, protecting the cells from their cytolytic effect, and this may contribute to the T-cell dysfunction seen in this disease ([128], [149]). Thus, with early disease, the CD40 activation induces growth and survival of the CLL cells, and with continued growth of tumor, there is suppression of $CD4^+$ T

cells ([128], [149]).

More recently, “nurselike” cells have been identified in CLL patients, which may produce survival factors for the leukemia cells ([150]). A subset of peripheral blood $CD14^+$ mononuclear cells develops into large adherent cells when grown in the presence of CLL cells, and these nurselike cells support the survival of the CLL cells. These cells share common antigens with myelomonocytic cells but differ from typical monocytes in having low $CD14^+$, low $CD33^+$, and higher $CD68^+$. The putative cytokine produced by these cells is stromal-derived factor-1, although others have not found that stromal-derived factor-1 protects CLL cells from apoptosis *in vitro* ([75]).

CLINICAL FINDINGS

Although most CLL patients are elderly, approximately 10% of patients are younger than 50 years old ([151], [152]). However, the presenting features are similar regardless of age ([151], [152]). Nowadays, approximately 50% of patients are asymptomatic at diagnosis, and most are found to have an isolated peripheral blood lymphocytosis during a routine blood test ([2]). Alternatively, lymphadenopathy, splenomegaly, or both may be detected during a regular physical examination. When symptomatic, the most frequent complaint is fatigue or a vague sense of being unwell. Less frequently, enlarged nodes or the development of an infection is the initial complaint, and the most frequent infections are bacterial pneumonias. In contrast to lymphomas, fever and weight loss are uncommon.

Most symptomatic patients have enlarged lymph nodes, as well as splenomegaly. Enlargement of the cervical and supraclavicular nodes occurs more frequently than axillary or inguinal lymphadenopathy. The lymph nodes are usually discrete, freely movable, and nontender. Painful enlarged nodes usually indicate superimposed infection, and these can be bacterial or viral. There is usually only mild to moderate enlargement of the spleen, and splenic infarction is uncommon. Less common manifestations are enlargement of the tonsils, abdominal masses due to mesenteric or retroperitoneal lymphadenopathy, and skin infiltration. Patients can also present with the features of anemia, which may be related to marrow replacement or, more rarely, to autoimmune hemolysis or aplasia. Alternatively, patients may have bruising or bleeding, secondary to thrombocytopenia, acquired von Willebrand disease, or an acquired inhibitor to factor VIII. Rarely, patients may present with a paraneoplastic syndrome, such as nephrotic syndrome, paraneoplastic pemphigus, or angioedema (see Autoimmune Manifestations).

LABORATORY FINDINGS

Peripheral Blood

Although a persistent lymphocyte count of greater than 10×10^9/L was originally required for the diagnosis of CLL ([153]), the diagnosis is now made with a count of greater than 5×10^9/L and the presence of typical immunophenotypic markers ([1]). The median lymphocyte count at diagnosis is 30×10^9/L, and in most patients, there is a continuous increase in the lymphocyte count over time ([151], [152]). In half the patients, it takes more than 12 months for the lymphocyte count to double; cyclic fluctuations of up to 50×10^9/L can occur in the lymphocyte counts of untreated patients, and in others, the count may remain stable for years ([152]).

In most patients, the leukemia cells have the morphologic appearance of normal small to medium-sized lymphocytes with clumped chromatin, inconspicuous nucleoli, and a small ring of cytoplasm. Cytoplasmic inclusions occasionally may be observed in CLL cells and may be crystalline, globular, tubular, or rod-shaped ([154], [155]). Ruptured lymphocytes (“basket” or “smudge” cells) are commonly seen in the blood smear, and the number of these cells increases with the lymphocyte count. There can be variations in cell morphology, with some cells being prolymphocytes, whereas others are larger with abundant cytoplasm, and some are plasmoid or cleaved ([101], [102], [156]). The French/American/British classification system divides patients into three groups depending on the percentage of abnormal cells ([156]). In *classical CLL*, more than 90% of cells are small, and when 11 to 54% of the cells are prolymphocytes, it is termed *CLL/PL*. When more than 15% of the lymphocytes are plasmoid or cleaved and less than 10% are prolymphocytes, it is termed *atypical CLL* ([101], [102], [156]). Approximately 80% of patients have classical CLL, and 20% have CLL/PL or atypical CLL. If more than 55% of the cells are prolymphocytes, the patient has prolymphocytic leukemia.

As discussed in the section Differential Diagnosis, a number of other conditions can produce peripheral lymphocytosis, but a careful examination of the blood smear and immunophenotyping can differentiate these disorders ([2], [3], [101], [102], [156]).

Bone Marrow and Lymph Nodes

There are four patterns of marrow involvement in CLL ([157]). The infiltration may be interstitial, nodular, mixed (nodular and interstitial), or diffuse, with mixed being the most common and nodular the least common. Diffuse involvement, in which there is effacement of the fat spaces by tumor, carries the worst prognosis ([157]). The marrow involvement is sporadic and contrasts with follicular lymphomas, in which paratrabecular involvement is the rule. In contrast to marrow, involvement of the lymph node is diffuse. Proliferation centers with prolymphocytes and paraimmunoblasts are commonly seen in both marrow and lymph nodes ([101]).

Immunophenotyping

CLL is generally believed to develop by the malignant transformation of a single B lymphocyte and its subsequent clonal expansion ([3], [5], [6], [26]). It has been suggested that a small proportion of cases (<1%) may be of T-cell origin ([158]). However, these cases may be more accurately classified as a small-cell variant of T-cell prolymphocytic leukemia rather than as T-cell CLL ([159]). When viewed by electron microscopy, these cells have nucleoli and, like T-cell prolymphocytic leukemia, contain abnormalities of chromosomes 14 and 8 and strongly express CD7 ([158], [159]). In addition, both these T-cell leukemias may involve the skin and are aggressive and generally resistant to therapy ([158], [159]). In classical B-cell CLL, the cells have a number of distinct markers that help in its diagnosis and differentiation from other disorders ([2], [101], [160], [161], [162] and [163]) (Table 92.2). The leukemic cells have the B-cell markers CD19, CD20 (low), CD43, and CD79b (low) and, by definition, are also $CD5^+$. In addition, the cells show clonal light chain restriction, weak expression of sIgM and sIgD, and are $CD23^+$ and $CD10^-$. These cells are also $CD27^+$ ([34], [35]), consistent with the recent data suggesting that these cells are memory B cells ([5]). Alternatively, the presence of CD27, in addition to CD5 and CD23, could reflect the activated nature of the CLL cells, as these markers all increase with cellular activation ([164]). Based on the above, Matutes et al. ([162], [165]) have recommended the use of five markers to differentiate CLL from other B-cell malignancies (Table 92.3). Typical CLL should be surface Ig (weak), $CD5^+$, $CD23^-$, CD79b/CD22 (weak), and $FMC7^-$.

TABLE 92.2. Immunophenotypes of Chronic Lymphocytic Leukemia and Other Chronic B-Cell Disorders

Condition	smIg	CD5	CD10	CD11c	CD19	CD20	CD22	CD23	CD25	CD43	CD79b	CD103'	FMC7
Chronic lymphocytic leukemia	Dim	++	-	-/+	++	Dim	-/+	++	+/-	+	-	-	-/+

TABLE 92.3. Scoring System for Diagnosis of Chronic Lymphocytic Leukemia

Marker	Marker Intensity	Score	Marker Intensity	Score
Surface immunoglobulin	Weak	1	Strong	0
CD5	+	1	-	0
CD23	+	1	-	0
CD22/CD79b	Weak	1	Strong	0
FMC7	-	1	+	0

+, present; -, absent.

NOTE: Diagnosis of chronic lymphocytic leukemia requires a score of 4 or 5.

Adapted from Matutes E, Polliack A. Morphological and immunophenotypic features of chronic lymphocytic leukemia. Rev Clin Exp Hematol 2000;4:22–47; and Moreau EJ, Matutes E, A'Hern RP, et al. Improvement of the chronic lymphocytic leukemia scoring system with the monoclonal antibody SN8 (CD79b). Am J Clin Pathol 1997;108:378–382.

To define the stage of maturation of the CLL cell, Damle et al. ([30]) measured CD38 levels in CLL. Approximately 50% of patients had greater than 30% CD38 $^{+}$ cells, and these patients had a worse prognosis than those with less than 30% CD38 $^{+}$ cells. Activation of CD38 $^{+}$ cells, but not CD38 $^{-}$ cells, through sIgM induces apoptosis and through IgD prolongs cell survival and induces differentiation ([166]).

One of the typical features of the CLL cell is the overexpression of membrane CD23, which is an activation marker and may play a role in the decreased apoptosis observed in this disease ([167]).The presence of CD23 is useful to differentiate CLL from mantle cell lymphoma, which is also CD5 $^{+}$ ([163] , [167]). Recently, it has been demonstrated that the increased expression of CD23 in CLL is related to deregulation of Notch2 signaling ([168]). Cell-surface CD23 undergoes spontaneous proteolysis, producing elevated serum levels of CD23, the level of which is a marker of disease stage and progression ([3]).

The B-cell antigen receptor complex is required for the proliferation of B cells after immune stimulation and is a complex formed by sIg and Iga/Igß (CD79a/CD79b) ([3]). CLL cells lack CD79b, which is related to overexpression of an alternatively spliced form of the gene ([169]). Very small numbers of CLL cells may be identified through the detection of CD19 $^{+}$/CD5 $^{+}$ cells that are CD79b $^{-}$, and 3.5% of adults older than 40 years of age have small numbers of these cells in their peripheral blood ([170]). Whether these patients will eventually develop CLL is unknown, but the cells are monoclonal by surface Igs and are in the “good prognosis” group by being CD38 $^{-}$ and showing mutations of the *IgV* gene. FMC7 is usually strongly expressed in hairy cell leukemia and prolymphocytic leukemia, and approximately 16% of CLL cases also stain positively ([160]). It has been shown recently that FMC7 reacts with an epitope of CD20; as CD20 staining is low in typical stable CLL, this explains the low positivity seen with FMC7 staining ([171]). In general, those patients who are FMC7 $^{+}$ have high levels of surface IgM, low expression of CD23, and poor prognosis ([160]). Myelomonocytic antigens (CD11b, CD13) may also be expressed in CLL, and this is associated with diffuse marrow involvement, CD5 negativity, and poor survival ([172]).

The CD5 antigen is most commonly associated with mature T cells and is expressed weakly on thymocytes ([3] , [173]). However, normal B cells carrying the CD5 marker are located in the mantle zone of the lymph node, and small numbers of these cells are also present in the peripheral blood ([3] , [173]). The CD5 molecule has been cloned and appears to be involved in the activation of T lymphocytes. The function of CD5 on the B cell remains unknown, but its induction has been shown to be inhibited by the T cell–derived cytokine IL-4. CD5 $^{+}$ B cells can be stimulated to secrete anti-DNA antibodies and rheumatoid factors *in vitro*, and increased numbers are found in the peripheral blood of patients with rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome ([4]). It has been suggested that the normal counterpart of the CLL cell is the CD5 $^{+}$ B cell ([3] , [4]), although a recent study using detailed immunophenotyping demonstrated significant differences between the two groups ([3] , [4] , [164]). Thus, the CD5 $^{+}$ B cell appears to be a resting antigen-naïve cell, whereas the CLL cell is activated and antigen-experienced ([164]). Moreover, the specific activation marker expression pattern varies between cells that have *IgV* gene mutations and those that do not, with the unmutated group resembling B cells at an earlier state of activation ([164]). It has been shown that approximately 5% of patients with the morphologic features of CLL are CD5 $^{-}$ ([160] , [162] , [171]). These cases are more likely to be FMC7 $^{+}$, CD23 $^{-}$, CD11b $^{+}$, and CD13 $^{+}$ and have a poorer prognosis than those with CD5 $^{+}$ CLL ([160] , [162]). However, it has more recently been suggested that these CD5 $^{-}$ patients do not have CLL ([174]), and the National Cancer Institute–sponsored Working Group (NCI-WG) on CLL now includes CD5 $^{+}$ as an essential criterion for the diagnosis of CLL ([1]).

Apart from having either ? or ? light chains on the cell-surface membrane ([1] , [3] , [4]), clonality is confirmed by the presence of unique idiotypic specificities of the Igs produced by CLL cells ([175]) and by Ig gene rearrangements ([3] , [4] , [173]). CLL cells have low to undetectable amounts of monoclonal polyreactive IgM autoantibodies, frequently of the rheumatoid factor type, on their surface ([3] , [4] , [173]). Thus, the same monoclonal autoantibody produced by a leukemia cell may react with a variety of antigens (e.g., IgG, cardiolipin, histones, or single- or double-stranded DNA) ([173]). Surface and cytoplasmic Igs contain either ? or ? light chains but never both. Most cells display a single heavy chain class, usually µ, although some display µ and d. Less commonly, ?, a, or no heavy chain determinant is found. Although the CLL cell has traditionally been believed to be frozen at a particular stage in maturation, recent evidence has demonstrated that up to 50% of CLL patients have IgM $^{+}$ leukemia cells, which are able to undergo isotype switching to IgA (usually) or to IgG ([176] , [177]). Rearrangements of Ig heavy and light chain genes are readily demonstrated in patients with CLL ([166] , [178]). Abnormal patterns, such as multiple cytoplasmic µ bands, may correlate with advanced clinical stages of the disease ([178]). In addition, approximately 25% of patients with CLL appear to have rearrangements of the T-cell receptor ß gene ([179]) but rarely, if ever, of the T-cell receptor ? gene ([180] , [181]). In other T-cell malignancies, both ß- and ?-genes are rearranged. Rearrangement of the T-cell receptor ß gene may indicate transformation to prolymphocytic leukemia ([180]).

In more than half the cases, CLL cells can be induced to secrete monoclonal antibodies *in vitro* ([3] , [4] , [166]). Using sensitive techniques, monoclonal proteins can be detected in the serum of virtually all patients ([182]), although less than 5% of patients produce large enough quantities of monoclonal proteins to be detected by routine serum electrophoresis.

Functional Immune Abnormalities

With disease progression, patients with CLL develop immunosuppression, partly as a result of their disease and partly because of chemotherapy, and 80% of patients have recurrent infections, with sepsis being the major cause of death ([183]). Apart from typical bacterial infections, CLL patients are also susceptible to opportunistic infections, particularly if they have received nucleoside analogs or monoclonal antibodies ([184] , [185] , [186] and [187]). The nucleoside analogs are highly toxic to T lymphocytes, whereas monoclonal antibodies may be cytotoxic to B cells, T cells, or both depending on the antibody used ([186] , [187]). The major cause of infection is hypogammaglobulinemia, although CLL patients also have abnormalities in T cells, complement, and neutrophil function.

The characteristics of the CLL cells are described in other sections, but in essence, these cells have no useful immune function ([183] , [184]). The cells show poor stimulatory activity in mixed lymphocyte culture ([188]) and in response to B-cell mitogens, such as pokeweed mitogen, lipopolysaccharide, and the Epstein-Barr virus ([189] , [190]). However, phorbol esters, *Staphylococcus aureus* protein A from Cowan I, anti-µ antibodies, anti-CD40, and loxoribine have been shown to be potent mitogens ([191] , [192]). Moreover, these cells are poor antigen-presenting cells and, as discussed below, can interfere with normal B- and T-cell function ([193]).

Hypogammaglobulinemia and agammaglobulinemia are usually observed in CLL, and the severity increases with the duration and stage of disease ([183] , [184] , [194]). The

Ig levels are all decreased, and within the IgG class, reduced levels of IgG2 and IgG4 correlate best with the risk of infection; however, the decline in IgA levels is the most important predictor of infection ([194], [195]). Patients with CLL have reduced primary and secondary responses to immunization ([183]). Although patients with higher levels of gammaglobulin usually show better responses than those with low levels, the response of both groups is abnormal. The pathogenesis of the hypogammaglobulinemia is poorly understood. However, impaired B-cell function and regulatory abnormalities of T cells (including the reversal of normal helper/suppressor cell ratios) probably play a role. In addition, CLL-derived natural killer (NK) cells have been shown to suppress Ig secretion by normal B cells *in vitro* ([196]).

The absolute number of T cells may be increased in untreated B-cell CLL, but there are marked abnormalities in the surface markers, including inversion of the T-helper cell to T-suppressor cell ratio, suggesting perturbations in T-cell function ([183], [197], [198]). The increase in the absolute number of T-suppressor cells may correlate with the degree of hypogammaglobulinemia ([199]). The T cells usually respond normally to mitogens, such as phytohemagglutinin, *in vitro* and produce IL-2 and ?-interferon ([200]), but their reactivity to allogeneic and autologous B cells is impaired ([201], [202]). Functional studies of the T cells have sometimes shown decreased T-helper functions ([201], [202]). Spontaneous and antibody-dependent cytotoxicity are reduced, suggesting an abnormality in the large granular lymphocyte population, including NK cells ([203]).

The cause of these abnormalities is unclear, but in some cases, there is clonal expansion of T-cell subsets, which has been ascribed to stimulation by CLL cells ([183], [204]). Alternatively, the B-, T-, and NK-cell functions may be suppressed by means of immunosuppressive factors produced by CLL B cells. One potential candidate is TGF-ß, which is secreted by CLL cells and marrow stromal cells in CLL, and has been shown to be a potent inhibitor of normal B and T cells ([136], [137], [138] and [139]). In addition, CLL cells express both CD40 and the CD40L (CD154), and these cells decrease CD154 expression by normal T cells with resultant effects on normal B-cell differentiation and isotype switching ([205]).

In addition to the above abnormalities, the levels of different complement components are decreased in CLL, particularly in patients with advanced disease ([206]). As well, multiple defects in neutrophil function have been described in CLL, and these are associated with an increased risk of infection ([207]).

Autoimmune Manifestations

Although CLL patients are immune deficient, they have an increased incidence of autoimmune disorders, particularly of the hematopoietic system, and the incidence is highest in those with advanced disease who have undergone therapy ([208], [209] and [210]). Four percent to 25% of patients develop autoimmune hemolytic anemia, and this is usually associated with a warm-type antibody against the Rhesus system. The incidence of this disorder is higher in men, those with lymphocyte counts greater than 60 × 10^9/L, and those older than 60 years of age ([208]). Immune thrombocytopenia occurs in 2% of patients, and the diagnosis is based on an increase in platelet size in the peripheral blood and an increase in megakaryocytes in the marrow, although the latter is often difficult to ascertain as the marrow usually is heavily infiltrated with CLL cells. It is interesting that approximately one-third of these patients have a positive Coombs test ([210]). Whether autoimmune neutropenia occurs in CLL is unclear ([210]). Pure red cell aplasia occurs in approximately 1% of cases and may be caused by a T-cell mechanism rather than the formation of autoantibodies ([209], [211]). Apart from the autoimmune hematologic disorders, nephrotic syndrome, related to membranous or membranoproliferative glomerulonephritis, acquired angioedema, and autoimmune blistering skin diseases also occur in CLL ([210]). The glomerulonephritis is believed to be secondary to deposition of monoclonal Ig and remits with treatment of the CLL ([210], [212]). Acquired angioedema is associated with recurrent angioedema and abdominal pain and is related to inactivation of the inhibitor of the first component of complement by a paraprotein produced by the lymphoid malignancy ([210]). CLL is also a cause of paraneoplastic pemphigus, which produces painful mouth ulcers, conjunctivitis, and pruritic blistering skin lesions ([210], [213]). This disorder is diagnosed by distinct histologic changes in the skin and the presence of autoantibodies in the blood directed against cutaneous epitopes ([210], [213], [214]).

Normal $CD5^+$ B cells can produce autoantibodies to IgG and single- and double-stranded DNA, as well as other autoantigens, and the number of these cells is increased in autoimmune disorders ([3], [4], [172]). CLL cells also can be induced to secrete IgM molecules that react with a comparable spectrum of antigens ([172], [215]). However, several observations suggest that the clinically significant autoantibodies are not produced by the leukemic clone. First, the antibodies are polyclonal and are usually IgG. Second, the autoimmune disorders may occur while the patient's disease is responding to therapy ([208], [209] and [210], [216]). This was initially observed during or after treatment with fludarabine ([216]), although subsequent studies in untreated patients have shown a similar incidence of this complication regardless of whether the patients received fludarabine or other agents ([217], [218]). It is therefore likely that the high incidence of autoimmune hemolytic anemia in the initial studies with fludarabine was associated with advanced and alkylator-resistant disease ([208], [209] and [210], [216]). It has been suggested that CLL cells act as antigen-presenting cells for either normal $CD5^+$ or $CD5^-$ antibody-producing B cells and that antibody production is increased after inhibition of T cells either with advancement of disease or because of therapy ([4], [215]). Alternatively, the CLL cells might be the source of antibody, as it has been demonstrated that IgM^+ CLL cells can undergo isotype class-switching to IgG^+ cells, which could be a source of the typical “warm reactive” antibodies normally seen with autoimmune disease ([175], [176]). Additional support for CLL cells being the source of autoantibody is provided by the association between autoimmune hemolytic anemia in CLL and the expression by the leukemia cells of specific Ig variable-region genes ([219]).

DIAGNOSIS

The CLL working groups, the International CLL Workshop ([153]) and the NCI-WG ([1]), have summarized the diagnostic criteria for CLL.

The International CLL Workshop proposed the following criteria in 1989:

1. A sustained peripheral blood lymphocyte count of =10 × 10^9/L, with most of the cells being mature-appearing lymphocytes.
2. A bone marrow aspirate showing greater than 30% lymphocytes.
3. Peripheral blood lymphocytes that have a B-cell phenotype consistent with CLL (i.e., weak expression of surface Ig, $CD5^+$, and rosette formation with mouse erythrocytes).

The diagnosis of CLL is confirmed if criterion 1 plus criterion 2 or 3 are present. If the peripheral blood lymphocyte count is less than 10 × 10^9/L, then both criteria 2 and 3 must be present.

The NCI-WG in 1996 recommended that the diagnosis of CLL require

1. A peripheral blood lymphocyte count of greater than 5 × 10^9/L, with less than 55% of the cells being atypical. The cells should have (a) B cell–specific differentiation antigens (CD19, CD20, and CD23) and be $CD5^+$, without other pan–T-cell markers; (b) either ? or ? chain surface Ig, confirming monoclonicity; and (c) low-density surface Ig.
2. A bone marrow aspirate showing greater than 30% lymphocytes.

DIFFERENTIAL DIAGNOSIS

In most patients, the diagnosis of CLL is easily made after a careful review of the peripheral smear and immunophenotyping, although other conditions must be considered (Table 92.4). On occasion, immunohistochemistry or gene rearrangement studies are required to exclude other diagnoses.

TABLE 92.4. Differential Diagnosis of Chronic Lymphocytic Leukemia

Benign causes
Bacterial (e.g., tuberculosis)
Viral (e.g., infectious mononucleosis)

- Persistent polyclonal B-cell lymphocytosis
- Hyperreactive malarial splenomegaly

Malignant causes

- B Cell
  - Prolymphocytic leukemia
  - Leukemic phase of non-Hodgkin lymphomas
    - Mantle cell lymphoma
    - Follicular small cleaved cell lymphoma
    - Splenic lymphoma with circulating villous lymphocytes
    - Marginal zone lymphomas
    - Large cell lymphoma
  - Hairy cell leukemia
  - Waldenström macroglobulinemia
- T Cell
  - Prolymphocytic leukemia
  - Adult T-cell leukemia/lymphoma
  - Sézary syndrome
  - Large granular lymphocytic leukemia

Benign Causes

T-CELL–ASSOCIATED CAUSES Chronic infections, such as tuberculosis or syphilis, may produce a lymphocytosis. Transient but fairly profound increases in the number of small lymphocytes in the blood may be seen in viral illnesses, such as pertussis, infectious lymphocytosis, or infectious mononucleosis. However, these are usually found in children or young adults and should be easily distinguished from CLL by the clinical features and the morphologic appearance of the cells.
B-CELL–ASSOCIATED CAUSES Persistent polyclonal B-cell lymphocytosis is a rare and benign condition seen typically in middle-aged female smokers with a familial tendency ([220], [221] and [222]). The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in Igs and a strong association with HLA-DR7, and an isochromosome 3q $^{+}$ (i3)(q10) is observed in some cases ([220], [221]). These cells show *IgV* gene mutations and immunophenotypically are splenic marginal zone lymphocytes [i.e., CD27 $^{+}$, IgM (high), CD21 (high), CD5 (low)] ([222]). Delage et al. ([221]) have demonstrated multiple *bcl-2/Ig* gene rearrangements in this disease and described a family in which there was a high incidence of the gene rearrangements in first-degree relatives in association with a paternal HLA haplotype ([221]). These findings suggest that persistent polyclonal B-cell lymphocytosis can be a familial disorder and that the *bcl-2/Ig* gene rearrangements may represent the first abnormality before B-cell expansion ([221]). Tropical splenomegaly syndrome or hyperreactive malarial splenomegaly occurs in most countries in the malaria belt and may mimic CLL ([223], [224]). This disease is believed to be a disordered response to malarial antigens leading to overproduction of B cells and is characterized by massive splenomegaly, an increase in IgM, and, in 10% of cases, an increase in the peripheral lymphocyte count. The disorder responds to proguanil (an antimalarial compound), and this is used to differentiate hyperreactive malarial splenomegaly from CLL.

Malignant Causes

Malignant disorders that may be confused with CLL are discussed in detail later in this section, but their main clinical and laboratory features are summarized here for comparative purposes and as an aid in differential diagnosis (Table 92.4). Over the past decade, the identification of new disorders has increased, partly as a result of greater attention to morphologic details, but also as a result of increasing sophistication in immunophenotyping and molecular genetic and cytogenetic studies ([163], [225]).

Before flow cytometry became a routine investigation, many patients were diagnosed as having CLL but in fact had other disorders (Table 92.2). Approximately 50% of cases of peripheral lymphocytosis seen in some referral centers are caused by CLL ([226]), and the most common malignancies to be confused with CLL are prolymphocytic leukemia and the leukemic phase of non-Hodgkin lymphomas. Morphologically, these disorders may appear similar to CLL, particularly to atypical CLL.

B-CELL–ASSOCIATED CAUSES
B-Cell Prolymphocytic Leukemia B-cell prolymphocytic leukemia is characterized by larger, less mature-appearing cells than are seen in CLL, and the nucleus has condensed chromatin and prominent central nucleoli ([227], [228]). Patients with CLL/PLL have 11 to 54% prolymphocytes, but in prolymphocytic leukemia, =55% of the cells are prolymphocytes ([156]). Prolymphocytic leukemia appearing *de novo* is an aggressive disease, and patients frequently are symptomatic with fever, weight loss, or abdominal discomfort and are found to have massive splenomegaly, minimal lymphadenopathy, and resistance to therapy ([227], [228]). Leukocyte counts in excess of 150 × 10 ^{9}/L, consisting almost entirely of prolymphocytes, are common, as are anemia and thrombocytopenia. The cells have invariably intense staining for surface membrane Ig, FMC7, CD20, and CD79b, whereas this may or may not occur with CLL/PLL ([156]). One-third of cases have a deletion of 11q23, one-half a deletion of 13q14, and three-fourths a mutation of p53 ([229], [230]). Although occasional patients may initially have stable disease, progression is the rule, and the median survival is 65 months ([228]).
Leukemic Phase of Non-Hodgkin Lymphoma The leukemic phase of non-Hodgkin lymphoma used to be referred to as *lymphosarcoma cell leukemia* and includes the leukemic phase of mantle cell (intermediate cell) lymphoma, follicular lymphoma, splenic lymphoma with villous lymphocytes (splenic marginal zone lymphoma), other marginal zone lymphomas, and, rarely, large cell lymphomas. The lymphocytes in mantle cell lymphoma are larger than those seen in CLL and have more cytoplasm; in contrast to CLL and the other disorders, there is variation in cell morphology, with some cells looking like classical CLL cells, others having irregular nuclei, and some looking like prolymphocytes ([231], [232]). Two-thirds of patients have marrow involvement and one-third leukemic involvement ([231]). Patients with a leukemic picture have aggressive disease. The cells strongly express surface Ig and are CD19 $^{+}$, CD20 $^{+}$, CD5 $^{+}$, CD23 $^{-}$, CD10 $^{-}$, and FMC7 $^{+}$ ([2], [163]). These cells have the t(11;14)(q13;q32) and, by immunohistochemistry, stain strongly for cyclin D1. As the breakpoint for t(11;14)(q13;q32) covers a large area, PCR using only one set of primers misses many cases, and Southern blot analysis or FISH may be required ([233], [234]). The leukemic phase of follicular lymphomas may be confused with CLL; usually, the cells are small, the nuclear chromatin is smooth and not clumped, there is almost no cytoplasm, and the nucleus is indented ([163], [235]). Occasionally, large cells are seen, and, when possible, a lymph node biopsy should be carried out to type the follicular lymphoma. The cells are identified by immunophenotyping and are CD19 $^{+}$, CD20 $^{+}$, FMC7 $^{+}$, CD23 $^{-}$, CD5 $^{-}$, and CD10 $^{+}$. The diagnosis can be confirmed by demonstrating a t(14;18)(q32;q21).
Approximately 10% of peripheral B-cell lymphocytosis is caused by splenic lymphoma with villous lymphocytes; these cells have characteristic filamentous projections and, frequently, a nucleolus ([226], [236]). The cells are usually SIg $^{+}$ (strong), CD19 $^{+}$, CD20 $^{+}$, CD23 $^{-}$, CD5 $^{-}$, CD79b $^{+}$, and FMC7 $^{+}$. The other forms of marginal zone lymphomas, which include the mucosa-associated lymphoid tissue and monocytoid B-cell lymphomas, may also rarely involve the marrow and peripheral blood ([225]).
Hairy Cell Leukemia *Hairy cell leukemia* (Chapter 93) is so called because the leukemia cells have hairy cytoplasmic projections that are usually visible under light, phase, or electron microscopy. Almost always, this is a B-cell disorder, and the cells are of moderate size with eccentric oval nuclei and variable prominent nucleoli. The cells differ from CLL cells in being CD5 $^{-}$ but FMC7 $^{+}$, CD11c $^{+}$, CD25 $^{+}$, HC2 $^{+}$, and CD103 $^{+}$ (B-ly-7 $^{+}$) ([237]). In contrast to classical hairy cell leukemia, in which the lymphocyte count is usually low, the variant form of hairy cell leukemia has a higher lymphocyte count, but the cells have prominent nucleoli, are tartrate-resistant acid-phosphatase negative, and are CD25 $^{-}$ ([238]).
Waldenström Macroglobulinemia Waldenström macroglobulinemia (Chapter 100) is characterized by the proliferation of cells having plasmacytoid features and, frequently, abundant basophilic cytoplasm. Peripheral lymphocytosis is only moderate, the cells have surface and cytoplasmic IgM, and produce large quantities of monoclonal IgM ([225]).
T-CELL–ASSOCIATED CAUSES The chronic T-cell disorders are much less common than the B-cell disorders but can be classified into four groups ([156]).
T-Cell Prolymphocytic Leukemia T-cell prolymphocytic leukemia is morphologically identical to B-cell prolymphocytic leukemia, but lymphadenopathy and skin involvement are more common ([239], [240]). Most often, these cases are CD3 $^{+}$, CD4 $^{+}$, CD7 $^{+}$, and CD8 $^{-}$, but in one-third of patients, the cells are both CD4 $^{+}$ and CD8 $^{+}$ or, more rarely, CD4 $^{-}$ and CD8 $^{+}$ ([239]). Although the median survival for this disease is only 7.5 months, good responses have recently been observed with alem-tuzumab (Campath-1H), a monoclonal antibody against CD52 ([241]).

Adult T-Cell Leukemia/Lymphoma Adult T-cell leukemia/lymphoma is most common in the Orient and has a variety of clinical presentations ([242], [243]). Patients may present acutely with lymphadenopathy or hepatosplenomegaly, although skin involvement, lytic bone lesions, hypercalcemia, and involvement of other organs have been described. Alternatively, there may be a chronic form of the disease with peripheral lymphocytosis and skin involvement, which may either resolve entirely or develop into the acute form of the disease ([243]). More recently, a prognostic classification has been developed based on the proliferative capacity of the peripheral blood leukemic cells ([244]). The cells are usually $CD4^+$ and are infected with human T-cell leukemia/lymphoma virus-1.

Sézary Syndrome Sézary syndrome is the leukemic form of mycosis fungoides, and affected patients have diffuse skin involvement plus lymphadenopathy and splenomegaly, although peripheral lymphocytosis can occur in isolation ([245]). The cells are typically large with cerebriform nuclei, coarse chromatin, and inconspicuous nucleoli and are usually $CD4^+$ ([245]). The diagnosis of Sézary syndrome requires a peripheral blood Sézary cell count of greater than 1×10^9/L or that greater than 20% of the lymphocytes be identified as Sézary cells ([245]).

Large Granular Lymphocytic Leukemia Large granular lymphocytic (LGL) leukemia is characterized by moderate lymphocytosis (1 to 49×10^9/L) and the presence of cells that are bigger than CLL cells and have abundant cytoplasm containing azurophilic granules ([246], [247] and [248]). However, there is considerable variation, even within the same patient, and in some cases, the lymphocytes may appear normal, and the granules may be coarse, fine, or absent ([246]). Large granular lymphocytes may be $CD3^-$ NK cells that mediate non–major histocompatibility complex-restricted cytotoxicity or $CD3^+$ cells that mediate non–major histocompatibility complex-restricted cytotoxicity ([246]). T-LGL leukemia is the most common form, making up 85% of cases, and is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis (25%), but this is a distinct entity from Felty syndrome ([246]). Recent evidence has suggested that the neutropenia is related to the expression of Fas ligand by LGL cells ([249]). The usual immunophenotyping of T-LGL leukemia is $CD3^+$, $CD4^-$, $CD8^+$, $CD16^+$, $CD56^-$, $CD57^+$, and $TCR\alpha\beta^+$, and T-cell receptor gene rearrangement studies confirm T-cell monoclonicity. If therapy is required, responses may be observed with cyclosporin or methotrexate ([250], [251]). NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia ([247]). However, chronic NK-cell leukemia can occur, with a clinical course similar to that of T-LGL leukemia ([248]). These cells are usually $CD3^-$, $CD4^-$, $CD8^-$, $CD16^+$, $CD56^+$, and $CD57^-$ ([246]).

INVESTIGATIONS AND STAGING

Investigations

A complete blood count, review of the peripheral smear, and immunophenotyping are required for diagnosis and prognosis in CLL. A bone marrow aspirate/biopsy is not required for diagnosis but is useful to assess normal marrow reserve, and the pattern of involvement of the marrow by CLL is prognostically important ([1], [157]). A reticulocyte count, Coombs test, renal and liver function tests [including lactate dehydrogenase (LDH)], serum protein electrophoresis and/or immunoelectrophoresis, and Ig levels are also required. Monoclonal proteins, if found, should be typed and measured in the serum and the urine. The plasma β_2-microglobulin level should also be measured, as this is a simple and important prognostic measure ([252]). If available, cytogenetic analysis and, particularly, FISH provide important prognostic information.

Staging

Two staging systems are in general use, and both are very useful for estimating disease severity and prognosis in CLL ([253], [254]). The Rai staging system is generally used in North America, and the original system divided patients into five groups on the basis of the presence of lymphadenopathy, splenomegaly, and anemia or thrombocytopenia (Table 92.5) ([253]). A simplified three-stage version of this scheme is now generally accepted (Table 92.5) ([1]). Patients are classified into three groups with a significantly different prognosis, making the classification useful in clinical decision making (Fig. 92.7).

TABLE 92.5. Rai Classification System for Chronic Lymphocytic Leukemia

Stage	Modified Stage	Description	Median Survival (yr)
0	Low risk	Lymphocytosis	>10
I	Intermediate risk	Lymphocytosis [a] + lymphadenopathy	9
II	Intermediate risk	Lymphocytosis + splenomegaly ± lymphadenopathy	7
III	High risk	Lymphocytosis + anemia [a] ± lymphadenopathy or splenomegaly	5
IV	High risk	Lymphocytosis + thrombocytopenia [a] ± anemia ± splenomegaly ± lymphadenopathy	5

[a] Lymphocytosis, lymphocyte count >5 × 10^9/L for >4 weeks; anemia, hemoglobin <110 g/L; and thrombocytopenia, platelets <100 × 10^9/L ([253], [257]).

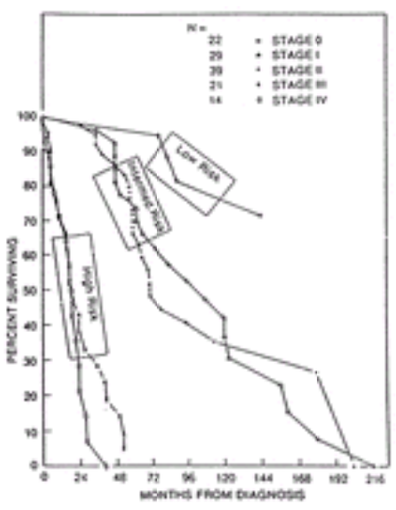

Figure 92.7. Survival of patients with chronic lymphocytic leukemia staged according to the Rai system (Table 92.5). Stages I and II are indistinguishable and are combined in the intermediate (Intermed)-risk group. Similarly, stages III and IV are combined in the high-risk group. (From Rai KR, Han T. Prognostic factors and clinical staging in chronic lymphocytic leukemia. Hematol Oncol Clin North Am 1990;4:447–456, with permission.)

The Binet staging system is most frequently used in Europe ([254]), and staging using this system is based on the number of involved areas, the level of hemoglobin, and the platelet count (Table 92.6). The five areas of involvement considered in this system include three lymph node areas (cervical, axillary, and inguinal, whether unilateral or bilateral), the spleen, and the liver. Most hematologists continue to use either the Rai or the Binet system, but the International Workshop on CLL has recommended the integration of these two systems with special provisions for Rai stage 0 patients ([153]). This amalgamated system recognizes categories A(0), A(I), A(II), B(I), B(II), C(III), and C(IV) ([1]). The influence of the different stages on survival and the correlation with the other prognostic markers are discussed in Prognosis.

TABLE 92.6. Binet Classification for Chronic Lymphocytic Leukemia

Stage	Blood Counts	Involved Areas [a]	Median Survival (yr)
A	Hb >100 g/L and platelets >100 × 10^9/L	<3	>10
B	Hb >100 g/L and platelets >100 × 10^9/L	>3	7
C	Hb <100 g/L, or platelets <100 × 10^9/L, or both	Any number	5

Hb, hemoglobin.

[a] The five areas of involvement include head and neck, axillae, groins, palpable spleen, and clinically enlarged liver (254, 257).

PROGNOSIS

As indicated in the previous section, there is considerable variation in survival in CLL. Some patients may have a prolonged survival without treatment, and, indeed, an occasional patient can have a spontaneous remission (255). However, some patients suffer a rapid downhill course leading to death. The Rai or Binet clinical staging systems are simple and reliable prognostic measures (Fig. 92.7) (253, 254). However, there is considerable variation in the prognosis of patients within any of these groups, and other prognostic measures must be used in conjunction with staging (Table 92.7). Some of these studies, such as lymphocyte morphology and doubling time, immunophenotyping, pattern of marrow involvement, serum LDH, and ß $_2$-microglobulin levels, are routinely available, but others are either experimental or only available at specialized centers. Considerable effort is now being made to determine the association between these markers and to assess the relative importance of the individual markers by multivariate analysis (29, 31, 83). Clearly, the stratification of patients into different risk groups will allow for a more rational approach to treatment options and will identify specific patient groups to be studied in clinical trials.

TABLE 92.7. Markers of Poor Prognosis in Chronic Lymphocytic Leukemia

Routine studies
Advanced Rai or Binet stage
“Atypical” morphology or chronic lymphocytic leukemia/prolymphocytic leukemia
Peripheral lymphocyte doubling time of <12 mo
Immunophenotyping
High surface IgM, FMC7 $^+$, CD23 $^-$, CD11b $^+$, CD13 $^+$
CD38 $^+$
High ß $_2$-microglobulin level
Diffuse marrow histology
High lactate dehydrogenase
Poor response to chemotherapy
Investigational studies
Lack of *IgV* gene mutations
Expression of ZAP-70 protein
Fluorescence *in situ* hybridization studies showing del 11q (loss of *ATM* gene), del 17p (loss of p53), or trisomy 12
Increased serum levels of CD23, tumor necrosis factor-a, and thymidine kinase

Ig, immunoglobulin.

Rai and Binet Staging

The median survival of patients in the Rai staging *low-risk* group (31%), who have an isolated lymphocytosis, is more than 10 years and similar to that for the “normal” population, and therapy is therefore not indicated. Patients in the *intermediate-risk* group (61%), who have lymphadenopathy, splenomegaly, or both, have a median survival of 7 to 9 years. They carry a significantly greater tumor load and may develop signs and symptoms attributable to the presence of tumor masses. Patients in the *high-risk* group (8%) have anemia, thrombocytopenia, or both and have a median survival of approximately 5 years. The median survival of patients with Binet stage A (63%) is greater than 10 years, stage B (30%) is 7 years, and stage C (7%) is 5 years (256, 257).

Although both staging systems provide useful prognostic information, they do not correlate well with each other. Thus, there are twice as many patients with Binet stage A disease as in the Rai low-risk group, and the opposite is true for Binet stage B disease and the Rai intermediate-risk group. Although the median survival of patients with stage A disease or in the low-risk group is greater than 10 years, 40% of these patients will progress to a more advanced disease, and 50% of patients will require therapy at some point, with 25% dying from their disease (256, 257).

Age and Sex

Approximately 10% of CLL patients are younger than 50 years old, and the clinical features and staging at presentation are similar in this group to those older than 50 years (151, 152). Survival of both groups of patients is the same, although the proportion of deaths that can be directly attributed to CLL is greater for the younger age group (152). These results indicate that a subgroup of younger patients have aggressive disease. In addition, the risk of a Richter transformation is fivefold higher in the younger age group (152). The male to female ratio for CLL is 2:1, and women are more likely to have early-stage disease. However, regardless of stage and age, women have a better prognosis than men (258).

Lymphocyte Characteristics

MORPHOLOGY Approximately 20% of patients have atypical CLL or CLL/PLL, and these patients have a more advanced stage, a higher proliferative index, and a poorer prognosis (101, 102, 113, 162). Moreover, these patients are also more likely to have trisomy 12 or deletion of 17p13 (p53 mutation), to be CD38 $^+$, and not to have mutations of the *IgV* gene (102, 113, 162). However, in a multivariate analysis, aberrant cell morphology was found to be an independent prognostic marker (259).
NUMBER Survival decreases with increasing lymphocyte count (260). The median survival is 8.6 years for a lymphocyte count =20 × 10^9/L and 3.7 years if the count is greater than 40 × 10^9/L.
DOUBLING TIME The lymphocyte doubling time is a useful measure of disease aggressiveness. Indolent CLL is associated with a slow lymphocyte doubling time, whereas patients with a lymphocyte doubling time of less than 12 months have a significantly worse survival rate (261, 262).
IMMUNE MARKERS Variations in immunophenotyping, such as an increase in surface Igs, FMC7 $^+$, and CD23 $^-$ or increased intensity of CD20, may be associated with atypical morphology, trisomy 12, and poor prognosis (101, 160, 161, 263). A number of studies have demonstrated the importance of CD38 $^+$ as a prognostic marker (Fig. 92.8) (29, 30 and 31, 84, 264, 265 and 266). Although Damle et al. (30) initially found a correlation between the presence of an *IgV* gene mutation and CD38 $^-$ (<30% CD38 $^+$ cells), this has not been confirmed by others (29, 31, 83). In all of these studies, CD38 $^+$ has been associated with shorter survival (29, 30 and 31, 84, 264, 265 and 266) and correlates with increasing Rai stage, intrathoracic and -abdominal lymphadenopathy, short doubling time, increased ß $_2$-microglobulin levels, and atypical morphology (Fig. 92.8) (264, 265 and 266). Moreover, the CD38 status is useful to predict which patients within a particular clinical stage will progress (265, 266).

When followed over time, CD38 $^{-}$ patients may become CD38 $^{+}$, and this is associated with deletion of 17p13 (p53 mutation) and disease progression ([266]).

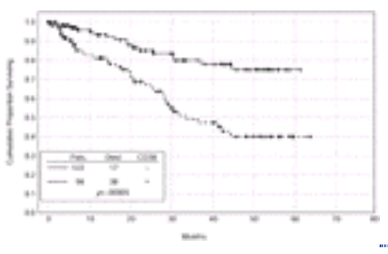

Figure 92.8. Survival according to CD38 status. Patients (Pats) with greater than 20% CD38 $^{+}$ chronic lymphocytic leukemia cells have a poorer survival than those with less than 20% CD38 $^{+}$ cells. (From Ibrahim S, Keating M, Do K-A, et al. CD38 expression as an important prognostic factor in B-cell chronic lymphocytic leukemia. Blood 2001;98:181–186, with permission.)

A low CD4/CD8 ratio and a decreased number of NK cells are observed in advanced disease and are associated with hypogammaglobulinemia ([267]). In addition, a low gammaglobulin level is associated with reduced survival ([268]).

MOLECULAR GENETICS AND CYTOGENETICS As discussed previously, chromosomal analysis provides prognostic information about overall survival (Fig. 92.2 and Fig. 92.6) ([91], [93], [96], [97], [98], [99] and [100]). Because of the difficulty in obtaining metaphases in CLL, interphase FISH has become the standard technique in staging this disease and provides important prognostic information (Fig. 92.6) ([29], [31], [79], [84], [91]). Patients with deletions of 17p13 (p53 mutations) or 11q22-11q23 have very poor prognosis ([29], [31], [79], [84], [266]). Patients with trisomy 12 have atypical morphology and immunophenotyping, advanced disease, and a poorer prognosis than those with normal molecular genetics or a deletion 13q14 ([79], [101]).

P53, ATAXIA TELANGIECTASIA MUTATION, RETINOBLASTOMA, AND P27 ^{Kip1} Status Mutations of p53 are present in 10 to 15% of patients and are predictive of resistance to chemotherapy, both *in vitro* ([269]) and *in vivo* ([79]). Mutations of p53 can be detected by a deletion of 17p13, as demonstrated by FISH, or by an increase in p53 protein, as assessed by immunohistochemistry ([78], [79], [113]). The abnormality is associated with aberrant cell morphology and very poor survival (Fig. 92.2 and Fig. 92.6). ATM and Rb protein levels are reduced in 34 and 42% of patients, respectively, and these patients have advanced stage disease and reduced survival ([83], [90]). Overexpression of p27 ^{Kip1} is associated with a short lymphocyte doubling time and poor survival ([91]).

SOMATIC HYPERMUTATIONS OF THE IMMUNOGLOBULIN GENE Approximately 50% of patients with CLL have somatic mutations of the *IgV* gene, and these patients have stable disease and normal cell morphology (Fig. 92.2) ([5], [6], [29], [30], [84]). In contrast, patients without *IgV* mutations are more likely to have atypical morphology, deletion of 11q23, advanced disease, and a poor prognosis ([29]). Whether patients without *IgV* mutations have an increased incidence of p53 mutations or trisomy 12 is controversial ([29], [31], [83]).

Marrow Histology

Nodular and interstitial growth patterns in the marrow are associated with similar marrow tumor burdens and median survival times of 90 and 46 months, respectively, whereas diffuse infiltration or a “packed marrow” is associated with a greater marrow tumor burden and a median survival time of only 28 months ([1], [157]). However, a more recent study has not shown that the pattern of marrow involvement adds additional information to staging alone ([270]). Fibrosis of the marrow also indicates an aggressive clinical course ([271]). There is more reproducibility in assessing the extent and type of marrow infiltration with the aspirate compared with the biopsy, but Montserrat et al. ([272]) only found that the biopsy provided useful prognostic information.

The pattern of marrow involvement after chemotherapy is also prognostically important. Patients with persistent lymphoid nodules in the marrow after chemotherapy [nodular partial remission (PR)] have persistent leukemia and have a shorter time to relapse compared to those in complete remission (CR) ([273]). However, the extent of involvement does not correlate with the rapidity of disease recurrence ([274]).

Serum Markers

Increased levels of the serum markers LDH ([31]), ß $_2$-microglobulin ([252], [264], [265], [275]), CD23 ([142], [167]), thymidine kinase ([276]), and TNF-a ([277]) can help identify patients who are at risk of disease progression. Serum LDH, ß $_2$-microglobulin, and CD23 levels presumably reflect tumor burden, whereas thymidine kinase is involved in the “salvage pathway” for DNA synthesis and reflects the number of dividing cells.

TREATMENT

In general, it is estimated that one-third of CLL patients never require therapy, one-third need treatment as soon as they are seen, and one-third have disease progression over the years and require therapy at some point ([257]). As all forms of treatment can carry some risk, it is important to ensure that the CLL patient really requires therapy before initiating treatment. Using the above prognostic indicators, it is possible to assess which patients do not require treatment. For example, patients with Binet stage A disease having a lymphocyte count of less than 30 × 10 ^{9}/L, a doubling time of more than 12 months, hemoglobin of more than 130 g/L, and a nondiffuse marrow morphology are classified as having “smoldering” CLL ([278], [279]). These patients have a life expectancy no different from that of the age- and sex-matched population and definitely do not require treatment ([278], [279] and [280]). In fact, premature treatment may actually cause harm. Thus, treatment of patients with Rai 0 or Binet A disease with chlorambucil may delay disease progression but does not improve survival and may increase the incidence of epithelial tumors and acute leukemia ([256]). Thus, treatment is reserved for patients with *low*- or *intermediate-risk* disease who are symptomatic or have progressive disease, as evidenced by increasing organomegaly or a lymphocyte doubling time of less than 12 months. Patients with *high-risk* disease are usually treated in an attempt to improve hemoglobin and platelet counts, although asymptomatic patients can be monitored and treatment initiated when there is clear evidence of disease progression. In addition, patients are usually treated if they have systemic symptoms, bulky lymphadenopathy or hepatosplenomegaly, autoimmune hemolytic anemia/thrombocytopenia, or a rapidly rising lymphocyte count.

Response Criteria

To facilitate comparisons of results obtained in clinical trials, the NCI-WG ([1]) has established criteria for complete and partial responses to therapy in CLL, and the details of these definitions are outlined in Table 92.8. A *CR* was defined as including the resolution of systemic symptoms, lymphadenopathy, and hepatosplenomegaly with the normalization of blood counts (hemoglobin, >110 g/L; neutrophils, >1.5 × 10 ^{9}/L; and platelets, >100 × 10 ^{9}/L). These criteria must be maintained for longer than 2 months, after which time a bone marrow aspiration and biopsy must contain less than 30% lymphocytes and no lymphoid nodules. In the original NCI-WG definitions and International Workshop, patients were considered to be in CR even if there were lymphoid nodules in the marrow, as these can occur normally ([281]). However, it was subsequently demonstrated that patients in CR achieved a shorter remission if there were nodules in the marrow, indicating that some of these nodules are malignant ([282]). Thus, patients with residual lymphoid nodules in the marrow are classified as *nodular PRs*. A *PR* includes a greater than 50% decrease in lymphocyte count and a greater than 50% reduction in lymphadenopathy, hepatosplenomegaly, or both, with normalization of the neutrophils, hemoglobin, and platelets ([1]). The use of more sophisticated techniques to confirm a CR, such as immunophenotyping, FISH, and assaying for clonal rearrangement of Ig genes, is being evaluated ([1], [282], [283]).

TABLE 92.8. Criteria for Clinical Response in Chronic Lymphocytic Leukemia

CR
No constitutional symptoms
No hepatosplenomegaly or lymphadenopathy by physical examination or radiography
Normal complete blood count (hemoglobin, >110g/L; neutrophils, >1.5 × 10 ^{9}/L; and platelets, 100 × 10 ^{9}/L)

The above should be maintained for 2 mo, after which a normal marrow aspirate and biopsy (normocellular, with no lymphoid nodules and <30% lymphocytes) should be documented. If marrow is hypocellular, a repeat examination should be carried out in 4 wk. If the marrow contains lymphoid nodules, then the patient is not in CR but is classified as “nodular PR.”

If the patient remains anemic or thrombocytopenic but is otherwise in CR, they are considered to be in PR.

PR

>50% decrease in peripheral blood lymphocyte count and >50% decrease in lymphadenopathy and/or splenomegaly (or hepatomegaly)

The above should be maintained for 2 mo in conjunction with one or more of the features below

Hemoglobin >100 g/L or >50% improvement from baseline

Neutrophils >1.5 × 10^9/L or >50% improvement from baseline

Platelets >100 × 10^9/L or >50% improvement from baseline

PD

>50% increase in the sum of the products of >two nodes on at least two determinations carried out 2 wk apart, and/or

>50% in liver and/or spleen size, and/or

>50% increase in lymphocyte count to at least 5 × 10^9/L, and/or

Transformation to a more aggressive histology

Stable disease

Patients who do not fit the criteria for CR, PR, or PD

CR, complete remission; PD, progressive disease; PR, partial remission.

Chemotherapy

ALKYLATING AGENTS The most commonly used treatment for CLL is the alkylating agent chlorambucil, which likely produces its antitumor effect by binding covalently with DNA, RNA, and cellular proteins ([284], [285]). Chlorambucil has been used in CLL for 50 years, but the interpretation of the early studies is difficult, as the strict criteria for the diagnosis of this disease and the definitions of response have only recently been formulated ([1], [281]). Chlorambucil is usually administered continuously in a daily dosage of 0.1 mg/kg or intermittently as 0.4 mg/kg every 2 weeks, and these treatment schedules have equivalent efficacy, although the intermittent route may produce less myelosuppression ([286], [287]). By the intermittent route, the dose is increased in increments of 0.1 mg/kg until the maximum tolerated dosage is reached (between 0.4 and 1.8 mg/kg). Overall, the response rate with these regimens is 40 to 60%, with 4 to 10% of patients achieving a CR ([217], [286], [287], [288] and [289]). Cyclophosphamide has also been used in the treatment of CLL and differs little, if at all, from chlorambucil in its effectiveness ([289]). Cyclophosphamide usually is given in a daily dose of 2 to 3 mg/kg or 20 mg/kg once every 2 to 3 weeks. To improve response rates, alkylating agents have been combined with steroids or other agents, or the dose of the alkylating agents has been increased. The monthly administration of chlorambucil with prednisone increased the response rate (47%) and survival compared to daily chlorambucil plus prednisone (response rate, 37%) or prednisone alone (response rate, 11%) ([286]). In one study, the frequency of response and the number of patients alive at 2 years were higher when chlorambucil (6 mg/day) was combined with prednisone (30 mg/day) for 6 weeks than when chlorambucil was used alone; however, no difference in median survival was demonstrated between the two groups ([291]). In practice, prednisone is frequently combined with chlorambucil to produce a more rapid decrease in lymph node and spleen size, and this is usually accompanied by an initial increase in the peripheral lymphocyte count. It has become clear that the response rate to chlorambucil is highly dependent on the dose of drug used ([290]). Jaksic et al. ([292], [293]) have demonstrated that the CR rate could be increased in CLL using high-dose chlorambucil, and with this regimen, the continuous route appeared to be preferable to the intermittent. Chlorambucil was administered as 15 mg/day until CR or toxicity or for a maximum period of 6 months in comparison to 75 mg weekly for 6 weeks; the CR rate for the continuous route was 70% compared with 31% for the intermittent route, and those patients receiving continuous chlorambucil had a longer survival ([292]). In a subsequent multicenter randomized study in untreated patients comparing the continuous regimen with modified CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), the CR rate with chlorambucil was 59.5% (CR and PR, 89.5%) ([293]). Nonrandomized studies initially reported excellent responses using intermittent cyclophosphamide, vincristine, and prednisone (COP) in patients with advanced CLL ([294], [295]), with approximately 44% of patients achieving a CR ([294]). However, a subsequent randomized study comparing COP to chlorambucil showed no difference in survival or disease progression at 9 ([296]) or 53 ([297]) months. When COP was compared with chlorambucil and prednisone therapy in untreated patients, the response and survival rates were identical ([298]). In a similar study, a significantly higher response rate was observed using COP (59%) compared to chlorambucil and prednisone (31%), but the CR and overall survival rates were similar for both groups ([299]). In other trials, the addition of low doses of doxorubicin to COP (CHOP) or CAP (cyclophosphamide, doxorubicin, and prednisone) or the use of multiple agents has been examined. The French Cooperative Group on CLL compared COP to CHOP in previously untreated patients with Binet stage C disease ([300], [301]). The 3-year survival rates were 28% with COP and 71% with CHOP, and the median survival times were 22 and 62 months, respectively ([301]). However, these results are controversial, as no survival advantage has been observed when CHOP is compared with standard chlorambucil and prednisone ([302], [303]). Indeed, higher doses of chlorambucil (15 mg/day continuously) produced a statistically higher response rate than CHOP (89.5% vs. 75.0%) and an improved survival (median, 68 months vs. 47 months) ([293]). Other combination regimens have been studied. Sixty-three patients with advanced or refractory disease were treated with the M2 program, consisting of cyclophosphamide, bischloroethylnitrosourea, melphalan, and prednisone, with a CR rate of only 17% and a PR rate of 44% ([304]). The median survivals were 47, 20, and 19 months for Rai stages II, III, and IV, respectively, which are not significantly different from survival rates achieved with less aggressive regimens. A CR rate of 30% was achieved with patients not previously treated ([304]). A combination protocol including prednisone, vincristine, cytosine arabinoside, cyclophosphamide, and doxorubicin (POACH) achieved response and survival rates not significantly different from those reported for chlorambucil and prednisone, with complete and overall response rates of 21 and 56%, respectively, for previously untreated patients and 6 and 21%, respectively, for previously treated patients ([305]). The Eastern Cooperative Oncology Group has examined VAD (vincristine, doxorubicin, and dexamethasone) in relapsed or refractory CLL ([306]). No CRs were observed, and although 21% had a PR, 33% had progressive disease. To determine whether aggressive multiagent therapy is better than standard chlorambucil (with or without prednisone) in CLL, a metaanalysis of ten randomized studies involving 2035 patients, mostly with Binet stage B and C disease, was carried out comparing standard treatment with COP, CHOP, and chlorambucil/epirubicin ([280]). This analysis did not reveal an improvement in survival by using an anthracycline-containing regimen compared to standard chlorambucil, demonstrating that more aggressive treatment approaches are not required to make an impact on survival.

NUCLEOSIDE ANALOGS The nucleoside analogs have demonstrated significant activity in the low-grade lymphoproliferative disorders (Fig. 92.9) ([307]). 2'-Deoxycoformycin (dCF; pentostatin; Nipent) is an inhibitor of adenosine deaminase, which is responsible for the deamination of deoxyadenosine and adenosine to deoxyinosine and inosine, respectively. After therapy with dCF, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyadenosine diphosphate, and dATP, and this occurs preferentially in lymphocytes ([308]). The intracerebral accumulation of deoxyadenosine and adenosine likely causes the nausea/vomiting that is a major toxicity with this agent ([309]). CdA (cladribine; Leustatin) and F-arabinosyladenine (F-ara-A) are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-adenosine monophosphate (fludarabine; Fludara); fludarabine is rapidly dephosphorylated in the plasma to F-ara-A ([310], [311]). Like deoxyadenosine, CdA and F-ara-A accumulate in lymphocytes as their phosphorylated derivatives and can kill lymphocytes in three ways (Fig. 92.10 and Fig. 92.11) ([46], [312]). First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome *c* from the mitochondria; the released cytochrome *c* interacts with Apaf-1 and dATP causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of the triphosphates can enhance the effects of endogenous dATP on the apotosome, inducing apoptosis. Finally, CdA differs from the other two drugs in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to CdATP, which is directly toxic to the mitochondria.

(From Genini D, Adachi S, Chao Q, et al. Deoxyadenosine analogs induce programmed cell death in chronic lymphocytic leukemia cells by damaging the DNA and by directly affecting the mitochondria. Blood 2000;96:3537–3543, with permission.)

Although dCF has demonstrated remarkable activity in hairy cell leukemia, producing CR in more than 90% of patients ([307]), it is much less impressive in CLL. CR and PR rates of 16 to 25% have been noted in previously treated patients, with an additional 20 to 30% of patients exhibiting other forms of clinical improvement ([313], [314]). The standard dose is 4 mg/m ^{2} intravenously (IV) every other week ([307], [314]). Toxicities include infection, myelosuppression, nausea/vomiting, and pruritus. Fludarabine has demonstrated significant activity in CLL. Although usually administered IV, the drug appears equally efficacious when administered orally, although a higher dose is required as absorption is approximately 50% ([315]). Using 25 to 30 mg/m ^{2} IV daily for 5 days, repeated monthly, the overall response rate is approximately 45% in previously treated patients, with the CR rate being 3 to 20% ([315], [316], [317] and [318]). In untreated patients, the response rate is approximately 70%, with the CR rate being 20 to 40% ([217], [218], [318], [319]). The main toxicities with fludarabine are myelosuppression and infections, particularly when patients have been previously treated with alkylating agents. Nausea, vomiting, and neuropathy rarely occur. In an attempt to reduce toxicity, fludarabine has been administered as 30 mg/m ^{2} IV daily for 3 days, repeated every 4 weeks ([320]). Compared to the standard 5-day treatment schedule, the response rate was lower at 46% (CR, 10%), but there was a significant reduction in the infection rate and no difference in survival. The addition of prednisone to fludarabine therapy does not improve the response rate over fludarabine used alone and significantly increases the risk of unusual infections (i.e., *Pneumocystis carinii* pneumonia and *Listeria monocytogenes* sepsis) ([321]). Three major phase III studies have determined whether initial treatment with fludarabine could produce an increased remission rate compared with standard chemotherapy and whether this would translate into improved survival (Table 92.9) ([217], [218], [318]). These are summarized as follows:

TABLE 92.9. Phase III Studies Comparing Fludarabine and 2-Chlorodeoxyadenosine to Alkylating Agents

Reference	Treatment	Patients (No.)	Complete Remission (%)	Partial Remission (%)	Median Response (Mo)	Median Survival (Mo)
European Cooperative Group (318)	Fludarabine	52	23	48	Not reached	Not reached
	CAP	48	17	43	208 d	1580 d
French Cooperative Group (218)	Fludarabine	341	40 [a]	31	32.0	69
	CAP	240	15 [a]	43	28.0	70
	CHOP	357	30 [a]	42	29.5	67
InterGroup (217)	Fludarabine	170	20	43	25.0	66
	Chlorambucil	181	4	33	14.0	56
	Fludarabine/Chlorambucil	123	20	41	Not reached	55
Polish group (288)	2-Chlorodeoxyadenosine	126	47	40	21.0	78% [b]
	Chlorambucil	103	12	45	18.0	82% [b]

CAP, cyclophosphamide, doxorubicin, and prednisone; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone.

[a] Actually denoted as *clinical remissions* as marrow studies were not carried out on many after therapy.

[b] At 24 mo.

- The European Cooperative Group study on CLL has compared six courses of fludarabine with CAP in 100 untreated and 96 treated patients with Binet B or C CLL ([318]). In untreated patients, the responses with fludarabine (71%; CR, 23%) were similar to those for CAP (60%; CR, 17%), but the duration of responses was significantly longer with fludarabine. Although there was a tendency toward a longer survival of patients treated with fludarabine, the follow-up period has

been too short to confirm this. In previously treated patients, a higher response rate was observed with fludarabine (48%; CR, 13%) compared to CAP (27%; CR, 6%), but there was no improvement in the median remission duration or survival between the two groups.

- In a French Cooperative Group study ([218]), 938 untreated CLL patients with Binet stage B or C disease were randomized to a 6-month course of CHOP, CAP, or fludarabine ([218]). The response rates were similar for CHOP and fludarabine, and both were better than those for CAP. However, time to relapse and survival rates were similar regardless of initial treatment.
- Finally, in a North American Inter-Group study ([217]), 509 untreated CLL patients were randomized to receive fludarabine (25 mg/m ^{2} IV daily × 5 days, repeated every 28 days), chlorambucil (40 mg/m ^{2} orally every 28 days), or a combination of fludarabine (20 mg/m ^{2} IV daily × 5 days, every 28 days) with chlorambucil (20 mg/m ^{2} orally every 28 days). Treatment was continued for a maximum of 12 months and was discontinued if a patient achieved a CR or if response plateaued for 2 months. Nonresponding patients receiving fludarabine or chlorambucil were switched to the other drug; patients off therapy who relapsed more than 6 months after discontinuation of treatment were started back on the same drug, whereas those who relapsed less than 6 months after discontinuation of drug were switched to the other drug. Accrual to the combination of fludarabine plus chlorambucil was discontinued when it was found that this arm was more myelotoxic and produced a similar response rate to the fludarabine only arm. There was a higher response rate, longer duration of response, and improved progression-free survival in patients treated with fludarabine. The CR and PR rates with fludarabine were 20 and 43%, respectively, whereas the corresponding responses with chlorambucil were 4 and 33%. The median remission for fludarabine was 25 months, and for chlorambucil, it was significantly shorter at 14 months (Fig. 92.12A). For patients previously treated with chlorambucil, the response rate to subsequent fludarabine was 46%. In contrast, only 7% of patients who had become resistant to fludarabine responded to chlorambucil. However, regardless of which drug was used first, there was no significant difference in survival (Fig. 92.12B).

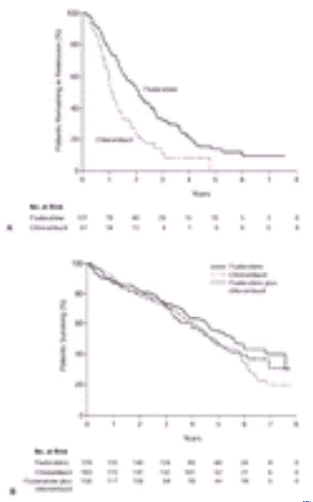

Figure 92.12. A: Proportion of patients with an initial response to fludarabine or chlorambucil who continued in remission. Shown are the proportions of 107 patients assigned to fludarabine and 67 assigned to chlorambucil who had a response to treatment and remained in complete or partial remission. In both groups combined, 78% of patients (135 of 174) had relapses. The median duration of the response was significantly longer in the fludarabine group than in the chlorambucil group (25 vs. 14 months, p <.001). **B:** Survival according to treatment group. Shown are the proportions of 178 patients assigned to fludarabine, 193 assigned to chlorambucil, and 136 assigned to fludarabine plus chlorambucil who were still alive during follow-up. Forty-seven percent, 57%, and 56% of the patients in the three groups, respectively, died. There was no statistically significant difference in overall survival among the three groups (median, 66 months, 56 months, and 55 months, respectively; p = .21). (From Rai KR, Pererson BL, Appelbaum FR, et al. Fludarabine compared with chlorambucil as primary therapy for chronic lymphocytic leukemia. N Engl J Med 2000;343:1750–1757, with permission.)

CdA has been less extensively evaluated in CLL than fludarabine but probably has equivalent antitumor activity ([288] , [307] , [322] , [323] , [324] , [325] , [326] and [327]). The drug is given in monthly cycles, in doses of 0.1 mg CdA/kg/day by continuous infusion × 7 days ([324]), or 0.12–0.14 mg/kg/day over 2 hours × 5 days ([322] , [325]), or 10 mg/m ^{2}/day orally × 5 days ([327]). The results of studies with CdA have varied greatly ([288] , [322] , [323] , [325]), with response rates in previously treated patients varying from 48 to 72% and CR rates varying from 4 to 39% ([307] , [322]). In previously untreated patients, approximately 80% of patients respond, and the CR rate varies from 10 to 45% ([288] , [307] , [322] , [323] , [324] , [325] and [326]). In a multicenter study with patients randomized to receive initially either CdA or chlorambucil, and resistant patients being switched to the other drug, CdA produced a higher remission rate and more prolonged remissions than chlorambucil (Table 92.9) ([288]). However, as with the randomized studies comparing fludarabine with alkylating agents ([217] , [218] , [318]), survival was similar whether the initial treatment was with CdA or chlorambucil ([288]). The variation in the response rates to CdA in previously treated patients may be related to the extent of prior therapy. *In vitro* studies have shown that CdA is more myelosuppressive than fludarabine ([310]), and in the clinical setting, repeated treatments with CdA can produce prolonged thrombocytopenia ([288] , [322] , [323] , [324] , [325] , [326] and [327]). Like fludarabine, CdA is very immunosuppressive, and infections are the major toxicity, particularly when given in conjunction with prednisone ([184] , [288] , [326]). Neither CdA nor fludarabine causes the accumulation of adenosine, which likely explains the lack of nausea/vomiting observed with these agents when compared to dCF. However, all these nucleoside analogs can produce neurotoxicity, and peripheral neuropathy is now being documented as a potential devastating toxicity of these drugs ([328]). The nucleoside analogs are all highly immunosuppressive, being both myelosuppressive and producing a marked fall in the CD4 $^+$ cell count, which may persist for years ([307]). As these agents are now frequently combined with other immunosuppressive agents, such as monoclonal antibodies (see below), the number and variety of opportunistic infections observed in CLL are likely to increase ([184]). Although initial studies suggested that the nucleoside analogs could trigger autoimmune hemolytic anemias, the frequency of this complication appears no greater with the analogs than with other agents ([217] , [218] , [288]). Graft-versus-host disease has been observed in patients being treated with nucleoside analogs who receive blood transfusions, and it has been recommended that these patients receive only irradiated blood products ([329]). Reports have also indicated a higher incidence of acute myeloid leukemia/myelodysplasia in patients receiving nucleoside analogs ([330] , [331] and [332]), and this risk may be further increased in patients receiving a combination of chlorambucil and fludarabine ([332]). Recent studies have demonstrated that fludarabine can be toxic to the lung, apart from predisposing these patients to pneumonia ([333]). Once infections have been ruled out, these patients can respond to steroids ([333]). An *in vitro* study has demonstrated cross-resistance between fludarabine and CdA in the leukemic cells of 90% of patients ([310]), and clinical studies have confirmed that patients resistant to fludarabine are unlikely to respond to CdA, and vice versa ([326] , [334]). In a clinical trial of 28 patients who were resistant to fludarabine, only one patient had a PR with CdA ([334]). Thus, patients who are resistant to one of the nucleoside analogs should not be treated with another, particularly as such therapy increases the risk of infections secondary to myelosuppression and immunosuppression ([334]).

COMBINATION THERAPY WITH NUCLEOSIDE ANALOGS As the nucleoside analogs alone do not increase survival in CLL, these drugs have been combined with other agents in an attempt to improve antitumor activity. Combined therapy with steroids does not improve antitumor effect and markedly increases the risk of infection ([321] , [325]). However, the initial addition of steroids may be useful in selected patients to produce more rapid marrow clearing and to improve blood counts ([290]). *In vitro* studies have demonstrated that the nucleoside analogs can inhibit DNA repair, which explains the synergistic antitumor activity seen between these agents and irradiation and alkylating agents ([335] , [336] and [337]). Moreover, this effect is seen preferentially in CLL cells compared to normal marrow cells ([336]). Synergy has also been observed between fludarabine and cyclophosphamide in phase II clinical studies ([337] , [338] and [339]). O'Brien et al. ([338]) combined fludarabine 30 mg/m ^{2} IV daily × 3 with cyclophosphamide 300, 350, or 500 mg/m ^{2} IV daily × 3 and demonstrated a 38% response rate in patients who were resistant to fludarabine alone. In previously untreated patients, more than 80% responded with a 35% CR. Moreover, the durations of response were longer than for fludarabine alone. Similar responses have been seen with other combinations of fludarabine and cyclophosphamide ([338] , [339] and [340]), and these promising combinations are now being evaluated in phase III clinical trials. However, myelosuppression remains a significant problem, and there is concern that the combinations may be leukemogenic, as may be the case when fludarabine and chlorambucil are combined ([332]). There is thus considerable interest in combining monoclonal antibodies with the nucleoside analogs, regimens that theoretically should enhance antitumor activity without affecting the marrow (see Monoclonal Antibodies).

STEROIDS As steroids kill CLL cells with a p53 mutation ([63]), they can be useful for palliation in patients resistant to alkylating agents and nucleoside analogs ([290] , [341]). A frequent starting dose is 50 or 100 mg prednisone/day to control symptoms and then maintaining the patient on alternate-day prednisone or gradually tapering the dose according to response. Methylprednisolone at 1 gm/m ^{2}/day × 5 days, repeated monthly, can be helpful in end-stage patients, who are drug resistant and have bulky disease, marrow failure, or both ([341]). These patients are at risk of all the complications of steroids. The management of CLL patients maintained on steroids is discussed in Systemic Complications Requiring Therapy.

Monoclonal Antibodies

The chimeric monoclonal antibody rituximab (Rituxan) contains a human IgG1 immunoglobulin constant region and a murine variable region directed against the

cell-surface antigen CD20, which plays an important role in the activation, proliferation, and differentiation of B cells ([342]). This agent has shown significant activity against low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity through activation of complement (complement-mediated cytotoxicity), antibody-dependent cell-mediated cytotoxicity, or by the direct induction of apoptosis ([342] , [343] and [344]). Each of these mechanisms likely plays a role, and in the blood, target cells may be lysed by high concentrations of complement (complement-mediated cytotoxicity mechanism), whereas circulating cells coated with Ig can be removed by Fc receptor–containing effector cells, such as NK cells, monocytes, and macrophages (antibody-dependent cell-mediated cytotoxicity mechanism) ([342]).

Using the standard rituximab regimen that is effective in follicular lymphomas (375 mg/m ^{2} IV weekly × 4), initial studies showed that rituximab had little activity in CLL (13% response rate), compared to a 50% response rate in the follicular lymphomas ([345]). This decreased activity was attributed to the low levels of CD20 on CLL cells and the high plasma CD20 levels observed in CLL; the high plasma CD20 levels are believed to divert rituximab from the cellular target and to reduce the half-life of the antibody ([342] , [346]). The plasma CD20 is believed to be derived from cell breakdown, and the level correlates with disease stage but not the lymphocyte count ([346]). However, two more recent studies have shown that rituximab can rapidly, albeit transiently, reduce the peripheral lymphocyte counts of CLL patients ([347] , [348]). The treatment had little effect on lymphadenopathy and did not normalize blood counts, and this discrepancy has been related to the fact that the CLL CD20 levels are lower in the nodes and marrow than in the peripheral blood ([349]). In an attempt to increase the effectiveness of rituximab in CLL, the dose of rituximab has been escalated, using either a weekly or thrice weekly schedule, and response rates of 36 to 45% have been achieved without a significantly higher toxicity than is observed with the standard schedule ([350] , [351]). Rituximab can cause allergic reactions (e.g., fevers/rigors, dyspnea, hypotension, and nausea/vomiting) as a result of the release of inflammatory cytokines (e.g., IL-6, IL-8, TNF-a, and ?-interferon) ([347] , [348] , [350] , [351]). This usually occurs with the first treatment, and the likelihood of a reaction decreases with each subsequent treatment. Initial studies suggested that this complication occurred in patients with lymphocyte counts of greater than 50 × 10 ^{9}/L ([347] , [348]), although this was not confirmed in a more recent study ([351]). Pretreatment with prednisone or “stepped-up dosing” decreases the severity or likelihood of a reaction ([348]).

Alemtuzumab (Campath-1H) is a humanized IgG1 antibody against CD52, with the antigen-binding site being of rodent origin. Both B and T lymphocytes are targets, and there is sparing of the normal hematopoietic stem cells. As with rituximab, alemtuzumab can kill tumor cells by complement-mediated cytotoxicity, antibody-dependent cell-mediated cytotoxicity, or the direct induction of apoptosis ([352]). Patients with CLL who were resistant to standard chemotherapy have received alemtuzumab 30 mg IV three times per week for 12 to 16 weeks, and the response rate was 33 to 53%, with most responses being PRs ([352] , [353] , [354] and [355]). Patients had infusion-related toxicities (i.e., nausea/vomiting, fevers, rigors, and rash) with the initiation of treatment and infections. Despite antibiotic therapy, infections, including opportunistic infections (most frequently cytomegalovirus), occurred later. Alemtuzumab has also been evaluated in untreated patients using the subcutaneous route, with the dose of alemtuzumab gradually increased to 30 mg three times per week for a maximum of 18 weeks ([356]). Of 41 patients, 38 received more than 1 week of treatment, and in this group, the CR rate was 19% and the PR rate 68%. Ninety percent of patients had local injection-site reactions, with erythema/edema, pruritus, and pain at the site of injection. In most cases, the reactions disappeared with continued treatments, usually within 2 weeks. However, the infusion-related toxicities described above with intravenous treatments were rarely seen. Infectious problems were much less severe than observed in previously treated patients.

There is interest in combining the monoclonal antibodies with chemotherapy to enhance antitumor activity without increasing myelosuppression. Moreover, as rituximab is effective for the treatment of autoimmune hemolytic anemia in CLL ([357]), the addition of rituximab might prevent the development of this complication, which can occur with chemotherapy ([208] , [209] and [210] , [216]). Synergy has been demonstrated between rituximab and chemotherapy *in vitro*, although the mechanisms underlying this phenomenon are unclear ([343] , [358] , [359] , [360] and [361]). However, the synergy may be related to effects of rituximab on the levels of antiapoptotic proteins, as rituximab reduces the cellular levels of bcl-2 in lymphoma cell lines *in vitro* ([358]), and the levels of Mcl-1 and XIAP are decreased in the CLL cells of patients undergoing treatment with the antibody ([343]). Alternatively, fludarabine may down-regulate the expressions of CD46, CD55, and CD59 on the CLL cells, proteins that antagonize the effects of activated complement ([362] , [363]).

Rituximab has been combined with fludarabine in the clinic ([362] , [363]). In one study, 31 previously treated or untreated CLL patients received four monthly cycles of fludarabine (25 mg/m ^{2} IV daily × 5 days) combined with four monthly treatments with rituximab (375 mg/m ^{2} IV), the first two rituximab treatments given with the last two cycles of fludarabine ([362]). The CR rate was 33%, the PR rate was 55%, and treatment was well tolerated. A second study compared concurrent versus sequential treatment with fludarabine and rituximab in untreated CLL patients ([363]). Fifty-one patients received six cycles of fludarabine followed by four weekly treatments with rituximab (sequential regimen), while 53 patients received six cycles of concurrent fludarabine and rituximab followed by consolidation with four weekly treatments with rituximab. In the concurrent regimen, there were 47% CR rates and 43% PR rates, whereas the sequential regimen appeared less effective with 28% CR and 49% PR. Treatment was generally well tolerated; infusion-related toxicity, myelosuppression, and infections were the major toxicities. The M. D. Anderson Cancer Center has combined fludarabine with cyclophosphamide and rituximab, and preliminary results on 60 patients showed a response rate of 95% with 66% CR ([364]). It is interesting that responses have been observed on combining fludarabine with alemtuzumab in six CLL patients treated previously with either fludarabine or alemtuzumab alone, suggesting that the combination might reverse drug resistance ([365]).

Bone Marrow Transplantation

As CLL is not curable with standard therapy, there has been interest in bone marrow transplantation (BMT) in this disease, particularly in younger patients who are more able to withstand aggressive treatment. In addition, recent advances in the identification of biologic risk factors indicative of aggressive disease (i.e., those with unmutated *IgV* genes and those with deletions of 11q22-23 or 17p13) have permitted the recognition of patients who have a very poor prognosis with standard therapy and might benefit from BMT. As genomic abnormalities are known to develop over time in CLL, it would appear most reasonable to consider early transplantation in these patients before the development of drug resistance and more aggressive disease. However, this is a relatively recent treatment modality in CLL, and many of the studies are still only reported in abstract form. Several excellent reviews have been published on the subject ([366] , [367]).

Autologous BMT is an attractive option in CLL, as the mortality of this procedure is low and prolonged remissions may be obtained. However, at the present time, this is not a curative procedure, and there is no plateau in the survival curves of patients receiving this treatment ([366] , [367]). An update of patients followed by the European Group for Blood and Marrow Transplantation (EBMT) register showed that treatment-related mortality is 11% and that 79% of patients will be alive at 3 years, although 41% will relapse during this time ([368]). The prognosis is better for patients who are transplanted early in the course of their disease, have chemosensitive disease (as assessed by a CR before transplant), and receive total body irradiation (TBI) with the transplant ([368] , [369]). The risk of relapse correlates with the persistence of minimal residual disease ([283] , [370] , [371]). All these factors suggest that optimum CRs before transplantation and the purging of the harvested stem cells improve outcome. The optimum therapy before transplant is still unknown, and although fludarabine is highly effective in CLL, it is myelotoxic, and this may make it difficult to harvest marrow subsequently ([372]). However, as most patients receiving fludarabine before transplant have also received other drugs, it is unclear how much of the marrow toxicity can be attributed to fludarabine. Indeed, a recent study using fludarabine/cyclophosphamide in previously untreated patients showed that there was no difficulty in harvesting cells after treatment ([339]). Regardless, it has been suggested that harvesting should only be attempted more than 2 months after the last fludarabine treatment ([372]).

The monoclonal antibodies may also be useful before transplant, as they produce synergistic antitumor activity with chemotherapy, may reverse drug resistance, and are not myelotoxic. Rituximab has been combined with fludarabine/cyclophosphamide for this purpose, and alemtuzumab has been used to produce further marrow clearing after a maximum response to fludarabine or dCF ([364] , [373]). Elimination of tumor from the marrow harvests has also been carried out by “double purging” (i.e., CD19 depleting and CD34 enriching) ([374]). However, although remissions were prolonged, there was an increased risk of life-threatening infections. Although the morbidity and mortality associated with autologous BMT are relatively low, these patients have an increased risk of acute myeloid leukemia/myelodysplasia and second tumors ([366]). The cumulative incidence of acute myeloid leukemia/myelo-dysplasia for CLL patients 5 years post-autologous BMT is 6%, similar to that observed with autologous BMT in other lymphomas ([366] , [375]).

Whereas autologous BMT is basically high-intensity chemotherapy, allogeneic BMT has the added advantage of cellular immune therapy, which explains the higher efficacy of this treatment, albeit at the cost of toxicity ([376] , [377] , [378] , [379] , [380] and [381]). Of 90 patients in the EBMT registry who have undergone allogeneic BMT for CLL and are evaluable for response, 40% died from causes related to the transplant, and at 3 years, 55% were alive, with the risk of relapse by that time being 25% ([368]). As with autologous BMT, patients do better if the transplant occurs soon after diagnosis. However, in contrast to autologous BMT, the outcome is less dependent on the sensitivity of the tumor to chemotherapy, and the survival curve plateaus posttransplant, suggesting that long-term survival might be possible ([379] , [380]). The

difference in responses with these two types of BMT is related to the graft-versus-leukemia effect, as the CLL cells disappear with the onset of graft-versus-host disease ([382], [383] and [384]). Patients transplanted with marrow from unrelated donors also have significant graft-versus-host disease, and out of 33 evaluable patients in one study, 64% achieved a CR and 15% a PR ([381]). The 3-year disease-free survival was 44%. However, the mortality of this procedure can be as high as 50%, in part related to the immune incompetence of these patients.

The demonstrated graft-versus-tumor effect associated with allogeneic transplantation has raised interest in nonmyeloablative transplantation in CLL ([385], [386]). The advantage of this approach is that end-organ damage and the profound pancytopenia and infections associated with intense induction chemotherapy are avoided, while the beneficial graft-versus-tumor effects are retained ([385]). McSweeney et al. ([385]) carried out nonmyeloablative BMT in 45 patients with a variety of hematologic malignancies, including seven patients with CLL. Patients received TBI followed by cyclosporin and mycophenolate mofetil to prevent host-versus-graft and graft-versus-host diseases. Donor lymphocyte infusions were given at 2-month intervals, depending on the absence of graft-versus-host disease, persistence of chimerism, and either persistent or progressive disease. Of the seven CLL patients, four achieved a CR, one a PR, and two had progressive disease. The treatment was relatively well tolerated, and half of all patients received their entire treatments as outpatients. However, acute graft-versus-host disease occurred in one-half of the patients, grade II in 36%, and grade III in 11%. Rejection occurred in 20% of patients, and as this developed primarily in patients who had not received prior intensive chemotherapy, the authors added fludarabine as part of the preparative regimen. It is interesting that molecular remissions occurred while patients were receiving immunosuppression to control their graft-versus-host disease, indicating the potency of the graft-versus-tumor effect. Of 63 patients followed by the EBMT, mortality related to the procedure was 19%, and with a median follow-up of 8 months, overall survival was 80% with the probability of relapse being 16% ([386]).

Radiotherapy

As there are now a variety of treatment options for CLL, there is little need for radiotherapy as primary treatment for this disease. However, for many decades, irradiation of the spleen was the primary treatment for CLL ([387], [388], [389], [390], [391], [392] and [393]); irradiation of the mediastinum ([394], [395]), extracorporeal irradiation of the blood ([396], [397]), TBI ([398], [399], [400], [401] and [402]), and hemibody body irradiation ([403]) may also reduce the peripheral blood lymphocyte counts and the size of lymph nodes, spleen, and liver.

Splenic irradiation has produced survival rates comparable to those achieved with chlorambucil or COP in Rai stage III and IV patients ([390]). However, in general, splenic irradiation is reserved to treat patients with large painful spleens or those with cytopenias related to splenomegaly who are not medically fit for splenectomy. Although almost all patients experience a reduction in spleen size and relief from pain with irradiation, the effects on hemoglobin and platelets are more variable ([389], [391]). It is likely that differences in therapeutic effect are related to the extent of prior treatments, as untreated patients respond much better to irradiation than those who have previously undergone therapy ([387]). High doses of splenic irradiation may cause neutropenia and thrombocytopenia, and it is thus recommended to initially use small fraction sizes (e.g., 0.25 to 0.50 Gy on alternate days, for three times per week) ([387], [389]). The dose of irradiation is gradually increased according to response and toxicity, and the usual maximum dose is between 5 and 10 Gy.

TBI has been given alone ([398], [399] and [400]) or in combination with chemotherapy ([401], [402]). Patients treated with TBI plus cyclophosphamide and prednisone had higher response rates than those treated with TBI alone ([401]). Intermittent low doses of irradiation may also be effective ([397], [400]). In one study, 48 patients with progressive disease received 5- to 10-rad TBI three to five times per week for a total of 100 to 400 rad ([399]). Eighty-eight percent of the patients responded, with one-third achieving a CR, although mild anemia and thrombocytopenia persisted in some individuals. The regimen was generally well tolerated, although significant myelosuppression occurred, and rest periods of weeks to months were intermittently required to allow marrow recovery. The Ig levels returned to normal in most of the patients who achieved a CR.

Splenic irradiation can produce systemic effects with a decrease in lymphadenopathy and a reduction in lymphocyte count and can induce CRs ([387], [393]). The mechanism(s) underlying these phenomena is unclear, and many factors may be involved ([387]). CLL cells are highly sensitive to ionizing radiation *in vitro*, and a correlation has been observed between the radiosensitivity of CLL cells *in vitro* and the patients' clinical response to radiation therapy ([404]). However, irradiation may also produce its effects through the inhibition of $CD8^+$ T cells and the induction of cytokine release from CLL cells ([387], [405]). Finally, radiation of the spleen can produce a “radiotherapeutic splenectomy,” thus decreasing “pooling” and improving normal blood counts.

Splenectomy

Splenectomy is primarily carried out in CLL for the treatment of autoimmune hemolytic anemia or thrombocytopenia but may also be useful for patients with painful splenomegaly or in whom the leukemia is predominantly confined to the spleen ([406], [407], [408] and [409]). In addition, splenectomy may be considered when cytopenias are believed to be due to hypersplenism and have not responded to chemotherapy ([406], [407], [408] and [409]). Neal et al. ([409]) noted an improvement in the hemoglobin and platelet counts in two-thirds of patients with advanced-stage CLL who underwent splenectomy, and the improvement was maintained during the 1-year follow-up. In this study, neither the spleen size nor the degree of marrow involvement was predictive of response, although others have observed a correlation between spleen size and the improvement in blood counts after splenectomy ([406]). Approximately 50% of patients have postoperative infections, and half of these require antibiotics ([406]). Moreover, the perioperative mortality from sepsis is 5 to 10%, and this is primarily in patients with advanced disease and poor performance status ([406]). Thus, in selected patients with good performance status, splenectomy may increase the blood counts sufficiently to permit aggressive chemotherapy.

Biologic Response Modifiers

a-Interferon can decrease the lymphocyte count and produce PRs in patients with early-stage CLL ([410], [411]). However, a-interferon is less active against early-stage disease having features of an aggressive course, and it does not prolong progression-free survival or overall survival ([412]). Furthermore, a-interferon is ineffective in patients with advanced disease who have received prior therapy ([413]). a-Interferon has been evaluated as maintenance therapy in patients after treatment with chlorambucil ([414]) or fludarabine ([415], [416]). However, a-interferon did not influence residual disease after fludarabine and did not increase the duration of remission ([415], [416]).

Systemic Complications Requiring Therapy

Patients with CLL have an increased risk of infection, which is partly related to the effects of the disease and partly to the effects of chemotherapy. CLL can cause hypogammaglobulinemia, neutropenia, hypocomplementemia, and T-cell dysfunction, and the incidence of infections increases with disease stage and the degree of hypogammaglobulinemia ([184], [417], [418]). However, risk of infections, particularly opportunistic infections, is increased with the use of steroids, reduction in $CD4^+$ cells by nucleoside analogs, and lymphocytolytic effects of monoclonal antibodies ([185], [186], [321]). In general, vaccines are ineffective because of an impairment in the immune system ([183]).

High-dose Ig, administered as 400 mg/kg IV every 3 weeks, reduces the incidence of bacterial infections by 50%, particularly those caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*, but the total number of severe bacterial infections and nonbacterial infections is not reduced, and this treatment does not prolong survival ([419]). A subsequent study using this regimen showed that the reduction in infections did not improve the patients' quality of life or survival and that the treatment was not cost effective, in part because of the high doses of Ig infused ([420]).

More recently, it has been shown that lower doses of gammaglobulin may be as effective, for instance, 250 mg/kg every 4 weeks or 10 g every 3 weeks ([421], [422]). Molica et al. ([423]) randomized CLL patients with an IgG of less than 0.6 g/L and a serious infection in the previous 6 months to 300 mg/kg gammaglobulin every 4 weeks or to observation. Patients receiving gammaglobulin had a reduced number of infections, but the effectiveness did not correlate with restoration of the IgG levels. Thus, selected patients with hypogammaglobulinemia and frequent bacterial infections may benefit from prophylactic Ig, although the cost benefit of this treatment is questionable.

Granulocyte-macrophage colony-stimulating factor can increase the neutrophil count and function in CLL, although whether this reduces the incidence of infections remains unclear ([424], [425]). However, the use of granulocyte colony-stimulating factor after fludarabine has been shown to reduce the risk of neutropenia and the incidence of pneumonia ([426]). Prophylactic antibiotics may be of benefit, particularly when patients are receiving nucleoside analogs, monoclonal antibodies, and

steroids, and frequently, antibiotics are incorporated into the newer and more immunosuppressive regimens. Thus, patients may be maintained on trimethoprim-sulfamethoxazole to prevent *P. carinii* pneumonia, acyclovir to prevent herpes simplex, and fluconazole to prevent candidal infections.

Autoimmune hemolytic anemia occurs in 5 to 37% of patients, autoimmune thrombocytopenia in 1 to 3% of patients, and pure red cell aplasia is less frequent ([208], [209]). These disorders usually occur late in the disease and may be provoked by chemotherapy, which can cause an imbalance in the lymphocyte subtypes, allowing emergence of an antibody-producing B-cell clone ([208], [209]). Although pure red cell aplasia is rare in CLL, it may well be underreported, as there are usually other causes to explain the anemia, but the diagnosis should be considered in any patient who has a disproportionate anemia compared to the other blood counts ([209]). These immune disorders are generally treated initially with steroids, using prednisone 1 mg/kg/day, and 75% of patients respond to this therapy ([208]). A response may be seen within days, although it may take several weeks in some patients. Patients with hemolytic anemia should also be maintained on folic acid, 5 mg/day, and after the hemoglobin and reticulocyte counts have normalized (usually in 1 to 2 weeks), the prednisone can be tapered slowly over a period of 2 to 3 months. These patients should be watched for all the usual complications of prednisone, such as gastric irritation, diabetes mellitus, an increased risk of opportunistic infections, and osteoporosis. Thus, these patients may need to be maintained on an H_2-blocker, may require oral hypoglycemics/insulin, and should be maintained on prophylaxis against *P. carinii* [e.g., trimethoprim-sulfamethoxazole (one double-strength tablet orally twice a day on Saturdays and Sundays, or one double-strength tablet three times a week)] ([427]). They are also at risk of other infections, such as oral thrush or herpetic infections and may require therapy or prophylactic antibiotics. Many of these patients are elderly, and the prolonged course of prednisone increases the risk of osteoporosis and vertebral collapse. Thus, patients should be maintained on bisphosphonates. The author prefers an intravenous formulation to reduce the risk of gastric irritation, which may already be a problem because of prednisone (e.g., pamidro-nate 30 mg IV every 3 months) ([428]). It is important that patients with autoimmune hemolytic anemia and dangerously low hemoglobins are transfused, because, despite theoretical concerns, these patients rarely have severe transfusion reactions ([429]). In addition, any infection should be treated promptly, as sepsis can inhibit compensatory reticulocytosis and worsen anemia.

If the patient does not respond to prednisone within 7 to 10 days, intravenous Ig 0.4 g/kg/day × 5 days should be added ([209]). This can produce a rapid response, but the response is transient, and retreatments are generally required every 3 to 4 weeks ([209], [430]). There is no standard therapy for patients who do not respond to this therapy or who cannot be weaned off prednisone without a relapse. Cyclosporin is a reasonable option and produces a major response in two-thirds of CLL patients with immune thrombocytopenia or anemia and is highly effective in red cell aplasia ([208], [431], [432] and [433]). In one study using cyclosporin 300 mg/day, the median time to initial response was 3 weeks (range, 1 to 13 weeks), and the median time to best response was 10.5 weeks (range, 1 to 48 weeks) ([433]). The median duration of response was 10 months (1+ to 39+ months), and some patients who had fludarabine-associated cytopenias were retreated effectively with fludarabine. Immune cytopenias also may be treated with other immunosuppressive drugs, such as 6-mercaptopurine or cyclophosphamide, although no controlled trials related to their use have been published ([209]).

Splenectomy may also be considered, although this is rarely carried out, as most patients with CLL are elderly and there is significant risk with this surgery, particularly in patients who are actively hemolyzing and are on steroids. Of 113 patients who underwent a splenectomy for immune hemolytic anemias, only four had underlying CLL ([434]). Thus, there is little information as to the benefit of this procedure in CLL or the long-term response rate. Splenic irradiation may be carried out in those who are not surgical candidates, but it may take up to 2 months to see a response; the responses last for approximately 1 year ([209], [389]). Finally, rituximab may be useful in these immune cytopenias ([357], [435]): Eight patients with heavily pretreated CLL who had steroid-resistant autoimmune hemolytic anemia were treated with a combination of rituximab, cyclophosphamide, and dexamethasone given at monthly intervals ([357]). All patients responded on a median of three cycles, with the time to maximum response ranging between 4 and 14 weeks. Five patients relapsed at a median of 13 months (range, 7 to more than 23). Three patients with immune thrombocytopenia had rapid and prolonged responses to four weekly cycles of rituximab at 375 mg/m^2 IV/week ([435]).

Anemia that is related to marrow involvement by leukemia and has not corrected with standard treatments may respond to erythropoietin ([436], [437]). In one study, erythropoietin was injected at 150 U/kg subcutaneously three times per week, with a gradual escalation up to 300 U/kg if necessary to achieve a response. Seventy-seven percent of patients responded, and 50% achieved a stable hematocrit of greater than 0.38 L/L ([437]). Erythropoietin decreased transfusion requirements in the majority of patients and improved the quality of life in responding patients.

Summary

The indications for treatment of patients with CLL differ somewhat between institutions; however, if the patient is not participating in a clinical trial, the following general guidelines are considered useful ([1]):

- Patients with stable *low-risk* “smoldering” CLL, or Binet stage A CLL, do not require therapy, and survival may actually be shortened with chemotherapy due to treatment-related complications.
- Many patients with *intermediate-risk* CLL, or Binet stage B CLL, do not require therapy, but treatment should be initiated with chlorambucil or fludarabine if there is evidence of progressive disease or uncomfortable organomegaly. Chemotherapy should be continued until the maximum response is obtained.
- Patients with *high-risk* CLL, or Binet stage C disease, should be treated with chlorambucil or fludarabine.
- Compared to chlorambucil, fludarabine produces a higher remission rate and more prolonged remissions in previously untreated patients. However, there is no evidence that survival is prolonged by treating patients initially with fludarabine. Increased response rates are observed on combining fludarabine with cyclophosphamide, and this may be further enhanced by the addition of a monoclonal antibody (rituximab or alemtuzumab). Furthermore, combination therapy may reverse drug resistance. Ongoing studies are determining the potential clinical utility of these combinations.
- The standard dose of chlorambucil is 4 to 8 mg orally OD, although higher remission rates may be obtained using higher doses. The standard dose of fludarabine is 25 mg/m^2/day × 5 days IV monthly, or 25 mg/m^2/day × 3 days IV monthly for older or frail patients. Patients not responding to fludarabine may be considered for one of the newer combination regimens or standard CHOP.
- Steroids should be avoided, if possible, as there is no evidence that they increase the response rate obtained with alkylating agents or nucleoside analogs alone, and they increase the risk of infection. Steroids should be reserved to treat immune cytopenias. Alternatively, if used judiciously, prednisone may be combined with chlorambucil if a more rapid response is required, either to reduce organomegaly or to improve blood counts.
- Radiotherapy is reserved for local lesions that are particularly bulky and troublesome and is used only when chemotherapy is not required for control of more disseminated disease. The lowest dose of radiotherapy capable of shrinking the tumor mass should be used. Splenic irradiation may be helpful in patients who require a splenectomy but who are not surgical candidates.
- Splenectomy may be useful in patients with painful splenomegaly or who have cytopenias that are unresponsive to other therapies. Minimally invasive surgical techniques should be considered.
- Prophylactic gammaglobulin is useful in reducing the frequency of infections in patients with hypogammaglobulinemia and frequent episodes of sepsis. Prophylactic antibiotics (e.g., trimethoprim-sulfamethoxazole, fluconazole, or acyclovir) may also be useful to prevent recurrent bacterial, herpetic, or fungal infections and in high-risk patients receiving nucleoside analogs or steroids.
- Although not standard therapy, BMT may be considered for the younger patient with CLL, preferably in the setting of a clinical trial.

DISEASE COURSE

Based on cytogenetic and molecular studies, it has been demonstrated that multiple clones may occur in CLL and that clonal evolution is a frequent occurrence ([107], [108], [109] and [110]). Rarely, the disease may convert to prolymphocytic leukemia, diffuse large cell lymphoma (Richter syndrome), Hodgkin disease, acute leukemia, or multiple myeloma ([438]).

Prolymphocytic transformation of CLL occurs slowly over several years and is associated with increasing anemia, thrombocytopenia, lymphadenopathy, splenomegaly, and resistance to treatment ([438], [439] and [440]). However, an occasional excellent response to aggressive therapy is observed ([439]). Both typical CLL cells and an increasing number of prolymphocytes are observed in the circulation simultaneously. In most cases, the prolymphocytic transformation has likely developed from the CLL cells, as the leukemic cells have similar surface characteristics, including low-intensity surface Ig and the presence of CD5 ([438], [439]). The clinical picture and immunophenotyping are thus quite different from those in *de novo* prolymphocytic leukemia.

Richter syndrome occurs in 3% of CLL patients and is characterized by increasing lymphadenopathy, splenomegaly, fever, and weight loss ([441], [442], [443], [444] and [445]). In addition, these patients frequently have extranodal involvement with infiltration of kidneys, lungs, and the gastrointestinal tract; most patients die within 1 year. It is important to rule out opportunistic infections in these patients, and the definitive diagnosis is made by needle aspirate and cytology/flow cytometry of a node or a node

biopsy ([444] , [445]). Eighty percent of patients have an increase in LDH, and it has been suggested that high-dose (7- to 10-mCi) gallium-67 scans may assist in the diagnosis by showing increased uptake into involved lymph nodes ([442]). However, a more recent study has not confirmed these findings ([443]). In 39 patients reported by the M. D. Anderson group ([444] , [445]), transformation occurred at a median time of 4 years from the diagnosis of CLL. Patients with all stages of disease were affected, and the incidence was not increased in patients treated with fludarabine or CdA. Response to standard chemotherapy is poor, with a median survival of 5 months, although responses may be obtained with standard and nonmyeloablative allogeneic BMT ([446]). Some studies provide evidence for the clonal transformation of CLL cells into diffuse large cell lymphoma ([444] , [445] , [446] , [447] , [448] and [449]), whereas others suggest that some of these large cell lymphomas are an independent B-cell malignancy ([449] , [450]). Foon et al. ([438]) have estimated that one-half of cases arise from the same clone as the CLL cell and one-half from a different B cell. Richter's transformation in CLL resembles the occurrence of large cell lymphomas in various immune deficiency states, even though there is no increase in the incidence of Richter's transformation in CLL patients treated with the highly immunosuppressive agents, fludarabine or CdA ([444]).

Occasionally, Hodgkin disease develops in CLL, and this is frequently called *Richter syndrome with features of Hodgkin disease*. Histologically, there may be classical Hodgkin disease or scattered Reed-Sternberg cells in a field of typical CLL cells ([455]). As with typical Richter syndrome, patients frequently present with fever, lymphadenopathy, and weight loss ([445] , [451] , [452]). Hodgkin disease develops approximately 4 years after the diagnosis of CLL, and in general, these patients have advanced Hodgkin disease and poor response to therapy with a median survival of 14 months ([451]). Using a variety of techniques, it has been demonstrated that the Reed-Sternberg cell evolves from the CLL cell, and in some cases, the Epstein-Barr virus has been found in the Reed-Sternberg cells, suggesting a pathogenetic role for the virus ([453] , [454] and [455]). It is interesting that recent evidence suggests that Reed-Sternberg cells containing the Epstein-Barr virus have a different Ig gene rearrangement than the CLL cells, suggesting that in these cases, the Hodgkin disease did not evolve from the CLL clone but had a separate cell of origin ([456]). In contrast to Hodgkin disease, the Epstein-Barr virus does not appear to be important for the development of the diffuse large cell form of Richter syndrome ([457]).

Acute leukemia occurs in less than 1% of CLL patients, and this contrasts with the almost invariable progression of patients with chronic myeloid leukemia to acute leukemia ([458]). Of 31 cases of acute leukemia developing in patients with preexisting CLL, ten were lymphoblastic, seven myeloblastic, and one plasmacytic; in 13 cases, the cell type was not identified ([458]). As 29 of these 31 patients had received chemotherapy, it was assumed that many of the acute myeloid leukemia cases were attributable to therapy ([458]). However, acute myeloid leukemia was found in a patient who had recently been diagnosed as having CLL and who had not received chemotherapy ([459]). Both acute B- and T-cell lymphoblastic leukemias have been described in CLL ([460] , [461] , [462] , [463] and [464]), and although this usually occurs after many years, the concomitant presentation of CLL and acute lymphoblastic leukemia also has been reported ([460]). In B-CLL, evidence of clonal evolution has been documented in some cases, whereas in T-cell cases, a common lymphoid progenitor precursor has been postulated as the source of both malignancies ([460] , [461] , [462] , [463] and [464]).

Multiple myeloma may also develop in patients with CLL ([465] , [466] , [467] , [468] and [469]). Some studies have suggested clonal evolution ([467] , [468]), but Ig gene rearrangement studies have not confirmed this ([469]). It thus appears likely that, in some cases, the two diseases develop separately, whereas in others, multiple myeloma develops from the CLL clone.

There is an increased risk of second malignancies in CLL, and excluding non-Hodgkin lymphomas (which may arise from the CLL itself), the risk for Hodgkin disease is highest at 7.69%, but there is also an increased risk of melanomas, central nervous system tumors, and lung cancer ([470]). It has been suggested that the risk of second malignancies is not influenced by chemotherapy ([152] , [332]), although recent evidence suggests that chlorambucil, particularly if combined with fludarabine, increases the risk of myeloid malignancies ([471]). An analysis of 791 patients treated with fludarabine has not shown any increase in the incidence of second malignancies, although follow-up at the time of this report was very short (median, 1.1 years) ([332]).

Hairy Cell Leukemia

Hairy cell leukemia (HCL), or leukemic reticuloendotheliosis, is a chronic B-cell disorder that was initially described by Bouroncle et al. in 1958 ([1]). The disease is characterized by the presence of typical hairy cells in the peripheral blood and marrow, pancytopenia, and a variable degree of splenomegaly ([1], [2], [3], [4], [5] and [6]). The disease has always aroused interest, initially over the unique clinical features of this disorder and the origin of the hairy cell. More recently, there has been intense interest in the treatment of HCL after the observation that remissions could be readily obtained in this disease using interferon (IFN)-a or the nucleoside analogs 2'-deoxycoformycin (dCF) and 2-chlorodeoxyadenosine (CdA) ([5], [6]).

INCIDENCE AND ETIOLOGY

HCL is a rare disorder, accounting for 2% of all leukemias, and occurs more frequently in men, with an incidence in the United States of 2.9 per million per year for men and 0.6 per million per year for women ([5], [7]). The etiology of HCL is unknown, and a possible relationship to radiation exposure remains controversial ([7], [8]). A familial predisposition is suggested by reports of the disorder in a father and son ([9]), a mother and daughter ([10]), a mother and son ([11]), two brothers ([12], [13]), and three siblings, all with the same haplotype—A1, B7 ([14]).

PATHOGENESIS

Although the normal cellular counterpart of the hairy cell has not been identified, findings of multiple immunologic ([15], [16], [17] and [18]), molecular genetic ([19], [20]), and chromosomal ([21], [22]) studies indicate that the hairy cell is of B-cell origin. Although some T-cell features have been reported ([23], [24], [25], [26], [27] and [28]), including two cases in which the retrovirus human T-cell leukemia virus type II was isolated ([29], [30]), no instances of T-cell receptor gene rearrangements have been found. Fluctuations in the expression of T- and B-cell markers have been demonstrated both *in vivo* and under various *in vitro* culture conditions ([31], [32], [33] and [34]). In most instances, the alteration noted was between a surface immunoglobulin–positive (SIg^+) $CD2^-$ phenotype and an SIg^- $CD2^+$ phenotype. Other B-cell antigens, however, such as CD20, were retained, even with the loss of SIg and the appearance of CD2 ([33]).

The marginal zone B cell has been suggested as a likely normal couterpart of the hairy cell ([35], [36]). Hairy cells characteristically undergo high rates of somatic mutations within the variable regions of H- and L-chain Ig genes and are thus derived from a postgerminal center cell ([37], [38] and [39]). These cells are similar to a subset of normal circulating B prolymphocytes, as well as to “monocytoid” B cells that are a prominent cellular component of mucosa-based lymphoid tissue and that proliferate within the sinuses of some patients with nonneoplastic lymphadenopathy (e.g., in toxoplasmosis) ([40], [41] and [42]). From a developmental standpoint, marginal zone B cells appear to represent a stage just before the terminal differentiation of an activated B cell to a plasma cell (a preplasma cell) ([43]). These data, together with the evidence of multiple heavy chain classes detected on the surface of hairy cells ([44]) and their reactivity with a monoclonal antibody against PCA-1, a structure present only at an early stage of plasma cell differentiation ([45]), support the hypothesis that the marginal zone B cell may be the normal counterpart of the malignant hairy cell ([36]). Using single cell analysis in HCL, it has been demonstrated that individual cells are able to synthesize multiple isotypes and contain transcripts of preswitched (IgM/IgD) and postswitched (IgG/IgA) immunoglobulins ([37]). Thus, the hairy cell may be arrested at a point at which isotype switching is occurring. It has been suggested that the point of differentiation of the hairy cell is more distant to that of the normal counterpart of the B–chronic lymphocytic leukemia (CLL) cell. Thus, when CLL cells are stimulated with 12-O-tetradecanoylphorbol 13-acetate or the protein kinase C activator, Bryostatin 1, the cells develop the morphologic and immunologic features of hairy cells ([46], [47] and [48]). Interestingly, one patient has been described who had CLL that subsequently transformed to HCL *in vivo* ([49]). In addition, hybrid leukemias have been described that have immunologic features of both HCL and CLL, being $CD11c^+$ and $CD5^+$ ([50], [51]).

Cytogenetics

Cytogenetic studies have been difficult to carry out in HCL, as the number of circulating hairy cells is small, and attempts at marrow aspiration are usually unsuccessful. In addition, until recently, it has been difficult to induce hairy cells to proliferate and to obtain hairy cells in metaphase. In early reports, the abnormalities observed in HCL tended to be nonclonal ([52], [53]). However, more recently, 15 of 19 patients were found to have an abnormal karyotype, and a $14q^+$ marker involving the breakpoint q32 at the Ig heavy chain locus was the most frequent clonal abnormality ([21]). Abnormalities involving the short arm of chromosome 12 have been observed in four patients ([17]). Haglund et al. ([54]) observed deletions and inversions in 67% of patients. Clonal abnormalities of chromosome 5 were found in 40% of cases (most commonly, trisomy 5, pericentric inversions, and interstitial deletions involving 5q13). The frequency with which these abnormalities occur is unique and is not found in other B-cell malignancies. Abnormalities in 5q13 thus occur in one-third of patients, and subsequent studies have identified three expressed sequences as candidates for a putative tumor-suppressor gene at 5q13.3 ([55]). Cytogenetic analysis has been carried out using monoclonal antibodies to CD40, as this appears to be the most effective way of inducing hairy cell proliferation ([56]). This technique allowed cytogenetic analysis in 42 of 43 cases and demonstrated that clonal abnormalities were present in 19% of cases and involved numeric or structural abnormalities in chromosomes 5, 7, and 14. In contrast, abnormalities of chromosome 5 were not observed in the HCL variant, and translocations more frequently involved either chromosome 2 or 14 ([57]).

More recently, a high incidence of p53 mutations has been observed in HCL ([58], [59]). Using fluorescence *in situ* hybridization, a deletion of 17p13 (site of the p53 gene) has been demonstrated in 75% of patients with typical HCL and 100% of patients with the variant form ([59]). However, others have not confirmed these findings ([60]). König et al. ([58]) have observed p53 mutations in 28% of 61 HCL patients, although the codons typically affected in other hematologic malignancies were not involved. These results are surprising, as p53 mutations are usually associated with drug resistance and an aggressive clinical course, whereas typical HCL is an

indolent disease that is highly responsive to treatment.

Oncogenes

To date, there has been little information regarding the role of oncogenes in CLL. It has been shown that *c-fms*, which encodes the receptor for macrophage colony-stimulating factor and is normally expressed in macrophages/monocytes, is highly expressed in hairy cells ([61]). The addition of macrophage colony-stimulating factor to hairy cells causes enhanced mobility of the cells, the extent of which depends on the underlying stratum, and this effect is mediated through alterations in the integrin a $_{v}$ß $_{4}$ ([62]). More recently, it has been demonstrated that, compared to normal lymphocytes, hairy cells have markedly increased levels and activities of the protein tyrosine kinase pp60 $^{c\text{-}src}$, which is the product of the protooncogene *c-src* ([63]). This increase was not observed in CLL cells and was unrelated to the amplification or structural rearrangements of the gene ([63]). Cyclin D1 messenger RNA (mRNA) and protein levels are increased in HCL, but the increase is less than is seen in mantle cell lymphoma and is not related to t(11;14)(q13;q32), which is typically observed in mantle cell lymphoma ([64], [65]). Finally, because of the high frequency of abnormalities of chromosome 5 in classic HCL, it has been suggested that a transforming oncogene might be located at 5q13.3 ([51], [55], [58]).

Cytokines

There has been great interest in the role of cytokines in the pathogenesis of HCL ([66]). Identified factors that may be involved include interleukin-2 (IL-2), tumor necrosis factor (TNF)-a, IL-4, IL-6, B-cell growth factor, and interferon (IFN)-a ([66]). Some of these factors may be produced by the hairy cells themselves or by normal T cells ([66], [67]). T-cell clones have been shown to produce cytokines that stimulate the growth of hairy cells, but not normal B cells; this effect is prevented by the addition of IFN-a ([67]).

A feature of classic HCL is the reactivity of the hairy cells with anti-Tac (CD25), which detects the a-chain of the IL-2 receptor ([20], [68], [69], [70] and [71]). By immunofluorescence, these cells also can be shown to express the ß-chain of the IL-2 receptor ([58], [59]), although this has not been confirmed using other techniques ([70]). In contrast, the hairy cells of the HCL variant express the ß- but not the a-chain, and normal B cells do not express the receptor or only express it very weakly ([66], [68]). Increased serum levels of IL-2 receptor have been found in untreated HCL patients, and there is evidence that the leukemic cells release the receptor ([71]). The serum levels of IL-2 receptor correlate with the extent of disease and decrease after effective therapy with IFN-a ([72], [73]). Paradoxically, even though the IL-2 receptor is present on hairy cells, these cells do not respond to stimulation by IL-2 ([20]), and IL-2 probably does not play a major role in the pathogenesis of HCL ([66]).

It has been demonstrated that TNF-a, but not TNF-ß, stimulates the growth of hairy cells, whereas in CLL, both forms of TNF stimulate leukemic cell growth ([74], [75]). Hairy cells can also produce TNF-a ([76], [77]), and the serum level of TNF-a is increased in HCL, the level correlating with the tumor burden ([77]). The TNF-a receptor can also be detected in the serum of these patients, and the level of this receptor also decreases after treatment with IFN-a ([78], [79]). These findings suggest that TNF-a production by the hairy cells may play an important role in the pathogenesis of HCL by stimulating further growth of hairy cells and producing pancytopenia through the inhibition of normal marrow function ([74], [76], [77]).

Hairy cells secrete low levels of IL-6, and the serum level of this cytokine is increased in HCL ([66], [80]). The production of IL-6 mRNA and IL-6 secretion is markedly increased by incubating HCL cells with TNF ([80]). IL-6 antisense oligonucleotide can inhibit the effect of TNF on IL-6 secretion and DNA synthesis, suggesting that IL-6 mediates the activity of TNF in HCL ([80]).

Information regarding the role of other ILs is more fragmentary, but IL-4 has been shown to induce DNA synthesis in hairy cells, and B-cell growth factors can support the survival of hairy cells in long-term culture ([66]).

CLINICAL FINDINGS

The median age of HCL patients is between 50 and 55 years, with a range of 22 to 85 years, and the male to female ratio is 4:1 ([1], [2], [3], [4], [5] and [6], [81]). Classically, these patients present with weakness and easy fatigue, and the symptoms can usually be related to pancytopenia and splenomegaly (Table 93.1) ([1], [2], [3], [4], [5] and [6], [81]). Ninety percent of patients have a palpable spleen, which may be massive, and one-third of patients have hepatomegaly ([1], [2], [3], [4], [5] and [6], [81]). Peripheral lymphadenopathy is uncommon ([5]), but with computed tomography scanning, significant abdominal lymphadenopathy may be observed ([82], [83]). The degree of abdominal lymphadenopathy correlates with the duration and extent of disease. The incidence at presentation is 17% but increases to 56% at relapse after chemotherapy ([82]). Less frequently, mediastinal node enlargement may also be observed ([84]). Compared to 30 years ago, patients are now being diagnosed earlier and have less marked splenomegaly and anemia at presentation ([6]).

TABLE 93.1. Hairy Cell Leukemia: Clinical Manifestations

Manifestation	Incidence (%)
Weakness, easy fatigue	80
Fever, sweats, weight loss, anorexia	20–35
Infection	20–30
Easy bruising, bleeding	20–30
Left upper quadrant abdominal discomfort	25
Autoimmune disorders	15–30
Splenomegaly	80–90
Hepatomegaly	30–40
Ecchymoses, petechiae	20–30

Most patients have pancytopenia, the etiology of which is multifactorial but is primarily related to marrow failure and splenomegaly. Marrow failure is related to replacement of marrow by hairy cells and the associated reticulin fibrosis and to the inhibition of myelopoiesis by cytokines, such as TNF-a, released by the hairy cells ([74], [76], [77], [85]). Splenomegaly in HCL may produce pancytopenia by three mechanisms. First, the major factor responsible for the cytopenias is pooling (sequestration, margination) of normal peripheral blood cells in the enlarged spleen ([85], [86], [87], [88], [89] and [90]). As much as 90% of the peripheral platelet mass ([86], [91]), 30% of the red cell mass ([89], [91]), and 65% of the granulocytes ([87], [91]) may pool in a massively enlarged spleen. These cellular elements often are not destroyed by the spleen at an increased rate but slowly reenter the circulation ([91]). Pooling occurs in the red pulp, Billroth cords, and venous sinuses. In HCL, apparently because of the formation of blood-filled pseudosinuses by the hairy cells, a greater proportion of the peripheral red cell volume (as much as 48%) may be pooled in a massively enlarged spleen ([89]). A second mechanism responsible for cytopenias with splenomegaly is the increased destruction of cells in the spleen. Finally, an expanded plasma volume contributes to the appearance of cytopenia with splenomegaly; this is particularly true for the observed anemia ([85], [88], [91]).

Infections

Recurrent infections are a major problem and the leading cause of death for patients with HCL ([5], [92], [93], [94] and [95]). Fever is rarely a manifestation of the underlying HCL; when present, it should prompt a careful search for an infectious process. Approximately 30% of patients present with infection, and 70% have either documented or suspected infections during the course of the disease ([81], [92]). Pyogenic infections account for approximately 50% of infectious episodes; gram-negative and gram-positive bacteria are identified with approximately equal frequency ([81], [92]). However, nonpyogenic infections occur in more than 30% of

patients ([81], [92]), and infections can occur with unusual organisms such as atypical mycobacteria, including *Mycobacterium kansasii*, which is a unique feature of HCL, in comparison to other lymphoproliferative disorders ([81], [93], [96]). Other common organisms include *Toxoplasma* ([97]), various fungi ([81], [95], [98]), *Legionella* ([81], [99]), *Listeria monocytogenes* ([100]), *Pneumocystis carinii* ([95]), and viruses ([95]).

The high infection rate can be ascribed primarily to neutropenia, although several other immune defects have been described. Monocytopenia is often a prominent feature ([101], [102]), and functional abnormalities of monocytes and granulocytes may occur ([99], [101], [103], [104] and [105]). The defects in monocyte production and function may account for the unusual susceptibility of these patients to atypical mycobacterial and other fungal infections ([94], [95]). Natural killer (NK) cell activity is also severely depressed and is probably related to an absolute decrease in the number of these cells in the peripheral blood ([106], [107] and [108]). A depressed helper to suppressor T-cell ratio associated with a decrease in the number of T-helper cells and an increase in the number of T-suppressor cells also has been demonstrated ([109]). As expected, lymphocyte functional studies reveal impaired delayed-type hypersensitivity to recall antigens, as well as near-absent antibody-dependent cellular cytotoxicity ([106]). In contrast to CLL, the serum Ig levels are normal ([110]).

Autoimmune Disorders

Clinical manifestations secondary to various autoimmune disorders are being recognized with increasing frequency in patients with HCL ([95], [111], [112], [113], [114] and [115]). In one series of patients, these complications were second only to infection as a cause of morbidity ([95], [112]). The onset may occur any time during the course of the disease and is not related to the tumor burden. Infection, however, particularly with mycobacterial organisms, often coexists ([95]). Most frequently, patients present with arthritis, arthralgias, palpable purpura or nodular skin lesions resulting from cutaneous vasculitis, and low-grade fever ([95], [112], [114]). Occasionally, patients may have involvement of the lung, liver, intestine, and kidney, with a clinical picture that resembles poly-arteritis nodosa ([95], [112], [113], [115]). These patients often have fever, malaise, and weight loss, and a coexistent infection must be ruled out ([95], [112]). If skin lesions are present, the diagnosis can be confirmed by biopsy, which usually shows changes compatible with a diagnosis of polyarteritis nodosum or leukocytoclastic vasculitis; occasionally, a vasculitis related to the invasion of the vessel wall by hairy cells occurs; this may appear very similar to polyarteritis nodosa with the presence of aneurysms ([114]). In some organs, such as the lung, a granulomatous vasculitis may be found ([95], [112]). Angiography may reveal peripheral aneurysms ([112], [115]). Antinuclear antibodies, rheumatoid factor, immune complexes, and hepatitis B antigen are variably positive ([105]). Cryoglobulinemia has been detected in some patients ([116], [117]). It has been postulated that the increased incidence of vasculitis in HCL may be related to infections with hepatitis B and other viruses, cross-reactivity of antibodies against hairy cells with epitopes on endothelial cells, and decreased clearance of immune complexes by the impaired immune system ([114]).

These autoimmune manifestations may be self-limited, but if therapy is required, a short course of corticosteroids is usually effective ([95], [114]). Remissions have also been observed after splenectomy, IFN-a, and dCF therapy ([95], [112], [114], [115]).

Unusual Manifestations

LYTIC BONE LESIONS Although the immunophenotypic profile of hairy cells closely resembles that of B cells at a developmental stage just before terminal differentiation to plasma cells, lytic bone lesions are distinctly unusual (Table 93.2) ([118], [119], [120] and [121]). In some patients with osteolytic lesions, HCL and multiple myeloma were thought to coexist ([122], [123]). However, several patients with classic HCL and without any evidence of plasma cell proliferation have been reported to develop osteolytic lesions ([119], [120] and [121]). These lesions have a predilection for the proximal femur and usually are associated with extensive bone marrow infiltration by hairy cells ([120], [121]). The lesions, like those seen in association with multiple myeloma, respond well to radiotherapy. The administration of corticosteroids can produce prompt relief of bone pain ([119]).

TABLE 93.2. Hairy Cell Leukemia: Unusual Clinical Manifestations

Manifestation	Incidence (%)
Peripheral lymphadenopathy	<5
Lytic bone lesions	3
Skin involvement	5
Splenic rupture	<5
Other organ dysfunction	<5

SKIN INVOLVEMENT Cutaneous lesions referable to thrombocytopenia (ecchymoses, petechiae), infection, or vasculitis are common during the course of HCL, but lesions caused by infiltration of the skin by hairy cells are unusual ([124], [125]). In a retrospective review of 600 cases, skin lesions thought to be due to infiltration by hairy cells were reported in 8.0% of cases, but histopathologic verification was present in only 1.3% ([124]). Infiltrative lesions usually are widely disseminated and consist of erythematous maculopapules. Biopsy shows the infiltrates to be perivascular, involving the dermis but not the epidermis ([126]).
SPLENIC RUPTURE Surprisingly, even with massive splenomegaly, spontaneous splenic rupture is rare in HCL, occurring in approximately 2% of cases ([1], [95], [127]).
OTHER ORGAN DYSFUNCTION Although hairy cell infiltration of multiple organs and tissues is a frequent finding at autopsy, clinically significant organ dysfunction is unusual ([128]). Infiltration of connective tissue and fat surrounding organs is common ([128]). Central nervous system involvement is unusual, and only a rare case of meningeal involvement has been documented ([128], [129]). Infection is by far the most frequent cause for neurologic complications ([129]). Pleural effusions, ascites, protein-losing enteropathy, and spinal cord compression may occur rarely in HCL and result from tissue infiltration by hairy cells ([118]).

LABORATORY FINDINGS

The relative incidence of the most characteristic laboratory findings is listed in Table 93.3. In a series of 725 cases studied by the Italian Cooperative Group, 80% of patients had pancytopenia at presentation, with one-third of all patients having a hemoglobin less than 85 g/L, neutrophils less than 0.5×10^9/L, and platelets less than 50×10^9/L ([6]). A careful inspection of the peripheral blood smear demonstrates the presence of typical hairy cells in more than 85% of patients ([1], [6]), and in 13% of cases, there are more than 5×10^9/L hairy cells ([6]). In Bouroncle's series of 82 patients, hairy cells accounted for 10% or more of the leukocytes in 80% of patients and 50% or more in 43% of patients ([2]). The total leukocyte count was elevated in 20%, but in only 4% did the count exceed 50×10^9/L ([2]).

TABLE 93.3. Hairy Cell Leukemia: Laboratory Manifestations

Manifestation	Incidence (%)
Pancytopenia	70
Neutropenia	80
Thrombocytopenia	80
Anemia	75
Monocytopenia	98
Leukocytosis	15
Hairy cells in peripheral blood	85
Hairy cells in bone marrow	99

Abnormal liver function studies, usually with an isolated elevation of the serum alkaline phosphatase level, are obtained in 10 to 19% of individuals with HCL ([4]). The leukocyte alkaline phosphatase scores are high in most cases. Monoclonal gam-mopathy is rare, occurring in 1 to 3% of patients ([3], [4]). It has been difficult to prove that the hairy cells are secreting the paraprotein ([130]); in other cases, the M band was thought to be related to a coexisting myeloma ([120], [122], [123]).

Hairy Cells

The characteristic morphologic appearance of hairy cells on a Wright-stained peripheral blood smear is the single most important diagnostic finding (Fig. 93.1) ([6]). The cells are mononuclear with relatively abundant cytoplasm and a cell diameter in the range of 10 to 25 µm. The cytoplasm is pale blue-gray and agranular with a variable number of elongated (hairy) projections. The nuclei are round, oval, reniform, or dumbbell-shaped with a nuclear chromatin pattern that is homogeneous and less clumped and lighter staining than that of normal mature lymphocytes and those seen in classic CLL and prolymphocytic leukemia ([6], [23]). A prominent nucleolus is rarely seen. On both transmission and scanning electron microscopy, the cytoplasmic projections appear as elongated slender microvilli or broad-based ruffles or pseudopods (Fig. 93.2) ([131]). Other ultrastructural features include numerous mitochondria, polyribosomes, strands of rough endoplasmic reticulum, intermediate filaments, and some lysosomal granules ([23]). In 50% of cases, cytoplasmic inclusions known as *ribosome-lamellar complexes* are found ([6], [132]). These complexes appear as rod-shaped structures under light microscopic analysis ([132]). Although seen most frequently in individuals with HCL, they are not pathognomonic, having been reported in association with other chronic B-cell lymphoproliferative disorders, acute monocytic leukemia, and even nonhematologic neoplasms ([133]). The characteristic filamentous projections can be seen readily in living hairy cells; using supravital dyes and phase-contrast microscopy, one can observe the cytoplasmic projections protruding and then retracting constantly ([6]).

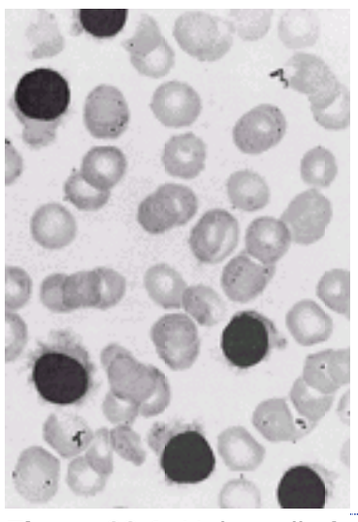

Figure 93.1. Hairy cells from a peripheral blood smear (light microscopy). Cells have abundant agranular cytoplasm with multiple cytoplasmic projections. Nucleus is round, oval, or reniform with light-staining homogeneous nuclear chromatin (Wright stain, ×1500).

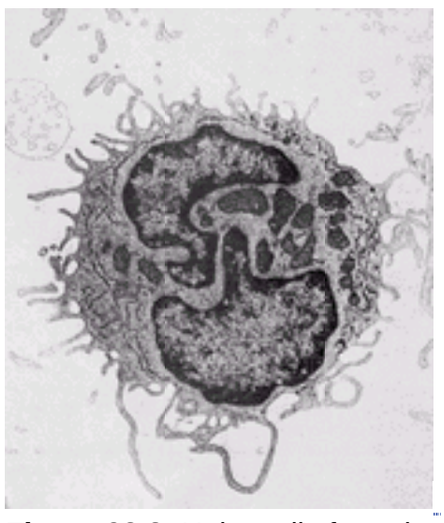

Figure 93.2. Hairy cells from the peripheral blood (transmission electron microscopy). The characteristic and delicate cytoplasmic projections are striking. Nucleus is irregular in shape with marginated chromatin (×11,000).

A useful diagnostic test for HCL is the presence of acid phosphatase isoenzyme 5 in the cytoplasm of hairy cells, but this can also be positive in other disorders ([6], [134], [135], [136] and [137]). Cytochemical staining procedures demonstrate that this isoenzyme, unlike other acid phosphatase isoenzymes, is not inhibited by tartrate ([134], [135], [136] and [137]). The enzyme concentrates primarily in the Golgi area and nuclear membrane ([134]). Even though a positive tartrate-resistant acid phosphatase (TRAP) stain is not pathognomonic for the diagnosis of HCL, it has stood the test of time as an important tool in the differential diagnosis of this disease ([136]). The test is positive in more than 95% of cases ([4]). In one report ([136]), the TRAP stain was positive in 76%, intermediate in 21%, and negative in only 3% of 29 patients with HCL. In contrast, in 37 patients with CLL and other lymphoproliferative disorders, the test was positive in only 3%, intermediate in 32%, and negative in 65% ([136]). A limiting factor of the TRAP stain is that it cannot be carried out on paraffin-embedded tissue. This problem has been circumvented recently with the development of an immunohistochemical technique using 9C5, a monoclonal antibody to TRAP ([137], [138]). The majority of cases of HCL are detected using this antibody, although only 50% of the cells stain positively ([138]).

Immunophenotyping has proved very useful in assisting in the diagnosis of HCL and in differentiating it from variants and other B-cell malignancies ([139], [140], [141] and [142]). Using flow cytometry, hairy cells can be detected in the peripheral blood of 92% of patients, even if the hairy cells comprise less than 1% of the lymphocytes ([140]). Table 93.4 shows the immunophenotype of typical HCL in comparison to other chronic B-cell disorders that have “hairy” cells (i.e., the HCL variant and splenic lymphoma with villous lymphocytes). In HCL, the leukemia cells have SIg (IgM $^{+/-}$, IgG, IgD, or IgA) and B-cell associated antigens (CD19, CD20, and CD22); typically, the cells are positive for CD25, the IL-2 receptor. CD11c (leu-M5), which reacts with the a subunit of p150/95, a member of the lymphocyte function-associated antigen subfamily of integrin molecules, is present on virtually all hairy cells, but it is also present on monocytes and neutrophils and on the cells of other lymphoid malignancies ([6], [139], [140]). A number of antibodies have been raised against hairy cells, although none is entirely specific for this leukemia. B-ly 7 reacts with a 144-kd antigen (mucosal lymphocyte antigen; CD103) on hairy cells and on a small number of normal lymphocytes, which have been postulated to be the normal hairy cell counterpart ([139], [141]). Like B-ly 7, the antibodies HML-1, Ber-ACT8, and LF61 can also recognize CD103 ([141]). Two further antibodies, RAB-I and anti-HC2, are also relatively specific for hairy cells ([6]). Important markers to help differentiate HCL from the other B-cell malignancies include CD5 $^{-}$, CD10 $^{-}$, CD23 $^{-}$, CD25 $^{+}$ (strong), CD11c $^{+}$ (strong), FMC7 $^{+}$, HC-2, and CD103 $^{+}$ ([140], [141] and [142]).

TABLE 93.4. Hairy Cell Leukemia (HCL): Immunophenotypic Profile

Antigen	Prototype Monoclonal Antibody	HCL	HCL Variant	Splenic Lymphoma with Villous Lymphocytes
CD19, CD20	B4, B1	+	+	+
CD22	Leu-14	+	+	+

HLA-DR	Anti–HLA-DR	+	+	+
Nonclustered	FMC7	+	+	+
Surface Ig	Anti-Ig	+	±	+
CD11c	Leu-M5	+	+	±
CD103	B-ly-7	+	±	±
CD25	Anti-Tac (interleukin-2 receptor)	+	-	±
Nonclustered	HC2	+	-	-
CD23	MHM6	±	-	±
CD3, CD4, CD8	Leu-4, Leu-3a, Leu-2a	-	-	-
CD5	Leu-1	-	-	±
CD10	Common acute lymphocytic leukemia antigen	-	±	±

+, positive in nearly all cases; ±, positive in less than 50% of cases; -, less than 10% positive; CD, cluster of differentiation; Ig, immunoglobulin.
Adapted from Cornfield DB, Mitchell Nelson DM, Rimsza LM, et al. The diagnosis of hairy cell leukemia can be established by flow cytometric analysis of peripheral blood, even in patients with low levels of circulating malignant cells. Am J Hematol 2001;67:223–226; Frassoldati A, Lamparelli T, Federico M, et al. Hairy cell leukemia: a clinical review based on 725 cases of the Italian Cooperative Group (ICGHCL). Leuk Lymph 1994;13:307–316; Matutes E, Morilla R, Owusu-Ankomah K, et al. The immunophenotype of hairy cell leukemia (HCL). Proposal for a scoring system to distinguish HCL from B-cell disorders with hairy or villous lymphocytes. Leuk Lymph 1994;14(Suppl 1):57–61; and Robbins BA, Ellison DJ, Spinosa JC, et al. Diagnostic application of two-color flow cytometry in 161 cases of hairy cell leukemia. Blood 1993;82:1277–1287.

The above antibodies are primarily used on viable or frozen cells, but antibodies have also been developed that can recognize formalin-resistant hairy cell antigens. One of these is DBA.44, which strongly stains hairy cells fixed in formalin or Bouin solution and is thus useful for detecting residual disease in the marrow after chemotherapy ([143], [144]). However, DBA.44 is not entirely specific for hairy cells and also stains mantle zone lymphocytes and a variety of low- and high-grade B-cell lymphomas ([143], [144]). The specificity and sensitivity for the diagnosis of HCL by immunohistochemistry can be increased when DBA.44 staining is used in conjunction with the 9C5 antibody to detect TRAP and an anti-CD20 antibody to detect B cells ([138]).

Bone Marrow

More than 99% of patients have marrow infiltration by biopsy, although the occasional patient can have isolated involvement of the spleen ([3], [145]). The pattern of bone marrow involvement on biopsy specimens is near to pathognomonic for HCL (Fig. 93.3) ([146], [147] and [148]). Classically, the infiltration is diffuse and has a “honeycomb” appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm (Fig. 93.3). The individual cells have been described as resembling a fried egg. This pattern of infiltration is quite different from that seen in other chronic lymphoproliferative disorders, such as CLL, well-differentiated lymphocytic lymphoma, and lymphoplasmocytic lymphoma in which the lymphocyte nuclei closely approximate each other ([138], [139], [140] and [141]). In prolymphocytic leukemia, monocytoid B-cell lymphoma, marginal zone lymphoma, and large granular lymphocytic (LGL) leukemia, in which the malignant lymphocytes are about the size of hairy cells with a low nuclear to cytoplasmic ratio, the infiltrates are similar to those seen in HCL. Bone marrow involvement in systemic mast cell disease and even in some nonhematologic neoplasms, such as mesenchymal chon-drosarcoma, also may mimic HCL ([149]). The hairy cells may be more easily identified using immunohistochemistry with antibodies to CD20 (L26) or DBA.44.

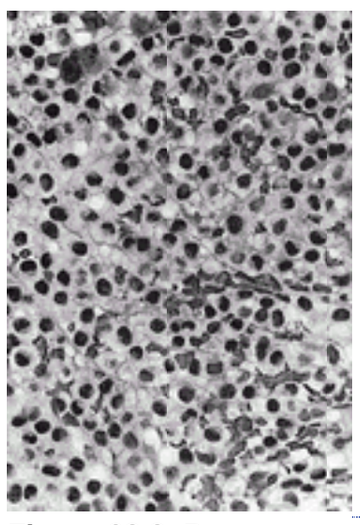

Figure 93.3. Bone marrow biopsy (plastic embedded) in hairy cell leukemia. Pattern of the infiltration gives a “honeycomb” appearance with the nucleus of each hairy cell surrounded by a halo of cytoplasm. Nuclei are bland and round, oval, or indented (hematoxylin and eosin, ×600).

Silver staining demonstrates diffuse reticulin fibrosis, without a collagenous component; this likely explains the usual difficulty in obtaining a marrow by aspirate (“dry tap”) ([147], [148], [150]). Recently, it has been demonstrated that this feature is related to the ability of hairy cells to synthesize fibronectin ([151]). In addition, hairy cells contain the fibronectin receptor, very late antigen-5, and are able to assemble the fibronectin molecule into multimers ([151]). In some patients, the bone marrow is not diffusely involved by hairy cells; instead, focal (patchy) or interstitial infiltrates are seen ([146], [147] and [148]). The focal areas may be well-circumscribed nodules, or they may have irregular borders. Extravasation of red cells into areas of involvement is often present ([147]). Islands of normal hematopoiesis, particularly erythroid islands, are common. Increased numbers of plasma cells, lymphocytes, and mast cells may also be seen.

The overall marrow cellularity is increased in 55% of patients and normal in 38% of patients ([6]). However, in 7% of cases, the cellularity is decreased; this can lead to the erroneous diagnosis of aplastic anemia or hypoplastic myelofibrosis ([149], [150], [152], [153]). Patients with hypocellular marrows frequently do not have splenomegaly, suggesting that these patients may have an early stage of the disease ([95]).

Spleen and Liver

The spleen is almost always involved in HCL, and the pattern of hairy cell involvement, like that in the bone marrow, is nearly pathognomonic for HCL ([146], [153], [154] and [155]). The infiltrates are confined to the red pulp, and, unlike other lymphoproliferative disorders, the white pulp is not expanded and is actually atrophic. Although a variable degree of red pulp involvement is seen in association with all leukemias, it is not a feature of most lymphomas until a leukemic transformation occurs. Blood-filled pseudosinuses lined by hairy cells are a characteristic feature, and, despite monocytopenia, the number of histiocytes is increased in the red pulp. Infiltration of the liver occurs in both portal areas and sinuses ([128]). Pseudosinuses, some resembling hemangiomas, may be present ([128]).

DIAGNOSIS

The diagnosis of HCL usually is not difficult ([1], [2], [3], [4], [5] and [6]). Most patients have splenomegaly in the absence of peripheral lymphadenopathy, and a variable degree of pancytopenia with severe monocytopenia. Typical hairy cells are evident in the peripheral blood on a routine smear or on a buffy coat in more than 90% of cases, and the suspected hairy cells should be TRAP positive. The marrow aspirate is “dry,” and the bone biopsy should reveal the classic pattern of infiltration that may be diffuse, focal, or interstitial with increased reticulin. When hairy cells cannot be demonstrated in the peripheral blood, the bone marrow findings are critical for diagnosis. When the bone marrow findings are not typical, particularly in those patients in whom the TRAP stain is negative, immunophenotyping is helpful (Table

93.4). Analysis for Ig and T-cell receptor gene rearrangements occasionally may be necessary, particularly in individuals with one of the “variant forms” of the disease. Rarely, the diagnosis is confirmed only after splenectomy ([145]).

The HCL variant makes up 10% of all HCL cases and was originally described as having morphologic features intermediate between hairy cells and prolymphocytes ([156] , [157]). However, there are other presentations of the HCL variant, including hybrid forms of HCL and prolymphocytic leukemia or CLL, a blastic form of HCL, and an HCL multilobular form ([156] , [157] , [158] , [159] , [160] , [161] and [162]). These patients have many of the clinical and laboratory features of typical HCL ([156] , [157] , [158] , [159] , [160] , [161] and [162]). Splenomegaly without peripheral lymphadenopathy is seen in all patients, and a pattern of exclusive red pulp infiltration in the spleen is evident in most. The HCL variant differs from typical HCL in the following ways ([142] , [157] , [160] , [163] , [164]):

- Patients are older, the median age being 71 years.
- The peripheral leukocyte count usually is higher (often >50 × 10^9/L).
- Hairy cells may or may not be TRAP $^+$.
- The monocyte count is normal.
- Hairy cells show a higher nuclear to cytoplasmic ratio, and the nuclear chromatin is more condensed with more prominent nucleoli.
- Classic HCL is CD25 $^+$, HC2 $^+$, CD11c $^+$, and CD103 $^+$, whereas the HCL variant is CD25 $^-$ and HC2 $^-$ and may or may not be CD11c $^+$ and CD103 $^+$.
- The marrow usually can be aspirated in the HCL variant, and there is an interstitial pattern of infiltration seen in the bone marrow with a variable degree of fibrosis.
- The HCL variant responds more poorly to IFN-a and the nucleoside analogs than classic HCL ([157] , [160] , [163] , [164]) but may respond to splenectomy ([157]). In one report, none of the seven patients responded to IFN-a, and only two of three patients achieved a partial response (PR) to dCF ([160]). Of four patients treated with CdA, one achieved a complete response (CR), and two achieved a PR ([163]). Others have observed similarly poor responses ([157]).
- Survival is shorter than for typical HCL, with the median survival in one report being 9 years (vs. >12 years for typical HCL) ([157]).

DIFFERENTIAL DIAGNOSIS

Disorders to be considered in the differential diagnosis of HCL include lymphoid malignancies that present with splenomegaly in the absence of lymphadenopathy and are listed in Table 93.5 ([165]).

TABLE 93.5. Hairy Cell Leukemia: Differential Diagnosis

Splenic lymphoma with villous lymphocytes
Marginal zone B-cell lymphoma
Monocytoid B-cell lymphoma
Small lymphocytic lymphoma
Primary splenic chronic lymphocytic leukemia
Lymphoplasmacytoid lymphoma, including Waldenström macroglobulinemia
Chronic lymphocytic leukemia
Mantle zone (intermediate) lymphoma
Myeloproliferative disorders
Malignant histiocytosis
Primary lymphoma of spleen
Chronic prolymphocytic leukemia
Large granular lymphocytic leukemia
Systemic mast cell disease
Hairy B-cell lymphoproliferative disorder

The normal cellular counterpart of the malignant lymphocyte in splenic lymphoma with villous lymphocytes ([152] , [153] , [154] and [155]), marginal zone B-cell lymphoma ([39] , [170]), monocytoid B-cell lymphoma ([171] , [172] and [173]), and HCL may be similar. Marginal zone B cells, found in the marginal zone of the normal spleen, are large mononuclear cells with abundant cytoplasm, a variable number of cytoplasmic projections, and condensed nuclear chromatin ([39]). Monocytoid B cells, initially identified and referred to as *sinus histiocytes* that proliferate in certain reactive lymph nodes (e.g., toxoplasmosis), are morphologically and immunologically similar to marginal zone lymphocytes ([38] , [39]). A similar B cell is also found in the perifollicular areas of lymph nodes, particularly in the mucosa-based lymphoid tissue ([173]). The malignant cell in these disorders is a mononuclear cell with abundant cytoplasm, a variable degree of cytoplasmic projections, condensed nuclear chromatin, and usually a prominent nucleolus ([39]). In tissue sections, these lymphomas closely resemble hairy cell infiltrates, but the cytologic appearance of the malignant cells with the clumped nuclear chromatin and shorter and fewer cytoplasmic projections distinguishes them from the typical hairy cell. These disorders may be differentiated by immunophenotyping and by the TRAP stain, which is positive in HCL and usually negative or only weakly positive in the other disorders ([171]). The pattern of infiltration in the bone marrow and spleen also is different from that of HCL.

In splenic lymphoma with villous lymphocytes, previously known as *malignant lymphoma simulating leukemic reticuloendotheliosis* ([166]) and now considered to be one of the splenic marginal zone lymphomas ([35]), the white cell count is usually higher than in HCL, being 3 to 38 × 10^9/L ([166] , [168]). Typically, these patients have prominent splenomegaly and no lymphadenopathy; they may have an IgM paraprotein and a Coombs-positive hemolytic anemia and respond to chlorambucil or splenectomy ([168]). The leukemia cell is smaller and frequently contains a nucleolus, and the villi are shorter, fewer, and more uneven than in a typical hairy cell and are frequently concentrated at one end of the cell. A small monoclonal band is found in the serum or urine in two-thirds of patients. Marrow involvement is patchier without the “fried-egg” pattern or reticulin fibrosis; in the spleen, the white pulp is expanded, and there is a variable degree of red pulp expansion without pseudosinus formation ([166] , [167] , [168] and [169]). Immunophenotyping can also assist in differentiating these cells from hairy cells ([166]). Although these cells have many markers similar to those of hairy cells, only 25% of cases are CD25 $^+$, and these do not have the classic markers for HCL (CD11c, HC2 $^+$, and B-ly-7). In marginal zone B-cell lymphoma, the pattern of bone marrow infiltration also tends to be patchy or focal without reticulin fibrosis, but in the spleen, the infiltration is predominantly in the red pulp, such as occurs in HCL ([170]). In monocytoid B-cell lymphomas, the infiltrates resemble those of HCL, but the clinical presentation is different ([171] , [172]). These patients usually have peripheral lymphadenopathy without splenomegaly and a high incidence of extranodal involvement ([173]). Bone marrow involvement is less frequent and usually is paratrabecular; peripheral blood involvement is rare ([171]). In lymph nodes, the infiltration is interfollicular and sinusoidal, often with preservation of some lymph follicles, a finding similar to that seen in hairy cell involvement of lymph nodes ([171] , [172]).

Patients with small lymphocytic lymphoma (SLL) ([174] , [175]), lymphoplasmacytic lymphoma ([161]), primary splenic CLL ([176]), typical CLL, and mantle cell lymphoma ([177] , [178]) can have the same clinical presentation as HCL, but the laboratory features are quite different. The cytologic appearance of the malignant cells on Wright stain and the appearance and distribution of the infiltrates in the bone marrow, spleen, and lymph nodes distinguish these disorders from HCL. In SLL/CLL, the lymphocytes are small with scant cytoplasm and clumped nuclear chromatin. The bone marrow usually is diffusely involved in CLL, but a focal interstitial pattern may be evident early in the course of the disease. In SLL, the bone marrow may not be involved early in the course, and the pattern initially is more focal. Involved lymph nodes in SLL and CLL show diffuse infiltration with small mature lymphocytes that completely efface the nodal architecture. The spleen shows not only white pulp expansion, but also a variable degree of red pulp expansion. The malignant lymphocytes in both SLL and CLL are typically CD5 $^+$ in contrast to hairy cells, which are CD5 $^-$. In the lymphoplasmacytic disorders, particularly Waldenström macroglobulinemia, splenomegaly, peripheral lymphadenopathy, and a variable degree of pancytopenia are a more common presentation. Like hairy cells, these malignant B cells are CD5 $^-$, but they are CD103 $^-$ and usually CD11c $^-$ and CD25 $^-$. In addition, the cytologic appearance (plasmacytoid lymphocytes) and the frequent presence of a serum IgM monoclonal spike distinguish them from HCL. Although mantle cell lymphoma is usually associated with generalized lymphadenopathy, splenomegaly may be a prominent feature ([177] , [178]). Again, this lymphoma can be differentiated

from HCL by the cytologic appearance of the cells, immunophenotyping, and the pattern and nature of the infiltration in lymph nodes, spleen, and bone marrow. The malignant cells are small mature lymphocytes with scant cytoplasm, a round or cleft nucleus, and clumped nuclear chromatin. The bone marrow may demonstrate diffuse or patchy involvement. Lymph nodes are diffusely infiltrated and often show expansion of the mantle zone with residual isolated benign-looking germinal centers ([177], [178]). A similar pattern is seen in the expanded white pulp in the spleen with a variable degree of red pulp expansion ([177], [178]).

Various myeloproliferative disorders present with splenomegaly without peripheral lymphadenopathy, but the diagnosis is established easily by bone marrow biopsy and the findings on a peripheral blood smear.

Malignant histiocytosis occasionally is associated with splenomegaly as the predominant manifestation ([179]). The characteristic cytologic and cytochemical features of the malignant histiocytes and the subsequent course of the disease make the process of differential diagnosis easy.

Rarely, a diagnosis cannot be made for a patient with symptomatic splenomegaly short of splenectomy; these patients may have primary lymphoma of the spleen ([180], [181]) or, less commonly, primary splenic HCL ([134], [182]).

Prolymphocytic leukemia may have a presentation very similar to that of HCL, with splenomegaly and minimal or no peripheral lymphadenopathy ([183]). Prolymphocytic leukemia can usually be distinguished from HCL in that the nuclear chromatin is more clumped than in hairy cells, the level of peripheral lymphocytosis is high, the TRAP stain is negative or only weakly positive, and expansion of the white pulp in the spleen is evident. The immunologic profile is slightly different; prolymphocytic leukemia cells are CD25 $^{-}$, CD11c $^{-}$, and CD5 $^{+/-}$ ([165], [183]).

LGL leukemia frequently presents with splenomegaly without peripheral lymphadenopathy ([184]). The disease is characterized by the presence of cells that are bigger than CLL cells and have abundant cytoplasm containing azurophilic granules. Large granular lymphocytes may be CD3 $^{-}$ NK cells that mediate non–major histocompatibility complex–restricted cytotoxicity, or they may be CD3 $^{+}$ cells that mediate non–major histocompatibility complex–restricted cytotoxicity ([185]). T-LGL leukemia is associated with neutropenia (which may be cyclical), red cell aplasia, and rheumatoid arthritis but is a distinct entity from Felty syndrome ([184]). The usual immunophenotyping of T-LGL leukemia is CD3 $^{+}$, CD4 $^{-}$, CD8 $^{+}$, CD16 $^{+}$, CD56 $^{-}$, CD57 $^{+}$, and TCRaß $^{+}$. NK-LGL leukemia occurs most frequently in Japan and has an acute fulminant course with high fever, hepatosplenomegaly, and pancytopenia. However, chronic NK-LGL leukemia can occur with clinical features similar to those of T-LGL leukemia ([184]). These cells are usually CD3 $^{-}$, CD4 $^{-}$, CD8 $^{-}$, CD16 $^{+}$, CD56 $^{+}$, and CD57 $^{-}$ ([184], [185]).

Systemic mast cell disease, in which splenomegaly may be a prominent feature, rarely presents a problem in differential diagnosis, except for the appearance of the mast cell infiltrates in tissue sections that can closely mimic HCL ([186]).

More recently, a condition called *hairy B-cell lymphoproliferative disorder* (HBLD) has been described in five patients from Japan ([187], [188]). All patients were middle-aged women who presented with clinical and laboratory features consistent with the HCL variant and had a polyclonal increase in IgG. However, the hairy cells were polyclonal. This condition is thus similar to persistent polyclonal B-cell lymphocytosis, a rare and benign condition seen typically in middle-aged female smokers with a familial tendency ([189], [190] and [191]). The lymphocytes are binucleated and have abundant cytoplasm. There is a polyclonal increase in Igs and a strong association with HLA-DR7 ([189]). However, HBLD differs from persistent polyclonal B-cell lymphocytosis in that (a) the patients in HBLD are not smokers; (b) there is a polyclonal increase in IgG in HBLD as opposed to the polyclonal increase in IgM seen with persistent polyclonal B-cell lymphocytosis; (c) the cells in HBLD are not binucleated and are CD11c $^{+}$; and (d) there is no association with HLA-DR7 in HBLD ([187], [188], [189], [190] and [191]).

TREATMENT

Although splenectomy used to be the standard treatment for HCL, therapy for this disease has been transformed over the past 20 years with the development of IFN-a and the nucleoside analogs ([192], [193] and [194]). Splenectomy and IFN-a may still be used for HCL under specific circumstances, but the standard therapy consists of the nucleoside analogs dCF or CdA, which produce complete and durable remissions in the majority of patients ([192], [193] and [194]). More recently, it has been demonstrated that the monoclonal antibody rituximab, which is directed against CD20, and the immunotoxins LMB-2 and BL22, which are directed against CD25 and CD22, respectively, have significant activity against nucleoside-resistant HCL ([195], [196], [197], [198], [199] and [200]).

Splenectomy

Until the mid-1980s, the standard therapy for HCL was splenectomy ([5], [195], [196], [197] and [198]). The variable degree of pancytopenia in all patients during the course of their disease is to a great extent a direct result of splenomegaly ([86], [87], [88], [89] and [90]). An enlarged spleen may be responsible for the development of peripheral cytopenias by one or more of three mechanisms: increased sequestration or pooling, increased rate of peripheral destruction, or dilution of the cellular elements in the peripheral blood by an expanded plasma volume ([88]). Other clinical manifestations, such as hypermetabolism, weight loss, early satiety, and left upper quadrant abdominal discomfort, are also caused by splenomegaly ([88]). Occasional patients may achieve a CR with splenectomy, and these patients may have a pure “splenic” form of HCL ([2], [145]). Approximately two-thirds of patients have a hematologic response with splenectomy; this results in an improvement in the quality of their lives. In addition, splenectomy also alleviates early satiety, weight loss, and abdominal discomfort ([5]). However, it is unclear whether this procedure prolongs survival, as all the studies are retrospective, and, because of the obvious clinical benefit of splenectomy, randomized prospective trials have not been carried out ([5]). Early studies, with small numbers of patients, demonstrated no overall improvement in survival for patients after splenectomy ([195], [196]). However, in a large, multicenter retrospective analysis of 391 patients, a highly significant survival advantage (p <.0001) was demonstrated for those patients who underwent splenectomy ([197]). In the multicenter analysis, a CR, defined as a postsplenectomy hemoglobin greater than 110 g/L, neutrophils greater than 1 × 10 ^{9}/L, and platelets greater than 100 × 10 ^{9}/L, was achieved in 40% of patients ([197]). An increase was noted in the hemoglobin in 92%, neutrophils in 84%, and platelets in 92% of patients ([197]). Jansen et al. ([197]) also reported that patients with larger spleens responded better than those with smaller spleens, but this has been disputed ([198]). The duration of response after splenectomy is variable, but some patients remain asymptomatic for years. Approximately one-third, however, achieves only a minimal response or relapse within a few months. In an analysis of prognostic variables after splenectomy in 194 patients, the most important were bone marrow cellularity and the platelet count ([199]). *Failure-free survival*, defined as time from splenectomy to death or the need for more therapy, was significantly worse if the postoperative bone marrow cellularity was greater than or equal to 85% or the platelet count was less than 60 × 10 ^{9}/L, or both ([199]).

Although splenectomy is now rarely required in HCL, it may be of value for (a) patients with splenic rupture; (b) patients with the pure “splenic” form of the disease; and (c) patients with splenomegaly and profound thrombocytopenia, having megakaryocytes in the marrow ([5]).

Interferon-a

IFN-a, both the natural form and the two recombinant forms (IFN-a2a and IFN-a2b), is effective in the treatment of HCL ([192], [200], [201], [202], [203], [204], [205], [206], [207] and [208]), and a recent study has provided insight into the mechanism for this activity ([209]). IFN-a has been shown to induce apoptosis in nonadherent hairy cells; this is related to an increase in the production of TNF by the hairy cells associated with sensitization of the hairy cells to TNF-a ([209]). The sensitization is due to a decrease in the levels of inhibitors of apoptosis by IFN-a. Interestingly, IFN-a does not induce apoptosis in hairy cells adhering to vitronectin or fibronectin, because IFN-a does not affect the inhibitors of apoptosis in adherent cells. The receptors for TNF-a are not changed by IFN-a. These results may explain why IFN-a can clear hairy cells rapidly from the bloodstream, but not from the tissues, in which the leukemic cells presumably are adherent.

After the observation that remissions could be obtained with IFN-a, it became necessary to define responses ([192]). A CR was defined as normalization of the peripheral blood counts (hemoglobin >120 g/L, platelets >100 × 10 ^{9}/L, and neutrophils >1.5 × 10 ^{9}/L) with less than 5% hairy cells in the marrow ([192]). A PR was defined as the normalization of peripheral blood counts and the persistence of more than 5% hairy cells in the marrow; however, treatment must have produced a greater than 50% fall in the hairy cell infiltration in marrow ([192]). The aggregate results of 13 studies show that the overall response rate with IFN-a is approximately 80%, with 13% having a CR and 69% having a PR ([192], [207], [208] and [209]). Responding patients have a reduced incidence of infections, even if they remain neutropenic ([200], [201] and [202], [205]). The responses occur rapidly, regardless of whether the patients have previously had a splenectomy, with hairy cells disappearing from the

peripheral blood within the first week; the platelet counts return to normal within 2 months, the hemoglobin level within 4 months, and the neutrophil counts within 4 to 6 months ([200], [205]). The percentage of hairy cells in the bone marrow decreases, but they rarely disappear completely, and the reticulin fibrosis persists ([210], [211]). Patients with $CD5^+$ hairy cells ([212]) and HCL-variant patients ([160]) respond poorly to IFN-a.

The optimal dose schedule to maximize response and prevent relapse has yet to be established. In most series, the dose is 2 to 4 × 10^6 U/m^2 SC three to seven times weekly for 12 months. Higher doses do not appear to increase the response rate and are associated with more severe toxic reactions ([204], [213]). In addition, extending the treatment beyond 12 months does not improve the response rate, and the development of a chronic fatigue syndrome is more prevalent and severe ([214]). Doses 1 log lower (2 × 10^5 U/m^2 three times weekly) show activity, but the response is inferior to that achieved with higher IFN-a doses ([215]). However, the relapse rate is high (33 to 77%) after the discontinuation of IFN-a, usually 6 to 31 months after cessation of therapy ([192], [206], [216]). It has been demonstrated that maintenance low-dose IFN-a (1 × 10^6 U, three times/week, or 3 × 10^6 U, once a week) can prolong remissions with minimal toxicity ([209], [217], [218]). In one study, patients received either no maintenance therapy or 1 × 10^6 U IFN-a three times/week; 37 of the 56 patients who did not receive maintenance therapy relapsed in a median time of 19 months, whereas none of the 28 patients receiving maintenance therapy relapsed, with the median follow-up time being 30 months ([217]). When patients relapse after IFN-a therapy, a further remission can generally be obtained with IFN-a ([217], [218]) or the nucleoside analogs ([192], [193] and [194]). In addition, patients who relapse after therapy with the nucleoside analogs respond to IFN-a, confirming the lack of cross-reactivity between these agents ([219]).

Neutralizing anti-IFN antibodies appear to develop in one-third of patients treated with IFN-a2a ([220]), but this does not occur with IFN-a2b ([221]). The clinical significance of these neutralizing antibodies and their role in the induction of resistance to therapy are controversial. In 51 patients with HCL treated with INF-a2a, 31 (61%) developed antibodies after a median of 6 months of therapy, and in 16 of these, the antibodies neutralized the antiviral activity of recombinant INF-a2a *in vitro* but had no effect on natural IFN-a ([220]). Interestingly, six of the patients with antibodies were clinically resistant to IFN-a, whereas none of the patients without antibodies were resistant. However, in a follow-up study, no further patients were noted to have developed antibodies, and antibodies to IFN could no longer be detected in patients who previously had antibodies, although they continued to receive IFN-a ([222]).

Virtually all patients experience toxicity with IFN-a therapy, and the frequency and severity are dose and age related ([192], [200], [201], [202], [203], [204], [205] and [206], [213]). Flulike symptoms occur in most patients with the initiation of treatment; these symptoms can usually be controlled with acetaminophen or by reducing the IFN-a dosage, and symptoms usually resolve within 2 to 4 weeks. Less common symptoms include nausea and vomiting; diarrhea; central nervous system manifestations such as somnolence and confusion; cardiovascular disorders including hypotension and tachycardia; and skin changes such as rash and pruritus ([213]). With high doses, leukopenia, thrombocytopenia, and anemia may occur, but this is rare with the doses of IFN-a used for HCL. A worsening of preexisting autoimmune disorders, or the emergence of new autoimmune problems, has also been reported with IFN-a therapy; this appears to be related to the development of multiple autoantibodies ([223]). In most reports, patients developed thyroiditis, autoimmune thrombocytopenia, or anemia ([224], [225]). Kampmeier et al. ([226]) reported an increased incidence of second malignancies in HCL patients treated with IFN. Of 69 patients treated with IFN-a2b for 12 to 18 months, 13 (19%) developed second malignancies; this incidence was substantially higher than predicted. Six of the tumors were hematologic, and seven were adenocarcinomas. The tumors developed 17 to 105 months after the initiation of IFN-a. However, these results have not been confirmed, and no increase in the incidence of second malignancies was observed in 200 HCL patients in another study, of which 147 had been treated with IFN-a ([227]).

Nucleoside Analogs

The nucleoside analogs dCF (pentostatin; Nipent, SuperGen, San Ramon, CA), CdA (cladribine; Leustatin, Ortho Biotech, Raritan, NJ), and fludarabine (F-ara-A AMP; Fludara, Berlex Laboratories, Richmond, CA) have significant activity in the low-grade lymphoid malignancies (Fig. 93.4) ([192], [193] and [194]). Both dCF and CdA have now replaced IFN-a as first-line therapy for HCL, and fludarabine is now one of the standard treatments for CLL.

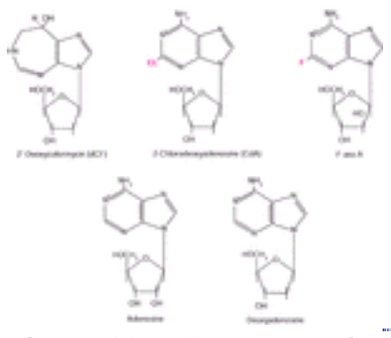

Figure 93.4. Structures of nucleoside analogs.

After therapy with dCF, deoxyadenosine and adenosine accumulate in the plasma; after uptake into cells, deoxyadenosine is phosphorylated to deoxyadenosine monophosphate, deoxyaden-osine diphosphate, and deoxyadenosine triphosphate (dATP); this occurs preferentially in lymphocytes ([228]). The intracerebral accumulation of deoxyadenosine and adenosine likely causes the nausea and vomiting that are a major toxicity of this agent ([229]). CdA and F-ara-A are halogenated derivatives of deoxyadenosine that are resistant to degradation by adenosine deaminase. For clinical use, F-ara-A is administered as the more water-soluble monophosphate, F-ara-AMP (fludarabine), which is rapidly dephosphorylated in the plasma to F-ara-A ([230], [231]). Like deoxyadenosine, CdA and F-ara-A accumulate in lymphocytes as their phosphorylated derivatives and can kill lymphocytes in three ways (Fig. 93.5 and Fig. 93.6) ([232], [233]). First, the triphosphate forms can trigger DNA breaks, which result in the release of cytochrome *c* from the mitochondria; the released cytochrome *c* interacts with Apaf-1 and dATP, causing the activation of caspase 9 and, subsequently, apoptosis. Second, the increased levels of triphosphates can enhance the effects of endogenous dATP on the apotosome, inducing apoptosis. Finally, CdA differs from the other two drugs in that it is phosphorylated by deoxyguanosine kinase in the mitochondria to CdATP, which is directly toxic to the mitochondria.

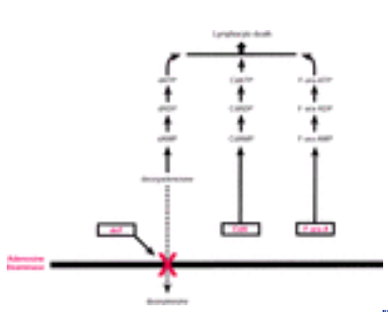

Figure 93.5. Metabolism of the nucleoside analogs. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; CdA, 2-chlorodeoxyadenosine; d, deoxy; dCF, 2'-deoxycoformycin.

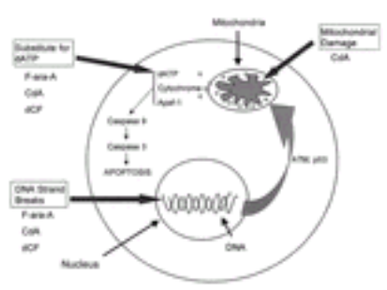

Figure 93.6. Mechanism of action of the nucleoside analogs. CdA, 2-chlorodeoxyadenosine; dATP, deoxyadenosine triphosphate; dCF, 2'-deoxycoformycin. (Modified from Genini D, Adachi S, Chao Q, et al. Deoxyadenosine analogs induce programmed cell death in chronic lymphocytic leukemia cells by damaging the DNA and by directly affecting the mitochondria. Blood 2000;96:3537–3543, with permission.)

dCF is highly effective in HCL and produces a much higher rate of durable CR than is observed with IFN-a (Table 93.6) ([234]). dCF has been administered in a variety of different doses and schedules for HCL, but regardless of the mode of administration, it produces responses in most patients. Of 960 patients in nine studies, the CR rate ranged from 44 to 89% (median, 76%), and the PR rate varied from 0 to 52% (median, 16%) ([234], [235], [236], [237], [238], [239], [240], [241] and [242]). Patients who relapse after splenectomy or who are resistant to IFN-a also respond to dCF, with a median CR rate of 42% and a PR rate of 45% ([242], [243] and [244]). In two large studies, the response rates to dCF were similar in untreated patients and in patients treated with IFN-a ([234], [241]). Moreover, these studies identified young age, initial high hemoglobin, high white cell count, and little or no splenomegaly as favorable prognostic features ([234], [241]). The most commonly used treatment regimen is dCF 4 mg/m ^{2} every second week; the average number of treatments to CR is 8 (range, 4 to 15) ([234], [237]). The peripheral blood lymphocyte count falls rapidly after the initiation of treatment, with the hairy cell count decreasing by 50 to 95% in the first week ([245]). Concomitantly, there is a rapid increase in platelets followed by recovery of neutrophils and hemoglobin; the median time to documented peripheral and marrow CR is 4 months ([245]). In contrast to IFN-a, there is resolution of the marrow fibrosis after therapy with dCF ([245], [246]). Using immunophenotyping of peripheral blood or bone marrow, immunohistochemistry of the bone biopsy, or gene rearrangement studies, one can detect residual hairy cells in HCL patients who are in morphologic CR after dCF, suggesting that dCF cannot entirely eliminate the hairy cell population ([246], [247]). In addition, relapses are observed after discontinuation of treatment without evidence of a plateau, although there is no correlation between the extent of residual disease and the time to relapse. However, the duration of remissions is considerably longer than for IFN-a ([234], [238], [245], [248], [249] and [250]).

TABLE 93.6. Response Rates of Standard Treatments for Hairy Cell Leukemia

Drug	Author (Reference)	Dose and Schedule	Number of Patients	Complete Response (CR) (%)	Partial Response (%)
Interferon-a	Spielberger (216)	2 × 10 ^{6} U/m ^{2} SC; 3 ×/wk for 12 or 18 mo	68	13	62
	Grever (234)	3 × 10 ^{6} U SC; 3 ×/wk for 12 mo	159	11	27
	Rai (208)	2 × 10 ^{6} U SC; 3 ×/wk for 12 mo	55	24	49
2'-Deoxycoformycin	Spiers (236)	5 mg/m ^{2} IV daily × 2; repeated every 14 days until CR	27	59	37
	Johnston (235)	Cycles (4 mg/m ^{2} IV/wk × 3); q8wk until CR + 2 further cycles	28	89	11
	Grever (234)	4 mg/m ^{2} IV q2wk; until CR + 2 to max 12 mo	154	76	3
	Maloisel (241)	4 mg/m ^{2} IV q2wk until max response or failure	230	79	16
2-Chlorodeoxyadenosine	Cheson (264)	0.1 mg/kg/day cont IV × 7 days	861	50	37
	Saven (265)	0.1 mg/kg/day cont IV × 7 days	349	91	7
	Juliusson (276)	3.4 mg/m ^{2} SC daily × 7 days	73	81	14
	Robak (275)	0.1 mg/kg/day IV over 2 h × 5 or 7 days	23	83	17
	Lauria (279)	0.15 mg/kg IV over 2 h weekly × 6	30	73	27

cont, continuous; max, maximum.

A number of studies have evaluated the long-term outcome of patients treated with dCF ([240], [241], [249], [250], [251], [252] and [253]) (Table 93.7). The longest follow-up is provided by the National Cancer Institute of Canada study, in which 28 patients have been followed for a median of 125 months (range, 61 to 137 months) ([252]). Nine (36%) of the 25 patients who achieved a CR have relapsed at a median time of 49 months (range, 15 to 122 months). The largest study was a phase III intergroup study, in which patients were randomized to receive dCF, 4 mg/m ^{2} IV every 2 weeks, or IFN-a, 3 × 10 ^{6}U SC three times a week ([234], [253]). Patients not responding to one treatment were switched to the other agent. Two hundred and forty-one patients received dCF and have been followed for a median of 9.3 years; 154 received dCF as initial therapy, and 87 received dCF after failure with IFN-a. For all patients, the estimated 5- and 10-year survivals were 90 and 81%, similar to those predicted for the general population. The survival was similar whether patients were treated initially with dCF or were crossed over to dCF after treatment with IFN-a (Fig. 93.7A). Patients younger than 55 years of age did significantly better than patients 55 years of age or older, and the 10-year survivals for the two groups were 93 and 68%, respectively (Fig. 93.7B). Similarly, in a large multicenter retrospective study from France, the estimated survivals at 5 and 10 years in 230 evaluable patients treated with dCF were both 89% ([241]). In that study, a hemoglobin less than 100 g/L, a white cell count less than 2 × 10 ^{9}/L, and lymphadenopathy were associated with decreased survival.

TABLE 93.7. Long-Term Follow-Up of Patients with Hairy Cell Leukemia

Drug	Author (Reference)	Number of Patients	Number Alive	Median Follow-Up Months (Range)	Number of Relapses after Complete Response (%)	Median Complete Response Duration for Relapsed Patients (Mo)
Interferon-a	Grever (234)	159	152	57 (19–82)	12 (70)	(9–27)
2'-Deoxycoformycin	Kraut (249)	24	23	82 (54–104)	11 (48)	30 (7–80)
	Dearden (251)	165	NA	71 (6–139)	40 (24)	51.5 (14–105)
	Johnston (252)	28	23	125 (61–137)	9 (36)	49 (15–122)
	Flinn (253)	241	201	112 (19–139)	32 (18)	NA
	Maloisel (241)	238 [a]	213	63.5 (0.39–138.4)	26 (14.3)	56 (11–89)
2-Chlorodeoxyadenosine	Hoffman (266)	49	NA	55	6 (16)	19 (12–55)

[c] Only 50 evaluable for response.

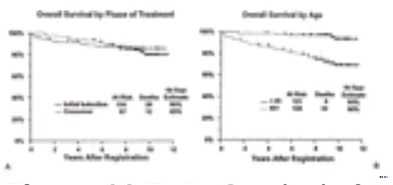

Figure 93.7. A: Survival of patients treated initially with 2'-deoxycoformycin (dCF) or after crossover from interferon-a. Survival is similar in both groups (*p* = .59). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for dCF therapy, by phase of treatment. **B:** Overall survival by age of patients treated with dCF. Survival is significantly better for patients younger than 55 years of age (*p* <.0001). Figure shows estimated distributions of overall survival (Kaplan-Meier estimates) from date of registration for dCF therapy, by age at start of initial therapy. (From Flinn IW, Kopecky KJ, Foucar MK, et al. Long-term follow-up of remission duration, mortality, and second malignancies in hairy cell leukemia patients treated with pentostatin. Blood 2000;96:2981–2986, with permission.)

dCF is generally well tolerated, although nausea and vomiting and lethargy can occur ([234], [235], [236], [237], [238], [239], [240], [241] and [242]). Drug-induced neutropenia with fever commonly occurs with initiation of treatment ([235], [248]), and deaths from infection have occurred ([248]). However, for patients receiving 4 mg/m ^{2} dCF every 2 weeks, infections can be avoided by delaying the treatments if the white blood count is less than 1.5 × 10 ^{9}/L ([237]). dCF decreases the number of T cells to a greater extent than that of B cells, and CD4 $^+$ cells are affected to a greater extent than CD8 $^+$ cells or NK cells, whereas Ig levels are not affected ([246], [254], [255] and [256]). The CD4 $^+$ and CD8 $^+$ cell counts fall to less than 0.2 × 10 ^{9}/L during therapy ([246], [254], [255]); after discontinuation of dCF, the CD4 $^+$ counts gradually recover and normalize in 3.0 to 49.5 months (median, 14.5 months) ([246]). The CD8 $^+$ and B cells recover at the same rate ([246], [254], [255]). Associated with the decrease in T cells during therapy is an increase in the incidence of herpetic infections, which are easily treated with acyclovir, and there is a gradual decrease in the incidence after discontinuation of therapy ([246], [254], [255]). However, there is no increase in more unusual opportunistic infections, either during therapy or during long-term follow-up, and there is no evidence of a significant increase in second malignancies ([249], [250]). Although neurotoxicity is a problem with high doses of dCF ([257]), the major neurologic problems encountered with the doses of dCF used in HCL are nausea and vomiting and somnolence ([234], [235], [236], [237], [238], [239], [240], [241] and [242]).

CdA appears to have activity equivalent to that of dCF in HCL, and it has the advantage of rarely causing nausea and vomiting (Table 93.6) ([258], [259], [260], [261] and [262]). In initial studies, CdA was administered by continuous infusion, as *in vitro* studies indicated that a prolonged exposure to CdA was required for cytotoxic effect ([263]). Thus, most early clinical trials in HCL used CdA 0.1 mg/kg/day by continuous infusion for 7 days ([263]). From eight studies comprising 1552 patients, the CR rate ranged from 50 to 91% (median, 78%), and the PR rate varied from 0 to 37% (median, 16%) ([258], [259], [260], [261] and [262], [264], [265] and [266]). As with dCF, there was a rapid recovery in blood counts, with the platelet count increasing almost immediately, followed by an increase in neutrophils and hemoglobin ([258], [259], [260], [261] and [262]). Some patients achieved a CR with normal blood counts, whereas the marrows remained hypocellular ([267]). Technetium 99m sulfur colloid scans have demonstrated increased uptake in the distal appendicular skeleton in some of these patients, suggesting abnormal areas of hematopoiesis ([267]). Although hairy cells may not be seen in the marrow 3 to 4 months after CdA treatment ([262], [263]), the leukemic cells can still be detected by immunostaining, using the monoclonal antibody, DBA.44 ([267], [268]), or by using the polymerase chain reaction with clonospecific probes for heavy-chain Ig genes ([269]). When marrows were intermittently examined by DBA.44 for 25 months after treatment with CdA, there was no increase in the number of hairy cells in the marrow in most cases, suggesting stabilization of residual disease ([268]). However, others have suggested that the presence of residual disease is predictive of relapse ([270]). As CdA was developed after dCF, there is less information related to the long-term effectiveness of CdA as compared to dCF ([251], [262], [265], [266], [271]) (Table 93.7). However, Dearden et al. ([251]) have found that relapses occur significantly earlier in patients treated with CdA compared to those treated with dCF (Table 93.7). In a large long-term study from the Scripps Clinic, 91% of patients achieved a CR with CdA, and these 349 patients were followed for a median of 52 months (range, 1 to 134 months) ([265]). Twenty-four percent of these patients relapsed at a median time of 30 months (range, 7 to 85 months). The overall survival at 48 months was 96%.

A number of patients who were resistant to dCF have obtained remissions with CdA, suggesting a possible lack of cross-resistance between these agents ([241], [272]). This may be related to the additional action of CdA on the mitochondria of the leukemia cells ([232], [233]).

There has been interest in investigating different modes of CdA administration to simplify the treatment and minimize toxicity. Liliemark et al. ([273]) demonstrated an identical “area under the curve” for drug concentration versus time using the same CdA concentration given by continuous infusion, as a 2-hour infusion, or given orally using twice the IV dose. Similar responses have been obtained with CdA in HCL using 0.1 mg/kg IV over 2 hours daily × 5 ([274], [275]) or 0.1 mg/kg SC daily × 7 ([276], [277]) and when the drug was administered as 0.1 mg/kg/day by continuous infusion × 7. In addition, lower doses of CdA (e.g., 2 mg/m ^{2} SC daily × 5) ([278]) or altered schedules (e.g., 0.15 mg/kg IV each week) ([279], [280]) appear to be as effective and less toxic than the traditional schedule of CdA ([258], [259], [260], [261] and [262], [264], [265] and [266]). In particular, the weekly regimen is associated with significantly less myelosuppression and risk of infection and hospitalization than the continuous infusion regimen, with efficacy equivalent to that of the standard regimen ([279], [280]).

CdA can be toxic and was implicated as the cause of deaths in the National Cancer Institute group C phase II study in 1.1% of 979 patients ([264]). The major CdA toxicity is marrow suppression, and one-third to one-half of patients develop severe neutropenia with infections and often required prolonged blood support after therapy ([258], [259], [260], [261] and [262], [264], [265] and [266], [281]). This problem is not prevented by prophylactic antibiotics, and, although an infectious cause for the fever is not found in most cases, affected patients usually require hospitalization for septic work-up and antibiotics ([264], [278]). The likelihood of this complication occurring increases with the severity of initial marrow involvement, and it has been suggested that these patients should initially be treated with IFN-a ([281]). Alternatively, to reduce the risk of infections, granulocyte colony-stimulating factor has been administered using 5 µg/kg/day SC on days -3, -2, and -1 before a standard 7-day course of CdA, and then after CdA until the neutrophil count was above 2 × 10 ^{9}/L for 2 consecutive days ([282]). Although granulocyte colony-stimulating factor increased the neutrophil count before therapy and reduced the severity of neutropenia after CdA, there was no decrease in the number of febrile episodes and the number of hospitalizations for antibiotics. An identical phenomenon is observed after treatment of HCL with dCF ([235], [248]), and it has been suggested that the fever is related to tumor lysis and the release of cytokines by the tumor ([261]). However, infections, sometimes opportunistic, do occur in some of these patients, and deaths have been reported ([260], [278]). Like dCF, CdA produces a profound fall in CD4 $^+$ and CD8 $^+$ cells after treatment, and although CD8 $^+$ cell counts may recover within 3 months, the CD4 $^+$ count may take longer than 3 years to normalize ([283], [284]). Despite this, there have, to date, been no long-term problems with opportunistic infections after therapy with CdA ([256], [261]). Significant neurotoxicity has also been observed with CdA and includes neuropathies affecting the legs or arms ([264]). Transfusion-associated graft-versus-host disease has been observed with multiple cycles of CdA or fludarabine in low-grade lymphomas and CLL ([285], [286]), but, to the author's knowledge, this has not yet been observed in HCL.

Fludarabine has not yet been evaluated extensively in HCL. However, complete and partial responses have been observed in the few patients treated so far ([287], [288]).

Monoclonal Antibodies

Monoclonal antibody therapy is an attractive option for HCL, as many of these patients have significant neutropenia at the time of diagnosis; in contrast to chemotherapy, this should not be worsened by antibodies. The chimeric monoclonal antibody rituximab (Rituxan; Genentech, Inc., South San Francisco, and IDEC Pharmaceuticals, San Diego, CA) contains a human IgG1 Ig constant region and a murine variable region directed against the cell-surface CD20, an antigen that plays an important role in the activation, proliferation, and differentiation of B cells ([289]). This agent has shown significant activity against the low-grade lymphomas, which have high surface concentrations of CD20, and is believed to exert its antitumor activity through activation of complement (complement-mediated cytotoxicity), antibody-dependent cell-mediated cytotoxicity, or the direct induction of apoptosis ([289], [290] and [291]). In two preliminary studies, rituximab, 375 mg/m ^{2} IV once a week for 4 weeks, produces a response rate of approximately 50% in HCL patients with relapsed or progressive disease, with a variable number of these being CRs ([292], [293]).

Kreitman and colleagues have developed two immunotoxins, LMB-2 and BL22, directed against CD25 and CD22, respectively ([294], [295] and [296]). LMB-2 contains the variable heavy and light chain regions against CD25 linked to a truncated *Pseudomonas* exotoxin, and cell death is induced once the exotoxin is internalized ([294], [295]). Of four nucleoside-resistant HCL patients, one achieved a CR and three a PR with LMB-2 ([294], [295]). Sixteen CdA-resistant HCL patients were treated with BL22, and 11 achieved a CR and 2 a PR ([296]). Interestingly, 7 of the 11 complete responders had never achieved a CR with the nucleoside analogs, and none of the other

4 patients had achieved a CR longer than 6 months with CdA. Moreover, all three patients with the HCL variant achieved a CR with BL22. With a median follow-up of 16 months (range, 10 to 23 months), 3 of the 11 patients relapsed, and all had a second CR with retreatment.

OTHER TREATMENTS As HCL is now so easily and effectively treated with the nucleoside analogs, IFN-a, or the monoclonal antibodies, other treatments have become redundant. However, for completeness and interest, they are reviewed briefly. Chlorambucil was most frequently used when the disease progressed after splenectomy ([297], [298]). Although some patients improved, the course in others was often worse, with more myelosuppression. The best results were reported by Golomb et al. ([298]), who administered chlorambucil, 4 mg orally/day for at least 6 months, to 24 postsplenectomy patients with progressive disease. A reduction in the number of circulating hairy cells and an increase in one or more of the normal peripheral blood cellular elements occurred in most patients. Six deaths occurred, and time to response was 6 months or longer. Other chemotherapeutic agents, either alone or in combination, have demonstrated some benefit, but the toxic effects were often severe ([299], [300]). These agents included doxorubicin ([301]), rubidazone ([302]), combinations of rubidazone, cytarabine, and cyclophosphamide, or cytarabine and cyclophosphamide ([303]). PRs also have been reported with androgens ([304], [305]), as well as with a combination of lithium carbonate and immunotherapy with Calmette-Guérin bacillus ([306]). A transient increase in neutrophils can be obtained with granulocyte colony-stimulating factor and may be a useful adjunct to more definitive therapy ([282], [307]). Steroids are ineffective and increase the risk of infection ([4]).
BONE MARROW TRANSPLANTATION One case of successful bone marrow transplantation from an identical twin has been reported ([309]).
LEUKAPHERESIS Clinical and hematologic improvements, lasting as long as 26 months, have been reported by using leukapheresis to reduce the number of hairy cells in the peripheral blood ([309], [310]). However, others have found the responses less predictable and more transient ([311]).
RADIATION THERAPY Low-dose radiotherapy to the spleen can produce transient clinical and hematologic improvements, but the response is slow and unpredictable ([312]). However, radiation therapy can be effective for the treatment of massive retroperitoneal lymphadenopathy and lytic bone lesions ([313]).

SUMMARY

Patients with HCL may not require therapy for many years but should be considered for treatment if they are symptomatic or if there is significant pancytopenia (hemoglobin <110 g/L, platelets <100 × 10^9/L, or neutrophils <1 × 10^9/L).

The standard therapy for HCL is with one of the nucleoside analogs, dCF or CdA, which appear to have equal efficacy and produce CRs in the majority of patients. The greatest experience has been with dCF, which is usually administered as 4 mg/m^2 IV every second week until CR, followed by two additional treatments for consolidation. The majority of patients achieve a CR with this drug, and the 5- and 10-year survivals are similar to those of the control population. CdA appears to have similar efficacy as dCF and traditionally has been administered as 0.1 mg/kg/day × 7, by continuous infusion. However, the drug appears to be equally effective when administered as daily 2-hour infusions or SC, or on a weekly schedule. Because of the effectiveness of dCF and CdA in HCL and the rarity of this disease, it is unlikely that there will be any prospective studies to compare the efficacy of these two agents and the different treatment regimens.

The major toxicity with the nucleoside analogs is myelosuppression and the risk of infections with initiation of treatment. This is most common in patients with severe marrow impairment; in such cases, it might be preferable to use IFN-a initially to obtain marrow clearing before treatment with a nucleoside analog. Alternatively, weekly CdA might be preferable to the standard 5- or 7-day schedule. The blood counts should be followed closely during and after therapy and with weekly CdA or biweekly dCF; treatments can be held until the neutrophil count has recovered from the previous treatment. Whereas the less-intensive induction regimens can significantly reduce the risk of neutropenic sepsis with initiation of treatment, it is unknown whether these regimens reduce the likelihood of long-term remissions. A morphologic CR can be obtained in approximately 75% of patients and a PR in 15% of cases, although residual hairy cells can invariably be detected by immunostaining, even with a morphologic CR. Remissions are prolonged, and relapsing patients respond to a second cycle of therapy. It is unclear whether survival is longer for patients who achieve a CR or a PR. Response to CdA and dCF is poorer for patients with the HCL variant and for those with bulky abdominal lymphadenopathy ([314]). Prognosis for patients treated with dCF is worse for those older than 50 to 55 years of age and those with a hemoglobin less than 10 g/L and white cell counts less than 2 × 10^9/L ([241], [253]). Both dCF and CdA should be used with caution in the presence of renal or hepatic dysfunction.

IFN-a (3 × 10^6 U SC three times/week for 12 months) produces a lower response rate than the nucleoside analogs (8% CR and 74% PR), and relapses occur after discontinuation of the drug. However, IFN-a may be useful initially in patients with an active infection or severe neutropenia.

Initial studies with the monoclonal antibodies against CD20, CD22, and CD25 suggest that these agents may be useful for the treatment of patients refractory to the nucleoside analogs, for patients with a poor marrow reserve, and for patients with the HCL variant.

Two-thirds of patients benefit from splenectomy, but a CR is rare. Splenectomy is required for patients who have a splenic rupture and may be of value for patients with pure “splenic” HCL, as well as for patients who have severe thrombocytopenia with increased numbers of megakaryocytes in the marrow.

SECOND MALIGNANCIES

There has been controversy as to whether patients with HCL have an increased incidence of malignancies and whether this may be related to therapy ([241], [253], [264], [265], [315], [316], [317], [318], [319] and [320]). A number of studies have demonstrated an increased incidence of second tumors in HCL, and the incidence appears to be highest in the first 2 years after diagnosis. However, the increase may occur before the diagnosis of HCL, or concurrently, suggesting that these patients have an inherent tendency to develop second malignancies ([315], [316] and [317]). Kampmeier et al. ([316]) demonstrated that 19% of 69 patients observed for a median of 91 months after treatment with IFN-a developed a second malignancy, and the authors suggested that the increased incidence was related to the more prolonged survival of these immunocompromised patients rather than an effect of the IFN-a. However, it has been observed more recently that the incidence of second malignancies is less when patients are treated with dCF or CdA than with IFN-a, suggesting that the second malignancies may be directly related to active HCL ([319]). In 349 patients treated with CdA and a median follow-up of 58 months, 8% developed a second malignancy (primarily solid tumors), a rate 1.8–1.9-fold higher than expected ([265]). However, Kurzrock et al. ([319]) observed a 7.4% incidence of second malignancies in 350 HCL patients after a mean follow-up of 7.1 years, and this incidence was not significantly greater than expected and was not influenced by treatment with IFN-a or the nucleoside analogs. Others have made similar observations ([241], [253]). In a large multicenter prospective crossover study with dCF and IFN-a and a median follow-up of 112 months, there was no increase in the number of second malignancies as compared to that of the control population ([253]).

PROGNOSIS

Before the availability of IFN-a and the nucleoside analogs, the median survival of HCL patients followed by Bouroncle ([2]) was 4.6 years for nonsplenectomized patients and 6.9 years for splenectomized patients, although the range of survival was very broad, with a few patients surviving for a couple of decades from the time of diagnosis. However, prognosis for HCL patients has improved markedly with present therapies, and the predicted 5- and 10-year survival rates for patients treated with dCF are now similar to those of the general population ([253]). It appears likely that a similar survival benefit will be seen with CdA. However, long-term follow-up is required to determine the relapse rate, the percentage of patients who become resistant to the nucleoside analogs and, subsequently, the monoclonal antibodies, and whether there will be long-term complications from these treatments.

Cutaneous T-Cell Lymphomas: Mycosis Fungoides and Sézary Syndrome

Cutaneous lymphomas are a heterogeneous group of non-Hodgkin lymphomas (NHLs) of T- and B-cell origin where the skin is the primary organ of involvement. Primary cutaneous lymphomas usually present without signs of extracutaneous malignancy at onset of symptoms; they represent an entity distinct from nodal lymphomas with secondary cutaneous involvement. In 1975, Lutzner, Edelson, and associates introduced the term *cutaneous T-cell lymphoma* (CTCL) to describe the spectrum of skin-based lymphomas of T-cell origin, including classic mycosis fungoides (MF) and Sézary syndrome (SS) ([1], [2]). This chapter is a review of the history, epidemiology, clinicopathologic features, and therapy of these lymphomas.

HISTORICAL PERSPECTIVE

Clinical Description

The first clinical description of MF was in 1806 by Alibert, a French physician, who identified a 56-year-old man with skin tumors resembling mushrooms after having a desquamating rash over several months; the lesions waxed and waned for 5 years before the patient died with a “hectic” fever ([3]). In 1832, Alibert first used the term *mycosis fungoïde* to describe the mushroom-like tumors in his treatise on diseases of the skin ([4]). Bazin described the three classic cutaneous stages in 1870: (a) the premycotic stage, which can be localized or diffuse with superficial eczematous or erythematous lesions; (b) the infiltrative plaque stage; and (c) the tumor stage ([5]). The mycosis *d'emblée* variant was described by Vidal and Brocq in 1885 in which tumors rapidly develop without a preceding premycotic or plaque stage ([6]). In the early 1890s Besnier and Hallopeau described the erythrodermic variant, which later became known as SS ([7], [8]).

Histopathology

By the end of the 19th century, most authorities agreed that the small round cells infiltrating the epidermis and forming tumors were lymphoid in origin ([9]). Although the French authorities considered the disease lymphadenomatous in nature, the German, English, and American authorities were divided between sarcomatous and granulomatous (infectious) etiologies ([9], [10]).

The unique appearance of the cells involved in CTCL was identified in 1938 by Sézary and Bouvrain, who reported a triad of erythroderma, leukemia with circulating mononuclear cells that had convoluted nuclei, and adenopathy infiltrated with the same cells ([11]). In the 1950s, SS was recognized in the English literature by several groups but was not described in the American medical literature until 1961 by Taswell and Winkelmann at the Mayo Clinic ([12], [13]). In 1968, Lutzner and Jordan extended the light microscopic description of the Sézary cell by using electron microscopy to visualize the serpentine or cerebriform cell nucleus ([14]).

Immunology

The 1970s witnessed the introduction of cellular immunology into the study of hematopoietic neoplasms and in 1971 Crossen et al. confirmed the lymphocyte origin of SS ([15]). In 1973, Broome et al. ([16]) and Brouet et al. ([17]) identified the neoplastic cell as a T cell, and Broder et al. demonstrated in 1976 that the cells usually are of the helper phenotype ($CD4^+$) ([18]).

Studies performed in the early 1990s further characterized the circulating malignant T cells in patients with SS as “memory” helper T cells due to the expression of $CD45RO^+$ ([19]). In 1992, Vowels et al. detected a cytokine profile similar to that produced by murine Th2 cells from both stimulated peripheral blood mononuclear cells and serum from patients with SS ([20]). Additional studies identified a Th2 cytokine profile [interleukin-4 (IL-4), IL-5, IL-6, IL-10] to be present in the skin of patients with MF and SS ([21], [22] and [23]). Increased levels of IL-4 and IL-5 produced by the malignant T-cell clone may account for the eosinophilia and increased levels of immunoglobulin E (IgE) and IgA in the serum of patients with advanced CTCL ([24]).

Immunologic studies have addressed the pathogenesis of MF and SS by examining the complex interactions among malignant cerebriform T cells, keratinocytes, Langerhans cells, and other immunomodulating cells ([24], [25]). Lymphocytes, malignant and inflammatory, that home to cutaneous sites, differ from lymphocytes in noncutaneous infiltrates by expressing the cutaneous lymphoid antigen (CLA). CLA binds to the endothelial cell adhesion molecule E-selectin that is preferentially induced on cutaneous venules ([19], [26], [27], [28], [29], [30], [31] and [32]). Both circulating and skin-based malignant T cells from patients with MF and SS have been shown to

express CLA, which may explain how the cells preferentially home into the skin (Fig. 94.1) ([19] , [28] , [29] , [30] and [31]).

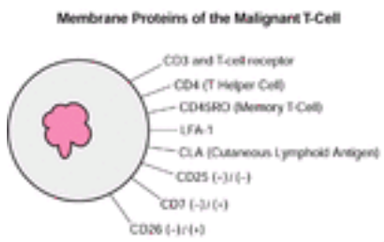

Figure 94.1. Membrane proteins of the malignant T cell. The cutaneous lymphoid antigen (CLA) is a membrane protein expressed by a vast majority of T cells found in inflamed skin, including cutaneous T-cell lymphoma. BE-2 is a tumor-related antigen late activation marker expressed on many cutaneous T-cell lymphoma cells. LFA-1 is a ß $_2$ integrin expressed by all mature white blood cells.

The epidermotropism of the malignant T cell is partially explained by the discovery of increased expression of intercellular adhesion molecule-1 (ICAM-1) by epidermal keratinocytes in early MF lesions ([33]). The binding of ICAM-1 to a lymphocyte function–associated protein expressed by lymphocytes may explain the histologic finding of atypical lymphocytes nesting within the epidermis ([34]). Some authorities speculate that the expression of ICAM-1 by keratinocytes is induced by the release of interferon-? (IFN-?) from infiltrating CD8 $^+$ T cells or natural killer (NK) cells responding to the malignant T-cell population within the dermis (Fig. 94.2) ([24] , [25] , [35]).

Figure 94.2. Early cutaneous T-cell lymphoma: mechanisms of epidermotropism. The release of interferon (IFN)-? by early, reactive CD8-cytotoxic T cells or natural killer (NK) cells leads to increased keratinocyte expression of intercellular adhesion molecule-1 (ICAM-1) and release of the C-X-C chemokine IP-10, which binds to the CXCR3 receptor and may lead to nesting of CTCL cells within the epidermis. CXCR3 is preferentially expressed on the Th1 subset of helper T cells.

Adhesion molecules other than ICAM-1 (CD54/CD18) have been implicated in the phenomenon of epidermotropism and include CD58/CD2, B7/CD28, CD49a (VLA-1), CD49c (VLA-3), CD49f (VLA-6), and E-cadherins ([24] , [36] , [37]). Soluble chemotactic factors may also play a role in the epidermotropism of MF. The expression of the CXC chemokine IP-10 (IFN-?–inducible protein-10), which is chemotactic for CD4 $^+$ lymphocytes, has been shown to be markedly increased by basal and suprabasal keratinocytes in MF lesions ([35]). Several studies suggest that, in early MF, epidermal Langerhans cells convert to hyperstimulatory antigen-presenting cells (CD1a $^+$, CD1b $^+$, CD36 $^+$), with a high expression of class II major histocompatibility complex (MHC) molecules and adhesion molecules capable of activating tumor-infiltrating lymphocytes ([24] , [38] , [39] and [40]).

More advanced lesions of MF, characterized clinically as tumors or generalized erythroderma, often demonstrate a loss of epidermotropism with malignant T cells infiltrating the deep dermis ([25]). In 1989, Nickoloff et al. found markedly diminished ICAM-1 expression by keratinocytes from a patient with SS ([33]), and similar findings in tumor-stage patients were reported by Vejlsgaard et al. ([41]). Rook et al. ([25]) have suggested that unknown mechanisms lead to an evasion of the host immune response with subsequent expansion of the malignant clonal population and increased production of IL-4. Increased levels of IL-4 could inhibit the production of IFN-?, leading to decreased ICAM-1 expression by keratinocytes and, thus, reduced binding of malignant T cells within the epidermal compartment ([25]) (Fig. 94.3).

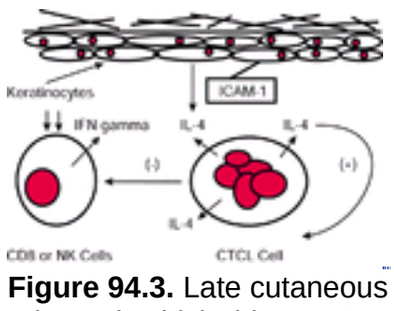

Figure 94.3. Late cutaneous T-cell lymphoma (CTCL): loss of epidermo-tropism. As the clonal population of CTCL cells expands, more interleukin-4 (IL-4) is released, which drives autocrine-induced proliferation of the CTCL cells and inhibition of CD8-cytotoxic T cells and natural killer (NK) cells. The impaired release of interferon (IFN)-? may lead to less intercellular adhesion molecule-1 (ICAM-1) expression and decreased keratinocyte–CTCL cell adhesion.

Recently, CXCR3, a T-cell chemokine receptor, has been shown to be expressed by lymphocytes in early-stage MF but is absent in cases of transformed MF, when epidermotropism is often absent ([42]).

As the disease progresses, cell-mediated immunity, critical for tumor cell recognition and destruction, is slowly dismantled (Fig. 94.4).

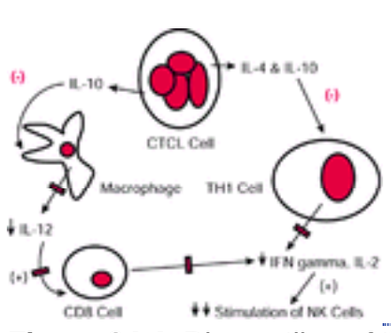

Figure 94.4. Dismantling of the immune system by cutaneous T-cell lymphoma (CTCL). The continued release of interleukin-4 (IL-4) and IL-10 by proliferating CTCL cells may impair cell-mediated immunity by inhibiting the functions of macrophages and Th1 helper T cells critical for tumor recognition and destruction. IFN gamma, interferon-?; NK, natural killer.

IL-4 and IL-10 secreted by the malignant T cell may inhibit Th1 cells responsible for coordinating cell-mediated immune functions ([2] , [25] , [43]). Also, the inhibition of IL-12 secretion from macrophages may diminish the cytokine's stimulatory effect on CD8-cytotoxic T cells ([24] , [25] , [44]). With Th1 cells, CD8-cytotoxic T cells, macrophages, and NK cells partially disabled, the malignant clone can escape immune surveillance and proliferate.

Molecular Genetics

Clonality in T-cell lymphoma was difficult to establish before the development of molecular genotyping methods in the 1980s. Initial evidence of clonality in MF/SS was provided by cytogenetic analysis ([45], [46], [47], [48], [49] and [50]). Several of these early studies demonstrated the same abnormal clone in separate lesions from skin, peripheral blood, lymph nodes, and bone marrow ([46], [48], [50]).

The identification of a defined cytogenetic abnormality would be a major advance in the diagnosis and understanding of the pathogenesis of MF/SS ([51]). Unfortunately, to date, no such abnormality has been identified consistently in MF, with most reported findings being largely of a random nature ([51], [52] and [53]). A few studies have suggested that complex cytogenetic abnormalities are found more commonly on chromosomes 1 and 2 (43% of SS cases) and 6 (38% of SS cases) ([54]) and may involve activation of oncogenes such as ERB-A, K-RAS, V-FPS, ICK, and C-MYC ([52], [54], [55], [56], [57] and [58]). Abnormalities in chromosome 10 have been correlated with progression to tumor stage, including loss of heterozygosity on 10q and microsatellite instability ([59]). In addition, using comparative genomic hybridization, the circulating tumor cells in SS, as opposed to circulating tumor cells in MF, have been shown to have a loss of chromosome 10q25-26, with possible candidate tumor-suppressor genes MXI 1 and DMBT 1 ([60]). Lastly, p16 ^{INK4a}, a protein coded at the 9p21 locus, has been shown to be silenced in tumor-stage MF ([61]).

Overexpression of the tumor-suppressor gene p53 has been detected in some cases of high-grade CTCL, such as cutaneous anaplastic large cell lymphoma (ALCL), but rarely in low-grade CTCL ([58], [62], [63] and [64]). Fracchiolla et al. identified gene rearrangements of the nuclear factor-kappa B (NF-?B) transcription factor LYT-10 (NFKB2/p52), an important regulator of lymphocyte activation and gene expression, in 2% (5 of 228) of lymphoid malignancies, including CTCL ([65]). Two additional recent studies found LYT-10 gene rearrangements in a minority of CTCL cases ([58], [66]). Aberrant expression of the BCL-2 gene, which normally codes for an inner mitochondrial membrane protein, can suppress apoptosis, an important pathogenic mechanism in lymphomas ([67]). Although Dummer and colleagues detected BCL-2 expression in 22 of 26 MF patients, it was also present in five of six patients with benign inflammatory dermatoses ([68]).

In 1985, Aisenberg et al. and Weiss et al. independently described Southern blot analysis techniques using probes for the ß-chain of the T-cell receptor (TCR) to establish clonality in T-cell lymphoproliferative disorders ([69], [70]). Because earlier cytogenetic studies suggested that CTCL arises from a single malignant clone of mature T cells ([45], [46], [47], [48], [49] and [50]), the presence of TCR ß-chain rearrangement in pathologically suspicious tissue has been considered the strongest evidence for the diagnosis of CTCL ([71], [72], [73], [74], [75], [76], [77] and [78]). However, in early lesions of MF, or the *patch stage*, where the number of infiltrating malignant T cells is minimal, the Southern blot technique fails to consistently detect clonal T-cell populations. Other limitations of the Southern blot technique include its necessity for large amounts of preserved DNA, as well as its extensive time and labor requirement ([77], [79], [80]). Therefore, the detection sensitivity of Southern blotting of DNA derived from skin biopsy specimens of early lesions is too low and may fail as a diagnostic test when the clinical and histologic diagnosis is most difficult ([81]).

More sensitive techniques involving the polymerase chain reaction (PCR) have been developed to evaluate clonality in CTCL and related skin diseases and are becoming more readily available ([51], [52], [73], [82], [83], [84], [85], [86], [87], [88], [89], [90] and [91]). The PCR is an *in vitro* imitation of the enzymatic DNA repair and replication that takes place in all proliferating cells but amplifies short specific lengths of DNA in the order of 10^{9} to 10^{12} and, therefore, permits the use of very small amounts of starting DNA ([51]). Although the vast majority of CTCL express the a/ß TCR heterodimer, most labs using the PCR technique take advantage of the fact that all a/ß TCR-positive T cells also contain at least one rearranged allele of the TCR ?-chain gene ([85], [92]). The ? gene contains only 8 V segments and 2 C regions, making it possible to use specific primers for all known TCR ? V segments ([93], [94]). It is estimated that this PCR-based technique, in combination with high-resolution nondenaturing polyacrylamide gel electrophoresis, is 10 to 50 times more sensitive than conventional Southern blot analysis in the detection of small T-cell clones ([88]). A few groups have extended the PCR technique by incorporating a multiprobe RNAase protection assay ([95]) or a denaturing gradient gel electrophoresis.

EPIDEMIOLOGY

The incidence of MF in the United States decreased slightly from 0.4 cases per 100,000 in 1984 to 0.36 cases per 100,000 in 1992, based on data from nine cancer registries that participate in the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute (NCI) ([96], [97]). During that period, MF represented 3% of all reported NHLs ([96], [97]). Because the number of patients with early-stage MF is often not reported to tumor registries, the actual incidence may be higher. In a well-defined population such as Rochester, Minnesota, the annual incidence was 0.9 per 100,000 between 1970 and 1984 ([98]). Thus, the incidence of new cases in the United States in the 1990s is more than 1000 cases per year. The incidence of MF increases with advancing age, and the median age is usually between 60 and 70 years ([99], [100], [101] and [102]), with a specific estimate of 69 years during the period of 1989 through 1991 (National Center for Health Statistics, 1991). MF is rare in patients younger than 30 years; however, there have been several reports of children and adolescents affected with MF and SS ([103], [104], [105], [106], [107], [108], [109], [110], [111], [112] and [113]). One recent study found that 4% to 5% of patients with MF had onset of their eruption before 20 years of age ([107]).

Blacks are almost twice as likely to develop MF compared to whites and Asians, with the greatest racial differences seen among the younger patient populations. The male to female ratios are dependent on race, with Asian, black, and white ratios of 5.2, 2.3, and 1.8, respectively ([96], [97]). The etiology of MF/SS remains unknown, but genetic, environmental, and infectious agents have been implicated as possible factors triggering lymphocyte activation or transformation ([51], [52], [114]). A recent study found that, not only did the antioxidative effects of wine consumption fail to protect against the development of MF, but that patients consuming more than 24 g of alcohol per day demonstrated a higher incidence of MF than matched control groups (adjusted odds ratio = 3.02; 95% confidence interval = 1.34–6.79) ([115]). Also significant was that the alcohol effect remained constant regardless of beverage type.

Rare familial clusters of CTCL cases have been reported ([116], [117]), and an increased incidence has been noted in patients with certain histocompatibility antigens ([118], [119]). Early reports implicated an increased risk of developing CTCL in people employed in manufacturing occupations, particularly those related to petrochemicals, textiles, or metals, or in farming, with exposure to pesticides or herbicides ([120], [121] and [122]). However, two case-control studies have failed to confirm these observations ([123], [124]). Results of other studies have suggested that patients with MF have increased contact allergies, but Whittemore and colleagues were unable to substantiate the association in a case-control clinical study ([124]).

Human retroviruses have been suggested as possible etiologic agents in CTCL. Human T-cell lymphotrophic virus type 1 (HTLV-1) was described initially in a CTCL patient who had an aggressive clinical course; however, this disease was later identified as adult T-cell leukemia/lymphoma (ATLL), which is endemic to Japan, the Caribbean, and other areas of the world but can have cutaneous lesions similar to CTCL (see Chapter 90) ([125]). Serologic findings for HTLV-1/2 in patients with CTCL are negative in a vast majority of patients ([126], [127], [128], [129], [130], [131] and [132]). In support of the association of HTLV-1/2 and MF, virus particles indistinguishable from HTLV-1 have been identified using electron microscopy on immortalized MF cells ([133]), and combined PCR/Southern blot analysis has demonstrated HTLV pol, tax, and/or rex sequences in peripheral blood mononuclear cell lysate extracts and lesional skin from patients with MF/SS ([126], [131], [134], [135], [136], [137], [138], [139], [140], [141], [142], [143], [144] and [145]). Further support of a potential HTLV-1/CTCL association was suggested after inoculation of immunosuppressed rats with peripheral blood mononuclear cell extracts from patients with MF/SS. A novel anti–HTLV-1 antibody was detected in the serum of 29% of the animals, whereas peripheral blood mononuclear cells from healthy controls did not elicit an anti-HTLV-1 antibody response. These findings lend further support to the role of HTLV-1 as being at least a cofactor in the pathogenesis of CTCL ([146]). Based on these studies, some authors contend that the strongest evidence of an etiologic and pathogenic factor for CTCL relates to the presence of a defective or variant HTLV-1 virus ([81], [135]). Other authorities ([132], [147], [148] and [149]), however, disagree, citing seven series that found no proviral HTLV-1 sequences in 332 CTCL patients ([130], [132], [141], [150], [151], [152] and [153]) and four studies that detected the proviral sequences in 10% of 176 patients. Future development ([134], [137], [144], [145]) of advanced molecular techniques should eliminate the difficulty of establishing with certainty the presence or absence of HTLV-1 proviral sequences in patients with CTCL ([147], [154]).

CLINICAL PRESENTATION

MF usually evolves over a long period, so patients often have a long premycotic or premalignant phase with eczematous skin eruptions 4 to 10 years before a histologic diagnosis is established ([81], [99], [155]). The differential diagnosis during this period includes chronic eczematous or atopic dermatitis, which may evolve slowly into eruptions clinically suggestive of parapsoriasis en plaque, poikiloderma atrophicans vasculare, or other benign papulosquamous skin diseases ([99], [155], [156]

). Failure of the lesions to respond to standard topical therapy may be an early clue of a different diagnosis. However, initial lesions occasionally appear to improve after topical steroid application, which masks early recognition of the underlying malignancy ([157]). Because of the difficulty in diagnosis in the premycotic phase of MF, careful follow-up with serial skin biopsies is warranted in patients with suspect lesions (see Diagnostic Evaluation).

The earliest diagnostic phase of MF is the patch phase, characterized by scaly macules and patches that vary in size, tend to involve sun-protected sites, and are occasionally associated with pruritus (Fig. 94.5A) ([5], [101], [156]).

Figure 94.5. A–E: The cutaneous phases of cutaneous T-cell lymphoma (CTCL). **A:** Early patch stage lesions in a sun-protected region. **B:** Hyperpigmented diffuse patches on the back of a dark-skinned patient. **C:** Scattered thin and thick plaques on the back. **D:** Early keratoderma of the sole. **E:** Ulcerated tumor within a plaque on the posterior leg. **F:** Coalescing nodules and tumors with dermal thickening, forming “leonine facies” in this patient with transformed CTCL. See Color Plate.

Other, less common early skin findings in CTCL include poikiloderma ([158]), hypopigmentation ([159]), hyperpigmentation (Fig. 94.5B), alopecia, pruritus alone ([160], [161] and [162]), and porokeratosis-like lesions ([163]). Recently, several cases of “invisible” MF were described. Afflicted patients presented only with persistent, generalized pruritus and no clinical eruption ([160], [161] and [162]). Random biopsies of “normal” skin confirmed the diagnosis of MF.

Plaques are sharply demarcated, scaly, elevated lesions that may have annular, arcuate, or serpiginous borders (Fig. 94.5C). Plaques with thick scales can mimic psoriasis or nummular eczema, whereas annular lesions with central clearing may be confused with tinea corporis ([156]). Ultraviolet radiation occasionally induces regression of patches and plaques, further delaying correct diagnosis. Prominent involvement of the palms or soles or both may result in hyperkeratosis, fissuring, or frank keratoderma (Fig. 94.5D) ([164], [165]).

The tumor phase is heralded by the onset of dome-shaped, deep red to violaceous nodules emerging in areas of uninvolved skin or in preexisting plaques ([156]). The tumors may ulcerate and become secondarily infected (Fig. 94.5E), and there is a predilection for the body folds and face, where dermal thickening, coalescing plaques, and tumors may result in characteristic “leonine facies” (Fig. 94.5F). The tumor stage is more clinically aggressive than the patch and plaque stages and may be associated with histologic transformation to a large cell process with a vertical growth phase (see Histopathology and Prognosis) ([156]). Rarely, patients with MF will present initially with tumors without the preceding patch and plaque phases (the mycosis *d'emblee* variant) ([6], [166]). It is very common for more advanced patients to have patches, plaques, or tumors present simultaneously on different areas of their skin ([81]).

Generalized erythroderma may develop as the initial presenting sign of MF/SS or may accompany plaques and tumors ([81], [99], [167], [168]). In SS, the leukemic variant of MF, erythroderma and circulating tumor cells, or *Sézary cells*, in the peripheral blood may be accompanied by generalized lymphadenopathy, splenomegaly, keratoderma, vitiligo-like hypopigmented patches ([169]), alopecia, ectropion, nail dystrophy, and ankle edema ([155], [167], [170]). Intense pruritus and cutaneous pain are common in SS, and when the palms and soles are affected with scaling and fissuring, walking and manual dexterity can become difficult ([155], [170]).

CLASSIFICATION OF CUTANEOUS T-CELL LYMPHOMA

The term CTCL is a general term that encompasses a variety of diseases, including MF and SS. In addition, there are other cutaneous T-cell lymphoproliferative disorders that appear to be specific entities with unique clinical, histologic, and prognostic features. In an effort to recognize the separate disease processes, proposals for classification of primary CTCL were formulated by the World Health Organization and the European Organization for Research and Treatment of Cancer (Table 94.1) ([171], [172] and [173]). The following sections focus on the histopathology and immunopathology of MF and SS. Other types of primary CTCL will be briefly discussed in the differential diagnosis section and in more detail in Chapters 90 and 91.

TABLE 94.1. Comparison of Primary Cutaneous T-Cell Lymphoma Classification Schemes Proposed by the European Organization for Research and Treatment of Cancer (EORTC) and the World Health Organization (WHO)

EORTC	WHO
Indolent	
Mycosis fungoides	Mycosis fungoides
Follicular mycosis fungoides	Mycosis fungoides
Pagetoid reticulosis	Pagetoid reticulosis
Lymphomatoid papulosis	Lymphomatoid papulosis
Large cell CTCL, $CD30^+$	Anaplastic large cell lymphoma, primary cutaneous type
Aggressive	
Sézary syndrome	Sézary syndrome
CTCL, large cell, $CD30^-$	Peripheral T-cell lymphoma, NOS or natural killer/T-cell lymphoma
Provisional	
Granulomatous slack skin	Granulomatous slack skin
Pleomorphic small to medium-sized CTCL	Peripheral T-cell lymphoma, unspecified
Subcutaneous panniculitis-like T-cell lymphoma	Subcutaneous panniculitis-like T-cell lymphoma

CTCL, cutaneous T-cell lymphoma; NOS, not otherwise specified.
Modified from Jaffe et al., Willemze et al., and the EORTC Classification of Primary Cutaneous Lymphomas, 171, 173.

DIAGNOSTIC EVALUATION

Tissue Handling

Skin biopsies for diagnosis of MF/SS must be properly handled to maximize the diagnostic information obtained. These studies include routine histology, immunophenotyping, and molecular genotyping. Communication between the clinical staff, dermatologists, and pathologists is essential to ensure that the appropriate types of biopsies are done and are properly handled. In general, 6-mm punch biopsies are recommended. Multiple biopsies from different skin lesions may be necessary to establish a definitive diagnosis of MF/SS, particularly in early patch-stage lesions. It has been recommended that steroids be discontinued for 2 to 3 weeks before biopsy ([174]). A careful drug history should be taken before biopsy because certain drug eruptions can closely mimic early MF, particularly phenytoin and other anticonvulsants ([175]). Skin biopsies for possible CTCL should be sent to the pathology or dermatopathology lab fresh on saline-soaked gauze or in tissue culture media such as RPMI. These biopsies can then be divided for the various diagnostic studies. Punch biopsies can be divided into halves; one half for routine histology, and the other half for immunophenotyping or molecular diagnostic studies or both. Sections for routine histology should be fixed in a good nuclear fixative such as B5 to facilitate evaluation of nuclear morphology and recognition of characteristic cerebriform cells. If it is a large biopsy of a cutaneous tumor or a lymph node biopsy, it may provide adequate tissue to prepare cell suspensions for immunophenotyping by flow cytometry and for cytogenetic studies. The tissue for immunophenotyping by flow cytometry should be promptly delivered to the appropriate laboratory in cell culture media. Tissue for molecular studies should be snap-frozen in liquid nitrogen and stored at -70°C. For leukemic infiltrates, cytochemical stains can be performed on air-dried touch imprints from freshly cut surfaces. A small sliver of the biopsy can be shaved off and fixed in glutaraldehyde for electron microscopy if needed. Lymph nodes should be worked up as previously described ([176]).

Histopathology

CUTANEOUS FEATURES OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME In general, the histologic diagnosis of MF/SS in skin biopsies is based on criteria similar to those used for the diagnosis of other lymphoid neoplasms, including the presence of an infiltrative or destructive growth pattern and cytologic atypia. The distribution of the infiltrate within the skin biopsy is also important (Fig. 94.6A).

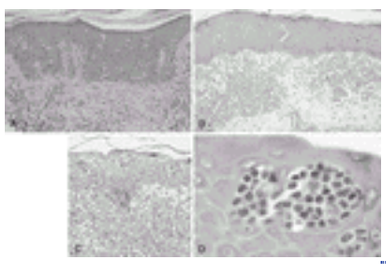

Figure 94.6. A: Mycosis fungoides (MF), patch stage. A bandlike lymphocytic infiltrate occupies the superficial papillary dermis with single-cell epidermotropism by atypical, “haloed” cerebriform T cells, preferentially involving the basal layer (hematoxylin and eosin, ×50). **B:** MF, plaque stage. A bandlike lymphocytic infiltrate occupies the papillary dermis with epidermotropism by atypical cerebriform T cells, focally forming small Pautrier microabscesses (hematoxylin and eosin, ×25). **C:** MF, thick plaque. A dense, bandlike lymphocytic infiltrate fills the papillary dermis and extends into the reticular dermis. Prominent epidermotropism by atypical, enlarged cerebriform T cells creates large Pautrier microabscesses (hematoxylin and eosin, ×25). **D:** MF, Pautrier microabscess. High magnification of a Pautrier microabscess shows characteristic small to medium-sized cerebriform T cells with highly convoluted nuclear folding. The Pautrier microabscess recapitulates normal interactions between components of the skin-associated lymphoid tissue [i.e., cutaneous T cells, Langerhans histiocytes (two cells with large, pale nuclei in the center), and keratinocytes] (hematoxylin and eosin, ×500). See Color Plate.

The characteristic atypical lymphocytes in MF and SS are dysplastic cerebriform T cells (CTCs) with enlarged hyperchromatic nuclei and complex nuclear folding. Demonstration of cerebriform nuclear folding requires good fixation (we prefer B5 fixation), thin (4 µm) sections, and examination under 100× oil immersion. Others have used special methods, such as 1-µm sections of plastic-embedded tissue, electron microscopy, or nuclear morphometry ([177] , [178] and [179]). Diagnostic criteria for cutaneous involvement by MF are best illustrated in plaque-stage lesions (Fig. 94.6B , Fig. 94.6C). The essential criteria for diagnosis are (a) a bandlike lymphocytic infiltrate in the superficial papillary dermis, (b) epidermotropism, and (c) atypical CTCs in the dermal and epidermal infiltrates ([180]). Pautrier microabscesses (Fig. 94.6D) are characteristic of MF but are often absent in patch-stage lesions, erythroderma, and nonepidermotropic tumors. Diagnosing early patch-stage lesions is often difficult. Histologic features that can be helpful in biopsies lacking Pautrier microabscesses include accumulation of “haloed” epidermotropic CTCs along the basal layer of the epidermis, medium to large cerebriform cells in the epidermis and clustered in the dermis, and a lack of fibrosis in the papillary dermis ([180] , [181]). Spongiosis should be minimal in relation to epidermotropism in MF and SS. Biopsies with prominent spongiosis must be differentiated from eczematous or spongiotic dermatitis. Eosinophils and plasma cells are often present in early patch- and plaque-stage MF and represent a nonspecific reactive component. It is important to understand that a definitive diagnosis of MF may not be possible in some early patch-stage lesions. Multiple biopsies of separate skin lesions, immunophenotyping, and TCR gene rearrangement studies may help confirm the diagnosis in difficult cases. However, even these ancillary studies may be inconclusive in early lesions. Tumor-stage MF is characterized histologically by a dense dermal infiltrate involving the papillary and reticular dermis, often with extension into the subcutis. In contrast to patch- and plaque-stage lesions, MF tumors are often nonepidermotropic and may spare the dermal–epidermal interface. Furthermore, the malignant T cells in tumor-stage MF often display various degrees of histologic transformation with medium and large pleomorphic cells, immunoblastic large cells, and anaplastic large cells ([182] , [183] and [184]). The diagnosis of malignancy in the tumor stage is rarely in question, but recognition of MF origin for tumors with large cell transformation may be obscured by their resemblance to other NHLs. A careful search for dysplastic CTCs and residual foci of epidermal infiltration near the edges of tumors often provides histologic evidence of MF origin in difficult cases ([182]). Previous or concurrent biopsies of earlier-stage lesions should confirm MF origin for tumors with large cell transformation. Generalized exfoliative erythroderma is characteristic of SS but may also occur in MF ([155] , [185]). Cutaneous biopsies of erythroderma in MF/SS often lack prominent epidermotropism. In one study, up to 17% of skin biopsies of patients with established SS were considered nondiagnostic due to insufficient epidermo-tropism ([168]). However, Pautrier microabscesses may be found in many cases ([185]). The dermal infiltrate in erythrodermic MF and SS patients may be similar to that found in patch and plaque stage MF; however, there may be a decrease in the density of the infiltrate. Evaluation of the peripheral blood for circulating tumor cells and or molecular analysis of the skin biopsy for a clonal rearrangement of the TCR may help establish the diagnosis of MF/SS in cases in which skin biopsies are histologically suspicious but nondiagnostic.

LARGE CELL TRANSFORMATION OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME Approximately 20% of low-grade MF and SS undergo secondary transformation to high-grade large cell lymphoma with a predominance (>50%) of large transformed lymphocytes (Fig. 94.7) ([182] , [186]).

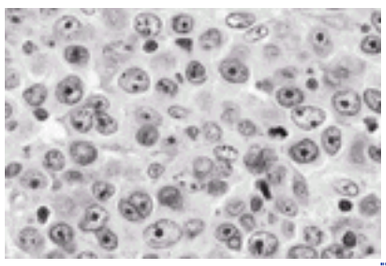

Figure 94.7. Large cell transformation of cutaneous T-cell lymphoma. This represents secondary transformation of low-grade mycosis fungoides to high-grade immunoblastic large cell lymphoma. This tumor is composed of sheets of large transformed cells or immunoblasts with round to oval nuclei, dispersed chromatin, and prominent nucleoli. Several mitoses are present (hematoxylin and eosin, ×500). See Color Plate.

Secondary large cell transformation of MF/SS may resemble immunoblastic large cell lymphoma, pleomorphic large cell lymphoma, or ALCL ([182] , [183] , [187]). It has been shown that secondary large cell lymphoma is immunophenotypically and clonally related to earlier MF/SS biopsies taken before transformation ([182] , [188] , [189]). Cutaneous large cell transformation usually occurs late in tumor-stage lesions but can occasionally be seen in plaques or erythrodermic MF and may be present in the initial diagnostic biopsy (mycosis *d'emblée* variant). Lymph nodes are the most common site of extracutaneous large cell transformation, but it may also occur in other extracutaneous sites. Approximately 50% of secondarily transformed large cell lymphomas express CD30 ([182] , [190]). It is important to distinguish secondary large cell transformation of MF/SS from unrelated primary cutaneous large cell lymphoma and secondary cutaneous involvement by systemic large cell lymphoma because of prognostic differences ([191]). This is particularly true for secondary $CD30^{+}$ large cell lymphoma resulting from transformation of MF/SS, which has a poor prognosis, in contrast to primary cutaneous $CD30^{+}$ ALCL, which has a favorable prognosis ([182] , [192] , [193] and [194]).

EXTRACUTANEOUS MYCOSIS FUNGOIDES AND SÉZARY SYNDROME Extracutaneous dissemination is generally considered to be a late occurrence in MF/SS because the disease is clinically limited to the skin for prolonged periods in most patients ([195]). However, histologic staging has documented extracutaneous disease in up to 50% of CTCL patients within 6 months of initial diagnosis ([196] , [197]). Using more sensitive techniques such as cytogenetics, electron microscopy, and immunophenotypic studies, extracutaneous disease has been found in nearly 90% of MF/SS patients at initial staging ([198]). TCR gene rearrangement studies have confirmed a high frequency of lymph node involvement by MF/SS ([69]). Moreover, autopsy studies have histologically documented widespread extracutaneous

disease in most patients ([199] , [200] , [201] and [202]). Extracutaneous MF/SS has histologic features, which are usually similar to those seen in the skin ([199] , [200]). Dysplastic CTCs are the most helpful diagnostic feature for recognition as extracutaneous disease. Almost every organ has been involved by MF/SS in autopsy series, but the most frequent sites are the lymph nodes, liver, spleen, and lungs, which are involved in more than 50% of cases ([199] , [200] , [201] and [202]). Other common sites include kidney, bone marrow, thyroid, heart, pancreas, and gastrointestinal and central nervous systems. Lymph nodes also represent the most frequent site of extracutaneous disease in pathologic staging studies; up to 50% of lymph nodes are positive by light microscopy at initial staging ([196]). Visceral involvement is present in approximately 15% of initial-staging liver and bone marrow biopsies ([182] , [196] , [203]). In staging laparotomies, approximately 30% of spleens are microscopically involved by MF/SS ([197]). Extracutaneous CTCL, particularly visceral disease, is strongly associated with advanced-stage skin disease and SS ([196] , [197] and [198] , [203]). Because tumor-stage MF and generalized erythroderma are frequently nonepidermotropic, it has been suggested that loss of epidermotropism may play an important role in systemic dissemination ([155]).

LYMPH NODE PATHOLOGY With up to 50% of staging lymph node biopsies being microscopically involved by MF/SS, lymph nodes are the earliest and most common site of extracutaneous dissemination ([196]). Partially effaced nodes often have an interfollicular pattern with preservation of reactive follicular centers, but eventually most lymph nodes become completely effaced. As lymph nodes become progressively infiltrated, the CTCs tend to become larger and more pleomorphic, with increased numbers of large transformed cells ([184] , [204]). More than 35% of positive lymph nodes show complete large cell transformation with pleomorphic, immunoblastic, or anaplastic large cell morphology ([182] , [184] , [204]). In contrast to MF, lymph nodes from patients with SS tend to be effaced by more monomorphic infiltrates of small to medium-sized CTCs ([205] , [206]) but may also undergo large cell transformation in some cases ([182] , [190]).

BONE MARROW INVOLVEMENT The bone marrow in MF and SS is generally thought to be spared until late in the course of the disease, including patients with large numbers of circulating Sézary cells ([81] , [196] , [198] , [207]). Early studies suggested that antemortem marrow involvement occurred in less than 3% of MF/SS patients ([195] , [198]), yet the marrow is involved in nearly 50% of patients at autopsy ([199] , [200] , [201] and [202]). Marrow involvement is usually manifested as nonparatrabecular lymphoid aggregates with cerebriform lymphocytes. In patients with Sézary syndrome, subtle small interstitial clusters of Sézary cells have been identified in up to 90% of cases, suggesting that most patients with circulating Sézary cells have early systemic dissemination of disease ([203]). Detection of these subtle interstitial infiltrates of Sézary cells requires careful examination under oil immersion (100×) to identify the cells with abnormal cerebriform nuclear folds, which can be facilitated with immunoperoxidase studies for T-cell markers such as CD3.

OTHER EXTRACUTANEOUS SITES Visceral involvement by MF and SS is most commonly documented by liver biopsy. Liver involvement in initial staging procedures has been found in 8% to 16% of cases ([196] , [197] , [208]). Disseminated MF and SS tend to form nodular infiltrates of atypical CTCs within the portal tracts or hepatic lobules. CTCs within the hepatic sinusoids without formation of focal aggregates are not considered diagnostic of liver involvement in the presence of peripheral blood involvement ([208]). Splenic infiltration was documented in 31% of staging laparotomies in one series ([197]). The atypical CTCs usually infiltrate the red pulp diffusely but may home to the periarteriolar lymphocyte sheath ([200]). Splenic rupture has been reported in a rare case with massive splenic involvement by CTCL ([209]). Antemortem pulmonary manifestations of MF and SS are generally uncommon but may occasionally present clinically as interstitial or nodular pulmonary infiltrates ([210]). However, the lungs are frequently involved by MF/SS at autopsy ([199] , [200] , [201] and [202]). Infiltrates of atypical CTCs usually spread along the alveolar septae with preservation of the alveolar architecture. In some cases, the infiltrates may also fill alveolar spaces.

BLOOD INVOLVEMENT In general, patients with at least 10% to 20% Sézary cells with large nuclear size (>15 mm) and high nuclear contour index may be classified as having peripheral blood involvement. In one study, increased large Sézary cells correlated significantly with poorer survival ([211]). However, size criteria alone would fail to recognize the small Sézary cell variant, which is similar in size to a normal resting lymphocyte ([212]). Because of the inherent difficulties in diagnosing peripheral blood involvement by MF/SS on peripheral smear review, additional technologies are now used, including flow cytometry and molecular studies such as PCR. Either a CD4:CD8 ratio greater than 10:1 or an abnormal phenotype by flow cytometry along with a clonal population by PCR is now considered adequate evidence to constitute a positive peripheral blood for staging purposes ([213]). The proposal is to designate such involvement as blood stage B2.

Immunophenotype

T-cell origin of the neoplastic cells in MF and SS is well established ([17]). Moreover, the vast majority are derived from T-helper cells ([18] , [214]) which express CD4 and other T-cell–associated antigens, including CD2, CD3, CD5, and aß TCRs (Fig. 94.8) ([215] , [216]).

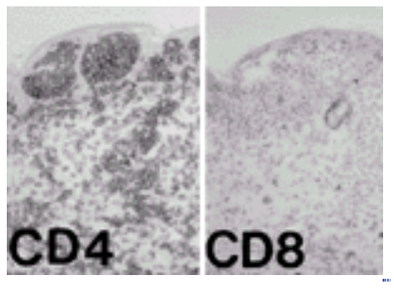

Figure 94.8. Frozen-section immunohistochemistry of a cutaneous plaque in a patient with mycosis fungoides shows a marked predominance of CD4 $^{+}$ T-helper cells within Pautrier microabscesses and within the dermis. CD8 is essentially negative (diaminobenzidine and hematoxylin, ×50). See Color Plate.

However, a small number of CD8 $^{+}$ CTCLs ([182] , [215] , [217]) and ?d CTCLs have been reported ([218] , [219]). In addition, it has been shown that MF/SS is a neoplasm of memory T cells, which are CD29 $^{+}$ and CD45R0 $^{+}$ ([215] , [220]) and express CLA (HECA-452), the cutaneous lymphoid antigen homing receptor ([30]). Activation-associated (HLA-DR, CD25, CD30, CD38) and proliferation-associated (CD71, Ki-67) antigens are also frequently expressed in MF/SS, particularly in advanced stages ([182] , [221]).

Aberrant T-antigen expression is often seen in MF and SS, particularly advanced plaque- or tumor-stage lesions, and can be used to help differentiate reactive dermatitis from MF/SS ([215] , [222] , [223] and [224]). Aberrant T-cell phenotypes are defined as diminished or absent expression of pan T-cell antigens (CD2, CD3, or CD5), absent T-subset antigen expression (CD4 $^{-}$ CD8 $^{-}$), or coexpression of T-subset antigens (CD4 $^{+}$ CD8 $^{+}$). Diminished or absent CD7 expression is one of the most common aberrant T-cell phenotypes in tissue sections of MF and SS ([224] , [225]). However, the isolated findings of loss of CD7 expression must be considered in the context of other clinical, histologic, and immunophenotypic findings in that expanded populations of CD7-negative T cells can also be seen in benign dermatitis ([215] , [225]). Aberrant loss of TCR antigen expression may also occur in advanced-stage MF/SS and strongly supports a malignant T-cell proliferation ([216]).

Flow cytometry or frozen section immunohistochemistry or both on fresh or frozen tissue has been considered the preferred method for immunophenotyping in the past because these methods provided access to a broader range of antibodies than what was made available by immunohistochemistry on paraffin-fixed tissue. Recently, however, the number and quality of commercially available paraffin-reactive antibodies together with heat or microwave antigen retrieval techniques have dramatically improved paraffin section immunophenotyping of lymphoproliferative disorders. In cases in which the histologic diagnosis of lymphoma is established, these paraffin-reactive reagents can reliably differentiate between T-cell lymphomas, B-cell lymphomas, and Hodgkin disease. The most widely used paraffin-reactive T-cell antibodies include CD45RO (UCHL1), CD43, polyclonal CD3, CD4, CD8, CD5, ßF1, and TCR aß. Recently, a CD7 paraffin-reactive antibody has become commercially available and has been shown to be helpful in evaluating early MF biopsies in conjunction with other clinical histologic and molecular findings ([226] , [227]). NK cell or cytotoxic lymphocyte markers (CD56, granzyme B, and TIA-1) are also available. L26 (CD20), CD79a, LN1 (CDw75), and CD45RA are the most widely used B-cell paraffin-reactive antibodies. Other useful paraffin-reactive antibodies for cutaneous lymphomas include CD45 (LCA), CD30 (Ber-H2), and CD15 (Leu-M1). When used in panels, these antibodies allow subclassification of most cutaneous lymphomas.

DIFFERENTIAL DIAGNOSIS

The clinicopathologic differential diagnosis for MF/SS includes several forms of benign dermatitis, other primary low-grade CTCLs, and secondary cutaneous involvement by disseminated lymphomas or leukemias (Table 94.2). Differentiation of these mimickers from CTCL often requires careful correlation of clinical, histopathologic, immunophenotypic, and genotypic characteristics and may require multiple or serial biopsies. The following discussion describes methods to differentiate MF/SS from similar benign conditions—indolent CTCL and other primary CTCLs.

TABLE 94.2. Clinicopathologic Differential Diagnosis for Cutaneous T-Cell Lymphoma

1. Benign conditions
   Small- and large-plaque parapsoriasis
   Poikiloderma vasculare atrophicans
   Pityriasis lichenoides et varioliformis acuta
   Benign erythroderma
   Actinic reticuloid
   Follicular mucinosis
2. $CD30^+$ lymphoproliferative disorders
   Lymphomatoid papulosis
   Primary cutaneous anaplastic large cell lymphoma
3. Other primary cutaneous T-cell lymphomas
   Pagetoid reticulosis
   Granulomatous slack skin
   Follicular mycosis fungoides
   $CD8^+$ mycosis fungoides
   Primary cutaneous ?d + T-cell lymphoma
   Pleomorphic small/medium-sized CTCL
   Subcutaneous panniculitic T-cell lymphoma
4. Secondary lymphoma/leukemia
   Adult T-cell leukemia/lymphoma
   Peripheral T-cell lymphoma
   Hodgkin lymphoma
   Leukemia cutis
5. B-cell lymphoma
   Follicular lymphoma
   Marginal zone lymphoma
   Large B-cell lymphoma
   Extramedullary plasmacytoma
   Intravascular large B-cell lymphoma

Benign Conditions

Benign inflammatory skin lesions are most likely to be confused with early patch-stage MF. In general, these conditions have clinical presentations and courses that are different from MF, lack enlarged atypical CTCs, and lack epidermotropism, which is disproportionately increased in relationship to spongiosis. However, in difficult cases, immunophenotypic analysis and gene rearrangement studies may be necessary to look for aberrant T phenotypes or clonal TCR gene rearrangements. The benign inflammatory dermatoses that most closely resemble CTCL include small plaque parapsoriasis and large plaque parapsoriasis (LPP), poikiloderma vasculare atrophicans (PVA), pityriasis lichenoides et varioliformis acuta (PLEVA), benign erythroderma, contact dermatitis, persistent arthropod bite reactions, drug eruptions, lymphomatoid papulosis (LyP), and actinic reticuloid (AR) ([228]).

LPP is clinically indistinguishable from patch-stage MF. Because of clinical and histologic overlap, some authorities consider LPP to be an early stage of MF ([229]). Others consider LPP to be a latent form of MF ([230]) because approximately 10% of patients eventually develop overt MF ([231]). This view is supported by the recent demonstration of clonal TCR gene rearrangement in 50% of LPP biopsies ([85]). Furthermore, recent demonstration of clonal TCR gene rearrangements in small plaque parapsoriasis has suggested that this may be an abortive form of MF ([232]). Histologically, the lymphoid infiltrate of LPP is perivascular and less dense with less epidermotropism than MF; Pautrier microabscesses are not seen in LPP. Furthermore, cytologically atypical CTCs with highly convoluted nuclei are inconspicuous or absent in LPP. However, immunophenotypic analysis is usually not helpful for differentiating LPP from patch-stage MF because both have a predominance of $CD4^+$ helper cells with absent CD7 and Leu 8 (CD62L) expression ([158]).

PVA can also present similarly to early MF. The macules and patches of PVA show the poikilodermatous features of hypopigmentation, hyperpigmentation, atrophy, and telangiectasias. PVA macules/patches also tend to be localized to sun-protected sites, most commonly appearing on the buttocks, breasts, and flexural areas, and, like LPP, some clinicians believe that PVA may potentially precede or coexist with MF ([157]). Histologically, the dermis in PVA demonstrates chronic, ill-defined inflammatory changes and is accompanied by a thin epidermis. Often, lymphoid cells form a bandlike pattern in the superficial dermis, with a limited number of these cells appearing in the epidermis.

PLEVA is a benign cutaneous disorder characterized by recurrent, self-healing papulonecrotic lesions ([233]). Biopsies may show slightly atypical CTCs with some epidermotropism, but vacuolar degeneration of the epidermal basilar layer and necrotic keratinocytes in PLEVA distinguish it from MF. The lymphoid infiltrate is predominantly composed of $CD8^+$ cells, as opposed to the typical $CD4^+$ phenotype of MF ([233]). The malignant potential of PLEVA is controversial. Some consider PLEVA to be a T-cell lymphoproliferative disorder related to LyP ([234]), and clonal TCR gene rearrangement has been demonstrated in a few cases ([235]). However, patients with PLEVA do not develop overt lymphoma ([233]).

Erythroderma may occur in a variety of benign dermatologic disorders, including psoriasis, pityriasis rubra pilaris, eczematous dermatitis, seborrheic dermatitis, severe contact dermatitis, and drug eruptions ([167]). These patients may also have circulating cerebriform cells and lymphadenopathy, further complicating the diagnosis. Erythroderma secondary to drug reactions, especially anticonvulsants such as phenytoin, can be particularly difficult to distinguish from MF/SS due to the presence of convoluted CTCs and the formation of Pautrier microabscesses ([175]). Differentiation of benign erythroderma from erythrodermic MF can usually be accomplished through careful evaluation of the history, biopsy of the more typical lesions of the underlying disease, and serial biopsies over time ([167]). Numerous eosinophils favor a drug reaction. Aberrant T phenotypes or clonal TCR gene rearrangements are usually not present in benign erythroderma.

Subacute or chronic spongiotic dermatitis and interface dermatitis due to contact dermatitis, drug eruption, and persistent arthropod bite reaction may have atypical CTCs with epidermotropism and Pautrier-like microabscesses mimicking MF ([228]). Therefore, caution should be exercised in interpretation of epidermotropism associated with significant spongiosis ([180]). Immunophenotyping may be helpful in this differential diagnosis because cutaneous T-cell pseudolymphomas do not show aberrant loss of CD2, CD3, or CD5 expression, but may be negative for CD7 and CD62L (Leu 8), similar to MF ([228]). The utility of gene rearrangement studies in this setting is unclear because clonal TCR gene rearrangements have been reported in some cutaneous T-cell pseudolymphomas ([92] , [236]). The following drugs have been implicated as causing pseudolymphoma: alprazolam, amitriptyline, atenolol, carbamazepine, cefixime, chlorpromazine, cimetidine, clarithromycin, clonazepam, clonidine, co-trimoxazole, cyclosporine, desipramine, diltiazem, doxepin, fluoxetine, furosemide, gemfibrozil, gold, lamotrigine, lithium, lorazepam, losartan, methotrexate, nizatidine, perphenazine, phenytoin, ranitidine, sulfamethoxazole, sulfasalazine, terfenadine, and thioridazine ([237]).

AR is a severe form of photosensitive dermatitis that may closely mimic MF or SS clinically and histologically when fully developed ([238]). AR is a chronic, persistent eruption that can be induced by a broad spectrum of light wavelengths. The skin lesions are typically plaques and papules on the sun-exposed areas of the face and hands but may extend to covered areas or even become generalized erythroderma. In contrast to MF, epidermotropism is not prominent, but small Pautrier microabscesses may be found in some cases. Severe cases of erythrodermic AR may have generalized lymphadenopathy and circulating Sézary cells mimicking the Sézary syndrome. Preferential involvement of sun-exposed areas, absence of large dysplastic CTCs, and a $CD8^+$ phenotype help distinguish AR from MF/SS. AR does not appear to be associated with progression to malignant lymphoma, and clonal TCR rearrangements have not been reported ([238]).

Indolent Cutaneous T-Cell Lymphoma, Excluding Mycosis Fungoides and Sézary Syndrome

The differential diagnosis for suspected MF or SS also includes a variety of related conditions, which are equally concerning for their malignant or premalignant clinical course. These potentially malignant CTCL variants are discussed below and include pagetoid reticulosis (PR), granulomatous slack skin (GSS) disease, and LyP. Other related conditions discussed below include follicular mucinosis; follicular MF; CD8 $^{+}$, MF, ?d $^{+}$ T-cell lymphomas; and pleomorphic small to medium-sized CTCL.

LyP is a CD30 (Ki-1)-positive T-cell lymphoproliferative disorder characterized by chronically recurring, self-healing crops of mildly pruritic papulonodular lesions that are clinically benign but histologically malignant ([239]). LyP initially presents with crops of erythematous papules that wax and wane, becoming hemorrhagic and necrotic before undergoing spontaneous regression with scar formation. Individual lesions range from 2 mm to 2 cm in diameter (usually less than 1 cm) and have an average duration of 5 weeks, ranging from 2 weeks to 6 months ([240]). LyP is divided into three histologic types—type A, type B, and type C ([241]). LyP type A, the most common type, is characterized by a polymorphous infiltrate of eosinophils, neutrophils, and scattered anaplastic large transformed lymphocytes and binucleate Reed-Sternberg–like cells resembling ALCL (Fig. 94.9) ([242] , [243]).

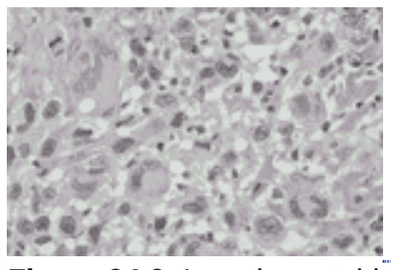

Figure 94.9. Lymphomatoid papulosis, type A. Anaplastic large cells with abundant cytoplasm, reniform nuclei, and prominent nucleoli are scattered among small lymphocytes and eosinophils. Note occasional binucleate Reed-Sternberg–like cells (hematoxylin and eosin, ×250). The large cells were strongly positive for CD30 (not shown). See Color Plate.

LyP type B is characterized by small to medium-sized CTCs resembling MF. LyP type C is characterized by sheets of large, anaplastic CD30 $^{+}$ cells and can be histologically identical to primary cutaneous ALCL. Atypical cells in all three types are CD4 $^{+}$ T cells, which often have clonal rearrangement of the TCR gene, and absent or diminished expression of pan T-cell antigens ([244] , [245] and [246]). However, CD30 expression differs between the types; the large transformed cells in type A and C are CD30 $^{+}$, similar to CD30 $^{+}$ ALCL, whereas the atypical CTCs in type B LyP do not express CD30 ([240] , [247] , [248]). Clinical behavior of both types of LyP is usually benign; however, overt lymphoma has been documented in approximately 10% to 20% of patients—usually MF, primary cutaneous ALCL, or Hodgkin lymphoma ([240] , [249] , [250]). The cumulative risk for malignant transformation of LyP over 15 years of disease may be as high as 80% ([251]). No clinical, histologic, immunophenotypic, or molecular genetic features have been identified that can predict cases in which patients will develop lymphoma, but two studies suggest that malignant transformation is more strongly associated with type A than type B LyP ([240] , [250]). Onset of LyP at a younger age may be associated with increased cumulative risk for overt lymphoma ([251]). The benign or malignant nature of LyP is controversial, but some authorities now consider LyP type A to be a latent or low-grade stage of primary cutaneous ALCL ([171] , [230]). Its clinical, histologic, and immunophenotypic similarities to primary cutaneous ALCL, aberrant T-cell antigen expression, clonal TCR gene rearrangements ([252] , [253]), and increased risk for transformation to malignant lymphoma support this view.

Differentiation of primary cutaneous CD30 $^{+}$ large cell lymphoma from type A LyP and secondary CD30 $^{+}$ large cell lymphoma resulting from large cell transformation of MF/SS is important because of differences in prognosis and therapy ([243] , [254]). Primary cutaneous ALCL has a good prognosis and can be effectively managed with local excision or radiation therapy or both ([255]), whereas secondary CD30 $^{+}$ large cell lymphoma due to large cell transformation of MF/SS has a very poor prognosis requiring aggressive combination chemotherapy ([191] , [192] , [254]). LyP also has a good prognosis and can often be managed with no therapy or topical chemotherapy and phototherapy without the need for aggressive therapy ([243]). Furthermore, primary cutaneous ALCL must be differentiated from secondary cutaneous involvement by extracutaneous ALCL. Primary nodal ALCL and secondary cutaneous involvement by extracutaneous ALCL are more aggressive than primary cutaneous ALCL ([192] , [256]). A thorough dermatologic examination, history, and staging for extracutaneous disease are necessary to exclude secondary large cell transformation of low-grade MF or secondary cutaneous involvement by extracutaneous lymphoma before a case is accepted as primary cutaneous ALCL. Primary cutaneous ALCL is differentiated from LyP type A by cohesive sheets or more than 75% CD30 $^{+}$ large transformed cells, fewer admixed neutrophils and eosinophils, a diffuse infiltrate that extends into the deep dermis versus a more superficial wedge-shaped infiltrate, larger solitary or localized nodules or tumors instead of crops of papules, and higher frequency of persistent or progressive cutaneous lesions with less frequent or incomplete spontaneous regression ([243] , [254] , [257]). Other aspects of ALCL are discussed in more detail in Chapter 90.

Other Primary Cutaneous T-Cell Lymphomas

Numerous subtypes of MF exist, and each must be considered in the differential diagnosis. These variants are described below and include PR, GSS disease, follicular mucinosis, folliculotropic MF, CD8 $^{+}$ MF, pleomorphic small to medium-sized CTCL, and subcutaneous panniculitic T-cell lymphoma (SPTL).

PR and GSS disease are low-grade clonal T-cell lymphomas that generally follow a benign course but may behave aggressively over time. Pagetoid reticulosis is a rare epidermotropic variant of MF, which usually presents as localized, hyperkeratotic, verrucous plaques on the hands or feet (Woringer-Kolopp disease) ([258]) but may also present with disseminated cutaneous plaques (Ketron-Goodman disease). Localized PR may mimic ([259]) a more unusual variant of MF localized to the palms and soles known as *MF palmaris et plantaris* ([260]). Skin biopsies show pagetoid epidermotropism by enlarged, atypical CTCs, with relative sparing of the dermis (Fig. 94.10).

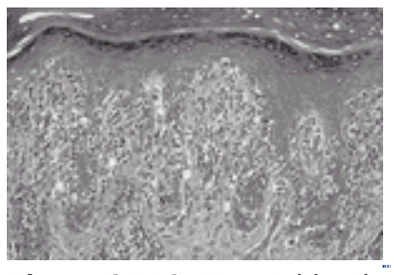

Figure 94.10. Pagetoid reticulosis. Note the pronounced pagetoid pattern of epidermotropism by enlarged, atypical, cerebriform T cells (hematoxylin and eosin, ×50). See Color Plate.

Localized and disseminated PR may be CD4 $^{+}$, CD8 $^{+}$, or negative for both CD4 and CD8. However, in contrast to conventional MF and SS, which are CD4 $^{+}$, nearly half of PR cases are CD8 $^{+}$ ([261]). In addition, they are often CD30 $^{+}$. PR may be derived from either aß ([261]) or ?d T-cells ([219] , [262] , [263] and [264]) but express ?d TCR more frequently than either MF or SS ([216] , [218]). Clonal TCR gene rearrangement and aberrant T-cell antigen expression support classification of PR as a form of CTCL ([261] , [265]); however, localized PR has a clinically benign course with only rare reports of cutaneous dissemination of localized PR ([261] , [266] , [267]). Although rare, disseminated PR is usually indolent but may be aggressive, as reported in cases of ?d $^{+}$ PR ([261] , [262]). Further studies are needed to confirm whether phenotypic differences in PR have clinical relevance. Local excision or radiation therapy are generally adequate treatment for PR, especially the localized form ([261] , [266]).

GSS disease is a rare but distinctive variant of MF that begins with patches and plaques that steadily progress to characteristic pendulous, erythematous skin folds in

the axilla and groin ([268]). GSS has histologic features of MF, including superficial papillary dermal and epidermotropic infiltrates of atypical CTCs, but also exhibits expansive infiltration into the deep dermis and subcutis with extensive elastolysis and a prominent granulomatous reaction with multinucleated giant cells (Fig. 94.11).

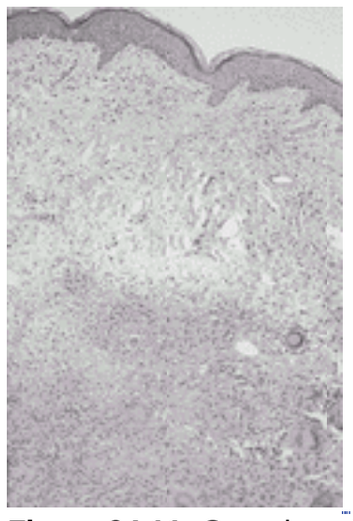

Figure 94.11. Granulomatous slack skin. This variant of mycosis fungoides shows a deep lymphocytic infiltrate with dermal edema, disruption of elastic fibers, and numerous foreign body giant cells (hematoxylin and eosin, ×10). See Color Plate.

Similar to MF, GSS is a clonal proliferation of $CD4^+$ T-helper cells that frequently lack expression of CD7 and CD62L ([269]). GSS usually remains localized to the skin, although lymph node involvement and fatal systemic dissemination have been reported ([268]). Interestingly, GSS patients have an increased incidence of Hodgkin lymphoma ([268]).

Follicular mucinosis is frequently associated with MF, and this variant of MF must be differentiated from idiopathic follicular mucinosis or alopecia mucinosa ([270]). In general, alopecia mucinosa does not have atypical CTCs and has less lymphocytic infiltration of follicular epithelium than follicular mucinosis associated with MF. Clonal TCR gene rearrangement has been reported in some cases of follicular mucinosis and can be helpful in identifying cases associated with MF ([74]). A recent long-term follow-up study of seven patients with follicular mucinosis concluded that, despite the presence of a clonal TCR gene rearrangement, there was no evidence of progression to CTCL in any patient ([271]).

Follicular MF is another rare variant of CTCL with preferential perifollicular and folliculotropic infiltration by atypical CTCs with minimal or absent epidermotropism and mucin ([272] , [273] , [274] , [275] and [276]) (Fig. 94.12).

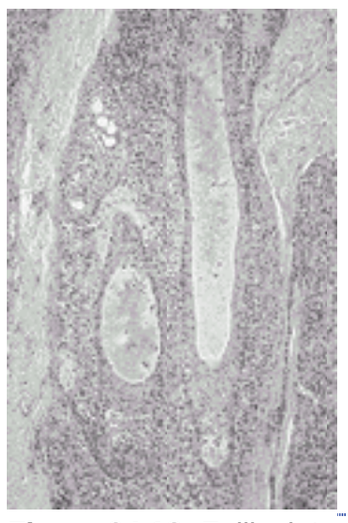

Figure 94.12. Folliculotropic mycosis fungoides with follicular mucinosis. Note the preferential pattern of perifollicular infiltration by atypical cerebriform T cells with prominent folliculotropism forming small Pautrier microabscesses. Also note the bluish pools of mucin within the hair follicles (hematoxylin and eosin, ×25). See Color Plate.

Folliculotropic CTCs are $CD4^+$ ([273] , [274] and [275]) and may express an aberrant T-cell phenotype with loss of CD7 and other T-cell antigens ([273]). Differential up-regulation ICAM-1 (CD54) on follicular epithelium instead of epidermal keratinocytes has been implicated in the folliculotropic homing pattern of folliculotropic MF ([273]). Lymph node involvement and large cell transformation have also been described ([273]). Follicular MF, regardless of whether it exhibits follicular mucinosis, has shown a more aggressive course than classic MF. Approximately 7% of reported cases have demonstrated rapid lymph node involvement ([276] , [277]). One case report describes a patient who bypassed traditional MF plaques and tumors, progressing directly from T1 stage to positive lymph node status in 3 months ([278]).

$CD8^+$ MF is an unusual immunophenotypic variant of MF, comprising up to 4% of CTCL in one series ([217]). Aggressive and indolent $CD8^+$ subtypes have been described (278a) ([217]). Both subtypes are strongly epidermotropic, with pagetoid features suggesting a relationship to PR. The indolent cases of $CD8^+$ MF have a clinical and histologic appearance similar to ordinary patch-stage MF, whereas the aggressive form appears to present with widespread eruptive papulonodular, ulcerative lesions with a predilection for involving the palms and soles of the feet. Aggressive $CD8^+$ MF is more likely to show large cell transformation and aberrant loss of expression of CD2 and other pan T-cell antigens than indolent cases ([182] , [217]). The clinical heterogeneity of $CD8^+$ MF should be considered when planning therapy, as some cases do not require aggressive treatment.

CTCLs expressing the $?d^+$ receptor are rare and have different clinicopathologic presentations, including lesions resembling MF, PR, peripheral T-cell lymphoma, unspecified, and SPTL ([218] , [219] , [262] , [279] , [280] , [281] , [282] , [283] and [284]). In contrast to $aß^+$ MF and SS, $?d^+$ CTCL is typically negative for both CD4 and CD8, with rare $CD8^+$ cases ([283] , [284]). Moreover, cytotoxic T-cell phenotypes have recently been documented for $?d^+$ CTCL ([285] , [286]) and $?d^+$ SPTL ([279]). Most reports suggest that primary $?d^+$ CTCL are aggressive and poorly responsive to therapy ([218] , [280]). Patients presenting with nodules, tumors, or plaques predominantly localized to the extremities should alert the clinician to $?d^+$ CTCL. A recent series looking at $?d^+$ CTCL found all 23 patients to have nodules or tumors on the extremities, with less than half exhibiting concurrent truncal lesions ([283]).

Pleomorphic small to medium-sized CTCL differs from ordinary MF and SS in its clinical presentation and histologic appearance ([287] , [288]). This lymphoma presents initially with papulonodular lesions, tumors, or deep plaques without preceding erythematous patches. Most lesions do not exhibit epidermotropism, and the small pleomorphic lymphocytes do not have cerebriform nuclear convolutions. Similar to MF and SS, most pleomorphic small cell CTCL cases are clonal $CD4^+$ T-cell proliferations with widespread cutaneous lesions. HTLV-1 testing should be performed to differentiate these lymphomas from cutaneous involvement by HTLV-1^+ ATLL. In contrast to the aggressive behavior of ATLL, pleomorphic small cell CTCL appears to follow an indolent course.

SPTL presents as tender, erythematous nodules or subcutaneous palpable masses mostly on the legs, trunk, arms, or face. This rare T-cell lymphoma appears histologically as a lipotrophic lymphohistiocytic infiltrate and typically follows one of two distinct clinical courses. The first involves a prolonged, recurrent panniculitis,

and the second is marked by a rapid clinical decline secondary to hemophagocytic syndrome (HPS) ([289]). SPTL is one of several conditions associated with HPS. A review of 72 cases of SPTL found HPS to be present in 45% of all patients and to be associated with a grave prognosis (50% total case fatality rate and 81% HPS mortality rate) regardless of treatment modality ([289], [290]). Repeat biopsies may be necessary to confirm the diagnosis of SPTL. Once confirmed, early induction of combination chemotherapy with or without radiotherapy may yield remission and prevent the development of HPS ([289]). (For further discussion of SPTL, please refer to Chapter 90.)

Other Hematopoietic Neoplasms with Similar Cutaneous Presentations

Other lymphomas and hematopoietic tumors that may involve the skin include HTLV-1 $^{+}$ ATCL (Fig. 94.13), angiocentric NK/T-cell lymphoma, Hodgkin lymphoma, cutaneous B-cell lymphomas, and leukemia cutis or granulocytic sarcoma.

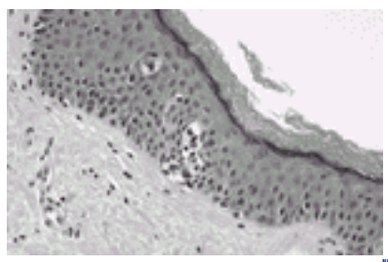

Figure 94.13. Cutaneous involvement by human T-cell lymphotrophic virus type 1 (+) ATLL showing epidermotropism and formation of a Pautrier microabscess (hematoxylin and eosin, ×50). See Color Plate.

Peripheral T-cell and NK/T-cell lymphomas are discussed in Chapter 90. Hodgkin lymphoma is discussed in Chapter 95. Cutaneous B-cell lymphoma, leukemia cutis, and granulocytic sarcoma are discussed below.

Primary cutaneous B-cell lymphomas are uncommon and must be differentiated from secondary cutaneous involvement by systemic B-cell lymphoma and cutaneous lymphoid hyperplasia of B-cell type. Primary cutaneous B-cell lymphomas include follicular lymphomas, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type (immunocytoma), plasmacytoma, intravascular large B-cell lymphoma, and diffuse large B-cell or immunoblastic lymphoma ([291], [292]). Cutaneous B-cell lymphomas usually present as single or multiple violaceous nodules on the head and neck or trunk and tend to infiltrate the deeper portions of the dermis, sparing the epidermis (“bottom-heavy”). Follicular lymphomas are the most common cutaneous B-cell lymphoma. Cutaneous follicular lymphomas may have a nodular or a nodular and diffuse growth pattern and more frequently have a predominance of large noncleaved cells than their nodal counterparts (Fig. 94.14).

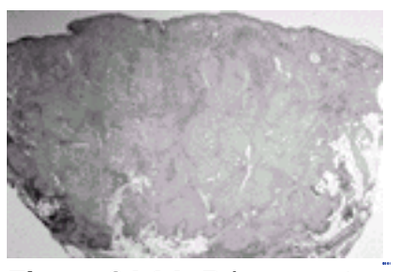

Figure 94.14. Primary cutaneous follicular large cell lymphoma. Note the back-to-back nodular pattern. The infiltrate extends from the superficial reticular dermis to the superficial subcutis in a “bottom-heavy” pattern sparing the papillary dermis and epidermis (hematoxylin and eosin, ×2). See Color Plate.

In contrast to the aggressive behavior of nodal large cell follicular lymphomas, primary cutaneous large cell follicular lymphomas tend to be localized, follow an indolent course, and can often be managed with local excision and radiation therapy ([293], [294] and [295]). However, careful staging must be performed to exclude extracutaneous lymphoma before a case is classified as primary cutaneous B-cell lymphoma. When the large cell lymphoma is restricted to the legs, it is often referred to as *primary cutaneous large B-cell lymphoma of the legs*. Although there is still debate regarding whether this is a distinct entity, several reports show a poor prognosis and a clear predilection for the elderly (average age of onset, 78 years) ([296], [297]). A more detailed discussion of cutaneous B-cell lymphomas is beyond the scope of this chapter.

Leukemia cutis and granulocytic sarcoma are cutaneous infiltrates of myeloblasts and immature myeloid precursors that are often difficult to differentiate from cutaneous lymphoma ([298], [299]). Granulocytic sarcoma, also known as *extramedullary myeloid cell tumor*, usually presents as nodules or tumors that are often solitary, whereas leukemia cutis presents with multiple skin lesions with a varied clinical appearance, including papules, nodules, plaques, palpable purpura, or ulcerated lesions. Histologically, granulocytic sarcoma and leukemia cutis tend to infiltrate between collagen bundles and fat spaces in an interstitial pattern (Fig. 94.15).

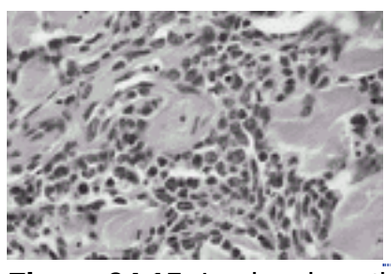

Figure 94.15. Leukemia cutis. Clusters of myeloblasts with fine chromatin and scant cytoplasm infiltrate between collagen bundles in the reticular dermis (hematoxylin and eosin, ×250). See Color Plate.

Cytologically, the myeloblasts of granulocytic sarcoma and leukemia cutis are medium-sized cells with finely dispersed chromatin, small or inconspicuous nucleoli, and scant cytoplasm. Occasionally, eosinophilic or neutrophilic granules may point to the cells' myeloid lineage. In difficult cases, immunohistochemistry, flow cytometry, and cytochemical stains usually confirm the diagnosis and exclude lymphoma. The most useful confirmatory antibodies for immunohistochemistry are myeloperoxidase, CD117, and lysozyme to confirm myeloid lineage and CD34 to confirm their precursor or stem cell level of maturation ([300]). Myeloperoxidase, Sudan black B, and chloroacetate esterase cytochemical stains can be used to confirm myeloid differentiation if air-dried touch imprints are available. Bone marrow and peripheral blood examination are also important.

STAGING

In 1979, a staging system for CTCL was proposed by an international panel of experts who devised a tumor, node, metastasis (TNM) system ([301], [302] and [303]) (Table 94.3).

TABLE 94.3. Cutaneous T-Cell Lymphoma Workshop Staging Classification

T	Skin	N	Lymph Nodes	M	Visceral Organs

T1	Limited plaques (<10% body surface area)	N0	No adenopathy; histology negative	M0	No involvement
T2	Generalized plaques	N1	Adenopathy; histology negative	M1	Visceral involvement
T3	Cutaneous tumors	N2	No adenopathy; histology positive		
T4	Generalized erythroderma	N3	Adenopathy; histology positive		
Stage I	Limited (IA) or generalized plaques (IB) without adenopathy or histologic involvement of lymph nodes or viscera (T1N0M0 or T2N0M0)				
Stage II	Limited or generalized plaques with adenopathy (IIA) or cutaneous tumors with or without adenopathy (IIB); without histologic involvement of lymph nodes or viscera (T1–2N1M0, T3N0–1M0)				
Stage III	Generalized erythroderma with or without adenopathy; without histologic involvement of lymph nodes or viscera (T4N0–1M0)				
Stage IV	Histologic involvement of lymph nodes (IVA) or viscera (IVB) with any skin lesions and with or without adenopathy (T1–4N2–3 M0 for IVA; T1–4N0–3M1 for IVB)				

Stage I refers to patients with only skin disease without adenopathy and is divided into IA for patients with less than 10% body surface area involvement (T1) and IB for more generalized patches and plaques (T2). Stage II has two unique categories: IIA patients have patches/plaques with palpable adenopathy (histology negative), whereas IIB patients have tumors with or without palpable adenopathy (histology negative). Patients with erythroderma are placed into stage III with or without palpable adenopathy (histology negative). Stage IV patients have biopsy-proven extracutaneous CTCL, with stage IVA patients having nodal involvement without visceral disease and IVB patients having visceral disease. In the original TNM staging system, peripheral blood involvement with more than 5% atypical circulating cells is indicated by a separate peripheral blood stage B1 (vs. B0) and does not affect the clinical stage designation. However, two large series have shown that blood involvement is more commonly seen in higher-stage disease, with 0% to 12% of patients with only plaques, 16% to 27% of patients with tumors, and more than 90% of patients with erythroderma, demonstrating peripheral blood involvement ([196], [304], [305]).

In 1984, the Mycosis Fungoides Cooperative Group recommended a staging system for CTCL based only on the extent of skin involvement and palpable adenopathy ([306]). Although clinically practical, this staging system has been seldom used in therapeutic trials ([307]), which would make it difficult to compare the results from studies using the TNM staging system.

After failing to find a significant difference in survival between patients with stage IB and IIA disease, as well as between those with stage IIB and III disease, Kashani-Sabet et al. recently challenged the TNM staging system by proposing several modifications ([308]) based on histologic discrimination between patches and plaques. Patch-stage MF displayed the following characteristics: papillary dermal fibrosis, psoriasiform epidermal hyperplasia, and sparse intraepidermal and papillary dermal infiltrate. Plaque-stage MF was distinguished by the presence of a more prominent lichenoid infiltrate and cellular atypia. Two major changes to the 1979 system were suggested after retrospective data analysis of 450 patients with stage I–III CTCL showed patients with plaques predicting a poorer prognosis when compared to patches or noninvolvement. The first modification involved further dividing those with T2 disease into subtypes according to their predominant lesion, with T2a describing patch predominance and T2b describing plaque predominance. The scope of stage IIA was therefore narrowed to include only T2a and stage IIB to include only T2b. The second modification involved splitting stage III into two subclasses: IIIA and IIIB. Accordingly, tumor stage (T3) was reclassified as IIIA instead of IIB, and generalized erythroderma was reclassified as IIIB ([308]). Further studies are needed to support a need to change the current staging system.

Staging procedures recommended by the international panel in 1979 included lymph node biopsy of a nonpalpable lymph node in patients without adenopathy and liver and bone marrow biopsies for advanced stages (II, III, IV) ([302]). These procedures may be considered in patients in clinical trials but are rarely helpful in those patients with limited skin disease and no lymphadenopathy. Table 94.4 outlines staging procedures for CTCL adapted from the Proceedings of the 1993 International Symposium on Cutaneous T-Cell Lymphoma ([309]). All patients should have a complete physical examination with special attention to skin and lymph nodes. Careful mapping of skin involvement and total body photographs are recommended to document the initial extent of disease at diagnosis and to assess response to treatment ([310]). Laboratory studies should include serum chemistries, lactate dehydrogenase, complete blood count with differential, and Sézary cell count. A recent study showed there is no significant benefit in performing bone marrow biopsies for staging purposes ([311]).

TABLE 94.4. Staging Procedures for Cutaneous T-Cell Lymphoma

Complete history and physical examination
Whole-body mapping of skin lesions
Complete blood count, differential, platelet count, and Sézary cell count
Serum chemistries (include liver and renal function tests, calcium, phosphorus, and uric acid)
Chest radiograph
Skin biopsy and lymph node biopsy (palpable node from draining area; cervical before axillary before inguinal)
Evaluation of other organs if foregoing tests suggest involvement; consider bone marrow biopsies from patients with stages III and IV

The role of diagnostic imaging in the initial staging of CTCL has been examined by several authors ([312], [313], [314] and [315]). Kulin et al. studied the results of gallium citrate Ga 67 scintigraphy, liver–spleen scans, lymphangiography, and computed tomography (CT) used in the initial staging of 62 CTCL patients (85% with stage I or II disease) and found that none of the results added significantly to the information obtained from physical examination and routinely performed lymph node biopsy (73% of 62) ([313]). In contrast, a study of 63 CTCL patients (78% with stage I or II disease) who had staging body CT scans found positive findings in 18 (29%) patients, one-half of whom had clinically unsuspected advanced-stage disease ([312]). Eight of these 18 patients had biopsies with five of eight confirming extracutaneous CTCL ([312]). Of the 38 patients with stage I disease, however, only two had positive findings on CT scan ([312]). Another retrospective study of 33 CTCL patients (70% with stage I or II disease) who had CT scans found that 3 of the 20 patients with initial clinical stage I disease were staged higher on the basis of CT findings as stage II ([314]). Subsequent lymph node biopsies confirmed extracutaneous disease in all three patients (stage IVA) ([314]). In summary, pelvic, abdominal, and thoracic CT scans have a low yield in patients without palpable adenopathy (stage I) and are not necessary for staging these patients. The highest yield of CT scans appears to be in patients with non-MF/SS CTCL (nonepidermotropic, transformed CTCL, ALCL) and stage III disease (erythroderma), in contrast to stage II and IV patients, in whom CT findings often do not change treatment or stage ([312]). Most investigators agree that CT scanning is useful for accurate baseline assessment of advanced skin stage patients with palpable adenopathy and to follow for disease progression ([316]).

Positron emission tomography may provide an alternative staging and response-assessment tool for patients with CTCL. However, despite a case report detailing this procedure as a sensitive diagnostic modality in aggressive SPTL, other data are lacking ([315]). Invasive tests such as liver biopsy or staging laparotomy have added little diagnostic information for patients with early and advanced stage disease ([197], [208], [317]).

Bone Marrow

Studies of bone marrow involvement in MF patients at initial staging found disease in 2% to 22% of patients ([198], [203], [318]). Histologic findings in involved marrows include clusters of $CD3^+$ atypical lymphocytes with cerebriform nuclei and occasional large dysplastic cells ([203]). Bone marrow involvement by MF is more common in higher-stage disease and correlates with a poorer prognosis; however, when other factors such as skin stage and visceral involvement were considered, bone marrow involvement was not shown to be an adverse prognostic factor ([319]). These findings were supported by a recent study that evaluated the prognostic significance of histologic and molecular evidence of bone marrow involvement at the time of diagnosis. This study also showed a correlation between histologic or molecular bone marrow involvement and clinical stage of disease, but bone marrow involvement failed to be an independent prognostic indicator ([311]). Therefore, despite being considered in initial staging of non-MF/SS lymphoma patients, routine staging bone marrow biopsies in patients with MF are not currently

recommended.

Lymph Nodes

Although the presence of palpable nodes has prognostic value, lymph node histology is even more important in staging and assessing prognosis, not only at diagnosis but also later in the course of the disease. Enlarged lymph nodes from MF/SS patients show either dermatopathic lymphadenopathy or involvement by MF/SS. Sausville et al. described a system of grading lymph nodes in CTCL patients [NCI–Veteran's Administration (NCI-VA) classification] that correlated well with prognosis: LN1, a few atypical cutaneous T cells; LN2, dermatopathic lymphadenopathy with small clusters (<6 cells) of atypical cutaneous T cells; LN3, dermatopathic lymphadenopathy with large clusters (>6 cells) of atypical cutaneous T cells; and LN4, partial or complete effacement of lymph node architecture ([196], [304]). Although clusters of atypical cutaneous T cells are present in grades LN2 and LN3, lymph node architecture is preserved. Only LN3 and LN4 lymph nodes are considered involved with CTCL (histology positive) for purposes of the TNM staging system (Table 94.5). The NCI-VA classification has been criticized because of the nonspecificity of grades LN1 through LN3 and because lymph nodes from patients with unrelated diseases can show similar findings, and many consider LN3 lymph nodes to be histologically borderline ([187], [320], [321] and [322]).

TABLE 94.5. Histopathologic Grading Scheme for Cutaneous T-Cell Lymphoma with Lymph Node Involvement

Grade	Histopathologic Features
LN1	DL with occasional CTC
LN2	DL with CTC singly or in small clusters (<6 cells)
LN3	DL with numerous CTC, singly or in large clusters (>15 cells)
LN4	Partial or complete effacement by MF/SS ± DL

CTC, cerebriform T cells; DL, dermatopathic lymphadenopathy; LN, lymph node; MF, mycosis fungoides; SS, Sézary syndrome.
Modified from Clendenning WE, Rappaport HW. Report of the committee on pathology of cutaneous T cell lymphoma. Cancer Treat Rep 1979;63:719–724.

In general, there is good correlation between histologic and molecular evaluation of lymph nodes for involvement by MF/SS. Three studies have shown that most histologically negative lymph nodes (LN1–2) do not show TCR gene rearrangements, whereas approximately 90% or more histologically involved lymph nodes (LN4) do show clonal TCR gene rearrangements by Southern blot analysis ([323], [324] and [325]). All three studies also showed a mixture of clonal and polyclonal populations in histologically borderline cases (LN3 or histologically equivalent to LN3). Although not statistically significant in all studies, histologically borderline cases that have a positive TCR gene rearrangement tend to have a poorer prognosis, similar to cases with histologically involved lymph nodes (LN4) ([323]).

Fine-needle aspiration of lymph nodes to assess for involvement by MF/SS has been evaluated in a limited number of patients with good correlation between cytologic grade of the fine-needle aspiration specimen and histologic classification of the lymph node biopsy ([322], [326]). However, as with other types of lymphomas, there is an inherent risk of sampling only low-grade involvement and missing a focal area of transformation to a large cell lymphoma.

Peripheral Blood

The Committee on Staging and Classification of Cutaneous T-Cell Lymphomas defined peripheral blood involvement by MF/SS as >5% peripheral blood lymphocytes with Sézary cell morphology (Fig. 94.16) ([302]); however, this criterion is not uniformly agreed upon.

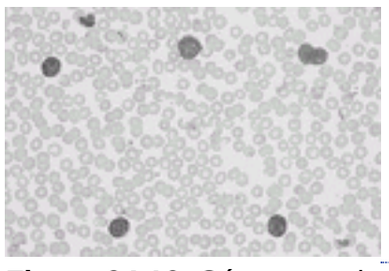

Figure 94.16. Sézary syndrome. The peripheral blood shows lymphocytosis. Most lymphocytes are Sézary cells with enlarged, highly convoluted nuclei and scant cytoplasm (hematoxylin and eosin, ×250). See Color Plate.

Because Sézary cells can be seen in the peripheral blood of patients with benign dermatitis or erythroderma ([327]), other investigators have suggested that 10% to 20% Sézary cells be used to define peripheral blood involvement ([211]). Most recently, the International Society for Cutaneous Lymphomas has recommended using two categories of peripheral blood involvement ([213]). Peripheral blood containing more than 5% Sézary cells is designated B1. A variety of findings are designated B2 and include (a) absolute Sézary cell count of 1000 cells/mm ^{3} or more, (b) a CD4:CD8 ratio of 10 or more due to an increase in CD3 $^+$ or CD4 $^+$ cells by flow cytometry, (c) aberrant expression of T-cell markers by flow cytometry (CD2, CD3, CD4, CD5) or decreased CD7 expression with an expansion of CD4 $^+$ T cells, (d) an increased lymphocyte count with molecular evidence of a T-cell clone in the peripheral blood, or (e) a chromosomally abnormal T-cell clone. If a patient meets criterion 1, 2, or 4 but does not demonstrate MF/SS substantiated via skin or lymph node biopsies, additional evidence of malignancy is required to avoid misdiagnosis.

In addition to the number of Sézary cells present, quantification of nuclear size and nuclear irregularity has been recommended to improve the specificity of Sézary cell counts ([178], [211], [328]).

Because of the inherent difficulties in diagnosing peripheral blood involvement by MF/SS on peripheral smear review, additional technologies are now used, including flow cytometry and molecular studies such as PCR. Flow cytometry analyzes the ratio of CD4 $^+$ to CD8 $^+$ T cells and looks for an aberrant phenotype. As discussed above, aberrant phenotypes include the absence of T-cell markers such as CD2, CD3, CD5, and CD7, which are usually expressed on normal T cells, or coexpression or absence of both CD4 and CD8. A CD4:CD8 ratio of greater than 10:1 or an aberrant phenotype constitutes an abnormal population. Because decreased CD7 expression on T cells has been seen in patients with benign skin conditions, the International Society for Cutaneous Lymphomas recommends that 40% or more of the CD4 $^+$ T cells lack CD7 for it to be considered significant. Recently, PCR of peripheral blood has been shown to detect a clonal population of T cells in approximately one-third of patients with stage I–II disease and a majority of patients with stage III–IV disease ([329], [330]). Recently, loss of CD26 expression on circulating CD4 $^+$ T cells has been reported in most cases of MF and SS ([331], [332]). The usefulness of this assay for diagnostic purposes needs to be confirmed, but it may provide a more sensitive way to use flow cytometry to evaluate peripheral blood for involvement by MF/SS.

PROGNOSIS

Prognosis correlates with the extent of skin disease and status of the lymph nodes, blood, and visceral involvement. MF behaves in a manner similar to other low-grade or indolent NHLs with prolonged survival despite recurrent relapses (see Chapter 90). The median survival in the Stanford University series of 464 CTCL patients is nearly 10 years from the date of first visit, and the approximate percentage of patients surviving according to skin stage at 10 years are 85% for limited plaques (T1), 55% for generalized plaques (T2), 20% for tumors (T3), and 30% for erythroderma (T4) ([99]). Similarly, Zackheim et al. assessed relative (observed/expected) long-term survival among the four skin stages. Stage and survival data for 489 CTCL patients was extracted from a University of California, San Francisco, CTCL registry dated 1957 through 1994 and compared to a control group matched for age, sex, race, and geographic variables. Using the control group to

generate expected survival values, researchers found a relative survival at 10 years for each group as follows: 100% for T1, 67% for T2, 40% for T3, and 41% for T4 ([333]).

The TNM staging system has correlated well with prognosis demonstrating the following 5-year survival rates: 95% for stage I, 76% for stage II, 45% for stage III, and 51% for stage IV ([333]). Data from a retrospective cohort analysis suggest that the long-term (30-year) survival of patients with stage IA (limited patch/plaque) MF is similar to the expected survival of a matched control population ([334]). Therefore, it is unlikely that stage IA MF will affect the life expectancy of afflicted patients.

Using histology to differentiate between patch and plaque predominance within stage T2, one study found plaque predominance to negatively influence relative survival ([306]). A retrospective analysis by Sausville et al. of 152 consecutively staged patients at the NCI identified advanced skin stage (T3, T4), palpable adenopathy, visceral involvement, blood involvement, eosinophilia, and lymph node histopathology (NCI-VA classification LN3 or LN4) as significant univariate adverse prognostic factors ([196]). Skin stage (T3, T4 vs. T1, T2) and visceral involvement were the most significant independent predictors of survival, with palpable adenopathy and lymph node histopathology classification showing marginal significance using multivariate analysis ([196]). Three prognostic groups were identified, with the most favorable low-risk group having limited skin disease without visceral or blood involvement (TNM stages IA, IB, IIA) and the least-favorable high-risk group demonstrating effaced lymph nodes (NCI-VA LN4, TNM stage IVA) or visceral involvement (TNM stage IVB) ([196] , [316]). The intermediate-risk group includes all other patients (TNM stages IIB, III) and stage IVA patients with grade LN3 lymph node histopathology. As noted in the previous section on staging, several recent reports suggest that patients with grade LN3 lymph nodes with TCR ß gene rearrangement have a worse prognosis than similar patients without evidence of gene rearrangement ([323] , [324]). It is reasonable to assume that patients who have grade LN3 lymph nodes with TCR ß gene rearrangement would fall into the least-favorable high-risk prognostic group.

In a small series of 43 CTCL patients, 29 of whom received systemic chemotherapy, multivariate analysis indicated that skin stage (T) and the serum lactate dehydrogenase value influenced survival as independent variables in their clinical model, whereas skin stage and thickness of the skin infiltrate showed statistical significance in their clinicopathologic model ([335]). Extracutaneous spread lacked prognostic value in this series.

A more recent study of 57 patients demonstrated serum lactate dehydrogenase to reflect tumor burden in erythrodermic CTCL, with levels being inversely related to hematologic stage and survival ([336]). This study used a univariate model, which found lymph node stage and hematologic stage to poorly predict survival. On multivariate assessment, however, only lymph node stage served as an important prognostic indicator of survival.

The prognosis for patients with extracutaneous disease is poor, with median survivals between 1 and 2.5 years ([99]). Virtually all patients with extracutaneous disease die of CTCL as compared to nearly one-third of patients with generalized plaques and a majority of patients with tumors or erythroderma without visceral involvement ([310] , [337]). Very few patients with limited plaques (T1) actually die of MF, with most deaths due to cardiovascular events or other malignancies ([99] , [310]). Overall, illnesses directly attributed to CTCL or indirectly implicated via CTCL-related complications contribute up to a mere 19% of deaths in CTCL patients ([333]). Thus, the bulk of patients with CTCL do not die from their malignancy ([99] , [100]). Second malignancies other than skin cancers include NHL, Hodgkin disease, colon cancer, and lung cancer ([338]). Infection remains the most common cause of death in patients who die from CTCL, with *Staphylococcus aureus* and *Pseudomonas aeruginosa* as the most common pathogens infecting the skin, leading to bacteremia and sepsis ([100] , [337] , [339]). Visceral involvement with CTCL may lead to organ failure and, ultimately, death ([99] , [310]).

THERAPY

The mainstay of treatment of CTCL has been control of the cutaneous manifestations of disease with topical therapies in the hope of preventing spread to extracutaneous sites. However, due to the risk of progression to extracutaneous sites and worsening cutaneous symptoms, systemic agents alone or in combination with topical therapies have been studied to control more advanced disease. Therapy in MF/SS is based on the extent of disease, age, performance status, potential for remission, availability of treatments, efficacy, and treatment toxicity ([340] , [341] , [342] and [343]). Because MF usually behaves as a low-grade or indolent lymphoma, controversial issues have involved the timing, selection, and intensity of systemic therapy ([99] , [100] , [340] , [341] , [342] and [343]). Unfortunately, there are few randomized clinical trials comparing the efficacy of the numerous therapeutic options available for patients with MF/SS (Table 94.6) ([333]). The following discussion summarizes the efficacy and toxicity of each therapy and relates these parameters to the disease stage (Fig. 94.17).

TABLE 94.6. Therapy for Cutaneous T-Cell Lymphoma

Topical
Chemotherapy (HN_2, BCNU)
Phototherapy (PUVA)
Electron beam radiotherapy (EBRT)
Photon irradiation
Systemic chemotherapy
Single agents
Combination chemotherapy
Combined modality therapy
Chemotherapy + EBRT
Other
Extracorporeal photochemotherapy
Interferons
Monoclonal antibody therapy
Interleukin-2 and fusion toxin therapy
Other agents

BCNU, bischloroethylnitrosourea; HN_2, nitrogen mustard; PUVA, psoralen and ultraviolet A light.

Treatment of cutaneous T cell lymphoma: current status and future directions. Am J Clin Dermatol 2002;3:193–215.)

Topical Chemotherapy

Mechlorethamine hydrochloride, or nitrogen mustard (HN_2), was introduced in 1947 as the first topical agent to demonstrate activity in treating MF ([344], [345]) and remains one of the major therapies of choice for early-stage MF ([346]). HN_2 is an alkylating agent that undergoes rapid degradation to an active ethy-lenimonium ion that has high antimitotic activity and a brief half-life ([99]). Studies have suggested that the mode of action of HN_2 may involve interference with the activation of M-phase promoting factor ([347]), gene-specific DNA cross-links ([348]), and blockage of transcription factor binding sites ([349]). Some investigators have suggested that immunogenic properties of HN_2 demonstrated by its propensity to induce delayed-type hypersensitivity contribute to its antineoplastic activity ([346], [350]). Topical HN_2 may be prepared in a variety of ways; initial studies involved dissolving HN_2 in water to reach a concentration of 10 to 20 mg/dl ([351]), whereas, more recently, HN_2 has been suspended in an emollient such as xipamide (Aquaphor) at concentrations of 0.01% and 0.02% ([352], [353]). Topical HN_2 is applied once daily to the entire skin surface with relative sparing of the eyelids, genitalia, rectum, lips, and intertriginous areas. The length of treatment is variable but usually involves daily applications until the patient achieves a complete or significant clearing of skin lesions followed by a maintenance regimen of daily or every-other-day applications for a period of 6 months to 2 years ([354], [355]). No author has advocated a maintenance regimen of indefinite HN_2 applications. Treatment may be intensified for localized lesions by increasing either the concentration or frequency of application ([354]).

The response rate of topical HN_2 is related to the morphology (patch/plaque vs. tumor) and extent of disease (T1 vs. T2). Three large series with more than 100 patients have been reported ([355], [356] and [357]). Overall response (OR) rates between the three studies are difficult to compare because of differences in the clinical stages treated, adjunctive therapies, and staging systems. The percentage of patients with early-stage MF achieving an initial complete remission (CR) ranged from 64% ([356]) and 75% ([355]) (stage I) to 50% ([357]) (stage I–III). More than 80% of patients with T1 skin stage can be expected to have significant clearing of skin lesions. The median time to achieve CR is shorter for stage I patients than more advanced stages. Disease progression to a higher skin stage has been recently reported in 12% and 17% of T1 and T2 patients, respectively, treated initially with HN_2 ([357]). The freedom-from-progression rates in this study at 10 years were 85% and 83% for T1 and T2 patients, respectively. Kim et al. observed relapses in 42% of 107 patients after an initial CR, all of which occurred within 5 years ([357]). Vonderheid et al. found a durable CR to HN_2 lasting more than 8 years occurring in 34 of 324 (10%) patients with early-stage CTCL ([355]).

The side effects of topical HN_2 include local allergic reactions, xerosis, hyperpigmentation, and secondary cutaneous cancers ([346]). Immediate hypersensitivity reactions manifesting as urticaria are rare but do occur in approximately 5% of patients using topical HN_2 and necessitate discontinuing treatment to avoid a potentially life-threatening anaphylactic reaction ([346], [356], [358]). Delayed-type hypersensitivity reactions (allergic contact dermatitis) manifesting as erythematous eczematous patches occur in up to 58% of patients treated with aqueous HN_2 ([355], [356]) but occur less frequently (<10%) with the ointment-based preparation ([352], [354], [357]). Some investigators have suggested that the delayed-type hypersensitivity reaction to topical HN_2 may have a beneficial effect in clearing MF lesions ([346], [350]) and advocate topical desensitization ([356], [359]) rather than discontinuation of the HN_2 when delayed-type hypersensitivity reactions occur ([346]). Hyperpigmentation of the skin, especially in sites of MF involvement, occur commonly in patients using topical HN_2, and patients should be reassured that the hyperpigmentation will spontaneously resolve within several months ([346], [350], [360], [361]).

In their study of 331 patients treated with HN_2, Vonderheid et al. calculated an 8.6-fold (N = 31, 9%) and 1.8-fold (N = 27, 8%) increased risk for the development of squamous cell carcinoma and basal cell carcinoma of the skin, respectively, when compared to the general U.S. population ([355]). In contrast, Kim et al. found basal cell carcinoma or squamous cell carcinoma skin neoplasms in only 8 of 203 (4%) CTCL patients treated initially with HN_2 ([357]). Because HN_2 is a known radiomimetic agent ([362], [363]) its carcinogenic potential may be amplified with the simultaneous use of other agents, most notably ultraviolet therapy ([346]). To help minimize this risk, patients using HN_2 should adhere to strict protection from sun exposure ([346], [355], [356]). The risk of environmental contamination from topical HN_2 appears to be minimal, as there are no epidemiologic data of increased malignancy in family members of treated patients; however, treatment assistants should wear latex gloves and wash accidentally exposed skin thoroughly ([364], [365]).

Topical carmustine, a nitrosourea compound, is also used to treat early-stage MF, although experience is more limited than with topical HN_2 ([346], [366]). The use of topical nitrosoureas for the treatment of MF was first reported in 1972 ([367]), and its principal mode of action is alkylation ([368]). Patients mix a 5-ml (10-mg) aliquot of a 0.2% alcoholic stock solution with 60 cc of tap water and apply the solution only to the involved areas of MF ([346]). Applications are repeated daily for no more than 8 to 10 weeks at a time. Zackheim et al. reported a CR in 86% of stage T1 patients and 48% of stage T2 patients treated with topical carmustine solution ([366]). In their follow-up report of 188 early-stage MF patients treated with topical carmustine, 91% of stage T1 patients and 62% of stage T2 patients had not failed treatment after 36 months, and 5-year survivals were 97% and 80%, respectively ([346]). Side effects included erythema and skin tenderness in a great majority of patients, telangiectasia after less common severe cutaneous reactions, allergic cutaneous reactions (<10%), and mild leukopenia (4%) ([346]).

Electron Beam Radiotherapy and Photon Beam Irradiation

Radiation was one of the earliest effective treatments for MF first reported in 1902 ([369]). In 1953, Trump et al. were the first to suggest using accelerated electrons for treatment ([370]). Modern total skin electron beam radiotherapy (TSEBRT) is among the most effective and well-studied therapies for CTCL ([371], [372]). The total skin surface can be treated by linear accelerator-generated electron beams that are scattered by a penetrable plate at the collimator site ([100], [373]). The usual depth of penetration is much less than 10 mm and is proportional to the energy of the electrons generated, allowing effective dosing to the skin and adnexal structures without internal organ toxicity ([372]). The most common technique uses a dual fixed-angle six-field or rotation methods with 4 to 9 MeV electrons. Total doses range between 2400 and 3600 cGy over an 8- to 10-week period ([372], [374], [375]). With this technique, relatively lower doses are delivered to the scalp, soles, and areas of self-shielding, such as the ventral penis, perineum, upper medial thighs, perianal skin, inframammary folds, and folds under any pannus ([99], [372]). Only the eyes are routinely shielded, and unless there is involvement of the head and neck, a scalp shield is used after a dose of 2500 to 2600 cGy has been delivered to decrease the degree of alopecia ([99], [372], [375]). The hands, forearms, ankles, and dorsal penis may receive doses above 100%, and shielding all of these structures for part of TSEBRT is not uncommon ([372], [376]).

The long-term results of 561 MF patients treated at Stanford University and Hamilton Regional Cancer Centre from the mid-1950s to 1993 with TSEBRT alone were summarized by Jones et al. ([372]) (Table 94.7). More than 80% of stage IA patients can be expected to achieve a CR after TSEBRT with 40% to 60% remaining relapse free at 5 years ([372]). Less encouraging were the relapse-free rates at 2.5 years for stages IB (35% to 40%), IIA (21% to 37%), IIB (7% to 26%), and III (10% to 23%) ([372]). However, most patients who relapse with what is usually minimal disease will reenter remission with other topical therapies ([372]). Logistic regression analysis of data from 333 CTCL patients treated with varying doses and energies of TSEBRT found that skin stage (T1 > T2–4) and energy (=3.5 MeV) were independently associated with complete cutaneous remission (p <.0001) ([372]). Similar analysis of 320 patients from Hamilton Cancer Centre found stage and dose, not energy, to be independently correlated with remission ([372]). Neither dose nor energy was associated with relapse-free survival for the 230 patients in remission from the same center. Skin stage T1, lower lymph node stage, and receiving TSEBRT for a new diagnosis of MF significantly predicted a greater relapse-free survival ([372]). Another report suggests that prognosis for tumor stage patients with less than 10% skin involvement treated with TSEBRT is significantly better than patients with more than 10% involvement ([377]).

TABLE 94.7. Summary of Selected Series of Patients Treated with Total Skin Electron Beam Radiation Therapy (TSEBRT) Alone in Cutaneous T-Cell Lymphoma

Institution	No. of Patients	Stage (NCI-VA)	Complete Response	Freedom from Relapse [a] (%)			Survival (Death from All Causes) (%)			Comments
				2.5-yr	5-yr	10-yr	5-yr	10-yr	15-yr	

Stanford University (1958–1993)	241	IA	25/26 (96%)	73	56	52	92	83	78	Most patients treated since 1980 have received adjuvant topical HN_2 after TSEBRT. Since the mid-1970s, the standard dose was 3600 cGy (2.5–9.0 MeV).
		IB	29/52 (56%)	35	25	14	75	57	46	
		IIA	40/63 (63%)	21	13	11	71	56	33

Adapted from Jones GW, Hoppe RT, Glatstein E. Electron beam treatment for cutaneous T-cell lymphoma. Hematol Oncol Clin North Am 1995;9:1057–1076.

Acute cutaneous side effects peaking 1 to 2 weeks after TSEBRT include erythema, edema, dry or moist desquamation, tenderness, and rare blister formation that is most severe at sites of disease ([372], [378], [379] and [380]). Total-body alopecia and loss of nails occurs in all unshielded patients, but the skin appendages normally regrow within 6 months ([372]). During the first year, heat intolerance may develop due to the suppression of sweat gland production, which may be permanent ([100], [381]). Patients with erythroderma (T4) may experience more severe acute side effects from TSEBRT; however, radiation may be effective in stage III, especially with no blood involvement ([340], [375], [382]). When there is blood, lymph node, or visceral involvement in patients with erythroderma, combined modality therapies—in particular, photopheresis—should be explored ([382], [383]). Chronic cutaneous side effects most commonly include xerosis, superficial atrophy, telangiectasia, and dyspigmentation ([99], [372], [384]). The role of TSEBRT in the development of secondary cutaneous malignancies has not been clearly established, as most patients have received a variety of therapies, which could contribute to the development of skin cancer ([372]).

Two studies have evaluated the response and toxicity of multiple courses of TSEBRT for CTCL ([385], [386]). Wilson et al. ([385]) reported on 14 CTCL patients—five patients who received three courses of TSEBRT, and nine patients who received two courses. The total median dose was 5700 cGy (range, 4500 to 8200 cGy) with 86% (N = 12) achieving a CR after the second course of therapy (median relapse-free interval, 11.5 months) and three of five (60%) achieving a CR after a third course (limited follow-up) ([385]). Three patients developed skin cancers (basal cell carcinoma in three; one with squamous cell carcinoma) ([385]).

Because of the toxicities of TSEBRT and the effectiveness of topical therapies, most authorities recommend using TSEBRT for patients with progressive disease, those who do not respond to topical therapies, or those with extensive, deeply infiltrated plaques and tumors ([100], [340], [343], [371], [372], [387]). Due to the high relapse rates after TSEBRT, posttreatment with nitrogen mustard, photopheresis, and psoralen and ultraviolet A light (PUVA) have been studied to maintain remissions ([371], [382], [383], [387]).

Small-field megavoltage photon beam irradiation can be applied as palliation either to deep-seated cutaneous lesions in the tumor phase or for extracutaneous disease ([388]). Nearly all cutaneous lesions completely respond, with the risk of relapse (up to 45%) inversely proportional to the dose, and with recurrence usually developing within 2 years of treatment ([389]).

Systemic Chemotherapy

Single- and multiagent chemotherapy are reserved for patients who have relapsed, have refractory disease, have extracutaneous disease at diagnosis, or are part of a clinical trial ([341], [390], [391]). Single-agent chemotherapy used for CTCL includes oral corticosteroids, alkylating agents, methotrexate, doxorubicin, bleomycin, vincristine, vinblastine, cisplatin, and etoposide and has resulted in an objective response in a majority of patients with CR ranging from 15% to 25% ([390], [392]). However, median relapse-free intervals are usually short lasting—less than 6 months and ranging from 3 to 22 months ([340], [390], [391]). The majority of patients with CTCL advanced enough to justify the immunosuppressive and toxic side effects associated with systemic chemotherapy do not have significant improvement in long-term survival.

Low to intermediate weekly doses of oral methotrexate may result in long remissions for erythrodermic CTCL patients ([393]) and has been used in advanced-stage patients after induction with intravenous methotrexate followed by oral citrovorum factor, showing a median duration of response of 24 months ([394]). As an adjunct, methotrexate has also been used to treat patients with patch- or plaque-stage MF after other treatments have failed.

Combination chemotherapy has been studied primarily in small trials and has been reviewed with objective response rates of 60% to 100% (Table 94.8). The mean CR is 38% (range, <10% to 80%), and response ranges from 5 to 41 months ([390]). In contrast to prior reports of combination chemotherapy inducing longer durations of remission than single-agent chemotherapy, follow-up studies have shown little difference in survival between numerous single- and multiagent regimens ([391], [395]).

[a] Taken from the review of Broder and Bunn (reference 101).

Modified from Bunn et al. (reference 390).

SS has been successfully treated with chlorambucil, an alkylating agent. Prior studies have evaluated daily administration of chlorambucil and prednisone (Winkelmann regimen) or chlorambucil and fluocortolone (396 , 397 and 398). Fluocortolone is favored, as it lacks a mineralocorticoid effect, while sharing a similar potency with prednisone. In a recent uncontrolled pilot study, 13 patients with erythrodermic CTCL were treated with chlorambucil (10 to 12 mg per day for 3 days) and fluocortolone (first day, 75 mg; second day, 50 mg; and third day, 25 mg). Initially, doses were pulsed every 2 weeks and then subsequently prolonged according to clinical status. Seven patients achieved a CR and six had a partial remission, with a mean duration of remission of 16.5 months. At the time of follow-up (mean 31.5, median 27 months), six patients remained in CR and three patients showed stable PR, with no treatment-related severe side effects observed among the group (398).

One class of antineoplastic agents that has shown activity in CTCL are the purine nucleoside analogs: 2-deoxycorformycin (dCF or pentostatin) (399 , 400 , 401 , 402 and 403), cladribine (404 , 405 , 406 and 407), and fludarabine (408 , 409). dCF inhibits adenosine deaminase, an enzyme of purine metabolism found in high concentration in T lymphocytes, whereas phosphorylated cladribine and fludarabine resist degradation by this enzyme and accumulate in cells inhibiting DNA synthesis and repair (404 , 407 , 410). Several small studies using dCF in heavily pretreated patients with MF and SS demonstrated an OR of 41% (range, 14% to 67%) with less than 7% CR and short response durations (390 , 399 , 402 , 410). In a recent study of 20 patients, six with tumor-stage CTCL and 14 with SS, dCF treatment was administered intravenously at a starting dose of 3.75 to 5.0 mg/m ^{2} per day for 3 days every 3 weeks. Results of this study included an OR of 71% and a CR of 25% (median response duration, 2 to 3.5 months) (411).

Kuzel et al. (405) reported the results of a phase II trial of 2-chlorodeoxyadenosine used to treat 21 heavily pretreated MF/SS patients and found an OR in 28% and a CR in 14%, with a median duration of response of 4.5 months. 2-Chlorodeoxyaden-osine was administered at a dose of 0.1 mg/kg per day as a continuous intravenous infusion for 7 days but was subsequently reduced to 5 days after hematologic toxicity occurred. Each cycle consisted of 28-day intervals. The most significant toxicities during this study were bone marrow suppression (62%) and infectious complications (62%) (405). Fludarabine alone has shown similar ORs (409) but, in combination with IFN, has demonstrated a higher response rate (51%) and a slightly longer median relapse-free interval of 5.8 months (408).

Gemcitabine, a pyrimidine antimetabolite, has shown low toxicity and prompt results when used experimentally on 30 patients refractory to other therapies (412). In this phase II trial, gemcitabine was given on days 1, 8, and 15 of a 28-day schedule at a dose of 1200 mg/m ^{2} intravenously over 30 minutes for a total of three courses. Patients with stage T3 and T4 disease yielded a 70% OR and a 10% CR. One to two cycles of gemcitabine were sufficient to induce tumor reduction in approximately 83% of patients with stage IIB MF. Side effects, although mild in extent, included neutropenia (34%), thrombocytopenia (25%), cutaneous hyperpigmentation (17%), and elevated liver enzymes (13%) (412). Several reports have implicated gemcitabine as the cause of isolated cases of cardiotoxicity, including atrial fibrillation, myocardial infarction, and congestive heart failure (412 , 413 and 414).

Altering a drug's vehicle can improve its efficacy and lower its toxicity, as evidenced by the new pegylated liposomal preparation of doxorubicin (415). A recent study treated 10 patients with stages IB, IIA, IIB, and IVA with relapsing or recalcitrant CTCL with pegylated liposomal doxorubicin. The drug was administered at a dosage of 20 mg/m ^{2} once a month, with an upper limit of 400 mg or eight infusions to induce a clinical response. Sixty percent of patients experienced a CR, 10% PR, and 10% stable disease after this monotherapy (416 , 417).

Temozolomide, another novel systemic chemotherapeutic agent, although yet to complete phase II trials, has demonstrated promising efficacy in the treatment of CTCL. This alkylating agent produces O ^{6}-alkylguanine adducts, which are deactivated by O ^{6}-alkylguanine-DNA alkyltransferase, a DNA repair enzyme often found in tumor cells. Dolan et al. found that patients with MF demonstrated lower-than-expected levels of O ^{6}-alkylguanine-DNA alkyltransferase in tumor cells, thus emphasizing temozolomide's potential therapeutic efficacy in this specific malignancy (418). Phase I studies of temozolomide use in various malignancies, including CTCL, have shown myelotoxicity to be a dose-limiting factor (419 , 420). Subsequently, the recommended dose for phase II trials is 150 mg/m ^{2} orally for 5 days (total dose, 750 mg/m ^{2}), and if no major myelosuppression is detected on day 22 of the 4-week cycle, the subsequent courses can be given at 200 mg/m ^{2} for 5 days (total dose, 1 g/m ^{2}) on a 4-week cycle. Using this 5-day schedule, one patient with MF achieved a CR lasting 7 months (419).

Depsipeptide is a histone deacetylase inhibitor, loosening DNA-histone contacts and thus rendering DNA vulnerable to damage. Depsipeptide inhibits class I enzymes, functioning as a stable prodrug. After uptake into cells, a glutathione-mediated step converts the drug into its active form. Thus, a benefit of depsipeptide lies in its ability to counteract glutathione-mediated drug resistance (421). *In vitro* and *in vivo*, depsipeptide is cytotoxic to both murine and human tumor cell lines. In a phase I trial of depsipeptide conducted at the NCI, three patients with CTCL had a PR and one patient with peripheral T-cell lymphoma, unspecified, had a CR. Doses were 12.7 or 17.8 mg/m ^{2} and were infused over 4 hours on days one and five of a 21-day cycle. After treatment, Sézary cells isolated from patients had increased histone acetylation (422). An ongoing phase II, multicenter, open-label trial is currently evaluating the activity and tolerability of depsipeptide in progressive or persistent CTCL. Depsipeptide is being dosed at 13 mg/m ^{2} on days 1, 8, and 15 of a 28-day cycle, and preliminary results are pending (422a). A likely role for depsipeptide in combination therapy has been suggested (422).

Retinoids

Retinoids are a class of pharmaceuticals whose structure and function resemble vitamin A and its metabolites. Vitamin A and its analogs, the retinoids, have antiproliferative activity, may induce cellular maturation, and probably modulate immune response (423). Isotretinoin and etretinate, a monoaromatic retinoid compound, have demonstrated similar efficacy in the treatment of CTCL (424). Three clinical trials have demonstrated overall objective clinical responses in 66 of 113 patients (58%) treated with isotretinoin or etretinate, and a CR in 19% (424 , 425 and 426). Median duration of response, however, has ranged from 3 to more than 8 months (424 , 425 and 426). Etretinate is no longer available and has largely been replaced with acitretin because of its better safety profile. Acitretin may reduce the thick palmoplantar keratoderma of advanced MF or SS (423).

In 1999, the U.S. Food and Drug Administration approved the use of bexarotene capsules, a novel retinoid, for the treatment of CTCL. Unlike isotretinoin and acitretin, which bind to nuclear RAR retinoid receptors, bexarotene binds to and activates nuclear RXR receptors and is therefore referred to as a *rexinoid*. The RXR receptors are unique in that they form heterodimers with a vast array of nuclear receptors, including the RAR receptors and peroxisome proliferator activator receptors (392). The ultimate antiproliferative effect is mediated, in part, by the induction of apoptosis and expression of adhesion molecules (427 , 428 and 429). Two multicenter clinical

trials established the optimal dose of 300 mg/m ^{2} per day with an OR rate of 45% ([430], [431]). Higher response rates were seen in patients with higher initial doses (up to 650 mg/m ^{2}), but side effects of hypertriglyceridemia were dose limiting. Subsequent pancreatitis occurred in 4 of the 152 patients enrolled in the two clinical trials ([430], [431]). The advanced-stage CTCL trial showed a relapse rate of 36%, but an impressive median duration of response of 299 days ([428]).

Talpur et al. recently summarized the experience of treating 70 patients with CTCL using bexarotene capsules as monotherapy combined with other modalities ([432]). Many of the patients participated in the two pivotal clinical trials. The OR rate seen in the monotherapy group (N = 54) was 48% in contrast to the 69% OR rate in the combination therapy group. Bexarotene was safely added to the photopheresis [extracorporeal photochemotherapy (ECP)], ECP/IFN, IFN/PUVA, and ECP/IFN/PUVA. Adverse effects were similar between the clinical trials and included hypertriglyceridemia (87%), central hypothyroidism requiring thyroid supplementation (80%), neutropenia (41%), skin peeling (43%), hypercholesterolemia (20%), and pancreatitis (3%). Seventy-eight percent of the monotherapy group (N = 54) and 100% of the combination therapy group (N = 16) required at least one lipid-lowering agent (LLA). Of the ten patients with diabetes, three had hypertriglyceridemia that could not be controlled with an LLA ([432]). In this series, atorvastatin and fenofibrate were the LLAs of choice. Interestingly, 9 out of 10 (90%) patients on bexarotene monotherapy taking two LLAs responded significantly higher than those groups on one or no LLA (p = .0001). The explanation for this finding is not clear, but using two LLAs may allow patients to maintain maximum doses of bexarotene ([432]). Vigilance should be exercised when combining atorvastatin and fenofibrate to monitor for rhabdomyolysis. Gemfibrozil and drugs that inhibit the cytochrome P 3A4 enzyme are contraindicated with bexarotene to avoid elevated drug levels and worsened side effects.

Bexarotene is also available as a 1% gel. The gel formulation is most helpful in early-stage patients (IA) without prior therapies. Bexarotene 1% gel is applied only to lesional skin once daily the first week and twice daily the second week, tapering up to four times daily as tolerated ([433]). In the multicenter trial, patients achieved an OR rate of 63% and a clinical CR of 21%. Median projected time to onset of response was 20.1 weeks (range, 4.0 to 86.0 weeks), and the estimated median response duration from the start of therapy was 99 weeks ([433]). The most common side effect is irritation (retinoid dermatitis) at the sites of application, which can make it difficult to assess response to the drug.

Interferon

IFNs are glycoproteins, naturally occurring or synthesized by recombinant DNA technology. These agents act as immunomodulators with both cytostatic and antiviral activity ([340], [434]). Although three classes—alpha (IFN-a), beta (IFN-ß), and gamma (IFN-?)—are described, the alpha IFNs have been most extensively studied in MF and SS, and their efficacy was first reported by Bunn et al. in 1984 ([435]). The exact mechanism of action of IFN in MF and SS is unknown. IFN may act to inhibit IL-4 and IL-5 production by normal and aberrant T cells in patients with SS ([20], [25]), induce myelomonocytic My7 antigen (CD13) in epidermal basal cells ([436]), induce the double-stranded RNA-dependent enzyme 2'5'-oligoadenylate synthetase leading to cleavage of cellular RNAs, and phosphorylate eukaryotic initiation factor-2, a peptide elongation initiation factor that blocks protein synthesis ([434]). The pharmacokinetics of IFN delivered via the intramuscular and subcutaneous routes are equivalent, allowing patients the opportunity to self-administer the drug subcutaneously ([437]).

The phase II NCI trial reported by Bunn et al. in 1984 used high doses of recombinant IFN-a2a (50 × 10 ^{6} units/m ^{2} = 50 MU/m ^{2} subcutaneously three times per week) in 20 heavily pretreated MF patients and demonstrated an objective response in 45%, including three patients (15%) who achieved a CR ([435], [438], [439]). Treatment of MF and SS with IFN-a has been reported in more than 200 patients, and the results have been summarized ([390], [434]). Over three-fourths of the patients received IFN-a2a (Roferon-A, Hoffman-LaRoche, Nutley, NJ) although there were no apparent differences in clinical efficacy between IFN-a2a and IFN-a2b (Intron-A, Schering-Plough Research Institute, Kenilworth, NJ) ([390], [434]). The OR rate for IFN-a alone was 52%, with a 17% CR among 207 MF and SS patients summarized by Bunn et al. ([390]). However, interpretation of pooled data is complicated by variations in initial dose, target dose, frequency, and length of therapy among study centers ([434]). There are conflicting reports regarding the impact of clinical stage on the likelihood of response to systemic IFN-a ([434], [440], [441] and [442]). In their study of 51 MF and SS patients, Jumbou et al. found that patients with early disease (stages I and II) demonstrated a higher response rate to IFN-a than those with advanced disease ([443]).

In an attempt to define the optimal dose of IFN-a in CTCL, a randomized study from Duke and Northwestern Universities was designed, comparing low-dose (3 MU per day) to escalating doses (up to 36 MU per day); however, because of slow patient accrual, the proposed study was terminated ([440]). For the 22 patients evaluated, the objective response rate was 64% and was greater, although not statistically significant for those receiving high doses (11 of 14) compared to those receiving low doses (three of eight), due in part to late responses in unresponsive patients who crossed over into the higher-dose arm ([390], [440]). Of interest, two of the three CR patients were induced by the low-dose regimen, suggesting that patients could achieve a CR with 3 MU daily of IFN-a2a ([434], [440]). An intermediate daily dose of 18 MU of IFN-a2a for 3 months followed by the same dose three times a week resulted in an impressive 80% objective response rate (27% CR, 53% PR) in 15 CTCL patients reported by Tura et al. ([444]).

Daily dosing of IFN-a2a for an induction period of several months was used by all of the larger studies of IFN-treated CTCL patients ([435], [440], [441] and [442], [444]), whereas many fewer patients have been studied using an initial three-times-a-week schedule ([445], [446], [447], [448] and [449]). Nonetheless, some authorities ([390]) recommend an optimal dose of 3 MU of IFN-a2a three times a week, based in part on randomized dose studies in B-cell indolent NHL showing no benefit to higher-dose IFN with respect to response rate or duration ([450]). Maximum daily dosing is dependent on several patient factors but, in general, should not exceed 15 MU ([451]). Two to 5 months is generally necessary to obtain an objective response with IFN, but a complete or maximal response can take much longer ([434], [440], [442]). Treatment is generally continued for approximately 1 year after a CR to prevent the high potential for relapse when treatment is discontinued before clearing ([434]). Three studies have reported a median duration of response to IFN-a as follows: 6 months ([435]), 8 months ([441]), and 14 months ([442]). Olsen et al. noted a mean duration of PR while on therapy of 7.9 months (range, 2.1 to 26.5 months) and durations of CR off therapy ranging from 4 to 28 months ([434], [440]). Two NCI phase II trials combined IFN-a2a with the adenosine analogs dCF and fludarabine to treat CTCL and demonstrated no clear advantage over either drug alone ([400], [408]).The numerous side effects associated with IFN have led to dose reductions in 50% to 86% of patients in some studies ([440], [444]).

Besides producing anti-IFN antibodies, patients with MF can also exhibit decreased responsiveness to IFN through acquired resistance to IFN-a–induced gene expression. Specifically, a resistant CTCL cell line exhibits disrupted signal transduction in a pathway that is normally activated by IFN-a when therapeutic. In particular, STAT1 expression is reduced in these cells, which interrupts the JAK/STAT signaling pathway ([452]).

In two studies, intralesional recombinant IFN-a2b was injected into selected plaques of 15 MF patients over 4 weeks and resulted in clinical (not histologic) clearing in 83% of those treated ([447], [453]). A majority of patients (56% to 83%) experienced systemic side effects to the intralesional injections. Recombinant IFN-a and IFN-ß have been studied in many fewer CTCL patients, as they appear to offer no major advantage over IFN-a ([454], [455], [456] and [457]). IFN-ß has reportedly shown little effectiveness in treating CTCL ([454]), and IFN-? has been linked with more intense and frequent side effects than IFN-a ([434]).

Photopheresis or Extracorporeal Photochemotherapy

Because of the development of resistance to conventional chemotherapy and radiation and the high potential for relapse in advanced-stage patients, new modalities to treat CTCL have been developed. Leukophoresis, which had been used in patients with high Sézary cell counts ([458]), was the forerunner for a new adaptation of PUVA called ECP or photopheresis. In the original protocol, patients ingested 8-methoxypsoralen before undergoing fractionation of their blood. A leukocyte-enriched blood fraction was then isolated and exposed to ultraviolet A in an extracorporeal system, which photoactivated the psoralen ([459]). The photopheresis procedure currently performed uses liquid 8-methoxypsoralen injected directly into the collection bag containing the enriched white blood cell fraction to achieve a concentration of 340 ng/ml within the collection bag. All treated and untreated blood products were then returned to the patient.

In 1987, Edelson et al. were the first to report responses in 27 of 37 patients (64%) with resistant CTCL treated with ECP, including eight of ten patients with lymph node involvement and 24 of 29 patients with erythroderma. However, patients with extensive plaques or tumors did not respond as well (three of eight patients) ([459]).

The immunomodulatory mechanism underlying patient response to ECP is still under debate. However, evidence currently supports the following two simultaneous and synergistic processes occurring during ECP: induction of apoptosis in malignant T cells, and a mass conversion of blood monocytes to dendritic cells ([460], [461], [462], [463], [464], [465] and [466]). Animal studies demonstrate that ECP induces a CD8 $^+$ T-cell response against expanded clones of pathogenic T cells ([464], [467]), as well as an

increased synthesis of class I MHC molecules on murine T-cell lymphoma cells ([463]). Recent *in vitro* studies using family-specific monoclonal antibodies and magnetic bead technology demonstrated a tumor-specific cytolytic CD8 $^{+}$ T-cell response to distinctive class I surface peptides on CTCL tumor cells of four patients with advanced disease. These results suggest that reduced class I expression of relevant tumor antigen epitopes may limit the extent of CD8 $^{+}$ T cell-mediated cytolysis ([462]). In support of this hypothesis, investigators have found a favorable response to correlate with the following two scenarios at the onset of ECP: normal or near-normal numbers of CD8 $^{+}$ peripheral blood T cells ([460]) and a lower CD4:CD8 ratio in the peripheral blood ([468]).

Other investigators have found that ECP and *in vitro* PUVA induce apoptosis in peripheral blood lymphocytes but not in monocytes ([461]). The apoptosis induction mechanism remains unknown but may be explained by the observation that a significant amount of tumor necrosis factor-a, which mediates various antitumor effects, is produced by macrophages after ECP ([469]). Berger et al. identified monocytes transitioning to immature dendritic cells during overnight incubation in gas-permeable bags of ECP-treated white blood cells from five patients with intractable CTCL ([470]). Both the initial leukapheresis step and the subsequent passage through the narrow photoactivation plate initiated and contributed to monocytes-to–dendritic cell differentiation ([470]). Edelson recently proposed that the innumerable encounters of monocytes with the plastic surface of the photoactivation plate activated the cells to begin differentiation to immature dendritic cells ([465]). An immature dendritic cell can engulf an apoptotic T cell and present tumor antigen via MHC class I molecules, which stimulates a potent antitumor CD8 T-cell response ([465] , [466] , [470]).

Treatment of CTCL with ECP has been reported in more than 400 patients ([459] , [471] , [472] , [473] , [474] , [475] , [476] , [477] , [478] , [479] , [480] and [481]) and has been recently summarized ([482]). The majority of CTCL patients treated with ECP have exhibited generalized erythroderma (skin stage T4), a finding most likely due to Edelson et al.'s encouraging preliminary study results ([459]). Combined analysis of five North American series ([459] , [471] , [476] , [477] and [478] , [482]) of ECP-treated CTCL patients (N = 157) demonstrates an objective response (greater than 25% improvement of skin lesions) in 67 of 111 stage T4 patients (60%), with approximately 20% achieving a CR. A long-term follow-up study of the original 29 erythrodermic CTCL patients in the report of Edelson et al. ([459]) demonstrated a median survival of 60 months, which compared favorably to historical controls ([468]). Investigators at an International Consensus Conference for Cutaneous T-Cell Lymphoma recommended that ECP be considered the first line of treatment for erythrodermic-stage patients ([483]). However, other authorities differ in their opinions regarding the role of ECP in the treatment of CTCL, stating that the data have been inconsistent ([390] , [484] , [485]).

Preliminary and long-term follow-up studies by Zic et al. on 20 refractory CTCL patients treated with ECP and adjunctive therapies demonstrated an objective response (greater than 50% clearing of skin lesions) in 9 of 14 (64%) stage T2 patients with CR in four ([471] , [486]). Seven patients achieved a CR at some point in their treatment, with a median time to clearing of 11 months. The mean relapse-free interval for the seven patients weaned off of ECP was approximately 45 months (range, 20 to 64 months); two patients experienced a cutaneous relapse ([486]). Many patients received adjunctive therapy (IFN, topical nitrogen mustard, methotrexate, or PUVA phototherapy) after several months of ECP monotherapy to achieve their highest response rate ([486]). Observations by Rubegni et al. question the use of ECP to treat stage IB patients when less expensive and more widely accessible therapies are available ([487]).

ECP is well tolerated, with few complications or adverse effects ([482]). Uncommon adverse reactions are usually vascular related and include fluid-responsive hypotension and venipuncture-site hematomas ([486]). Rarely, adverse reactions have included exacerbation of congestive heart failure or arrhythmias ([483]), superficial thrombophlebitis ([483]), catheter-related sepsis ([488]), herpes infections ([483]), disseminated fungal infection ([483]), and a single episode of hemolysis ([471]).

Currently, few studies have focused on the effects of combining ECP with systemic chemotherapy, PUVA ([471]), IFN and other cytokines ([471] , [489] , [490] , [491] and [492]), radiation therapy ([471]), bexarotene ([392]), and nitrogen mustard ([471]).

Combined Modality Therapy

Because there is no single therapy for CTCL that can consistently induce long-lasting remissions, various combinations of therapeutic modalities have been studied. The results of several small studies suggested that better survival could be achieved by combining TSEBRT with chemotherapy (Table 94.9) ([493] , [494] , [495] , [496] and [497]). Hallahan et al. evaluated TSEBRT followed by combination chemotherapy for 21 patients with tumor-stage CTCL, demonstrating an objective response in 19 (90%) with a median duration of remission of 12 months, but all patients relapsed within 25 months ([495]). Two nonrandomized studies suggested a benefit for early-stage CTCL patients who receive TSEBRT followed by chemotherapy ([493] , [496]). A more recent study evaluated the combination of TSEBRT with the systemic retinoid etretinate and found no significant advantage to the combination, although the median follow-up was only 2 years ([379]). After TSEBT, subsequent PUVA therapy appears to aid in maintaining remission status in patients with CTCL. A significant benefit in disease-free survival but no statistically significant improvement in overall survival was observed; however, prospective, randomized data are needed to confirm these results. Incidentally, PUVA has also demonstrated its effectiveness as a salvage therapy after TSEBT in early-stage patients with recurrence and acceptable toxicity ([498]).

TABLE 94.9. Combined Electron Beam Radiotherapy (EBRT) and Chemotherapy for Cutaneous T-Cell Lymphoma

Institution	Drug Agent(s)	No. of Patients	Stage	Complete Response (%)	Complete Response + Partial Response (%)	Response Duration in Mo (median)	Comments
University of Chicago (495)	COPP or MOPP	21	15 T3 (IIB); 6 T3N3 (IVA)	11 (50)	19 (90)	2–24 (12)	All patients relapsed with cutaneous plaques within 25 mos; median survival from initiation of EBRT was 6 yrs.
National Cancer Institute (496)	Mechlorethamine	13	I	10 (77)	13 (100)	>48	Received 3000 cGy before chemotherapy. Overall 6-yr survival was 92%; six remain alive and disease-free beyond 6 yrs.
National Cancer Institute (496)	VAB/CMP	26	II–IV	6 (23)	23 (88)	(6.5)	Received 2400 cGy before chemotherapy. Median disease-free survival for complete responding patients was 26 mos; overall 6-yr survival was 26%.
National Cancer Institute (499)	Cyclophosphamide; doxorubicin, etoposide, vincristine	52	11 I, 11 II, 1 III, 29 IV	20 (38)	47 (90)	26–118 (75)	No survival benefit of combined method vs. conservative therapy (see text and Fig. 94.18); significant toxicity: 12 hospitalizations for febrile neutropenia; 5 congestive heart failure; 2 acute nonlymphocytic leukemia.

COPP, cyclophosphamide, Oncovin (vincristine), procarbazine, prednisone; MOPP, mechlorethamine, Oncovin (vincristine), procarbazine, prednisone; VAB/CMP, vinblastine, doxorubicin, bleomycin/cyclophosphamide, methotrexate, prednisone.

The most significant study to evaluate the role of combined modality therapy was that of Kaye et al. at the NCI who compared TSEBRT and combination chemotherapy (cyclophosphamide, doxorubicin, etoposide, and vincristine) to conservative topical therapy (beginning with topical HN_2 followed sequentially, if needed, by PUVA, TSEBRT, and combination chemotherapy) in a randomized trial of 103 patients with MF ([499]). Although the rate of CR was significantly increased in the combined modality arm (38% vs. 10%, $p = .032$), toxicity was greater and no significant difference was noted between the groups in disease-free or overall survival (Fig. 94.18).

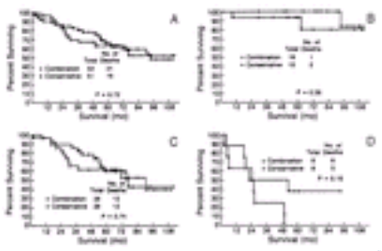

Figure 94.18. Survival curves from randomized study at the National Cancer Institute comparing intensive combined therapy. **A:** Overall survival. **B:** Survival among low-risk patients (stage IA, IB, or IIB). **C:** Survival among intermediate-risk patients (stage IIB, III, or IVA). **D:** Survival among high-risk patients (stage IVB). (From Kaye FJ, et al. A randomized trial comparing combination electron beam radiation and chemotherapy with topical therapy in the initial treatment of mycosis fungoides. N Engl J Med 1989;321:1784, with permission.)

Thus, this study indicated that, similar to other low-grade lymphomas, early aggressive therapy in MF does not have a major impact on survival.

A nonrandomized study from Yale University compared relapse-free survival and overall survival between CTCL patients who achieved a CR after TSEBRT, with subsequent treatment consisting of either adjuvant chemotherapy (cyclophosphamide and doxorubicin; N = 77), photopheresis (N = 11), or no adjuvant therapy (N = 43) ([500]). Adjunctive therapy was also offered to 32 patients who achieved a “good PR” to TSEBRT. The statistical analysis found no appreciable impact on relapse-free survival among the patients receiving adjuvant chemotherapy or photopheresis when compared to patients receiving no adjuvant therapy. However, a marginally significant (p <.06) improvement on overall survival was demonstrated when stage T3/T4 patients treated with adjuvant photopheresis (N = 7) were compared to stage T3/T4 patients receiving no adjuvant therapy (N = 22) ([500]).

Retinoids and IFN-a have been combined to treat CTCL in several open studies ([501] , [502] , [503] , [504] , [505] , [506] , [507] , [508] , [509] and [510]). Combined analysis of the results of 102 reported patients treated with retinoids and IFN-a showed that approximately 60% of patients respond and 10% achieve a CR, which is similar to the response for IFN-a alone ([390]). PUVA therapy has been combined with systemic retinoids to treat CTCL in two studies ([511] , [512]) demonstrating response rates similar to PUVA alone. Bexarotene has been combined with ECP, PUVA phototherapy, and IFN-a in several patients with potential beneficial effects, as well as no increased toxicity ([432]).

The combination of PUVA and IFN-a has generated considerable interest recently with impressive CR ([513] , [514] , [515] , [516] , [517] , [518] and [519]). In the combined analysis of the phase I and phase II trials of IFN-a and PUVA for CTCL at Northwestern University, 39 CTCL patients (stage IB, N = 14; IIA, N = 5; IIB, N = 6; III, N = 8; IVA, N = 5; IVB, N = 1) received intramuscular or subcutaneous IFN-a2a three times a week at initial intermediate doses (6 MU, N = 3; 12 MU to 18 MU, N = 13; 21 MU to 30 MU, N = 23) with subsequent dose reduction in 19 patients due to apparent toxicity ([514]). IFN-a was continued for the planned 2-year period in only 10 of the 39 patients (26%), with eight patients receiving 4 or fewer months of IFN-a due to tumor progression, toxic effects, or patient request. PUVA was initiated three times per week and tapered to one monthly treatment indefinitely for patients achieving a CR. The overall objective response rate was 90%, with 24 patients (62%) achieving a pathologically confirmed CR, 15 of whom had early-stage disease (stage IB/IIA). Nineteen patients (54%) relapsed, demonstrating a median duration of response of 28 months (range, 1 to 64 months). Median survival for the entire cohort was 62 months, with mean survivals for stage I/II and stage III/IV patients of 55 and 35 months, respectively ([514]). Although patients respond impressively, a majority of patients will relapse despite maintenance PUVA and will also experience nontrivial toxicities. In a smaller study, PUVA was discontinued approximately 2 months after clearing, and low-dose IFN-a was continued as maintenance therapy in 16 CTCL patients ([518]). Thirteen of 16 (81%) patients demonstrated an objective response with a CR in ten of the patients; however, within the short follow-up period of 10 to 40 months, 50% of the patients developed progressive disease, a cutaneous relapse, or Hodgkin lymphoma (N = 1) ([518]). The overall impact on survival of combined PUVA and IFN-a has yet to be determined.

A prospective phase II trial examined escalating doses of IFN-a2a combined with PUVA in 63 symptomatic patients representing all stages of MF and SS ([519]). Fifty-one patients achieved a CR (74.6%) or PR (6%), with a median response duration of 32 months. The 5-year overall survival rate was 91% and included 17 patients with advanced disease ([519]). In another similar study, 25 stage I and II patients with MF received a target dose of 18 MU per week of IFN-a2b combined with PUVA and demonstrated an OR rate of 96%. The projected probability of freedom from treatment failure was 82% at 12 months and 62% at 24 months, with a disease-free survival projected to 48 months of 75% ([520]).

Recently, Stadler and colleagues completed a prospective, randomized multicenter trial to compare IFN plus PUVA and IFN plus acitretin in stage I and II patients with CTCL (N = 82 evaluable patients) ([521]). IFN-a2a was administered subcutaneously at 9 MU three times weekly and combined with either PUVA at an initial interval of five times weekly, or with acitretin up to 50 mg daily. IFN-a plus PUVA (N = 40) was significantly superior to the IFN plus acitretin (N = 42), as marked by a 70% complete remission rate in the former, versus a 38.1% complete remission rate in the latter ([521]).

Immunotherapy

Over the past decade, researchers have developed immunotherapies to correct abnormalities in the immune response, cellular growth, and differentiation pathways in patients with CTCL. As described in previous sections, recombinant forms of natural cytokines such as IFNs and immunomodulation with photopheresis have shown promise in the treatment of CTCL, with tolerable toxicity profiles and reasonable efficacy. This section focuses on other cytokines and monoclonal antibody therapies for the treatment of CTCL.

Fusion toxin therapy takes advantage of the preferential expression of specific receptors on the surface of malignant cells. Conjugation (“fusion”) of a plant or bacterial toxin gene to a specific receptor ligand can guide the toxin gene to the target cell, where it can be internalized via receptor-mediated endocytosis and translocated into a toxic moiety in the cytosol ([410]). The IL-2 receptor (IL-2R) is present in low-, medium-, and high-affinity forms. The high-affinity form of the IL-2R is a three-subunit peptide, and one of the three subunits contains CD25. The high-affinity IL-2R has been a specific target that is commonly present on cells in ATLL ([522] , [523] and [524]) and on mature, activated T cells. Approximately 60% of patients with CTCL will show expression of IL-2R on their mature T cells, but there is both interpatient and intrapatient variability of expression ([525]).

DAB $_{486}$IL2 and DAB $_{389}$IL2 were the first fusion toxins to be used in clinical trials and are composed of the nucleotide sequence of the enzymatically active and the membrane translocating domains of diphtheria toxin conjugated to the amino acid sequence of human IL-2 ([410] , [522] , [523] , [526] , [527] , [528] , [529] , [530] , [531] and [532]). In a phase II trial of DAB $_{486}$IL2 reported by Foss et al. ([526]), 3 of the 14 CTCL patients demonstrated an objective response (one patient with a PR, two patients with slightly less than 50% improvement). The authors observed that IL-2R expression was necessary, but not sufficient, to predict response. DAB $_{389}$IL2 (denileukin diftitox), a second-generation molecule, replaced DAB $_{486}$IL2 because it showed a more favorable pharmacokinetic profile.

A pivotal phase III trial evaluated the safety, efficacy, and pharmacokinetics of two dose levels of denileukin diftitox ([533]). This randomized, blinded, parallel-grouped study focused on the use of denileukin diftitox in the treatment of 71 patients with persistent or recurrent stage IB to IVA CTCL. For study inclusion, patients had to have detectable CD25 on at least 25% of their tissue biopsy lymphocytes via immunoperoxidase assay. After therapy, 30% of patients experienced an objective response (20% PR and 10% CR), whereas 32% experienced stable disease and 3% demonstrated progressive disease. Dosages of 9 and 18 µg/kg per day were compared and showed similar tolerability and no evidence of cumulative toxicity. There were no statistically significant differences found between the two dosing regimens with respect to response rate and duration of response (median, 6.9 months; range, 2.7 to 46.1+ months) ([533]). On stratification with respect to disease stage, 18 µg/kg per day of denileukin diftitox proved more effective in treating stage IIB patients (36% OR) than the lower dose (23% OR) ([533]). The U.S. Food and Drug Administration approved denileukin diftitox in 1999 for the treatment of patients with persistent or recurrent CTCL whose malignant cells express the CD25 component of the IL-2R.

Ongoing studies are examining the efficacy of denileukin diftitox in CTCL patients with less than 20% of their lymphocyte population expressing CD25. The effectiveness and tolerability of alternate dosing regimens is also being explored.

Another small phase III study focused on the use of steroid premedication to improve the tolerability of denileukin diftitox. Fifteen CTCL patients received prednisone or dexamethasone immediately before each dose of denileukin diftitox, which was administered at two dose levels (9 or 18 µg/kg/day) for 5 consecutive days every 3

weeks. This cycle was repeated up to eight times. After therapy, a significant decrease in the incidence of acute hypersensitivity reactions was noted, and a 60% response rate was observed. These findings prompted the authors to conclude that steroid premedication not only made denileukin diftitox more tolerable, but also performed this task without compromising clinical response ([534]).

Side effects of denileukin diftitox have included reversible elevated hepatic transaminases (61% total, 15% with grade 3 or 4) and flulike symptoms (fever/chills, nausea/vomiting, and arthralgias/myalgias) seen in 92% of patients in the pivotal trial. A delayed vascular leak syndrome (hypoalbuminemia, edema, and hypotension) was seen in 25% of patients in the same patient population. Increasing hydration may decrease the incidence of vascular leak syndrome, but this theory currently lacks supporting data. Acutely, hypersensitivity reactions during infusion may show as dyspnea, back pain, chest pain, and hypotension. As noted above, pretreatment of these patients with steroids make acute hypersensitivity reactions less likely. Bone marrow suppression or secondary immunosuppressive effects have not been noted as significant adverse events related to denileukin diftitox ([410] , [533]). Infections were seen in 56% of subjects. However, 80% of these infections were typical in patients with advanced-stage or heavily pretreated CTCL, and were thus not attributed to therapy ([533]).

IL-12 supplementation has been the focus of recent immunotherapy techniques, as CTCL patients experience substantially depressed cytokine production and subsequent impaired cell-mediated immunity. IL-12 is critical for antitumor cytotoxic T-cell responses. Subcutaneous and intralesional IL-12 has been studied in a phase I dose escalation trial of ten refractory patients with MF/SS and showed an OR rate of 50%, including two complete responders with plaque-stage disease ([535]). IL-12 was administered twice weekly. Side effects were minor, including headache and low-grade fever. Results supported the role of supplemental IL-12 in augmentation of cytotoxic T-cell responses to tumor cells ([535]).

The development of monoclonal antibodies directed at specific antigens on T cells led to trials of monoclonal antibodies for therapy and staging of CTCL ([524] , [536] , [537]). In a trial of high-dose T-101, a murine antibody directed against CD5, four of ten CTCL patients (40%) achieved a brief objective clinical response, and 50% of the CTCL patients developed human antimouse antibodies ([536]). To enhance cytotoxicity, toxic moieties have been conjugated to the antibodies ([524] , [537] , [538]). In a phase I trial by Rosen et al. ([537]), five CTCL patients received between 100 and 151 mCi of iodine-131–conjugated to T-101. All patients demonstrated a brief clinical remission initially, two patients responded to retreatment, and three patients experienced dose-related myelosuppression. LeMaistre et al. ([538]) conjugated ricin, a potent inhibitor of protein synthesis, to T-101 in a phase I trial of 14 CTCL patients and demonstrated a PR in 28% lasting 3 to 8 months. The toxicities of monoclonal antibody therapy are usually mild and reversible and include fever, pruritus, myalgia, dyspnea, hypoalbuminemia, weight gain, elevated liver function tests, a poorly understood capillary leak–like syndrome, and, rarely, anaphylaxis ([410]).

Similarly, CAMPATH-1H (alemtuzumab), a monoclonal antibody directed against CD52, has been studied in the treatment of advanced, low-grade NHL, including CTCL. This humanized antibody targets T and B lymphocytes and appears to have a predilection for circulating cells, relatively sparing those localized within lymph nodes ([539]). Dearden et al. reported a 100% response rate among three CTCL patients treated with alemtuzumab administered three times per week ([540]). Similarly promising, in a phase II study of eight patients with MF, four demonstrated significant responses, with two classified further as CR ([541]). However, the side effect profile for CAMPATH-1H includes significant neutropenia with subsequent increased susceptibility to opportunistic infections and bacterial septicemia, thus limiting its utility in the treatment of severely ill patients. Larger clinical trials are needed to clarify the role of alemtuzumab in the treatment of CTCL.

Hematopoietic Stem Cell Transplantation

Because patients with advanced CTCL have a poor prognosis, with only a small chance of sustained remission, treatments as invasive as hematopoietic stem cell transplantation (HSCT) have been increasingly explored using various donor sources and therapeutic conditioning regimens. A more detailed discussion of HSCT is included in Chapter 25.

Autologous bone marrow transplantation (ABMT) may have the lowest treatment-related mortality but the highest relapse rate. ABMT has been attempted in a small number of patients with advanced/erythrodermic MF ([542] , [543]). Although five of six patients with advanced CTCL achieved a CR after ABMT, three patients relapsed in less than 100 days, and two were alive with no evidence of disease at 12-month follow-up ([542]). In a more recent study, Olavarria et al. used various forms of myeloablation before ABMT and, of the nine subjects, seven relapsed, one died of sepsis, and one had a CR at 10 months. Despite disease recurrence in the seven patients, most relapsed into a less aggressive disease course, responding favorably to conventional therapy ([544]).

Molina et al. obtained a CR within 30 to 100 days in six of six patients receiving allogeneic stem cell transplants for CTCL. Four of these patients had matched siblings as donors and two had unrelated matched donors. After HSCT, the authors repeated each patient's peripheral blood TCR gene rearrangement, cytogenetic, and flow cytometric studies, which demonstrated that the clonal T-cell populations originally found in four of the six patients became undetectable within 30 days of treatment and had not recurred at the time of abstract submission. Also, one of the six patients died secondary to graft-versus-host disease complications at 16 months' posttreatment ([545]).

Similarly, Guitart et al. reported three advanced-stage CTCL patients who each received a sibling HLA–matched allogeneic stem cell transplantation ([546]). Two patients exhibited complete and sustained remissions of 14 months and 4.5 years. The third patient exhibited a CR for 9 months followed by a limited low-grade recurrence localized to the skin. The authors hypothesized that, although allogeneic stem cell transplantations cannot ensure a sustained CR, progression beyond a localized cutaneous form could be prevented by an allogeneic graft-versus-tumor effect ([546]). Matched unrelated allogeneic transplant has been successful in a case of refractory disease ([547]). Further studies are needed to explore the use of HSCT in the treatment of advanced CTCL. Based on preliminary findings, allogeneic stem cell transplantation, albeit more toxic, appears more likely to induce long-standing remissions than autologous stem cell transplantation.

Other Therapies

Other therapies have been effective in CTCL and include thymopentin ([410] , [548] , [549]) and antiviral therapy ([390] , [550] , [551] and [552]). The mechanism of action of each of these drugs in CTCL is poorly understood. The numbers of patients treated with these agents are relatively small; however, because the toxicities usually are mild and the mechanisms probably are different from chemotherapy, radiation, or IFN, these agents may be useful in combination with other methods.

SUMMARY AND FUTURE INVESTIGATIONS

Molecular studies are unraveling the complex interactions of cytokines, adhesion molecules, and the immune system responsible for the pathogenesis of CTCL and are continuing to provide insight for novel approaches to treatment. As with other indolent lymphomas, an array of therapies can produce responses in CTCL but are generally not curative. In contrast to other lymphomas, however, is the high degree of efficacy of topical treatments (nitrogen mustard, TSEBRT, and PUVA) for patients with early-stage MF/SS. Because CTCL is not cured by systemic chemotherapy, initial management of early-stage disease should include skin-directed therapy. Ongoing clinical trials may define the roles of systemic therapy in managing more advanced-stage patients, including combinations of skin-directed therapies, chemotherapy agents, photopheresis, retinoids, monoclonal antibodies, IFN, and stem cell transplantation.

ACKNOWLEDGMENT

This work is dedicated to Dr. Kevin E. Salhany, who provided photomicrographs for the histopathology.

Hodgkin Disease

Hodgkin disease is a lymphoproliferative malignancy that accounts for approximately 1% of newly diagnosed malignancies in the United States. However, the disease's importance to the field of medical oncology is out of proportion to its clinical incidence. From a historical point of view, Hodgkin disease was the first disease in which the curative potential of combination chemotherapy was demonstrated. Second, because Hodgkin disease is often a disease of young people, there is huge potential for adding years of productive life by curing patients with Hodgkin disease. Third, because patients with Hodgkin disease are often cured, Hodgkin disease serves as a clinical laboratory for investigating the late effects of cancer therapy.

Hodgkin disease usually presents as solitary or generalized lymphadenopathy and most commonly occurs in young adults, although any age group may be affected. The disease appears to spread in a contiguous fashion, and most patients present with disease limited to the lymph nodes or to the lymph nodes and spleen. Even when disease is advanced, cure is possible. Overall, cure can be achieved in approximately 80% of patients with Hodgkin disease. Treatment of limited disease generally incorporates radiation therapy, whereas treatment of advanced disease is more often limited to combination chemotherapy alone.

Although Hodgkin disease has been a success story of modern cancer medicine, this success has in some ways been paradoxic. First, successful therapy has been empirical and dependent on understanding prognostic features and patterns of spread. Clinical success has been independent of understanding the pathogenesis of Hodgkin disease or its cell of origin. These latter subjects remain areas of controversy. Second, major clinical advances in Hodgkin disease depended on studies that used pathologic staging, including staging laparotomy. However, because both radiation therapy and chemotherapy are curative modalities, and because many relapsing patients can be cured, clinical staging rather than surgical staging is generally used as the basis for therapeutic planning without obvious negative clinical consequences. Staging laparotomy has become a procedure of historical interest rather than a key part of clinical practice. Third, the success of salvage therapy means that it is difficult to make a specific optimal treatment recommendation for many patients with Hodgkin disease. Therapies that produce superior disease-free survival may not necessarily be superior in the long term because therapy of relapsed disease can be curative, and late complications, including malignancy, can compromise the long-term efficacy of treatments that appear superior in the short run. As a result, when considering therapy for patients with Hodgkin disease, one must realize that valid alternatives exist in addition to what may be considered the “best therapy.”

That the management of Hodgkin disease is a subject of paradox and controversy is fitting. In 1832, Thomas Hodgkin made a major contribution to medical science by describing the primary lymphoid malignancy that bears his name. However, his report was based on gross findings at autopsy and did not include any microscopic evaluation. Some of the cases included in Hodgkin's initial report were likely cases of tuberculous lymphadenopathy or even non-Hodgkin lymphoma.

EARLY HISTORY

In 1832, Thomas Hodgkin presented a paper entitled *On Some Morbid Appearances of the Absorbent Glands and Spleen* ([1]). His report was an autopsy description of seven patients, and the major original thesis presented in the paper was that the entity he was describing was a *primary* process involving the lymph glands and spleen rather than a *reactive* inflammatory condition. In 1856, Samuel Wilks published a series of cases involving enlargement of the lymph glands ([2]) and noted Hodgkin's original description. In 1865, Wilks wrote *Cases of Enlargement of the Lymphatic Glands and Spleen (or Hodgkin's Disease) with Remarks*, updating and extending his findings ([3]). Thus, Thomas Hodgkin's name became linked to the disorder.

After these gross pathologic descriptions, the first microscopic description of Hodgkin disease was reported by Langhans ([4]) in 1872. This report was followed by independent reports by Sternberg in 1898 ([5]) and by Reed in 1902 ([6]) describing the characteristic giant cells that came to be known as *Reed-Sternberg cells*. At the time of these early reports, all comments regarding the cause of Hodgkin disease were purely speculative. Not surprising, these early authors were divided over whether Hodgkin disease represented an infectious disease, an inflammatory disorder, or a malignancy involving the lymph glands. Considering that Hodgkin disease is a malignant disease for which there is epidemiologic evidence of a possible viral etiology and that the microscopic appearance is that of a small number of malignant cells surrounded by an exuberant host reaction, all of these opinions (malignant, inflammatory, infectious) may be partially correct.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 7500 new cases of Hodgkin disease are diagnosed in the United States each year. The male to female ratio is 1.3 to 1.4:1.0. In most economically developed countries, there is a bimodal age distribution, with one peak occurring in the third decade of life and the second peak occurring after age 50 years ([7]). The occurrence of Hodgkin disease in patients between the ages of 15 and 39 has been positively associated with increased maternal education, decreased numbers of siblings and playmates, and single-family dwellings in childhood ([8]). In less economically developed countries, Hodgkin disease is less common but affects children, most of whom are boys; mixed cellularity Hodgkin disease and lymphocyte-depleted Hodgkin disease are more commonly seen ([9]). These data have been interpreted as supporting the hypothesis that Hodgkin disease is caused by an infectious agent, and it has been postulated that malignancy is more likely to occur when exposure to the agent in question is delayed until late adolescence or early adulthood ([9], [10], [11] and [12]). This concept of differential sequelae dependent on age at exposure to an infectious agent is similar to that used to explain the association of paralysis with poliovirus in susceptible populations.

The arguments for an infectious etiology of Hodgkin disease date back to the earliest descriptions of the disorder. *Mycobacterium tuberculosis* was the first organism to be suspected of causing Hodgkin disease ([13], [14]). However, once it was known that Hodgkin disease is associated with immune defects, *M. tuberculosis* came to be seen as a consequence rather than a cause of Hodgkin disease. In the 1970s, the hypothesis of an infectious etiology for Hodgkin disease was supported by reports of clustering among exposed high school students in New York state ([15], [16]). However, additional population-based studies have led to the conclusion that

the apparent clustering was due to chance alone ([17]).

Epstein-Barr virus (EBV) has been another proposed cause of Hodgkin disease, and the circumstantial evidence is considerable. The incidence of Hodgkin disease is elevated among patients with a history of EBV infection ([18] , [19] and [20]). EBV has been associated with other related malignancies, including Burkitt lymphoma and the lymphomas that occur after organ transplantation. Using modern molecular biology techniques, EBV genome fragments have been found in Reed-Sternberg cells from approximately one-half of patients with Hodgkin disease ([21] , [22] and [23]) and, more commonly, in cases of mixed cellularity Hodgkin disease ([23]). Hodgkin disease occurring in early childhood or in older adults is more likely to be EBV associated than are cases of Hodgkin disease occurring in young adults ([24]). Additionally, the EBV DNA associated with Reed-Sternberg cells in Hodgkin disease has been shown to be monoclonal, establishing that EBV preceded the development of Hodgkin disease ([21] and [22]). However, the association of EBV with Hodgkin disease does not prove a causal relationship. The data are equally compatible with the fact that EBV may predispose patients to the development of Hodgkin disease. Further confusing the relationship between EBV and Hodgkin disease are two reports that prognosis is better in Hodgkin disease that is EBV positive, as compared to cases that are EBV negative ([25] , [26]). Although studies of the relationship between EBV and Hodgkin disease continue ([27]), this controversy is unlikely to be resolved in the near future.

The idea that Hodgkin disease may represent an uncommon host response to a common agent has received additional support in a study of monozygotic and dizygotic twins. Monozygotic twins, who would be expected to have similar immune responses, had a 99-fold increased risk of being concordant for having Hodgkin disease, supporting a role for genetic susceptibility or abnormal immune response, or both, in the etiology of Hodgkin disease ([28]). If an abnormal immune response is related to the development of Hodgkin disease, one might expect an increased incidence of Hodgkin disease in immunodeficient patients, including those patients infected with the human immunodeficiency virus (HIV). Although the initial data were mixed, it has become clear that the incidence of Hodgkin disease is elevated in patients with HIV and acquired immunodeficiency syndrome (AIDS) ([29] , [30] , [31] , [32] , [33] and [34]). An increased incidence of Hodgkin disease has been noted in recipients of allogeneic bone marrow transplants ([35]). Additionally, a patient has been reported with reversible methotrexate-associated lymphoproliferative disorder that eventually evolved into Hodgkin disease ([36]).

HISTOPATHOLOGY

Accurate histopathology plays a critical role in the management of the patient with Hodgkin disease because the diagnosis of Hodgkin disease requires biopsy of an involved lymph node or, rarely, of an involved extranodal site. Fortunately for clinicians, concordance between pathologists regarding the diagnosis of Hodgkin disease is high, often exceeding 90% ([37]). Hodgkin disease can be confused with atypical inflammatory reactions that can occur in some patients with infectious mononucleosis ([38]) or in patients receiving diphenylhydantoin ([39]). An additional problem in Hodgkin disease relates to surgical sampling of nodes. Nodes showing only inflammation may be interspersed with nodes showing Hodgkin disease, and if the surgeon chooses which node to biopsy solely on the basis of simplifying the procedure, the diagnosis may be missed ([40]). In general, it is probably worthwhile to biopsy the largest node in a patient suspected of having Hodgkin disease or non-Hodgkin lymphoma. However, a notable exception to this occurs in patients with inguinal adenopathy, which may reflect reactive processes and provide misleading information. Whenever the diagnosis of Hodgkin disease or non-Hodgkin lymphoma is considered, the handling of the biopsy should be coordinated between the operating room and the hematopathology laboratory so that the tissue is processed in a manner that minimizes artifact and maximizes the opportunity to obtain a diagnosis.

The grouping of lymphomas into the mutually exclusive categories of Hodgkin disease and non-Hodgkin lymphoma gives the impression that these disorders are totally separate. However, although the distinction between Hodgkin disease and non-Hodgkin lymphoma is clear in the majority of cases, the boundary between the disorders is indistinct in some areas. Patients with chronic lymphocytic leukemia can develop large transformed cell lymphomas (Richter syndrome) ([41] , [42]) that may resemble Hodgkin disease. The nodular subtype of lymphocyte-predominant Hodgkin disease may resemble low-grade non-Hodgkin lymphoma. Approximately one-fourth of cases originally classified as lymphocyte-depleted Hodgkin disease were reclassified as non-Hodgkin lymphoma when present classification criteria were used ([43]). Studies of Ki-1–positive anaplastic large cell lymphoma illustrate that Hodgkin disease and this subtype of non-Hodgkin lymphoma have marked morphologic similarities. However, the majority of studies have shown that the t(2;5) gene rearrangement occurs only in anaplastic large cell lymphoma ([44] , [45] and [46]).

Pathologically, Hodgkin disease is distinguished from other lymphomas by the presence of large binucleated or multinucleated cells (i.e., Reed-Sternberg cells) generally surrounded by a benign reactive host response consisting of lymphocytes, histiocytes, granulocytes, eosinophils, and plasma cells. Reed-Sternberg cells are large cells with abundant cytoplasm and generally contain two or more nuclei and two or more inclusionlike nucleoli. Variant forms of Reed-Sternberg cells exist, especially in the nodular sclerosis subtype of Hodgkin disease and the nodular form of lymphocyte-predominant Hodgkin disease. Reed-Sternberg cells are not absolutely specific for Hodgkin disease and have been noted in cases of infectious mononucleosis ([47]) and other malignancies including lymphoma, carcinomas, and sarcomas ([48]). Therefore, Reed-Sternberg cells are not sufficient to establish the diagnosis of Hodgkin disease because that diagnosis depends on the presence of both the characteristic Reed-Sternberg cells and the characteristic cellular environment in which the Reed-Sternberg cells are found. In addition to the use of standard hematopathologic criteria, immunostaining for CD-15 (Leu-M1) and CD-30 (Ki-1) may be helpful in confirming the diagnosis of Hodgkin disease. The neoplastic cells of Hodgkin disease, both classic Reed-Sternberg cells and Reed-Sternberg variants, tend to stain positively with these antibodies ([49] , [50]).

The subclassification of Hodgkin disease depends in large part on the ratio of neoplastic to reactive cells. The Jackson-Parker classification ([51]) proposed in 1947 is of historical interest only and divided Hodgkin disease into three subtypes: paragranuloma, granuloma, and sarcoma. Because 80% of the cases were granuloma, this subclassification was minimally helpful to clinicians. In 1966, Lukes and Butler ([52]) proposed a six-part classification of Hodgkin disease that was modified that same year at the Rye Conference ([53]) into a four-part system: lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. Nearly all of the major clinical studies that form the basis of our present understanding of Hodgkin disease have used the Rye classification system. The only major modification to the Rye system relates to the proposal by German hematopathologists ([54]) to subclassify the lymphocyte predominance subtype into three categories: nodular, diffuse, and other.

The percent distribution of Hodgkin disease cases with respect to histologic subtype is shown in Table 95.1. The data are taken from one large tumor registry ([55]) and three large series of referred patients ([37] , [56] , [57]) and are subject to any biases in the selection process. However, the general agreement among the series suggests that this is a fairly reliable estimate regarding the relative incidence of the subtypes of Hodgkin disease.

TABLE 95.1. Relative Incidence of Histopathologic Subtypes of Hodgkin Disease

Author (Reference)	Lymphocyte Predominant (%)	Nodular Sclerosis (%)	Mixed Cellularity (%)	Lymphocyte Depleted (%)
Dorfman (56)	7	74	17	2
Jones (37)	2	65	26	6
Bernhards (57)	3	74	22	1
Medeiros (55)	7	63	26	4

NOTE: Percentages refer to “classified” cases, as some studies contain cases of unclassified Hodgkin disease.

Because the subtypes of Hodgkin disease differ slightly with respect to common clinical features, the histopathologic subclassification of Hodgkin disease provides the clinician with some useful information. Lymphocyte-predominant Hodgkin disease is associated with the least tendency to have advanced disease and with the most favorable prognosis, whereas lymphocyte-depleted Hodgkin disease is associated with the greatest tendency to have advanced disease and the worst prognosis. Nodular sclerosing Hodgkin disease and mixed cellularity Hodgkin disease are intermediate in this regard, with nodular sclerosing Hodgkin disease being more favorable than mixed cellularity Hodgkin disease.

Prognostic differences between histologic subtypes of Hodgkin disease are largely dependent on stage. Although histopathologic subtype does have value in predicting prognosis, this is largely because stage co-varies with histologic subtype. Thus, if two patients have identical clinical presentations, and one has nodular

sclerosing Hodgkin disease and the other has mixed cellularity Hodgkin disease, the patient with mixed cellularity Hodgkin disease is more likely to have advanced stage disease on completion of staging and is, therefore, more likely to have a poorer prognosis. However, if the patients are found to have the same stage on completion of staging, expected differences in prognosis would be minimal. When patients with Hodgkin disease have been stratified with respect to stage and have then received equivalent therapy, differences attributable to histologic subtype have been either trivial or nonexistent ([58], [59], [60] and [61]). Therefore, it is probably not of critical importance that concordance between pathologists regarding subclassification of Hodgkin disease has only been fair, 66 to 72% ([37], [62]), and that the major area of disagreement has involved distinguishing between the two most common types of Hodgkin disease—nodular sclerosing Hodgkin disease and mixed cellularity Hodgkin disease.

In lymphocyte-predominant Hodgkin disease (Fig. 95.1), Reed-Sternberg cells, eosinophils, and histiocytes are sparse, and the predominant cell is a small mature lymphocyte (Fig. 95.1). As a result, the disease may be mistaken for a diffuse small B-cell non-Hodgkin lymphoma. Variant lymphocytic and histiocytic cells are common. These cells have multilobated nuclei and have been called *popcorn cells* because of their resemblance to a popped kernel of corn (Fig. 95.2). Only 5 to 10% of cases of Hodgkin disease are of the lymphocyte predominance subtype. This subtype has the greatest tendency to present as stage I disease and is often associated with a prolonged clinical course even in the absence of cure ([63]). Death caused by lymphocyte predominance Hodgkin disease is uncommon ([63]). However, these patients appear to be at increased risk of developing non-Hodgkin lymphoma ([64], [65]).

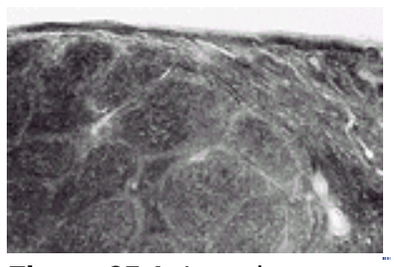

Figure 95.1. Lymphocyte-predominant Hodgkin disease, nodular type. Low magnification demonstrates a nodular growth pattern that compresses a rim of uninvolved node. See Color Plate.

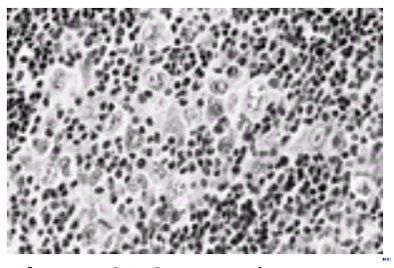

Figure 95.2. Lymphocyte-predominant Hodgkin disease. High magnification shows variant lymphocytic and histiocytic cells (L and H cells), which have “popcorn” nuclei. A background of small lymphocytes and histiocytes is present. See Color Plate.

In nodular sclerosing Hodgkin disease, nodularity is produced by dense collagenous bands that divide the cellular portion of the node into sections (Fig. 95.3 and Fig. 95.4). In this type of Hodgkin disease, Reed-Sternberg cell variants, rather than classic Reed-Sternberg cells, are commonly found in the cellular areas. These lacunar Reed-Sternberg cells have faintly stained cytoplasm and appear separated from adjacent cells by empty space, an artifact of formalin fixation (Fig. 95.5). Nodular sclerosing Hodgkin disease is the most distinctive form of Hodgkin disease. Although the other subtypes of Hodgkin disease may be regarded as a histologic continuum and transformation among other subtypes is commonly seen, when patients with the nodular sclerosing subtype of Hodgkin disease undergo repeat biopsies, the nodular sclerosing form of Hodgkin disease is confirmed in more than 90% of cases ([66]). This form of Hodgkin disease classically presents as stage I or II disease with cervical and mediastinal involvement in young adults, although more advanced stages of disease are not uncommon (Table 95.2).

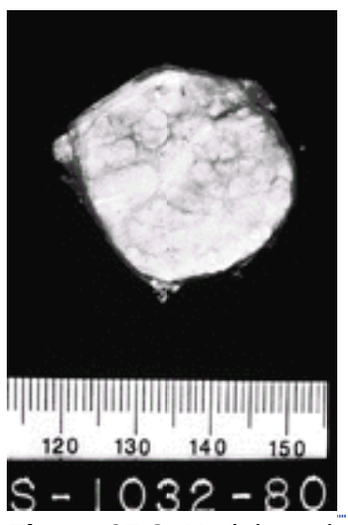

Figure 95.3. Nodular sclerosing Hodgkin disease. Gross appearance of the cut surface of a resected node shows a thickened capsule, white fibrous bands, and yellow parenchymal nodules. See Color Plate.

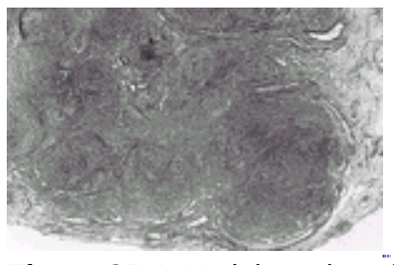

Figure 95.4. Nodular sclerosing Hodgkin disease. Low magnification shows a fibrous capsule and bands of sclerosis circumscribing abnormal lymphoid nodules. See Color Plate.

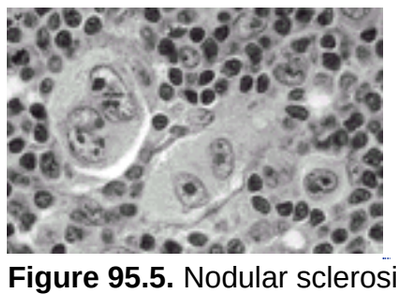

Figure 95.5. Nodular sclerosing Hodgkin disease. High magnification shows Reed-Sternberg cells and lacunar variants in B5 fixed material. See Color Plate.

TABLE 95.2. Relative Incidence of Each Stage of Hodgkin Disease for Each Histopathologic Subtype of Hodgkin Disease

Stage	Histologic Subtype			
	Lymphocyte Predominant (%)	Nodular Sclerosis (%)	Mixed Cellularity (%)	Lymphocyte Depleted (%)
IA and IB	47	8	12	9
IIA and IIB	38	52	34	14
IIIA and IIIB	14	29	41	41
IVA and IVB	1	11	13	36
Total	100	100	100	100

Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980.

A “syncytial variant” of nodular sclerosing Hodgkin disease has been recognized in which numerous Reed-Sternberg cell variants have been observed in sheets and clusters. This variant of Hodgkin disease may be confused with non-Hodgkin lymphoma, thymoma, or metastatic cancer ([67]). Subclassification of nodular sclerosing Hodgkin disease into two subtypes based on cellularity of the nodules and the degree of sclerosis has been considered, but the value of this subclassification is not generally established ([68] , [69] and [70]).

Hodgkin disease of the mixed cellularity pattern is a diffuse lymphoma (Fig. 95.6) composed of a mixture of cells including Reed-Sternberg cells (Fig. 95.7). Distinguishing mixed cellularity Hodgkin disease from diffuse mixed forms of non-Hodgkin lymphoma may be difficult. Because some lacunar cells may be present, cases that a consensus panel defines as mixed cellularity Hodgkin disease are often classified as nodular sclerosis Hodgkin disease by a minority of hematopathologists. This subtype of Hodgkin disease has a greater tendency than nodular sclerosing Hodgkin disease to be advanced at the time of presentation and associated with symptomatic disease. As a result, this subtype of Hodgkin disease is associated with a poorer prognosis. Mixed cellularity Hodgkin disease and nodular sclerosing Hodgkin disease make up the majority of Hodgkin disease cases.

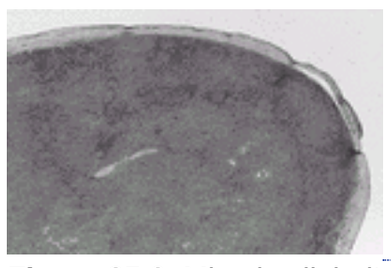

Figure 95.6. Mixed cellularity–type Hodgkin disease. Low magnification shows obliteration of nodal architecture. See Color Plate.

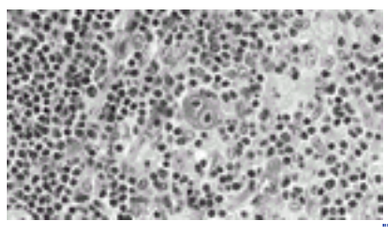

Figure 95.7. Mixed cellularity–type Hodgkin disease. High magnification shows a classic Reed-Sternberg cell in a mixed background of small lymphocytes, plasma cells, and eosinophils. See Color Plate.

Lymphocyte-depleted Hodgkin disease is composed predominantly of histiocytes and lymphocytes with varying numbers of eosinophils and Reed-Sternberg cells (Fig. 95.8 and Fig. 95.9). The host reaction is often scant relative to the number of malignant giant cells, making the diagnosis of Hodgkin disease difficult. A varying amount of fibrosis is generally present, and the original Lukes and Butler classification defined two forms of lymphocyte-depleted Hodgkin disease: reticular and diffuse fibrosis. The reticular subtype is composed of sheets of pleomorphic cells and resembles a large transformed cell non-Hodgkin lymphoma. The disease is the least common type of Hodgkin disease and tends to be advanced at diagnosis (i.e., stage III or IV). Most patients have B symptoms ([71]), retroperitoneal nodal involvement is common, and approximately one-half of patients have bone marrow involvement ([72] , [73] and [74]). Because of the advanced stage of most patients, this subtype of Hodgkin disease has the worst prognosis, but advanced disease is probably as curable with chemotherapy as other histologies of Hodgkin disease. Many cases that would previously have been diagnosed as lymphocyte-depleted Hodgkin disease are now classified as peripheral T-cell lymphomas ([43]) or anaplastic large cell lymphomas ([75] , [76]). As a result, any information regarding lymphocyte-depleted Hodgkin disease based on pathologic evaluations performed before 1985 must be regarded with caution.

Figure 95.8. Lymphocyte-depleted type Hodgkin disease, diffuse fibrosis subtype. Low magnification shows depletion of cellularity of node and scattered large dysplastic cells. See Color Plate.

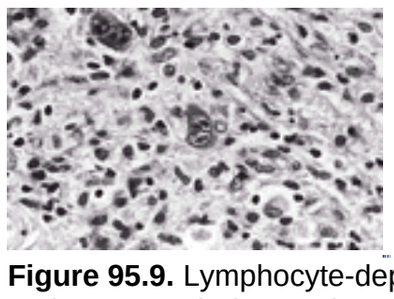

Figure 95.9. Lymphocyte-depleted type Hodgkin disease, diffuse fibrosis subtype. Reed-Sternberg cells are easily found, and the background is depleted of cellularity and composed of amorphous eosinophilic connective tissue. See Color Plate.

Because lymphocyte-predominant Hodgkin disease appears to be a B-cell neoplasm in most cases, the Revised European-American Lymphoma Classification system has proposed that Hodgkin disease be divided into nodular lymphocyte-predominant Hodgkin disease (NLPHD) and four types of “classic” Hodgkin disease: nodular sclerosis, mixed cellularity, lymphocyte-depleted, and lymphocyte-rich classic Hodgkin disease (LRCHD) ([77]). This latter category is considered a provisional

category that includes cases of Hodgkin disease in which the background is primarily lymphocytes but in which the tumor cells have the characteristics of classic Reed-Sternberg cells (i.e., they are CD30 or CD15 positive but negative for the B-cell marker CD20) (Fig. 95.10).

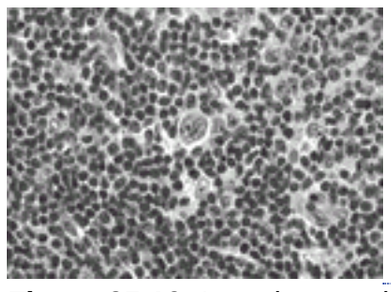

Figure 95.10. Lymphocyte-rich "classic" Hodgkin disease. The background is primarily lymphocytes, and the Reed-Sternberg cells are usually CD15 and CD30 positive and negative for the B-cell marker CD20. See Color Plate.

Although this separation of lymphocyte-predominant Hodg-kin disease into two entities makes biologic sense, at the time this division was proposed, there were no clinical data supporting the relevance of the distinction. Since that time, a retrospective study of 426 cases initially classified as lymphocyte-predominant Hodgkin disease was reported ([78]). Of the 426 cases, adequate tissue was available for review in 379 cases. Of these 379 cases, 58% were reclassified as lymphocyte-predominant Hodgkin disease, 30% were classified as LRCHD, 5% were classified as other types of classic Hodgkin disease, 3% were classified as non-Hodgkin lymphoma, and 4% were considered to be reactive processes.

Both NLPHD and LRCHD patients had predominantly early stage disease: 81% were stage I and II disease for NLPHD, and 70% were stage I and II disease for LRCHD. Patients with LRCHD were significantly older (43 years of age vs. 35 years of age) and were more likely to have a mediastinal mass (15% vs. 7%). Disease-free survival and overall survival were similar for the two groups and similar to survival among patients with other types of Hodgkin disease and limited stage disease. The one difference of note was that multiple relapses occurred in 27% of patients with NLPHD and only 5% of patients with LRCHD. Because therapy in Hodgkin disease is generally based on stage rather than on histologic subtype, the clinical implications of these findings are not clear. However, these preliminary observations support efforts to distinguish NLPHD from LRCHD.

CELL OF ORIGIN

The recognition that lymphomas are tumors of the immune system and could be rationally classified with respect to the cell of origin represented a major advance in the scientific classification of non-Hodgkin lymphoma. In the case of Hodgkin disease, however, this has led to controversy and confusion because, until recently, studies regarding the cell of origin of Hodgkin disease have yielded inconsistent results.

The Reed-Sternberg cell is presumed, but not proven, to be the malignant cell of origin of Hodgkin disease ([79]). It has been postulated at various times that the Reed-Sternberg cell is a B cell, a T cell, a histiocyte, or an interdigitating reticulum cell ([80], [81], [82], [83], [84] and [85]), and this complex area of research and speculation has been the subject of reviews ([86], [87]). Because the Reed-Sternberg cell represents only a minority of the cells in Hodgkin disease, work regarding the origin of the Reed-Sternberg cell has been difficult. However, recent studies have shown that some Reed-Sternberg cells express B-cell antigens, such as CD19, CD20, and CD22 ([88], [89], [90], [91] and [92]), or T-cell antigens, such as CD2, CD3, or CD4 ([88], [93]), whereas other Reed-Sternberg cells appear to lack markers of either cell lineage. The antigens most commonly associated with Hodgkin disease, CD15 (Leu M-1) and CD30 (Ki-1), do not help clarify the origin of the Reed-Sternberg cell because these antigens are not lineage specific. CD15 is present on normal granulocytes, and CD30 has been found on activated T cells and B cells and EBV-transformed cell lines, as well as on the malignant lymphocytes of anaplastic large cell lymphoma.

Reed-Sternberg cells have also been tested for gene rearrangements in an attempt to document the cell of origin. In a summary of published data ([94]), it was found that the majority of cases were germline in configuration, 14% demonstrated an immunoglobulin gene rearrangement, and 6% demonstrated T-cell receptor gene rearrangements. Another study of immunoglobulin gene rearrangement in patients with Hodgkin disease yielded the unexpected finding that although some cases of Hodgkin disease showed monoclonal rearrangements of immunoglobulin genes, other cases appeared to be polyclonal ([95]). However, this apparent polyclonality may be a technical artifact, as single-cell polymerase chain reaction studies have supported the association between Hodgkin disease and monoclonal immunoglobulin gene rearrangements ([96]).

Cytogenetic studies have not been helpful in establishing a cell of origin for Hodgkin disease. Because the Reed-Sternberg cell comprises a small proportion of the cells in Hodgkin disease, there is a technical problem in that any cytogenetic study largely involves benign reactive cells. Therefore, it is not surprising that most studies of chromosomes in Hodgkin disease have yielded normal results, although abnormal cytogenetic findings have been reported ([97], [98], [99], [100] and [101]). By combining the techniques of fluorescence immunophenotyping with interphase cytogenetic analysis, chromosomes of $CD30^{+}$ cells can be studied. When this was done, numerical chromosome abnormalities were detected in the majority of $CD30^{+}$ cells in all 30 cases studied ([102]). However, as with other cytogenetic studies, no chromosomal abnormalities specific for Hodgkin disease have been identified.

The best data for a cell of origin for the Reed-Sternberg cell relate to the nodular variation of lymphocyte-predominant Hodgkin disease in which the cells consistently express CD20 and appear to be of B-cell origin ([103], [104]). Additionally, in this subtype of Hodgkin disease, monoclonal light chain mRNAs have been demonstrated within the Reed-Sternberg cells ([104]). Data for other subtypes of Hodgkin disease are less definitive. Whereas earlier studies demonstrated a trend for nodular sclerosis Hodgkin disease and mixed cellularity Hodgkin disease to express T-cell antigens ([85], [93]), more recent data have supported a B-cell origin for the majority of cases of classic Hodgkin disease ([95], [105], [106] and [107]).

Further information regarding the cell of origin of Hodgkin disease has come from studies of the well-known, but uncommon, association of Hodgkin disease and follicular non-Hodgkin lymphoma ([108]). Two reports ([95], [109]) have studied three patients who had both classic Hodgkin disease and non-Hodgkin lymphoma. In each of the patients, the same monoclonal immunoglobulin gene rearrangement was found in both neoplasms. This finding in cases with two distinct morphologic neoplasms does not establish that the Reed-Sternberg cell in all other cases of Hodgkin disease is of B-cell origin, but it strongly supports the hypothesis that Hodgkin disease is a B-cell neoplasm.

In summary, although the data are somewhat equivocal, recent evidence supports the hypothesis that the cell of origin of Hodgkin disease is a B cell. Clearly, further studies are necessary to clarify what type or types of B cell become a Reed-Sternberg cell. However, regardless of whether Hodgkin disease involves a single cell of origin or represents multiple common biologic pathways, the pathologic picture of Hodgkin disease and the body of clinical data concerning Hodgkin disease clearly justify its consideration as a clinical entity.

CYTOKINES IN HODGKIN DISEASE

Because the inflammatory response is as much a part of Hodgkin disease as the cell of origin, it is not surprising that investigators have studied potential humoral mediators of the host response to the Reed-Sternberg cell. In studying humoral mediators, investigators have often studied Hodgkin disease–derived cell lines, although recent studies have involved isolated Reed-Sternberg cells. Although studies of cell lines provide a greater opportunity for manipulation, the relevance of such observations to *in vivo* phenomena is unknown.

Interleukin (IL)-1, a cytokine that might explain the fever and night sweats associated with Hodgkin disease, has been demonstrated in Hodgkin disease–derived cell lines ([110]), as has the CD25 antigen, which is the IL-2–receptor a-chain. A Hodgkin disease–derived cell line has been described in which both a- and ß-chains of the IL-2 receptor have been detected ([111]). Tumor necrosis factor (TNF)-a and TNF-ß have also been shown to be produced by Hodgkin disease cell lines ([110]). TNF-a, also known as *cachexin*, might explain some of the weight loss associated with Hodgkin disease. Although the mechanism of fibrosis in Hodgkin disease is unknown, production of TNF-ß has been associated with a Hodgkin disease cell line ([112], [113] and [114]). TNF receptor–associated factor 1 (TRAF1), which protects lymphoid cells

from apoptosis, has also been shown to be elevated in Hodgkin disease ([115]). Additionally, production of granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor ([116]), IL-5 ([117] , [118]), IL-6 ([118] , [119]), IL-7 ([120]), and IL-13 ([121]) has been shown to occur in Reed-Sternberg cells using mRNA probes or fluorescence *in situ* hybridization. Although this is a promising area for research ([122]), overall, the relationship between these cytokines and the pathogenesis of Hodgkin disease remains speculative.

CLINICAL EVALUATION

Physical Examination: Sites of Disease

Staging, the basis for treatment planning in Hodgkin disease, begins with the physical examination. Hodgkin disease almost always presents as lymphadenopathy, and the involved nodes are usually freely movable with a rubbery consistency. Cases in which the microscopic appearance reveals fibrosis or sclerosis can be associated with hard, firm nodes. Although any lymph node group can be involved (Table 95.3), cervical and supraclavicular adenopathy are the most common physical findings, and axillary presentations are not rare ([123] , [124]).

TABLE 95.3. Frequency of Involvement of Nodal Sites in Hodgkin Disease

Site	Frequency of Involvement (%)	Frequency of Involvement as Only Site of Disease (%)
Left cervical and/or supraclavicular nodes	70	7
Right cervical and/or supra-clavicular nodes	62	4
Mediastinum	60	1
Spleen [a]	36	0
Paraaortic nodes [a]	34	<1
Left axillary nodes	25	1
Right axillary nodes	25	1
Hilar nodes	21	0
Iliac, inguinal, femoral nodes	16	1

[a] Data based on surgically staged patients.

Modified from Kaplan HS. Contiguity and progression in Hodgkin's disease. Cancer Res 1971;31:1811–1813; and Kaplan HS, Dorfman RF, Nelsen TS, et al. Staging laparotomy and splenectomy in Hodgkin's disease: analysis of indications and patterns of involvement in 285 consecutive, unselected patients. Natl Cancer Inst Monogr 1973;36:291–301.

Mediastinal disease is often present, but it is rarely the only site of disease because it usually occurs in conjunction with cervical or supraclavicular disease. Hodgkin disease can present with iliac, inguinal, or femoral adenopathy, and in approximately 3% of cases, only subdiaphragmatic disease is present ([125] , [126]). However, in a large series of cases in which the original diagnosis of Hodgkin disease was not confirmed on review, two features that predicted errors in diagnosis were primary extranodal disease and primary subdiaphragmatic disease ([127]). Thus, the pathologic diagnosis of Hodgkin disease should be considered very carefully in cases with subdiaphragmatic presentation. A complete physical examination of the patient with Hodgkin disease should include an evaluation of Waldeyer ring and epitrochlear nodes even though these sites are only rarely involved.

Splenomegaly is noted at presentation in approximately 10% of cases of Hodgkin disease. However, splenomegaly may be a nonspecific manifestation of the Hodgkin disease, and in only one-half of patients with splenomegaly is splenic involvement confirmed at laparotomy ([124]). Additionally, splenic involvement may occur in 20 to 30% of patients in the absence of splenomegaly ([124]) even when abdominal computed tomography (CT) scans are used to assess splenomegaly by three-dimensional measurements ([128]). This latter fact should not be surprising, because splenic involvement may be limited to a few microscopic nodules.

Extranodal disease can occur at any site. However, the central nervous system and the testis, which are not uncommon sites for non-Hodgkin lymphoma, are exceptionally rare sites for Hodgkin disease. At presentation, lung, liver, bone, and bone marrow are the most common extranodal sites of disease, with each of these sites seen in approximately 5 to 10% of cases ([129] , [130]). Disease at other individual sites occurs in less than 5% of cases, and as noted previously, primary extranodal Hodgkin disease should always lead the clinician to consider the possibility of an incorrect pathologic diagnosis.

Pattern of Spread

Hodgkin disease tends to spread in a contiguous fashion ([123] , [131]). In fact, when one considers that the left supraclavicular area and the upper abdomen are contiguous (via the thoracic duct), a contiguous pattern of disease can be established at presentation in more than 90% of cases ([123]). For patients with only right supraclavicular involvement at presentation, abdominal disease is found in only 8% of cases; for patients with left supra-clavicular involvement at presentation, the incidence of abdominal involvement is 40%. Hilar involvement with Hodgkin disease does not occur unless mediastinal disease is present. Pulmonary involvement by Hodgkin disease does not occur in the absence of mediastinal and hilar involvement ([132]).

The spleen is the most commonly involved abdominal site of disease, possibly representing hematogenous spread. Liver involvement is uncommon at presentation in patients with Hodgkin disease, and it is exceptionally rare in the absence of splenic involvement ([123] , [133]). Within the abdomen, the pattern of disease detected at staging laparotomy suggests spread from the spleen in a contiguous fashion. In a series in which staging laparotomies were performed with rigorous attention to biopsy of all nodal groups, the spleen and contiguous nodes were involved in 71% of cases, the spleen and noncontiguous nodes were involved in 16% of cases, and lymph nodes were involved in the absence of splenomegaly in 13% of cases ([134]). It is unknown whether the cases of apparent discontiguous spread represent cases in which early hematogenous dissemination has occurred or cases in which Hodgkin disease has spread through a node without involving the node.

Symptoms: Clinical History

Key aspects of the history include determining whether the patient has symptoms that have a prognostic significance, as well as focusing on any symptoms that suggest a specific extranodal site (e.g., bone pain). Proof that extranodal disease is present may lead to a modification of therapy and establishes the need for follow-up studies on completion of treatment. Symptoms that are known to have prognostic value are unexplained fever, drenching night sweats, and weight loss equal to 10% of the patient's weight. Fever in Hodgkin disease can have any pattern, including continuous low-grade fever or occasional fever spikes. The pattern of recurrent episodes of daily high fevers separated by days without fever, Pel-Ebstein fever, was first associated with Hodgkin disease in 1885 ([135] , [136]). However, it is uncommon and occurs only in very advanced disease. Because Hodgkin disease generally presents with palpable lymphadenopathy, Hodgkin disease is often not considered in the diagnosis of unexplained fever. However, patients with the lymphocyte-depleted subtype of Hodgkin disease may present with fever and disease limited to retroperitoneal nodes or the bone marrow, or both ([72]).

Pain at the site of Hodgkin disease in association with the ingestion of alcohol is well described and can be the first hint of a recurrence. The mechanism of this phenomenon is unknown and does not have prognostic significance. The occurrence of alcohol-induced pain has become less common in recent decades, perhaps in association with earlier diagnosis and more effective therapy. Pruritus may be a nonspecific manifestation of Hodgkin disease, but it is not considered when classifying patients as symptomatic or asymptomatic because it has no prognostic implications when it is the sole symptom. Similarly, fatigue and weakness may occur in patients with Hodgkin disease but do not cause a patient with Hodgkin disease to be classified as symptomatic.

Although the staging classification divides patients into categories A and B for asymptomatic and symptomatic, respectively, clinicians are well aware that this binary

classification is an oversimplification and that the presence and absence of symptoms vary along a continuum ([137], [138]) with respect to their clinical significance. When patients with stage IB and stage IIB Hodgkin disease were reviewed, it was found that the presence of fevers was associated with a relative risk of relapse after treatment of 4.3. For weight loss alone, the relative risk of relapse after treatment was 2.4; for night sweats, the relative risk of relapse was 0.8 (i.e., not increased) ([137]). Nevertheless, the presence of symptoms may suggest advanced disease. Symptoms are found in less than 10% of patients with stage I disease and in approximately two-thirds of patients with stage IV disease ([139]). The presence of B symptoms in a patient with apparent stage I disease is, therefore, highly suggestive that further evaluation will lead to the discovery of more advanced stage disease.

Staging

The stage of the patient is the main determinant of therapy and prognosis in Hodgkin disease. The current classification system is the Cotswold classification system ([140], [141]) (Table 95.4). Proposed in 1990, it uses the same criteria for defining four stages of Hodgkin disease and for defining symptomatic disease as the Ann Arbor classification system originally proposed in 1971 ([142]). However, the Cotswold classification system includes many of the modifications, such as anatomic substage of stage III disease, that had been proposed to the Ann Arbor classification system since that system was first proposed. Stage I disease is the involvement of a single lymph node region (or a single lymphoid structure). Stage II disease is the involvement of multiple lymph node regions (e.g., cervical nodes, supraclavicular nodes) but on only one side of the diaphragm. Stage III disease is the involvement of lymph node regions on both sides of the diaphragm and is further subdivided as to anatomic substage. Disease limited to the upper abdomen (i.e., spleen, splenic hilar nodes, celiac nodes, or porta hepatis nodes) in a patient with stage III disease is defined as substage III_1. Patients with stage III disease in whom abdominal nodal involvement includes paraaortic, iliac, or inguinal nodes are classified as substage III_2. Stage IV disease is visceral involvement (e.g., lung, liver, or bone marrow) that is not due to direct extension from a nodal site. Direct extension from a nodal site, such as extension of a mediastinal mass directly into the lung, is represented by the subscript *E*: II_E ([129]). The designations *A* and *B* are used to represent the absence and presence of symptoms (e.g., fever, drenching night sweats, and weight loss of 10% of body weight), respectively. The presence of “bulky” disease, defined as a mediastinal mass with a diameter greater than one-third the diameter of the chest as measured at the T5-T6 interspace on a posteroanterior chest x-ray, or any nodal mass with a greatest diameter of more than 10 cm, is represented by the designation *X* ([143], [144]). The terms *CS* and *PS* are used to designate *clinical stage* and *pathologic stage*, respectively (i.e., whether the stage has been determined by staging laparotomy or by biopsy of a site that establishes stage IV disease). The relative incidence of each stage of Hodgkin disease is shown in Table 95.5.

TABLE 95.4. Cotswold Staging Classification for Hodgkin Disease

Stage I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring)
Stage II	Involvement of =2 lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes are lateralized); number of anatomic sites should be indicated by a suffix (e.g., II_3)
Stage III	Involvement of lymph node regions of structures on both sides of the diaphragm
III_1	With or without splenic hilar, celiac, or portal nodes
III_2	With paraaortic, iliac, or mesenteric nodes
Stage IV	Involvement of extranodal site(s) beyond that designated *E*
A	No symptoms
B	Fever, drenching sweats, weight loss
X	Bulky disease, >1/3 widening of the mediastinum, >10 cm maximum dimension of nodal mass
E	Involvement of a single extranodal site, contiguous or proximal to a known nodal site
CS	Clinical stage
PS	Pathologic stage

Modified from Lister TA, Crowther D. Staging for Hodgkin's disease. Semin Oncol 1990;17:696–703.

TABLE 95.5. Distribution of Hodgkin Disease Cases with Respect to Stage and Symptomatic Status

Stage	A (%)	B (%)	A and B (%)
I	11.4	0.8	12.2
II	34.1	12.4	46.5
III	17.5	13.1	30.6
IV	3.3	7.4	10.7
Total	66.3	33.7	100.0

Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980.

The purpose of clinical evaluation is not only to determine the stage of the patient as a basis for determining therapy, but also to establish a clinical baseline so that the completeness of remission can be assessed on completion of therapy. Staging should begin with a clinical history and a physical examination. The procedures that constitute the basic clinical evaluation are presented in Table 95.6.

TABLE 95.6. Recommended Staging Procedures for Patients with Hodgkin Disease

History and physical examination
Special attention to history of B symptoms (i.e., fever, night sweats, weight loss of >10% in past 6 mo)
Examination of all peripheral lymph node regions, liver, and spleen
Radiologic studies
Chest x-ray
CT scan of thorax
CT scan of abdomen and pelvis
Laboratory studies
Hematocrit, white blood cell count, differential, platelet count
Erythrocyte sedimentation rate
Blood urea nitrogen, creatinine
Bilirubin, alkaline phosphatase, lactic dehydrogenase, “hepatocellular” enzymes
Bone marrow aspiration and biopsy
Tests to be considered in selected circumstances

Gallium scan or positron emission tomography scan
Bone scan

CT, computed tomography.

Radiologic studies should include a chest x-ray and CT scans of the chest and abdomen. Thoracic CT scanning is useful in detecting pulmonary disease, pleural disease, pericardial disease, and extension into the chest wall ([132], [146], [147] and [148]). If present, these findings are of clinical significance because they may require modifications of the planned radiation ports or may lead to a change in the planned treatment modality from radiation therapy to chemotherapy or from chemotherapy alone to combined modality therapy.

The abdominal CT scan has become the standard approach to evaluating the presence or absence of abdominal Hodgkin disease. Abdominal CT scanning is less sensitive than lymphangiography in detecting abdominal nodal disease because CT scanning can only detect enlarged nodes, rather than detect effacement of internal nodal architecture ([149], [150] and [151]). However, as technical expertise in performing and interpreting lym-phangiography has diminished, the relative merits of the two procedures have become clinically irrelevant. In most settings, abdominal CT scanning has become the only procedure that is available to evaluate retroperitoneal adenopathy. Theoretically, CT scanning can evaluate nodes in the celiac axis, porta hepatis, and the mesentery, sites that are not well evaluated by lym-phangiography. However, this advantage is of minimal clinical value because nodal involvement at these sites is often below the size at which CT scans can detect abnormalities ([152]).

The gallium scan is not specific and its use in evaluating abdominal disease is compromised because uptake can occur in normal liver, spleen, and bowel. Gallium scans have been advocated by some clinicians as an additional means of defining *baseline* involvement of the mediastinum ([153]), but the major use of the gallium scan has been in evaluating patients who have *residual* mediastinal disease after therapy. However, there has been little evidence regarding whether a positive gallium scan after treatment was likely to represent a true-positive or a false-positive finding. Recently, King et al. ([154]) reported a series of patients who underwent gallium scanning after completing therapy for Hodgkin disease. Except for residual mediastinal disease, there was no suggestion of tumor persistence or progression. In this series of 33 patients, 13 had a positive gallium scan, of whom 12 relapsed. Twenty patients had a normal scan, and in this group, only two patients relapsed. The positive predictive value (ability of a positive scan to predict relapse) in this series was 93%; the negative predictive value (ability of a negative scan to predict freedom from relapse) was 90%. These results were superior to results achieved with thoracic CT scans, for which the positive predictive value was 48% and negative predictive value was 83%. Because evaluation of patients with radiographic evidence of residual mediastinal disease can be a perplexing clinical problem, confirmation of these findings may establish the role of gallium scanning in the baseline staging as well as the clinical restaging of these patients.

Although preliminary studies have suggested that the use of high-dose gallium-67 single photon emission CT may provide more reliable data in this regard, projected estimates of predictive value are based on clinical assumptions regarding whether scans are true- or false-positives ([155]). Thus, the role of these scans in the routine staging and evaluation of Hodgkin disease remains uncertain. Similarly, the role of MRI scanning in the staging and reevaluation of Hodgkin disease remains undefined even though MRI scans can detect apparent sites of disease that are missed by thoracic CT scans ([156]).

More recent studies have supported the value of whole body PET (positron emission tomography) scanning using 18-fluorodeoxyglucose in the diagnosis of residual masses in patients with Hodgkin disease ([157], [158] and [159]). In one study of 34 patients who had completed therapy for Hodgkin disease or non-Hodgkin lymphoma, 17 were found to have negative PET scans, and all of these patients remained disease free for a median follow-up of 62 weeks ([157]). In 17 patients, PET scans were positive on completion of therapy. In 7 of these 17 patients, the significance of the PET scan could not be determined because a biopsy was not performed and therapy was given when the results of the PET scan were noted. In seven of the other ten patients with positive PET scans, Hodgkin disease was confirmed by biopsy either at the time of the PET scan or shortly thereafter. Clearly, among patients with residual mediastinal masses on CT scans after the completion of therapy, the risk of relapse is greater among patients who have positive PET scans. However, relapses can occur in patients who have negative PET scans. Also, it is not clear what percent of patients with a positive PET scan have false-positive tests. Further clarification of the false-positive and false-negative rates will help define the role of PET scans in the staging and restaging of Hodgkin disease. Because follow-up PET scans are of value in determining the nature of residual masses detected by CT scans, a baseline PET scan should be obtained, when possible, to prove that the tumor is PET positive if there is a high likelihood that a follow-up PET scan will be performed on completion of therapy.

Although generally supplanted by the more easily performed abdominal CT scan, lymphangiography can detect nodes that are not enlarged (and therefore not detectable by CT scan) but in which Hodgkin disease has disrupted the internal architecture of the node. Lymphangiography is generally uninterpretable in the inguinal regions and only visualizes nodes in the lower abdomen, below the level of the second lumbar vertebrae. The major drawback to lymphan-giography is that the validity of the test is highly dependent on the physician who performs the procedure and who interprets the radiologic films. Thus, data in the literature citing an 80 to 90% accuracy of lymphangiography as reported from centers performing the test routinely in past decades ([149], [152], [160], [161]) are of limited relevance to a clinician at an institution where the procedure is not often used. At the present time, most institutions have either limited experience or no experience with lymphangiography. In such circumstances, a negative lymphangiogram may all but exclude disease in the lower abdominal lymph nodes, but a positive lymphangiogram may have a predictive value as low as 35% ([162]). Thus, despite its potential for providing useful information, lack of familiarity with the procedure and subjectivity of interpretation have made lymphangiography a technique of historical interest rather than a major part of clinical care. If lymphangiography is performed, the procedure should not be undertaken until after the chest x-ray film has been reviewed, as the procedure invariably causes embolization of dye to the lungs and thus may be tolerated poorly in patients with coexistent pulmonary disease or with extensive pulmonary or mediastinal involvement by Hodgkin disease.

Blood tests performed in the evaluation of the patient with Hodgkin disease should include a hematocrit, white blood cell count, and differential, as well as an erythrocyte sedimentation rate (ESR). Anemia is present at diagnosis in approximately 40% of patients with Hodgkin disease ([139]) and is more commonly observed in advanced stages of disease. The anemia is generally the normochromic normocytic anemia of chronic disease and is usually mild (i.e., hemoglobin between 10 and 12 g/dl). Coombs-positive hemolytic anemia has been reported in Hodgkin disease ([163]) but is rarely seen at diagnosis.

Mild leukocytosis, monocytosis, and lymphopenia may occur in patients with Hodgkin disease. As with anemia, the phenomena are more commonly seen in patients with advanced disease. Although the ESR has been shown to be a statistically significant predictor of relapse when CS stage I and II patients receive radiation therapy ([164]), the test has never been included in formal staging classifications. An unexplained rise in the ESR after therapy has been shown to be an indicator of relapse ([165], [166]). However, the test is nonspecific, and although an elevated ESR may justify evaluating a patient for the possibility of relapse, an elevated ESR, in itself, does not mean recurrent disease.

Similarly, elevated levels of ß $_2$-microglobulin (ß $_2$M) at presentation have been associated with a lower rate of relapse-free survival ([167]). Although levels of ß $_2$M are more commonly elevated in patients with advanced disease, ß $_2$M is a predictor of relapse even when patients are stratified by stage ([167]).

A bone marrow aspiration and biopsy should also be performed as part of initial staging, although these tests are rarely positive unless other evidence of advanced disease (at least stage III) is present ([130], [168]). The majority of patients with bone marrow involvement have B symptoms as well as abnormal blood counts ([130], [168]). Nevertheless, a bone marrow biopsy should be obtained at baseline in all patients because the results may not only influence the choice of initial therapy but also affect future decisions at the time of relapse [e.g., a decision on the feasibility of autologous bone marrow transplantation (ABMT)]. Bone marrow involvement correlates with histologic subtype of Hodgkin disease because bone marrow involvement is seen more often in the mixed cellularity and lymphocyte-depleted subtypes of Hodgkin disease ([74], [130], [168]). Whereas the diagnosis of Hodgkin disease at extranodal sites generally requires the presence of Reed-Sternberg cells, this is not required for the diagnosis of Hodgkin disease involving the bone marrow. Reed-Sternberg cells are seen in the bone marrow of only two-thirds of cases of Hodgkin disease determined to have bone marrow involvement. The presence of marrow fibrosis in a patient with an established diagnosis of Hodgkin disease has long been accepted as a sufficient pathologic criterion for bone marrow involvement ([130]).

Biochemical tests that are routinely performed should include renal function tests (blood urea nitrogen and creatinine) and tests of hepatic status (bilirubin, albumin, lactate dehydrogenase, and hepatocellular enzymes). These latter tests are not specific for Hodgkin disease involving the liver and may be elevated as a nonspecific manifestation of Hodgkin disease or due to intercurrent problems. Therefore, the only means of establishing a diagnosis of Hodgkin disease involving the liver is to

perform a liver biopsy.

In past years, a major controversy with respect to staging involved the performance of staging laparotomy ([127], [169], [170]). Staging laparotomy includes inspection of the abdomen, liver biopsies (wedge biopsy of the left lobe as well as needle biopsy of both lobes), splenectomy, and systematic biopsies of splenic hilar, celiac, porta hepatis, mesenteric, paraaortic, and iliac lymph nodes. Staging laparotomy is the most accurate means of determining the extent of abdominal involvement by Hodgkin disease. However, the major lesson from staging laparotomy is that the procedure is not needed as part of standard staging. Staging laparotomy can only be justified if the findings at laparotomy will improve the results of therapy. Given the available clinical options, including effective salvage therapy, there is no reason to suspect that staging laparotomy will lead to better long-term results than can be achieved with clinical staging, and there is certainly no evidence that it does so. As a result, in clinical practice, treatment is almost always based on clinical staging—including CT scans—without performing either a staging laparotomy or a lymphangiogram.

The early studies of staging laparotomy revealed that as many as one-third of patients with CS I or II disease were found to have abdominal disease at laparotomy and were therefore upstaged to stage III disease ([127]). This seemed a particularly cogent argument for performing routine staging laparotomy until reexamination of the data showed that for the majority of patients, this abdominal disease was limited to the upper abdomen (substage III_1). Extended field radiation therapy, as might be given in the absence of a laparotomy, would likely be adequate to treat these patients. Thus, the percentage of patients who might benefit from laparotomy is much less than the percentage of patients whose stage would change by doing the procedure.

Some clinicians have advocated selective use of laparotomy and have noted that there are many subsets of patients for whom laparotomy is especially unlikely to change the CS ([171], [172]). For example, among patients with CS I disease, women, patients of either gender with disease limited to the mediastinum, and men with lymphocyte-predominant disease have such a low probability of having abdominal disease (<5%) that radiation therapy without laparotomy represents a justifiable strategy. Among patients with CS II disease, women younger than 27 years of age with fewer than three supradiaphragmatic sites are reasonable candidates for radiation therapy without staging laparotomy.

Staging laparotomy is associated with complications including pneumonia, pulmonary emboli, small bowel obstruction, wound infection, pancreatitis, and ileus in approximately 10% of patients ([173], [174] and [175]). Mortality has been zero in several published series ([173], [176]), and even outside of major centers, the mortality should be less than 1%. However, the procedure places patients at an increased life-long risk of fatal sepsis due to *Streptococcus pneumoniae* and *Haemophilus influenzae* ([177]). These latter risks can be diminished, but not eliminated, by vaccination. Thus, even though staging laparotomy can provide some information about the extent of Hodgkin disease within the abdomen, it is no longer part of the routine staging of the patient with Hodgkin disease.

Prognosis

As noted above, stage is the major prognostic factor in Hodgkin disease and the major basis on which therapy is determined. However, just as the international prognostic index has been used to stratify risk in patients with non-Hodgkin lymphoma, patients with Hodgkin disease can be stratified for risk on the basis of prognostic factors in addition to stage. In a study of 5141 patients with “advanced” Hodgkin disease, primarily stage III and IV disease, Hasenclever and associates ([178]) performed a multivariate analysis of risk factors. Seven independent factors that predicted freedom from progression (FFP) were identified: albumin less than 4.0 g/dl; hemoglobin less than 10.5 g/dl; male sex; 45 years of age or more; stage IV disease; leukocytosis at or above 15,000/mm^3; and lymphocytopenia (lymphocytes =600/mm^3 and/or lymphocytes <8% of total white count). For patients with no risk factors (7% of all patients), FFP was 84%. For patients with one risk factor (22% of all patients), FFP was 77%. For patients with two risk factors (29% of all patients), FFP was 67%. For patients with three risk factors (23% of all patients), FFP was 60%. For patients with four risk factors (12% of all patients), FFP was 51%. For patients with five or more risk factors (7% of all patients), FFP was 42%. Of note, B symptoms did not have independent prognostic value in this model. Prospective use of this stratification system is needed to establish its clinical value.

OVERVIEW OF RADIATION THERAPY

Six years after the discovery of x-rays by Roentgen in 1895, Pusey reported that x-rays could shrink enlarged nodes in patients with Hodgkin disease ([179]). However, given the orthovoltage techniques of the day, therapy was only palliative. The modern radiotherapy era began with the Swiss radiotherapist Gilbert in 1925 ([180]). Based on observed patterns of spread in patients with Hodgkin disease, Gilbert advocated treatment of both involved areas and adjacent apparently uninvolved areas. This approach was also adopted by Vera Peters who, in 1950, was the first to report that radiation therapy of Hodgkin disease could produce cures ([181]). Over the next two decades, the curability of Hodgkin disease was confirmed by Peters ([182], [183]), Eason and Russell ([184]), and Kaplan ([185], [186]), the latter investigator establishing the critical relationship between radiation dose and the risk of recurrence in the treatment field (Fig. 95.11).

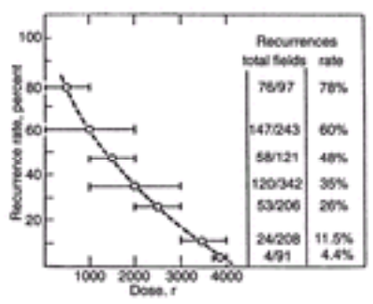

Figure 95.11. Rate of recurrence in a given treatment field as a function of radiation dose delivered to that field. (From Kaplan HS. Evidence for a tumoricidal dose level in the radiotherapy of Hodgkin disease. Cancer Res 1966;26:1221–1224, with permission.)

Kaplan demonstrated that cure could be achieved within a given treatment field 95% of the time if a dose of 35 Gy was administered in 4 weeks and that cure within a given field could be achieved 98% of the time at a dose of 40 Gy ([186]). Because the response in each treatment field is independent, use of large treatment fields in patients with multiple sites of disease can be curative, although at a somewhat lower rate. For example, treatment of five areas (bilateral supraclavicular/cervical nodes, bilateral axillary nodes, mediastinum) would be projected by Kaplan's data to have a cure rate of 0.98^5 or 90% if 40 Gy were delivered to each field and a cure rate of 0.95^5 or 77% if 35 Gy were delivered to each field. From these calculations, it is easily seen how critical it is to deliver the appropriate dose to all involved areas when large fields are treated.

As originally suggested by Gilbert, the principle of treating involved and adjacent apparently noninvolved areas (i.e., extended field therapy) has become the standard radiotherapeutic approach to Hodgkin disease. With the advent of staging laparotomy and evidence that the retroperitoneum could represent a potentially involved adjacent area of disease, the concept of extended field therapy came to include the standard mantle, paraaortic/splenic, and pelvic radiation ports shown in Figure 95.12 ([187]).

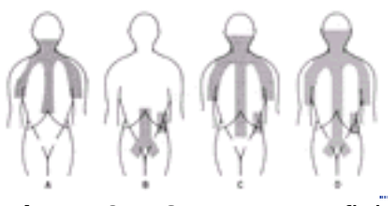

Figure 95.12. Treatment fields used as extended field irradiation of Hodgkin disease. **A:** Mantle field. **B:** Inverted Y field. **C:** Mantle and paraaortic field (extended mantle field). **D:** Total nodal field. The spleen is irradiated in conjunction with the fields in **(B)**, **(C)**, and **(D)**, unless it has been surgically removed.

For the majority of patients who present with disease above the diaphragm, extended field therapy includes both the mantle and the paraaortic/splenic ports (Fig.

95.12). These ports are treated sequentially at many institutions but may be treated simultaneously as an “extended mantle port” ([188]), which obviates the need to match radiation fields over the spinal cord. For patients presenting with disease below the diaphragm, “inverted Y” therapy, which combines pelvic and paraaortic/splenic fields, is generally given. Sequential administration of all three fields constitutes total nodal radiotherapy (TNRT). Although TNRT may be used to treat stage III disease, the effectiveness of chemotherapy in patients who would otherwise be candidates for TNRT has limited the number of patients with Hodgkin disease receiving TNRT in recent years.

Optimal results using radiation therapy depend on careful staging and attention to technique ([189] , [190] and [191]). Technical aspects of radiation therapy have been well covered in reviews ([192] , [193]), but major principles of radiation therapy deserve emphasis. Attention must be paid to shaping fields with lead blocks to shield normal tissues (heart, lung, marrow, liver, and kidneys) while radiating involved and adjacent areas ([193]). Individualized lead shields should be constructed for each patient and may need to be modified during treatment. For example, in a patient with a large mediastinal mass that shrinks during therapy, failure to modify the treatment ports might lead to delivery of a greater-than-intended dose to normal lung. Verification port films, generated by the treatment equipment, should be obtained to ensure proper alignment ([193]). Daily doses should not exceed 180 to 200 cGy, with a total dose of 35 to 44 Gy recommended for involved areas and 30 to 36 Gy recommended for adjacent clinically uninvolved areas ([193]). In treating the mantle port, equal delivery of dose from anterior and posterior fields is essential to limit the risk of pericardial and myocardial injury, which was substantial when this was not standard practice ([194]). A 6- to 10-MeV linear accelerator should be used to permit treatment of large fields at a distance that limits skin toxicity. If the spleen is treated, the entire spleen must be included in the therapeutic port. Thus, one advantage of staging laparotomy is that there is decreased radiation of the left kidney and the base of the left lung.

Complications of radiation therapy depend on technique, dose, and the volume of irradiated tissue. Common complications include hair loss within the treatment fields, radiation pneumonitis, radiation pericarditis, mediastinal fibrosis, and pulmonary fibrosis. Symptoms of radiation pneumonitis generally occur within 1 to 3 months of completing therapy and are nonspecific because they include dyspnea, cough, and fever. Such complications are rarely seen at lung doses less than 15 Gy and occur in less than 5% of patients receiving routine mantle irradiation. The presence of a large mediastinal mass or the concomitant use of chemotherapy essentially doubles the risk of radiation pneumonitis ([195] , [196]). Although infection and recurrent Hodgkin disease must be considered in the differential diagnosis of radiation pneumonitis, radiation injury is likely to be confined to the area of the lung that was irradiated. Infiltrates with sharp borders, representing the edge of the radiation field, strongly suggest the presence of radiation pneumonitis. Because Hodgkin disease and its therapy are both associated with immunosuppression, whenever radiation injury is considered in the differential diagnosis of a patient with Hodgkin disease, one must also consider the diagnosis of *Pneumocystis carinii* pneumonia.

Cardiac toxicity of radiation therapy can include myocarditis, arrhythmias, pericarditis (including constrictive pericarditis and tamponade), valvular heart disease, and coronary artery disease ([197] , [198] , [199] , [200] , [201] , [202] , [203] , [204] , [205] , [206] , [207] and [208]). Although an increased risk of myocardial infarction appears to exist after radiation therapy ([207]), this risk is greater for patients who received radiation therapy before 1966, suggesting that modern treatment techniques have minimized this risk.

Spinal cord injury should not occur with modern radiation therapy techniques but may occur if radiation fields overlap. Splicing of fields over the spinal cord should be done with great care. The one neurologic problem that may occur despite the use of appropriate technique is the Lhermitte sign ([139]), which includes numbness and tingling in the arms, legs, or both and electrical sensations up and down the spine made worse by flexion of the head. This complication is usually transient and of no clinical consequence.

It is generally recognized that splenectomy, performed as part of staging laparotomy, places patients at risk of sepsis with encapsulated organisms. Less well recognized, but as well documented, is that administration of standard radiotherapy doses to the spleen as part of therapy for Hodgkin disease can produce functional hyposplenia. In an autopsy series of patients treated with splenic radiation, median splenic weights were significantly reduced, 75 g versus 210 g, in patients who had received radiotherapy to the spleen ([209]). Liver-spleen scans have confirmed functional hyposplenia in patients after radiotherapy ([210]), and the clinical significance of the phenomenon has been confirmed by the reporting of fatal pneumococcal sepsis after splenic radiotherapy ([209]).

Hypothyroidism is a common complication of radiation therapy ([211]), with actuarial analysis indicating that 52% of patients develop hypothyroidism 20 years after radiation ([211]). Thyroid cancer is an uncommon complication, but, based on the hypothesis that chronic elevations of thyroid-stimulating hormone in patients after thyroid irradiation may lead to thyroid tumors, the administration of thyroid replacement has been advocated in patients with an elevated thyroid-stimulating hormone even if they are clinically euthyroid ([211]).

In addition to thyroid cancer, an increased risk of second malignancies, including lung cancer ([212] , [213]), stomach cancer ([212]), melanoma ([212] , [214]), and breast cancer ([215] , [216] and [217]), has been noted in patients receiving radiation therapy for Hodgkin disease. These malignancies generally occur 10 to 20 years after radiation therapy, with the risk of second malignancies being increased in patients who have also received chemotherapy. Patients who received radiation therapy for Hodgkin disease have a disproportionate tendency for tumors to develop in the medial (radiated) area of the breast, as compared with the location of breast cancers in women who have never received radiation ([216]). Additionally, the relative risk of breast cancer secondary to radiation is age related. The relative risk of developing breast cancer is 38 for patients radiated before age 20; the relative risk is 17 for patients radiated between the ages of 20 and 29; the relative risk is 4 for patients radiated after the age of 30, a relative risk that is not significantly different from 1 ([215]). Fortunately, the baseline risk of breast cancer in patients younger than age 30 is low, muting the quantitative impact of this increase in relative risk. Nevertheless, it has been recommended that women who receive radiation therapy for Hodgkin disease should receive mammography starting 8 years after completion of therapy because 95% of such tumors occur more than 10 years after radiation ([216]).

OVERVIEW OF CHEMOTHERAPY

The development of cancer chemotherapy arose from the observation of lymph node necrosis in soldiers exposed to nitrogen mustard gas during World War I. Therefore, it is not surprising that Hodgkin disease and non-Hodgkin lymphoma were among the first disorders treated with nitrogen mustard when the drug was developed for therapeutic use ([218] , [219]). Since then, several chemotherapeutic agents in several classes of drugs have been shown to be effective in Hodgkin disease. Single agents generally produced partial rather than complete remissions, and unmaintained remissions rarely lasted more than 3 months, with maintained remissions lasting 8 to 10 months (Table 95.7) ([220] , [221] , [222] and [223]). During the 1960s, efforts were made to combine effective agents ([224]), culminating in the landmark demonstration by DeVita et al. that MOPP [Mustargen (mechlorethamine), Oncovin (vincristine), procarbazine, and prednisone] combination chemotherapy could cure advanced Hodgkin disease ([225]). In the initial publication reporting results achieved with the MOPP regimen ([226]), 81% of patients with advanced Hodgkin disease achieved a complete remission, and by actuarial analysis, 47% were projected to be long-term disease-free survivors. Follow-up studies ([227] , [228]) confirmed that these long-term disease-free survivals were equivalent to cure and projected cure rates of 56% ([228]).

TABLE 95.7. Results of Single Agent Therapy in Hodgkin Disease

Agent	Representative Dose and Route	Response Rate (%)	
		CR	CR and PR
Nitrogen mustard	0.2–0.4 mg/kg IV, q4–6wk	13	65
Vincristine	0.2 mg/kg/wk IV	36	58
Procarbazine	50–150 mg/kg/d PO	38	69
Prednisone	40–60 mg/d PO	0	61
Cyclophosphamide	2 mg/kg/d PO	12	54
Chlorambucil	0.2 mg/kg/d PO	16	60
Vinblastine	0.2 mg/kg/wk IV	30	68
Bischloroethylnitrosourea	100–200 mg/m ^{2} IV, q6wk	4	47
Doxorubicin	30–60 mg/m ^{2} IV, q3–4wk	8	41
Bleomycin	5 mg/m ^{2} IV, varying schedules	6	37

DTIC	200 mg/m ^{2} IV, daily ×5, variable	6	56
Etoposide	50–120 mg/m ^{2} IV, daily ×5, variable	7	25
Cisplatin	75 mg/m ^{2} IV, q3–4wk	8	35

CR, complete response; PR, partial response.
Modified from Kaplan HS. Hodgkin's disease, 2nd ed. Cambridge: Harvard University Press, 1980:199–201.

This study of MOPP in advanced Hodgkin disease ([226]) established combination chemotherapy as the treatment of choice for advanced Hodgkin disease (Table 95.8) ([226] , [227] , [228] , [229] , [230] , [231] , [232] , [233] , [234] , [235] and [236]). Additionally, by demonstrating the cumulative and synergistic efficacy of combining drugs with different mechanisms of action and—to a degree—separate toxicities, it established the rationale for the use of combination chemotherapy in other malignancies. The study also raised two issues that have remained critically important to the present day. If combination chemotherapy is the optimal approach to advanced Hodgkin disease, what specific regimen is the optimal regimen and what specific stage or stages of disease should be considered “advanced”? These issues are addressed in the sections on therapy for Hodgkin disease.

TABLE 95.8. Combination Chemotherapy Regimens Effective in the Treatment of Hodgkin Disease

Regimen (Drugs)	Recommended Dose (mg/m ^{2})	Route	Days
MOPP			
Nitrogen mustard	6	IV	1, 8
Vincristine	1.4	IV	1, 8
Procarbazine	100	PO	1–14
Prednisone	40	PO	1–14
MVPP			
Nitrogen mustard	6	IV	1, 8
Vinblastine	6	IV	1, 8
Procarbazine	100	PO	1–14
Prednisone	40	PO	1–14
BCVPP			
Bischloroethylnitrosourea (Carmustine)	100	IV	1
Cyclophosphamide	600	IV	1
Vinblastine	5	IV	1
Procarbazine	50	PO	1
	100	PO	2–10
Prednisone	60	PO	1–10
ChlVPP			
Chlorambucil	6	PO	1–14
Vinblastine	6	IV	1, 8
Procarbazine	100	PO	1–14
Prednisone	40	PO	1–14
ABVD			
Doxorubicin	25	IV	1, 15
Bleomycin	10	IV	1, 15
Vinblastine	6	IV	1, 15
Dacarbazine	375	IV	1, 15
MOPP/ABVD alternating			
Alternating months of MOPP and ABVD, administered as above			
MOPP/ABV hybrid			
Nitrogen mustard	6	IV	1
Vincristine	1.4	IV	1
Procarbazine	100	PO	1–7
Prednisone	40	PO	1–14
Doxorubicin	35	IV	8
Bleomycin	10	IV	8
Vinblastine	6	IV	8
VBM			
Vinblastine	6	IV	1, 8
Bleomycin	10	IV	1, 8
Methotrexate	30	IV	1, 8

NOTE: Each cycle lasts 28 days.

Just as there are technical considerations with respect to radiation therapy for Hodgkin disease, there are critical technical factors with respect to the use of chemotherapy in patients with Hodgkin disease. Standard chemotherapy regimens should not be altered arbitrarily without considering that reductions in dose may decrease the possibility for cure. Although it is generally stated that chemotherapy of Hodgkin disease requires six cycles of chemotherapy, the actual data indicate that one should administer a *minimum* of six cycles of chemotherapy and should treat until a complete remission, or maximal response, is achieved and then treat for two additional cycles ([225] , [226]). If this policy is used, approximately one-fourth of patients receiving combination chemotherapy will receive more than six cycles. Although adding additional cycles to induction therapy is standard treatment of Hodgkin disease, there is no evidence that routine consolidation or maintenance therapy has any clinical benefit in patients with Hodgkin disease ([227] , [237]).

The primary toxicity of combination chemotherapy is hematologic, with neutropenia being more common than thrombocytopenia. Drug toxicity tends to be cumulative, with neutropenia having an increased degree and duration with each cycle of chemotherapy. Because there is evidence that giving the greatest dose over the shortest period is essential to achieving the best therapeutic results ([228] , [231] , [238] , [239]), it is reasonable to support patients with granulocyte colony-stimulating factor to avoid delays of therapy. Drug doses should not be modified for minimal cytopenias (i.e., white blood cell counts >3000/mm ^{3} or platelet counts >100,000/mm ^{3}).

Additional toxicity depends on the individual drugs used. Neurotoxicity with vincristine is generally limited to mild sensory neuropathy (tingling of fingers and toes). This should not lead to dose modifications unless the sensory neuropathy involves the entire fingers. Motor neuropathy and obstipation are indications for dose reduction, but to limit the need for this dose modification, patients receiving vincristine should receive prophylactic laxatives. Some clinicians cap the vincristine dose

at 2.0 or 2.5 mg regardless of patient size, but there is no evidence that this can be done without compromising results. Alternatively, there is evidence that the efficacy of vincristine in Hodgkin disease is dose related ([228], [238]).

Bleomycin may produce pulmonary fibrosis, and doxorubicin may produce cardiac toxicity. However, these toxicities are related to total dose administered. Bleomycin lung toxicity is seen in approximately 10% of patients receiving more than 250 mg/m ^{2} of bleomycin ([240]); clinical evidence of cardiac toxicity is observed in a similar percentage of patients receiving more than 450 mg/m ^{2} of doxorubicin ([241], [242] and [243]). Thus, these toxicities are uncommon even when ABVD [Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine] is used and are rarely seen when hybrid regimens such as MOPP/ABV are administered. Even patients who receive eight cycles of MOPP/ABV chemotherapy at 100% of the planned dose would receive only 80 mg/m ^{2} of bleomycin and 280 mg/m ^{2} of doxorubicin. For patients receiving eight cycles of ABVD, the total cumulative doses would be 160 mg/m ^{2} of bleomycin and 400 mg/m ^{2} of doxorubicin, which would be much nearer the toxic threshold. The threshold for drug toxicity is not absolute, and evidence of drug toxicity may be observed at lower doses, especially in older patients or in patients who have received radiation therapy to ports that include the lung or heart. Unless there is reason to suspect preexistent heart or lung disease, clinical evaluation before and during treatment is adequate, and ancillary studies such as multigated cardiac output studies or pulmonary function studies generally are not necessary.

If the history or physical examination during ABVD therapy raises the suspicion of bleomycin pulmonary toxicity, a chest x-ray should be obtained, and tests such as a chest CT scan and pulmonary function tests with diffusing capacity of lung for carbon monoxide should be considered. Absolute criteria for the discontinuation of bleomycin have not been established, but we strongly caution against the continuation of bleomycin in the face of a corrected diffusing capacity of lung for carbon monoxide of less than or equal to 50%. In making a decision about further use of bleomycin, the clinician must consider the risks of further therapy as well as the risk of early discontinuation of an effective agent.

Sterility is another toxicity of Hodgkin disease that must be considered in planning therapy because this complication may have a significant impact on a patient's quality of life. Administration of three to six cycles of MOPP chemotherapy can produce azoospermia in 90 to 100% of patients ([244], [245] and [246]). Even with long-term follow-up exceeding 10 years, recovery is uncommon when six cycles of MOPP are administered ([246], [247]). Limited data suggest that ABVD is associated with only transient azoospermia ([248]), whereas the VBM (vinblastine, bleomycin, and methotrexate) regimen, used as an adjuvant to radiation therapy for limited stage disease, has not been associated with infertility ([249]). MOPP alternating with ABVD (and, presumably, the MOPP/ABV hybrid) may be associated with permanent azoospermia. Although cryopreservation of semen before chemotherapy and artificial insemination have been successful in achieving pregnancy ([250]), the presence of decreased sperm counts and abnormal sperm motility before therapy in patients with Hodgkin disease limit this approach ([251]).

In women, the effects of chemotherapy appear to be highly dependent on the age of the patient. More than 50% of women become amenorrheic during chemotherapy, with hormonal findings consistent with a diagnosis of ovarian failure ([252], [253]). In younger women, recovery of menses and recovery of fertility are generally seen. In women older than age 35, menses may resume, but menopause may occur prematurely. In women who are premenopausal at the time of chemotherapy, menses may cease permanently ([254]). Although the detrimental effects of combination chemotherapy on fertility are well documented, neither the occurrence of infertility nor its persistence can be predicted with 100% certainty. Patients desiring to avoid pregnancy should be advised not to rely on chemotherapy as their only form of contraception. In addition to decreased fertility, hormonal effects of chemotherapy have been associated with decreased libido in both men and women receiving chemotherapy for Hodgkin disease ([255], [256]).

COMBINED MODALITY THERAPY

With radiation therapy proven to be curative in limited stage disease and combination chemotherapy proven to be curative in advanced stage disease, it is only logical that combined modality therapy (radiotherapy plus combination chemotherapy) would be investigated in Hodgkin disease. The rationale for such an approach is that combination chemotherapy may fail to produce cures in bulky sites of disease, and radiation therapy may miss occult disease outside of treatment ports. Logical candidates for combined modality therapy would therefore be stage II-X patients with large mediastinal masses ([143], [144] and [145]) or patients whose disease was staged as stage IIB ([138]), stage IIIB ([257]), or stage III $_2$ ([58], [134])—on the basis that occult stage IV disease might be present. Other investigators have studied combined modality therapy in all patients with advanced (stage III and IV) disease ([258], [259] and [260]).

Studies in the early 1970s illustrated that full doses of MOPP could be administered after radiotherapy, including TNRT, in patients with Hodgkin disease ([261], [262] and [263]). Extensive radiation can be administered after MOPP chemotherapy, but this has been associated with marked tissue reactions as well as increased morbidity and mortality ([264]). Although combined modality therapy remains a primary treatment option, the major limitation to its use has been that it is associated with an increased risk of acute nonlymphocytic leukemia, which is often preceded by myelodysplasia. The risk of acute nonlymphocytic leukemia is almost nonexistent after radiotherapy alone ([211], [265], [266], [267] and [268]) and is minimal in patients receiving only chemotherapy ([269], [270] and [271]). It is also less common in patients receiving ABVD as compared with patients receiving MOPP ([272]). However, the risk of acute nonlymphocytic leukemia may be as high as 7 to 10% during the first 10 years after combined modality therapy if MOPP is combined with more than involved field radiotherapy ([265], [266], [267], [268], [269], [270], [271] and [272]).

In addition to an increased incidence of acute nonlymphocytic leukemia, an increased incidence of non-Hodgkin lymphoma has been noted in patients receiving combined modality therapy for Hodgkin disease ([273], [274]). These lymphomas tend to be intermediate- or high-grade lymphomas, appear to have a propensity to involve the bowel and retroperitoneum, and have an overall risk of approximately 2%. Proof that these non-Hodgkin lymphomas represent second neoplasms rather than a different morphologic appearance of the same neoplasm has been hampered by limited knowledge regarding the cell of origin and the molecular basis for the development of Hodgkin disease.

Although the risk of acute leukemia becomes minimal 10 years after completion of combined modality therapy ([275]), this high incidence of acute leukemia makes it impossible to justify combined modality therapy with full-dose chemotherapy and full-dose radiotherapy as a routine approach to all patients. Many of the patients previously treated with combined modality therapy are now treated with either radiotherapy or chemotherapy, with the other therapeutic modality reserved for treatment at the time of relapse. Alternatively, when combined modality therapy is administered, radiotherapy to a limited field or to a limited dose may be combined with combination chemotherapy ([276]). For patients in whom radiation therapy is considered the critical modality, combined modality therapy may use a chemotherapy regimen that might be considered suboptimal for advanced disease (VBM) but less leukemogenic and, therefore, safer as part of combined modality therapy ([277]).

OVERVIEW OF HODGKIN DISEASE TREATMENT

Two effective treatment modalities—radiation therapy and combination chemotherapy—are curative in Hodgkin disease. Patients relapsing after radiation therapy can be *cured* by chemotherapy. Patients relapsing after chemotherapy can be *cured* by high-dose chemotherapy in conjunction with ABMT. These facts are good news for patients with Hodgkin disease and for the physicians who care for them, but they complicate the work of clinical investigators who attempt to perform or to summarize clinical trials ([226], [277], [278]). In other malignancies, relapse-free survival can be determined early in the course of a clinical trial and can be used as a reliable indicator of cure and of the superiority of a therapeutic approach. In Hodgkin disease, however, only long-term follow-up and determination of actual long-term survival can determine which of two therapeutic regimens is superior. In studies that use radiation therapy, this is further complicated by the fact that the mortality due to radiation therapy, such as the occurrence of second malignancies, may occur 10 to 20 years after the administration of radiation.

Thus, in choosing the optimal therapy for a patient with Hodgkin disease, one must consider the curative potential of the regimen, the long-term side effects of the regimen (including mortality), and the potential of salvage therapy to produce cure. Although the major cause of death in patients with Hodgkin disease has been said to be Hodgkin disease itself, mortality due to complications of therapy approaches the mortality due to Hodgkin disease ([279]). In patients with limited stage Hodgkin disease, a recent publication ([280]) demonstrated that fewer deaths were attributable to Hodgkin disease (60 deaths) than to second malignancies (59 deaths) and cardiac/pulmonary events (22 deaths). These latter deaths, many of which are treatment related, were primarily late events, as it was not until 14 years after diagnosis that deaths due to causes other than Hodgkin disease exceeded tumor mortality ([280]). Thus, therapeutic approaches that produce superior relapse-free survival in Hodgkin disease are not superior if an alternative regimen associated with a lower disease-free survival produces less morbidity and mortality. One must also consider the fact that patients who relapse after therapy have an opportunity to achieve cure with salvage therapy, thus eliminating the apparent advantage of a regimen with increased relapse-free survival.

As a result of this complexity, there are only general guidelines rather than definitive recommendations for the treatment of each stage of Hodgkin disease (Table

95.9). Fortunately, despite the controversies regarding optimal therapy of Hodgkin disease, as noted in Table 95.10, these approaches provide for excellent overall survival for the patient with Hodgkin disease.

TABLE 95.9. Therapeutic Options for Hodgkin Disease

Stage	Therapeutic Options
IA and IIA	Involved field radiation therapy plus abbreviated combination therapy (e.g., four cycles ABVD) [a]
	Extended field radiation therapy [b]
	Involved field radiation therapy [b]
	Combination chemotherapy
IB and IIB	Involved field radiation therapy plus combination chemotherapy [a]
	Combination chemotherapy [a]
	Extended field radiation therapy plus combination chemotherapy
	Extended field radiation therapy [c]
IX and IIX	Combination chemotherapy with involved field radiation therapy [a]
	Combination chemotherapy [d]
III $_1$A	Combination chemotherapy [a]
	Involved field radiation therapy plus combination chemotherapy [a]
	Extended field radiation therapy [e]
III $_2$A	Combination chemotherapy [a]
	Extended field radiation therapy plus combination chemotherapy [f]
IIIB	Combination chemotherapy [a]
	Extended field radiation therapy plus combination chemotherapy
IVA and IVB	Combination chemotherapy [a]
	Combination chemotherapy with radiation boost to large tumor masses [a]

[a] Authors' preference.

[b] Only selected patients may receive this option on the basis of clinical staging (see text).

[c] Omission of chemotherapy in a patient with B symptoms requires a staging laparotomy to rule out advanced stage disease.

[d] Only if combination chemotherapy produces a complete remission. If not, radiation therapy is indicated.

[e] Omission of chemotherapy requires staging laparotomy in these patients.

[f] Leukemogenic risk weighs heavily against this approach.

TABLE 95.10. Estimated Probability of Cure as Related to Stage of Hodgkin Disease

Stage	Probability of Cure (%)
IA and IIA	80–90
IB and IIB	80–85
IIIA	75–85
IIIB	60
IVA and IVB	60

Treatment of Limited Stage Disease

STAGE IA AND IIA Radiation therapy is a standard approach to stage IA and IIA Hodgkin disease. Historically, the cure for Hodgkin disease using radiation therapy depended on radiating involved areas and adjacent apparently noninvolved areas (181 , 182 , 183 , 184 and 185) (i.e., extended field radiotherapy). However, with the advent of curative salvage combination chemotherapy, the superiority of extended field therapy over involved field therapy with respect to survival has not been definitively established. Several studies (281 , 282 , 283 , 284 , 285 and 286) have compared extended field therapy (total lymphoid radiotherapy or subtotal lymphoid radiotherapy) to limited field radiation. Although freedom from relapse has been superior with extended field radiotherapy in some of these studies (281 , 282), there has been no significant difference between the two approaches with respect to survival (Table 95.11). As expected, results are slightly inferior in patients with CS IA and IIA disease as compared with patients with PS IA and IIA disease, as the clinically staged patients would be expected to include a few more patients with more advanced disease. However, even in the CS IA and IIA patients, there is no proven survival advantage for extended field radiation therapy as compared with involved field radiotherapy. Nevertheless, because extended field radiation therapy provides the opportunity to achieve cure with one treatment effort, rather than having to use salvage therapy, extended field radiation therapy is more commonly used than involved field radiation.

CS, clinical staging; PS, pathologic staging.

Modified from Mauch PM. Controversies in the management of early stage Hodgkin's disease. Blood 1994;83:318–329.

The failure to establish the superiority of extended field radiation therapy depends on both the increased mortality of extended field radiation therapy and the ability of chemotherapy to salvage patients who relapse after involved field radiation. Therefore, in an attempt to improve on the results achieved with radiation therapy, many

investigators have used limited field radiation therapy in conjunction with combination chemotherapy ([287], [288], [289], [290] and [291]) (Table 95.12). Relapse-free survival has tended to be superior with combined modality therapy ([281], [286], [287], [288], [289] and [290]), and in some cases, the differences in favor of combined modality therapy are statistically significant ([287], [289]). However, survival has generally been equivalent with the two approaches to therapy.

TABLE 95.12. Disease-Free Survival and Survival with Combined Modality Therapy (CMT) and Radiotherapy Alone (RT) in Stage I and II Hodgkin Disease

[a] All stage IIIA patients had "minimal" abdominal involvement (i.e., no mass >5 cm and <5 splenic nodules).
Modified from Mauch PM. Controversies in the management of early stage Hodgkin's disease. Blood 1994;83:318–329.

Because individual clinical trials may lack the power to find differences between treatment approaches, the therapy of limited stage Hodgkin disease has been studied in a metaanalysis of 3888 patients in 23 randomized clinical trials ([292]). Among patients receiving more extensive, as compared to less extensive, radiation therapy, the risk of treatment failure was reduced significantly from 43% to 31%, $p < .00001$. However, because of the effectiveness of salvage therapy, 10-year survival was equivalent for the two treatment groups: 77% in both treatment groups. In a second analysis presented in the same paper ([292]), the addition of chemotherapy to radiation therapy was found to significantly reduce the risk of relapse from 33% to 16%, $p < .0001$. However, with respect to survival, the effect of adding chemotherapy to radiation therapy was minimal. Survival at 10 years was 79% with combined modality therapy as compared to 77% with radiation therapy alone, $p > .05$. Whereas deaths due to Hodgkin disease were decreased by combined modality therapy as compared to radiation alone (12.3% vs. 15.4%, $p > .05$), deaths due to other causes, such as secondary malignancies, were increased by combined modality therapy (12.4% vs. 10.0%, $p > .05$). The overall conclusion from this major metaanalysis was that because of the efficacy of salvage therapy, it has yet to be shown that survival in limited stage Hodgkin disease can be improved either by increasing the radiation fields or by adding chemotherapy. When combined modality therapy is used to treat limited stage Hodgkin disease, the question arises as to which combination chemotherapy regimen should be used. Many published studies of combined modality therapy have used a standard regimen such as 6 months of MOPP ([281], [286], [287] and [288]). However, if one is administering combination chemotherapy to deal with occult disease, rather than as the sole treatment for advanced stage disease, one might consider using less toxic chemotherapy regimens. Accordingly, investigators at Stanford have studied the combination of VBM in conjunction with involved field radiation ([249]), and other investigators have studied involved field radiation in conjunction with a limited number of cycles of MOPP or ABVD ([291], [293]). As with the use of radiation therapy and six cycles of MOPP, relapse-free survival tends to be better with these combined modality regimens than with radiotherapy alone. However, as with six cycles of MOPP therapy, a survival advantage for these combined modality regimens has not been established. It is worthy to note, however, that in a randomized trial, involved field radiation therapy plus VBM chemotherapy produced an actuarial 5-year relapse-free survival of 95%. This result compares favorably with involved field radiation, to which it was being directly compared, as well as to involved field therapy plus MOPP as administered in other studies. Thus, there is strong suggestive evidence that if combined modality therapy is used in limited stage Hodgkin disease, one does not need to use a regimen that would be regarded as standard therapy for advanced stage disease. With several effective therapeutic options available for stage I and II patients, one approach is to select therapy for each patient based on the presence or absence of clinical prognostic factors. Several clinical features have been identified as being associated with an increased risk of relapse or decreased survival in patients with PS IA and IIA disease. The most consistent unfavorable prognostic feature is the presence of a large mediastinal mass ([294], [295]). It is generally accepted that patients with a mediastinal mass having a maximal diameter greater than one-third the diameter of the chest are at such high risk of relapse that these patients and patients with extensive pericardial or pleural disease are not suitable candidates for radiation therapy alone. These patients should be treated with combination chemotherapy, usually in conjunction with limited field radiotherapy ([278], [296]), because there is evidence that chemotherapy alone places these patients at an increased risk for mediastinal recurrence and, perhaps, long-term treatment failure ([226]). Stage IA and IIA patients older than 40 years of age also have a significantly inferior survival. This might reflect an intrinsic change in the biology of Hodgkin disease in these older patients, or it might reflect a greater tendency of these patients to develop second malignancies after therapy. In any case, the inferior survival of patients older than 40 years of age has been used by some investigators to recommend staging laparotomy in these patients so that treatment can be limited to the minimal therapy necessary to achieve cure, thus decreasing the complications associated with therapy. Patients whose stage has been determined only by clinical staging rather than pathologic staging are another group of stage I and II patients with a relatively poor prognosis. For this reason, many radiation therapists are reluctant to treat patients with radiation therapy alone unless a staging laparotomy has been performed. A negative staging laparotomy can identify patients who are candidates for radiation therapy alone. Furthermore, there is evidence that a negative staging laparotomy can be used to justify the use of *mantle* radiotherapy, without paraaortic/splenic fields, in PS IA and IIA patients ([285], [286], [297], [298]), especially in patients with nodular sclerosis or lymphocyte-predominant Hodgkin disease who do not have bulky supradiaphragmatic disease ([297]). Certain subsets of patients with limited CS disease are at such low risk of having advanced stage disease found at laparotomy that they may be treated with radiation therapy alone without surgical staging. This includes CS IA women, CS IIA women younger than 27 years of age with fewer than three supradiaphragmatic sites of disease, and CS IA men with lymphocyte-predominant or nodular sclerosing Hodgkin disease or with disease limited to the mediastinum ([172]). Because the risk of abdominal disease in these patients is small but not absent, extended field radiation therapy (mantle and paraaortic/splenic fields) is the most reasonable approach to these patients ([172]). However, these patients probably represent less than one-fourth of patients with CS IA and IIA disease. For other CS IA and IIA patients, the majority of clinicians are uncomfortable using radiation therapy alone without pathologic staging, and, as pathologic staging (i.e., laparotomy) has fallen out of favor, alternative clinical options are generally chosen for these patients (Table 95.9). Faced with controversies regarding the optimal radiation ports, the role of combined modality therapy, and the role of staging laparotomy in patients with stage I and II disease, clinical investigators have attempted to get around these controversial issues by using chemotherapy alone as treatment for limited stage disease. Although the successful use of combination chemotherapy in advanced stage Hodgkin disease and the accumulating data regarding the late long-term effects of radiotherapy suggest that this is a reasonable approach, the data do not support the use of combination chemotherapy alone as the standard treatment of limited stage disease. Two randomized controlled trials of chemotherapy in limited stage Hodgkin disease have been conducted. In the study conducted at the National Cancer Institute (NCI) ([299]), relapse-free survival favored the MOPP chemotherapy group, and overall survival was better, approaching statistical significance, in the MOPP group. However, the study included patients with large mediastinal masses. For these patients, the radiotherapy alone option would generally be regarded as inadequate. When these patients were excluded from analysis, the trends for disease-free survival and for survival favoring MOPP were not statistically significant (Table 95.13). However, MOPP therapy was significantly better for patients with large mediastinal masses or with stage III $_1$A disease.

[a] Excludes patients with large mediastinal masses.
Modified from Mauch PM. Controversies in the management of early stage Hodgkin's disease. Blood 1994;83:318–329.

In an Italian study, which compared combination chemotherapy with extended field radiotherapy for limited stage Hodgkin disease ([300], [301]), relapse-free survival was

similar in the two treatment arms. However, due to an exceptionally poor survival of only 15% after relapse in the patients treated with chemotherapy, overall survival was superior in the patients treated with radiation therapy. Although this result casts doubt on the role of combination chemotherapy in limited stage Hodgkin disease, it must be recognized that salvage approaches including ABMT might be expected to improve on the survival of patients who relapse after combination chemotherapy. As a result, although radiation therapy remains the standard therapy for limited stage Hodgkin disease, the role of combination chemotherapy as primary treatment in these patients cannot be totally rejected and must be regarded as an unresolved issue.

STAGE IB AND IIB The development of treatment recommendations for stages IB and IIB disease has been limited by the relative infrequency of these stages of disease. As noted previously (Table 95.5), less than 1% of patients with Hodgkin disease have stage IB disease, and approximately 12% of patients have stage IIB disease. As the majority of patients with B symptoms have stage IIIB or IVB disease, one approach to patients with CS IB or IIB disease has been to assume that more advanced disease is present and to treat the patients with chemotherapy alone or with combined modality therapy ([289], [290], [302], [303] and [304]) in the absence of surgical staging. However, when these patients have been evaluated with surgical staging, it has been shown that extended field radiation therapy can produce excellent results. In a retrospective review of stage IB and IIB patients treated at Stanford University and the Joint Center for Radiation Therapy at Harvard University, Crnkovich et al. ([137]) reported a 7-year relapse-free survival of 74% and a 7-year survival of 87% for patients receiving radiotherapy alone. Results were insignificantly different for concurrent patients receiving combined modality therapy. In those patients, the 7-year relapse-free survival was 84%, with a 7-year survival of 86%. These results are similar to those obtained in surgically staged patients with IA and IIA disease ([281], [282], [283] and [284]). The high relapse rate in stage IIB patients with large mediastinal masses (42% at 7 years) has been considered a strong argument that these patients should be treated with combined modality therapy rather than radiation therapy alone ([137]), even though salvage at the time of relapse is effective when radiotherapy *alone* has been used as initial treatment. This point is quantitatively significant because approximately 20 to 25% of stage IIB patients have large mediastinal masses (i.e., stage IIE by the Ann Arbor staging system or IIX by the Cotswald classification). Additionally, the presence of both fever and weight loss is associated with less than a 50% relapse-free survival, suggesting that patients in this subset of stage IB and IIB are poor candidates for radiotherapy alone and also that aggressive combination chemotherapy, rather than combined modality therapy, might be most appropriate for these patients ([137]). If one elects to treat a subset of stage IB and IIB patients with radiation therapy, it is necessary to perform a staging laparotomy to exclude the presence of stage IIIB or IVB disease. Combination chemotherapy is the critical therapeutic modality for stage IIIB and IVB patients. The administration of radiation therapy to one of these patients, under the incorrect assumption that the patient has stage IIB disease, may compromise the delivery of combination chemotherapy. This is an important consideration. Although only 40% of patients with Hodgkin disease have stage III or IV disease, among patients with B symptoms, the situation is reversed, and 60% of patients with B symptoms are found to have stage III or IV disease on completion of staging. If radiation therapy is administered to patients with stage IB or IIB disease, the question arises as to what is the appropriate radiation therapy port. Some radiation therapists favor the administration of TNRT, but in these surgically staged patients, the data support the use of mantle and paraaortic fields without the use of pelvic radiotherapy ([137]).

Treatment of Stage IIIA Disease

With radiation therapy regarded as the key modality in the treatment of limited (stage I and II) disease and chemotherapy regarded as the key modality in the treatment of advanced (stage IV) disease, it is not surprising that the management of stage III Hodgkin disease has been a subject of controversy. As early as the late 1960s, investigators at Stanford University began studies comparing radiation therapy alone with radiation therapy plus chemotherapy (combined modality therapy). As with stage IA and IIA disease, it was clear that the use of radiation therapy alone was associated with a significantly increased risk of relapse compared with that observed with the use of combined modality therapy ([305], [306]) (Table 95.14). However, radiation therapy alone with chemotherapy used at the time of relapse produced overall survival similar to that achieved with combined modality therapy ([305], [306]). Because the use of radiotherapy alone would obviously spare 30 to 40% of patients from the need to receive chemotherapy, radiation therapy alone was advocated as the treatment of choice for stage IIIA patients ([307]).

[a] p <.05 when compared to other treatment modalities.

[b] Survival and relapse-free survival are estimated from life tables.

Despite the excellent results achieved at Stanford, several issues limited the acceptance of radiation therapy alone as the treatment of choice for stage IIIA Hodgkin disease. First, the results achieved at Stanford involved the use of special techniques such as whole-liver irradiation in the presence of splenic involvement and whole-lung irradiation in the presence of ipsilateral hilar involvement. This meant that the results achieved at Stanford were not necessarily achievable at other institutions. Second, although combined modality therapy was not significantly superior to radiation therapy alone with respect to survival, the trend for improved survival favored combined modality therapy. The possibility that a biologically significant result was being missed due to small sample size could not be excluded. On the other hand, with the demonstration that combined modality therapy was associated with an increased risk of acute leukemia, especially when wide field radiation was used, combined modality therapy could not be justified on the basis of an insignificant trend.

To analyze therapy of stage III Hodgkin disease, Desser et al. ([134]) proposed that stage III disease be divided into anatomic substages based on the extent of abdominal nodal involvement (see section Staging). After a number of studies suggesting that the extent of abdominal nodal disease was an important prognostic indicator of disease-free survival after radiation therapy ([134], [308], [309] and [310]), a large pooled retrospective analysis was performed ([58], [311]). This review strongly suggested that radiation therapy *alone* could be justified only for patients with stage III $_1$A disease and only when the staging had been determined at laparotomy. For patients with stage III $_2$A disease, radiotherapy plus chemotherapy produced significantly superior survival as compared with radiotherapy alone. Even though these stage III $_2$A patients had undergone staging laparotomies that did not establish stage IV disease, they were at substantial risk of early relapse after radiation therapy alone. The use of extended field radiation therapy in these patients compromised their ability to receive chemotherapy at the time of relapse and led to inferior long-term results.

In a similar examination of prognostic features in patients treated at Stanford, Hoppe et al. ([312]) did not confirm that substage was a prognostic factor. No subgroups of patients were found in whom the addition of chemotherapy to radiotherapy led to a significant improvement in survival. However, as noted previously, radiation therapy administered at Stanford included radiation of lung and liver in selected patents. As a result, stage III $_2$A patients treated with radiation alone at Stanford did not have the risk of treatment failure associated with more conventional radiation therapy techniques ([310], [311]). Thus, this study ([312]) cannot be used to justify the use

of standard radiation therapy alone in patients with stage III $_2$A Hodgkin disease.

Larger series have suggested that even in stage III $_1$A disease, radiotherapy alone may be inadequate therapy ([313]). In a large retrospective trial, survival was better, although only approaching statistical significance, for stage III $_1$A patients receiving combined modality therapy (89%) as compared with survival in patients receiving either mantle/paraaortic radiation (78%) or total nodal irradiation (70%).

If radiation therapy is inadequate for the majority of patients with stage III disease, the logical question is whether chemotherapy alone or combined modality therapy is the appropriate approach. However, only limited data are available to answer the question (Table 95.14). In a study in which treatment was partially randomized and partially stratified by substage, Lister et al. ([314]) found that chemotherapy produced superior relapse-free survival when compared with radiation therapy alone in patients with stage IIIA disease; survival in the two treatment groups was equivalent. Combined modality therapy was not used in that study. In a study comparing chemotherapy with chemotherapy followed by radiation therapy, Crowther et al. ([315]) observed no differences with respect to either relapse-free survival or overall survival. In a randomized study, Grozea et al. ([316]) found no difference between chemotherapy alone and combined modality therapy with respect to relapse-free survival or survival in patients with stage III disease. Further support for the use of chemotherapy alone comes from the long-term follow-up of patients receiving MOPP at the NCI. In patients with stage IIIA, IIIB, or IVA, overall survival at 15 years was 96% ([226] , [228]).

Although a single specific optimal therapy cannot be advocated for patients with stage IIIA disease, the following conclusions can be drawn from the available data. Foremost is that the use of radiation therapy alone in stage IIIA Hodgkin disease can be justified only in patients with minimal (stage III $_1$A) disease and only when a laparotomy has been performed and, even then, with some concerns that overall survival may be compromised ([313]). For patients with advanced stage III disease (stage III $_2$A), there is support for the use of combined modality therapy ([58] , [311] , [313] , [314] and [315]) or combination chemotherapy alone ([226] , [228] , [314] , [315] and [316]). However, the use of combined modality therapy in stage III $_2$A should logically require surgical staging to decrease the probability that stage IV disease is present. Because it is difficult to justify a staging laparotomy in patients for whom chemotherapy is acceptable treatment, a reasonable approach to stage IIIA disease is to use combination chemotherapy in all patients for whom there is clinical evidence of stage III disease in the absence of staging laparotomy. Although this might lead to unnecessary toxicity for some patients, there is no evidence that this approach compromises long-term survival for any patient.

Treatment of Advanced Stage Disease

STAGES IIIB, IVA, AND IVB Combination chemotherapy is the treatment of choice for advanced stage Hodgkin disease. As in other stages of disease, controversy regarding therapy exists; the specific issues for patients with advanced stage disease are the identification of the best specific regimen and the question of whether supplemental radiotherapy has any role in treating advanced stage disease. After the introduction of MOPP chemotherapy by DeVita et al. ([225]), the development of combination chemotherapy has included three general categories of regimens: (a) minor modifications of MOPP, (b) regimens composed of drugs non–cross-resistant to MOPP, and (c) regimens that combine—either in alternating cycles or in one hybrid regimen—both MOPP and a non–cross-resistant regimen. Doses and schedules for the commonly used regimens are presented in Table 95.8 . Results achieved using these regimens in representative studies ([227] , [228] , [229] , [230] and [231] , [234] , [236] , [299] , [318] , [319] , [320] and [321]) are presented in Table 95.15 . Duration of follow-up differs among these studies but generally exceeds 5 years. Because more than 90% of relapses occur within 4 years of treatment, data regarding relapse-free survival are clinically meaningful. However, survival after chemotherapy for Hodgkin disease declines for 10 years after treatment. Thus, comparing survival data across regimens that report data for different periods of follow-up is of limited meaning. Only data from comparative trials can be given much credence in this regard.

TABLE 95.15. Results of Combination Chemotherapy in Hodgkin Disease

Regimen (Author, Reference)	Complete Response (%)	Disease-Free Survival (%) (Yr) [a]	Survival (%) (Yr) [a]
MOPP and minor modifications of MOPP			
MOPP (Longo, 228)	84	54 (15)	48 (10)

MOPP/ABVD alternating (Canellos, 318)	83	65 (5)	75 (5)
ChlVPP/EVA hybrid (Radford, 320)	68		80 (5)

[a] In many cases, results are estimated from graphs of actuarial survival and actuarial disease-free survival. Survival is determined by multiplying the complete remission rate by the percent relapse-free survival in those patients who obtained a complete remission.

[b] Results include patients who received consolidation radiotherapy to a solitary residual nodal abnormality after six cycles of chemotherapy.

Additionally, results achieved with combination chemotherapy depend not only on the regimen being used, but also on the patients who are treated. As discussed, over the past 10 to 15 years, it has been recognized that combination chemotherapy represents an appropriate approach to patients with stage III disease. Because a decision to use chemotherapy obviates the need to perform a staging laparotomy, recent chemotherapy studies are performed on patients who are clinically staged. Thus, in contrast to the original MOPP studies, in which the majority of patients receiving combination chemotherapy were PS IV, recent studies of combination regimens include patients in CS III and IV. This fact must be considered when results obtained with newer regimens are compared with older studies. Over the course of two decades, MOPP chemotherapy has been associated with complete remission rates between 67 and 91%. The best results have been achieved at the NCI ([228] , [299]), where long-term disease-free survival has been 54 to 65%. Several controlled clinical trials have been conducted using MOPP as one of the regimens. Investigators in the Eastern Cooperative Oncology Group compared MOPP with BCVPP (bischloroethylnitrosourea, cyclophosphamide, vincristine, procarbazine, prednisone) ([317]). Similar complete remission rates were observed with the two regimens, but complete remissions and overall survival were longer in patients receiving BCVPP than in patients receiving MOPP. As with most studies using MOPP conducted outside the NCI, the MOPP schedule was modified from that initially used at the NCI. Specifically, the vincristine dose was capped at 2 mg, and the interval between cycles was increased. Although this limits the comparison to MOPP, it is nevertheless true that this was the first study to demonstrate that combination chemotherapy regimens other than MOPP could produce not only excellent complete remission rates, but also excellent long-term results. As noted in Table 95.15 , BCVPP is considered a minor modification of the MOPP regimen because it includes alkylating agents, a vinca alkaloid, procarbazine, and prednisone. By contrast, regimens thought to be non–cross-resistant to MOPP have been developed, specifically ABVD ([232]) and streptozotocin, CCNU, Adriamycin, and bleomycin (SCAB) ([321] , [322]). SCAB has also been designated *CABS* ([299]). In uncontrolled observations ([232] , [321]), these regimens produced results similar to those achieved with MOPP. Shortly thereafter, Goldie and Coldman ([323]) predicted that the use of

alternating non–cross-resistant drug regimens would prevent drug resistance that might result from the use of a single combination regimen. This hypothesis led to the use of alternating cycles of MOPP and ABVD ([234]) as well as to an integrated hybrid regimen in which the drugs of the MOPP regimen were given on day 1 and ABV was given on day 8 ([236]) of each cycle. Comparative trials studying alternating regimens have been performed. In a large trial conducted by Cancer and Acute Leukemia Group B ([318]), MOPP (six to eight cycles) was compared to ABVD (six to eight cycles) and with MOPP/ABVD. The latter regimen consisted of a cycle of MOPP alternating with a cycle of ABVD for a total of 12 cycles. As compared with MOPP, complete remission rates as well as survival were significantly higher with both ABVD and MOPP/ABVD. Long-term follow-up of this trial has recently been published ([324]). With a median follow-up in excess of 13 years, relapse-free survival was superior for patients receiving ABVD and MOPP/ABVD as compared to MOPP. However, because of salvage therapy, survival was equivalent for all three treatment arms ([324]). Because the MOPP schedule had been attenuated from that used at the NCI, it is conceivable that MOPP as given at the NCI might be equivalent to ABVD or MOPP/ABVD. However, the MOPP dose modifications are not arbitrary and represent difficulties that investigators and patients have with the MOPP regimen as given at the NCI. It is therefore reasonable to conclude that ABVD and MOPP/ABVD represent rational alternatives to MOPP therapy. MOPP therapy, as it was given in this trial (which is the way MOPP is most often given in the community), is inferior to ABVD and MOPP/ABVD with respect to relapse-free survival, but not with respect to survival. Given that MOPP/ABVD was equivalent to ABVD in this randomized trial, the Goldie-Coldman hypothesis has not been confirmed in Hodgkin disease. Similarly, a trial comparing MOPP/CABS with MOPP showed no evidence for superiority of the alternating combination regimen ([299]). Despite the absence of confirmatory evidence, the Goldie-Coldman hypothesis remains attractive to clinical investigators. In that context, Klimo and Connors rationalized that if alternating cycles of combination chemotherapy could limit the development of drug resistance, alternating combinations within a given cycle might improve results even further. The result was the MOPP/ABV hybrid, which has been associated with superb clinical results ([236]). Using the MOPP/ABV hybrid, 97.5% of patients achieved a complete remission. The protocol allowed for involved field radiation to be administered to a solitary lymph node region if residual adenopathy was present after six cycles of chemotherapy. However, even if patients who received “consolidation radiotherapy” are excluded, the complete remission rate is 84%. More than 90% of patients achieving a complete remission were reported as disease free (median follow-up, 46 months), for a projected disease-free survival of 88%. Actuarial survival at 4 years was 93%. The MOPP/ABV hybrid regimen has been compared to sequential MOPP/ABVD in a randomized clinical trial ([325]). This study included patients with CS or PS III $_2$, IIIB, IVA, or IVB disease, as well as well patients with stage III $_1$ disease and five splenic nodules. Patients randomized to sequential therapy initially received six cycles of MOPP. If a complete remission was achieved, patients received three cycles of ABVD. If a partial remission was achieved, two additional cycles of MOPP were given, and, if a CR was achieved, the patients then received three cycles of ABVD. Patients randomized to MOPP/ABV received therapy for two cycles beyond complete remission to a maximum of 12 cycles. Complete responses were significantly higher in the group receiving MOPP/ABV: 83% versus 75%, $p = .02$. Eight-year failure-free survival was significantly higher for the hybrid regimen: 64% versus 54%, $p = .01$. Furthermore, 8-year survival was significantly higher for patients receiving the MOPP/ABV hybrid regimen: 79% versus 71%, $p = .02$. Nine cases of acute myelogenous leukemia were observed in patients receiving the sequential regimen as compared to only one among patients receiving the hybrid regimen. MOPP/ABV has also been compared to ABVD in a large-scale randomized clinical trial. However, only preliminary results have been reported ([326]). With limited follow-up, response rates, freedom from relapse, and overall survival were not significantly different when the two regimens were compared. However, more toxicity was associated with the MOPP/ABV hybrid regimen, and this study was closed to accession earlier than had been planned. As a result, ABVD is generally considered the standard chemotherapy regimen for the treatment of Hodgkin disease. However, long-term follow-up of the patients entered on the study will be of interest to see if any survival differences emerge.

Considering the favorable results achieved with stem cell transplantation as salvage chemotherapy, it is not surprising that dose-intense chemotherapy regimens have been investigated as initial therapy in patients with Hodgkin disease. Two such regimens are the BEACOPP (bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone) regimen reported by German investigators ([327]) and the Stanford V regimen reported by investigators at Stanford ([328]) (Table 95.16). The BEACOPP regimen has been studied in a large-scale randomized trial in which it was compared to COPP alternating with ABVD ([327]). In that study, two variants of BEACOPP were used—a standard dose and an escalated dose version. Radiation therapy was administered to patients with initial bulky disease or with suspected residual tumor. Although differences with respect to survival were not noted, response rates and freedom-from-treatment failure were superior for the pooled BEACOPP arms as compared to COPP/ABVD. Two-year freedom-from-treatment failure was 84% for the pooled BEACOPP arms of the study as compared to 75% for patients receiving COPP/ABV, $p < .05$. Further follow-up of this important study has been presented ([328]), and 5-year survival has been found to be significantly higher with the escalated BEACOPP regimen (91%) as compared to BEACOPP (88%) or COPP/ABV (83%), $p < .01$. Favorable survival was observed in the escalated BEACOPP group even though this regimen was associated with a higher incidence of treatment-related myelo-dysplasia or acute leukemia. This increased toxicity raises concern as to whether escalated BEACOPP or standard BEACOPP is the optimal regimen.

TABLE 95.16. Dose-Intense Therapy as Initial Treatment for Hodgkin Disease

Regimen (Drugs)	Recommended Dose (mg/m ^{2})	Route	Days
Stanford V (Bartlett, 329)			
Nitrogen mustard	6	IV	Day 1 of wk 1, 5, 9
Doxorubicin	25	IV	Day 1 of wk 1, 3, 5, 7, 9, 11
Vinblastine	6	IV	Day 1 of wk 1, 3, 5, 7, 9, 11
Vincristine	1.4	IV	Day 1 of wk 2, 4, 6, 8, 10, 12
Bleomycin	5	IV	Day 1 of wk 2, 4, 6, 8, 10, 12
Etoposide	60	IV	Day 1 and 2 of wk 3, 7, 11
Prednisone	40	PO	q.o.d. ×9 wk, taper during wk 10–12
Escalated BEACOPP (Diehl, 327)			
Bleomycin	10	IV	Day 8
Etoposide	200	IV	Day 1, 2, 3
Doxorubicin	35	IV	Day 1
Cyclophosphamide	1200	IV	Day 1
Vincristine	1.4 [a]	IV	Day 8
Procarbazine	100	PO	Day 1–7
Prednisone	40	PO	Day 1–14

[a] Maximum dose, 2.0 mg. Repeat on day 22.

Another dose-intense regimen studied as initial therapy in Hodgkin disease is the Stanford V regimen, which was initially studied in 65 patients with bulky mediastinal disease or stage III and IV disease ([329]). In contrast to BEACOPP, which escalated drug doses, the Stanford V regimen achieved dose intensity by decreasing the interval between treatments; total doses of drugs were lower than those used in standard regimens. As in the BEACOPP trial, radiotherapy was given as consolidation to sites of bulky disease. In the initial single institution report, actuarial 5-year survival was 96%, and 5-year failure-free survival was 89% ([330]). A feasibility trial has also been conducted in a multiinstitutional setting ([331]). Results were essentially identical to those reported in the initial Stanford study. Overall survival was 96% at 2 years and 5 years; FFP was 87% at 2 years and 85% at 5 years ([331]). Because Stanford V is associated with excellent long-term results and involves lower total drug doses and, therefore, a potential for less long-term toxicity, it is a very intriguing regimen. An intergroup study comparing Stanford V to ABVD has been initiated. As noted above, as initially administered, the MOPP/ABV regimen included radiotherapy for patients with a solitary site of residual disease after chemotherapy. Other regimens, such as Stanford V and BEACOPP, include radiotherapy to initial sites of bulky disease ([327] , [329]). By contrast, some investigators have advocated that on completion of chemotherapy, moderate doses of radiotherapy should be administered to *all* sites of disease that were initially present ([332] , [333] , [334] , [335] , [336] and [337]). Given that the investigators used effective chemotherapy regimens and that the administration of radiotherapy could not compromise the delivery of chemotherapy (because it was administered on completion of chemotherapy), it is not surprising that excellent results were obtained using radiotherapy on completion of chemotherapy. For example, Straus et al. reported an overall survival of 72% at 8 years using radiotherapy after completion of a number of chemotherapy regimens such as MOPP/ABVD ([332]). Prosnitz and associates reported a 15-year actuarial survival of 54% in patients who received radiotherapy after chemotherapy ([335]). However, 10% of patients treated in that series ([335]) developed second malignancies, with 6% of patients dying of these second malignancies. Thus, although these studies demonstrate the feasibility of a combined modality approach to patients with advanced Hodgkin disease, only a randomized trial can determine if such an approach is of value. To detect significant differences between chemotherapy and chemotherapy followed by radiation therapy requires such a large number of patients that it is unlikely that such a definitive large-scale prospective trial will ever be performed. However, a metaanalysis has been performed of studies that compared chemotherapy alone to combined modality treatment ([338]). Two clinical designs were noted. In the first group of trials, patients received a similar amount of chemotherapy in both arms, but one group received additional radiotherapy. In these trials, relapse-free survival was superior in the combined modality group, but

overall survival was not significantly improved by the addition of radiotherapy. In the second group of trials, radiotherapy was substituted for chemotherapy; in these trials, the patients receiving radiotherapy received fewer cycles of chemotherapy. In these trials, tumor control was the same with both treatment approaches. However, overall survival was better in patients who were *not* receiving radiotherapy. Thus, although radiotherapy might produce effective local control, long-term hazards of combined modality therapy made this approach counterproductive. The authors concluded that combined modality therapy of advanced disease should be limited to specific indications ([338]). Although the authors did not clarify this point, it seems logical to conclude that equivocal complete remissions would be considered such a circumstance. However, it is reasonable to speculate that the future use of PET scans might markedly decrease the number of cases thought to have equivocal responses to chemotherapy.

Summary of Treatment of Hodgkin Disease

With the recognition that effective salvage treatment of Hodgkin disease can produce cures, it has become harder to prove that a specific therapy is the best long-term option for a specific stage of Hodgkin disease. Nevertheless, based on an assessment of risks and benefits, several treatment recommendations can be made (Table 95.9). Treatment decisions are almost always based on the results of clinical staging, as staging laparotomy has all but been abandoned. As a result, the use of radiation therapy alone for limited stage disease has been limited to a small subgroup of very favorable patients who are at minimal risk of occult abdominal disease. Radiation therapy with abbreviated combination chemotherapy has become the most widely used approach in limited stage (stage IA and IIA) patients. For patients with stage IX and IIX disease and a large mediastinal mass, combination chemotherapy, usually ABVD, followed by radiation therapy, is the most logical approach. Anatomic substaging depends on staging laparotomy and is, therefore, of limited relevance when treatment planning is based on clinical staging. For patients with stage III or stage IV disease, combination chemotherapy is the treatment of choice, with the majority of data favoring the use of ABVD. The use of additional radiotherapy to large tumor masses is worth consideration but has not been proven to produce superior long-term results.

SALVAGE CHEMOTHERAPY

As with the initial therapy, salvage therapy of Hodgkin disease is associated with significant morbidity and, possibly, mortality. Therefore, if relapse is suspected in a patient with Hodgkin disease, it should be confirmed by biopsy, whenever possible, before the initiation of salvage therapy. Although the choice of a salvage chemotherapy regimen depends primarily on the prior therapy that the patient has received, the response to salvage therapy depends on several additional factors including the initial stage of the patient, the response to that therapy, and the relapse-free interval.

After radiation therapy, the majority of relapses occur in the first 2 years after treatment; 95% of patients who remain free of disease for 4 years after radiation therapy are cured ([337]). Relapses may occur in previously irradiated sites, in areas adjacent to treatment fields (marginal recurrences), or in previously unirradiated areas. In patients who experience marginal recurrences or recurrences in unirradiated areas after radiation therapy, retreatment with radiation therapy can be considered. However, this approach rarely leads to long-term relapse-free survival ([339] , [340]). Most often, combination chemotherapy is considered for salvage therapy in patients who relapse after radiation.

Any of the regimens used as primary chemotherapy of Hodgkin disease are reasonable in the setting of relapse after radiation therapy. Although there is probably more published experience with MOPP in patients who relapse after receiving radiation therapy, the leukemogenic risk of using MOPP as part of combined modality therapy suggests that ABVD may be a more reasonable choice than MOPP in these patients. Empirical results support the use of ABVD in this context. In patients who relapsed or progressed after receiving radiation therapy, Santoro et al. reported responses in 75% of patients who received MOPP as compared with 91% of patients who received ABVD ([341]).

The initial stage of disease is an important prognostic indicator in patients who relapse after radiation therapy and who then receive chemotherapy. Mauch et al. ([342]) reported that patients who relapsed after receiving radiation therapy for stage IA, IIA, IIB, or III $_1$A Hodgkin disease and then received salvage chemotherapy had a complete response rate of 86%, with 81% 4-year actuarial disease-free survival. By contrast, patients who initially presented with stage IIIB or III $_2$A disease and who relapsed after receiving radiation therapy had a complete response rate of only 56% and a 42% 4-year disease-free survival when salvage chemotherapy was given. Thus, advanced stage of disease predicts not only an increased likelihood of relapse after radiation therapy, but also a decreased chance of responding to chemotherapy at the time of relapse.

For the patient who relapses after chemotherapy, radiation therapy can be considered ([343]) in the case of a focal nodal recurrence, but chemotherapy is generally the treatment of choice. Given the large number of drugs effective in Hodgkin disease, a wide variety of empirical combinations have been studied as salvage regimens in patients who relapse after receiving chemotherapy for Hodgkin disease ([344] , [345] , [346] , [347] , [348] , [349] , [350] , [351] , [352] , [353] , [354] and [355]). Recently, platinum based salvage regimens similar to those used in non-Hodgkin lymphoma have been investigated ([356] , [357]), primarily in patients who were being considered for stem cell transplantation after such salvage chemotherapy. As would be expected from the fact that lymphocyte-predominant Hodgkin disease is a B-cell malignancy that is CD20 positive, preliminary reports have shown the effectiveness of rituximab in the treatment of this subtype of Hodgkin disease ([358]). Additionally, gemcitabine has recently been shown to be effective in heavily pretreated patients with Hodgkin disease, although patients who had previously undergone stem cell transplantation were excluded from the study ([359]).

The topic of salvage chemotherapy has been extensively reviewed ([226]). Doses of representative regimens are presented in Table 95.17, and results obtained with some of the most commonly used regimens are presented in Table 95.18. Although responses have been seen in more than half of the patients in some series, complete remission rates are generally between 30 and 40%, with long-term disease-free survival observed in only 15 to 20% of patients ([346] , [360]).

TABLE 95.17. Chemotherapy Regimens Effective as Salvage Treatment of Hodgkin Disease

Regimen (Drugs)	Recommended Dose (mg/m ^{2})	Route	Days
ABVD			
Doxorubicin	25	IV	1, 15
Bleomycin	10	IV	1, 15
Vinblastine	6	IV	1, 15
Dacarbazine	375	IV	1, 15
B-CAVe			
Bleomycin	5	IV	1, 28, 35
CCNU	100	PO	1
Doxorubicin	60	IV	1
Vinblastine	5	IV	1
SCAB or CABS			
Streptozotocin	500	IV	1–5
CCNU	100	PO	1
Doxorubicin	45	IV	1
Bleomycin	15	IV	1, 8
ABDIC			
Doxorubicin	45	IV	1
Bleomycin	5	IV	1, 5
Dacarbazine	200	IV	1–5
CCNU	50	PO	1
Prednisone	40	PO	1–5

VABCD			
Vinblastine	6	IV	1, 22
Doxorubicin	40	IV	1, 22
Bleomycin	15	IV	1, 8, 15, 22, 29, 36
CCNU	80	PO	1
Dacarbazine	800	IV	1, 22
CEP			
CCNU	80	PO	1
Etoposide	100	PO	1–5
Prednimustine	60	PO	1–5
EVA			
Etoposide	100	IV	1–3
Vinblastine	6	IV	1
Doxorubicin	50	IV	1
ASHAP			
Doxorubicin	10	IV, CI	1–4
Methylprednisolone	500 [a]	PO	1–5
Ara-C	1500	IV	5
Cisplatinum	25	IV, CI	1–4
ICE			
Ifosfamide	5000	IV, CI	2
Mesna	5000	IV, CI	2
Etoposide	100	IV	1–3
Carboplatinum	5 [b]	IV	2

CCNU, cyclohexylchloroethylnitrosourea; CI, continuous 24-hour infusion.
NOTE: Each cycle lasts 28 days, with the exceptions of BCAVe and VABCD, in which the cycle is 42 days.

[a] Methylprednisolone dose in ASHAP is 500 mg—not mg/m ^{2}.

[b] Carboplatinum dose in ICE is based on area under curve = 5, with a maximum of 800 mg total dose.
Modified from Longo DL. The use of chemotherapy in the treatment of Hodgkin's disease. Semin Oncol 1990;17:716–735.

TABLE 95.18. Results of Selected Salvage Chemotherapy Regimens in Hodgkin Disease

Regimen (Author, Reference)	Number of Patients	Complete Response (%)	Disease-Free Survival (Yr)
ABVD (Santoro, 344)	54	59	—
ABVD (Straus, 345)	27	4	—
ABVD (Harker, 346)	55	38	9% (6)
BCAVe (Harker, 346)	48	44	25% (6)
SCAB (Levi, 347)	17	35	—
ABDIC (Tannir, 349)	34	35	—
EVA (Canellos, 355)	45	40	29% (3)

Despite extensive use of salvage chemotherapy, no single regimen has emerged as optimal. Results using a specific regimen have varied widely across studies, and comparison of regimens across series is further limited because relapsing patients are heterogeneous with respect to important prognostic variables.

It is generally appreciated that the relapse-free interval is the major prognostic indicator in patients who relapse after initial chemotherapy ([360], [361]). Age older than 30 years at the time of initial chemotherapy has also been found to be an unfavorable prognostic factor with respect to survival after relapse ([346]). Although some investigators have found a trend for visceral relapses to carry a worse prognosis than nodal relapses ([345]), this has not been observed in other studies ([342], [346], [360]).

The importance of relapse-free interval was first noted by Fisher et al. ([361]). They reported that among patients relapsing after MOPP therapy, retreatment with MOPP was associated with a complete response in 93% of patients whose complete remission had lasted more than 1 year, whereas only 29% of patients who experienced a shorter response achieved a second complete remission with MOPP ([361]). With extended follow-up ([360]), it has become clear that the probability of cure is much greater for patients whose second complete remission follows a long first complete remission. When the first complete remission to chemotherapy lasted less than 1 year, only 14% of patients achieving a second complete remission are projected to remain in complete remission for more than 4 years. By contrast, among patients whose first remission was greater than 1 year, 45% of second complete remissions were projected by actuarial analysis to last more than 20 years ([360]). Studies using other salvage regimens have confirmed that the duration of the initial response is a reliable predictor of the response to salvage therapy ([346]). Not surprising, patients who did not achieve a complete remission in response to primary treatment have been found to be relatively resistant to salvage therapy ([226], [360]).

Thus, salvage chemotherapy offers the possibility of a second complete remission and possible cure to patients with Hodgkin disease. Although retreatment with the regimen used initially can be associated with good results, especially if the first complete remission was greater than 1 year, the general trend is to consider drugs not used in the initial regimen. With the increased use of MOPP alternating with ABVD or the hybrid MOPP/ABV regimen as primary therapy, this is a somewhat moot point, as nearly all of the drugs effective in Hodgkin disease will have already been used at the time of relapse. Although retreatment with a seven- or eight-drug combination is feasible in these patients, the more common policy in patients who relapse after receiving MOPP/ABV or MOPP alternating with ABVD is to move directly to high-dose therapy in conjunction with ABMT or autologous peripheral blood stem cell transplantation (ASCT).

Stem Cell Transplantation as Salvage Therapy

Over the past decade, high-dose chemotherapy in conjunction with ASCT has become a standard salvage approach to the patient with relapsed Hodgkin disease. Numerous clinical studies have been conducted ([362], [363], [364], [365], [366], [367], [368], [369], [370], [371], [372], [373], [374] and [375]), and the subject has been extensively reviewed ([376], [377]). Although this therapy is often called *ASCT*, it is the high-dose chemotherapy (or chemotherapy plus radiation therapy) that is effective in treating relapsed Hodgkin disease. The autologous bone marrow (or autologous peripheral blood committed progenitor cells) merely provides a source of blood cell progenitors so that the patient can survive the augmented dose therapy, which would otherwise cause lethal damage to the hematopoietic system. Because results are similar regardless of whether stem cells are obtained from bone marrow or from the peripheral blood, the terms *autologous bone marrow transplantation* and *autologous peripheral blood stem cell transplantation* are often used interchangeably.

ASCT is based on the fact that the dose-limiting toxicity of the drugs effective in Hodgkin disease involves the bone marrow. By using frozen bone marrow, or peripheral blood progenitor cells, obtained from the patient before the administration of chemotherapy, doses of chemotherapeutic agents can be escalated to levels that would ordinarily be lethal. Because Hodgkin disease is a highly chemosensitive malignancy and patients who relapse after chemotherapy often respond to

readmitration of the same chemotherapeutic agents at the same doses, ASCT with augmented doses of drugs is a curative therapeutic approach for many patients.

Early studies of ABMT in heavily pretreated patients with Hodgkin disease were associated with a treatment-related mortality of approximately 40% ([365]). With improvements in supportive care and patient selection, treatment-related mortality on the order of 5% is now expected in experienced centers ([373] , [375]). A number of high-dose combination chemotherapy regimens have been used in conjunction with autologous transplantation; doses and schedules of CBV [cyclophosphamide, bischloroethylnitrosourea (carmustine), and VP16-213 (etoposide)], CBVP, and BEAM (bischloroethylnitrosourea, etoposide, ara-C, melphalan) ([373] , [374] and [375]), some of the commonly used regimens, are presented in Table 95.19.

TABLE 95.19. Chemotherapy Regimens Used in Conjunction with Autologous Bone Marrow Transplantation

Regimen (Drugs)	Recommended Dose (mg/m ^{2})	Route	Days [a]
CBV			
Cyclophosphamide	1800	IV	7, 6, 5, 4
BCNU	600	IV	3
Etoposide	800	IV	7, 6, 5
CBV			
Cyclophosphamide	1500	IV	5, 4, 3, 2
BCNU	300	IV	5
Etoposide	300	IV	5, 4, 3
CBVP			
Cyclophosphamide	1800	IV	6, 5, 4, 3
BCNU	500	IV	2
Etoposide	2400	IV	7 [b]
Cisplatin	50	IV	7, 6, 5
BEAM			
BCNU	300	IV	6
Etoposide	100–200	IV	5, 4, 3, 2
Cytosine arabinoside	200–400	IV	5, 4, 3, 2
Melphalan	140	IV	1

BCNU, bischloroethylnitrosourea.

[a] For transplant regimens, the preparative chemotherapy regimen is routinely given with the day of transplant considered as day = 0.

[b] Given as a 36-hour infusion.

With a heterogeneous group of patients being treated with high-dose therapy in conjunction with ABMT or ASCT, results have been highly variable. Among the best results is the report of Reese et al. ([375]), which used CBV or CBVP as the treatment regimen. With a median follow-up of 2.3 years, the actuarial progression-free survival for the entire series of 58 patients treated in first relapse was 64%. Three major negative prognostic factors were identified in this study: B symptoms at relapse, initial complete remission less than 1 year, and extranodal disease at relapse. If none of these negative features was present, actuarial relapse-free survival was 100%; if all three negative features were present, actuarial relapse-free survival was 0%. If one considers only the relapse-free interval, actuarial relapse-free survival was 85% in patients whose first response lasted more than 1 year and 48% in patients whose initial complete remission was less than 1 year.

The majority of patients receiving ASCT for Hodgkin disease have received high-dose combination chemotherapy as the preparative regimen. The use of wide field radiation therapy as part of the initial treatment of Hodgkin disease often precludes the use of total body radiation therapy as part of the salvage therapy used in conjunction with ABMT. Recently, however, total body irradiation has been combined with cyclophosphamide and etoposide as the conditioning regimen in 22 patients who had not received prior radiation therapy. Both the toxicity and the results of therapy were similar to that achieved using a combination chemotherapy regimen of cyclophosphamide and etoposide along with bischloroethylnitrosourea ([378]). As chemotherapy alone becomes the initial therapeutic approach for a greater percentage of patients, especially those patients with advanced disease and a relatively greater risk of relapse, it is expected that the use of preparative regimens using total body irradiation will be applicable to more patients with relapsing Hodgkin disease.

With respect to autologous transplantation in general, it is not known whether bone marrow or peripheral blood represents the optimal source of stem cells. For patients with hypocellular bone marrows or with tumor involvement of the bone marrow, peripheral blood stem cells would appear to be the stem cell source of choice. The feasibility of this approach has been demonstrated ([374]), and, considering that relatively unfavorable patients were treated, results similar to the results of ABMT have been reported. Because of the ease of obtaining peripheral blood stem cells and the quicker recovery of peripheral blood counts when peripheral blood stem cells are used, peripheral blood has generally replaced bone marrow as a source of autologous stem cells for use in transplantation in patients with Hodgkin disease.

Whereas the curative potential of ASCT in patients with relapsed Hodgkin disease has been demonstrated, the major remaining issue is when the procedure should be used. In non-Hodgkin lymphoma, randomized trials of conventional salvage therapy versus ASCT have been performed to demonstrate the superiority of ASCT. However, such randomized trials have not been conducted in Hodgkin disease. It has, therefore, been argued that conventional dose salvage chemotherapy should be used before moving to high-dose therapy in conjunction with autologous transplantation. However, in view of the minimal mortality of autologous transplantation and the excellent results of autologous transplantation, autologous transplantation has been recommended as the treatment of choice for all patients relapsing after initial chemotherapy ([377]). When the majority of patients received a seven- or eight-drug regimen as initial chemotherapy for Hodgkin disease, the choice between autologous transplantation or salvage chemotherapy with drugs that had not been administered was moot, as the most effective drugs had already been administered. However, as ABVD becomes standard initial chemotherapy for Hodgkin disease, the question of using salvage chemotherapy or moving to autologous transplantation at first relapse will become a clinically relevant issue.

The good results obtained using ASCT as salvage therapy have suggested that ASCT should be considered as consolidation therapy in patients with Hodgkin disease who are considered “high risk” ([379] , [380]). Not surprising, clinical studies have shown that this approach is feasible. However, if this approach is used in *high-risk patients*, defined as patients who are estimated to have a cure rate of 40 to 50% ([380]), approximately half of patients treated in this manner are cured before receiving the ASCT. Such patients have the risk of fatal toxicity associated with ASCT, approximately 5%, with no benefit. The real issue is not whether such therapy is feasible, it is whether such therapy improves results over those that could be obtained if transplantation were used at the time of relapse. That question can only be answered by a randomized clinical trial. Such information is not available.

Another approach to the patient with relapsed Hodgkin disease is to use allogeneic bone marrow as the source of bone marrow stem cells. Allogeneic stem cells have the advantage that occult Hodgkin disease is not present in the marrow infusion. Additionally, there is the theoretic benefit of graft-versus-lymphoma effect. However, the risks of graft-versus-host disease are of considerable magnitude. As a result, although allogeneic bone marrow transplantation has been successfully used in patients with Hodgkin disease ([367] , [381] , [382] and [383]), it has been studied much less extensively than ABMT and has been used in only limited circumstances, such as patients with bone marrow involvement, patients who have received pelvic radiation therapy, and patients with stem cell disorders resulting from prior treatment.

The International Bone Marrow Transplant Registry has reported results in 100 patients receiving allogeneic transplants for relapsed Hodgkin disease ([384]). In this negatively selected group of patients, the 3-year probability of chronic graft-versus-host disease was 45%, the 3-year probability of relapse was 65%, and the 3-year disease-free survival was only 15%. Because the patients are not comparable with patients generally selected for ABMT, direct comparisons of these results to those obtained with ABMT are not appropriate. A different approach to transplantation has been taken by investigators at the Johns Hopkins Oncology Center who gave

allogeneic transplantation priority over autologous transplantation in patients with relapsed Hodgkin disease ([385]). This study, therefore, frees the allo-geneic transplant group from the handicap of negative prognostic features. In this study ([385]), disease status (sensitive vs. resistant) and year of transplant were significant predictors of event-free survival after transplant. Allogeneic transplant versus autologous transplant did not predict event-free survival. In patients with sensitive disease at the time of transplant, however, there was a nonsignificant trend for relapse to occur less frequently in patients receiving allogeneic transplantation rather than autologous transplantation (34% vs. 51%), confirming the existence of a graft-versus-tumor effect. Additionally, secondary myelodysplasia or acute leukemia occurred only in the patients receiving autologous transplantation. However, despite these benefits of allogeneic transplantation, overall survival was no better in the patients receiving allogeneic transplantation because of the higher treatment-related mortality associated with allogeneic transplantation.

This paper ([385]) adds more heat than light to the question of what is the role of allogeneic transplantation in Hodgkin disease. In “favorable” patients, with sensitive disease, the benefits of graft-versus-tumor effect were not shown to overcome the mortality associated with allogeneic transplantation, and results with autologous transplantation were equivalent to results obtained with allogeneic transplantation. In patients with “unfavorable” disease (i.e., disease resistant to chemotherapy), the high transplant-related mortality and high relapse rate did not justify the use of allogeneic transplantation. Thus, the question of when, if ever, to use allogeneic transplantation in relapsed Hodgkin disease remains unanswered.

As for patients who relapse after undergoing autologous transplantation for Hodgkin disease, the diversity of such patients precludes any definitive recommendations for therapy. If the patient previously had a long response to a combination chemotherapy regimen, treatment with that regimen with palliative intent is a reasonable option. In a series of 17 patients who relapsed after an autologous transplant, vinblastine, 4 to 6 mg/m ^{2}, every 1 to 2 weeks, produced responses in 59% of patients, with 12% of those responses being complete remissions ([386]). Whereas median event-free survival in that series was only 8.3 months, median overall survival was 38.8 months. The two complete responders remained in remission at 4+ years and 9+ years at the time of publication. These results are impressive, but the relative role of this approach as compared to other salvage approaches, including allogeneic transplantation after autologous transplantation, is unknown.

HODGKIN DISEASE AND HUMAN IMMUNODEFICIENCY VIRUS

Although Hodgkin disease is not considered an AIDS-defining illness, the incidence of Hodgkin disease is increased among patients with HIV infection ([33] , [34]). In contrast to patients without HIV infection, Hodgkin disease in patients with HIV infection is most commonly of the mixed cellularity subtype and is associated with B symptoms and with advanced stage, commonly due to bone marrow involvement ([387]). Despite the excellent results seen in patients with advanced stage Hodgkin disease in the absence of HIV infection, median survival in HIV-positive patients with Hodgkin disease is generally less than 2 years ([387]). In a group of patients who did not receive highly active antiretroviral therapy, the ABVD regimen was minimally effective, producing a median survival of only 18 months ([388]). In a group of patients treated with Stanford V and highly active antiretroviral therapy, 53% of patients were predicted to be disease free at 2 years ([389]). Because marked differences between ABVD and Stanford V have not been noted in patients who are HIV negative, these differences may indicate that the critical factor may well be the administration of highly active antiretroviral therapy in conjunction with chemotherapy. Alternatively, the differences may reflect selection bias in the two series. Further studies are needed to define the optimal approach to treatment in Hodgkin disease patients who are positive for HIV.

PEDIATRIC HODGKIN DISEASE

The biology, natural history, and clinical considerations are similar for children with Hodgkin disease as compared with adults with Hodgkin disease ([390]), although some differences do exist. There is a slight increase in the percent of cases of the lymphocyte-predominant subtype in children with Hodgkin disease as compared with adults ([391] , [392] and [393]). The lymphocyte-predominant subtype represents 2 to 7% of adult cases of Hodgkin disease, but it represents approximately 20% of cases of childhood Hodgkin disease. There is a trend for stage I disease to be slightly more common in children than in adults ([390]). On a stage-by-stage basis, children with Hodgkin disease do slightly better than adults with the same stage of disease ([139]).

The involvement of specific sites of disease in children with Hodgkin disease is similar to that of adults ([394]) (Table 95.20), and the tests recommended for staging of children with Hodgkin disease are the same as those recommended for adults. As in the case of adults, the role of staging laparotomy in children with Hodgkin disease remains controversial. Whereas the stage of the patient is likely to change in one-third of children based on findings at laparotomy, it has not been established whether this information leads to a clinical benefit. Additionally, the risk of postsplenectomy sepsis may be greater in children than in adults, offsetting the potential benefits.

TABLE 95.20. Frequency of Involvement of Nodal Sites in Children with Hodgkin Disease

Site	Frequency of Involvement (%)
Left cervical and/or supraclavicular nodes	78
Right cervical and/or supraclavicular nodes	74
Mediastinum	60
Spleen	33
Right hilar nodes	28
Left axillary nodes	26
Right axillary nodes	22
Paraaortic nodes, celiac nodes, splenic hilar nodes	22
Left hilar nodes	20

Based on a series of 129 surgically staged cases from Donaldson SS, Kaplan HS. A survey of pediatric Hodgkin's disease at Stanford University: results of therapy and quality of survival. In: Rosenberg SA, Kaplan HS, eds. Malignant lymphomas, etiology, immunology, pathology, treatment. New York: Academic Press, 1982:571–590.

The major difference between children and adults with Hodgkin disease is that high-dose large-volume irradiation is likely to be associated with impaired growth. Substantial height impairment has been documented in children who received high-dose radiation to the entire spine at a prepubertal age ([395]), with the greatest effect seen in boys radiated before 11 year of age and in girls radiated before 9 years of age ([395]). As a result, there is a general tendency to depend on chemotherapy, with or without low-dose involved field radiation therapy, in younger children.

Whereas preservation of fertility is often a concern in treating young adults, it is always a concern when treating children. As a result, oophoropexy during staging laparotomy is a reasonable approach if pelvic radiation is planned. Before menarche, women may be relatively, but not absolutely, protected from the infertility that may be caused by chemotherapy. There is no evidence, however, that prepubertal boys are spared the risks of infertility that are associated with chemotherapy. For this reason, ABVD might be a more logical choice than MOPP or MOPP/ABV when chemotherapy is used in children. However, the long-term cardiac effects of doxorubicin are not fully known, and this long-term risk must also be considered when a chemotherapy regimen is chosen.

The risks of second malignancies must also be considered when making therapeutic decisions in children. For the most part, this involves limiting the use of wide field radiation therapy and combination chemotherapy. However, in this regard, there is really no major difference between children and adults, as a secondary leukemia or a second tumor is no less devastating in a 50-year-old than in a teenager or young adult. The overall risk of solid tumors may be as high as 15% 20 years after treating patients for Hodgkin disease ([396] , [397]), and because the latent period for the development of tumors can exceed 20 years, long-term follow-up is mandatory for all children treated for Hodgkin disease.

HODGKIN DISEASE AND PREGNANCY

Because Hodgkin disease is commonly seen in women of childbearing years, it is not surprising that Hodgkin disease may occur in women who are pregnant. This problem has been extensively reviewed ([398]); although agreement regarding optimal management of these patients does not exist, several key observations have been made, and guidelines for therapy have been advocated. Pregnancy does not affect the course of Hodgkin disease as compared to age-adjusted controls with Hodgkin disease who are not pregnant ([399]).

Transmission of Hodgkin disease to the fetus occurs rarely, if at all. There is only one such case report in the literature ([400]), and considering that the case was reported in 1926, the accuracy of the pathologic diagnosis can be questioned.

Staging of the pregnant patient with Hodgkin disease must be modified to decrease the risks associated with radiation exposure of the fetus. Such an evaluation must be performed in the context of treatment planning. If the overall plan is to delay treatment until after delivery, unless bulky disease is found, then a modified approach to staging is reasonable. A chest x-ray, complete blood counts, liver and renal function tests, serum lactic dehydrogenase, and bone marrow biopsy are indicated. Abdominal ultrasound is probably adequate to establish or rule out the presence of extensive abdominal disease ([396]).

Although radiation therapy can be given during pregnancy if uterine shielding is used, the fact that patients have not been totally staged usually means that such treatment is a “holding action” and not definitive therapy. As such, unless bulk disease requires intervention, radiation therapy may be delayed until after delivery. In a patient who is thought to require radiation in the first trimester, therapeutic abortion is a consideration, although healthy infants have been born to women irradiated in the first trimester. The risk of fetal malformations is approximately 15% when chemotherapy is given in the first trimester and possibly no greater than normal when given in the second and third trimester ([401]). The risk of late sequelae of chemotherapy to the fetus is unknown. Therefore, unless disease is clearly bulky, symptomatic, or stage III or IV, one can consider following patients to term if disease is diagnosed in the late second or third trimester.

If a decision is made to delay therapy until after delivery, the patient should be monitored closely, and the clinical plan should be reevaluated if progressive disease is noted. If chemotherapy is given during pregnancy, it is probably best to avoid chemotherapy during the 3 weeks before delivery to avoid having the baby be neutropenic at birth.

MEDICAL-LEGAL ISSUES IN HODGKIN DISEASE

In a litigious society, it should not be surprising that the diagnosis and management of Hodgkin disease are often the subject of malpractice suits. Having been consulted on numerous occasions as an expert witness, the senior author of this chapter (Richard S. Stein) has concluded that a substantial amount of time and effort could be saved if attorneys appreciated the following facts regarding Hodgkin disease.

The diagnosis of Hodgkin disease is often associated with a delay of several months after the first appearance of adenopathy. In many patients with Hodgkin disease, adenopathy waxes and wanes, justifying a delay in performing a diagnostic biopsy. Additionally, in many patients with Hodgkin disease, the initial biopsy does not establish a diagnosis, and repeat biopsy, which may reasonably be delayed for months, may be necessary to establish a diagnosis.

A delay in diagnosis may lead to Hodgkin disease being diagnosed at a more advanced stage than was likely present at initial presentation. However, the impact of an increase in stage is less for Hodgkin disease than for other malignancies, such as breast cancer or lung cancer, in which advanced stage IV disease is almost certainly fatal. As shown in Table 95.10, for the majority of patients with stage IV Hodgkin disease, the expectation is that cure will be achieved.

The use of combination chemotherapy, such as ABVD, in conjunction with radiation therapy is a rational approach to stage I Hodgkin disease. The argument that delay in diagnosis led to advanced stage disease, which required more extensive, toxic therapy, must be considered in the context of that fact.

For each stage of Hodgkin disease, there are many rational treatment options, all of which are consistent with the standard of care (Table 95.9). Treatment options that are associated with superior short-term results often have delayed toxicities, which render them equivalent, in the long term, to therapies that are associated with higher rates of early relapse. It is impossible for physicians to define a single “standard of care” treatment for each stage of Hodgkin disease.

Some patients with Hodgkin disease die of disease or of complications of therapy. The treatment of Hodgkin disease is one of the success stories of modern oncology. Additionally, the enthusiasm of physicians has led them to emphasize the high probability of cure. Nevertheless, the cure rate of Hodgkin disease is not 100%. Depending on the choice of therapy, up to 25% of patients with advanced disease have no success with initial therapy or relapse shortly after completion of therapy. Salvage therapy, such as high-dose therapy in conjunction with stem cell transplantation, is effective. However, this approach has a cure rate near 50% only for patients with sensitive disease at relapse. Not all patients have sensitive disease at relapse.

Finally, as physicians try to improve the imperfect results in Hodgkin disease with more intense initial therapies ([327] , [328]), an increase in early deaths due to bacterial sepsis and opportunistic infections is likely to be observed, even if these regimens eventually lead to superior long-term clinical results.

FUTURE PROSPECTS

Major advances in the curability of Hodgkin disease have been dependent on the use of standard approaches to staging and the rational selection of radiation therapy, combination chemotherapy, or combined modality therapy based on the stage of the disease. Because curative salvage therapy exists and newer therapeutic approaches can be tested only in patients who have not had success with presently available curative therapy, it is unlikely that major clinical advances are going to occur in the treatment of Hodgkin disease in the near future. Instead, results of ongoing clinical studies are likely to fine-tune present issues, such as determining whether dose-intense chemotherapy, such as Stanford V, is really superior to ABVD.

It should be recognized that the last two decades of clinical progress have occurred without a basic understanding of the biology of Hodgkin disease. Although there is considerable speculation regarding the role of EBV in the etiology of Hodgkin disease, the cause of Hodgkin disease is unknown, as is the nature of the cell or cells of origin. If progress in Hodgkin disease is to occur in the next decade, it is likely to involve an increase in our understanding of the biology of Hodgkin disease. Even so, the present state of the art and science is such that caring for the patient with Hodgkin disease can be among the most satisfying experiences in medicine.

Practical Aspects of the Clinical Approach to Patients with Monoclonal Immunoglobulin Disorders

This chapter presents a general and practical approach to the management of patients with immunoglobulin (Ig) disorders, with special emphasis on plasma cell neoplasms. Details about the specific diseases are provided in the chapters devoted to these diseases. The first step in the management of patients with monoclonal Igs is accurate diagnosis, including the correct classification into the different stages of the disorder ([1]). We review the general recommendations for the management of these disorders as a way of introducing the following chapters, which discuss the specific details of the biology and therapy of these disorders.

GENERAL PRINCIPLES

Ig abnormalities can be classified as one of three main categories (Table 96.1): hypogammaglobulinemia, polyclonal Ig elevations, and monoclonal Ig disorders. For any of these abnormalities, a careful medical history and thorough laboratory evaluation are needed to confirm a suspected diagnosis, particularly because of the major implications of the diagnosis and potential prognosis for a person with a monoclonal Ig disorder. From the initial interview and examination of the patient and review of the laboratory studies, it should be possible to address the following:

1. Is there an abnormality of the Igs—that is, are the levels increased or decreased?
2. If hypergammaglobulinemia is present, is it polyclonal or monoclonal?
   a. If the protein is monoclonal, is it IgM or another type?
      I. If it is IgM, is it
         a. IgM monoclonal gammopathy of undetermined significance (MGUS)?
         b. Waldenström macroglobulinemia?
         c. Other (lymphoproliferative disorders or IgM myeloma)?
      II. If it is not IgM, is it
         a. Non-IgM MGUS?
         b. Smoldering multiple myeloma (SMM)?
         c. Multiple myeloma (MM)?
         d. Plasmacytoma (intra- or extramedullary)?
      III. Is there evidence of light chain–associated amyloidosis (AL)?
   b. If the protein is polyclonal, is there
      I. An underlying infectious, inflammatory, or neoplastic disorder?
      II. Evidence of liver disease?
3. If hypogammaglobulinemia is present, is it
   a. Hereditary?
   b. Acquired?

TABLE 96.1. Classification of Immunoglobulin Abnormalities

1. Hypogammaglobulinemia
   a. Manifested by encapsulated organism infections (*Streptococcus pneumoniae*, *Staphylococcus* sp., *Haemophilus influenzae*)
   b. Childhood (Bruton X-linked)
   c. Young adults (common variable immunodeficiency)
2. Polyclonal gammopathy
   a. Inflammatory (chronic infections)
   b. Autoimmune
   c. Associated with neoplasms
   d. Liver disease (cirrhosis, chronic hepatitis)
3. Monoclonal gammopathies
   a. IgM type
      (i) IgM MGUS (may also be biclonal)
      (ii) Smoldering Waldenström macroglobulinemia
      (iii) Waldenström macroglobulinemia
      (iv) Other (including lymphoma and IgM MM)
   b. Non-IgM type
      (i) Non-IgM MGUS (may also be biclonal)
      (ii) SMM

(iii) MM
(iv) Plasma cell leukemia

c. Amyloidosis complicating a B-cell neoplasm (AL)
d. Miscellaneous monoclonal gammopathy–associated conditions
(i) Osteosclerotic MM with peripheral neuropathy
(ii) POEMS syndrome
(iii) Cryoglobulinemia
(iv) Peripheral neuropathy associated with MGUS
(v) Fanconi syndrome
(vi) Castleman disease
(vii) Scleromyxedema
(viii) Necrobiotic xanthogranuloma
(ix) Systemic capillary leak syndrome
(x) Angioimmunoblastic lymphadenopathy with monoclonal protein
(xi) Other

AL, amyloidosis; IgM, immunoglobulin M; MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes; SMM, smoldering multiple myeloma.

After these questions have been answered, the laboratory information is combined with information from the history and physical examination to narrow the diagnosis.

IMMUNOGLOBULIN ABNORMALITIES: METHODS OF DETECTION

Clinical Scenarios

Increasingly, monoclonal Ig disorders are diagnosed in the asymptomatic stage, with many of the patients having MGUS or SMM ([2], [3]). These patients require no immediate therapy and must be distinguished from those with active MM. Also, the monoclonal protein may be detected when the clinical suspicion of MM is high. If the suspicion is high, one has to be alert to the possibility that in a small fraction of patients with MM (<2%), no monoclonal protein can be detected in the serum or urine.

In addition to situations in which a plasma cell neoplasm is suspected, there are others for which high-resolution agarose electrophoresis may be desirable. We recommend performing it if patients have unexplained weakness or fatigue, unexplained anemia, an elevated erythrocyte sedimentation rate, back pain, osteoporosis, osteolytic lesions, fractures, hypercalcemia, excretion of light chains in the urine (i.e., Bence Jones proteinuria), renal insufficiency, or recurrent infections.

TIP: Bence Jones proteinuria is used to describe light chains (? or ?), usually in the urine. However, if the patient has monoclonal light chains (no heavy chains) in the blood only (not in the urine) and no symptoms, the condition has been called *idiopathic Bence Jones proteinemia*.

Protein Electrophoresis

The best method for detecting a monoclonal protein is high-resolution agarose gel electrophoresis. This test detects abnormalities in the migration of the proteins on electrophoresis. The test can be performed with samples from the serum (SPEP) or urine (UPEP). The resulting densitometric tracing shows a spike that is commonly referred to as the *monoclonal spike*, or *M spike* (Fig. 96.1). After a localized band or spike has been recognized on electrophoresis, immunofixation or immunosubtraction with capillary electrophoresis should be performed to determine the type of monoclonal protein.

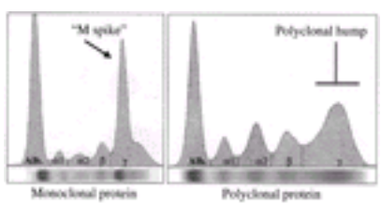

Figure 96.1. Images of a serum protein electrophoresis depicting a monoclonal protein **(left)** and a polyclonal protein **(right)**. Alb., albumin. (Figure courtesy of Drs. R. A. Kyle and J. A. Katzmann, Mayo Clinic.)

A monoclonal spike is seen as a discrete band that usually migrates to the ? or ß region of the electrophoretic strip, and rarely the a $_2$ region. A polyclonal increase in Igs produces a broad-band or broad-based peak and is limited to the ? region. Two monoclonal proteins (biclonal gammopathy) occur in 8 to 9% of sera containing monoclonal protein abnormalities ([4]). Rarely, a triclonal gammopathy (three monoclonal proteins) is found.

Small amounts of monoclonal proteins may be detected using the SPEP or UPEP, even when the total concentration of the Igs is within the normal range. Occasionally, small amounts of monoclonal proteins may be detected only with sensitive techniques such as immunofixation. These proteins are usually found at concentrations of less than 5 g/L.

TIP: Monoclonal antibodies that migrate to the ? region may be of the IgG or any other isotype. Thus, migration to the ? region does not imply an IgG isotype, and an Ig isotype cannot be defined with SPEP alone. Also, it should be noted that not all monoclonal spikes arise from monoclonal IgM proteins and that the *M* refers only to the *m*onoclonal nature of the patterns in the electrophoretic strip!

Immunofixation, Immunoelectrophoresis, and Immunodiffusion

The structural type of a monoclonal protein is determined best by immunofixation (Fig. 96.2). Therefore, immunofixation should be performed whenever a monoclonal protein of unknown identity is detected with SPEP. Immunofixation may also be performed when a B-cell or plasma cell neoplasm is suspected but no monoclonal spike is apparent, as is frequently the case with AL or nonsecretory MM. Immunofixation may also be used to monitor for disease relapse in patients who have achieved a complete response to therapy. In the past, we used immunoelectrophoresis to characterize monoclonal proteins. This test is more difficult to perform, and it is not as sensitive as immunofixation. Other methods for characterizing monoclonal proteins include capillary zone electrophoresis and immunosubtraction. Monoclonal proteins of the IgD and IgE isotypes usually are measured by immunodiffusion.

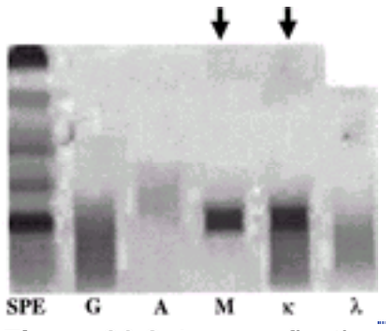

Figure 96.2. Immunofixation study done to characterize the monoclonal protein as a monoclonal immunoglobulin M ? protein. The arrows indicate the lanes that show reactivity with the specific antibodies. The reactivity is consistent with the same migration seen in the left column that shows the electrophoresis (SPE). Thus, in this assay, the nature of the monoclonal protein seen in the electrophoresis is elucidated: isotype M and light chain ?. See Color Plate.

Quantitative Immunoglobulins (Nephelometry)

At the time of diagnosis and to monitor disease, Igs may be quantified directly with rate nephelometry. This test is frequently ordered as “quantitative Igs.” In addition to determining the serum concentration of the same isotype as the monoclonal protein, the test can detect a decrease in uninvolved, normal Igs. Nephelometry is rapid and reliable. However, it is not useful when the concentration of the monoclonal protein is low, because nephelometry cannot differentiate between monoclonal and polyclonal Igs.

TIP: It is important to compare the results of SPEP only with subsequent SPEP determinations, and nephelometry results with subsequent nephelometry determinations. One should not compare nephelometry to SPEP (or vice versa) because of the inherent technical differences in the techniques. Monitoring with both tests may be ideal.

It should be noted that the serum concentration of Igs may be falsely elevated as determined by nephelometry. For instance, IgM levels may be reported as much as 30 g/L higher than the value reported by SPEP; similar observations have been made in the case of IgG and IgA.

Free Light Chain Assays

Tests for serum free light chains are an important part of the workup of patients with suspected plasma cell neoplasms or AL ([5], [6]). These tests measure both free ? and ? light chains and provide a ratio between them ([5], [6]). Excessive skewing indicates the possibility of a monoclonal protein. It is noteworthy that for serum free light chains, the ratio between ? and ? is skewed toward ? ([5], [6]).

Urine Studies

Patients with monoclonal proteins in the serum are also likely to have monoclonal proteins in the urine. Although both heavy and light chains may be excreted, only light chains are common in the urine. Traditionally, the excretion of light chains in the urine has been referred to as *Bence Jones proteinuria*. If patients have measurable monoclonal Igs (usually =10 g/L) in the serum or if MM or AL are suspected, urine should be collected for determining protein excretion. A timed 24-hour collection is best. For patients in whom this is done for the first time, immunofixation is also recommended to characterize fully the monoclonal protein present. Immunofixation is also recommended if no monoclonal protein is detected with UPEP.

Generally, the amount of monoclonal light chain in the urine reflects the tumor mass of the patient. However, the presence of Bence Jones proteinuria alone does not necessarily indicate a diagnosis of MM, as it also occurs in up to 30% of patients with MGUS. Patients with a pattern of nonselective proteinuria (i.e., albumin predominance) are more likely to have AL with kidney involvement (Fig. 96.3).

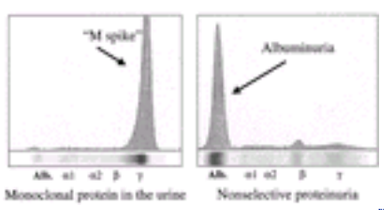

Figure 96.3. Patterns of proteinuria indicative of those observed in patients with plasma cell proliferative disorders. **Left:** The electrophoresis shows excretion of a large amount of monoclonal protein, usually a light chain as seen in many patients with multiple myeloma. **Right:** A case of nonselective proteinuria, as commonly seen in amyloidosis, that results in massive excretion of albumin (Alb.). (Figure courtesy of Drs. R. A. Kyle and J. A. Katzmann, Mayo Clinic.)

Diagnostic Algorithm: Key Questions

IS THE HYPERGAMMAGLOBULINEMIA MONOCLONAL OR POLYCLONAL? Commonly, abnormalities of Ig levels are first noted incidentally when quantitative Igs or SPEP is performed during diagnostic testing for an unrelated condition. The first—and most important—question that a clinician must answer when increased Ig levels are noted is whether the increase is monoclonal (i.e., neoplastic) or polyclonal (i.e., reactive) (Fig. 96.4). However, it should be noted that many monoclonal proteins are associated with nonmalignant conditions and, in the majority of patients, are never associated with complications or evolution to malignancy (Fig. 96.1). Once a monoclonal increase in Ig has been identified, a differential diagnosis is formulated to help make a final diagnosis.

Figure 96.4. Simple diagnostic algorithm for patients with immunoglobulin (Ig) abnormalities. CVID, common variable immunodeficiency; MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SMM, smoldering multiple myeloma.

IS THE MONOCLONAL PROTEIN IMMUNOGLOBULIN M OR NON–IMMUNOGLOBULIN M? The second question is, “What is the type of monoclonal protein? Is it IgM or another type?” Abnormal Igs are produced by differentiated B cells that become “professional antibody-producing cells,” that is, plasma cells. However, late in the process of differentiation, B cells are capable of producing IgM-type Igs. The type of protein production immediately identifies the type of neoplastic problems for which the protein may be a marker. Patients with IgA or IgG (rarely IgE or IgD) monoclonal proteins most commonly have a monoclonal proliferation of plasma cells in the bone marrow. In contrast, IgM monoclonal proteins are produced preferentially by lymphocytic and lymphoplasmacytic cells residing in lymphoid organs ([7]). We suggest that clinicians think of two classes of monoclonal Igs: IgM or non-IgM monoclonal proteins (Table 96.2). Non-IgM monoclonal proteins are associated with non-IgM MGUS and MM, whereas IgM monoclonal proteins are associated with IgM MGUS, Waldenström macroglob-ulinemia, and other lymphoproliferative disorders.

TABLE 96.2. Classification of Monoclonal Proteins

Condition	Non-IgM Monoclonal Proteins	IgM Monoclonal Proteins

Premalignant or undetermined	IgG, IgA, and other MGUSs	IgM MGUS
		Other lymphoproliferations
Intermediate	Smoldering multiple myeloma	Smoldering macroglobulinemia
Malignant	Active multiple myeloma	Waldenström macroglobulinemia
	Plasma cell leukemia	Other

Ig, immunoglobulin; MGUS, monoclonal gammopathy of undetermined significance.

This classification has some exceptions, but they are rare. For example, MM of the IgM type has been reported ([8], [9] and [10]). How best to differentiate IgM MM from Waldenström macroglobulinemia with bone lesions or renal failure is a matter of debate. Some genetic markers may be able to differentiate the two disorders ([11], [12]). Also, patients with B-cell chronic lymphocytic leukemia (CLL) may have coexistent monoclonal Igs in the serum ([13]). The proportion of patients in whom this protein is produced by the CLL cells is not known, and in some cases at least, it may represent coexistent non-IgM MGUS and B-CLL. Patients who have monoclonal B-cell disorders that have morphologic and immunophenotypic similarities to Waldenström macroglobulinemia but produce IgG monoclonal proteins have also been described ([14]). **TIP:** Aside from a few exceptions, it is useful to think of monoclonal proteins as either IgM or non-IgM because of implications for the differential diagnosis.

DIAGNOSIS

Laboratory Tests

In addition to the tests for monoclonal proteins, other basic laboratory studies should be performed to assist in making an accurate diagnosis. At minimum, a basic laboratory profile should include a complete blood count, serum levels of calcium and creatinine, and ß $_2$-microglobulin levels (see Chapter 98) ([15]). Other tests are considered according to the clinical suspicion raised by the history and physical examination findings.

The number of circulating monoclonal plasma cells should be quantified. Many studies have shown that a high number of circulating plasma cells is associated with progression from SMM to MM ([16]), and, in the case of MM, with shorter survival ([17]). In patients with a monoclonal IgM, serum viscosity may be determined, depending on the clinical indications (see Chapter 100). Testing for rheumatoid factor, antinuclear factors, and other autoantibodies may be important in diagnosing the cause of a polyclonal gammopathy. In nonneoplastic disorders, liver function tests, imaging of the liver, and tests for infectious and inflammatory diseases are important. Tests for the human immunodeficiency virus may be necessary in some patients with nonneoplastic or neoplastic plasma cell disorders.

TIP: The erythrocyte sedimentation rate is elevated in the presence of monoclonal Igs, particularly monoclonal IgM; thus, it is not a reliable indicator of an underlying inflammatory condition.

Bone Marrow Examination

For most patients with evidence of a monoclonal protein, an examination of the bone marrow is recommended. This examination should include both an aspirate and a biopsy sample and an MM-specific test. At our institution, we also include the plasma cell labeling index (PCLI). This is a reliable test for estimating the proportion of cells undergoing mitosis (Box 1).

BOX 1. Bone Marrow Plasma Cell Labeling Index (PCLI)

We always perform a PCLI assay in the workup of patients with plasma cell neoplasms. The PCLI is a surrogate of cells undergoing mitosis and is the most useful prognostic marker in multiple myeloma. This is a slide-based test (one slide is labeled with anti-? and one with anti-? fluorescent antibodies) that scores the number of plasma cells (usually out of 500) that incorporate bromodeoxyuridine. Bromodeoxyuridine is taken up by cells undergoing DNA synthesis and can be detected with fluorescent-specific antibodies. The test can also be performed on blood samples mainly to detect circulating plasma cells. Because the test is also done with clone-specific fluorescent antibodies, it provides an estimate of the plasmacytosis and the ratio between ? and ? (to detect clonality). The test can provide information about clonality, plasmacytosis, and labeling index (mitotic activity).

The major limitation to the test is that it can be done only on samples incubated with bromodeoxyuridine at the time of bone marrow aspiration.

Radiologic Tests

Patients with an IgM monoclonal protein should have abdominal and chest computed tomography to exclude organomegaly (hepatomegaly and splenomegaly) and bulky lymphadenopathy ([18]). Patients with evidence of MM should have a radiologic examination of the axial and appendicular skeleton (“bone survey”). In some special circumstances, more sophisticated tests such as magnetic resonance imaging (MRI) have been recommended ([19]). Other tests such as positron emission tomography are being explored ([20]).

NEOPLASTIC IMMUNOGLOBULIN DISORDERS

Non–Immunoglobulin M Monoclonal Gammopathy of Undetermined Significance

GENERAL PRINCIPLES Most patients with a monoclonal gammopathy do not have MM ([3]). MGUS represents the earliest stage of a monoclonal plasma/lymphoid cell proliferation. As mentioned above, it is critical to distinguish between IgM MGUS and non-IgM MGUS. IgM MGUS is discussed below with Waldenström macroglobulinemia.

DIAGNOSIS By definition, non-IgM MGUS is a discrete proliferation of monoclonal plasma cells ([3]). Multiple diagnostic criteria have been applied but the essence is the same—a discrete proliferation of plasma cells without evidence of the clone resulting in disease for the host. One criterion for diagnosis is fewer than 10% plasma cells in the bone marrow. Because of the heterogeneous nature of disease involving the bone marrow and different ways for determining the percentage of plasma cells (aspirate, biopsy, or PCLI—all of which possibly are contaminated by dilution), the size of the monoclonal proteins is usually considered a diagnostic criterion. Most people consider MGUS to have evolved into a more advanced plasma cell neoplasm if the serum monoclonal spike is greater than 30 g/L ([3]). An important focus of the physical examination in non-IgM MGUS is the search for bone disease. Percussion tenderness (spine and sternum) should raise the diagnostic possibility of MM. This is particularly important in patients with IgA MGUS, which may be more difficult to differentiate from MM. Also, clinicians must be aware of the classic signs and symptoms of AL (see below) ([21]). AL may be present even with the smallest concentration of monoclonal proteins (occasionally not even detectable), and this possibility should always be kept in mind.

CLINICAL MANAGEMENT AND MONITORING Because of the nonmalignant nature of MGUS, patients do not experience end-organ damage. Complications such as anemia, renal failure, hypercalcemia, bone lesions, or extramedullary growth in tissues should prompt a search for MM or other explanations ([3]). If a patient has evidence suggestive of possible bone disease (pain in the shaft of extremities that worsens with movement or weight bearing), a bone radiographic survey should be done. It has long been the practice not to examine the bone marrow of patients with suspected MGUS. Although the size of the monoclonal spike generally correlates with tumor burden, it is not precise enough to conclude definitively that the diagnosis is MGUS and not SMM. In older persons (e.g., >75 years), it may be reasonable to diagnose MGUS on the basis of laboratory findings alone, but bone marrow analysis is highly desirable for all others regardless of the size of the monoclonal spike (Box 2). Monoclonal gammopathy of the IgD or IgE type presents unique problems because the size of the monoclonal spike is usually small and cannot be used to estimate tumor burden. In these cases, a bone marrow examination is mandatory. Patients with IgE monoclonal proteins often present with the most aggressive phenotype of plasma cell neoplasms, namely, plasma cell leukemia.

BOX 2. How We Evaluate a Patient with a Monoclonal Gammopathy

Tests for patients presenting with a monoclonal gammopathy include the following:

- Hemoglobulin and serum levels of calcium and creatinine
- Serum and urine protein electrophoresis and immunofixation
- Quantitative immunoglobulins
- Metastatic bone survey
- Bone marrow examination

Supplementary tests: lactate dehydrogenase, ß $_2$-microglobulin, and C-reactive protein, magnetic resonance imaging of the lumbar spine or suspected areas of involvement, plasma cell labeling index, and circulating plasma cells

The diagnosis of monoclonal gammopathy of undetermined significance is favored in patients with a low level of M protein (<30 g/L) and normal concentrations of hemoglobulin, calcium, and creatinine. The diagnosis is confirmed when bone marrow examination shows less than 10% of monoclonal plasma cells.

Although MGUS includes the term “undetermined significance,” non-IgM MGUS clearly is the most important risk factor for the subsequent development of MM ([3]). MGUS is not only a marker of persons at high risk for the development of MM, but, more important, is the latent, premalignant condition. When MGUS evolves to MM, the same Ig isotype is expressed in MGUS and MM. Patients should be followed indefinitely because the risk of progression to MM is never eliminated and has been estimated to be almost 1% per year ([3], [22]). Globally, the risk is greater for patients with higher concentrations of monoclonal proteins ([3], [22]). No good biologic markers are available that can discern or predict which patients will develop into MM. The need for long-term follow-up is implicit in the uncertainty of the diagnosis and the 1% risk annually for the development of MM or another serious disease of neoplastic plasma cells. For these patients the recommendation is to have a repeat SPEP in 6 months and, if that is normal, at least yearly thereafter. **TIP:** It is important to remind patients of the importance of having the monoclonal spike monitored at least annually. Because of the undetermined nature of the condition and the lack of symptoms, it is common for people to stop having screening tests after a few years, even more so for patients with complicated medical problems. By playing active roles in their medical care, patients can ensure monitoring.

Smoldering Multiple Myeloma (Asymptomatic Multiple Myeloma)

BIOLOGY SMM is an intermediate stage between MGUS and MM (Fig. 96.5) ([2]).

Figure 96.5. Progression from monoclonal gammopathy of undetermined significance (MGUS) to multiple myeloma (MM). SMM, smoldering multiple myeloma.

Conceptually, SMM is almost identical to MGUS—a plasma cell neoplasm without disease in the host—but represents a more advanced clone than that found in MGUS, usually with little evidence of proliferation ([23], [24]). Diagnostic criteria have been proposed, including a clonal plasmacytosis greater than 10% or a serum monoclonal protein of 30 g/L or greater. For the diagnosis of SMM to be made, no anemia, hypercalcemia, bone disease, or renal insufficiency related only to the plasma cell neoplasm must be present. A related diagnosis is indolent MM, which is nearly identical to SMM but with a small number of discrete bone lesions ([25]).
EVOLUTION TO MULTIPLE MYELOMA It is important to note that plasma cell neoplasms do *not* need to go through all the stages in an orderly fashion, and patients may quickly advance to the malignant phase of the disease from MGUS without a recognizable SMM stage. Similarly, patients may present to the hematologist with MM, without MGUS having been recognized previously. We think that all patients go through a premalignant, often unrecognized stage, the duration of which has not been established. It is difficult to estimate the actual risk of progression to MM from SMM because the available evidence is scant (see Chapter 98) ([3], [16], [22]). Many patients who have had MGUS may have had SMM, because in many of them, the bone marrow had not been examined. Patients with SMM usually have a low PCLI, few or no circulating plasma cells, and normal radiologic findings ([23], [24]). Occasionally, radiographs may show nonspecific abnormalities, and differentiating SMM from MM may be difficult. The use of MRI to detect patients at high risk for disease progression is being explored ([19]). Patients with normal MRI findings are believed to be at lower risk for progression. Despite the low volume of bone disease or bone marrow plasma cells greater than 30%, such patients, if asymptomatic, may be observed carefully and may remain stable for years; it is nevertheless important to monitor these patients actively, regularly, and indefinitely.
MONITORING Because of the perceived higher risk of evolution to MM, patients with SMM should be followed more closely than patients with non-IgM MGUS. Monitoring should occur every 3 months initially, and if the condition is stable, at least every 6 months thereafter. Follow-up tests should include a complete blood count, serum levels of calcium and creatinine, SPEP with measurement of the monoclonal spike, and quantitative measurement of the involved Ig (e.g., IgG levels in patients with IgG SMM).
RISK OF EXPECTANT OBSERVATION Of SMM, it is appropriate to say, “One does not want to treat too early, but also one does not want to treat too late.” The risk of expectant observation is that patients may have progression to MM and have a serious complication. The few data available suggest that serious progression is rare in SMM as long as monitoring is continued. The development of anemia is not a problem because it can be corrected readily with therapy, either supportive transfusions or the administration of erythropoietin. In the progression of SMM to active MM, the evolution to renal failure seems to be rare. The clinical presentation of renal insufficiency in patients with plasma cell neoplasms indicates that the monoclonal protein being produced has a nephrotoxic potential. Other factors, such as medications (e.g., nonsteroidal antiinflammatory drugs), contrast media, or volume depletion, augment this nephrotoxicity. The corollary to this is that patients who do not have renal impairment at diagnosis probably are less likely to develop it later in the course of the disease. Thus, it is important to recommend avoidance of renal insults and to provide an adequate intake of fluids in patients with SMM (urine output >2 L/day is commonly recommended). Also, the evolution to serious bone disease is unlikely but possible; careful attention to symptoms and a complete physical examination should minimize this possibility. The risks of expectant observation are counterbalanced by the immediate and long-term risks associated with MM therapy. Most agents have some immediate adverse effect, which may be lethal. For example, corticosteroid therapy may result in immunosuppression and opportunistic infections (*Pneumocystis carinii*), steroid myopathy, pancreatitis, aseptic necrosis of the femoral heads, and steroid-induced diabetes. Alkylators are associated with myelosuppression and the long-term risk of genotoxic damage to the bone marrow ([26], [27], [28], [29] and [30]). This can result in myelodysplasia and acute myelogenous leukemia, in time usually becoming refractory to treatment. Seemingly benign medications such as thalidomide also have important adverse effects, including somnolence, constipation, and, most notably, peripheral neuropathy ([31]). **TIP:** One recommendation is for treatment to be initiated for patients in whom therapy is likely to be necessary during the next 6 months (Kyle RA, *personal communication*).
TREATMENT Bisphosphonates such as pamidronate or zoledronic acid have been used to prevent progression of bone disease in patients with MM ([32]) and have been used by some to treat SMM. However, there is no good evidence to recommend the widespread use of these agents, and the decision should be made by the treating physician and patient. Current evidence-based treatment guidelines suggest that the data are insufficient to recommend the universal use of bisphosphonates in patients with SMM ([33]). One limitation is that the distinction between SMM and MM may not be straightforward. On the basis of imaging evidence (radiography, MRI, or mineral bone density study), increased urinary excretion of markers of bone metabolism (urinary amino-terminal collagen type 1 telopeptide), or indeterminate radiologic evidence of other bone disease and the good safety profile of the drugs, some hematologists recommend initiating treatment with bisphosphonates for patients with possible bone disease. Prospective randomized studies are needed to address this therapeutic dilemma. The administration of any antitumor therapy to patients with SMM must be considered experimental. No benefit has been reported for the treatment of early disease. In a randomized prospective clinical trial, early treatment did not result in longer survival ([34]). It is expected that any treatment that has efficacy in MM will also have activity against SMM, but this is not sufficient evidence to recommend treatment ([35]). It is imperative that prospective randomized studies address the impact of any treatment to be given for SMM, particularly with regard to progression and overall survival. In many patients, what is now diagnosed as SMM would previously have been diagnosed as MGUS; thus, it is possible that SMM in these patients will never evolve to active MM. To prevent evolution of SMM to MM by presently available therapeutic interventions, a long duration of treatment would likely be required; in addition, for reasons outlined previously, the number of patients needed to demonstrate significance in randomized trials is probably very large. Finally, the incidence of cumulative toxicity may be very high in patients treated for prolonged periods. In summary, better markers are needed to identify patients at high risk of progression to MM, and therapy for SMM should be administered only as part of a well-designed clinical trial.

Multiple Myeloma

MAGNITUDE OF THE PROBLEM MM is the most common malignancy of plasma cells. It causes 11,000 deaths annually and is diagnosed in nearly 15,000 people each year in the United States alone ([36]). The diagnosis of MM is straightforward when the patient has advanced bone lesions and anemia. However, a high level of

suspicion is needed to make the diagnosis promptly in a patient who presents with hypercalcemia or renal insufficiency ([37]).

HYPERCALCEMIA

Diagnosis Hypercalcemia must be diagnosed and treated promptly in MM. The symptoms may be protean and difficult to recognize if the degree of suspicion is not high ([37]). A classic complex may include polydipsia, polyuria, nausea, constipation, somnolence, confusion, and anorexia. Patients may have this constellation of signs and symptoms and believe they have a viral infection of the upper respiratory tract. Although the workup of other causes of hypercalcemia may be needed, the possibility of MM should take precedence, and empirical treatment may be considered while the diagnosis is being confirmed. Confirmatory tests can be performed rapidly, and hypercalcemia should be treated as soon as possible, preferably within hours after its diagnosis if MM is suspected.

Management The treatment of hypercalcemia associated with MM is based on three tenets: hydrate the patient, initiate treatment with bisphosphonates, and start therapy for MM. Of these three, hydration is the simplest and usually most important step because it can be done immediately, even without a confirmatory diagnosis ([38]). It is gratifying for a physician to recognize and treat MM-related hypercalcemia before renal damage occurs (see Chapter 98). Increased creatinine levels may be due to the volume depletion associated with hypercalcemia; this mandates prompt institution of volume replacement with normal saline. It is important to recognize that forced natriuresis will also force equimolar calciuria; thus, normal saline is the fluid replacement of choice. Loop diuretics should be given only when there is ample evidence of normal volume. Bisphosphonates have become the standard of care for the treatment of hypercalcemia of MM ([39]). Several preparations exist, but the prevailing view is that zoledronic acid may have a slight advantage in the rapidity with which it can control the hypercalcemia of malignancy ([39]). We also recommend instituting high-dose corticosteroid treatment for patients with suspected MM and hypercalcemia, even if the diagnosis is not firm ([40]). Corticosteroid treatment results in some of the most rapid and sustained improvement of hypercalcemia ([40]).

BONE DISEASE Bone destruction is an integral part of MM and is seen in at least 70% of patients ([41]). When more sensitive tests are used, nearly all patients have evidence of bone destruction, and its complications are some of the most devastating aspects of the disease ([42]). Bone disease associated with MM may involve the extremities, but most frequently it involves the spine. A characteristic feature is that movement and weight bearing exacerbate the pain (Fig. 96.6).

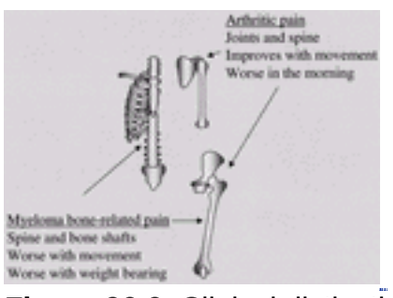

Figure 96.6. Clinical distinction between multiple myeloma bone disease and bone disease from arthritis. Patients seek a position that provides relief. Unlike arthritic pain, multiple myeloma pain is not localized to joint areas and does not improve with movement (“warming”).

RENAL FAILURE

Diagnosis Renal failure must be recognized early. Patients may present because of symptoms of uremia and only later report other symptoms of MM such as extensive bone pain. It is critical to assess renal function quickly by measuring the serum level of creatinine. Renal function (e.g., creatinine clearance) may be investigated in detail after therapy has been initiated. Patients with MM and renal failure (assuming they are not oliguric) commonly have Bence Jones proteinuria in excess of 1 g/24 hours.

Management Because renal failure in MM is often reversible with prompt treatment, it needs to be managed aggressively ([43] , [44]). The failure to correct renal failure early may result in permanent kidney damage that may severely limit therapeutic options and make patients dialysis-dependent ([45]). Patients with Bence Jones proteinuria are especially susceptible to MM cast nephropathy because the deleterious effects of dehydration and nephrotoxic agents are enhanced ([44]). Every effort should be made to ameliorate any insult to the kidneys. **TIP:** In MM, the kidney is much more susceptible to renal-offending agents, even at very low doses. Because of the common occurrence of bone pain in MM, it is important to recommend explicitly that patients avoid nonsteroidal antiinflammatory drugs. Also, reinforce the need for patients to keep adequately hydrated. Because acidification of the urine can exacerbate the nephrotoxic potential of Bence Jones proteins, vitamin C in large amounts should be avoided.

BACK PAIN Approximately 5 to 10% of patients with MM have back pain as a presenting feature ([46]). This pain may be severe and require hospitalization. Characteristically, it is movement related and aggravated by cough, sneeze, and strain. Patients may walk stiffly and have great difficulty getting onto and off the examination or x-ray table. MRI is the only reliable way to examine for a possible epidural tumor with potential spinal cord compression. **TIP:** As a rule of thumb, if spinal cord compression is possible, an MRI study of the back is performed. It is unwise to wait for signs of spinal cord compression to develop, such as bladder incontinence and reflex changes, because by then it may be too late. “If you think about it, do it.”

Special Conditions

SOLITARY PLASMACYTOMA Plasma cell neoplasms may present as a localized growth of plasma cells referred to as *plasmacytomas* ([47] , [48] and [49]). Plasmacytomas can occur in association with bony structures (*medullary*) or in other areas, most commonly the nasopharynx (*extramedullary*) ([47] , [48] and [49]). The term *solitary plasmacytoma* is applied to tumor growth in patients with no other evidence of MM. Patients with plasmacytoma frequently present with back pain, and, subsequently, a vertebral mass is discovered. A site-directed biopsy is usually recommended except in patients with overt MM. It is important to remember that other neoplasms may occur in patients with MGUS (see below). Plasmacytomas that arise from bone marrow have a high propensity (approximately 75%) for progressing to MM, but those originating from extramedullary sites are less likely to do so ([50] , [51]). With the disappearance of a detectable monoclonal protein after radiation treatment for plasmacytoma, the likelihood of definitive control is higher ([51]).

MULTIPLE MYELOMA MIMICRY Because 2% of patients older than 50 years have MGUS, it is important to confirm the histologic features of masses believed to be plasmacytomas or other pathologic bone lesions. Without overt MM, it is erroneous to assume that a person with a monoclonal protein in the serum and a bone lesion identified on radiologic study has a plasmacytoma. Thus, needle aspiration or biopsy of the mass is recommended. A patient with metastatic cancer may present with lytic bone lesions.

Light Chain–Associated Amyloidosis

AL is a serious complication of any B-cell neoplasm capable of producing a monoclonal protein (Fig. 96.7) ([21]).

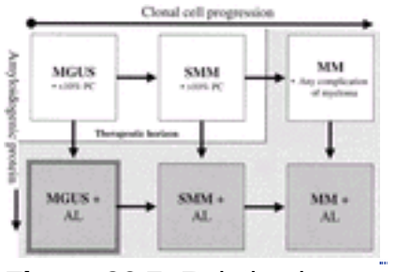

Figure 96.7. Relation between amyloidosis (AL) and other plasma cell (PC) neoplasms. MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SMM, smoldering multiple myeloma.

AL is associated most commonly with non-IgM MGUS and, in many cases, the amount of monoclonal protein may be minimal ([21]). One should be alert to the possibility of AL in any patient with a monoclonal protein. Although AL is slightly more common with ?-type light chains, it is also seen with ?-type light chains. AL should be suspected in a patient with a monoclonal protein and any of the following: nephrotic syndrome, restrictive cardiomyopathy, peripheral neuropathy, hepatomegaly, malabsorption, or a bleeding diathesis. Other features include the famous post proctoscopic periorbital purpura (4P sign), carpal tunnel syndrome, macroglossia, jaw claudication, orthostatic hypotension, diarrhea, and muscle pseudohypertrophy ([21]). Tissue diagnosis of AL should be sought, including Congo red staining of suspicious amyloid deposits. In some patients, AL is diagnosed on the basis of symptoms, and then tests for monoclonal protein are performed (Box 3) (see Chapter 99).

BOX 3. When to Suspect Amyloidosis

Amyloidosis should be suspected when evaluating older patients with the following:

- Nephrotic syndrome
- Congestive heart failure
- Peripheral neuropathy
- Carpal tunnel syndrome
- Orthostatic hypotension
- Hepatomegaly
- Malabsorption
- Mucosal and cutaneous bleeding

Serum and urine protein electrophoresis and immunofixation identify a monoclonal protein in 90% of patients with amyloidosis. A history of carpal tunnel syndrome or orthostatic hypotension is a strong clue for amyloidosis.

Macroglobulinemia and Other Immunoglobulin M–Producing Neoplasms

IgM monoclonal gammopathy is rarely a presenting sign of MM and should immediately point to the possibility of a lymphoproliferative disorder, particularly Waldenström macroglob-ulinemia ([18], [52]).

IMMUNOGLOBULIN M MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE A small proportion of patients with MGUS have an IgM monoclonal protein ([7]). In this case, lymphadenopathy, hepatomegaly, and splenomegaly are evidence of malignant disease, usually Waldenström macroglobulinemia, CLL, or a malignant lymphoma. All patients should have computed tomography of the abdomen and a bone marrow examination performed unless they are completely asymptomatic and the monoclonal protein level is less than 10 g/L. The probability of IgM MGUS evolving to one of these disorders is greater than 1% per year, nearly that of IgG monoclonal gammopathy ([7]).

WALDENSTRöM MACROGLOBULINEMIA Hepatomegaly, lymphadenopathy, splenomegaly, epistaxis, retinal hemorrhages, tortuosity of the retinal veins and "sausaging" are clues to the diagnosis of Waldenström macroglobulinemia (see Chapter 10) ([18], [52]). These signs are characteristic of Waldenström macroglobulinemia and are distinctly uncommon in MM. In most patients with Waldenström macroglobulinemia, the bone marrow is replaced extensively by monoclonal lymphocytes or cells with lymphoplasmacytic differentiation ([53], [54]). In typical cases of Waldenström macroglobulinemia, the IgM monoclonal spike is greater than 30 g/L, although there is no reliable cut-off value for excluding or making the diagnosis ([53], [54]). Hyperviscosity is the hallmark of the disease, but it is clinically significant in only 15% of patients ([55]).

NONNEOPLASTIC IMMUNOGLOBULIN DISORDERS

Polyclonal Gammopathy

By definition, polyclonal gammopathy represents an accumulation of nonneoplastic plasma cells ([56]). It is important to confirm with SPEP that the increased Igs are polyclonal; if the SPEP results are equivocal, immunofixation should be used. Polyclonal increases in the Igs can involve all or just one class of Igs ([56]). The evaluation of most patients who have polyclonal gammopathy should be straightforward. For most of them, no major diagnostic workup is needed because the cause is apparent. For other patients, a complete history and physical examination may provide clues to the origin of the polyclonal gammopathy. An increase in the erythrocyte sedimentation rate may be due to the increase in Igs; it is not a good surrogate marker of inflammation. Other markers of inflammation, such as C-reactive protein, may be used. A special condition to keep in mind as a cause of polyclonal gam-mopathy is temporal arteritis, for which effective treatment is available. Even if liver enzyme abnormalities are mild, liver disease should be suspected.

Hypogammaglobulinemia

In patients with recurrent encapsulated bacterial infections, humoral immune deficiency should be suspected. In these situations, it is advisable to perform SPEP and quantitative Igs. Knowing the age at onset of the problem facilitates diagnosis. In adults with recurrent sinus or pulmonary infections and low levels of IgG, IgA, and IgM, the most likely diagnosis is common variable immunodeficiency. Replacement therapy with intravenous Igs is corrective. The physician must be alert to the possibility of IgA deficiency in these patients because they are more likely to have adverse reactions to intravenously administered Ig. It is especially important to rule out MM in patients older than 50 years because Ig depression of the uninvolved Igs is frequently seen. This scenario is particularly common in patients with non-secretory MM. UPEP and immunofixation are also recommended because patients who have MM that produces only light chains may not have an apparent monoclonal protein in the serum. Children with hypogammaglobulinemia most likely have a hereditary condition such as Bruton type hypogammaglobulinemia, which is usually an X-linked recessive disorder.

Monoclonal Gammopathy of Undetermined Significance and Smoldering Multiple Myeloma*

HISTORICAL BACKGROUND

Waldenström introduced the term *essential hyperglobulinemia* in 1952 to describe patients with a small serum protein electrophoretic spike but no evidence of multiple myeloma (MM), Waldenström macroglobulinemia (WM), amyloidosis (AL), or related disorders. Since that time, many similar terms have been used, including idiopathic, asymptomatic, benign, nonmyelomatous, discrete, cryptogenic, and rudimentary monoclonal gammopathy; dysimmunoglobulinemia; lanthanic monoclonal gammopathy; idiopathic paraproteinemia; and asymptomatic paraimmunoglobulinemia. Waldenström ([1]) stressed the constancy of the size of the protein spike obtained by electrophoresis of serum, contrasting it with the increasing quantity of the monoclonal protein (M-protein) in MM patients. The term *benign monoclonal gammopathy* is misleading, because an M-protein may remain stable and benign, or it may develop into symptomatic MM, WM, AL, or a related condition.

The term *monoclonal gammopathy of undetermined significance* (MGUS) denotes the presence of an M-protein in persons without evidence of MM, WM, AL, or related plasma cell proliferative disorders. MGUS is characterized by a serum M-protein concentration of less than 30 g/L; less than 10% plasma cells in the bone marrow; little or no M-protein in the urine; absence of lytic bone lesions; and no related anemia, hypercalcemia, or renal insufficiency related to the plasma cell disorder ([2]).

M-proteins occur without MM or WM in approximately 3% of persons older than 70 years in Sweden, the United States, and France ([3] , [4] and [5]). In 6995 persons older than 25 years from Sweden, an M-protein was found in 1% ([3]). In a community cluster of cases of MM in a small Minnesota community, M-protein was detected in 15 of 1200 persons aged 50 years or older (1.25%), and in France, 303 of 17,968 persons aged 50 years or older (1.7%) had an M-protein ([4] , [5]). The incidence of MGUS is higher in older patients. Crawford et al. ([6]) found that 10% of 111 patients older than 80 years had a detectable M-protein. Ligthart et al. ([7]) reported that 23% of 4039 patients aged 75 to 84 years had an M-protein. Cohen et al. ([8]) reported an incidence of MGUS of 3.6% in 816 patients aged 70 years or older in North Carolina.

The incidence of M-proteins is higher in blacks than in whites ([9]). In the study by Cohen et al. ([8]), the prevalence of an M-protein was 8.4% in 916 blacks compared with 3.6% in whites ([8]). Only 2.7% of elderly Japanese patients had a monoclonal gammopathy ([10]). Kurihara et al. ([11]) found an M-protein in 71 of 2007 inpatients and outpatients (3.5%) in a Japanese university hospital. After exclusion of the 13 patients with MM and WM, the incidence was 2.9%, which is higher than has been reported previously.

The monoclonal gammopathies are a group of disorders characterized by the proliferation of a single clone of plasma cells that produces a homogeneous monoclonal M-protein (Table 97.1). Each M-protein consists of two heavy polypeptide chains of the same class and subclass and two light polypeptide chains of the same type. Polyclonal immunoglobulins are produced by many clones of plasma cells. The population of polyclonal immunoglobulins is heterogeneous with respect to heavy-chain classes and includes both light-chain types. The various types of immunoglobulins are designated by capital letters that correspond to the isotype of their heavy chains, which are designated by Greek letters: gamma (?) constitutes immunoglobulin G (IgG), alpha (a) is found in IgA, mu (μ) is present in IgM, delta (d) occurs in IgD, and IgE is characterized by epsilon (ϵ). IgG1, IgG2, IgG3, and IgG4 are the subclasses of IgG; the subclasses of IgA are IgA1 and IgA2. Kappa (?) and lambda (?) are the two types of light chains. An intact immunoglobulin consists of two heavy chains of the same class and two light chains of the same type. A monoclonal increase in immunoglob-ulins results from a clonal process that is malignant or potentially malignant, and a polyclonal increase in immunoglob-ulins is caused by a reactive or inflammatory process.

TABLE 97.1. Classification of Monoclonal Gammopathies

Monoclonal gammopathy of undetermined significance
Benign (IgG, IgA, IgD, IgM, and, rarely, free light chains)
Associated with neoplasms of cell types not known to produce M-proteins
Biclonal gammopathy
Idiopathic Bence Jones proteinuria
Malignant monoclonal gammopathies
Multiple myeloma (IgG, IgA, IgD, IgE, and free ? or ? light chains)
Overt multiple myeloma

Smoldering multiple myeloma
Plasma cell leukemia
Nonsecretory myeloma
IgD myeloma
POEMS: *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal protein, *s*kin changes (osteosclerotic myeloma)
Plasmacytoma
Solitary plasmacytoma of bone
Extramedullary plasmacytoma
Malignant lymphoproliferative disorders
Waldenström macroglobulinemia (primary macroglobulinemia)
Malignant lymphoma
Chronic lymphocytic leukemia or lymphoproliferative disorders
Heavy chain diseases
? Heavy chain disease
a Heavy chain disease
µ Heavy chain disease
Amyloidosis
Primary amyloidosis
With multiple myeloma (secondary, localized, and familial amyloidosis with no M-protein)

Ig, immunoglobulin.
From Kyle RA, Rajkumar SV. Monoclonal gammopathies of undetermined significance. Rev Clin Exp Hematol 2002;6:225–252, by permission of Accademia Nazionale di Medicina.

Analysis of serum or urine requires a sensitive, rapid, dependable screening method to detect the presence of an M-protein and a specific assay to identify it according to its heavy-chain class and light-chain type ([12], [13]). Agarose gel electrophoresis is more sensitive than cellulose acetate and is the preferred method of detection. After recognition of a localized band on electrophoresis, immunofixation or immunoelectrophoresis must be done to confirm the presence of an M-protein and to determine its immunoglobulin heavy-chain class and its light-chain type. Immunofixation or immunoelectrophoresis should also be done when MM, WM, AL, or a related disorder is suspected, because small amounts of M-protein may not be detected with serum protein electrophoresis ([14]).

Serum protein electrophoresis should be done when MM, WM, or AL is suspected ([15]). In addition, electrophoresis is indicated for any patient who has unexplained weakness or fatigue, elevated erythrocyte sedimentation rate, anemia, unexplained back pain, osteoporosis, osteolytic lesions or fractures, hypercalcemia, Bence Jones proteinuria, renal insufficiency, or recurrent infections ([16]). Serum protein electrophoresis should also be performed in adults with unexplained sensorimotor peripheral neuropathy, carpal tunnel syndrome, refractory congestive heart failure, nephrotic syndrome, orthostatic hypotension, or malabsorption, because a localized band or spike suggests AL. Weight loss, change in the tongue or voice, paresthesias, numbness, increased bruising, bleeding, and steatorrhea are additional indications for serum protein electrophoresis. Even when the serum protein electrophoretic pattern is nondiagnostic, immunofixation should be performed whenever MM, AL, or related disorders are suspected clinically.

All patients with a localized band on agarose gel electrophoresis or a localized spike on the densitometer tracing require immunofixation to confirm the presence of an M-protein and determine its type. The agarose gel should always be examined directly by the interpreter.

An M-protein is usually visible as a localized band on the agarose gel electrophoretic strip or as a tall, narrow spike or peak in the ß or ? region or, rarely, in the a $_2$-globulin area of the densitometer tracing (Fig. 97.1). A polyclonal increase in immunoglobulins produces a broad band or broad-based peak that migrates in the ? region.

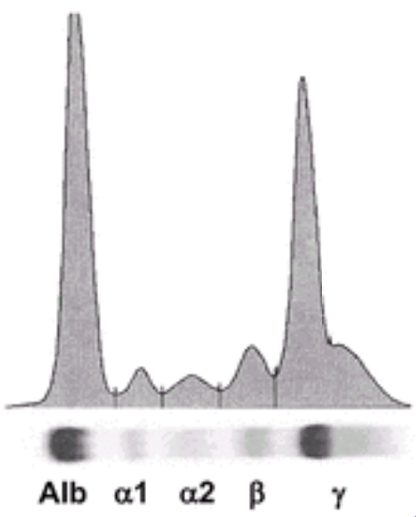

Figure 97.1. Top: Monoclonal pattern of serum M-protein by densitometry after electrophoresis on agarose gel. Note tall, narrow-based peak of fast ? mobility. **Bottom:** Monoclonal pattern from electrophoresis of serum on agarose gel (*anode on left*). Note dense localized band in fast ? area. Alb, albumin.

Immunofixation to determine the type of monoclonal protein may be performed by using commercial kits or systems such as Sebia, Pentafix, and 9-IF (Sebia, Norcross, GA) (Fig. 97.2) ([17]).

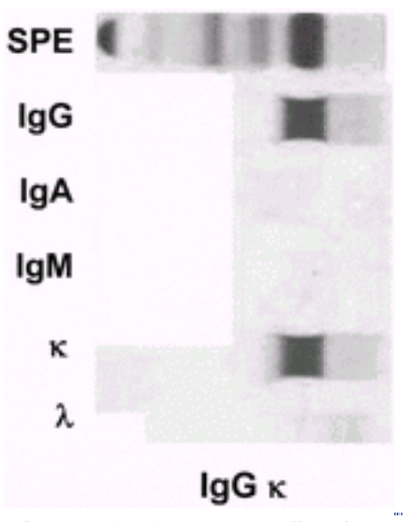

Figure 97.2. Immunofixation of serum with antisera to immunoglobulin G (IgG), IgA, IgM, ?, and ? shows a localized band with IgG and ? in the fast ? region indicating

an IgG ? monoclonal protein (immunofixation). SPE, serum protein electrophoresis.

Quantitation of immunoglobulins is best performed with a rate nephelometer, because it is not affected by molecular size and measures accurately 7S IgM, polymers of IgA, and aggregates of IgG. However, levels of IgM obtained by nephelometry may be 10 to 20 g/L higher than those expected on the basis of the serum protein electrophoretic tracing. The quantitative IgG and IgA levels may be increased similarly ([18]).

Analysis of urine is essential for patients with monoclonal gammopathies. All patients with a serum M-protein concentration of more than 15 g/L should have electrophoresis and immunofixation done. In addition, electrophoresis should be done in all instances of MM, WM, AL, and heavy chain diseases or when these entities are suspected. Immunofixation of urine should also be done in the evaluation of older patients with a nephrotic syndrome of unknown cause to recognize the presence of AL or light-chain deposition disease. A 24-hour urine specimen should be collected so that the amount of M-protein can be measured. This is done by multiplying the percentage of the M-spike in the densitometer tracing by the total protein in the 24-hour specimen. The amount of M-protein in the urine provides an index of the patient's tumor mass and is useful subsequently in monitoring the course of the patient's disease. Urinary M-protein is seen as a dense localized band on the agarose gel or a tall, narrow homogeneous peak on the densitometer tracing.

In 2001, a total of 1068 cases of monoclonal gammopathy were identified at Mayo Clinic: 659 (62%), MGUS; 172 (16%), MM; 90 (8%), AL; 37 (3%), lymphoproliferative; 39 (4%), smoldering MM (SMM); 8 (1%), solitary or extramedullary; 30 (3%), WM; and 33 (3%), other (Fig. 97.3).

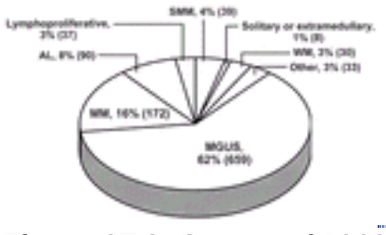

Figure 97.3. Causes of 1068 cases of monoclonal gammopathy, Mayo Clinic, 2001. AL, amyloidosis; MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SMM, smoldering multiple myeloma; WM, Waldenström macroglobulinemia. (From Kyle RA, Rajkumar SV. Monoclonal gammopathies of undetermined significance. Rev Clin Exp Hematol 2002;6:225–252. By permission of Accademia Nazionale di Medicina.)

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

MGUS is characterized by the presence of a serum M-protein value less than 30 g/L, fewer than 10% plasma cells in bone marrow, little or no monoclonal light chain in the urine, absence of lytic bone lesions, and no related anemia, hypercalcemia, or renal insufficiency (Table 97.2). The growth rate of the plasma cells (plasma cell labeling index) is low. MGUS may become evident unexpectedly during laboratory testing of an apparently normal person or may be found during evaluation for an unrelated disorder.

TABLE 97.2. Mayo Clinic Criteria for the Diagnosis of Monoclonal Gammopathy of Undetermined Significance, Smoldering Multiple Myeloma, and Multiple Myeloma

Disorder	Criteria
MGUS	Serum monoclonal protein <30 g/L *and* bone marrow plasma cells <10% *and* absence of anemia, renal failure, hypercalcemia, and lytic bone lesions.
SMM	Serum monoclonal protein <30 g/L *or* bone marrow plasma cells <10% *and* absence of anemia, renal failure, hypercalcemia, and lytic bone lesions.
MM	Presence of a serum or urine monoclonal protein, bone marrow plasmacytosis, *and* anemia, renal failure, hypercalcemia, or lytic bone lesions. Patients with primary systemic amyloidosis and <30% bone marrow plasma cells have both MM and amyloidosis.

MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma; SMM, smoldering multiple myeloma.

Modified from Rajkumar SV, Dispenzieri A, Fonseca R, et al. Thalidomide for previously untreated indolent or smoldering multiple myeloma. Leukemia 2001;15: 1274–1276. By permission of Nature Publishing Group.

MGUS is a common finding in the medical practice of all physicians. It is important for both the patient and the physician to determine whether the monoclonal gammopathy remains benign or progresses to MM or related disorders.

Mayo Clinic Study

The authors reviewed the medical records of all patients with monoclonal gammopathy who were seen at Mayo Clinic from 1956 through 1970. Patients with MM, WM, AL, lymphoma, or related disorders were excluded. Two hundred forty-one patients were eligible for long-term study.

After 24 to 38 years of follow-up, the number of patients who were still living and whose M-protein level had remained stable and could be classified as having benign monoclonal gammopathy had decreased to 25 (10%). Twenty-six patients (11%) had an increase of the M-protein level higher than 30 g/L, but MM, WM, and AL did not develop. One hundred twenty-seven patients (53%) died of unrelated causes without development of MM or related disorders. MM, WM, AL, or lymphoproliferative disease developed in 63 patients (26%). The actuarial rate at 10 years was 17%; at 20 years, 33% (Fig. 97.4); and at 25 years, 40%.

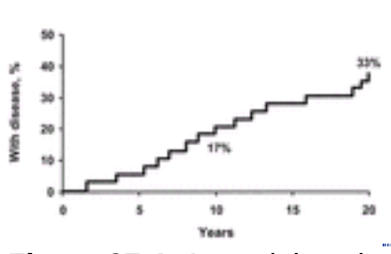

Figure 97.4. Actuarial analysis of incidence of multiple myeloma, macroglobulinemia, amyloidosis, or lymphoproliferative disease after recognition of monoclonal protein in 241 patients with monoclonal gammopathy of undetermined significance. [From Kyle RA, Lust JA. The monoclonal gammopathies (paraproteins). Adv Clin Chem 1990;28:145–218. By permission of Academic Press.]

Forty-three of the 63 patients (68%) with progression had MM (Fig. 97.5). Intervals from recognition of the M-protein to diagnosis of MM in the 43 patients ranged from 2 to 29 years (median, 10 years) (Table 97.3). In nine patients, the diagnosis was made 20 years after recognition of the serum M-protein. Median survival after diagnosis of MM was 33 months, similar to the expected survival.

WM developed in seven patients. All had a serum IgM ? protein level ranging from 31 to 85 g/L at diagnosis. Systemic AL was found in eight patients 6 to 19 years (median, 9 years) after the recognition of an M-protein in the serum. A malignant lymphoproliferative process developed in five patients 6 to 22 years (median, 10.5 years) after detection of the M-protein (Fig. 97.5; Table 97.3).

Long-Term Follow-Up in 1384 Monoclonal Gammopathy of Undetermined Significance Patients from Southeastern Minnesota

A population-based study was done to confirm the findings of the original Mayo Clinic study, which consisted mainly of patients referred to a tertiary care center. A total of 1384 persons who resided in the 11 counties of southeastern Minnesota were identified as having MGUS, defined by a serum M-protein value of 30 g/L or less, less than 10% plasma cells in the bone marrow (if the test was done), little or no M-protein in the urine, and the absence of lytic bone lesions, anemia, hypercalcemia, or renal insufficiency related to the M-protein. The patients were evaluated at Mayo Clinic from January 1, 1960, through December 31, 1994 ([19]). The median age at diagnosis of MGUS was 72 years. There were 753 men (54%) and 631 women (46%). Only 24 patients (2%) were younger than 40 years at diagnosis, compared with 810 (59%) who were aged 70 years or older. The M-protein level at diagnosis ranged from unmeasurable to 30 g/L. On the basis of the heavy-chain type of immunoglobulins, 70% of the M-proteins were IgG, 12% IgA, and 15% IgM. A biclonal gammopathy was found in 45 patients (3%). The light-chain type was ? in 61% and ? in 39%. The electrophoretic mobility of the M-protein and its heavy-chain class and light-chain type was unchanged throughout the period of observation. A reduction of uninvolved (normal or background) immunoglobulins was found in 38% of 840 patients in whom quantitation of immunoglobulins was determined. Electrophoresis, immunoelectrophoresis, and immunofixation of urine were performed in 418 patients. Twenty-one percent had a monoclonal ? light chain, 10% had ? at the time of recognition of the abnormal monoclonal gammopathy, and 69% were negative. Only 71 of 418 patients (17%) had an M-protein excretion higher than 150 mg/24 hours.

One hundred sixty patients (12%) had a bone marrow examination performed at the time of detection of the M-protein. The median percentage of bone marrow plasma cells was 3% (range, 0 to 10%). The initial hemoglobin values ranged from 57 to 189 g/L. The hemoglobin level was less than 100 g/L in 7% and 120 g/L or less in 23%. The anemia was due to causes other than the plasma cell proliferative process (e.g., iron deficiency, renal insufficiency, or myelodysplasia) in each instance. The serum creatinine level was higher than 2 mg/dl in 6% of the patients and was attributable to unrelated causes such as diabetes, hypertension, and glomerulonephritis.

The 1384 patients were followed-up for a total of 11,009 person-years (median, 15.4 years; range, 0 to 35 years). Nine hundred sixty-three patients (70%) died. During follow-up, MM, primary AL, lymphoma with an IgM serum M-protein, WM, plasmacytoma, or chronic lymphocytic leukemia developed in 115 patients (8%) (Table 97.4). The cumulative probability of progression to one of these disorders was 10% at 10 years, 21% at 20 years, and 26% at 25 years (Fig. 97.6). The risk of progression is approximately 1% per year; patients were at risk for progression even after 25 years or more of stable MGUS. In addition, 32 patients were identified in whom the M-protein value increased to higher than 30 g/L or the percentage of bone marrow plasma cells increased to more than 10% but in whom symptomatic MM did not develop. The cumulative probability of progression to MM or a related disorder plus an increase in M-protein to higher than 30 g/L or to more than 10% in bone marrow plasma cells was 12% at 10 years, 25% at 20 years, and 30% at 25 years (Fig. 97.6). These findings confirmed the results of the initial Mayo Clinic study.

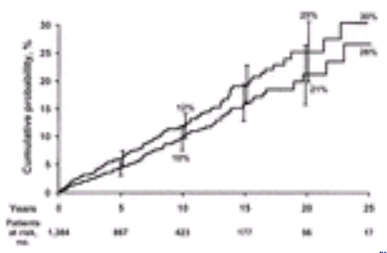

Figure 97.6. Probability of disease progression among 1384 residents of southeastern Minnesota in whom monoclonal gammopathy of undetermined significance (MGUS) was diagnosed from 1960 through 1994. The top curve shows the probability of progression to a plasma cell cancer (115 patients) or of an increase in the M-protein concentration to more than 30 g/L or in the proportion of plasma cells in the bone marrow to more than 10% (32 patients). The bottom curve shows only the probability of progression of MGUS to multiple myeloma, immunoglobulin M lymphoma, primary amyloidosis, macroglobulinemia, chronic lymphocytic leukemia, or plasmacytoma (115 patients). The error bars indicate 95% confidence intervals. (From Kyle RA, Rajkumar SV. Monoclonal gammopathies of undetermined significance. Rev Clin Exp Hematol 2002;6:225–252. By permission of Accademia Nazionale di Medicina.)

TABLE 97.4. Risk of Progression Among 1384 Residents of Southeastern Minnesota in Whom Monoclonal Gammopathy of Undetermined Significance Was Diagnosed, 1960–1994

Type of Progression	Number of Patients Observed	Number of Patients Expected [a]	Relative Risk (95% CI)
Multiple myeloma	75	3.0	25.0 (20–32)
Lymphoma [b]	19	7.8	2.4 (2–4)

Primary amyloidosis	10	1.2	8.4 (4–16)
Macroglobulinemia	7	0.2	46.0 (19–95)
Chronic lymphocytic leukemia [c]	3	3.5	0.9 (0.2–3.0)
Plasmacytoma	1	0.1	8.5 (0.2–47.0)
Total	115	15.8	7.3 (6–9)

CI, confidence interval.

[a] Expected numbers of cases were derived from the age- and sex-matched white population of the Surveillance, Epidemiology, and End Results program in Iowa [from Surveillance, Epidemiology, and End Results (SEER) Program Public Use Data (1973–1998). Bethesda, MD: National Cancer Institute, Cancer Statistics Branch, April 2001], except for primary amyloidosis, for which data are from Kyle RA, Linos A, Beard CM, et al. Incidence and natural history of primary systemic amyloidosis in Olmsted County, Minnesota, 1950 through 1989. Blood 1992;79: 1817–1822.

[b] All 19 patients had serum immunoglobulin M (IgM) monoclonal protein. If the 30 patients with IgM, IgA, or IgG monoclonal protein and lymphoma were included, the relative risk would be 3.9 (95% CI, 2.6–5.5).

[c] All three patients had serum IgM monoclonal protein. If all six patients with IgM, IgA, or IgG monoclonal protein and chronic lymphocytic leukemia were included, the relative risk would be 1.7 (95% CI, 0.6–3.7).

From Kyle RA, Therneau TM, Rajkumar SV, et al. A long-term study of prognosis in monoclonal gammopathy of undetermined significance. N Engl J Med 2002;346: 564–569, by permission of the Massachusetts Medical Society.

The number of patients with progression to a plasma cell disorder (115 patients) was 7.3 times the number expected on the basis of the incidence rates for those conditions in the general population (Table 97.4) ([20]). The risk of developing MM was increased 25-fold; WM, 46-fold; and AL, 8.4-fold ([21]). The risk of development of lymphoma was only modestly increased at 2.4, but this risk was underestimated because only lymphomas associated with an IgM protein counted in the observed number, whereas the incidence rates for lymphomas associated with IgG, IgA, and IgM proteins were used to calculate the expected number. The risk of development of chronic lymphocytic leukemia was only slightly increased (Table 97.3) when all six cases were included.

The 75 patients in whom MM developed accounted for 65% of the 115 patients who had progression to a plasma cell disorder. Four of the patients with MM had an initial plasmacytoma, and three other MM patients also had AL. In 24 patients (32%), the diagnosis of MM was made more than 10 years after detection of the M-protein, and five (7%) were recognized after 20 years of follow-up. The characteristics of these 75 MM patients were comparable to those of the 1027 patients with newly diagnosed MM referred to Mayo Clinic from 1985 to 1998, except that the southeastern Minnesota patients were older (median, 76 vs. 66 years) and less likely to be male (46% vs. 60%).

The mode of development of MM among the MGUS patients was variable. The M-protein level increased within 2 years of the recognition of MGUS in 11 patients, whereas the serum M-protein level was stable for more than 2 years and then increased within 2 years in 19 patients; in nine others, the M-protein level increased gradually after having been stable for at least 2 years. In nine patients, the M-protein level increased gradually during follow-up until the diagnosis of symptomatic MM was made. In ten patients, the serum M-protein level remained essentially stable; the diagnosis of MM was unequivocal in these ten patients because of an increase in bone marrow plasma cells, development of lytic lesions, or occurrence of anemia, renal insufficiency, or an increased level of urine M-protein. Seventeen patients had an insufficient number of serum M-protein measurements to determine the pattern of increase. In WM patients, the M-protein level showed a gradual increase in three, stable levels followed by a sudden increase in two, and insufficient data in two others.

The M-protein disappeared during follow-up in 66 patients (5%). All of these patients had low initial values of M-protein; only 17 had a value higher than 5 g/L at diagnosis. Treatment caused the disappearance of the M-protein in 39 patients whose condition had progressed to MM or lymphoma or who had other disorders such as idiopathic thrombocytopenic purpura and vasculitis unrelated to the monoclonal gammopathy. The M-protein disappeared without an apparent cause in 27 patients (2%). Only six of these 27 patients (0.4% of all patients) had a discrete spike on the densitometer tracing of the initial electrophoresis (median, 12 g/L). Thus, spontaneous disappearance of M-protein after the diagnosis of MGUS was rare.

Follow-Up in Other Series

In 20 years of follow-up, Axelsson ([22]) reported that 2 of 64 MGUS patients had died of MM and 1 died of lymphoma. Eleven percent of the patients with long-term follow-up had some evidence of progression of their “benign” monoclonal gammopathy. Carter and Tatarsky ([23]) found that 6.2% of 64 patients developed MM after a long period of stability. Paladini et al. ([24]) reported malignant transformations in 14% of 213 patients with MGUS followed up for 5 to 8 years and in 18% of 100 patients followed up for 13 years. Giraldo et al. ([25]) reported that the actuarial risk of development of MM, WM, or AL in 213 patients with MGUS was 4.5% at 5 years, 15% at 10 years, and 26% at 15 years. Malignant disease developed in 13 of 128 patients with MGUS who were followed up for a median of 56 months ([26]). The actuarial probability of the development of malignant disease was 8.5% at 5 years and 19.2% at 10 years.

Van de Poel et al. ([27]) found that 6.6% of 334 patients with MGUS had a malignant transformation after a median follow-up of 8.4 years. Baldini et al. ([28]) noted that 6.8% of 335 patients with MGUS had progression during a median follow-up of 70 months. In a series of 263 cases of MGUS, the actuarial probability of development of malignancy was 31% at 20 years ([29]). Eleven of 2192 persons older than 21 years (0.5%) in a New Zealand town had an M-protein ([30]). Hematologic malignancy developed in seven of the 11 patients (MM, four; WM, two; and lymphoma, one) after 31-year follow-up of the 2192 persons, 1065 of whom were aged 50 years or older. In a group of 1104 MGUS patients, more than 5% bone marrow plasmacytosis, presence of Bence Jones proteinuria, polyclonal immunoglobulin reduction, and high erythrocyte sedimentation rate were independent factors influencing MGUS transformation ([31]). In summary, all studies essentially confirm that the risk of progression from MGUS to MM or related disorders is approximately 1% per year. They also confirm that the risk does not disappear even after long-term follow-up.

Predictors of Malignant Transformation in Monoclonal Gammopathy of Undetermined Significance

No findings at diagnosis of MGUS can distinguish the patients whose condition remains stable from those in whom a malignant condition may develop ([32], [33]). When MM develops, the type of M-protein is the same as it was in MGUS.

SIZE OF M-PROTEIN In a series of 1384 patients with MGUS, the size of the M-protein at the time of diagnosis was the most important predictor of progression. Only the concentration and type of M-protein were independent factors among the evaluated baseline characteristics to predict progression of the monoclonal gammopathy; nonpredictors of progression included age; sex; presence of hepatosplenomegaly; levels of hemoglobin, serum creatinine, and serum albumin; presence, type, and amount of monoclonal urinary light chain; number of bone marrow plasma cells; and reduction in uninvolved immunoglobulins. The presence of a monoclonal urine protein (? or ?) (Table 97.5) and reduction of one or more uninvolved immunoglobulins also were not risk factors for progression (Table 97.6).

TABLE 97.5. Rates of Full Progression by Urinary Light Chain

Light Chain	Rate of Full Progression (%)			*p* Value

The initial concentration of the serum M-protein was the most important risk factor for progression to a plasma cell disorder. The relative risk of progression was directly related to the concentration of M-protein in the serum at the time of diagnosis of MGUS (Fig. 97.7). The risk of progression to MM or a related disorder 10 years after diagnosis of MGUS was 6% for patients with an initial M-protein level of 5 g/L or less, 7% for 10 g/L, 11% for 15 g/L, 20% for 20 g/L, 24% for 25 g/L, and 34% for 30 g/L. Rates for progression at 20 years were 14%, 16%, 25%, 41%, 49%, and 64%, respectively. The risk of progression in a patient with an M-protein level of 15 g/L was almost two-fold greater than that in a patient with an M-protein level of 5 g/L, and the risk of progression in a patient with an M-protein level of 25 g/L was 4.6 times that of a patient with a 5 g/L spike.

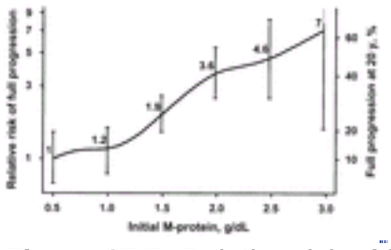

Figure 97.7. Relative risk of full disease progression by serum M-protein level at baseline, 1960–1994. Error bars indicate 95% confidence intervals. (From Kyle RA, Rajkumar SV. Monoclonal gammopathies of undetermined significance. Rev Clin Exp Hematol 2002;6:225–252. By permission of Accademia Nazionale di Medicina.)

Carter and Tatarsky ([23]) noted that one-third of their patients with MGUS had an M-protein level higher than 30 g/L but showed no greater risk for evolution to malignant disease. Bladé et al. ([26]) also reported no increase in transformation in patients with an M-protein level higher than 30 g/L. They suggested that limits to define MGUS should be more flexible.

TYPE OF IMMUNOGLOBULIN In the southeastern Minnesota series, patients with IgM or IgA M-protein had an increased risk of progression compared with those with IgG M-protein (*p* = .001) (Fig. 97.8). Bladé et al. ([26]) noted that MM developed more commonly in patients with an IgA M-protein than in the remainder.

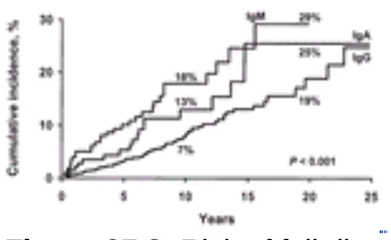

Figure 97.8. Risk of full disease progression by type of M-protein, 1960–1994. (From Kyle RA, Rajkumar SV. Monoclonal gammopathies of undetermined significance. Rev Clin Exp Hematol 2002;6:225–252. By permission of Accademia Nazionale di Medicina.)

BONE MARROW PLASMA CELLS The number of plasma cells in the bone marrow may help predict progression. Cesana et al. ([31]) reported that more than 5% bone marrow plasma cells was an independent risk factor for progression. Ucci et al. ([34]) reported that a value of 20% bone marrow plasma cells was a reasonable level to distinguish MGUS from MM. Baldini et al. ([28]) reported that the malignant transformation rate was 6.8% when the bone marrow plasma cell level was less than 10% and 37% in the MGUS group with a bone marrow plasma cell level of 10 to 30%.

OTHER PREDICTORS In the 263 patients with MGUS reported by Pasqualetti et al. ([29]), a multivariate regression analysis showed that only age was associated significantly with the risk of developing a malignant immunoproliferative disease. Increased bone resorption is an early sign of malignancy in patients with apparent MGUS ([35]). The presence of Bence Jones proteinuria and high erythrocyte sedimentation rate have been reported as independent factors of progression of MGUS ([19], [31]).

Life Expectancy and Cause of Death in Patients with Monoclonal Gammopathy of Undetermined Significance

It is important to know whether the presence of MGUS shortens the patient's life expectancy. Bladé et al. ([26]) found no statistically significant differences between the survival of patients with MGUS and that of a control population, but in the MGUS population, the trend was toward a shorter survival. Survival was significantly shorter among 241 patients with MGUS diagnosed before 1971 than among an age- and sex-adjusted 1980 U.S. population (13.7 vs. 15.7 years) ([32]). The median survival of the 1384 patients with MGUS was 8.1 years, compared with 11.8 years (*p*<.001) that was expected for Minnesota residents of matched age and sex. The rates of death at 10 years were 6% for plasma cell disorders and 53% for non–plasma cell disorders (such as cardiovascular and cerebrovascular diseases and non–plasma cell cancers). At 20 years, the rates were 10% for plasma cell disorders and 72% for non–plasma cell disorders. At 25 years, the rate was 11% for plasma cell disorders compared with 76% for non–plasma cell diseases. In the study by van de Poel et al. ([27]), the long-term survival of 334 patients with MGUS was slightly shorter than the expected survival of an age- and sex-adjusted population.

Differential Diagnosis

The differentiation of a patient with MGUS from one with MM may be difficult. Helpful indicators include the size of the M-protein, hemoglobin value, percentage of bone marrow plasma cells, amount of M-protein in the urine, presence of hypercalcemia or renal insufficiency, and lytic bone lesions. The serum M-protein level is of some help because higher levels are associated with a greater likelihood of malignancy ([36]). A serum M-protein level higher than 30 g/L usually indicates the presence of overt MM or WM, but some exceptions, such as SMM, do exist.

Levels of the immunoglobulin classes not associated with the M-protein (normal polyclonal or background immunoglobulins) are not helpful in differentiating benign from malignant monoclonal gammopathies. In patients with MM, the levels of uninvolved immunoglobulins are reduced in more than 90% ([19]). However, reduction of uninvolved immunoglobulins occurs in patients with MGUS ([37]). In the authors' series of 241 patients with MGUS, uninvolved immunoglobulins were reduced in 29%, and they were reduced in 38% of the authors' 1384-patient MGUS cohort. The reduction of uninvolved immunoglobulins, however, did not identify patients with subsequent progression ([19]).

An M-protein in the urine (Bence Jones proteinuria) may suggest a neoplastic process, but it is present frequently in patients with MGUS ([38], [39]). In the authors' MGUS cohort from southeastern Minnesota, 31% of the 418 tested patients had a monoclonal light chain in the urine. The value was higher than 150 mg/24 hours in only 17% of patients. Thus, the presence of a monoclonal light chain in the urine was not a risk factor for the subsequent development of MM.

The presence of more than 10% plasma cells in the bone marrow suggests MM, but the condition of patients with a higher level of plasmacytosis may remain stable for long periods. By definition, patients with 10% or more bone marrow plasma cells were classified as having SMM if no signs or symptoms of MM were present. The plasma cells in MM are often atypical, but these morphologic features may also be seen in MGUS and SMM. Milla et al. ([40]) reported that the presence of nucleoli was the most important feature in differentiating MM from MGUS.

The presence of osteolytic lesions suggests strongly a diagnosis of MM, but metastatic carcinoma also may produce lytic lesions and plasmacytosis and be

associated with an unrelated serum M-protein.

The plasma cell labeling index for detection of DNA synthesis is useful in differentiating MGUS or SMM from MM ([41]). An elevated plasma cell labeling index is strong evidence that MM is present or its development is imminent. However, approximately one-third of patients with symptomatic MM have a normal plasma cell labeling index. A good correlation exists between the plasma cell labeling index of peripheral blood and the bone marrow labeling index ([42]).

The presence of circulating plasma cells in the peripheral blood is a good marker of active disease. Plasma cells are infrequent in patients with MGUS or SMM ([43]).

Conventional cytogenetic studies are not useful in the differentiation of MGUS and MM, because abnormal karyotypes are seen rarely in MGUS on account of the small number of plasma cells and the low proliferative rate. Fluorescence *in situ* hybridization studies showed that abnormalities can be detected in bone marrow plasma cells from most patients with MGUS ([44], [45], [46], [47], [48] and [49]). Deletion of chromosome 13q occurs in patients with MGUS and is an early event in the development of monoclonal gammopathies ([50]).

Magnetic resonance imaging (MRI) may be helpful in differentiating MGUS from MM. Bellaiche et al. ([51]) reported that the MRI scans were normal in all 24 patients with MGUS, but abnormalities were found in 86% of 44 patients with MM. Patients with MGUS had normal bone remodeling, but bone resorption increased and bone formation decreased in patients with stage III myeloma ([52]). Although C-terminal telopeptide of type I collagen, osteocalcin, and serum bone-specific alkaline phosphatase may be elevated in patients with MGUS, it is not reliable for differentiation ([53]).

Ocqueteau et al. ([54]) identified a population of polyclonal plasma cells with CD38 expression and low forward light scatter. The plasma cells expressed CD19 but were negative for CD56. The monoclonal plasma cell population showed a lower CD38 expression and a higher forward light scatter population and expressed CD56 but not CD19. Ninety-eight percent of patients with MGUS had more than 3% normal polyclonal plasma cells, but only 1.5% of patients with MM had the same findings.

The serum level of interleukin-6 (IL-6) may aid in the differentiation of monoclonal gammopathies. IL-6 levels are elevated commonly in patients with MM but infrequently in patients with MGUS ([52], [55]).

IL-1ß is produced by plasma cells in all patients with MM but is undetectable in most patients with MGUS. IL-1ß has strong osteoclast-activating factor activity, increases the expression of adhesion molecules, and induces paracrine IL-6 production. This activity parallels the development of osteolytic bone lesions, homing of myeloma cells to bone marrow, and IL-6–induced cell growth ([56], [57]).

Using immunohistochemical techniques to identify micro-vessels, Vacca et al. ([58]) reported that bone marrow angiogenesis was increased in patients with MM but not in those with MGUS. Studies done at the authors' institution confirm these findings, although this test has limited value in differentiating MGUS from MM because angiogenesis is not increased in approximately one-third of patients with MM ([59]).

ß $_2$-Microglobulin levels are not helpful in differentiating MGUS from low-grade MM, because values for the two entities overlap ([60]). Neither the presence of J chains in malignant plasma cells nor the acid phosphatase level in plasma cells is reliable for differentiation ([61], [62]). Reduced numbers of OKT4 $^+$ T cells, increased numbers of monoclonal idiotype-bearing peripheral blood lymphocytes, and increased numbers of immunoglobulin-secreting cells in peripheral blood are characteristic of MM, but values overlap with MGUS ([63], [64] and [65]). Elevated telomerase activity was found in 21 of 27 patients with MM, and in one of five with MGUS ([66]). Methylation of p15(INK4b) and p16(IN4a) was found in similar frequencies in both MGUS and MM ([67]).

Management

Regardless of the results of sophisticated laboratory tests, the differentiation between MGUS and MM is based on clinical factors, such as symptoms, anemia, hypercalcemia, renal insufficiency, and lytic bone lesions. However, the presence of a high plasma cell labeling index in a patient with MGUS or SMM needs to be followed up more frequently for other evidence of progression. No single factor can differentiate a patient with a benign monoclonal gammopathy from one in whom a malignant plasma cell disorder develops subsequently. The serum M-protein level must be measured periodically, and clinical evaluation should be conducted to determine whether serious disease has developed.

In a patient with no features of MM or AL and a serum M-protein value less than 15 g/L, serum protein electrophoresis is repeated at annual intervals. Skeletal radiography, bone marrow examination, and 24-hour urine collection for immunofixation are not necessary in this situation.

If an asymptomatic patient has an M-protein level of 15 to 20 g/L, IgG, IgA, and IgM levels are measured, and a 24-hour urine specimen is collected for electrophoresis and immunofixation. The serum protein electrophoretic pattern should be determined again in 3 to 6 months, and if the pattern is stable, the test should be repeated in another 6 months and then annually (or sooner if symptoms occur). If the IgG or IgA serum M-protein value is higher than 20 g/L, a metastatic bone radiographic survey, including views of the humeri and femurs, should be done. Bone marrow aspiration and biopsy should also be performed. Cytogenetic studies, calculation of the plasma cell labeling index, and a search for circulating plasma cells in the peripheral blood should be done if available. If the patient has an IgM M-protein, aspiration and biopsy of the bone marrow and a computed tomographic scan of the abdomen may be useful for recognizing WM or a related lymphoproliferative disorder. Levels of ß $_2$-microglobulin and C-reactive protein should be determined. If results of these tests are satisfactory, serum protein electrophoresis should be repeated in 3 months, and if the results are stable, the tests should be repeated at 6- to 12-month intervals.

SMOLDERING (ASYMPTOMATIC) MULTIPLE MYELOMA

Patients with SMM have a serum M-protein level of 30 g/L or higher or 10% or more plasma cells in the bone marrow (Table 97.2). Frequently, they have a small amount of M-protein in the urine and a reduction of uninvolved immunoglobulins in the serum. These findings are consistent with a diagnosis of MM, but anemia, renal insufficiency, and skeletal lesions are not present. In addition, the plasma cell labeling index is low. Consequently, these patients have a benign monoclonal gammopathy or MGUS from the biologic standpoint, but this diagnosis is not possible when the patient is seen initially, because most patients with this level of bone marrow plasma cell infiltration and size of M-protein in the serum have symptomatic MM ([68]).

Prevalence of Smoldering Multiple Myeloma

SMM accounts for less than 15% of all cases of newly diagnosed MM ([69]). In a study conducted at the M. D. Anderson Cancer Center, 95 of 638 patients with myeloma (15%) were considered to have asymptomatic MM ([70]). Other investigators have found a higher proportion of patients with SMM, but the sample size in these studies is small ([71], [72]).

The prevalence estimates for SMM are distorted because many reports include asymptomatic patients with lytic bone lesions on skeletal survey. Some exclude patients with bone lesions on skeletal survey but include patients who have lytic lesions on MRI. Calculation of the true prevalence of SMM on the basis of strict criteria (Table 97.2) is not available.

Risk of Smoldering Multiple Myeloma Progression

Most patients with SMM progress eventually to symptomatic disease, and the risk of progression is higher than in those with MGUS ([69]). Some patients can remain free of progression for a number of years ([68]). The median time of progression to symptomatic disease is approximately 1 to 3 years. A recent study found the risk of progression to be only 20% at 6 years ([31]). However, this study considered patients to have SMM only if they demonstrated no disease progression after 1 year of follow-up.

Predictors of Smoldering Multiple Myeloma Progression

The assessment of prognostic factors for SMM is hampered by varying diagnostic criteria used to define the cohort. Several studies include patients with lytic lesions as well. Future studies of SMM need to use more uniformly accepted criteria so that results can be compared.

Patients with abnormal monoclonal plasma cells in the peripheral blood, defined as an increase in the number or proliferative rate of circulating plasma cells by immunofluorescent assays, are at higher risk for earlier progression to MM. In a study of 57 patients, Witzig and colleagues ([43]) found the median time to progression was 9 months for those with abnormal circulating plasma cell values, versus 30 months for those with normal results (p <.01). An elevated plasma cell labeling index is an adverse prognostic factor ([42], [73], [74]).

In a study conducted at the M. D. Anderson Cancer Center, the three most important prognostic factors for progression in SMM were a serum M-protein level higher than 30 g/L, the presence of an IgA subtype, and a urinary M-protein excretion of more than 50 mg/day. Patients with two or more of these features had a median time to progression of 17 months, those with one risk factor had a median time to progression of 40 months, and patients who had none of these factors had a progression time of 95 months ([75]). This study excluded patients with abnormalities on bone survey but did include patients with abnormal MRI results, which were present in 40% of patients. Abnormal MRI findings were associated with a shortened time to progression of 21 months.

Patients who undergo MRI studies for skeletal survey in the absence of lytic lesions often have abnormalities detected as a result ([69], [76]). In such patients, abnormalities depicted on MRI are an adverse prognostic factor for progression ([77]). Whether patients who have MRI abnormalities should be defined as having SMM is debatable. Nevertheless, these patients can be observed without therapy, similar to those with SMM.

Management of Smoldering Multiple Myeloma

The current standard of care in SMM is close follow-up once every few months without chemotherapy. This recommendation is based on the results of trials demonstrating no significant improvement in overall survival in patients who received immediate treatment with melphalan plus prednisone compared with those who received treatment at progression for stage I or asymptomatic MM. Hjorth and colleagues ([78]) randomly assigned 50 patients with asymptomatic stage I MM to observation versus chemotherapy with melphalan and prednisone. No differences were observed in overall survival between the two groups. Grignani and colleagues ([79]) reported similar survival time with immediate or deferred therapy in a series of 44 patients with asymptomatic MM. The recommendation to observe closely without treatment until progression is also based on the toxic effects of therapy and the fact that disease may not progress for months or years ([68], [80]).

Investigational approaches may be considered for selected patients enrolled in appropriate clinical trials. Thalidomide is being studied as a single agent with a preliminary partial response rate of approximately 35% ([81], [82]). Other studies are evaluating the role of bisphosphonates, IL-1ß inhibitors, clarithromycin, and dehydroepiandrosterone in an attempt to delay progression to symptomatic MM. Because the main goal of therapy in patients with SMM is to delay the need for chemotherapy, a phase 3 randomized trial is needed on the durability of response before this strategy can be recommended for standard clinical practice.

VARIANTS OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Biclonal Gammopathy

Biclonal gammopathies are characterized by the presence of two different M-proteins and occur in more than 5% of patients with monoclonal gammopathies. The two M-proteins may be caused by the proliferation of two different clones of plasma cells, each producing an unrelated M-protein, or by production of two M-proteins by a single clone of plasma cells.

Biclonal gammopathy of undetermined significance was found in 37 of 57 patients with a biclonal gammopathy ([83]). The age range was 39 to 93 years (median, 67 years). Twenty of the affected patients were women. The clinical findings of biclonal gammopathies are similar to those of monoclonal gammopathies ([83]). Thirty-five percent of the 57 patients had MM, WM, or another malignant lymphoproliferative disorder ([83]).

Riddell et al. ([84]) reported that 2.5% of 1135 patients with monoclonal gammopathy had a biclonal gammopathy. They postulated that complete class switching in a single plasma cell clone resulted in the production of two M-proteins, but in others the M-proteins arose from two separate plasma cell clones.

Triclonal Gammopathy

Triclonal gammopathy was reported in a patient with plasma cell dyscrasia in whom the acquired immunodeficiency syndrome developed subsequently ([85], [86]). Grosbois et al. ([87]) also described a patient with a triclonal gammopathy (IgM ?, IgG ?, and IgA ?). The investigators reviewed a group of cases with triclonal gammopathy from the literature. Sixteen cases were associated with a malignant immunolymphoproliferative disorder, five appeared in nonhematologic diseases, and three were of undetermined significance.

Benign Monoclonal Light-Chain (Idiopathic Bence Jones) Proteinuria

Benign monoclonal gammopathy of the light-chain type must be considered even though Bence Jones proteinuria is a recognized feature of MM, AL, WM, and other lymphoproliferative diseases. In one study, two patients with stable serum M-protein levels excreted 0.8 g/day or more of Bence Jones protein for more than 17 years without disease progression ([88]). Seven additional patients have been described who presented with Bence Jones proteinuria (>1 g/24 hours) but in whom no M-protein was found in the serum and who had no evidence of MM or a related disorder ([89]). One of these patients has excreted up to 1.8 g/24 hours of ?–light chain for 30 years without developing symptomatic MM or a related disorder. Although idiopathic Bence Jones proteinuria may remain stable for years, MM or AL often results. These patients must be followed up indefinitely.

Immunoglobulin D Monoclonal Gammopathy of Undetermined Significance

The presence of an IgD M-protein almost always indicates MM, AL, or plasma cell leukemia. However, IgD MGUS has been reported. O'Connor et al. ([90]) described a patient with an IgD ? protein level of 5 g/L who was followed up for more than 6 years without evidence of progressive disease. The authors have seen a patient at Mayo Clinic with an IgD ? MGUS who was followed up for more than 8 years without development of MM or AL ([91]).

ASSOCIATION OF MONOCLONAL GAMMOPATHY WITH OTHER DISEASES

Certain diseases are associated with MGUS, as would be expected in an older population. The association of two diseases depends on the frequency with which each occurs independently. In addition, an apparent association may occur because of differences in the referral practice or in other selected patient groups. Valid epidemiologic and statistical methods help in evaluating these associations. The need for appropriate control populations cannot be overemphasized.

For example, the association of monoclonal gammopathy and hyperparathyroidism has been reported ([92], [93]). Among 911 patients who had hyperparathyroidism and who were aged 50 years or older, immunoelectrophoresis demonstrated MGUS in nine (1%), which was the expected number ([94]). This prevalence of MGUS was similar to the 1.25 to 1.70% found in studies of three normal populations ([3], [4]). In another report, 4 of 386 patients with primary hyperparathyroidism had MGUS ([95]). In a recent report, 20 of 101 patients with hyperparathyroidism but only 2 of 127 controls had an M-protein ([96]). Thus, controversy continues concerning the association of hyperparathyroidism and MGUS.

Lymphoproliferative Disorders

In 1957, Azar et al. ([97]) reported that malignant lymphoma and lymphatic leukemia were associated with a myeloma-type serum protein. Kyle et al. ([98]) in 1960 described six patients with lymphoma who had serum electrophoretic patterns consistent with those of MM. Among 1150 patients with lymphoma, Alexanian ([99]) found M-proteins in 49 patients. M-proteins were reported in 29 of 640 patients (4.5%) with a diffuse lymphoproliferative disease (chronic lymphocytic leukemia, lymphocytic lymphoma, or reticulum cell sarcoma) but in none of 292 with a nodular lymphoma.

The authors reviewed the medical records of 430 patients in whom a serum IgM monoclonal gammopathy had been identified between 1956 and 1978 at Mayo Clinic (Table 97.7). The patients were classified as follows: (a) WM: IgM spike of 30 g/L or more in the serum protein electrophoretic pattern and an increase in lymphocytes or plasmacytoid lymphocytes in the bone marrow; (b) lymphoma: biopsy findings consistent with lymphoma and a lymph node or extranodal lymphoid tumor; (c) chronic lymphocytic leukemia: lymphocyte count higher than 9.0×10^{9}/L; (d) AL: biopsy specimen containing amyloid; (e) MGUS: IgM protein value less than 30 g/L, absence of constitutional symptoms, hepatosplenomegaly, and lymphadenopathy (no anemia or other findings requiring therapy); (f) malignant lymphoproliferative disease: not classified in the previous categories and characterized by an IgM protein value of less than 30 g/L, bone marrow infiltration with lymphocytes or plasmacytoid lymphocytes, and therapy required because of anemia or constitutional symptoms.

TABLE 97.7. Classification of Immunoglobulin M Monoclonal Gammopathies among 430 Patients, 1956–1978

Classification	Patients	
	Number	Percent
Monoclonal gammopathy of undetermined significance	242	56
Waldenström macroglobulinemia	71	17
Lymphoma	28	7
Chronic lymphocytic leukemia	21	5
Primary amyloidosis	6	1
Lymphoproliferative disease	62	14
Total	430	100

From Kyle RA, Garton JP. The spectrum of IgM monoclonal gammopathy in 430 cases. Mayo Clin Proc 1987;62:719–731, by permission of Mayo Foundation.

More than one-half of patients (56%) with an IgM protein had MGUS. During follow-up, 40 of the 242 (17%) with MGUS developed a malignant lymphoid disorder requiring therapy. In 22 patients, typical WM developed, nine others had a malignant lymphoproliferative process requiring chemotherapy, and lymphoma developed in six others. The median duration from the detection of the IgM protein until the diagnosis of lymphoid disease was more than 4 years (range, 0.4 to 22.0 years). In addition, ten patients (4%) with MGUS had an increase in serum M-protein level of more than 10 g/L, and nine others had an increase of 5 to 9 g/L. None of these 19 patients developed symptomatic WM or other lymphoid diseases requiring therapy.

The median survival of patients with WM and those with a malignant lymphoproliferative disease requiring therapy was similar (5.0 and 5.5 years, respectively). Consequently, no reason exists for differentiating patients with lymphoproliferative disease from those with WM. They can be included in future prospective studies of WM ([100]).

Leukemia

M-proteins have been reported in the serum of patients with leukemia ([101]). The authors described 100 patients with chronic lymphocytic leukemia and an M-protein in the serum or urine ([102]). IgM accounted for 28%, and IgG was found in 51%. The size of the M-protein was modest, with a median concentration of 10 g/L. No major differences were apparent in patients with chronic lymphocytic leukemia, whether they had an IgG or an IgM M-protein. Monoclonal gammopathy has also been recognized in hairy cell leukemia ([103]) and adult T-cell leukemia ([104]). Guglielmi et al. ([105]) reported eight patients with chronic myelocytic leukemia (Philadelphia chromosome positive) who had a monoclonal gammopathy. The authors have also seen several patients with chronic myelocytic leukemia and an M-protein in their serum, but an association between the two entities is unproven.

Other Hematologic Diseases

Acquired von Willebrand disease is uncommon, but it is often associated with a monoclonal gammopathy ([106], [107], [108], [109] and [110]). Patients with monoclonal gammopathy and a lupus anticoagulant activity have been reported ([111]).

Monoclonal gammopathies have been reported with pernicious anemia ([112]), congenital dyserythropoietic anemia type III ([113]), and pure red cell aplasia ([114]). Polycythemia vera ([115]), myelofibrosis ([116]), and myelodysplastic syndrome ([117]) have been reported with monoclonal gammopathies. Pratt et al. ([118]) found an IgG ? M-protein in 4 of 16 patients with Gaucher disease.

Connective Tissue Disorders

Rheumatoid arthritis ([119]) and seronegative erosive arthritis ([120]) have been reported in patients with monoclonal gammopathies. In a series of 279 consecutive patients who had rheumatoid arthritis at our institution, no notable increase in the incidence of M-protein was found.

Lupus erythematosus and other connective tissue disorders have been reported with M-proteins ([121], [122]). Polymyalgia rheumatica has been reported with monoclonal gammopathy, but both conditions occur more commonly in an older population, so the relationship is questionable ([123]). Polymyositis has been reported with monoclonal gammopathy ([124], [125]). Inclusion body myositis ([126]) and discoid lupus erythematosus ([127]) have been reported with an M-protein.

Neurologic Disorders

The authors found 16 cases of MGUS in 279 patients (6%) with a sensorimotor peripheral neuropathy of unknown cause ([128]). In another series, 16 of 56 patients with MGUS had a peripheral neuropathy ([129]). In an unselected series of patients with MGUS, neuropathy was noted in 2 of 34 patients (6%) with IgG, 2 of 14 (14%) with IgA, and 8 of 26 (31%) with IgM. The neuropathy was subclinical in six patients ([130]). Fourteen of 31 patients with an IgM MGUS had peripheral neuropathy ([131]). An association exists between MGUS and peripheral neuropathy, although the incidence is variable and depends on patient selection bias, the vigor with which the presence of an M-protein is sought, and whether the diagnosis of peripheral neuropathy is made on clinical or electrophysiologic grounds. A monograph on neurologic disorders associated with plasma cell dyscrasias has been published ([132]), and the association of neuropathies and monoclonal gammopathies has been the subject of excellent reviews ([133], [134] and [135]).

The most common monoclonal gammopathy associated with a neuropathy is IgM, followed by IgG and IgA. In approximately one-half of patients with an IgM monoclonal gammopathy and peripheral neuropathy, the M-protein binds to myelin-associated glycoprotein (MAG) ([136], [137]). The MAG-reactive polyneuropathies are characterized by a slowly progressive, mainly sensory neuropathy beginning in the distal extremities and extending proximally. Discriminative and proprioceptive modalities are more severely involved than touch, pain, and temperature. Motor involvement is less prominent than sensory involvement. Cranial nerve and autonomic functions are intact ([138]). The clinical and electrodiagnostic manifestations resemble those of chronic inflammatory demyelinating polyneuropathy. Patients with sensorimotor peripheral neuropathy may have an IgM protein binding to various peripheral nerve components. An extensive review of antibodies associated with

peripheral neuropathy has been published ([139]).

The authors reviewed their experience with 65 patients with MGUS and sensorimotor peripheral neuropathy at Mayo Clinic ([140]). Thirty-one patients had IgM, 24 had IgG, and ten had IgA. IgM was overrepresented in this group and was associated with sensory ataxia, slower nerve conduction, and more frequent dispersion of the compound muscle action potential compared with IgG or IgA neuropathies. Neither the amount of IgM nor the size of the monoclonal spike was associated with the severity of the neuropathy. In addition, the type and severity of neuropathy with anti-MAG were not greatly different from those without anti-MAG. The course of the neuropathy was progressive in more than two-thirds of patients ([140]). In a review of 40 patients with polyneuropathy associated with an IgM gammopathy, all but one had symmetric polyneuropathy. It was predominantly sensory in 13 and purely sensory in 17. Electrophysiologic studies revealed demyelination in 83% and axonal degeneration in 6%. Anti-MAG antibodies were found in 65% and were associated only with demyelinating polyneuropathies ([141]). The relationship of IgG and IgA M-proteins to peripheral neuropathy is less well documented ([142]).

MGUS neuropathies differ from those associated with AL in the following respects: (a) the lower extremities are peripherally affected in MGUS, but upper and lower extremities tend to be affected to a greater degree in AL; (b) the course in AL is always slowly progressive; and (c) although AL may appear to be a sensorimotor neuropathy, autonomic features (postural hypotension, sphincter dysfunction, anhidrosis) and organ (heart or kidney) failure often occur. Such autonomic features and organ failures do not occur in MGUS neuropathy.

The relationship between chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) and CIDP with MGUS is unclear. In a comparison of 77 patients with CIDP and 26 with CIDP and MGUS, the latter group had a more indolent course, less severe weakness, and more frequent sensory loss. The outcome in the two groups was similar ([143]). In a comparison of 45 patients with CIDP and 15 with MGUS-associated neuropathy, the latter group had less severe weakness, greater imbalance (ataxia), vibration loss in the hands, and absent median and ulnar sensory potentials ([144]). CIDP may occur at any age, motor symptoms tend to predominate over sensory symptoms, the course tends to be relapsing, and M-proteins are not found.

The results of treatment of patients with peripheral neuropathy and monoclonal gammopathy have been disappointing. Plasmapheresis has been of benefit in some patients ([145]). Thirty-nine patients with peripheral neuropathy and MGUS of the IgG, IgA, or IgM type were randomly assigned to undergo plasmapheresis or sham plasmapheresis in a double-blind trial at Mayo Clinic ([146]). Plasma exchange prevented worsening of or ameliorated the neuropathy. Patients with IgG or IgA gam-mopathy had a better response to plasma exchange than those with IgM gammopathy. In another study, 8 of 13 patients with a monoclonal gammopathy and peripheral neuropathy obtained benefit from plasma exchange ([147]). Patients who do not respond to this program may be given chlorambucil when the M-protein is of the IgM type or melphalan and prednisone for IgG and IgA gammopathies.

Fludarabine has produced some benefit in patients with IgM peripheral neuropathy ([148] , [149]). Rituximab is a monoclonal antibody directed against CD20, frequently found on the surface membranes of lymphocytes in lymphoma. Levine and Pestronk ([150]) reported all five patients with an IgM M-protein and neuropathy responded to rituximab. Intravenous immunoglobulin has been used, but the results have been disappointing ([151]).

Although several instances of monoclonal gammopathy and motor neuron disease have been reported, a causal effect is not proven. Eleven of 120 patients (9%) with motor neuron disease had an associated M-protein. Amyotrophic lateral sclerosis has been reported with MGUS ([152] , [153] and [154]). Myasthenia gravis has been associated with an M-protein ([155] , [156]). Ataxia-telangiec-tasia, an autosomal-recessive disorder, is characterized by cerebellar ataxia, and oculocutaneous telangiectasia has also been reported with monoclonal gammopathy ([157] , [158]).

Osteosclerotic Myeloma

Osteosclerotic myeloma (or POEMS syndrome) is characterized by a chronic sensorimotor polyneuropathy with predominating motor disability ([159]). Bardwick et al. ([160]) suggested the acronym POEMS for this syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes). Single or multiple osteosclerotic lesions are important features. The cranial nerves are not involved, except for the occurrence of papilledema. Hepatosplenomegaly and lymphadenopathy may occur. Hyperpigmentation, hypertrichosis, gynecomastia, and testicular atrophy may be seen. Polycythemia or thrombocytosis may be a prominent feature. Almost all patients have an M-protein of the ?–light chain type. The M-protein level is almost always less than 30 g/L. In contrast to MM, this syndrome is rarely associated with Bence Jones proteinuria, renal insufficiency, hypercalcemia, and skeletal fractures. The bone marrow aspirate and biopsy specimen usually contain less than 5% plasma cells ([161] , [162]).

The cause of POEMS syndrome is unknown. Patients have higher levels of IL-1ß, tumor necrosis factor-a, and IL-6 than patients with MM ([163]). Increased levels of vascular endothelial growth factor are frequently found and often decrease with successful therapy ([164]).

Single or multiple osteosclerotic lesions in a limited area should be treated with radiation in tumoricidal dosages of 40 to 50 cGy. More than one-half of patients have substantial improvement of the neuropathy. Improvement may be slow, and the authors have seen patients who continue to improve for 2 to 3 years after radiation therapy. If the patient has widespread osteosclerotic lesions, systemic therapy is necessary. Corticosteroids and plasma exchange generally have been of little benefit. Autologous stem cell transplantation after high-dose melphalan therapy is a consideration for younger patients with widespread osteosclerotic lesions.

Dermatologic Diseases

Lichen myxedematosus (papular mucinosis, scleromyxedema) is a rare dermatologic condition frequently associated with a cathodal IgG ? protein ([165]). Scleredema (Buschke disease) has been noted with an M-protein, but the role of the M-protein is unknown ([166]). Pyoderma gangrenosum has been associated with M-proteins ([167]). Necrobiotic xanthogranuloma is frequently found with an IgG M-protein ([168] , [169]). Schnitzler syndrome is characterized by the presence of chronic urticaria and an IgM monoclonal gammopathy ([170] , [171] and [172]). Monoclonal gammopathy has been associated with diffuse plane xanthomatosis or subcorneal pustular dermatosis ([173] , [174] , [175] and [176]). A comprehensive review of monoclonal gammopathies and skin disorders has been published ([177]).

More than a dozen patients have been described with an M-protein and Sézary syndrome; only two had MM ([178]). Five patients with mycosis fungoides and monoclonal gammopathy have been described ([179]). Thus, cutaneous T-cell lymphomas may be associated with monoclonal gammopathies. Several cases of Kaposi sarcoma and monoclonal gammopathy have been recognized ([180]). Erythema elevatum diutinum has been reported with monoclonal gammopathy ([181] , [182]).

Immunosuppression

M-proteins have been found in patients with acquired immunodeficiency syndrome. In a series of 130 homosexual men, human immunodeficiency virus (HIV) antibody was found in 65 patients, and four patients had an M-protein ([183]). The appearance or disappearance of a monoclonal gammopathy in patients with HIV infection did not appear to be of prognostic importance ([184]).

M-proteins were detected in 18 of 141 patients (12.7%) who had undergone renal transplantation ([185]). In another series, 27 of 213 patients (12%) had a monoclonal or multiclonal gam-mopathy after renal transplantation ([186]). Pollock et al. ([187]) reported M-proteins in 4 of 110 patients with renal transplants. A monoclonal gammopathy was found in 70 of 232 patients (30%) who were receiving immunosuppressive therapy after renal transplantation. The incidence was ten times greater than that in a control group with chronic renal insufficiency who were receiving dialysis ([188]). The presence of cytomegalovirus infection after renal transplantation in pediatric patients was associated with an increased incidence of M-proteins ([189]). In another series of 182 renal transplantation patients, an M-protein was found in 30%. The authors concluded that the M-protein was a reflection of the T-cell immune defect ([190]).

Hammarström and Smith ([191]) found transient monoclonal gammopathies after bone marrow transplantation in 18 of 42 patients (43%); the gammopathy was most often of the IgG ? class. In another report, transient oligoclonal and monoclonal gammopathies were found in 31 of 60 patients (52%) who underwent allogeneic (57 cases) or syngeneic (three cases) bone marrow transplantation. M-proteins appeared frequently and as early as 6 weeks after bone marrow transplantation in 40 children. IgM, IgG3, and IgG1 were the most common isotypes ([192]). In a report of 550 patients receiving autologous stem cell transplants, abnormal protein bands developed in 10%. Forty-eight additional patients had oligoclonal bands, and 23 had an isotope switch. The authors concluded that the oligoclonal bands and isotope

switching were due to recovery of immunoglobulin production rather than to alteration in the biology of the malignant plasma cell clone ([193]). In 12 of 47 patients, an M-protein developed after allogeneic bone marrow transplantation ([194]).

In 57 of 201 patients (28%), an M-protein developed after liver transplantation. Five of seven patients in whom a posttransplantation lymphoproliferative disorder developed had an M-protein, whereas only 52 of 194 (27%) without a posttransplantation lymphoproliferative disorder had an M-protein ([195]). In another series, 26 of 86 liver transplant recipients had an M-protein ([196]).

Miscellaneous Conditions

Gelfand et al. ([197]) described a patient with angioneurotic edema and acquired deficiency of C1 esterase inhibitor and reviewed the records of 14 other patients reported in the literature, including five with a 7S IgM M-protein. Pascual et al. ([198]) described two patients with acquired C1 inhibitor deficiency, an IgG ? protein, and recurrent episodes of febrile panniculitis and hepatitis. Lofdahl et al. ([199]) reported that eight of nine patients with systemic capillary leak syndrome had an M-protein in their serum. In some instances, the M-protein functions as an antibody that modifies the interaction between C1 inhibitor and its target protein ([200]). In a review of the literature, all 21 patients with a capillary leak syndrome had a monoclonal serum protein (IgG ? in 12; IgG ? in 7; IgA in 1; IgG with an unspecified light chain in 1) ([201]).

Although polyclonal increases in immunoglobulin are most common in liver disease, M-proteins have been noted in chronic active hepatitis ([202]). M-proteins have also been recognized in patients with primary biliary cirrhosis ([203]). Hepatitis C virus (HCV) infection and monoclonal gammopathies are associated. The incidence of HCV infection was 69% in 94 patients with mixed cryoglobulinemia and 14% in 107 patients without cryoglobulinemia ([204]). In another series of 102 cases of MM, WM, or MGUS, HCV infection was found in 16% of patients but in only 5% of controls ([205]). An M-protein was found in 11% of 239 HCV-positive patients but in only 1% of 98 HCV-negative patients. Thus, the prevalence of M-proteins in patients with HCV-related chronic liver diseases is high ([206]).

Also reported in association with monoclonal gammopathies were Henoch-Schönlein purpura ([207]), bacterial endocarditis ([208]), Hashimoto thyroiditis ([209] , [210]), septic arthritis ([211]), purpura fulminans ([212]), idiopathic pulmonary fibrosis ([213]), pulmonary alveolar proteinosis ([214]), idiopathic pulmonary hemosiderosis ([215]), sarcoidosis ([216]), thymoma ([217]), hereditary spherocytosis ([218]), Doyne macular heredodystrophy ([219]), eosinophilic fibrohistiocytic lesions of the bone marrow ([220]), corneal crystalline deposits ([221] , [222] , [223] and [224]), and hyperlipoproteinemia ([225]). The relationship of monoclonal gammopathy to these diseases is not clear and may be fortuitous.

Active glomerular lesions consisting of epithelial crescents and a rapidly progressive glomerulonephritis have been reported with monoclonal gammopathy ([226]). The association of proliferative glomerulonephritis with monoclonal gammopathy has been recognized in 25 cases, but the causal relationship is unknown ([227]).

The authors are not aware of any well-documented instances in which surgical removal of a nonhematologic tumor resulted in disappearance of the M-protein.

M-Proteins with Antibody Activity

Of 612 patients in whom monoclonal immunoglobulins were studied for their antibody activity against actin, tubulin, thyroglobulin, myosin, myoglobin, fetuin, albumin, transferrin, and double-stranded DNA, 36 (5.9%) had antibody activity ([228]).

In some patients with MGUS, MM, or WM, the monoclonal immunoglobulin has exhibited unusual specificities to dextran ([229]), antistreptolysin O ([230]), antinuclear activity ([231]), smooth muscle ([232]), riboflavin ([233] , [234]), von Willebrand factor ([235] , [236]), thyroglobulin ([237]), insulin ([238]), double-stranded DNA ([239]), apolipoprotein ([240]), thyroxine ([241]), cephalin ([242]), lactate dehydrogenase ([243]), anti-HIV ([244]), and antibiotics ([245]).

In one patient, xanthoderma-xanthotrichia (yellow discoloration of the skin and hair) was caused by an IgG ? protein with antiriboflavin antibody activity. Xanthoderma disappeared when the IgG level decreased to less than 20 g/L after chemotherapy ([233]). Another patient with similar clinical and laboratory features has been reported ([234]).

DiMinno et al. ([246]) described a patient with MM and a bleeding diathesis in whom an IgG1 ? protein reacted with platelet glycoprotein IIIa. This produced a thrombasthenia-like state. An IgM ? M-protein that agglutinated platelets and produced a pseudothrombocytopenia has been reported ([247]).

The binding of calcium by M-protein may produce hypercalcemia without symptomatic or pathologic consequences ([248] , [249]). This situation must be recognized so that patients are not treated for hypercalcemia ([250]). Copper-binding M-protein has been found in two patients with MM ([251]). Hypercupremia was noted in a patient with a benign IgG ? M-protein and carcinoma of the lung ([252]). Binding of an M-protein with transferrin, producing a high serum iron level, has been reported ([253] , [254]). Hilgard et al. ([255]) described a patient with multiple thrombi from intravascular precipitation of an IgG ? monoclonal cryoglob-ulin with transferrin and fibrinogen. Pettersson et al. ([256]) described a patient with an IgG ? protein that bound phosphate, producing a spurious elevation of the serum phosphorus level. Two other similar patients, one with MM and one with MGUS, have been described with hyperphosphatemia, presumably from binding of serum phosphorus by the M-protein ([257]).

Transient M-proteins with antibody activity have been recognized after infection. One report described a newborn with congenital toxoplasmosis who had an IgG ? protein. The same protein was not found in the mother, and it did not display antibody activity ([258]).

Waldenström ([259]) also emphasized the antibody activity of M-proteins. M-proteins with antibody activity in plasma cell dyscrasias have been reviewed by Merlini et al. ([260]).

Multiple Myeloma*

Multiple myeloma is a neoplastic plasma cell dyscrasia (PCD) characterized by a clinical pentad: (a) anemia; (b) a monoclonal protein in the serum or urine, or both, (c) abnormal bone radiographs and bone pain; (d) hypercalcemia; and (e) renal insufficiency or failure. With the exception of monoclonal gammopathy of undetermined significance (MGUS), it is the most common PCD, with an incidence of approximately 4.5 per 100,000 per year in the United States. Solitary plasmacytoma and plasma cell leukemia (PCL) are recognized as separate entities and are much less prevalent. The underlying pathogenesis of the plasma cell malignancies is not well understood but is an area of active investigation. At present, according to World Health Organization and Revised European American Lymphoma Classification systems, there is only one category for multiple myeloma ([1]). Results of clinical trials are confounded by this underclassification. Emerging information about the disease, however, will likely change this deficiency.

The interactions among the plasma cells, their antibody product, the local bone and bone marrow environment, and the other organs are complex. There is no cure for multiple myeloma, but there are many effective treatments that prolong and improve the quality of life in patients with the disease.

HISTORY

Earliest Diagnoses and Diagnostic Methods

Samuel Solley reported the first well-documented case of myeloma in Sarah Newbury in 1844 (mollities ossium) ([2] , [3]). Several years later, William MacIntyre described and recorded, from a case in Thomas Alexander McBean, the properties of the disease that is now called *multiple myeloma* ([4]). MacIntyre and Bence-Jones noted and described some of the peculiar urine properties of this same patient. On heating, the urine was found to "abound in animal matter," which dissolved on the addition of nitric acid but reappeared after cooling. These urinary proteins became known as *Bence Jones proteins* ([5]). MacIntyre and Dalrymple described the postmortem examination of McBean's bones ([4]): The former described the affected bones as softened and fragile, with their interiors replaced with a soft "gelatin form" blood-red substance. Dalrymple suggested that the disease began in the cancellous bone and extended through the periosteum. The nucleated cells, which formed the bulk of the gelatinous material, were heterogeneous in size and shape, but the majority were round to oval. Many of the larger and more irregular cells frequently contained two or three nuclei ([3]). The term *multiple myeloma* was coined in 1873 by von Rustizky ([3]) who independently described a similar patient to emphasize the multiple bone tumors that were present.

In 1889, Professor Otto Kahler ([3]) described a case involving a 46-year-old physician with multiple myeloma and published a major review of the disease. He described the skeletal pain, the albuminuria, the pallor, the anemia, a precipitable urinary protein, and the findings on necroscopy and linked these findings as part of a clinical syndrome, which bears his name (multiple myeloma is also known as *Kahler disease*).

In 1898, Weber ([6] , [7]) predicted the usefulness of roentgen x-rays in establishing the diagnosis ([6]) and later postulated that the Bence Jones protein was produced in the bone marrow ([7]). Wright ([8]) emphasized that multiple myeloma arose specifically from plasma cells of the marrow; Jacobson ([9]) recognized Bence Jones proteins in the bloodstream; and Walters ([10]) concluded that the Bence Jones protein was probably derived from blood proteins through the action of the abnormal

cells in the bone marrow. The technique of bone marrow aspiration ([3]) facilitated the diagnosis of multiple myeloma.

Bayne-Jones and Wilson ([11]) identified two similar but distinct groups of Bence Jones proteins by immunizing rabbits with Bence Jones proteins derived from patients. Precipitin tests on these Bence Jones preparations revealed two distinct groups: I and II. Using the Ouchterlony test, Korngold and Lipari showed that antisera to Bence Jones protein also reacted with myeloma proteins. The two classes of Bence Jones proteins have been designated *kappa* and *lambda* as a tribute to these two men. In 1962, Edelman and Gally ([12]) showed that the light chains prepared from an immunoglobulin (Ig) G monoclonal protein and the Bence Jones protein from the same patient's urine were identical.

Serum electrophoresis, described by Tiselius in 1937 ([13]), made it possible to separate serum proteins. Longsworth et al. ([14]) applied electrophoresis to the study of multiple myeloma and described the tall narrow-based “church spire” peak. The use of filter paper as a support for protein electrophoresis permitted the separation of protein into distinct zones that could be stained with various dyes ([15]). Because this technique was simple and less expensive, this test became universally available in clinical laboratories. Paper electrophoresis was supplanted by filter paper in 1957. Most recently, high-resolution electrophoresis on agarose gel is used in most laboratories. Immunoelectrophoresis ([3]) and immunofixation or direct immunoelectrophoresis ([16]) made it possible to detect small monoclonal light chains that were not recognizable by electrophoresis.

Kunkel ([17]) hypothesized that monoclonal proteins were the product of malignant plasma cells and were the equivalent of normal antibodies produced by normal plasma cells. Before 1960, the term *gamma globulin* was used for any protein that migrated in the gamma mobility region of the electrophoretic pattern; however, in 1959, Heremans ([18]) proposed the concept of a family of proteins with antibody activity. In 1961, in a Harvey Lecture ([19]), Waldenström distinguished between monoclonal and polyclonal hypergammaglobulinemia.

In 1928, Geschickter and Copeland ([20]) reported on the largest case series of multiple myeloma—13 cases—and reviewed the 412 cases reported in the literature since 1848. They documented a higher incidence in men than women and an overall survival of approximately 2 years. They emphasized six features: (a) involvement of the skeletal trunk, (b) pathologic rib fractures, (c) Bence Jones proteinuria in 65% of cases, (d) backache with early paraplegia, (e) anemia in 77% of cases, and (f) chronic renal disease. They did not note abnormalities of blood protein or an increased erythrocyte sedimentation rate ([3]). In 1931, Magnus-Levy ([21]) described amyloidosis as a complication of multiple myeloma. Salmon and Smith ([22]) and Durie and Salmon ([23]) developed methods to quantitate the total body burden of tumor cells ([22]) and to stage patients ([23]) in 1970 and 1975, respectively.

Earliest Treatments for Multiple Myeloma

In 1947, Snapper ([24]) reported that stilbamidine along with a low–animal protein diet relieved myeloma pain in 14 of 15 patients. Subsequent studies did not confirm this benefit. Urethane was believed to be effective until 1966 ([25]). It was first used in the treatment of multiple myeloma by Alwall in 1947 ([26]) and then by Loge and Rundles in 1949 ([27]). Their early observations were encouraging, and the use of urethane became widespread. Toxic effects included severe anorexia, nausea, and vomiting. Leukopenia, thrombocytopenia, and hepatic damage also occurred ([28]). In 1966, however, Holland et al. ([25]) published the results of a randomized controlled trial of urethane versus placebo in 83 patients with symptomatic multiple myeloma. They found that there was no difference in any objective measurement of improvement between the two groups and that the median overall survival was higher in the placebo group. Previously untreated patients had a median survival of 12 or 5 months, depending on whether they received placebo or urethane, respectively.

In 1950, Thorn et al. ([29]) reported the first observations on the salutary effects of adrenocorticotropic hormones on myeloma. During that decade, it was recognized that the adrenocorticotropic hormones cortisone and prednisone were useful agents in patients with multiple myeloma. Corticosteroids decreased bone pain, improved hypercalcemia, increased hemoglobin values, and decreased abnormal serum and urine globulin concentrations ([28]). However, it was not until 1967 that high-dose corticosteroids were recognized as effective antineoplastic agents against multiple myeloma ([30]).

Blokhin et al. ([31]) reported benefits in three of six patients with multiple myeloma who were treated with sarcolysin (a racemic mixture of the *d*- and *l*-isomers of phenylalanine mustard). Subsequently, the *d*- and *l*-isomers were tested separately, and the antimyeloma activity was found to reside in the *l*-isomer, melphalan. Bergsagel et al. ([32]) reported significant improvement in 14 of 24 patients with multiple myeloma with the use of melphalan; this activity was quickly substantiated by others ([33]). Similar effectiveness was noted with cyclophosphamide ([34]). Subsequently, interferon-a, doxorubicin, carmustine (BCNU), and thalidomide have each been reported to have activity as a single agent in myeloma ([35], [36], [37] and [38]) (Fig. 98.1).

INCIDENCE AND EPIDEMIOLOGY

Epidemiology of Myeloma

Approximately 14,400 new cases of multiple myeloma are diagnosed each year, and 11,200 deaths are recorded in the United States ([39]). Surveillance, Epidemiology, and End Results incidence-data age-adjusted rates from 1992 through 1998 show an overall incidence of 4.5 per 100,000 per year, with the incidence among whites being 4.2 per 100,000 per year and among blacks being 9.3 per 100,000 per year ([40]). The male to female ratio is 1.4 to 1 ([40]). The median age at diagnosis of myeloma is 71 years of age ([39]). Mortality rates are consistently higher among men than women and among blacks than whites in each age group ([40]). Myeloma accounts for 1% of all malignancies and 10% of all hematologic malignancies in whites and 20% of all hematologic malignancies in African Americans ([40]). International mortality data reveal that the highest rates of myeloma occur in Northern Europe, North America, Australia, and New Zealand, and the lowest rates are in Japan, Yugoslavia, and Greece ([41]). Geographic clusters ([42]) and familial clusters ([43], [44], [45], [46], [47] and [48]) of myeloma among first degree relatives have been documented. Modest increases in multiple myeloma rates were observed when incidence data from 1973 to 1992 were calculated in nine population-based cancer registries, with further projected increases by 2007 ([49]). Some of this increase could be due to a heightened awareness of the disease.

Etiologic Factors

RADIATION EXPOSURES

Atomic Bomb Exposure Reports of increased myeloma incidence and mortality among Japanese atomic bomb survivors have suggested an association between ionizing radiation and multiple myeloma. Evaluations of cancer incidence ([50]) and mortality ([51]) among Japanese atomic bomb survivors have demonstrated an increased risk of multiple myeloma with increasing radiation dose. However, with an additional 12 years of follow-up from the previous report, the findings of an increased myeloma risk associated with atomic bomb irradiation were not maintained ([52]).

Radiation-Related Occupation An excess of myeloma deaths among American radiologists was reported in the 1960s ([53]). Myeloma risk was considered to be two times higher among radiologists exposed to low doses of radiation than among physicians not exposed to radiation ([54]). However, among 27,000 Chinese diagnostic

radiography workers, no excess incidence of myeloma was observed in a 30-year period ([55]). An analysis of 115,000 workers from the combined roster of four different nuclear plants showed a positive association between multiple myeloma and radiation exposure in older age groups ([56]). Increases in multiple myeloma incidence and mortality have been observed among British military men who participated in atmospheric nuclear weapons testing ([57]) but not among New Zealand military personnel who participated in similar nuclear weapons testing ([58]).

Diagnostic and Therapeutic X-rays Diagnostic x-ray exposure has not been linked clearly with the development of multiple myeloma in most epidemiologic studies ([59] , [60] , [61] and [62]). A large, multicenter, population-based, case-control study showed no evidence of excess risk of myeloma among individuals who reported exposure for ten or more diagnostic radiographs ([63]). One study reported that the overall risk for multiple myeloma was not high (risk ratio, 1.14) but that there was evidence of increasing risk with exposure to increasing numbers of radiographic procedures ([64]). Of historic interest is the finding of an association between myeloma and the use of Thorotrast ([65]). Studies of the effects of therapeutic irradiation on myeloma risk have shown conflicting results, but a study of 180,000 women treated for cervical cancer demonstrated no overall excess risk of developing myeloma ([66]). Similarly, a study of 14,000 patients who had ankylosing spondylitis and were treated with radiation revealed no significant increase in the risk of developing myeloma ([67]).

WORKPLACE EXPOSURES

Agricultural Occupations and Exposures Several epidemiologic studies have evaluated the risk of myeloma among agricultural workers, with positive associations reported by many, but not all, of the studies ([68] , [69] , [70] , [71] , [72] , [73] , [74] , [75] and [76]). Khuder and Mutgi ([77]) found a relative risk of 1.23 in a metaanalysis of several studies.

Metal Industries Workers in various metal occupations and industries have been reported to have an increased myeloma risk ([78] , [79] and [80]).

Benzene Benzene has been suggested as a possible etiologic agent for multiple myeloma ([81] , [82] and [83]). A comprehensive review of published literature found no evidence of a link between benzene exposure and myeloma ([84]). Subsequently, Sonoda et al. ([85]) conducted a metaanalysis of case-control studies and showed no excess risk for the development of multiple myeloma. A metaanalysis by Wong and Raabe ([86]) of more than 350,000 petroleum workers similarly showed no increased risk.

LIFESTYLE FACTORS

Cigarette Smoking and Alcohol Consumption Multiple studies to date have found no etiologic role for cigarette smoking or alcohol consumption in the development of multiple myeloma ([87] , [88] , [89] and [90]).

Dietary Links Tavani et al. ([91]) suggested a dietary link for multiple myeloma and found a higher risk among people consuming large quantities of liver [odds ratio (OR), 2] and butter (OR, 2.8) and a lower risk among people consuming large amounts of vegetables (OR, 0.4). Coffee and alcohol had no association with multiple myeloma. No association between multiple myeloma and consumption of red meat has been found. Brown et al. ([92]) looked at diet and nutrition as risk factors for multiple myeloma among blacks and whites in the United States. Elevated risks were associated with obesity in comparison to people of normal weight. Obesity was more frequent in black than in white controls. Reduced risks were associated with the frequent intake of cruciferous vegetables, fish, and vitamin C supplements. The authors concluded that the greater use of vitamin C supplements by whites and the higher frequency of obesity among blacks may explain part of the higher incidence of multiple myeloma among blacks compared to whites in the United States.

Socioeconomic Status Some investigators have reported that there is an inverse relationship between the risk of multiple myeloma and socioeconomic status ([93]) and that this inverse correlation may account for a substantial amount of the black and white differential of multiple myeloma incidence ([94]). Earlier studies did not show a link between socioeconomic status and myeloma ([95]).

Hair Dyes Personal use of hair dyes was evaluated as a risk factor for myeloma ([96]), including two prospective studies ([97] , [98]). Thun et al. ([97]) found that women using permanent hair dyes are not generally at increased risk of fatal cancer. Women with prolonged use of dark, particularly black, hair dyes may have increased risk of fatal non-Hodgkin lymphoma and multiple myeloma, but these women are a small fraction of hair dye users. A recent metaanalysis by Correa et al. ([99]) showed no increased risk.

PRECURSOR MEDICAL CONDITIONS

Monoclonal Gammopathy of Undetermined Significance MGUS is considered a potential precursor condition for multiple myeloma. In a long-term study of prognosis in MGUS, Kyle et al. ([100]) identified 1384 patients in southeastern Minnesota in whom MGUS was diagnosed. During 11,009 person-years of follow-up, 115 of the 1384 MGUS patients progressed to multiple myeloma, IgM lymphoma, primary amyloidosis, macroglob-ulinemia, chronic lymphocytic leukemia, or plasmacytoma. The risk of progression of MGUS to multiple myeloma–related disorders is thus approximately 1% per year ([100]). Among a group of 1231 patients in Italy with MGUS and smoldering multiple myeloma, cumulative transformation probability at 10 and 15 years was 14% and 30%, respectively ([101]).

Chronic Antigenic Stimulation Repeated or chronic antigenic stimulation of the immune system may lead to myeloma. Several case-control studies have suggested that myeloma risk is associated with past history of infections ([89] , [102] , [103]), inflammatory conditions, connective tissue disorders, autoimmune illnesses, and allergy-related disorders ([69]). Increased risks of myeloma have been observed in some conditions, such as allergies ([104]) and rheumatoid arthritis ([105] , [106]). Other studies of individuals with these conditions have shown no increased risk of multiple myeloma ([107] , [108] , [109] and [110]).

Viral Infections Patients with the human immunodeficiency virus may have an increased likelihood of developing myeloma ([111] , [112]). In addition, myeloma and hepatitis C may be associated ([113] , [114] and [115]). The finding of human herpesvirus 8 has been suggested as a possible etiologic agent ([116] , [117]), but this has not been confirmed ([118] , [119] , [120] and [121]).

PATHOGENESIS AND PATHOPHYSIOLOGY

To date, no single molecular defect can account for the pathogenesis of multiple myeloma. Malignant plasma cells are long-lived cells, typically with low proliferative rates and labeling indices ([122] , [123]). A postgerminal cell origin is indicated by their somatically hypermutated, rearranged Ig genes ([124]). A multitude of abnormalities has been identified in signaling pathways, apoptotic mechanisms, the bone marrow microenvironment, and the cell cycle. Factors, including the level of gene expression, protein expression, and gene product phosphorylation status of cell cycle molecules, may all be relevant for the propagation of the malignant plasma cells. Extracellular signaling alterations include changes in stromal cell, osteoblast, osteoclast, vessel endothelial cell, and immune cell interactions. These changes may, in turn, result in activation, adhesion, and cytokine production that fuel myeloma cell proliferation and survival.

Cytokines and Cell Signaling

The search for a growth factor for myeloma cells culminated in the identification of interleukin (IL)-6, formerly known as *B-cell growth factor* or *hybridoma growth factor* ([125]). IL-6 is among the most important proliferation and survival factors in myeloma ([126]). Predominantly produced by bone marrow stromal cells—macrophages, fibroblasts, osteoblasts, osteoclasts, and monocytes (Fig. 98.2) ([127])—it serves as a growth factor and as an antiapoptotic factor ([128] , [129] and [130]). In the majority of cases, myeloma cells and cell lines are capable of producing IL-6 and the IL-6 receptor, resulting in autocrine stimulation ([129] , [131] , [132] and [133]). IL-6 transmits messages intracellularly through the signal-transducing protein gp130, which can activate two pathways: the JAK-STAT pathway ([134]) and the Ras–MAP kinase pathway ([135]). Through the former pathway, which includes JAK-2 and STAT3, the antiapoptotic proteins Mcl-1 ([134]) and Bcl-X_L ([136]) are up-regulated; through the latter pathway, transcription factors, such as ELK-1, AP-1, and NF-IL-6 ([134]), are up-regulated. Nuclear factor-?B (NF-?B) ([137]) and IL-6 ([138] , [139]) may also mediate the observed increase in the antiapoptotic proteins Bcl-2 ([140] , [141]), Mcl-1 ([138]), and Bcl-X_L ([138] , [139] , [142] , [143]). The overall effect of these pathways is prevention of apoptosis and enhancement of multiple myeloma proliferation. In addition, the constitutive activation of STAT3 may also be important in the pathogenesis of multiple myeloma, independent of IL-6 ([144]). Moreover, CD40 activation of myeloma cells can alter the cell surface phenotype, triggering autocrine IL-6 secretion regulating myeloma cell cycle in a p53-dependent fashion ([145]).

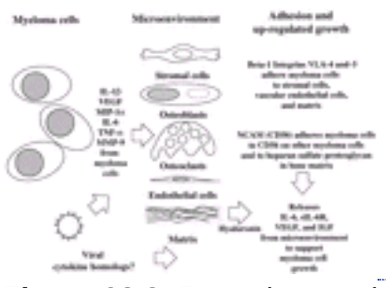

Figure 98.2. Paracrine myeloma cell growth model. Putative pathogenic mechanisms in myeloma. IGF, insulinlike growth factor; IL, interleukin; MIP, macrophage inflammatory factor; MMP, metalloproteinase; NCAM, neural cell adhesion molecule; TNF, tumor necrosis factor; VEGF, vascular-derived endothelial growth factor; VLA, very late antigen. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and

related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–59, with permission.)

Other cytokines and growth factors produced by myeloma and stromal cells that maintain myeloma growth ([146]) include IL-1ß ([147], [148] and [149]), vascular-derived endothelial growth factor (VEGF), insulinlike growth factor ([150], [151], [152], [153], [154] and [155]), and tumor necrosis factor-a ([156], [157]). Aberrant expression of IL-1ß may be a critical step in the transition of MGUS to multiple myeloma ([149], [158]). IL-1ß up-regulates production of IL-6, changes expression of cell adhesion molecules, and has been shown to have osteoclast-activating factor activity. Although IL-1ß does not stimulate myeloma cell proliferation directly, it induces production of IL-6 by virtue of its effect on stromal cells in the marrow ([159]). Myeloma cells are capable of expressing and secreting VEGF and responding to the cytokine in an autocrine fashion ([160], [161]). Moreover, stromal and microvascular endothelial cell exposure to VEGF induces an increase in IL-6 secretion ([160]), which then further stimulates myeloma cells. The precise role basic fibroblast growth factor (bFGF), another potent angiogenic factor, plays in the growth of myeloma cells is under active investigation ([162]). Higher bFGF levels have been found in more advanced stages of multiple myeloma ([162]). Insulinlike growth factor, which is believed to signal through the phosphatidylinositol-3'-kinase pathway ([150]), is capable of directly stimulating myeloma cell growth, enhancing myeloma cell responsiveness to IL-6 through mitogen-activated protein kinase ([153]), and also inhibiting apoptosis by increasing expression of BAD ([150]).

Bone Marrow Microenvironment

There is a synergistic, pathologic relationship between myeloma cells and the cells comprising the bone marrow microenvironment, including fibroblasts, osteoblasts, and osteoclasts. The stromal cells of the marrow of myeloma patients produce high levels of IL-6 *in vitro* ([163]). The IL-6 serves as a growth and survival factor for benign and malignant plasma cells, which produce IL-1ß ([158], [159]), VEGF, and macrophage inflammatory protein-1a (MIP-1a) ([160], [161]). In turn, IL-1ß and MIP-1a regulate and activate osteoclasts ([158], [164], [165]).

A cell adhesion molecule belonging to the Ig superfamily, CD56 (N-CAM), is strongly expressed in most plasma cells of myeloma patients ([166]) and is believed to play a role in myeloma homing and cell adhesion to the marrow. Increased levels of the adhesion molecules lymphocyte function-associated antigen-3 ([167]), lymphocyte function-associated antigen-1 (CD11a) ([168]), and very late antigen-4 are expressed on the myeloma cells in the majority of patients. Very late antigen-4 may act to bind myeloma cells to fibronectin in bone marrow ([169]), which, under appropriate conditions, can significantly increase IL-6 production by stroma ([156]). Cell-cell contact between marrow stromal cells and myeloma cells via vascular cell adhesion molecule-1 and $a_4ß_1$ integrin enhances production of osteoclast-stimulating activity ([170]). Hyaluronan, a glycosaminoglycan component of the bone marrow extracellular matrix, appears to be a survival and proliferation factor for myeloma cells ([171]).

The endothelial microvascular environment has also been shown to be important in multiple myeloma biology ([172]). There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating (S phase) fraction of marrow plasma cells in patients with multiple myeloma and in those with MGUS ([172], [173] and [174]). VEGF plays an important role in angiogenesis by acting as a potent inducer of vascular permeability as well as serving as a specific endothelial cell mitogen. Plasma cells in the bone marrow from multiple myeloma patients express VEGF, which can thereby interact with the Flt-1 and KDR high-affinity VEGF receptors highly expressed on bone marrow myeloid and monocytic cells surrounding the tumor ([173]).

Cell Cycle

Regulatory signals underlying proliferation of myeloma cells include increased cyclin D1 expression, hypermethylation of the cyclin-dependent kinase (CDK) pathway regulatory gene p16 ([175]), mutations of the *ras* oncogene ([176], [177]), loss of *p*53 ([178], [179] and [180]), and, possibly, overexpression of c- *myc* in progressive disease ([181]).

Approximately one-third of myeloma patients have up-regulation of cyclin D1 by immunohistochemistry; the plasma cells of these same patients tend to have higher proliferative rates ([182]). The t(11;14)(q13;q32) translocation, which juxtaposes the Ig heavy chain promoter and the cyclin D1 gene, is seen in approximately 25% of multiple myeloma patients ([183], [184], [185], [186] and [187]).

p15 and p16 are important cell cycle inhibitors that suppress cell proliferation through inhibition of CDK4 or CDK6, or both, thereby preventing the phosphorylation of the retinoblastoma gene (*RB*). Although large deletions of p15 and p16 are rare in myeloma (0 to 12% of cases) ([188], [189] and [190]), selective methylation of these genes, a form of transcriptional inactivation, occurs in as many as 67% and 75% of cases, respectively ([191], [192] and [193]). Most data, including that of the authors ([194]), suggest that hyper-methylation of p16 or p15 is associated with disease progression ([191], [193], [195], [196], [197] and [198]).

K- and N- *ras* mutations have been described in 25 to 100% of newly diagnosed multiple myeloma patients ([177], [199]), depending on the technique used for detection. A *p*53 tumor-suppressor gene deletion is present in less than one-third of plasma cells from newly diagnosed myeloma patients ([180]), and mutations are even less common ([200], [201], [202] and [203]). The c- *myc* protein and c- *myc* RNA are overexpressed in approximately 25% of multiple myeloma patients ([204], [205]). Rearrangements of c- *myc* gene are present in approximately 15% of patients with multiple myeloma or primary PCL ([206]). Dysregulation of c- *myc* appears to be caused principally by complex genomic rearrangements that occur during late stages of multiple myeloma progression ([181]).

CLINICAL MANIFESTATIONS

The symptoms of multiple myeloma may be nonspecific and include fatigue, bone pain, easy bruising and bleeding, recurrent infections, manifestations of anemia, hypercalcemia, lytic bone lesions, hyperviscosity, thrombocytopenia, and hypogammaglobulinemia. Weakness, infection, bleeding, and weight loss are reported in as many as 82%, 13%, 13%, and 24% of patients, respectively ([207], [208], [209] and [210]). Hypercalcemia is present in 18 to 30% of patients ([207], [208] and [209]). One- to two-thirds of patients present with spontaneous bone pain ([37], [38] and [39]). "Tumor fever" is present in less than 1% of presenting patients.

Anemia

The most common clinical feature of multiple myeloma is anemia. A hemoglobin concentration of less than 120 g/L occurs in 40 to 73% of patients at presentation ([207], [208] and [209]) and contributes to the weakness and fatigue observed in as much as 82% of patients ([207], [208], [209] and [210]). The anemia is normochromic, normocytic in most patients, but macrocytosis may be observed as well. When there are high concentrations of serum Ig, rouleau formation may be observed (Fig. 98.3). The combination of anemia and hyperproteinemia leads to a marked increase of the erythrocyte sedimentation rate in more than 90% of cases ([211]).

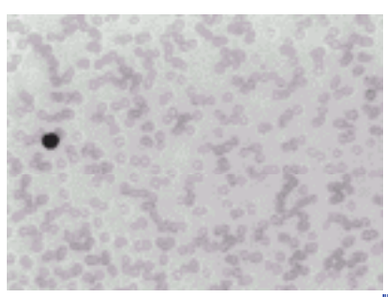

Figure 98.3. Rouleau formation. See Color Plate. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–109, with permission.)

The anemia is related partially to direct infiltration and replacement of the bone marrow. Hemoglobin concentration is also correlated directly with the percentage of

myeloma cells in S phase ([212]), suggesting that the bone marrow cytokine milieu, permissive for myeloma cell proliferation, is not conducive to efficient erythropoiesis. Cytokines, like tumor necrosis factor-a and IL-1, may inhibit erythropoiesis ([213]). Fas ligand–mediated erythroid apoptosis is also increased in patients with myeloma ([214]). Finally, relative erythropoietin deficiency from myeloma-induced renal insufficiency also contributes to the observed anemia.

Monoclonal Proteins

The M protein (also known as *M component*, *myeloma protein*, or *M spike*) is a hallmark of the disease; 97% of myeloma patients have an intact Ig or a free light chain that can be detected by protein electrophoresis (Fig. 98.4), immunoelectrophoresis, or immunofixation studies of the serum or urine ([208] , [209]). Those cases without a detectable monoclonal protein are referred to as *nonsecretory myeloma*. Historically, monoclonal proteins have had a valuable role in the fields of immunology and molecular biology for distinguishing MGUS from myeloma and for calculating myeloma tumor burden and kinetics ([22] , [100] , [215]). Practically, M protein concentrations are used to stage myeloma patients and to document their response to treatment.

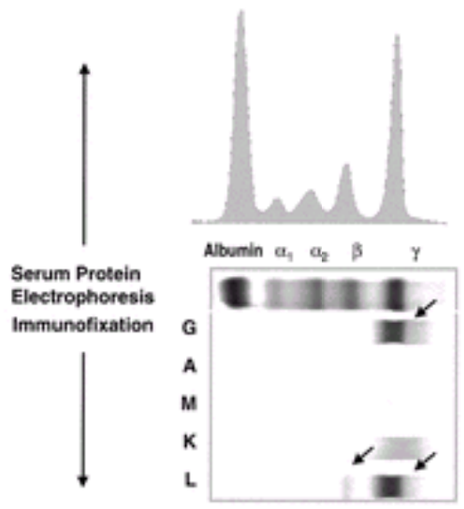

Figure 98.4. Serum protein electrophoresis patterns and immunofixation patterns. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–109, with permission.)

An M protein represents overproduction of a homogeneous Ig or Ig fragment. In a series of 1027 newly diagnosed cases of myeloma, the Ig type was IgG, IgA, IgD, and free light chain only (Bence Jones myeloma) in 52%, 20%, 2%, and 16% of cases, respectively ([208]). Fewer than 1% of myelomas are IgM; most IgM monoclonal proteins are associated with diagnoses of MGUS, lymphoma, Waldenström macroglobulinemia, or primary systemic amyloidosis ([216]). Ninety-three percent of patients have a monoclonal protein detected in their serum. Approximately 90% of myeloma patients have reduction in at least one of their uninvolved Igs ([216]). Approximately 70% of myeloma patients have a monoclonal protein—or fragment thereof—detected in the urine.

Bone Disease

Approximately one-third to two-thirds of patients present with bone pain ([207] , [208] , [209] and [210]). There is an uncoupling of the usually tightly regulated balance between osteoclastic and osteoblastic activity. Even before the development of bone lesions, enhanced osteoblastic recruitment with an increased generation of new osteoclasts is observed in early multiple myeloma ([217]). Regardless of the initiating signal, whether IL-1ß, IL-6 and sIL-6R, tumor necrosis factor-a, MIP-1a, receptor activator of NF-?B ligand, or para-thyroid hormone-related protein ([165]), the eventual outcome is bone destruction. Myeloma bone disease is a major source of morbidity and may present as an area of persistent pain or as a vague migratory bone pain, often in the lower back and pelvis. The type, location, and duration of the pain have no characteristic features. At times, pain and tenderness may be sudden in onset, especially when associated with a pathologic fracture, and are most commonly precipitated by movement. Persistent localized pain may also be associated with a pathologic fracture.

A myelomatous lesion may extend through the cortex of a vertebral body and may cause nerve root or spinal cord compression in less than 2% of patients ([207]). Alternatively, the myeloma can disturb the mechanical integrity of a vertebral body, resulting in compression fracture with retropulsion of plasmacytoma or bony fragments into the spinal canal, again causing neurologic deficit.

Approximately 75% of patients have punched-out lytic lesions, osteoporosis, or fractures on conventional radiography. The vertebrae, skull, ribs, sternum, proximal humeri, and femora are involved most frequently ([208] , [209] and [210]) (Fig. 98.5). A small subset of patients have *de novo* osteosclerotic lesions ([218] , [219] and [220]), and, in a few patients, osteosclerosis is seen after therapy and may serve as a marker of healing.

Figure 98.5. Skeletal survey. **A:** Skull. **B:** Long bone. **C:** Compression fracture. **D:** Diffuse signal abnormality, thoracolumbar spine, with compression fracture. T1 (*left*); T2 (*right*). (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–109, with permission.)

Because myelomatous bone lesions are characteristically lytic, conventional radiography is superior to technetium 99m bone scanning ([221] , [222]). Approximately twice as many myelomatous bone lesions are detected by radiograph than by bone scan; an exception to this general finding is at the lumbar spine and the rib cage, where the two methods are equally reliable ([222]). There have been reports supporting the use of technetium 99m sestamibi scans. These scans are almost as sensitive as plain radiographs for bone disease in untreated patients (i.e., patients with active disease) ([223]). They may be able to distinguish active myelomatous bone lesions from inactive lesions ([223]) and are quite sensitive for bone marrow involvement ([224] , [225] and [226]). There is a high concordance between scintigraphic findings and clinical status in patients undergoing chemotherapy or autologous stem cell transplantation ([227] , [228]). Fluorodeoxyglucose positron emission tomography also shows promise in the staging of myeloma, with sensitivity and specificity rates of 84 to 92% and 83 to 100%, respectively ([229]).

Computed tomography and magnetic resonance imaging (MRI) are more sensitive than conventional radiography. Both reveal specific lesions in 40% of stage I myeloma patients ([230]). The presence of lacunae larger than 5 mm with trabecular disruption on computed tomography appears to be sensitive and specific for myeloma. This information may be useful in distinguishing between senile and myelomatous osteoporosis and compression fractures ([231]). The finding of diffusely

decreased signal intensity and a multinodular appearance on MRI ([230]) may also be a useful indicator of early disease. Among asymptomatic multiple myeloma patients with normal radiographs, 50% have tumor-related abnormalities on MRI of the lower spine ([232]). In patients with stage I myeloma, MRI can distinguish patients at higher and lower risks of progression ([233]). One-third of patients with an apparently solitary plasmacytoma of bone have evidence of other plasma cell tumors on MRI ([234]).

MRI is superior to radiographs for the detection of lesions in the pelvis and the spine, but, overall, it is inferior to radiographs for detecting bone involvement in multiple myeloma (79% vs. 87%, respectively) ([235]). On MRI, vertebral fractures due to spinal infiltration or osteoporosis are seen in 48% of patients with symptomatic myeloma, and spinal canal narrowing with impingement occurs in 20% ([232]). MRI has been said to have predictive value in patients newly diagnosed with myeloma and in patients who have received chemotherapy ([236], [237]). Three patterns are described: focal lesions, diffuse involvement, and an inhomogeneous pattern of tiny lesions against a background of normal marrow (variegated) ([237], [238]). Not surprisingly, there are correlations between MRI patterns of marrow involvement and bone marrow plasmacytosis ([237], [239]), and the clinical stage ([238]). After treatment, resolution of marrow abnormality or persistent abnormality without enhancement corresponds to a complete response ([236]). In one analysis, the best independent prognosticators of survival were the MRI findings and C-reactive protein levels. Even though patients with the diffuse pattern had more bone marrow plasmacytosis, higher serum calcium values, higher ß $_2$-microglobulin (ß $_2$M) values, and lower hemoglobin concentration, these factors were not significant on multivariate analysis ([240]). However, given the expense of MRI, it cannot be recommended for routine clinical use in all symptomatic patients.

Hypercalcemia

Hypercalcemia occurs in 18 to 30% of patients. Approximately 13% have concentrations greater than 11 mg/dl. Rates of hypercalcemia at presentation have been decreasing since the 1980s, perhaps because of the earlier diagnosis of patients ([207], [208], [209] and [210]). Hypercalcemic patients may complain of fatigue, constipation, nausea, or confusion. Calcium can precipitate in the kidneys and can aggravate renal insufficiency. Inorganic phosphate is rarely decreased, except in cases of acquired Fanconi syndrome ([241]).

Renal Insufficiency

Approximately 25% of myeloma patients have a serum creatinine value greater than 2 mg/dl at diagnosis. Another 25% have mildly elevated creatinine values ([207], [208], [209] and [210], [242], [243] and [244]). Patients with Bence Jones or IgD myeloma have the highest rates of renal insufficiency ([243], [245]). Free light chain proteinuria is a risk factor for renal failure ([246]). Other contributing factors to the renal insufficiency include hypercalcemia, dehydration, hyperuricemia, and the use of nephrotoxic drugs ([247]). If the renal insufficiency reverses with therapy, as it does in more than one-half of cases ([246], [248]), survival is fourfold to sevenfold higher than in those in whom it does not ([242], [249]). Factors predicting for renal function recovery include a serum creatinine of less than 4 mg/dl, serum calcium value of greater than 11.5 mg/dl, proteinuria of less than 1 g per 24 hours, and adequate rehydration ([242]). For those patients with multiple myeloma and severe renal failure who survive the first 2 months on dialysis, 40% have an objective response to chemotherapy and a median survival of almost 2 years ([250]).

The pathologic lesion of myeloma kidney consists of monoclonal light chains in the tubules in the form of dense, often laminated, tubular casts. These casts contain albumin and Tamm-Horsfall protein. Light chains are normally filtered by the glomeruli and are reabsorbed and catabolized in the nephron's proximal tubules. It is postulated that these systems become overwhelmed, and casts result. When other causes contributing to renal insufficiency are excluded, there is a good correlation between the extent of myeloma cast formation and the severity of renal insufficiency ([251], [252]). Tubular atrophy and degeneration correlate well with renal dysfunction ([253]). The most common findings on autopsy include tubular atrophy and fibrosis (77%), tubular hyaline casts (62%), tubular epithelial giant cell reaction (48%), and nephrocalcinosis (42%). Evidence of acute and chronic pyelonephritis were observed in 20% and 23% of autopsy cases, respectively. Plasma cell infiltrates and amyloid may be observed in 10% and 5% of cases, respectively ([210]). Rarely, myeloma may be associated with the acquired Fanconi syndrome ([241]).

An important feature of myeloma kidney is that it is primarily a tubular, rather than a glomerular, disease ([253]). Glomerular function is preserved initially, and there is a predominance of Ig light chain protein in the urine instead of the nonspecific protein loss that is observed in glomerular disease. This feature helps predict the renal lesion: Nonspecific protein loss (i.e., mostly albumin) is more compatible with primary systemic amyloidosis, light chain deposition disease (LCDD) of the kidney, or proteinuria unrelated to PCD ([251]); a free light chain predominance is consistent with myeloma kidney.

Infection

Patients with multiple myeloma are at high risk for bacterial infections and for dying of overwhelming bacteremia. Overall, the incidence of infection is from 0.8 to 1.4 per patient-year ([254], [255] and [256]). During the first 2 months after initiating chemotherapy, the infection incidence is as high as 4.68 infections per patient-year ([256]) but decreases to 0.44 to 0.49 per patient-year in those reaching a plateau phase ([255], [256]). Risk factors for infection are serum creatinine values greater than or equal to 2 mg/dl ([254], [256]) and decreased levels of polyclonal serum Igs ([255], [256]).

Since the 1960s, gram-negative bacilli have become more common pathogens than *Streptococcus pneumoniae* in patients with myeloma ([257]). At disease onset, infections with encapsulated organisms, such as *S. pneumoniae* and *Haemophilus influenzae*, are most common ([257]). After diagnosis, the proportion of infections due to gram-negative bacilli and *Staphylococcus aureus* increases markedly, and they are responsible for more than 90% of deaths from infection ([257]). The mechanism of the immunodeficiency observed in these patients is not understood completely.

Hemostasis in Myeloma

Multiple myeloma can be associated with hemostatic abnormalities, more often bleeding than thrombosis. Bleeding as a complication of myeloma may be present in as many as one-third of patients ([271]) and is related to thrombocytopenia, uremia, hyperviscosity, and interference with the function of coagulation factors.

Rarely, myeloma proteins may also interact with coagulation proteins. The Ig may interfere with fibrin monomer aggregation ([271], [272]) or may serve as a specific inhibitor of thrombin ([273]), von Willebrand factor ([111]), and factor VIII ([271]). Heparinlike anticoagulants have been observed ([274]). Nonspecific inhibitors may also be present, but, unlike the specific inhibitors, they do not correlate with clinically observed bleeding tendencies ([271]). Depression of clotting factors II, V, VII, VIII, and X and fibrinogen has been described ([271]).

The association with thrombosis is less clear because of coexisting factors, such as old age and immobility, that confound the interpretation of available data; however, the risk of thrombosis may be increased in myeloma patients ([271], [275]). Individual cases of aberrance have been reported. Monoclonal proteins have been shown to be responsible for lupus anticoagulants ([276], [277]), acquired protein S deficiency ([278], [279]), acquired activated protein C resistance ([280]), and inhibition of tissue plasminogen activator ([281]).

Fewer than 7% of myeloma patients have a viscosity greater than 4 cP ([208], [209]). Symptoms of hyperviscosity include bleeding (particularly of the oronasal areas), purpura, decrease in visual acuity, retinopathy, neurologic symptoms, dyspnea, expanded plasma volume, and congestive heart failure. Most patients become symptomatic when the serum viscosity is 6 or 7 cP (normal is less than or equal to 1.8 cP).

“Acute Terminal Phase of Plasma Cell Myeloma” and Cause of Death

Bergsagel and Pruzanski ([282]) described the “acute terminal phase” of patients with myeloma, which they observed in approximately one-third of their preterminal patients. They defined the syndrome as *rapidly progressive disease* with an unexplained fever and pancytopenia and a hypercellular marrow. Extramedullary plasmacytomas are also not uncommon preterminally ([283]). As the disease progresses, and at autopsy, cutaneous, visceral, and even meningeal involvement is possible ([283]). Besides *progressive disease*, the most frequent causes of death are infection in 24 to 52% and renal failure in approximately 20% of patients ([210], [246], [282], [283]). Acute leukemia, myelodysplastic syndromes, and hemorrhage are the causes of death in a minority of patients ([210], [282], [283]). In one autopsy series, 85% of patients had evidence of bacterial or fungal infection, and myelomatous involvement was found in the spleen, liver, lymph nodes, and kidneys in 45%, 28%, 27%, and

10% of patients, respectively. Other, less frequent areas of myelomatous involvement were lung, pleura, adrenal glands, pancreas, and testis ([210]).

Special Cases of Myeloma

NONSECRETORY MULTIPLE MYELOMA Nonsecretory multiple myeloma accounts for 1 to 5% of myeloma cases ([209] , [284] , [285] , [286] , [287] and [288]). Immunoperoxidase or immunofluorescence studies should be performed for all patients in whom nonsecretory myeloma is suspected. More than 85% of cases have a cytoplasmic monoclonal protein; in the remainder, no monoclonal protein can be detected in the cytoplasm ([287] , [288] and [289]). Individuals in this latter group are referred to as *nonproducers*. From a clinical standpoint, both are termed *nonsecretory*. With more sensitive testing, such as immunofixation ([290]) and free light chain assays ([291]), many of these so-called nonsecretory patients are found to be low secretors or oligosecretory. At presentation, hypercalcemia and anemia may be present. A reduction in background Igs is common ([287] , [288]). There is minimal to no risk of myeloma kidney ([285] , [287]). Lytic bone disease is present in most patients ([284] , [285] , [286] and [287]). Median survival of these patients is at least as good as for those with secretory myeloma ([284] , [286] , [287]). Response is difficult to document, but, with the new serum assays, quantitation of free light chains is possible in approximately two-thirds of these patients ([291]).
IMMUNOGLOBULIN D MYELOMA IgD myeloma accounts for approximately 2% of all cases of myeloma ([292]). The presence of a monoclonal IgD in the serum usually indicates myeloma, but three cases of IgD MGUS have been documented ([285]). Patients with IgD myeloma generally present with a small band or no evident M spike on serum protein electrophoresis. Their clinical presentation is similar to that of patients with Bence Jones myeloma (light chain myeloma) in that both have a higher incidence of renal insufficiency and coincident amyloidosis, as well as a higher degree of proteinuria than in IgG or IgA myeloma ([292]). IgD myeloma patients, however, appear to have a higher frequency of monoclonal ? light chain than ? light chains ([292]). With an incidence of 19 to 27%, extramedullary involvement is more prevalent in patients with IgD myeloma ([293] , [294] and [295]). Survival with IgD myeloma has been reported to be inferior to that with other forms of myeloma, with a median of 12 to 17 months ([293] , [294] and [295]). In the Mayo Clinic series, however, median survival was 31 months in patients diagnosed after 1980 ([285] , [296]).
IMMUNOGLOBULIN E MYELOMA IgE myeloma is a rare form of myeloma. A disproportionate number of cases are PCL, although the sample size is small, with only approximately 40 cases of IgE myeloma reported in the literature ([297] , [298]).

HISTOPATHOLOGY

The bone marrow microenvironment is hospitable to malignant plasma cells that circulate through the blood. There is a complex interaction among the malignant clone, its surrounding stromal cells, and the remaining immune cells. The morphologic and immunologic phenotypes of myeloma cells can vary, and they often resemble normal plasma cells. Plasma cells are at least two to three times the size of peripheral lymphocytes and are round to oval, with one or more eccentrically placed nuclei (Fig. 98.6). The nucleus, which contains diffuse or clumped chromatin, is displaced from the center by an abundance of rough-surfaced endoplasmic reticulum—the site of specialized Ig synthesis. Intranuclear and cytoplasmic inclusions are not uncommon ([258]). There is a perinuclear clear zone that is the site of the Golgi apparatus, the machinery used for Ig packaging and glycosylation for secretion. Derangements of Ig secretion are responsible for an assortment of cytologic aberrations, including flaming cells, Mott cells, Russell bodies, and Gaucher-like cells. Flaming cells are plasma cells that have intensely eosinophilic cytoplasm with a magenta or carmine coloring of their margins, which is due to plugging of peripheral secretory channels by precipitated Ig or Ig fragments. These cells are most commonly seen in IgA myeloma. Thesaurocytes are large flaming cells with a pyknotic nucleus that is pushed to the side. Mott cells (grape cells or morula forms) are plasma cells filled with dense spherical Ig inclusions; these inclusions are colorless, pink, or blue. Other inclusions are Russell bodies and their intranuclear counterparts (intranuclear dense bodies); these appear cherry red and can be as large as several microns in diameter. Gaucher-like cells are not uncommon in myeloma infiltrates; these cells are macrophages laden with sphingolipids released by the dying plasma cells ([259]). None of these interesting inclusions are specific for malignancy nor do they have prognostic value.

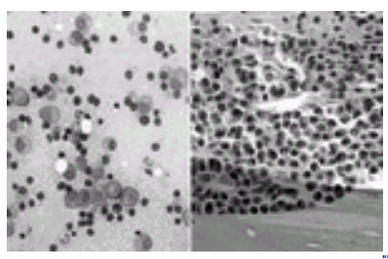

Figure 98.6. Bone marrow: plasma cells on aspirate and biopsy specimen. See Color Plate. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–109, with permission.)

In myeloma, there is often discordance between the nucleus and cytoplasm, the former appearing immature and the latter highly differentiated. Approximately 20% of myeloma cases have plasmablastic morphology: a diffuse chromatin pattern, a nucleus larger than 10 µm or a nucleolus larger than 2 µm, relatively less abundant cytoplasm, and a concentrically placed nucleus with little or no hof ([123] , [260]). Diffuse and nodular infiltration patterns can be observed, although the former is more common. A minority of patients have plasma cells that have a lymphoplasmacytic appearance. Myeloma cells are commonly present in cords around bone marrow microvessels. There is a high correlation between the extent of bone marrow angiogenesis, evaluated as microvessel area, and the proliferating fraction of marrow plasma cells in patients with multiple myeloma ([172] , [261]). Mild marrow fibrosis may be observed in as many as 27% of cases; extensive fibrosis is rare ([262] , [263]). Less than 1% of cases have an extensive idiopathic granulomatous reaction ([258]). Growth patterns may be nodular or infiltrative, or both. In cases in which the marrow involvement is focal rather than diffuse, bone marrow specimens from alternate sites may vary.

The immunophenotype of myeloma cells is complex. In general, myeloma cells are CD45 negative and CD38 and CD138 positive ([264]). CD19 and CD20 are earlier B-cell antigens that are variably expressed on myeloma cells. CD56 is strongly positive in approximately 55 to 78% of myeloma cases ([265] , [266]). CD56-negative myeloma cells tend to be present in more aggressive disease, such as end-stage myeloma or PCL ([167] , [266]). Other surface antigens, such as CD10 (CALLA), CD28, c- *kit*, and CD20, are present on a minority of patients' myeloma cells ([264] , [267] , [268]).

The labeling index of bone marrow plasma cells can be used to identify plasma cell clonality and rate of division. This assay has some value in differentiating MGUS from myeloma and indolent myeloma from active myeloma ([269] , [270]). This determination can be done by 5-bromo-2-deoxyuridine immunofluorescence staining, thymidine labeling, or flow cytometry. In general, myeloma is a low–growth fraction tumor with only a small percentage of cells in the S phase of the cell cycle at any given time.

No individual bone marrow finding, however, is pathognomonic for a malignant plasma cell process; the bone marrow diagnosis of myeloma relies on the percentage of clonal bone marrow plasma cells, with 10% accepted as a cutoff. The clinical diagnosis, of course, is made from a synthesis of bone marrow findings and other clinical features.

DIAGNOSIS

The definitions used to make a diagnosis of multiple myeloma have not been static. In 1973, the Chronic Leukemia-Myeloma Task Force (CLMTF) ([299]) set forth guidelines for the diagnosis of myeloma (Table 98.1). These criteria, which by today's standards are not stringent enough, have been replaced by a more modern definition (Table 98.2) ([269] , [300] , [301]). In the last three decades, the terms and definitions of *MGUS*, *smoldering myeloma*, *indolent myeloma*, and *symptomatic multiple myeloma* ([209] , [300] , [302] , [303]) have evolved and are now to be replaced by the following designations: *MGUS*, *inactive (smoldering) myeloma*, and *active (or symptomatic) myeloma* ([304]) (Fig. 98.7).

TABLE 98.1. Chronic Leukemia-Myeloma Task Force Definition of Multiple Myeloma, 1972

If M protein is present in serum or urine, one or more of the following must be present:
Marrow plasmacytosis =5% in absence of underlying reactive process

Tissue biopsy demonstrating replacement and distortion of normal tissue by plasma cells

More than 500 plasma cells per mm^3 in peripheral blood

Osteolytic lesion unexplained by other causes

If M protein is absent in serum and urine, there must be radiologic evidence of osteolytic lesions or palpable tumors, and one or more of the following must be present:

Marrow plasmacytosis of >20% from two sites in absence of reactive process

Tissue biopsy demonstrating replacement and distortion of normal tissue by plasma cells

Modified from proposed Guidelines for Protocol Studies, Chronic Leukemia—Myeloma Task Force, National Cancer Institute. Cancer Chemother Rep 1972;4:141–173, with permission.

TABLE 98.2. Criteria for Diagnosis of Monoclonal Gammopathy of Undetermined Significance, Smoldering Multiple Myeloma, and Multiple Myeloma, According to Kyle and Greipp

Monoclonal gammopathy of undetermined significance [a]
Serum monoclonal protein (<3 g/dl)
No anemia, renal failure, or hypercalcemia
Bone lesions absent on radiographic bone survey [b]
Bone marrow <10% plasma cells
Smoldering multiple myeloma [a]
Serum monoclonal protein (=3 g/dl) or =10% marrow plasma cells or aggregates on biopsy, or both
No anemia, renal failure, or hypercalcemia attributable to myeloma
Multiple myeloma
Monoclonal protein present in serum or urine
=10% marrow plasma cells on biopsy or histologic evidence of plasmacytoma
Plus one or more of the following:
Anemia
Lytic lesions or osteoporosis and =30% plasma cells in marrow
Bone marrow plasma cell labeling index =1%
Renal insufficiency
Hypercalcemia

[a] Patients with monoclonal gammopathy of undetermined significance and smoldering multiple myeloma must not have solitary plasmacytoma, amyloidosis, or light-chain deposition disease.

[b] Computed tomography or magnetic resonance imaging may be needed to rule out skeletal lesions.

From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:53–109, with permission.

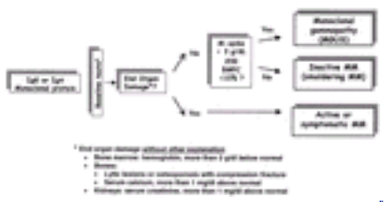

Figure 98.7. Diagnostic criteria. BMPC, bone marrow plasma cells; Ig, immunoglobulin; MGUS, monoclonal gammopathy of undetermined significance; MM, multiple myeloma. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:57–109, with permission.)

This internationally accepted classification schema is derived from more than three decades of experience of treating and studying multiple myeloma patients. Because multiple myeloma includes a spectrum of biologic features, physicians should not feel compelled to start treatment as a result of a single threshold value. The diagnosis of active myeloma is not a straightforward pathologic one; rather, it is a clinical diagnosis that requires thoughtful synthesis of multiple variables. Patients with Durie-Salmon stage I disease, who also meet the criteria for smoldering or asymptomatic myeloma, should be managed expectantly. Median progression-free survival in asymptomatic stage I patients, observed without any therapy, is 12 to more than 48 months ([305], [306], [307] and [308]); for similar stage II patients, progression-free survival is 12 months ([305]). No survival advantage has been demonstrated by treating asymptomatic myeloma patients ([303], [306], [307], [309]).

TREATMENT FOR MULTIPLE MYELOMA

Before starting therapy for multiple myeloma, a distinction must be made between inactive (smoldering, indolent, asymptomatic) myeloma and active myeloma, which requires therapy (Fig. 98.7). Approximately 20% of patients with multiple myeloma are recognized by chance without significant symptoms; such patients can be carefully monitored without instituting therapy. Risk factors for progression include a serum M protein of greater than 3 g/dl, IgA isotype, and a Bence Jones protein excretion of greater than 50 mg/day. Patients with two or more of these features required treatment at a median of 17 months, whereas the absence of any adverse variables was associated with prolonged stability (median, 95 months) (p <.01) ([310]). Patients with one or more lytic lesions ([311]) or circulating plasma cells ([312]) are also at higher risk for early progression.

Once the decision has been made to treat for symptomatic disease, a long-term plan for managing the disease should be formulated before instituting therapy. Figure 98.8 outlines a possible treatment algorithm. Because high-dose therapy with hematopoietic stem cell support has been accepted as an important treatment modality for patients younger than 65 years of age, alkylator-based therapy should be avoided before the collection of hematopoietic stem cells in patients considered candidates for high-dose therapy.

Figure 98.8. Suggested treatment algorithm for patients with newly diagnosed myeloma. At any point in the disease, consider clinical trial or investigational therapy directed at the particular phase of disease *(asterisk)*. VAD, vincristine, doxorubicin, and dexamethasone. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. permission.)

Systemic Therapy

GENERAL COMMENTS Historically, the bifunctional alkylating agents, such as melphalan and cyclophosphamide, have been the foundation of standard therapy for multiple myeloma. Myeloma cells tend to proliferate slowly, and alkylators, whose effectiveness does not rely heavily on cell division and DNA replication, are useful therapeutic agents. Before the recognition of thalidomide's activity in myeloma ([38]), the bifunctional alkylators, nitrosoureas, doxorubicin, and glucocorticoids were the primary agents shown to have single-agent activity against multiple myeloma *in vivo* ([313]). These drugs and vincristine, singly or in combination, have been the mainstay of chemotherapy for myeloma from the early 1960s to the present (Fig. 98.1). Even though vincristine has not been shown to have significant single agent *in vivo* activity or to improve overall survival ([314], [315], [316] and [317]), it is included in multiple therapeutic regimens. Decades of study also suggest that the higher response rates seen with regimens that combine multiple active agents as part of initial therapy do not result in improved overall survival rates ([318]). Interferon-a has been incorporated into induction and maintenance protocols with modest benefit ([35], [319], [320] and [321]). Autologous and allogeneic stem cell transplantation have received considerable attention since the description, by McElwain and Powles in 1983 ([322]), of the benefit of dose intensification of melphalan in patients with multiple myeloma. With the recognition of thalidomide as a new agent with activity against multiple myeloma in 1999 ([38]) and exciting new agents, such as the immune modulatory drugs and proteosome inhibitors ([323], [324]), there is hope that the next four decades of myeloma treatment will be even more promising than the last. Before discussing induction, transplantation, maintenance, and salvage therapies, two general concepts are reviewed: interpretation of study response data and the efficacy of single chemotherapeutic agents commonly used to treat myeloma. Table 98.3 serves as a 1 reference for commonly cited regimens.

TABLE 98.3. Commonly Cited Regimens and Their Dosage Schedules

Drug Regimen	VCR	Mel	CTX	BCNU	ADR	Corticosteroid
MP	—	9 mg/m ^{2}/d, d 1–4 q4wk, or 0.15 mg/kg/d, d 1–7 q6wk	—	—	—	Prednisone, 100 mg/d, d 1–4 q4wk; or prednisone, 60 mg/d, d 1–7 q6wk
CP [a]	—	—	250 mg/m ^{2}/d, d 1–4, or 1000 mg/m ^{2} IV	—	—	Prednisone, 100 mg/d, d 1–4; or prednisone, 50 mg qod
VMCP [b] (325)	1 mg, d 1	6 mg/m ^{2}/d, d 1–4	125 mg/m ^{2} per d, d 1–4	—	—	Prednisone, 60 mg/m ^{2}/d, d 1–4

INTERPRETING STUDY RESPONSE AND SURVIVAL DATA Four points are emphasized regarding the interpretation and comparisons of the myeloma treatment literature. First, definitions of response vary (Table 98.4). Second, definitions of patients who can be evaluated may be different. Third, concurrent corticosteroid therapy, as part of the regimen or for other indications, may confound interpretation of efficacy. Finally, patient population risk and prognosis may differ substantially. Lead-time bias and treatment of MGUS or smoldering myeloma can significantly distort survival figures, as can effective salvage regimens.

TABLE 98.4. Response Criteria

Response	Study (Reference)	Bone Marrow Plasma Cells (%)	M Protein		Duration (Wk)
			Serum	Urine	
Complete response	CLMTF (299)	Not defined			—
	SWOG (333)	<1 [a]	IF -	IF -	8
	ECOG (334)	=3	IF -	IF -	6
	IBMTR [b] (335)	<5	IF -	IF -	6
Objective response	SWOG	—	?=75% [c]	?=90%	8
Improvement	SWOG	—	?=50% [c]	?=75%	8
Partial response	CLMTF [d]	—	?=50%	?=50% [e]	—
	ECOG	—	?=50%	?=90%	6
	IBMTR	—	?=50%	?=90% [f]	6
Stable, no change, or no response	SWOG	—	< ± 25% [c]	< ± 25%	—
	ECOG	Not complete response, near complete response, or partial response			—
	IBMTR	Neither minimum response nor progression			—
Plateau	ECOG	—	< ± 20%	< ± 20%	4
	IBMTR	—	< ± 25%	< ± 25%	12
Progression	SWOG	—	=25% [c]	=25%	—
	ECOG	—	=50% [g]	=50% [h]	—
	IBMTR	—	=25% [i]	=25% [h]	—

IF, immunofixation.

NOTE: Other special categories include:

ECOG near complete response, which includes less than 5% bone marrow plasma cells or complete response by serum and urine tests but no confirmatory bone marrow testing performed.

IFM very good partial response, which includes greater than or equal to a 90% reduction of serum M protein (336).

IBMTR/ABMTR minimal response, which includes a 25 to 49% reduction of serum M protein and a 50 to 89% reduction of 24-hour urinary light chain excretion, which still exceeds 200 mg/24 hours.

[a] Clonal plasma cells as measured by cytoplasmic immunoglobulin flow cytometry.

[b] Makes allowance for nonsecretory myeloma and plasmacytomas.

[c] Change in synthetic index and *not* monoclonal protein concentration.

[d] Response also takes into account reduction in size of plasmacytomas, greater than 2 g/dl hemoglobin rise, weight gain, correction of calcium, renal function, and albumin.

[e] If the pretreatment value is greater than 1 g/24 hours, then decrease to 50% or less of pretreatment value; if the pretreatment value is 0.5 to 1 g/24 hours, then decrease to less than 0.1 g/24 hours; otherwise, if the pretreatment value is less than 0.5 g/24 hours, the variable should not be used to measure response.

[f] Or less than 200 mg/24 hours.

[g] Absolute increase must be at least 2 g/dl.

[h] Absolute increase must be greater than 200 mg/24 hours.

[i] Absolute increase must be greater than 0.5 g/dl.

From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:57–109, with permission.

The measurement of myeloma disease burden, and, therefore its response to therapy, is complex, and investigators have used different methods to define response (Table 98.4). The four most common response criteria are those of the CLMTF (299), the Southwest Oncology Group (SWOG) (333, 337), the Eastern Cooperative Oncology Group (334), and the Autologous Blood and Marrow Transplant Registry and the International Bone Marrow Transplant Registry (335). Although all take into account hemoglobin, calcium, bone changes, and bone marrow plasmacytosis, the main distinction among them is their consideration of the serum and urine M components. With the exception of the old SWOG criteria (333, 337), a partial response has been considered to be a 50% reduction in serum M component and a greater than 50 to 90% reduction in urine M component. In the earliest literature, response included such factors as increasing hemoglobin concentration or performance status or decreasing blood urea nitrogen levels. Some authors have included a minimal response (25 to 49% reduction in serum M protein) as a response. Neither the CLMTF nor SWOG originally had a complete response category, because it was unusual for the M protein to disappear completely. It was not until the advent of high-dose melphalan that investigators, such as Selby et al. (338) and Gore et al. (339), began to define a complete remission category. Their definition, unlike more modern definitions, only included disappearance of M protein as determined by electrophoresis, which is much less sensitive than immunoelectrophoresis or immunofixation. Subsequent definitions have required immunofixation negativity to qualify as complete remission (335). Until approximately 1990, a SWOG objective response was defined as a 75% reduction in the *tumor mass index* (*not* serum M protein) and improvement was defined as a 50 to 74% reduction in the *tumor mass index* (333). The Medical Research Council (MRC) Myelomatosis Trial evaluated the efficacy of treatment not by the degree of M component reduction but by the proportion of patients achieving a plateau phase (326). A new iteration of the SWOG response criteria uses the M component (rather than the tumor mass index) as the primary measurement of the plasma cell burden. In the current SWOG response criteria, the serum and urine protein response groups are defined as follows: (a) a partial response is a 50% reduction in the serum and urine M components, (b) a remission is a 75% reduction in the serum and a 90% reduction in the urine M components, and (c) a complete remission is the total absence of any monoclonal protein by immunofixation of the serum or urine (J. Crowley, *personal communication*, 2003). At the Mayo Clinic, the authors have adopted the Autologous Blood and Marrow Transplant Registry and International Bone Marrow Transplant Registry criteria, into which the authors incorporated the Intergroupe Français du Myélome (IFM) very good partial response category. The roving denominator also creates challenges in interpreting therapeutic studies. Often an intention-to-treat analysis is not used to describe response rates or survival, which artificially inflates these endpoints. Definitions of patients who can be evaluated may often include only those patients who received an adequate trial (3 or 6 months) of therapy, thereby excluding patients with early deaths or progression. In addition, in a steroid-responsive tumorlike myeloma, coincident use of prednisone or dexamethasone (340, 341) as an antiemetic or as therapy for hypercalcemia may seriously confound the results. Finally, the striking heterogeneity of prognoses in myeloma patients cannot be excluded as a major confounding factor in interpreting phase II and III trials. Several prognostic indicators have been identified, including stage, ß $_2$M, labeling index, renal function, and chromosomal abnormalities. However, their predictive value is limited and only skims the surface of myeloma biology and prognosis.

EFFICACY OF SINGLE CHEMOTHERAPEUTIC AGENTS

Melphalan Bergsagel et al. (32) demonstrated the benefit of melphalan in 14 of 24 patients with multiple myeloma. Others (Table 98.5) have substantiated that melphalan as a single agent results in response rates of 20 to 34% and median overall survival duration of 15 to 27 months (33, 326, 342, 343, 345).

TABLE 98.5. Early (1969 to 1982) Randomized Trials: Untreated Myeloma

L-P	L, 100 mg/m ^{2} qd; P, 0.8 mg/kg with taper	137	30	21

C, cyclophosphamide; CTX, cyclophosphamide; IV, intravenous; L, lomustine; M, melphalan; NG, not given; P, prednisone; po, by mouth; qd, daily.

[a] Overall survival is significant at $p = .03$. No corticosteroids allowed in trial.

[b] Survival estimated from survival curves.

[c] Patients stratified for good and poor risk; median survival is given for all patients (good risk, poor risk). The authors note that a much quicker response was observed with prednisone, but there was a worse survival with prednisone in poor-risk patients.

[d] Patients were required to have blood urea nitrogen =10 mmol. Difference not significant ($p = .16$).

[e] All patients had blood urea nitrogen =10 mmol.

[f] Response rate between melphalan and lomustine arms is significant. Median survival is not different.

Cyclophosphamide Korst et al. (34) were the first to report on the activity of oral cyclophosphamide. Twenty-four percent of multiple myeloma patients achieved a partial response (50% M protein reduction), and 48% had objective improvement—that is, an improvement in the peripheral blood values, bone marrow findings, or serum blood urea nitrogen. Median survival was 24.5 months in all 207 patients and 32 months in the group that received at least 2 months of cyclophosphamide therapy. The single-agent activity of cyclophosphamide (Table 98.5) has been demonstrated in a placebo-controlled trial (342), in multiple studies of previously untreated patients (344 , 346), and in those who relapsed or had refractory disease (348).

Glucocorticoids In 1950, Thorn et al. (29) reported the first observations on the beneficial effects of adrenocorticotropic hormone in myeloma. Adams and Skoog (28) observed a marked decrease in the myeloma serum protein in 18 of 26 patients treated with corticosteroids. Surprisingly, Mass (349) failed to show a difference between the survival of 55 patients randomly assigned to prednisone therapy or placebo, despite clinical improvement in the former group. Subsequently, high-dose corticosteroids (Table 98.6) have been shown to produce response rates of 40 to 50% in previously untreated patients, and 25% in refractory or relapsed patients (30 , 331 , 341 , 350 , 351 , 352 and 353). Despite their contribution to quicker and more abundant responses, there are conflicting data as to whether corticosteroids prolong survival (343 , 345 , 355).

TABLE 98.6. Corticosteroids

Study (Reference)	Agent	Schedule	Disease Status	N	Response Rate (%)	Overall Survival (mo)
Adams and Skoog, 1957 (28)	Corticosteroids	Various	All	NG	NG	NG

[a] According to SWOG response criteria, response according to tumor mass index.

Modified from Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:57–109, with permission.

The mechanism of action of this drug class is complex. Corticosteroids suppress the production of cytokines that are important in myeloma growth, such as IL-6 and IL-1ß, and reduce NF-?B activity, resulting in enhanced apoptosis (356 , 357 , 358 and 359).

Vincristine Alexanian et al. (360 , 361) suggested that regimens that included vincristine resulted in better patient outcome than protocols that did not include this agent. The theory behind its posited usefulness was that, after an initial kill of myeloma cells by alkylating agents, the subsequent increase in the mitotic index made myeloma cells more sensitive to vincristine (362). Reports by Lee et al. (363), Salmon (364), and Case et al. (327) have been cited as confirmatory evidence for activity of vincristine in myeloma. However, several randomized controlled trials do not support this premise (315 , 316 , 347 , 365) (Table 98.7). The most compelling of these is the fourth MRC Trial in Myelomatosis, which randomized 530 newly diagnosed myeloma patients to monthly melphalan and prednisone, with or without monthly vincristine. Median survival in both arms was 26 months (315). Although never evaluated as a single agent in newly diagnosed myeloma, vincristine has little activity as a single agent in refractory disease. Twenty-one patients were treated with a 0.5-mg bolus of vincristine followed by 0.25 to 0.50 mg/m ^{2}/day as a continuous infusion over 5 days on a 3-week schedule. Two patients had transient responses (1.2 and 2.2 months) (314). Finally, the activity credited to vincristine as a maintenance therapy is also ambiguous. Although a superior survival (35 months vs. 27 months, $p = .003$) was reported in patients treated with single agent melphalan and maintained on bimonthly vincristine (1 mg/m ^{2}) and prednisone (0.6 mg/kg for 7 days), the benefit could easily be attributed to prednisone alone (386).

NG, not given; NS, not significant; RR, response rate.

[a] Except where stated, response is according to Myeloma Task Force criteria or modification.

[b] SWOG response criteria.

[c] Significantly superior survival in combination chemotherapy arms compared to MP in the 174 stage III patients but not in the 74 stage I or II patients.

[d] The sequential arm was significantly worse than the MP ($p = .01$) or the MCBP ($p = .02$) arms and marginally worse than MCBPA arm ($p = .09$).

[e] Part of an interferon trial; stage III patients only.

Modified from Myeloma Trialists' Collaborative Group. Combination therapy versus melphalan plus prednisone as treatment for multiple myeloma: an overview of 6,633 patients from 27 randomized trials. J Clin Oncol 1998;16:3832–3842.

Anthracyclines Doxorubicin is the most commonly used anthracycline in the treatment of myeloma, but it has not been studied as a single agent in newly diagnosed myeloma patients. Its activity as a single agent in relapsed or refractory disease is modest, with response rates of approximately 10% (36, 387). A phase II trial of mitoxantrone as a single agent (12 mg/m ^{2} every 3 weeks) yielded a partial response rate of 3% (1 of 35). An additional four patients showed clinical improvement lasting 4 to 7 months (388). Idarubicin is another anthracycline that has been studied in multiple myeloma. Response rates of 0 to 27% have been observed in relapsed and refractory patients with single agent oral regimens (30 mg per week in three divided doses given 3 of 5 weeks or 40 mg/m ^{2} every 3 weeks) (389, 390).

Etoposide In relapsed and refractory disease, single agent etoposide (200 to 250 mg/m ^{2} over 5 days) has minimal activity; in 85 patients, the response rate was less than 5% (391). Barlogie et al. (392) treated 14 patients with 200 mg/m ^{2} by continuous infusion, and two patients responded. In addition, there are two anecdotal reports of activity of low-dosage (25 to 50 mg/day) oral etoposide (393, 394).

Nitrosoureas The nitrosoureas have single-agent activity in myeloma. In a randomized trial of 361 previously untreated patients (Table 98.5), objective response frequency with BCNU (40%) and lomustine (CCNU) (42%) was lower than that of melphalan (59%), although the survivals for all groups were not significantly different (347).

Interferon Since the original report by Mellstedt et al. (35) of activity of human leukocyte interferon in patients with myeloma, multiple studies have confirmed the findings with daily human leukocyte interferon [3 to 9 million international units (MU) per day] (319, 395) and with recombinant interferon-a (321, 396). Although the earliest studies suggested response rates of as great as 60%, subsequent studies yielded rates of 15 to 20% (395, 397, 398 and 399). Toxicity was not inconsequential (399). *In vitro* activity had good predictive value for *in vivo* clinical response in 26 patients studied (397). However, interferon has a stimulatory effect in approximately one-third of myeloma samples tested *in vitro* (397).

Thalidomide Recognition of the role of increased angiogenesis in the pathogenesis and progression of myeloma (172) and evidence of thalidomide's antiangiogenic properties (400) led to clinical trials in multiple myeloma (38, 401). The observed responses in patients without high-grade angiogenesis suggest that thalidomide may act via mechanisms other than antiangiogenesis (402). The actual antitumor mechanism is likely complex. *In vitro* data suggest that the drug and its metabolites may inhibit angiogenesis but, in addition, may modulate adhesion molecules of myeloma cells and their surrounding stroma, may modulate cytokines, and may affect natural killer cells. There is recent evidence that thalidomide and its analogs induce apo-ptosis and G_1 growth arrest in myeloma cells (402). Multiple studies have confirmed the activity of thalidomide as a single agent in relapsed myeloma (Table 98.8). Response rates are in the range of 25 to 45%, with a median response

duration of 9 to 12 months and a 2-year progression-free survival rate of 10 to 20% ([38], [404], [407], [408] and [409], [417]). Thalidomide is now considered a standard therapy for multiple myeloma, although Food and Drug Administration approval for this indication is pending.

TABLE 98.8. Thalidomide

Study (Reference)	Thalidomide Dose (mg/d)	Dexamethasone	Patients (No.)	Response Rate (%)
Previously untreated myeloma				
Weber et al. ([403])	100–600	—	28	36
Rajkumar et al. ([404], [405])	200–800	—	16	38
Rajkumar et al. ([406])	200	40 mg, d 1–4, 9–12, and 17–20 (odd cycles), d 1–4 (even cycles)	50	64

Tosi et al. ([408])	100–800	—	11	36
Juliusson et al. ([409])	200–800	—	23	43
Weber et al. ([410])	200–800	—	44	25
Durie and Stepan ([411])	50–400	—	33	24
Rajkumar et al. ([412])	200–800	—	32	38
Kneller et al. ([413])	200–800	—	17	65
Rajkumar et al. ([412])	200–800	—	16	25
Palumbo et al. ([414])	100	40 mg, d 1–4 each month	77	41
Dimopoulos et al. ([415])	200–400	40 mg, d 1–4, 9–12, and 17–20, followed by d 1–4 monthly	44	55
Coleman et al. ([416])	50–200	40 mg every 2 wk and clarithromycin, 250–500 mg twice a day	24	100
Weber et al. ([410])	200–800	20 mg/m^2, d 1–5 and 15–18	47	52

Other Agents Barlogie et al. ([392]) explored the usefulness of cisplatin therapy for patients with myeloma. Fourteen patients were treated with 10 mg/m^2 for 7 days by continuous infusion, and two patients responded. The drug has been incorporated into other regimens for relapsed disease ([392], [418], [419]) and induction therapy ([420]). Cytosine arabinoside ([421]), teniposide ([422]), topotecan ([423]), deoxycoformycin ([424], [425]), and paclitaxel ([426], [427]) have been reported to produce response rates of 7%, 28%, 16%, 0 to 15%, and 15 to 29%, respectively. Topotecan induces significant toxicity including grade 3 and greater granulocytopenia and thrombocytopenia in 93% and 53% of patients, respectively ([423]). Patients treated with paclitaxel were premedicated with 40 mg of dexamethasone every 21 days ([426], [427]), bringing into question whether the observed responses were attributable to dexamethasone or paclitaxel. Agents that do not appear to have any activity in myeloma include drugs that are interesting from a historical perspective and drugs that have known activity in other diseases. Agents in the former category include diamidines, such as stilbamidine; 1-aminocyclopentanecarboxylic acid; amsacrine ([428], [429]); aclarubicin ([430]); chlorozotocin ([431]); hexamethylmelamine ([432]); and azaserine ([33]). Other commonly used agents without activity against myeloma include methotrexate, 6-mercaptopurine, 6-thioguanine, 5-fluorouracil, fluorodeoxyuridine, hydroxy-urea, mitomycin C ([33]), vinblastine, vindesine ([341]), carboplatin ([433]), bleomycin ([387]), all- *trans*-retinoic acid, fludarabine ([434]), and 2-chlorodeoxyadenosine ([435]). Although Durie et al. ([436]) reported a 57% response rate with clarithromycin, subsequent reports did not corroborate this response rate, and the activity observed in the original report was attributed to concurrent corticosteroid therapy ([437], [438] and [439]).

INDUCTION CHEMOTHERAPY REGIMENS

Single Agent with or without Corticosteroids for Induction

Melphalan as Induction Therapy Since early reports by Blokhin et al. ([31]) and Bergsagel et al. ([32]), various schedules of melphalan have been tried, including continuous daily dose, 6 to 10 mg per day for 2 to 3 weeks, followed by maintenance therapy of 0.01 to 0.03 mg/kg per day; intermittent total doses of 0.25 mg per day given for 4 days every 4 to 8 weeks; or 0.15 mg/kg per day for 7 days every 6 weeks ([343], [440]). Several studies suggest that the intermittent schedule is superior to continuous daily dosing ([343], [440]). The combination of melphalan and prednisone (Table 98.5 and Table 98.7) has been studied extensively ([337], [345]). Response rates are 40 to 60%, and anticipated median survivals are 18 to 42 months ([306], [315], [318], [325], [328], [329], [337], [343], [345], [346], [361], [365], [366], [369], [370], [374], [375] and [376], [378], [379], [381], [382], [383], [384] and [385], [441]). Because of the variable gastrointestinal tract absorption of melphalan, intravenous regimens of 15 to 25 mg/m^2 every 4 weeks along with oral prednisone or dexamethasone have been tried and resulted in response rates of 50 to 82% ([385], [442]). Not until the report by McElwain and Powles ([322]) on the successful use of high-dose melphalan (140 mg/m^2 intravenously) had dose intensity (Table 98.9) been studied in myeloma. In previously untreated patients, Selby et al. ([338]) confirmed a 78% response rate, including 27% of patients whose M component was no longer visible by protein electrophoresis. This dose intensity without stem cell salvage was associated with prolonged, severe thrombocytopenia and leukopenia (lasting a median of 24 and 28 days, respectively). Treatment-related mortality was 19%. The benefit of melphalan dose intensification was confirmed by others who used attenuated doses (50 to 70 mg/m^2) and reported response rates of 50 to 85% ([444], [445], [447]). These dose schedules are associated with 8 and 6 days of severe neutropenia and thrombocytopenia, respectively ([445]).

TABLE 98.9. Intravenous Melphalan

Study (Reference)	Agent	Schedule	Disease Status	N	Response Rate (%)	Overall Survival (mo)
McElwain and Powles ([322])	Melphalan	100 to 140 mg/m^2 × 1	Untreated, refractory	9	100	NG
Selby et al. ([338])	Melphalan	140 mg/m^2 × 1	Untreated	41	78	NG
			Relapsed	15	66	—
Cornwell et al. ([386])	Melphalan and prednisone	Melphalan, 16 mg/m^2 q2wk × 3, then q4wk; prednisone, 0.8 mg/kg/d with taper	Untreated	195	38	NG
Petrucci et al. ([443])	Melphalan	25 mg/m^2, d 1	Refractory	34	35	8

NG, not given.

Cyclophosphamide as Induction Therapy Since the original report by Korst et al. ([34]) of the usefulness of cyclophosphamide in myeloma patients, several single agent induction regimens have been studied. Despite documented equivalency for low-dose oral regimens of cyclophosphamide and melphalan ([344]), induction therapies of melphalan and prednisone tend to be preferred over those of cyclophosphamide and prednisone. Most commonly, cyclophosphamide has been used in multidrug combinations for induction, for therapy in relapse, and for stem cell mobilization rather than as a single agent for induction, as has melphalan. For newly diagnosed myeloma, oral daily dosing of cyclophosphamide (150 mg per day) ([344], [448], [449]) or intravenous doses of 600 mg/m ^{2} every 3 weeks ([346]) with or without prednisone has resulted in a response rate of approximately 25% and median survival of 24 months.

Corticosteroids as Induction Therapy In previously untreated patients, approximately 43% have a 75% decrement in their *tumor mass index* with single-agent high-dose dexamethasone therapy (Table 98.6) ([351]), which is only 15% lower than for vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD). Dexa-methasone in lieu of VAD for induction in those patients destined for stem cell collection may be potentially advantageous. With single-agent dexamethasone, insertion of a long-term central venous catheter can be postponed until conditioning for the stem cell transplantation is required, thereby reducing the likelihood of catheter-related complications (i.e., thrombosis and infection) ([351]). This strategy has been used successfully, resulting in adequate collections of peripheral blood stem cells without any apparent adverse effects on complete remission rates or progression-free survival in a single-arm study ([450]).

Interferon as Induction Therapy Although the earliest studies of interferon suggested response rates of as great as 60%, subsequent studies produced rates of 15 to 20% ([395], [397], [398] and [399]). Ahre et al. ([451]) randomized 55 patients to melphalan and prednisone or interferon (3 to 6 MU daily); response rates in the melphalan and prednisone arm were significantly higher than in the interferon arm (44% vs. 14%, p <.001). Interferon-a and dexamethasone have been combined as an induction regimen in patients with newly diagnosed myeloma and a low tumor mass. A retrospective comparison showed that the response rate of this regimen (57%) was similar to the response rate (48%) previously observed with dexamethasone alone ([452]).

Thalidomide as Induction Therapy Thalidomide represents a new and distinct class of agents with significant activity against myeloma (Table 98.8). When thalidomide is used as a single agent in previously untreated patients, response rates of approximately 35% may be achieved ([403], [404]). Rajkumar et al. ([453]) showed that combined thalidomide and dexamethasone therapy in previously untreated patients resulted in response rates of 64%. Limited use of thalidomide pre–stem cell mobilization does not impair stem cell collection or engraftment, although preliminary data suggest that there may be a problem with longer continuous use ([454], 454a).

Combination Chemotherapy for Induction A combination of multiple active agents in an effort to achieve synergy was a logical corollary. For expediency, these regimens can be separated into four categories: alkylator-based without anthracyclines, anthracycline-containing regimens, anthracycline-containing regimens with intensified doses of corticosteroids, and induction regimens incorporating interferon. Thirty years of study indicate that multiagent combination chemotherapy as initial therapy results in higher response rates, but not longer overall survival rates, than standard melphalan and prednisone therapy ([318]) (Table 98.7; Fig. 98.9). Although it has been suggested that patients with more advanced disease benefit from combination chemotherapy as compared to melphalan ([326], [362], [367], [375], [455]), this hypothesis has not been proven ([306], [318]). In time, when physicians are better able to ascertain biologic differences ([456]) between myeloma patients and to classify them properly in a fashion similar to that used in lymphomas, a survival benefit with multiagent chemotherapy may be detected in particular subgroups.

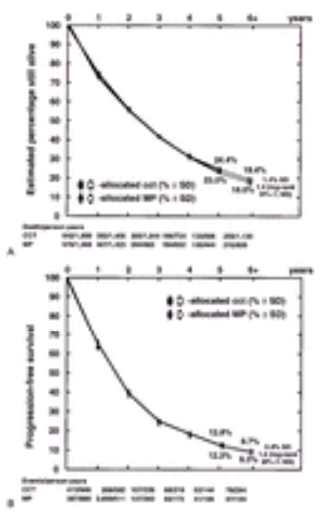

Figure 98.9. Melphalan and prednisone (*MP*) versus combined chemotherapy (*CCT*) as induction. Results from 6633 patients from 27 randomized trials. **A:** Overall survival. **B:** Response duration. NS, not significant. (From Myeloma Trialists' Collaborative Group. Combination chemotherapy versus melphalan plus prednisone as treatment for multiple myeloma: an overview of 6,633 patients from 27 randomized trials. Myeloma Trialists' Collaborative Group. J Clin Oncol 1998;16:3832–3842, with permission.)

Alkylator-Based Combination Chemotherapy without Anthracycline for Induction The 1970s and 1980s were a testing ground for various combinations of alkylators, corticosteroids, and doxorubicin. Melphalan, cyclophosphamide, and prednisone ([360]); BCNU, cyclophosphamide, and prednisone ([366], [369]); melphalan, cyclophosphamide, BCNU, and prednisone (MCBP) ([360], [367]); and vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) ([360]) resulted in response rates of 47%, 37 to 50%, 49 to 68%, and 62%, respectively. Median survivals with these regimens were 25 to 36 months ([360], [366], [367], [369]). Lee and Case ([327]) introduced the five-drug regimen of vincristine, BCNU, melphalan, cyclophosphamide, and prednisone (VBMCP or the M-2 regimen), which included the same four drugs as MCBP plus vincristine; dose intensities, however, were different in these two regimens. Response rate for VBMCP was approximately 85% in previously untreated patients with a median survival of 38 months ([327], [457]). The success of the VBMCP regimen supported the value of vincristine. However, the fourth MRC trial, which randomized 530 previously untreated patients with myeloma to melphalan and prednisone versus melphalan, vincristine, and prednisone, revealed no difference in response rate or overall survival between the two arms ([315]). VMCP has not produced any response or survival advantage over melphalan and prednisone ([379], [380]). Finally, the MOCCA regimen, which is essentially VBMCP, with CCNU replacing BCNU, results in response rates similar to those for VBMCP (75%), but, again, no survival benefit in comparison to melphalan and prednisone ([329]). Although subsequent randomized trials have substantiated the superior response rates of VBMCP over standard melphalan and prednisone (Table 98.7), they have not demonstrated superior survival ([328], [365], [376], [377]). In fact, the metaanalysis performed by the Myeloma Trialists' Collaborative Group ([318]), involving 6633 patients in 27 randomized trials, revealed a superior response rate (60.2% vs. 53.2%, p <.000001, two-tailed) but no survival benefit for combination chemotherapy over standard melphalan and prednisone (Fig. 98.9A). A prior metaanalysis of 18 published trials (3814 patients) also demonstrated no benefit for combination chemotherapy in terms of survival. There might be a survival advantage in the subgroup of patients with more aggressive disease ([455]), but this was not substantiated in the larger metaanalysis ([318]).

Combination Chemotherapy with Anthracycline for Induction The use of alkylator- and doxorubicin-based combination chemotherapy was stimulated by a report on the benefits of a combination of doxorubicin and BCNU in patients who had become resistant to melphalan ([458]). Regimens like melphalan, doxorubicin, and prednisone; cyclophosphamide, doxorubicin, and prednisone; vincristine, cyclophosphamide, doxorubicin (Adriamycin), and prednisone (VCAP); and vincristine, BCNU, doxorubicin (Adriamycin), and prednisone (VBAP) were tried; by SWOG response criteria, objective response rates were 41%, 46%, 64%, and 61%, respectively ([360], [459]). Median survival ranged from 30 to 32 months; subsequent analysis demonstrated a superior median survival for the VBAP arm of 37 months ([460]). Enthusiasm for alternating VMCP and VBAP (or VCAP) was generated by the SWOG study of 237 patients randomized to melphalan and prednisone or the previously mentioned regimens (Table 98.9) ([325], [374]). Response rates were superior in the alternating combination chemotherapy arms compared to the melphalan arm. Survival was also superior in the combination chemotherapy arms (43 months vs. 23 months for melphalan and prednisone, p = .004) ([459]). A subsequent analysis with longer follow-up showed less separation of the survival curves (median survival, 36 months vs. 25 months) ([460]). The survival benefits of this initial study were not reproducible in subsequent studies ([361], [378], [381], [382] and [383], [461], [462]). The fifth MRC myelomatosis trial randomized patients to ABCM (VBAP/VMCP without the vincristine or prednisone) or melphalan as a single agent on the basis of findings emanating from the fourth MRC trial, which demonstrated a lack of benefit attributable to the addition of vincristine. Median survival in the ABCM group was superior to that of the melphalan-only arm (32 months vs. 24 months, p = .0003) ([326]). When corrected for adverse prognostic factors, such as elevated ß $_2$M values, low hemoglobin values, renal insufficiency, performance status, and stage, the significance of the survival difference was p = .003 ([317]).

Combination Chemotherapy with Doxorubicin and Dose-Intensive Corticosteroids for Induction The next level of combination chemotherapy includes programs that contain anthracyclines and high-dose corticosteroids. VAD-like regimens are commonly used as induction therapy before stem cell collection and transplantation. These regimens include VAP ([341]); VAD ([330]); vincristine, doxorubicin (Adriamycin), and methylprednisolone (VAMP) ([331]); and cyclophosphamide, vincristine, doxorubicin (Adriamycin), and methylprednisolone (C-VAMP) ([331]), all of which had been tried with salutary effect in relapsed disease. Subsequently, several of these regimens were applied in previously untreated patients, and response rates were 50 to 84% ([332], [463], [464], [465], [466], [467], [468], [469], [470] and [471]). The complete response rate of C-VAMP is higher than that of VAMP alone, but survival is not different ([332]). Several other variations have been reported in which alternative anthracyclines or corticosteroids were used ([384]). Median survival for patients treated initially with VAD is approximately 36 months ([472]). In a randomized trial of 151 patients comparing the regimen of mitoxantrone (Novantrone), vincristine (Oncovin), and high-dose prednisone (NOP) to melphalan and prednisone,

response rates were equivalent (approximately 60%), but overall survival was inferior in the NOP arm (14 months vs. 31 months, $p = .02$) ([384]). Response rates of 80% have also been achieved using the cyclophosphamide, doxorubicin, and dexamethasone regimen ([473]). The addition of etoposide to cyclophosphamide, vincristine, doxorubicin (Adriamycin), and dexamethasone (CVAD) appears to contribute only toxicity ([474]).

Combination Chemotherapy with Interferon for Induction Interferon has been combined with melphalan and prednisone ([475], [476], [477], [478], [479], [480], [481] and [482]); VMCP ([481], [482], [483], [484] and [485]); VMCP-VBAP ([481], [482]); prednisone, cyclophosphamide, doxorubicin (Adriamycin), and BCNU ([486], [487]); VAD ([488]); VBMCP ([489]); VBAP ([481], [482]); and cyclophosphamide ([490]) as part of an induction regimen. Results have been mixed. Two metaanalyses have been performed in an attempt to reconcile these conflicting results ([481], [482]). The first, reported in 2000 by Ludwig and Fritz ([481]), used published data and included 17 induction trials ([475], [476], [477], [478], [479], [480], [481] and [482], [484], [485], [486], [487] and [488], [490]) with 2333 evaluated patients; the second, reported by the Myeloma Trialists' Collaborative Group in 2001 ([482]), used primary data from 12 induction trials ([475], [476], [477], [478], [479], [480], [481] and [482], [484], [486], [487], [489], [490] and [491]) involving 2469 patients. Overall, the results were similar. In the first metaanalysis, the benefits attributable to the addition of interferon to the induction regimen included a 6.6% higher response rate ($p < .002$) and a 4.8-month and 3.1-month prolongation of relapse-free ($p < .01$) and overall survival ($p < .01$) ([481]). In the second metaanalysis, patients receiving interferon had a slightly better response rate (57.5% vs. 53.1%, $p = .01$) and progression-free survival (30% vs. 25% at 3 years, $p < .0003$), with a superior median time to progression of approximately 6 months. The survival advantage of 2 months, however, was not significant ($p = 0.1$) ([482]). Figure 98.10 demonstrates progression-free survival and overall survival in patients receiving interferon as induction or maintenance versus those who received none ([482]).

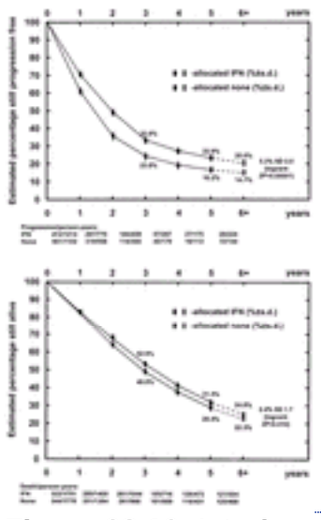

Figure 98.10. Interferon (IFN) chemotherapy as induction or maintenance therapy influences progression-free and overall survival curves from the metaanalysis by the Myeloma Trialists' Collaborative Group. Results from 24 randomized trials and 4012 patients. IFN curves include patients who received IFN as part of induction or of maintenance program. **A:** Progression-free survival after 23 months with IFN and 17 months without. **B:** Overall median survival after 40 months with IFN and 36 months without. (From Myeloma Trialists' Collaborative Group. Interferon as therapy for multiple myeloma: an individual patient data overview of 24 randomized trials and 4012 patients. Br J Haematol 2001;113:1020–1034, with permission.)

These metaanalyses suggest that incorporation of interferon into induction provides a modest prolongation of response and, possibly, of survival. The question is whether these significant differences are clinically relevant. Wisloff et al. ([492]) evaluated the quality of life of 583 patients randomized to melphalan and prednisone or melphalan, prednisone, and interferon as induction. During the first year of treatment with interferon, the patients reported significantly more fever, chills, dry skin, fatigue, pain, nausea and vomiting, and appetite loss than the control patients. After the first year, however, the only symptom that was reported more often was dizziness. Although patients receiving interferon had a 5- to 6-month prolongation of the response and plateau phase, there was no late quality-of-life benefit observed to compensate for the early impairment. The authors questioned the clinical value of the plateau phase prolongation and reported that only 60% of patients continued to receive interferon after 24 months, suggesting that their data might underestimate the potential toxicity of the drug. A cost-effectiveness estimation for induction was also performed. The authors concluded that interferon administration and monitoring expenses amounted to $41,319.28 to save a year of life of myeloma patients, assuming a dosage of 12.1 MU per week ([481]). A study on patient preference also deserves mention. Ludwig et al. ([493]) surveyed cancer patients about acceptable toxicity of an unidentified drug, which had the toxicity profile of interferon, relative to its hypothetical benefit. Approximately 50% of surveyed patients accepted the toxicity of an unidentified drug if remission or survival, or both, would be improved by at least 6 months. Of those patients who rejected the 6-month hypothetical benefit, 25 to 50% were willing to accept the toxicities if the benefits were greater than or equal to 12 months.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Autologous Transplant

To overcome resistance of the myeloma cells to conventional-dose chemotherapy, McElwain and Powles ([322]) pioneered the use of high-dose melphalan to treat multiple myeloma and PCL. The treatment was complicated by prolonged myelosuppression. Barlogie et al. ([494]) used a regimen combining high-dose melphalan with total body irradiation supported by autologous bone marrow transplantation in multiple myeloma patients refractory to VAD.

Cure rarely, if ever, occurs, and almost all patients relapse after autologous stem cell transplantation. Although high-dose therapy followed by autologous stem cell transplantation is not curative, it improves response rates and survival ([465], [494], [495], [496], [497], [498], [499], [500] and [501]). Response rates with transplantation are 75 to 90%, and complete response rates are 20 to 40% ([495]). The results of single institution and phase II trials are difficult to analyze because selection of patients for transplantation is subject to selection bias regarding the stage of disease, performance status, age, and renal function. The Nordic Myeloma Study Group ([502]) prospectively evaluated the impact on survival of high-dose therapy in the entire population of myeloma patients younger than 60 years of age. Survival was compared with that of historic controls derived from previous Nordic population–based studies of conventional-dose chemotherapy. Survival was prolonged with the high-dose therapy. Median survival of the control group was 44 months, and the median was not yet reached for the high-dose therapy group at 60 months. Other historical comparisons have suggested that survival in good-risk patients receiving only conventional chemotherapy is similar to that reported in selected series of patients treated with autologous transplantation ([503]). These examples illustrate the need for prospective randomized trials.

The IFM ([336]) published the first randomized trial comparing high-dose chemotherapy followed by autologous bone marrow transplantation with conventional chemotherapy (Fig. 98.11). Two hundred patients with previously untreated multiple myeloma were randomized to receive high-dose chemotherapy followed by an autologous bone marrow transplantation or combination intravenous chemotherapy. The 5-year event-free survival (28% vs. 10%) and overall survival rates (52% vs. 12%) were higher in the transplantation group. An updated analysis with a median follow-up of 7 years confirmed that high-dose chemotherapy improves event-free survival (median, 28 months vs. 18 months) as well as overall survival (median, 57 months vs. 44 months) ([504]).

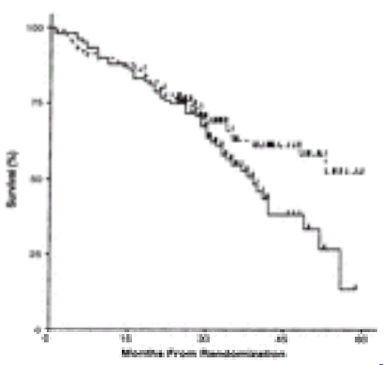

Figure 98.11. Attal transplant curve. (From Attal M, Harousseau JL, Stoppa AM, et al. A prospective, randomized trial of autologous bone marrow transplantation and chemotherapy in multiple myeloma. Intergroupe Français du Myélome. N Engl J Med 1996;335:91–97, with permission.)

The Spanish Cooperative Group ([505]) reported a prospective trial of 216 patients treated initially with four cycles of VBMCP and a regimen of vincristine, BCNU, doxorubicin, and dexamethasone. Responding patients were then randomized to receive eight additional courses of chemotherapy or intensification with high-dose therapy and stem cell transplantation. Among the 164 randomized patients, the complete response rate was significantly improved in the transplant recipients, but the progression-free survival and overall survival were not. These preliminary data have brought into question the magnitude of the survival benefit achieved with transplantation, but autologous stem cell transplantation is the current standard of care for eligible patients. These data are similar to those of the case-control study published by Alexanian et al. ([506], [507]). Sixty-eight patients with responsive disease received stem cell transplant within 1 year after the start of induction chemotherapy. Control patients were responsive to the same therapies but did not undergo stem cell transplantation because of refusal or economic hardship. The median overall survival of patients who underwent stem cell transplantation was 10 months longer than that of controls, but this did not reach statistical significance (p = .12).

Autologous peripheral blood stem cell transplantation has replaced autologous bone marrow transplantation, because engraftment is more rapid and there is less contamination with myeloma cells ([501], [508], [509]). Hematopoietic stem cells should be collected before the patient is exposed to alkylating agents ([499], [510]), because prolonged melphalan exposure leads to an impaired harvest of peripheral blood stem cells when stem cells are mobilized with chemotherapy plus growth factor ([511]) or growth factor alone ([512]). Even after four to six cycles of VMCP-VBAP, which is a regimen containing low doses of melphalan, sufficient stem cells could not be collected for transplantation in approximately 10% of patients ([336]). In contrast, successful stem cell collection is achieved in 95 to 100% of multiple myeloma patients treated with VAD before mobilization with high-dose cyclophosphamide ([502]). The absolute number of CD34 $^{+}$ cells per kilogram is the most reliable and practical method for determining the adequacy of a stem cell collection. The mortality rate from autologous stem cell transplantation is currently less than 5%. Age older than 65 years alone is not a contraindication for transplantation, although there are no randomized data proving or disproving the usefulness of transplantation in this age group. Such patients are candidates for transplantation if they have good functional status and limited comorbidities ([513], [514]).

TRANSPLANTATION FOR PRIMARY REFRACTORY MYELOMA In contrast to the experience with malignant lymphoma, stem cell transplantation appears to be effective for patients with primary resistant disease ([506], [515]). Patients with multiple myeloma in whom first-line therapy, such as VAD, fails can be sensitive to high-dose chemotherapy with stem cell reconstitution. Alexanian et al. ([506]) reported a decrease of 75% in tumor burden in 56% of patients and a marked improvement in survival compared to matched historical controls. Rajkumar et al. ([515]) also looked at stem cell transplantation in primary refractory disease and found no differences in overall and complete response rates between patients with primary refractory and relapsed disease. The median survival of the entire cohort from the time of diagnosis was 53 months.

SINGLE VERSUS DOUBLE TRANSPLANTATION The role of double or tandem autologous stem cell transplantation is controversial. Barlogie et al. ([420], [516], [517] and [518]) at the University of Arkansas advocate tandem (double) autologous stem cell transplantation to improve complete response rates and survival. In tandem transplantation, patients receive a second planned transplant on recovery from the first procedure. In a study of 231 patients with newly diagnosed myeloma, the overall survival with this approach was 68 months ([420]). Approximately 50% of patients in this cohort were 50 years of age or younger and had less than stage III disease. These results have prompted additional studies. Preliminary data from four different randomized trials indicated a slight increase in response rates and, possibly, event-free survival with tandem transplantation ([504]) but no clear improvement in overall survival (Table 98.10). In the largest study, that is, the IFM 94 study, at 2-year follow-up, there was no difference in event-free or overall survival between double and single autologous stem cell transplants ([523]). In another evaluation of this study of 403 patients ([504]), a subgroup of patients, those receiving stem cells derived from the peripheral blood rather than the bone marrow, had a modest overall survival benefit with tandem transplantation. There was no obvious explanation for the observed difference in survival between the groups. Most recently, the authors have reported in abstract form that this study is finally positive. Although the response rate was not significantly different between the two groups (complete response and very good partial response 42% in the single-transplant arm vs. 50% in the double-transplant group, p = .15), event-free survival and overall survival were improved in the double-transplant arm. Median survival in the two arms was not different, but the 7-year postdiagnosis probability of event-free survival was 20% [95% confidence interval (CI), 14 to 26] in the double-transplant arm versus 10% (95% CI, 5 to 15) in the single-transplant arm (p <.03). Overall survival rates 7-years postdiagnosis were 42% (95% CI, 34 to 49) for double transplants and 21% (95% CI, 13 to 29) for single transplants (p <.01). In this trial, four factors were associated with a longer survival: low ß $_2$M levels at diagnosis (p <.01), young age (p <.05), low lactate dehydrogenase at diagnosis (p <.01), and treatment arm (p <.05). The final results of this trial and the other three trials (Table 98.10) that are negative to date will provide a definitive answer to the question of tandem transplantation. Because the role of tandem or double transplantation is not settled, it is reasonable to harvest enough stem cells for two transplants.

TIMING OF TRANSPLANTATION The timing of the transplantation, up front as consolidation therapy or as salvage therapy at the time of relapse, is also a point of controversy. In one study ([524]), 185 patients were treated with one to two cycles of an intensified regimen of cyclophosphamide, hydroxydaunomycin, vincristine, and prednisone (CHOP) followed by peripheral blood stem cell collection and then randomized to three or four courses of VAMP followed by high-dose chemotherapy and autologous stem cell transplantation *or* to conventional chemotherapy (VMCP) until a stable plateau was reached, followed by autologous transplantation at disease progression. The median survival was essentially the same in both groups (65 months vs. 64 months). From the time of randomization, the median event-free survival in the early transplant group was 39 months compared to 13 months in the delayed transplant group. The main advantage of early transplantation was the avoidance of the inconvenience and cost of chemotherapy ([524]). The North American Intergroup Study (S9321) is a larger randomized trial comparing early to late transplantation. It met its accrual goal of approximately 1000 patients in October 2000. Results of this trial are not yet available.

CONDITIONING THERAPY AND STEM CELL TRANSPLANTATION In an effort to improve autologous stem cell transplantation, various preparative regimens have been used. There has been only one prospective randomized controlled trial comparing conditioning regimens in patients with myeloma ([525]). Moreau et al. ([525]) randomized 282 patients to receive melphalan (140 mg/m ^{2}) plus total body irradiation or melphalan alone (200 mg/m ^{2}). There was no difference in response rates or event-free survival. Survival at 45 months favored the melphalan alone arm (65.8% vs. 45.5%, p = .05). Toxicity with melphalan alone was significantly less. Most investigators have now discontinued the use of total body irradiation and give only melphalan (200 mg/m ^{2}) as the preparative regimen. Other regimens, including various combinations of melphalan, busulfan, cyclophosphamide, idarubicin, etoposide, or thiotepa, have been used ([501], [526], [527], [528], [529], [530], [531], [532] and [533]) without any evidence of superiority of these regimens over melphalan 200 mg/m ^{2}. Innovative trials supplementing melphalan with skeletal targeted radiation [samarium 153-ethylenediaminetetramethylene phosphonate ([534]) and holmium 166-1,4, 7,10-tetraazocyclodo-decane-1,4,7,10-tetramethylenephosphonic acid ([535])] are in progress.

ROLE OF PURGING It is unclear whether the purging of tumor cells from the collection of hematopoietic stem cells is beneficial. Purging marrow with cyclophosphamide derivatives ([536]) or with monoclonal antibodies ([537], [538]) has proven feasible, although associated with prolonged myelosuppression after transplantation. CD34 $^{+}$ selection of peripheral blood progenitor cells provided effective hematopoietic support in a group of 55 patients with advanced multiple myeloma after myeloablative chemotherapy ([539]). However, two large phase III randomized trials have shown no clinical benefit to using CD34 $^{+}$-selected autologous peripheral blood stem cells ([540], [541]).

Allogeneic Transplant

Allogeneic transplantation eliminates the problem of stem cell contamination by tumor cells that is inevitable with autologous stem cell transplantation. Furthermore, there is evidence of a graft-versus-myeloma effect with allografting ([542]). Allogeneic transplantation can lead to prolonged disease-free survival in a relatively small percentage of patients ([543], [544]). The high treatment-related mortality (approximately 30%) and significant toxicity from graft-versus-host disease (GVHD) have limited

the role of this procedure in the treatment of myeloma ([543], [545], [546]) (Table 98.11). There have been four case-controlled or cohort-controlled studies comparing autologous to allogeneic stem cell transplants (Table 98.11) ([547], [548], [549] and [550]). The largest of these is by Bjorkstrand et al. ([547]). In their retrospective analysis of data compiled by the European Blood and Marrow Transplantation Group, there was inferior survival for myeloma patients treated with allogeneic bone marrow transplants compared to case-matched controls treated with autologous transplants (18 months vs. 36 months) ([547]). The three smaller studies, which had relatively short follow-up, have shown mixed results with regard to progression-free survival and overall survival; transplant-related mortality, however, is consistently higher in the allogeneic groups (19 to 25%).

TABLE 98.11. Nonrandomized Comparisons of Autologous and Allogeneic Hematopoietic Stem Cell Transplantation for Multiple Myeloma

Study (Reference)	N	Treatment- Related Mortality (%)	Median Survival (mo)	*p*

NS, not significant.

[a] Chemotherapy-sensitive patients only.

[b] T-cell–depleted allogeneic stem cells.

From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:57–109, with permission.

In an effort to reduce transplant-related mortality, Lokhorst et al. ([551]) compared autologous stem cell transplants to T-cell–depleted allogeneic stem cell transplants. Myeloma patients were eligible if they had chemotherapy-sensitive disease. Genetic randomization was used. After 44-month median follow-up, overall survival had not yet been reached in either group. Transplant-related mortality in the allogeneic group was 18% compared to 4% in the autologous group.

In one series, only 5 of 80 patients were alive without evidence of disease at 4 to 7 years after an allogeneic bone marrow transplantation for multiple myeloma ([543]). It must be emphasized that the majority of these patients had chemotherapy-resistant disease before transplantation. Outcomes have improved over time ([552]). Of 690 allogeneic, matched, sibling donor transplants for multiple myeloma reported to the European Group for Blood and Marrow Transplantation registry, 334 were performed between 1983 and 1993 (all with bone marrow), and 356 were performed between 1994 and 1998. The 3-year overall survival was 35% for transplant recipients during the earlier period and 55% for recipients of bone marrow transplants during the later period. The improvement in survival since 1994 was the result of a significant reduction in transplant-related mortality, from 46 to 30% at 2 years ([552]).

Allogeneic transplantation produces higher rates of complete molecular responses. In a series of 229 myeloma patients, allogeneic transplantation resulted in a complete response of 38% compared to 22% after autologous transplantation ($p < .01$) ([553]). Among patients achieving a clinical complete response, 50% of the allogeneic transplant group had a molecular complete response compared to only 17% of those who had received an autologous transplant ([553]). The median relapse-free survival for those who had a molecular complete remission was 110 months compared to 35 months for those who did not. Moreover, in those with a complete molecular remission, the relapse rate was only 16% in the allogeneic group and 41% in the autologous group. This is strong evidence that molecular complete responses are associated with a longer relapse-free survival.

Donor Lymphocyte Infusions

A graft-versus-myeloma effect has been noted after the administration of donor peripheral blood mononuclear cells for relapse after allogeneic transplantation ([542]). Eight of 13 patients with myeloma relapse after an allogeneic bone marrow transplant responded to donor lymphocyte infusions. Four of the patients had a complete response ([554]). In a larger group of patients with a prolonged follow-up period, the factors that were correlated with response to donor lymphocyte infusions were a T-cell dose of more than 1×10^8 cells/kg, a response to reinduction therapy, and chemotherapy-sensitive disease before allogeneic transplantation ([555]).

Nonmyeloablative Allogeneic Transplant

Despite a significant decrease in the relapse rate and graft-versus-myeloma effects, allografts have been associated with inferior survival in nearly all comparisons because of high peritransplant mortality, late complications of chronic GVHD, and late infections. The mortality rate for allogeneic transplantation must be reduced before it can assume a major role in the treatment of multiple myeloma. Promising approaches include nonmyeloablative conditioning (mini) regimens, at relapse or immediately after autologous stem cell transplantation, for selected patients with myeloma (Table 98.12).

[a] All studies used cyclosporine as part of the graft-versus-host prophylaxis program.

[b] Patients had nonmyeloablative transplant after induction (most commonly vincristine, doxorubicin, and dexamethasone) and a standard autologous peripheral blood stem cell transplantation.

[c] Time between autologous and nonmyeloablative transplants.

[d] Time measured from autologous stem cell transplantation.

[e] Time to autologous transplant; time between transplants was 119 days.

Investigators from the University of Arkansas reported the results of nonmyeloablative allogeneic stem cell transplantation in 31 poor-risk myeloma patients (556, 557). Twenty-five were HLA-compatible siblings, and six of the recipient-donor pairs were unrelated but matched. The conditioning regimen consisted of melphalan at 100 mg/m ^{2} for related and melphalan at 100 mg/m ^{2} plus total body irradiation (250 cGy) plus fludarabine for unrelated allografts. Donor lymphocyte infusions were initially given on days 21, 42, and 112 to patients with no clinical evidence of GVHD. However, because of high rates of donor lymphocyte-induced GVHD, donor lymphocyte infusions were reserved for patients who needed to attain full donor chimerism or who required eradication of residual disease. All but one patient had received one or more than two prior autologous transplants. Fifty-five percent of the patients had progressive disease at the time of the allograft. Acute GVHD developed in 18 patients. Ten patients progressed to chronic GVHD, which was limited in six patients and extensive in four patients. Two patients failed to engraft even after a second allogeneic peripheral blood stem cell infusion. At a median follow-up of 6 months, 12 patients achieved complete remission, and another seven patients achieved nearly complete remission, whereas three patients achieved partial remission. There were three treatment-related deaths during the first 100 days and another six treatment-related deaths after 100 days, for an overall treatment-related mortality of 28%. Three patients died of progressive myeloma. Patients who received transplants with progressive disease or who had received more than one prior autograft had a statistically higher mortality rate. The authors also compared their nonmyeloablative transplant experience to their prior standard allogeneic experience and found that the nonmyeloablative group had a lower mortality during the first year (p = .09), most notably the subset who had received only one prior autologous transplant (p = .05).

Maloney et al. (560, 561) reported results on 54 newly diagnosed myeloma patients who were treated with a planned tandem autologous-nonmyeloablative allogeneic stem cell transplantation (Table 98.12). After induction with four cycles of VAD chemotherapy, followed by autologous stem cell transplantation using melphalan 200 mg/m ^{2} as conditioning, patients underwent a nonmyeloablative allograft. The conditioning for the second transplant was with total body irradiation (200 cGy) ± fludarabine. Matched sibling donor peripheral blood stem cells were infused immediately after the total body irradiation. Postgrafting immunosuppression included mycophenolate and cyclosporine. Fifty-two of the 54 patients received the planned nonmyeloablative transplant, with a median time between autologous and allogeneic transplant of 62 days. The granulocyte and platelet nadirs after the nonmyeloablative transplant were 760 cells/µl and 95,000 cells/µl, respectively. Acute GVHD was seen in 38% of patients and was grade 2 in all but four cases. Forty-six percent of patients developed chronic GVHD that required therapy. All patients achieved donor engraftment. Fifty-seven percent of patients who did not achieve a complete response after the first transplant achieved a complete response after the second transplant. With a median follow-up of surviving patients of 18 months, eight patients (15%) have died of transplant-related complications, two patients have died of progressive myeloma, and one patient died of lung cancer.

Kroger et al. (562) have applied a similar strategy of a planned standard-intensity autograft (melphalan, 200 mg/m ^{2}) followed by a dose-reduced regimen (fludarabine, 180 mg/m ^{2}; melphalan, 100 mg/m ^{2}; and antithymocyte globulin, 10 mg/kg on 3 days) before allografting (Table 98.12). GVHD prophylaxis included cyclosporine and mini methotrexate. Nine patients received allografts from related donors, and eight patients received allografts from unrelated donors. Acute GVHD stages II through IV occurred in six patients (38%). Chronic GVHD developed in 40% of the patients, but only one patient experienced extensive chronic GVHD requiring further immunosuppressive therapy. The 100-day mortality rate was 11%, and, with a median follow-up of 17 months after autologous transplantation and 13 months after allogeneic transplantation, 13 patients (76%) were alive. The rate of complete remission with negative immunofixation increased from 18% after autografting to 73% after allografting, and 12 patients remain free of relapse or progression.

Until further refinements are made and additional confirmatory studies with longer follow-up are completed, the role of nonmyeloablative allogeneic stem cell transplantation as initial therapy in myeloma must be considered investigational. See Table 98.12 for additional preliminary data.

MAINTENANCE THERAPY Strategies for maintenance therapy can be divided into two broad categories: (a) continued induction therapy ad infinitum and (b) addition of a novel therapy after induction therapy. The former strategy was prevalent until recognition of the risk of developing alkylator-induced myelodysplastic syndromes and leukemia (368, 566, 567, 568, 569 and 570). The latter strategy has predominantly applied immune modulators, including prednisone, interferon, and cellular therapies. No benefit has been observed with maintenance levamisole (361, 374), azathioprine (571), or bacillus Calmette-Guérin (459).

Maintenance Chemotherapy Through the 1970s and 1980s, several randomized studies established that alkylator-based maintenance therapy does not produce a survival benefit (306, 315, 317, 346, 376, 380, 571, 572 and 573). In general, patients not receiving maintenance had similar to slightly shorter remission duration than those receiving maintenance (306, 376, 380, 571, 573, 574) but had higher rates of second remission (573, 574). In some studies, there has been a trend toward longer survival in the former group (315, 317, 572). Unmaintained remissions tend to last approximately 12 months (571). Induction therapy is commonly discontinued after plateau is reached (no change in M protein of more than 25% for 4 to 6 months) (306, 315, 575). With standard therapy, the ability to achieve a plateau is as important, if not more important, than the degree of response achieved (306, 575, 576, 577 and 578). No benefit has been documented for treatment beyond 12 months (376), although it has been suggested—but not validated—that prolonged primary chemotherapy may be beneficial in patients achieving less than a partial response, that is, a minimal response or stable disease (579). Patients who relapse off chemotherapy have response rates of 25 to 80% with resumption of the original regimen (306, 459, 573, 574). Second response rates are lower in patients who progress or relapse during maintenance than in those who relapse without maintenance therapy (571, 574). In a study of 115 newly diagnosed patients treated with the M-2 regimen (VBMCP) for approximately 1 year, an initial response rate of 82% was achieved, with a median duration of response of 22 months. After a first relapse, 26 of 38 patients (68%) responded again and had a median duration of response of 11 months. After a second relapse, 7 of 16 patients (44%) responded, with a duration of response of 3.5 months (580).

Corticosteroids as Maintenance Therapy There are four studies that refer to the topic of corticosteroids as maintenance therapy. None justify a recommendation of prednisone as a standard maintenance regimen for all patients. The most recent study (SWOG 9210) compared prednisone, 10 mg every other day, to prednisone, 50 mg every other day, in patients who had responded (SWOG partial response or better) to 6 to 12 months of a VAD-based program—that is, a corticosteroid-intensive program. From the time of randomization to the two different alternate-day prednisone schedules, the median progression-free survival for the higher-dose prednisone arm was 14 months compared to 5 months for the lower dose (p = .003). Survival also was marginally better at 37 and 26 months (p = .05) (581). Although the more dose-intensive corticosteroid maintenance strategy does provide a longer progression-free survival in corticosteroid-responsive patients, these data cannot be generalized. By comparison, after alkylator-based therapy, the median unmaintained progression-free survival is 12 months in responding patients (571). An earlier randomized study, which compared dexamethasone maintenance to interferon maintenance after induction with melphalan and dexamethasone, demonstrated equivalence to inferiority of dexamethasone compared with interferon. Patients received maintenance treatment with interferon-a (3 MU three times a week) or dexamethasone (20 mg/m ^{2} orally daily for 4 days, repeated monthly) until relapse. Remission duration was identical (10 months); however, significantly more patients responded on reinstitution of the melphalan and dexamethasone at disease relapse in the interferon group than in the dexamethasone group (82% vs. 44%, p = .001) (582). The Cancer and Leukemia Group B 7461 study addressed this issue less directly. Patients were treated initially with alkylator therapy and were randomized to observation *or* vincristine and prednisone as maintenance. Survival and response rates were significantly longer and higher in the vincristine-prednisone maintenance group who had received up-front melphalan (median, 35.3 months vs. 27.0 months; p = .003) but not in patients who had received up-front BCNU or CCNU (386). Finally, SWOG 8624, which evaluated the influence of corticosteroid dose intensity on response and survival, indirectly provided data on corticosteroid maintenance. Higher, objective response rate and median survival were observed in patients who received prolonged administration of glucocorticoids (prednisone, 50 mg every other day) between chemotherapy courses. Patients given alternating VMCP and VBAP with and without alternate day prednisone had median overall survivals of 40 months versus 31 months, respectively (p = .02). The survival advantage may have been confounded by the complexity of the study; different treatment plans were assigned after 12 months of induction therapy, determined by tumor response (472). Moreover, one could argue that the corticosteroid was a part of the induction rather than the maintenance program.

Interferon as Maintenance Therapy

After Conventional Chemotherapy The initial positive findings by Mandelli et al. ([583]) in 1990 demonstrated a superior disease-free and overall survival in chemotherapy-responsive patients randomized to maintenance interferon-a. Subsequent studies have yielded divergent results. Ludwig and Fritz ([481]) analyzed 1615 patients in 13 maintenance trials ([385] , [480] , [481] , [484] , [583] , [584] , [585] , [586] , [587] , [588] , [589] and [590]); the Myeloma Trialists' Collaborative Group ([482]) used the individual data of 1543 patients enrolled in 12 randomized trials ([385] , [472] , [480] , [484] , [487] , [584] , [586] , [588] , [591] , [592] and [593]). Results were similar in that the first group found a 4.4-month prolongation of relapse-free survival (p <.01) and a 7-month increase in overall survival (p <.01) ([481]). The latter group reported a 3-year progression-free survival of 27 months versus 19 months (p <.00001) in favor of the interferon maintenance group. Interferon-a prolonged the overall survival by approximately 7 months (p = .04) ([482]) (Fig. 98.10). Survival time from progression to death was significantly worse in the interferon group than in the control group (OR, 1.21; p = .007). No analyzed factors predicted for the interferon benefit (i.e., pretreatment hemoglobin, calcium, ß $_2$M, creatinine, sex, performance status, or Ig isotype). The level of response (complete response, partial response, stable disease) or interferon dose intensity (<12 MU/week versus =12 MU/week) also did not predict for interferon effect ([482]). In 2000, the cost of the 1-year survival benefit in patients treated with interferon as maintenance was $18,968, assuming a dose of 11.6 MU/week ([481]).

In Combination with Corticosteroids Corticosteroids have been added to maintenance interferon in an attempt to intensify the program. Small numbers of patients have been treated with standard maintenance interferon and dexamethasone ([594]) or prednisone ([471] , [594]). In one small randomized study, the progression-free survival was longer in the corticosteroid-plus-interferon arm than in the interferon-only arm, although median survival was not different ([471]). The combination can also induce further partial remissions in more than one-half of responding patients so treated ([594]) and may also prolong the duration of a second remission ([595]).

After High-Dose Chemotherapy with Stem Cell Support Fewer data are available about the usefulness of interferon after autologous stem cell transplantation. There is one small randomized trial of 85 patients and a larger retrospective analysis of registry data by the European Group for Blood and Marrow Transplantation. The use of interferon in this setting cannot be recommended outside of clinical trials. After high-dose chemotherapy with stem cell support, Cunningham et al. ([592]) randomly assigned 85 patients to interferon at 3 MU/m ^{2} three times weekly or to observation. The median progression-free survival in the 43 patients randomized to interferon-a was 46 months compared to 27 months in the control patients (p <.025). Although there was a significant survival advantage at 54 months, at which time 12% of patients in the interferon group and 33% of patients in the no interferon group had died (p = .006), this survival advantage was no longer evident at a median follow-up of 77 months. The data from the European Group for Blood and Marrow Transplantation registry included 473 patients who had received maintenance and 419 patients who had not. However, the two groups were poorly matched. The patients who did not receive interferon had significantly more prior therapy, a higher stage at diagnosis, and a longer time to transplantation. They were also significantly older, and a higher percentage had received total body irradiation–containing conditioning regimens ([596]). Although these factors were “statistically corrected for” in the survival analysis, the imbalance makes interpretation of this retrospective collection of registry patients problematic. Prognostic factors, such as ß $_2$M, C-reactive protein, cytogenetics, and plasma cell labeling index (PCLI), were not included in the analysis. Overall survival was significantly better in the patients who received interferon (78 months vs. 47 months, p = .007). Paradoxically, there was a more prominent survival benefit in those patients who achieved a partial response (97 months vs. 46 months for interferon vs. no interferon, respectively; p = .03) rather than complete response (64 months vs. 51 months, p = .1). Curiously, the partial response group had a better overall survival than the complete response group.

Immunotherapy as Maintenance Therapy

Dendritic Cell–Based Vaccination In an effort to prolong duration of response and hopefully survival, idiotype-treated dendritic cell vaccines are being explored as a therapeutic modality for myeloma patients. B-cell malignancies, including multiple myeloma, are unique in their expression of Ig ([362]). The Ig on malignant cells can be distinguished from that on normal B cells or plasma cells by virtue of specific idiotypic determinants. Dendritic cells are the only known natural cells that can present antigen to naïve T cells ([597]). Antigen-pulsed dendritic cells can successfully induce humoral and cytotoxic cellular immune responses. Idiotypic vaccinations alone have met with limited success in human trials ([598] , [599] and [600]). However, dendritic cell–based vaccination appears to be a more potent way to induce antitumor immunity than vaccines with peptide alone ([601]). Trials looking at dendritic cell–based vaccinations for multiple solid tumors, as well as for myeloma, non-Hodgkin lymphoma, chronic myelogenous leukemia, and other hematologic malignancies, are ongoing. Preliminary evidence suggests that idiotype pulsed dendritic cells can stimulate antiidiotype responses ([602] , [603] , [604] , [605] and [606]). Clinical responses have also been observed by the authors and other investigators in the setting of relapsed disease and after hematopoietic stem cell transplantation ([602] , [604] , [605] , [607] , [608]).

MANAGEMENT OF RELAPSED OR REFRACTORY DISEASE Relapsed and refractory myelomas likely have distinct biologies but are commonly grouped together in discussions of chemotherapy regimens and trials. Differentiation between relapses occurring on therapy and off therapy should be made, with the former having a poorer prognosis. Similarly, primary refractory—the condition in which the disease has not responded to initial therapy—and secondary refractory (or resistant) disease should be differentiated. Finally, with the growing list of active agents now available, the class of agents or the treatment modality to which the patient is refractory should be specified. Before high-dose chemotherapy with stem cell support and thalidomide became common therapeutic strategies, treatment guidelines were more straightforward. If the relapse had occurred during an unmaintained remission, resumption of the patient's original therapy was a good rule ([574]). Fifty percent to 60% of patients respond again to repeat treatment if relapse occurs after unmaintained remission ([459] , [573] , [574] , [609]). Median survival is approximately 10 months ([574] , [610]). The myeloma cell doubling time and duration of response tend to decrease with each subsequent course of therapy ([282] , [580]). In the cases of primary refractory disease or acquired resistance on therapy, the mainstays of treatment had been clinical trials—anthracycline-based, corticosteroid-based, and alkylator-based regimens.

Single-Agent Glucocorticoids for Relapsed or Refractory Disease Salmon et al. ([30]) described clinical improvement in seven of nine relapsed or refractory patients treated with high-dose (200 mg) prednisone every other day. Subsequently, these observations (Table 98.6) were confirmed and extended using prednisone, methylprednisolone, and dexamethasone in pulsed or alternate-day schedules ([341] , [352] , [353]). Doses are typically high, with the exception of one small study in which continuous low-dose dexamethasone (4 mg per day) was administered to a small cohort of patients with a resultant 40% response rate ([354]). Overall, approximately 25% of relapsed or refractory patients respond; the median survival of responding patients is 16 to 22 months ([341] , [352] , [353]). In reviewing their experience with single agent dexamethasone and VAD, Alexanian et al. ([352]) noted that, in patients with refractory disease, response rates with single-agent dexamethasone were comparable to those with VAD (27% vs. 32%). In contrast, in relapsed disease, response rates achieved with single-agent dexamethasone are inferior to those with VAD. These data are not randomized but, rather, serial observations. On occasion, patients who do not respond to high-dose dexamethasone can be salvaged with intermittent high-dose methylprednisolone ([353]).

Thalidomide for Relapsed or Refractory Disease The first published report of the usefulness of thalidomide in patients with relapsed myeloma was by Singhal et al. ([38]). Eighty-four patients with relapsed myeloma, 76 of whom had relapsed after high-dose chemotherapy with stem cell support, were treated with escalating doses of thalidomide. Patients were started on 200 mg each evening; the dose was escalated every 2 weeks, if tolerated, to a final maximal dose of 800 mg daily. Twenty-five percent of patients had at least a 50% reduction in their serum paraprotein. An additional six patients had a 25% reduction in their serum paraprotein (minimal response). Preliminary evidence of response was apparent within 2 months in more than three-quarters of the patients who did respond. An update of the original report by Barlogie et al. ([407]), including 169 patients with advanced myeloma, verified a 30% response rate (50% reduction in the myeloma protein). Two-year event-free and overall survival rates were 20% and 48%, respectively. Other investigators have confirmed a partial response rate of 25 to 58%, with an additional 6 to 26% achieving a minimal response (Table 98.8) ([401] , [408] , [409] , [413] , [417] , [611] , [612] and [613]). The role of dose intensity in thalidomide effectiveness is unclear ([613] , [614]). In the original reports, the highest dose tolerated was administered ([38]). In high-risk patients there was a suggestion that response rates were higher and survival was longer in patients receiving high doses of thalidomide (=600 mg/day) ([407]). However, in some patients, responses may be seen with doses as low as 100 mg/day ([614]). There appears to be synergy between thalidomide and dexamethasone ([403] , [453]). Response rates of 41 to 55% ([410] , [414] , [415] , [615]) have been observed in patients with resistant myeloma. Doses of dexamethasone have ranged from 4 mg as a daily continuous dose ([615]) to 40 mg, days 1 through 4 of each month ([414] , [415]). Dimopoulos et al. ([415]) administered dexamethasone an additional 8 days (days 9 through 12 and 17 through 20) in the first month only. With these combination regimens, thalidomide dose levels have ranged between 100 and 400 mg/day, without any clear dose-response effect. Patients who are resistant to dexamethasone-based ([410] , [415]) or thalidomide-based ([616]) regimens can respond to the combination of these two agents. Coleman et al. ([416]) described a 100% response rate for relapsed or refractory disease treated with clarithromycin, low-dose thalidomide, and dexamethasone. These results have yet to be substantiated by other investigators, and clarithromycin alone is not an effective treatment ([437] , [438] and [439]). A combination of thalidomide, cyclophosphamide, etoposide, and dexamethasone has been reported to achieve a 68% response rate in relapsed and refractory patients ([617]); this program was associated with a 36% rate of severe infections. Toxicities associated with thalidomide include fetal malformations, constipation, weakness or fatigue, somnolence, skin problems, and sensory neuropathy in more than one-third of patients. There is also an increased risk of thrombosis in patients treated with thalidomide, which appears to be exacerbated by the use of concurrent combination chemotherapy, with rates as high as 28% ([618] , [619] and [620]). Other life-threatening complications have included Stevens-Johnson syndrome and hepatitis ([621] , [622]).

Interferon for Relapsed or Refractory Disease Despite the encouraging preliminary report by Mellstedt et al. ([35]) in untreated myeloma patients, results of single-agent interferon therapy in refractory myeloma are disappointing, with a response rate of only 10 to 20% ([396] , [623]). Duration of response varies from 2 months to 25 months. Several investigators have combined interferon with dexamethasone ([472] , [624]) or methylprednisolone ([625]) as therapy for patients with relapsed or refractory disease. With response rates of 29 to 66% ([624] , [625]), it is difficult to isolate the corticosteroid and interferon effects. There is no clear evidence that the response rate or the survival time improved compared to similar treatments without interferon ([626]).

Chemotherapy for Relapsed or Refractory Disease The subject of chemotherapy for relapsed or refractory disease is divided into four sections: alkylator-based regimens, anthracycline-based regimens with or without dose-intensified corticosteroids, and other, less commonly used regimens.

Alkylator-Based Regimens for Relapsed or Refractory Disease There is cross-resistance among the alkylators, but it is not absolute and may be circumvented by increasing dose intensity. Without extreme dose intensification, 5 to 20% of patients with melphalan-resistant disease respond to cyclophosphamide and BCNU as single agents or in combination with prednisone ([32], [610], [627], [628], [629], [630] and [631]). Response rates as high as 30 to 38% can be obtained if prednisone is administered with the cyclophosphamide ([632], [633] and [634]). Higher doses of cyclophosphamide (e.g., 600 mg/m ^{2} intravenously for 4 consecutive days) result in response rates of 29 to 43% ([348], [635]). Response duration and overall survival tend to be short, approximately 3 and 9 months, respectively ([348], [635]). Consolidating the chemotherapy into a 1-day schedule rather than a 4-day schedule did not improve response rate, but it did increase the toxicity ([636]). Similarly, administration of 3.6 g/m ^{2} over 2 days with prednisone appears to produce comparable responses ([637]). Dose intensification of melphalan (Table 98.8) can also be quite effective and is the basis for high-dose therapy with stem cell support ([322]). Selby et al. ([338]) reported that 66% of patients with resistant disease treated with 140 mg/m ^{2} without stem cell support responded, but median response duration was 6 months, with all patients relapsing within a year. Median times to leukocyte and platelet recovery were 42 and 37 days, respectively, and the regimen-related toxicity was 13%. Doses of 50 to 70 mg/m ^{2} result in a 50% response rate and leukocyte and platelet recovery times of 20 and 16 days, respectively ([444], [445]). Further reducing the intensity to 30 mg/m ^{2} every 2 months results in response rates of 38% and a progression-free survival of 10 months ([446]). VBMCP (the M-2 regimen) or MOCCA provides responses in 20 to 30% of refractory patients ([329], [340], [638]), with a median survival of approximately 11 months ([340]).

Anthracycline-Based Regimens without Corticosteroid Dose Intensification for Relapsed or Refractory Disease Various permutations of doxorubicin-containing chemotherapy regimens—doxorubicin and cyclophosphamide ([458]); doxorubicin, BCNU, cyclophosphamide, and prednisone ([639]); cyclophosphamide, doxorubicin, and prednisone ([640]); VCAP ([459]); VBAP ([641], [642]); and BCNU, doxorubicin, and prednisone (BAP) ([640])—have been tried in patients with relapsed and refractory disease, resulting in response rates of 7 to 28% ([459], [639], [640] and [641]). Response duration and survival tend to be short—less than 6 and 12 months, respectively. Responding patients tend to live 7 to 10 or even 22 months longer than nonresponders ([640], [641] and [642]). Patients who have relapsed disease, rather than resistant or refractory disease, have higher response rates (i.e., close to 30%).

Anthracycline-Based Regimens with Corticosteroid Dose Intensification for Relapsed or Refractory Disease Another approach to treating relapsed or refractory myeloma is supplementation of the anthracycline and vincristine with high-dose corticosteroids. Alexanian et al. ([341]) described a drug regimen of vincristine, doxorubicin (Adriamycin), and prednisone (VAP) (bolus vincristine, 1.5 mg on day 1; doxorubicin, 35 mg/m ^{2} on day 1; and prednisone, 45 mg/m ^{2} for 5 days, repeated every 8 days for three corticosteroid pulses); response rates according to SWOG response and improvement criteria were 47%. Barlogie et al. ([330]) published their experience with VAD, and numerous variants have followed. The overall response rate with VAD in 29 patients who had refractory or resistant disease was 59%, according to SWOG criteria. In the 20 patients who had not received prior doxorubicin, the response rate was 70%. VAD differed from VAP in that the former included continuous infusion vincristine and doxorubicin and a sixfold corticosteroid dose intensification ([330]). The activity of VAD has been substantiated by others ([643], [644] and [645]). Infection is the most important complication, with 38% of patients having fever and 28% having a documented infectious agent ([330]). Early catheter removal may occur in approximately 16% of patients as a result of thrombosis or infection ([352]). Variants of VAD include regimens that alter the type or dose of corticosteroid, the schedule of administration, and the type of anthracycline and that add additional drugs. The effectiveness of VAMP (methylprednisolone in place of dexamethasone) appears comparable to VAD, with a response rate and overall survival of 36% and 20 months in patients with resistant disease ([331]). Browman et al. ([646]) evaluated modified VAD, in which all of the vincristine and doxorubicin was given on day 1 over 2 hours, and the dexamethasone was given on days 1 through 4 and 15 through 18 only; the overall response rate was 27% (95% CI, 14 to 40%), and the median survival was 7.6 months. The authors expressed concern that this regimen might be less effective than standard VAD, but the confidence intervals of the response rate were large. The “inferiority” of the regimen could have been related to patient selection, a reduction in the efficacy of the drug combination produced by the shortened intravenous infusions, or the omission of one 4-day course of dexamethasone. Alternative anthracyclines have been tried, including mito-xantrone (NOP or a regimen of mitoxantrone, vincristine, and dexamethasone) ([647], [648] and [649]), which have resulted in response rates of 25 to 40% ([647], [649]), epirubicin ([469], [650]), and liposomal doxorubicin ([470]). In one randomized study, plateau duration was significantly longer in the VAD group than in the mitoxantrone, vincristine, and dexamethasone group, but there was no difference in overall survival ([649]). Several investigators have added additional drugs to the VAD-base without measurable benefit. Concurrent interferon ([488], [626]) adds nothing to response rate or overall survival. In single-arm studies, there does not appear to be any advantage to the addition of cyclophosphamide to VAD, VAMP, or the regimen of vincristine, epirubicin, and dexamethasone to derive CVAD, hyperCVAD, C-VAMP, or VECD ([331], [351], [469], [651], [652]).

Other Regimens for Relapsed or Refractory Disease After studying high-dose cytosine arabinoside, cisplatin, and etoposide as single agents, Barlogie et al. ([392]) did preliminary studies of dexamethasone, cytosine arabinoside, and cisplatin (Platinol) and later etoposide, dexamethasone, cytosine arabinoside, and cisplatin (Platinol) (EDAP). In patients with refractory disease, response rates with these treatments were 7%, 14%, 17%, 0%, and 40%, respectively. Median survival in patients treated with EDAP was 4.5 months. This regimen is extremely myelosuppressive, with more than one-half of treated patients requiring platelet transfusions and 80% requiring hospitalization for neutropenic fever. In the first month, treatment-related mortality was 15%. EDAP is part of Barlogie's “Total Therapy II” In one report, before two cycles of EDAP, 55% and 9% of patients had achieved objective response and complete response, respectively; after EDAP, 65% and 15% had objective response and complete response, respectively ([420]). Dimopoulos et al. ([653]) explored a combination of high-dose cyclophosphamide (3 g/m ^{2}) and etoposide (900 mg/m ^{2}) followed by granulocyte-macrophage colony-stimulating factor. Of the 52 patients with advanced and refractory multiple myeloma treated, 42% responded. Median time to granulocyte recovery was 19 days, and the median duration of remission was 8 months. Combinations of cisplatin with BCNU, cyclophosphamide, and prednisone have produced response in heavily pretreated patients ([419]); however, the addition of cisplatin and bleomycin to VBAP did not appear to produce better outcomes than standard VBAP ([392], [418], [419]).

Modulating Resistance Interferon has been shown to modulate the multidrug resistance phenotype and to reinduce chemosensitivity in patients with chemoresistant multiple myeloma. In one study, nonresponding patients received the same chemotherapy to which they were resistant, preceded by a 5-day course of interferon. An objective response was achieved in 4 of 14 patients (28.6%) ([654]). Because patients with multiple myeloma refractory to alkylating agents frequently express P-glycoprotein, which is associated with the multidrug resistance phenotype, cyclosporine, a multidrug resistance reversal agent has been combined with VAD in patients with refractory or progressive disease. No benefit was observed ([655], [656]). As a result of the findings of a phase I and II trial in patients with myeloma ([657]), PSC 833, a multidrug resistance glycoprotein modulator, has been incorporated into a phase III study of VAD versus VAD and PSC 833. Results are pending.

CLINICAL TRIALS AND NEW AGENTS Until myeloma is a curable disease in all patients, clinical trials will play a critical role in the treatment of these patients. They assist in defining a better classification system for the disease, clarify which treatments offer the most value, and bring new effective agents into standard clinical practice. The two most promising new agents for the treatment of multiple myeloma are PS-341 and CC-5013, both of which are still in clinical trials. PS-341 is a small molecule that selectively inhibits cellular proteasomes, offering a novel pathway for targeted anticancer therapy. The proteasome has a key role in protein degradation, cell cycle regulation, and gene expression. Tumor cells, including multiple myeloma, are heavily dependent on proteasome-regulated proteins for their growth and interaction with stromal cells. PS-341 generally has been well tolerated in phase I trials, with apparent clinical activity in patients with multiple myeloma. PS-341 represents a novel anticancer agent with an acceptable safety profile and evidence of antitumor activity in multiple myeloma. Monoclonal protein responses of a greater than 50% reduction are observed in 41% of patients with relapsed or refractory disease, or both ([324]). CC-5013, a small molecule derivative of thalidomide and a member of the immunomodulatory drug (IMiD) class, is more potent than thalidomide in mediating direct cytokine-related and immunomodulatory effects against human multiple myeloma cell lines and patient-derived cells *in vitro*. During the two recently completed phase I studies, activity has been documented in patients with refractory or relapsed multiple myeloma. Approximately 25% of relapsed or refractory patients have achieved a partial response. Another 25 to 35% of patients have had a minimal response (25 to 49% reduction in serum M component). No significant somnolence, constipation, or neuropathy has been seen ([323], [658], [659]). The human anti-CD20 antibody has demonstrated some effect in patients with myeloma. Approximately 20% of patients with myeloma have CD20 expression on their plasma cells. Preliminary data suggest that use of this agent may be beneficial in this subset of patients ([660]).

Radiation

As early as the mid 1920s, there was recognition that external beam radiation therapy could promote immediate relief of pain, healing of pathologic fractures, and resolution of extramedullary plasmacytomas ([20], [661], [662]). Until the 1950s, radiation therapy was the only effective treatment available for the management of plasma cell tumors. With the advent of systemic chemotherapy, indications for irradiation were primarily palliation of bone pain and solitary plasmacytomas. Concern for maintaining bone marrow reserve also constrains the use of radiation in patients with multiple myeloma. Sykes et al. ([663], [664]) showed that radiation has long-term effects on the bone marrow; the majority of patients receiving concentrated local doses of 3500 cGy or more showed persistent localized marrow aplasia. One must administer enough radiation to provide palliation, without jeopardizing opportunities for further systemic therapy. In a retrospective review, Norin ([665]) has found that objective improvement was lacking when the tumor dose was below a cumulative dose (single-dose equivalent) of 1000 cGy. For palliation, the recommendation is, therefore, a cumulative dose of 1500 cGy, corresponding to a tumor dose of 3400 cGy in 10 to 15 fractions ([665], [666]). Leigh et al. ([667]) recommended a total cumulative dose of 1000 cGy in these same patients. There is controversy as to whether the duration of response correlates with the radiation dose in myeloma patients ([667], [668]).

In contrast, patients with solitary plasmacytoma of bone should receive higher doses in an attempt at cure. Although the optimal dose has not been established by

randomized controlled trials, 4000 to 5000 cGy, encompassing all disease with a margin of normal tissue, is recommended by most experts ([669], [670] and [671]).

SEQUENTIAL HALF-BODY (HEMIBODY) IRRADIATION The first report of using whole body irradiation to treat myeloma was by Medinger and Craver ([672]) in 1942. Partial or complete relief of pain was noted in the majority of patients. Once effective systemic chemotherapy came into wide use, this approach became less popular, until 1971, when Bergsagel ([673]) postulated that sequential hemibody radiation could be a means of debulking tumor. He suggested that if a dose of approximately 725 cGy were given to the upper half of the body and if 1000 cGy were given to the lower half, a theoretical 3-log kill could be achieved and survival prolonged. After a series of retrospective studies ([589], [674], [675], [676], [677], [678], [679], [680] and [681]) and a randomized study ([462], [682]) evaluating its role in the earlier phases of myeloma, hemibody irradiation has once again fallen out of favor. In patients who have end-stage disease, with poor pain control, this treatment may still be important. The majority of series involving hemibody or sequential hemibody radiation are retrospective and include patients who were resistant to or relapsing from alkylator-based therapy. Significant relief of bone pain occurred in 80 to 90% of patients ([589], [674], [675], [676], [677], [678], [679], [680] and [681]), and the median duration of survival was 5 months to 11 months ([666], [676]). Objective biochemical response occurred in 25 to 50% of patients ([589], [676], [683]). Pain relief typically occurred 1 to 2 days after institution of therapy, with a maximal response in 1 to 2 weeks ([674]). The most common side effects were moderate myelosuppression, pneumonitis, nausea, vomiting, diarrhea, and stomatitis ([666], [674]). If an oral lead shield was not used, mucositis also occurred ([666]). Nadirs occurred within 3 weeks ([676]), and white cell count and platelet count recovery occurred by approximately 6 weeks ([666], [676]). Decrements in pulmonary function of 20% occurred in approximately one-half of the treated patients ([666]). The most serious complication was radiation-induced pneumonitis, which was seen in 14% of patients ([676]). The option of sequential half-body radiation therapy must be balanced against unpredictable and varying degrees of pancytopenia and alternative treatment options ([683]). Bergsagel's postulate ([673]) and preliminary data from several small studies ([675], [679], [680]) led two cooperative group studies (SWOG 8229 and Cancer and Leukemia Group B 8003) to incorporate systemic radiation therapy as consolidation therapy ([462], [682]). Neither study demonstrated a meaningful advantage to patients receiving adjuvant hemibody radiation ([462], [682]), and hemibody radiation is used only for pain palliation in end-stage chemotherapy–refractory myeloma patients.

STAGING AND PROGNOSIS

Survival of multiple myeloma patients varies from months to more than a decade ([576], [684]). There are no precise methods of identifying the subset of newly diagnosed patients who are best served by standard intensity therapies, maintenance therapies, novel therapies, or more intensive regimens, such as hematopoietic stem cell transplantation. Prognostic factors are needed for patient counseling, therapeutic decision making, and clinical trial stratification.

Staging is one form of prognostic modeling. The Durie-Salmon system (Table 98.13), which is the most widely accepted multiple myeloma staging system, separates patients predominantly by tumor burden and renal function ([23]). As the biology of myeloma is better understood, novel markers, reflecting myeloma cell kinetics, signaling, genetic aberrations, and apoptosis, have eclipsed the prognostic significance of tumor burden as a predictor of survival.

TABLE 98.13. Durie-Salmon Staging System

Criterion	Measured Myeloma Cell Mass, Cells × $10^{12}/m^2$
Stage I	
All of the following	<0.6 (low)
Hemoglobin =100 g/L	
Serum calcium <12 mg/dl	
On radiograph, normal bone structure (scale 0) [a] or solitary bone plasmacytoma only	
Low M component production rates	
IgG <50 g/L	
IgA <30 g/L	
Urine light chain M component on electrophoresis <4 g/24 h	
Stage II	
Fitting neither stage I or III	0.6–1.2 (intermediate)
Stage III	
One or more of the following	=1.2 (high)
Hemoglobin <85 g/L	
Serum calcium =12 mg/dl	
Advanced lytic bone lesions	
High M component rates	
IgG =70 g/L	
IgA =50 g/L	
Urine light chain M component on electrophoresis >12 g/24 h	
Subclassification	
A: Serum creatinine <2 mg/dl	
B: Serum creatinine =2 mg/dl	

[a] Scale of bone lesions: normal bones, 0; osteoporosis, 1; lytic bone lesions, 2; extensive skeletal destruction and major fractures, 3.

Adapted from Durie BG, Salmon SE. A clinical staging system for multiple myeloma: correlation of measured myeloma cell mass with presenting clinical features, response to treatment, and survival. Cancer 1975;36:842–854.

Although the Durie-Salmon system has some prognostic value ([23]), other biologic variables appear to be more valuable ([460], [685], [686], [687], [688], [689], [690] and [691]). At the time of its inception, the Durie-Salmon staging system was an elegant system that incorporated information about Ig production and half-life, hemoglobin, calcium, creatinine, and extent of bone disease to derive mathematically the total myeloma cell burden ([23]). Quantification of bone lesions used in this staging system, however, is not always reliable as a prognostic factor ([688]) in that patients classified as stage III solely on the basis of bone lesion criteria do not have a poorer prognosis.

Other variables, including patient age, performance status, serum albumin, Ig isotype, and bone marrow plasma cell infiltration, have long been recognized to predict survival ([692], [693] and [694]), and subsequent models have incorporated these factors ([346], [576], [691], [695]) (Table 98.14). Myeloma biology is better addressed by increased concentrations of serum ß $_2$M, C-reactive protein, circulating plasma cells by peripheral blood labeling index, other serum markers, bone marrow PCLI, and chromosomal abnormalities ([460], [685], [686], [689], [690] and [691], [695], [699], [700] and [701]). When designing a new staging system, one must choose between readily available, inexpensive markers, which frequently describe the host more than the intrinsic properties of the myeloma, or more esoteric, expensive markers, which reflect the intrinsic biology of the individual patient's myeloma cells. Each of these systems has value, but the goal is to reach a consensus and to standardize discussions and comparisons among clinical trials and outcomes. An international consensus panel is addressing this. With these basic concepts in mind, various prognostic markers are discussed independently, and Table 98.14 summarizes several investigators' efforts to introduce more meaningful staging systems.

TABLE 98.14. Prognostic and Staging Systems in Newly Diagnosed Multiple Myeloma Patients (Prognostic Categories Defined in Patients Treated with Standard Intensity Chemotherapy, Unless Stated Otherwise)

Study (Reference)	Patients (No.)	Risk or Stage	Patients (%)	Features	Median Overall Survival (mo)
Durie and Salmon, 1975, 1980 (23, 696)	150	IA	11	Defined in Table 98.13	61

Facon et al., 2001 (699) [f]	110	Low	20	No FISH del 13q and ß $_2$M <2.5 mg/L	=111
		Intermediate	50	FISH del 13q or ß $_2$M =2.5 mg/L	47
		High	30	FISH del 13q and ß $_2$M =2.5 mg/L	25

Alb, albumin; ß $_2$M, ß $_2$-microglobulin; BMPC, bone marrow plasma cells; BUN, blood urea nitrogen; CRP, C-reactive protein; FISH, fluorescence *in situ* hybridization; Hb, hemoglobin; PC, plasma cells; PCLI, plasma cell labeling index; RE, risk equation; SM, simplified model.

[a] See text for details. The Bartl staging system is a plasma cell morphology-based staging system.

[b] From risk equation and simplified model: RE: (2.2 × %S phase PC) + (0.8 × ß $_2$-microglobulin) + (1.2 × ECOG) + (0.9 × age). SM: (a) S phase =3% (+2); (b) ß $_2$-microglobulin =6 µg/ml (+1); (c) ECOG =3 (+1); (d) age =69 (+1); absence of each (+0).

[c] Patients received standard chemotherapy or high-dose chemotherapy with transplant.

[d] Metaphase cytogenetics.

[e] Tandem transplant study, rather than conventional chemotherapy.

[f] High-dose melphalan, single transplant, or tandem transplant.

Individual Prognostic Markers with Standard Intensity Chemotherapy

ß $_2$-MICROGLOBULIN ß $_2$M concentration is the strongest and most reliable prognostic factor for multiple myeloma that is routinely available (Table 98.14). It depends not only on tumor burden, but also on renal function. Elevated ß $_2$M values predict early death (686, 689, 702). Formulas to correct the ß $_2$M concentrations for the effects of renal insufficiency have not improved its predictive value (703); the ß $_2$M value is still prognostic in myeloma patients with normal renal function (685). The British MRC has shown that, after 2 years of survival, the initial ß $_2$M concentration loses its prognostic value (704). ß $_2$M value also predicts high-dose therapy outcome (i.e., event-free and overall survival) (336, 496, 705, 706, 707, 708 and 709).

C-REACTIVE PROTEIN French investigators first showed that C-reactive protein was useful as a univariate (710) and multivariate (689) prognostic marker in multiple myeloma (Table 98.14). These findings were substantiated in groups of patients from Mayo Clinic (686) and Eastern Cooperative Oncology Group clinical trials (711). C-reactive protein concentration does not appear to be useful as a marker of disease status (712). C-reactive protein value also predicts high-dose therapy outcome (187).

LACTATE DEHYDROGENASE Increased lactate dehydrogenase values identify a group of patients with poor prognosis and aggressive disease, sometimes a lymphomalike disease characterized by tumor masses and retroperitoneal adenopathy with a short clinical course (713, 714 and 715). Only 7 to 11% of patients with

newly diagnosed myeloma have an increased concentration of lactate dehydrogenase ([208], [715]), thereby limiting its utility.

BONE MARROW PLASMA CELL NUMBER AND MORPHOLOGY The quantity, growth patterns, and morphologic features of bone marrow plasma cells have been evaluated as prognosticators for patients with myeloma with variable results ([695], [716], [717], [718] and [719]). Although the estimation of percent bone marrow plasmacytosis is not always reproducible ([716], [717]), investigators have reported prognostic significance ([695], [719]). Bartl et al. ([695]) constructed an intricate study of bone marrow characteristics of myeloma patients (Table 98.14). The architectural pattern of growth—including interstitial, interstitial-sheets, interstitial-nodular, nodular, and packed—correlates with survival ([695], [719]), as does the plasma cell morphology ([695]). According to Bartl et al. ([695]), myeloma cell histologic features can be classified into six types: (a) Marschalko type, which is characterized by predominantly normal-appearing plasma cells with a mean size of 21 µm; (b) small cell type, which is characterized by small, round, and lymphoplasmacytoid cells with a mean size of 13 µm; (c) cleaved type, which is characterized by notched, cleaved, or even convoluted nuclei of variable size; (d) polymorphous type, which is characterized by marked cellular polymorphism and multinuclearity, with interspersed giant plasma cells and cytoplasmic inclusions; (e) asynchronous type, which is characterized by marked asynchronous maturation of the nucleus and cytoplasm, large eccentric nuclei, frequent nucleoli, and a pronounced perinuclear hof; and (f) blastic type, which is characterized by plasmablasts with large nuclei, prominent centrally located nucleoli with a moderate rim of basophilic cytoplasm, and a faint perinuclear hof (Table 98.14). Neither of these morphologic features—architecture or plasma cell phenotype—has been applied widely. Other investigators have demonstrated the powerful prognostic significance of immature or plasmablastic plasma cells ([123], [260], [687], [720], [721], [722], [723] and [724]). Plasmablastic morphology is associated with a high PCLI, a higher level of sIL-6R, and *ras* mutations ([687]). Electron microscopy confirms that immature nuclear morphology and nuclear cytoplasmic asynchrony correlate with one another and with poor prognosis ([725], [726]). Nuclear immaturity and three cytoplasmic abnormalities—scattered patterns of mitochondria, single-sac looplike structures, and numerous intramitochondrial granules—have been associated with poor outcome.

PLASMA CELL LABELING INDEX The PCLI of bone marrow plasma cells is a reproducible and powerful prognostic factor in multiple myeloma ([685], [686], [691], [727]) (Table 98.14). The PCLI is determined from an immunofluorescence slide-based assay ([123]). Cells in DNA S phase of the cell cycle incorporate bromodeoxyuridine, which can be recognized by using a monoclonal antibody. S-phase cells are then marked with a second antibody, and plasma cells are recognized by morphology and reactivity with antihuman Ig ?- and ?-light chains ([728]). An increased PCLI predicts a short remission and survival but does not predict response to therapy. All large studies published to date have confirmed the independent prognostic value of the PCLI for survival after treatment with conventional chemotherapy ([123], [685], [721], [729], [730]) or high-dose therapy ([709]). Other methods for determining proliferation include Ki67 immunohistochemical staining ([731], [732]) and determination of S phase by flow cytometry ([691], [733], [734]). Witzig et al. ([735], [736]) have also demonstrated the prognostic value of the peripheral blood labeling index.

CYTOGENETICS, FLUORESCENCE *IN SITU* HYBRIDIZATION, AND OTHER GENETIC ABNORMALITIES Nearly all myeloma patients have abnormal chromosomes by fluorescence *in situ* hybridization (FISH), including deletions, aneuploidy, and translocations ([737], [738]), although abnormal karyotypes are seen in only 18 to 30% of cases. This apparent contradiction is explained by the generally low proliferative rate of myeloma cells and the requirement of obtaining plasma cells (and not just the rapidly dividing normal myeloid precursors) in metaphase to generate conventional cytogenetics ([698], [739], [740]). Therefore, any abnormality in conventional cytogenetics identifies a group with a higher proliferative rate ([741]) and a particularly poor prognosis. There is an excellent correlation between abnormal conventional cytogenetics and a high plasma cell proliferative rate ([741], [742]). By interphase FISH, aneuploidy is present in the majority of newly diagnosed patients ([743]). Aneuploidy is characterized predominantly by a gain of chromosome numbers, but monosomy is not uncommon ([743]). With interphase FISH, several chromosomal abnormalities, such as Ig heavy chain translocations and deletion of chromosome 13, are observed at equal frequencies among the spectrum of plasma proliferative disorders, from MGUS to multiple myeloma to PCL ([744], [745]). Monoallelic loss of chromosome 13 (del 13) or its long arm (del 13q), when determined by metaphase cytogenetics, is a powerful adverse prognostic factor in patients treated with standard chemotherapy ([746]) or with high-dose chemotherapy and hematopoietic stem cell transplantation ([187], [420], [518], [747]) (Table 98.14). Approximately 50% of newly diagnosed multiple myeloma patients have del 13 or del 13q by FISH ([699], [742], [745]). The authors' group has shown that del 13q is associated with specific biologic features, including a higher frequency of ?-type multiple myeloma, slight female predominance, higher PCLI, and a higher frequency of a serum M component of less than 10 g/L ([456]). Patients with the deletion by FISH have a worse overall survival with standard chemotherapy ([456], [690], [697], [742]), high-dose therapy ([699], [748]), and interferon treatment ([456]). The absence of abnormalities of chromosomes 13 and 11 by conventional cytogenetics is associated with longer complete response duration, event-free survival, and overall survival in patients treated with high-dose therapy ([420]). The prognostic significance of del 13q by FISH is less than that for del 13 by conventional cytogenetics, because the latter test incorporates the chromosomal abnormality and a high rate of plasma cell proliferation, whereas the former captures only the chromosomal abnormality. Hypodiploid myeloma has a worse prognosis than diploid or hyperdiploid myeloma. This has been demonstrated by flow cytometric methods ([749], [750]) and metaphase cytogenetics ([698], [746], [751], [752] and [753]). Controversy exists about whether the deletion 13q adds any additional prognostic information to a hypodiploid karyotype ([698], [752], [753]). As much as 75% of patients with multiple myeloma have translocations involving the heavy chain gene on chromosome 14. These translocations include illegitimate switch recombinations of the variable regions of the Ig heavy chain gene at 14q32. Partners of the translocations into the IgH switch region on chromosome 14 include chromosomes 11, 4, 6, and 16 ([754]). The most common translocation in multiple myeloma is t(11;14)(q13;q32) ([755]), which increases expression of cyclin D1 ([186]), a protein involved in cell cycle progression. The prevalence of t(11;14)(q13;q32) is 16% in multiple myeloma ([756]). Previous publications had suggested that this translocation was associated with an adverse outcome in multiple myeloma ([187], [690]), but more recent data refute this hypothesis ([756]). The t(4;14)(p16.3;q32) is present in 10 to 20% of multiple myeloma patients ([757], [758], [759], [760] and [761]). This translocation results in the up-regulation of fibroblast growth factor receptor 3 and in the hybrid transcript IgH/MMSET ([757], [758]). The t(14;16)(q32;q23) is also seen in a small subset (approximately 5%) of patients with multiple myeloma ([758], [697]). In one study, there was a tight association of del 13 abnormalities and high ß $_2$M values with the unfavorable t(4;14) and t(14;16) abnormalities ([762]). The frequency of high ß $_2$M or del 13 was one-half that in patients with the t(11;14) abnormality. This suggests that the poor prognosis associated with del 13 may be because of other nonrandom, associated chromosomal abnormalities. Fonseca et al. ([697]) have recently demonstrated that three distinct staging groups can be defined by the presence of t(14;16)(q32;q23), t(4;14)(p16.3;q32), deletion 17p13, and del 13q by FISH (Table 98.13). Trisomy is common by FISH and includes chromosomes 3, 6, 9, 11, and 15 ([763]). In another study, trisomy of chromosomes 3, 7, and 11 accounted for more than 50% of the hyperdiploid cases ([743]). Trisomy of chromosomes 6, 9, and 17 was associated with prolonged survival ([764]). Mutations of *ras* have been noted in 30 to 50% of multiple myeloma patients, with increasing prevalence in the advanced stages of the disease ([176]) and shorter survival (K- *ras*) ([177]). Mutations of *ras* were first observed in fulminant disease ([179]) but have also been observed in 27 to 39% of newly diagnosed cases ([176], [177]). Patients with *ras* mutations had a median survival of 2.1 years versus 4 years for patients with wild-type *ras* ([177]). Inactivating mutation of *p53*, locus 17p13, is rare in freshly explanted myeloma cells but is common in human myeloma cell lines and in patients with a terminal phase of myeloma ([179]). Such mutations have been observed in approximately 5% of cases of early multiple myeloma versus 20 to 40% of cases of PCL ([200], [201], [202] and [203]). Deletions of *p53* as detected by FISH are present in 9 to 33% of patients with newly diagnosed myeloma ([178], [180]) and confer a poorer median survival (15.9 months vs. >38 months) ([180]). Epigenetic phenomena, such as methylation of the *p16* (Met- *p16*) promoter region, have been associated with progression in the PCDs ([195], [196], [197] and [198]). Met- *p16* is uncommon in MGUS and smoldering multiple myeloma, increases in frequency with advancing stages of the disease ([194], [198]), and is common in extramedullary multiple myeloma, including PCL. Zhan et al. ([765]) have studied the gene expression of 74 myeloma patients by using high-density oligonucleotide microarrays interrogating approximately 6800 genes. On hierarch-ical clustering analysis, four distinct subgroups of myeloma (MM1, MM2, MM3, and MM4) were identified. The expression pattern of MM1 was similar to normal PCs and MGUS, whereas MM4 was similar to multiple myeloma cell lines. Clinical variables linked to poor prognosis, including abnormal karyotype and high serum ß $_2$M levels, were most prevalent in MM4. Overexpression of genes involved in DNA metabolism and cell cycle control were observed in MM4. Novel candidate multiple myeloma disease genes have been identified.

ANGIOGENESIS Several studies have demonstrated prognostic significance of increased microvessel density (i.e., angiogenesis) in multiple myeloma ([172]). The first description was a comprehensive study of multiple myeloma and MGUS that showed a strong association with diagnosis and with an increased S phase fraction of plasma cells measured by the PCLI ([172]). This finding was corroborated in a prospective clinical trial ([766]). Median survivals were 4.4, 4, and 2 years in patients with low, intermediate, and high microvessel density, respectively. However, in this study of only 74 patients, there was no independent prognostic significance for angiogenesis in a model that included PCLI, ß $_2$M, and the percentage of marrow plasma cells ([766]). In another study, angiogenesis failed to predict survival ([767]). It is not known whether levels of angiogenic cytokines, such as VEGF, bFGF, or hepatocyte growth factor, are associated with poor survival, although concentrations are reduced during effective chemotherapy ([162]).

LYMPHOCYTE SUBSETS Low numbers of CD4 (helper T) cells at diagnosis are associated with a worse prognosis ([768], [769]); the prognostic importance of CD4 T cells is present throughout the course of disease, including after the completion of chemotherapy and at relapse ([770]). In the posttransplantation setting, the number of circulating lymphocytes appears to be an important prognostic factor. Porrata et al. ([771]) demonstrated lower relapse rates and prolonged survival for patients with higher absolute lymphocyte counts after autologous stem cell transplantation, suggesting an early graft-versus-tumor effect. The median overall survival and progression-free survival for myeloma patients were significantly longer in patients with an absolute lymphocyte count of greater than or equal to 500 cells/µl on day 15 than for patients with an absolute lymphocyte count of less than 500 cells/µl (33 months vs. 12 months; 16 months vs. 8 months). Researchers at the University of Arkansas made a similar observation. In a trial designed to evaluate the role of more intense conditioning, lymphocyte recovery, evaluated as a surrogate for immune recovery, was inferior in more intensively treated patients. Despite identical complete remission rates, event-free survival and overall survival were significantly decreased among patients receiving more intensive conditioning ([772]).

OTHER PROGNOSTIC FACTORS Other factors that have adverse prognostic value include decreased staining of bone marrow plasma cells for acid phosphatase ([773]), increased circulating plasma cells as measured by the peripheral blood labeling index ([736]), apoptotic index ([270]), increased sIL-6R ([687] , [774] , [775]), serum neopterin ([776]), a $_1$-antitrypsin ([777]), C-terminal telopeptide of type 1 collagen ([778] , [779] and [780]), serum bone sialoprotein ([781]), B $_{12}$ binding protein ([782]), soluble CD56 ([783]), soluble Fc receptor (CD16) ([784]), soluble syndecan or CD138 ([785]), and serum IL-6 levels ([786] , [787] and [788]). Although IL-6 is known to have a major role in myeloma pathogenesis, C-reactive protein levels correlate well with this more expensive and less readily available prognostic test. There are mixed results on the prognostic value of serum thymidine kinase ([789] , [790]).
DRUG RESISTANCE One form of drug resistance is marked by multidrug resistance-1 expression on plasma cells, as demonstrated by immunocytochemistry ([791]). The presence of this P-glycoprotein in the cell membrane of plasma cells of patients with multiple myeloma is associated with a poor prognosis. Drug resistance measured by immunocytochemical detection of lung resistance protein is highly correlated with failure of response to melphalan and poor subsequent survival ([792]).

Significance of the Extent of Response after Therapy

SIGNIFICANCE OF RESPONSE AFTER STANDARD INTENSITY CHEMOTHERAPY Response is often used as a measure of efficacy, and it is often assumed that complete remissions are a prerequisite for cure. Indeed, patients treated with standard-intensity chemotherapy with responsive disease tend to live a median of 18 months longer than do patients with resistant disease ([33] , [337] , [578]). However, tumor response may speak more to a patient's tumor biology than it does to the therapy in question. Most standard-intensity chemotherapy studies suggest that the degree of response does not correlate with survival ([578] , [579] , [793] , [794] and [795]). Rather, the ability to achieve a plateau of at least 6 months' duration is as important, if not more important, than the degree of response to therapy ([575] , [576] and [577]). The data from only 3 ([325] , [326] , [374]) of 27 ([318] , [329] , [365] , [366] , [372] , [375] , [377] , [382] , [441]) randomized induction trials suggest that the observed higher response rate translates into longer overall survival (Table 98.7). The importance of response kinetics is also a controversial topic. Some data support the premise that those with the most rapid responses to alkylator-based therapy have a shorter remission duration and survival ([573]), whereas other data contradict this assumption ([578]).
SIGNIFICANCE OF A COMPLETE RESPONSE AFTER HIGH-DOSE THERAPY It is unclear whether the achievement of a complete response, as defined by the disappearance of the M protein by immunofixation of the serum and urine after high-dose therapy with hematopoietic stem cell support, is of prognostic value. Multiple studies have produced inconsistent results ([336] , [500] , [517] , [545] , [546] , [796] , [797]). Several of these studies ([336] , [545] , [796]) did not use the more stringent definition of *complete response*; they relied on the absence of an M protein on an electrophoretic pattern rather than immunofixation negativity. These studies should be interpreted with caution, because they do not include several of the most powerful determinants of prognosis—PCLI and conventional cytogenetics ([187] , [420] , [685] , [686] , [691]). One of these studies is a retrospective study of 344 patients with multiple myeloma treated with high-dose chemotherapy followed by autologous stem cell transplantation. Patients were not treated uniformly. The 5-year overall survival was 48% in those who had no M protein on immunofixation and 21% in those with a persistent M protein ([797]). Alexanian et al. ([507]) reported on a series of 68 patients treated with dexamethasone-based induction therapy followed by early high-dose therapy; results were compared to those of 50 patients who were unable to receive high-dose therapy because of socioeconomic reasons. Patients who achieved an immunofixation-negative complete response by either means (i.e., high-dose or standard chemotherapy) had a superior overall survival compared to patients who achieved a partial response or less. The implication of these data is that a complete response may be an important surrogate marker of long survival and less aggressive myeloma biology. This study was also lacking important baseline prognostic information (i.e., PCLI and cytogenetics). In yet another study, Davies et al. ([500]) reported a series of 96 patients who received high-dose therapy and were assessed for the effect of response on survival. Although there was a trend toward an improved progression-free survival among patients with an immunofixation-negative complete response, compared to patients with a partial response (49.4 months vs. 41.1 months, $p = .26$), there was no improvement in overall survival. Finally, Rajkumar et al. ([798]) reported a complete response in 33% of 126 multiple myeloma patients who underwent stem cell transplantation. There was no difference in the overall survival or progression-free survival between patients who achieved a complete response and those who did not; rather, overall survival was significantly influenced by the level of the PCLI.

TREATMENT OF COMPLICATIONS AND SUPPORTIVE CARE

Treatment of Myeloma Bone Disease

Myeloma bone disease is a significant contributor to morbidity. The standard method of following patients is with periodic (every 6 to 12 months) skeletal radiographs; the use of more sophisticated imaging modalities is being explored. Cross-linked N-telopeptides of type 1 collagen, which can be measured in the serum or urine, appear to be a sensitive indicator of bone turnover ([799]), and urinary levels show a strong positive correlation with the dynamic histomorphometric indices of bone resorption ([800]). Despite careful monitoring, patients are at risk for skeletal events.

Monthly intravenous administration of pamidronate has been shown to reduce the likelihood of a skeletal event by almost 50% in patients with multiple myeloma ([801]). In this study, 392 patients with stage III myeloma and at least one lytic lesion received placebo or pamidronate, 90 mg intravenously administered as a 4-hour infusion monthly for 21 cycles. Skeletal events (pathologic fracture, radiation or surgery, and spinal cord compression) and hypercalcemia were assessed monthly. The mean number of skeletal events per year was less in the pamidronate group (1.3) than in the placebo-treated patients (2.2; $p = .008$), and the proportion of patients who developed any skeletal event was lower in the pamidronate group ($p = .015$). A recent study demonstrated equivalency of pamidronate and zoledronic acid ([802]). Median time to the first skeletal-related event was approximately 1 year in each treatment group, and the proportion of patients with at least one skeletal-related event was similar in all treatment groups.

When a lytic bone lesion is present, significant risk factors for fracture of a long bone include increased pain with use, and the involvement of more than two-thirds of the diameter of the bone. These lesions should be treated prophylactically with surgery if they are situated in weight-bearing bones ([803]). Endosteal resorption of one-half the cortical width of the femur weakens the bone by 70%. Surgical treatment should be considered for these lesions as well ([804]). Once a bone has fractured, healing can occur, especially if proper internal fixation is performed and if the patient has an anticipated survival of greater than 6 months. Much of the data regarding malignant bone disease are derived from patients with carcinoma rather than multiple myeloma. In patients with carcinoma metastatic to bone, modest postoperative radiation doses (=3000 cGy) as adjuvant therapy are associated with better healing ([805]), but the role of adjuvant radiation therapy in multiple myeloma patients is less clear. Multiple myeloma is often chemotherapy sensitive; adjuvant systemic chemotherapy in multiple myeloma patients may be more appropriate than adjuvant radiation therapy. In general, radiation therapy should be used for pain relief in chemotherapy-refractory disease, because it relieves pain in 80 to 90% of patients with bony metastases ([806]), with long-term relief in 55 to 70% ([807]).

Percutaneous vertebroplasty is occasionally an option for patients with vertebral body compression fracture. Pain relief is generally apparent within 1 to 2 days after injection and persists for at least several months to as long as several years ([808]). Complications are relatively rare, although some studies reported a high incidence of clinically insignificant leakage of bone cement into the paravertebral tissues. Compression of spinal nerve roots or neuralgia due to the leakage of polymer and pulmonary embolism have also been reported.

Spinal Cord Compression

In a paper published in 1979, it was estimated that nearly 10% of patients with myeloma present with spinal cord compression or develop it during the course of the disease ([809]); with higher awareness of myeloma and better imaging technology, the incidence is likely lower now. Cord compression, however, remains an important and emergent subject. The usual standard treatment is high-dose corticosteroids and radiation therapy ([810] , [811] , [812] and [813]). On rare occasions, surgical decompression may be considered. Because most myelomatous lesions arise from the vertebral body, an anterior surgical approach is generally used, which may contribute additional morbidity. One small randomized trial addressing the question of radiation versus laminectomy and radiation showed no benefit attributable to laminectomy ([811]); similarly, a larger retrospective series found no benefit ([810]). If the deficit is due to compression by the plasma cell tumor (rather than a bone fragment retropulsed by a pathologic compression fracture), outcomes with radiation therapy are probably equal to (or superior to) surgical intervention in a radiosensitive tumor like myeloma ([810] , [811]).

High-dose corticosteroids may provide immediate pain relief and improvement in neurologic function ([812] , [813]). The optimal corticosteroid dose has not been established, but common dose schedules for metastatic disease include dexamethasone in an initial bolus of 10 mg intravenously, followed by 4 mg orally four times daily ([814]), or a 100-mg intravenous bolus followed by 96 mg in four divided doses for 3 days followed by tapering doses ([812] , [813]).

Hypercalcemia

Patients with multiple myeloma are at risk of severe hypercalcemia that can precipitate acute renal failure, hypertension, nausea, vomiting, pancreatitis, cardiac arrhythmia, coma, and death. The extracellular volume depletion associated with hypercalcemia should be corrected by vigorous hydration ([676], [815]), followed by an antiresorptive agent, such as intravenous bisphosphonate. Serum calcium values usually decline rapidly, reaching the normal range within 2 to 3 days in more than 80% of cases. Occasionally they go below normal at the nadir. Corticosteroids can also reduce serum calcium concentration in approximately 60% of patients with hypercalcemia ([816]).

Gallium nitrate, mithramycin, and calcitonin are interesting from a historical perspective. Since the advent of bisphosphonates, they are not often used. Gallium nitrate therapy has been shown to be superior to maximally approved doses of calcitonin for acute control of cancer-related hypercalcemia ([817]).

Hematologic Complications, Including Anemia, Secondary Leukemia, Hyperviscosity, and Cryoglobulinemia

ANEMIA The anemia of multiple myeloma can result from many factors. When the anemia is due solely to myelomatous bone marrow infiltration, chemotherapy remedies the problem. Other patients have a relative erythropoietin deficiency related to renal injury due to the myeloma or age-related changes. In these patients, as in any patient with renal insufficiency, modest doses of recombinant erythropoietin are effective. For patients with chemotherapy-induced anemia, recombinant erythropoietin may be effective at higher doses (150 to 300 IU/kg thrice weekly or 40,000 units weekly). Two placebo-controlled trials in myeloma patients demonstrate significantly improved hemoglobin levels and a reduced number of red cell transfusions in patients receiving erythropoietin ([818], [819]). An inappropriately low endogenous erythropoietin concentration is the most important factor predicting response ([820]).
SECONDARY MYELODYSPLASIA AND ACUTE LEUKEMIA The most ominous cause of anemia in the setting of previously treated multiple myeloma is a secondary myelodysplastic syndrome or acute leukemia. Kyle et al. ([566]) were among the first to recognize that cytotoxic agents can induce myelodysplasia and acute myeloid leukemia ([567], [568] and [569]). The risk of a secondary myelodysplastic syndrome or acute leukemia is approximately 3% at 5 years and 10% at 8 to 9 years ([821], [822]). Estimates range from an actuarial risk of 25% at 5 years ([823]) to 0.7% over 10 years ([328]), with multiple other estimates somewhere in between ([368], [570]). A reasonable guideline is that the 10-year risk of myelodysplastic syndrome or acute myeloid leukemia is approximately 3% for every year of melphalan treatment ([821]). Some authors have suggested that higher cumulative doses of melphalan are implicated as a risk for acute leukemia ([821]). Others have shown no difference in incidence based on the number of courses of chemotherapy or the cumulative melphalan dose between the patients who did and did not develop acute leukemia ([822]). In the Finnish study, the mean number of chemotherapy cycles was 19.7 and 18.5 in patients with and without secondary leukemia; mean cumulative melphalan doses were 1440 mg and 1400 mg, respectively ([822]). Although cyclophosphamide has been shown to be leukemogenic, data suggest that it is less so than melphalan ([821], [824], [825]). After secondary leukemia is diagnosed, median survival tends to be short—approximately 2 months ([822]). The occurrence of multiple cases of concurrent acute leukemia in multiple myeloma suggests that there may be a proclivity for acute leukemia to develop in patients with myeloma ([826], [827]). After stem cell transplantation for myeloma, the risk of myelodysplastic syndrome appears to be related to prior chemotherapy rather than to the transplant itself, at least in one retrospective series ([828]).
CRYOGLOBULINEMIA Approximately 5% of myeloma gamma globulins exhibit reversible precipitation in the cold, so-called cryoglobulins, forming a flocculent precipitate or a gel-like coagulum when the serum is cooled ([829]).
HYPERVISCOSITY Plasmapheresis relieves the symptoms of hyperviscosity, but the benefit of this treatment in the absence of concurrent chemotherapy is short lived ([830]).

Renal Failure

Normal creatinine values are present in approximately 50% of multiple myeloma patients at diagnosis ([207], [208], [209] and [210], [242], [243] and [244]), and only 15 to 25% have a creatinine value of greater than 2 mg/dl ([208], [248]). Patients in whom the renal failure is reversed have a better overall survival than those without improvement ([247], [249]). Factors that increase renal tubular cast formation include dehydration, infection, and hypercalcemia. Maintaining a 24-hour fluid intake of at least 3 L can improve renal function ([247]).

Because light chains with the lowest isoelectric points tend to be more nephrotoxic in animal models, avoidance of a low or acidic urinary pH is recommended. Oral or intravenous bicarbonate is useful in the setting of acute renal failure ([831]). The MRC third myelomatosis trial randomized multiple myeloma patients with significant renal failure to oral sodium bicarbonate to neutralize urine pH (or not), and there was a trend toward better survival in the bicarbonate recipients ([247]).

The use of plasmapheresis in the setting of renal failure remains controversial. One small randomized study of patients with active myeloma and progressive renal failure suggested benefit in a subset of patients ([832]). Twenty-one patients were randomized to forced diuresis and chemotherapy (ten patients) or forced diuresis, chemotherapy, and plasmapheresis (11 patients). There was a trend toward better outcome in the plasmapheresis group, but the difference was not statistically significant. It is unclear whether the lack of significance is due to the small sample size or to an equivalence of the two therapeutic strategies. The study did demonstrate that the severity of myeloma cast formation directly correlated with lack of improvement regardless of treatment strategy.

Another randomized study in myeloma patients with severe renal compromise compared plasma exchange (and hemodialysis when needed) with peritoneal dialysis ([833]). All patients received chemotherapy and corticosteroids. Of the 29 patients in the study, 24 patients received dialysis, and five patients maintained serum creatinine concentrations of greater than 5 mg/dl without dialysis. Thirteen of the 15 patients in the plasmapheresis with or without hemodialysis group recovered renal function, reaching serum creatinine values of less than or equal to 2.5 mg/dl in most cases, whereas only two patients in the peritoneal dialysis group had enough improvement to stop dialysis. The 1-year survival rates were 66 and 28%, respectively (p <.01). The study's design was flawed in that one group received peritoneal dialysis and the other hemodialysis; the question about the role of plasmapheresis is not adequately settled.

Infection Management

Infections are a major cause of morbidity in myeloma patients ([834], [835]). Pneumonias and urinary tract infections caused by *S. pneumoniae*, *H. influenzae*, and *Escherichia coli* are most frequent ([257], [836], [837] and [838]). The susceptibility to infection varies with the phase of illness ([256], [839]). In one prospective study, the overall serious infection rate was 0.92 infections per patient-year and was four times higher during periods of active disease (1.90) than in plateau phase myeloma (0.49) ([255]). In a retrospective study evaluating the sequential incidence of infection, the first 2 months of initial chemotherapy emerged as a particularly high-risk period, with nearly one-half of the patients experiencing at least one clinically significant infection ([256]). Infections late in the course of multiple myeloma may be an inevitable result of long-standing immunosuppression and overwhelming tumor burden. Prevention of infection is a critical goal for improving survival.

Prevention of infections by the use of vaccines is an attractive strategy. However, responses to vaccines are poor among myeloma patients ([255], [840], [841] and [842]). Patients with myeloma were investigated to assess whether immunologic risk factors predisposing to serious infection could be identified ([255]). Specific antibody titers to pneumococcal capsular polysaccharides and tetanus and diphtheria toxoids were significantly reduced compared to the control population. Low antipneumococcal and anti– *E. coli* titers correlated with risk of serious infection. In addition, among 41 immunized patients, responses to pneumococcus vaccine and tetanus and diphtheria toxoids were poor. IgG subclass levels were significantly reduced, and a poor IgG response to pneumococcus vaccine immunization was associated with an increased risk of septicemia. The predominant site of infection was the respiratory tract. Decreased concentrations of the uninvolved Igs were significantly associated with at least one serious infection ([255]).

The two most common prevention strategies consist of prophylaxis with antibiotics ([843]) or intravenous Ig (IVIg) ([844]). A randomized, placebo-controlled trial of trimethoprim-sulfamethoxazole (TMP-SMX) demonstrated a significant decrease in severe infections among newly diagnosed myeloma patients randomized to TMP-SMX compared to controls ([843]). Fifty-seven patients about to begin chemotherapy for multiple myeloma were randomly assigned to prophylaxis for 2 months or to no prophylaxis (control). Antibiotic prophylaxis consisted of TMP-SMX (160 and 800 mg orally every 12 hours) administered for the first 2 months of initial chemotherapy. Bacterial infection occurred in 11 control patients but in only two patients assigned to receive TMP-SMX (p = .004). Eight severe infections occurred in controls compared to one severe infection in a TMP-SMX patient (p =.010). Severe infections included five cases of pneumonia (three with sepsis), two urinary tract infections with complicating pneumonia or sepsis, one diverticulitis with perforation, and one staphylococcal scalded skin syndrome. The rate of bacterial infection was 2.43 per patient-year for controls and 0.29 per patient-year for the TMP-SMX group (p = .001). Toxicity (skin rash in six patients, nausea in one patient) was not life-threatening but required discontinuation of TMP-SMX in 25% of patients. A randomized, double-blind, placebo-controlled trial demonstrated that IVIg significantly reduced the number of infections in high-risk patients with plateau phase multiple myeloma ([844]). Eighty-two such patients received IVIg (0.4 g/kg/month) or an equal

volume of placebo for 1 year. There were no episodes of septicemia or pneumonia in patients receiving IVIg compared to ten episodes in placebo patients (*p* = .002). There were 38 serious infections in 470 patient-months for the placebo group, compared to 19 serious infections in 449 patient-months for the IVIg group (*p* = .019). A poor antibody response to pneumococcal vaccination (less than twofold increase) identified patients who had maximum benefit from IVIg. However, IVIg is expensive and inconvenient and can be associated with toxicity. Therefore, use of this agent is recommended only for patients with a significant history of severe infections.

DIFFERENTIAL DIAGNOSIS

The diagnosis of multiple myeloma is made from a constellation of findings, including anemia, monoclonal proteins, bone lesions, renal complications, hypercalcemia, and bone marrow plasmacytosis. Often the diagnosis is straightforward, but other disease entities associated with hypergammaglobulinemia or monoclonal bone marrow plasma cells must also be considered. These include reactive plasmacytosis, MGUS, primary systemic amyloidosis, Waldenström macroglobulinemia, LCDD, acquired Fanconi syndrome, solitary plasmacytoma, osteosclerotic myeloma or POEMS (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes) syndrome, and PCL.

Reactive Plasmacytosis and Polyclonal Hypergammaglobulinemia

Reactive plasmacytosis and polyclonal hypergammaglobulinemia must be distinguished from a clonal process. Patients with liver disease; chronic infections, including human immunodeficiency virus; connective tissue diseases; other lymphoproliferative disorders; and carcinoma can have increased bone marrow plasmacytosis (polyclonal) and hypergammaglobulinemia (polyclonal) ([19], [110]). These conditions should not be confused with multiple myeloma or MGUS, which are clonal processes.

Monoclonal Gammopathy of Undetermined Significance

Two percent of patients older than 50 years of age have MGUS, which is a benign counterpart or precursor lesion of multiple myeloma ([100]). It is characterized by an M protein in the serum or urine, without evidence of multiple myeloma or other serious gammopathy-related disorder. MGUS patients do not have bone marrow suppression, lytic bone lesions, hypercalcemia, renal failure, or susceptibility to infection. Standard clinical features do not accurately predict which patients remain stable, and, in approximately 1% of patients per year, multiple myeloma develops ([100]). The clinical distinction between MGUS and asymptomatic multiple myeloma is derived from an arbitrary definition (Table 98.2), although the underlying biologic conditions may prove to be different.

The greatest challenges in differentiating MGUS from myeloma occur in patients who have MGUS and (a) senile osteoporosis, (b) renal insufficiency from another cause, or (c) hypercalcemia due to hyperparathyroidism. Approximately 50% of women older than 60 years of age have osteoporosis, and a fraction of these have vertebral compression fractures. Computed tomographic scan of the spine may help distinguish between senile osteoporosis and myelomatous bone disease. Similarly, renal insufficiency due to long-standing diabetes, hypertension, or nonsteroidal drug use is not uncommon. In such cases, a patient may still have MGUS (or asymptomatic myeloma, for that matter) and end-organ damage. The key is whether the damage is attributable to the plasma proliferative disorder or another cause. In some instances, renal biopsy may be required to clarify this issue.

Primary Systemic Amyloidosis

Primary systemic amyloidosis is a rare disorder that is characterized by the deposition of amyloid fibrils. These fibrils are composed of Ig light chain fragments in a ß-pleated sheet conformation. It should be suspected when a patient with a mono-clonal protein in the serum or urine presents with nephrotic-range proteinuria (primarily albumin) with or without renal insufficiency, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Patients usually present with weight loss or fatigue. Anemia is rare at presentation. Symptoms related to the affected organ are also seen. A monoclonal light chain is found in the serum or urine in nearly 90% of patients with amyloidosis. Most of the remaining patients have monoclonal plasma cells detectable in the bone marrow; the median percentage of clonal plasma cells in these patients is only 5%. A histologic diagnosis is made by demonstrating the amyloid fibrils—green birefringence under polarized light by using a Congo red stain or 8- to 10-nm nonbranching fibrils by electron microscopy. The fat aspirate is positive 70 to 80% of the time. The bone marrow demonstrates amyloid deposits approximately one-half of the time. Nearly 90% of patients with amyloidosis have a bone marrow or fat aspirate specimen positive for amyloid deposits. In the remaining 10%, a biopsy specimen of the affected organ is positive.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia should not be confused with IgM myeloma, which comprises only approximately 1% of myeloma cases ([208]). Patients with Waldenström macroglobulinemia may have anemia, hyperviscosity, “B” symptoms, bleeding, and neurologic symptoms. Significant lymphadenopathy or splenomegaly may also be present. Lytic bone disease is markedly uncommon; if present, consider whether the patient has IgM myeloma. In Waldenström macroglobulinemia, bone marrow biopsy typically reveals infiltration with clonal lymphoplasmacytic cells (CD20 positive). The natural history and treatment options for Waldenström macroglobulinemia are different from those of multiple myeloma ([845]).

Light Chain Deposition Disease

The nonamyloidogenic LCDD is due to pathologic protein deposition in various tissues and organs. Unlike the light chain deposits observed in patients with primary systemic amyloidosis, these infiltrates are not congophilic by light microscopy, and nonbranching fibrils are not observed by electron microscopy. Instead, amorphous nodular deposits are seen.

LCDD may occur with or without coexistent multiple myeloma. Renal involvement is most common, followed by cardiac and hepatic deposits. Clinically, LCDD can be differentiated from multiple myeloma and primary systemic amyloidosis by the following findings. As in primary systemic amyloidosis, early in the disease course, the light chain deposits have a predilection for the renal glomeruli rather than the tubules. This results in nonselective proteinuria, that is, a predominance of albuminuria, which is not usual in multiple myeloma. It is impossible, without tissue biopsy, to distinguish clinically the cardiomyopathy and hepatopathy from primary systemic amyloidosis. In LCDD, the underlying clone is more commonly monoclonal ? rather than ?.

The prognosis of patients who have this disorder depends on whether there is underlying multiple myeloma. In one retrospective study of 19 patients with LCDD, 5-year actuarial patient survival and survival free of end-stage renal disease were 70% and 37%, respectively ([846]).

Acquired Fanconi Syndrome

Fanconi syndrome is a rare complication of PCDs characterized by diffuse failure in reabsorption at the level of the proximal renal tubule and resulting in glycosuria, generalized aminoaciduria, and hypophosphatemia. Fanconi first described the syndrome in children. Subsequently, acquired forms were described in adults. Acquired Fanconi syndrome is usually associated with MGUS. Overt hematologic malignancies may occur, such as multiple myeloma, Waldenström macroglobulinemia, or other lymphoproliferative disorders. The prognosis is good in the absence of overt malignant disease. Clinical manifestations include slowly progressive renal failure and bone pain due to osteomalacia. The diagnosis of Fanconi syndrome can be made when a patient with a monoclonal plasma cell disorder presents with aminoaciduria, phosphaturia, and glycosuria. Electrolyte abnormalities typically include hypokalemia, hypophosphatemia, and hypouricemia. Bence Jones proteinuria is usually present and is almost always of the ? type. Rare patients have been reported with Fanconi syndrome associated with ? Bence Jones proteinuria.

Treatment consists of supplementation with phosphorus, calcium, and vitamin D. Chemotherapy may benefit patients with rapidly progressive renal failure or symptomatic malignancy.

Plasma Cell Leukemia

PCL is a rare form of PCD. Between 2% and 4% ([763], [847], [848]) of malignant PCD cases are PCL. By definition, there are more than 20% plasma cells in the peripheral blood with an absolute plasma cell count of more than 2×10^{9}/L. Some authors accept the diagnosis with only one of these criteria ([285]). The presentation may be

primary, *de novo*, or secondary, evolving from an existing case of myeloma as part of the terminal phase of the disease. Approximately 60 to 70% of cases are primary ([847]).

Although there is overlap, the phenotype of plasma cells from patients with primary PCL is different from those of myeloma patients. PCL plasma cells more frequently express the CD20 antigen ([763]) than those of multiple myeloma (50% vs. 17%), and they often lack CD56 antigen ([265], [763]), which is present on the majority of myeloma cells ([763]). CD56 is considered important in anchoring plasma cells to bone marrow stroma and is associated with a poor prognosis ([167], [266]). CD28 is more frequently expressed on malignant plasma cells in secondary than in primary PCL, which is consistent with an observation made in myeloma, that is, that acquisition of the CD28 antigen on plasma cells appears to correlate with an increased proliferative rate and disease progression ([849]).

PCL plasma cells have higher proliferative rates ([763]) and more complex karyotypes than myeloma plasma cells ([848]). By comparative genomic hybridization and by FISH techniques, losses on 13q ([850], [851]) and monosomy 13 ([763]) exist in more than 80% of PCL patients ([850], [851]). Losses on chromosome 16 also occur in approximately 80% of cases ([851]). Gains in 1q are present in approximately one-half of the patients by FISH ([763]), but in all by comparative genomic hybridization ([851]). In addition, PCL patients have unique losses of 2q and 6p ([851]). Overexpression of PRAD1/cyclin D1, which plays an important role in control of the cell cycle, has also been observed in PCL ([852]).

The clinical presentation of primary PCL is more aggressive than that of multiple myeloma, with a higher presenting tumor burden; higher frequencies of extramedullary involvement, anemia, thrombocytopenia, hypercalcemia, and renal impairment ([763], [847], [848], [853]); increased levels of serum lactate dehydrogenase and ß $_2$M; and plasma cell proliferative activity ([763]). The incidence of lytic bone lesions is slightly lower than that usually observed in multiple myeloma ([763], [854]).

Although the clinical and laboratory features of primary and secondary PCL are similar ([854], [855]), the response to therapy and overall survival in primary and secondary PCL go from poor to worse ([847], [848], [854], [855]). Higher response rates can be achieved with multiagent chemotherapy rather than single alkylator programs (47 to 66% vs. 8 to 13%) ([763], [847], [848], [854]). Regimens, such as VMCP-VBAP, VAD, and combination cyclophosphamide and etoposide, have resulted in median survivals of 18 to 20 months compared to 2 to 6 months when single-agent therapy is used ([763], [847], [848], [854]). Response and survival rates with secondary PCL remain low, however ([854], [855]). When thalidomide and dexamethasone are used, responses are possible (*personal observation*), which is not surprising, given the high response rates observed in patients with high PCLIs in the authors' thalidomide trial ([856]). There are anecdotal reports of excellent responses and 2- to 3-year disease-free survivals after autologous stem cell transplantation ([857], [858], [859], [860] and [861]). Two studies have independently noted the presence of an increased number of circulating large granular lymphocytes after stem cell transplantation ([857], [862]); disappearance of these cells in one patient coincided with relapse ([857]). The significance and implication of these observations are yet to be determined.

Solitary Plasmacytomas

SOLITARY PLASMACYTOMA OF BONE (INTRAMEDULLARY PLASMACYTOMA) Solitary plasmacytoma of bone is a rare form of plasma proliferative disease. Its true incidence has not been described, but it accounts for approximately 2 to 5% of malignant PCDs treated at large referral centers ([303], [863], [864]). In most series, the definition has required the following characteristics: (a) histologic proof that the solitary lesion is a plasmacytoma; (b) no other bone lesions on metastatic bone survey; (c) less than 5% plasma cells from a random bone marrow biopsy site; and (d) the absence of anemia, hypercalcemia, or renal insufficiency that had no attributable cause. Some definitions allow for less than 10% bone marrow plasma cells ([669]), and others restrict the quantity of the serum or urine M spike. Some exclude patients who developed disseminated myeloma within a year after diagnosis of the solitary plasmacytoma ([865]). There is a clear male preponderance, and the median age is 55 years ([669], [865], [866]). Plasmacytomas most commonly arise from the axial skeleton, particularly the vertebral bodies. Pain is the usual presentation. Spinal cord or nerve root compression may also be present. If the patient also has evidence of a peripheral neuropathy, and especially if the bone lesion is sclerotic, one should consider the diagnosis of POEMS (see the following discussion). Monoclonal proteins are present in approximately 50% of patients ([669], [865]). Careful staging should be done in all patients, including a complete blood cell count, protein electrophoresis and immuno-fixation of the serum and urine, a complete radiographic skeletal survey, and random bone marrow aspiration and biopsy. At a minimum, immunohistochemical stains should be done on the bone marrow to identify a clone apart from the solitary plasmacytoma. MRI of the entire spine and pelvis should also be done to determine whether the lesion is solitary. Using MRI, Moulopoulos et al. ([234]) found unexpected bone marrow involvement in 4 of 12 patients with apparently solitary plasmacytomas of bone. From a historical perspective, solitary plasmacytomas of bone were treated surgically with or without adjuvant radiation ([867]). Present day, single modality, definitive radiation therapy is the treatment of choice. Although the optimal dose has not been established by randomized controlled trials, 4000 to 5000 cGy encompassing all disease with a margin of normal tissue is recommended by most experts on the basis of retrospective local relapse rate data ([669], [670] and [671], [868]). Median 10-year disease-free survival is approximately 25 to 40% ([669], [869]). Median time to failure, that is, local relapse, appearance of another plasmacytoma, or disseminated myeloma, is approximately 2 years ([669], [869]). Risk factors for relapse include absence of a monoclonal protein at presentation (nonsecretory disease), depression of Ig values at presentation, and persistence of the monoclonal protein after treatment ([869]). The persistence of a monoclonal protein after radiation therapy does not guarantee relapse ([303], [669]), even after more than 10 years of follow-up ([869]). In rare instances, the maximum reduction of myeloma protein may take several years after completion of the radiation therapy ([303], [669]). Median survival for all patients presenting with solitary plasmacytoma of bone—based on data from patients staged before routine use of MRI and bone marrow clonality studies—was approximately 10 years ([669], [864], [869], [870]). For those who progressed to myeloma, the median survival was 44 months after the start of chemotherapy ([303]). Adjuvant chemotherapy has not been shown to produce a survival advantage and carries the risk of treatment-related myelodysplastic syndromes or acute leukemia; it cannot be recommended. With increasingly sensitive diagnostic techniques, the incidence of solitary myeloma will decrease, but the relapse rate probably will, too.

EXTRAMEDULLARY PLASMACYTOMA Solitary extramedullary plasmacytomas represent approximately 3% of all plasma cell neoplasms ([871]). They most commonly affect men in their early 60s and occur in the upper respiratory tract (paranasal sinuses, nose, nasopharynx, and tonsils). They also occur in lymph nodes, lung, thyroid, gastrointestinal tract, liver, spleen, pancreas, testes, breast, or skin ([872]). Amyloid involvement of the plasmacytoma occurs on occasion. Although extramedullary plasmacytomas are not common in newly diagnosed multiple myeloma, classic myeloma must be excluded by thorough staging. A monoclonal protein in the serum and urine, lytic bone lesions, anemia, renal insufficiency, and hypercalcemia should be excluded. Histologically, an extramedullary plasmacytoma should be differentiated from reactive plasmacytosis, plasma cell granuloma, poorly differentiated neoplasms, and immunoblastic lymphoma. Some extramedullary plasmacytomas may represent marginal zone B-cell lymphomas that have undergone plasmacytic differentiation ([873]). Dimopoulos et al. ([871]) compiled 128 extramedullary plasmacytoma patients from eight published series ([864], [872], [874], [875], [876], [877], [878] and [879]) and summarized their clinical course. The local failure rate was 7%, multifocal extramedullary relapse occurred in 13%, and classic myeloma developed in 15%. Local radiation therapy is the treatment of choice, and adjuvant chemotherapy is not recommended. The 10-year disease-free survival is 70 to 80%.

Osteosclerotic Myeloma (POEMS Syndrome)

Osteosclerotic myeloma is a rare variant of myeloma (=3.3% of cases) ([880]). There is a straight osteosclerotic variant that is similar to multiple myeloma in that anemia, significant bone marrow plasmacytosis, hypercalcemia, and renal insufficiency occur ([218]). Survival in these patients is comparable to that of classic multiple myeloma patients. There is, however, a more interesting form, which is known as *Crow-Fukase syndrome*, *PEP* (*P*CD, *e*ndocrinopathy, *p*olyneuropathy) *syndrome*, *Takatsuki syndrome*, and *POEMS* (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes) *syndrome* ([219], [220], [881], [882]). This variant is associated with multiple paraneoplastic phenomena, and its natural history is not similar to that of classic multiple myeloma. The acronym POEMS captures several of the dominant features of the syndrome, but it omits the sclerotic bone lesions, Castleman disease, papilledema, peripheral edema, ascites, polycythemia, thrombocytosis, fatigue, and clubbing commonly observed in the disorder ([220], [882], [883] and [884]). Not all features are required to make the diagnosis; at a minimum, however, a patient must have (a) peripheral neuropathy, (b) osteosclerotic myeloma (i.e., a clonal PCD and at least one sclerotic bone lesion) or Castleman disease, and (c) at least one of the other mentioned features ([882]). The peak incidence of POEMS syndrome is in the fifth and sixth decades of life, and there is a male predominance ([881], [882], [885]).

Although the precise mechanism of POEMS syndrome is unknown, VEGF appears to be a driving factor in this disorder ([883], [886], [887]). Despite the presence of osteosclerotic bone lesions, which microscopically contain clonal plasma cell infiltrates, bone marrow aspirate and biopsy of the iliac crest typically yield only approximately 5% monoclonal ? plasma cells ([220], [882], [883]).

Treatment for this disorder is far from standardized. Most agree that, for an isolated plasmacytoma, irradiation is the preferred treatment ([888], [889], [890] and [891]).

Radiation therapy produces substantial improvement of the neuropathy in more than one-half of the patients who have a single lesion or multiple lesions in a limited area. If there are widespread lesions, chemotherapy and, potentially, peripheral blood stem cell transplantation should be considered ([882], [892], [893], [894], [895], [896] and [897]). Responses of systemic symptoms and skin changes tend to precede those of the neuropathy, with the former beginning to respond within a month and the latter responding within 3 to 6 months.

The most common causes of death are cardiorespiratory failure, progressive inanition, infection, capillary leak–like syndrome, and renal failure ([220], [882]). The neuropathy may be unrelenting and may contribute to progressive inanition and eventual cardiorespiratory failure and pneumonia. Stroke and myocardial infarction, which may be related to the POEMS syndrome ([882]), are also observed causes of death. Patients do not die of classic myeloma (i.e., progressive bone marrow failure or hypercalcemia).

Immunoglobulin Light-Chain Amyloidosis (Primary Amyloidosis)*

HISTORY

> The term lardaceous change has… come more into use chiefly through the instrumentality of the Vienna School…. The term, lardaceous changes… has but very little to do with these tumours, and rather refers to things, upon which the old writers… who were better connoisseurs in bacon than our friends in Vienna, would hardly have bestowed such a name…. The appearance of such organs… are said to look like bacon, bears… a much greater resemblance to wax, and I have therefore now for a long time… made use of the term waxy change…. These structures… by the simple action of iodine… assume just as blue a colour as vegetable starch… ([1]).

On April 17, 1858, Rudolph Virchow gave a lecture entitled “Amyloid Degeneration.” Virchow defined how amyloid deposits stained blue with iodine and sulfuric acid. This chemical reaction was a marker for starch. Virchow concluded the substance was composed of wax, and coined the term *amyloid* ([2]). Virchow also used the opportunity to criticize Karl von Rokitansky. Virchow headed the pathology department in Berlin; Rokitansky was his chief competitor in Vienna. Rokitansky believed that amyloid was the deposition of a lardlike substance in patients with syphilis, tuberculosis, or malaria ([3]), perhaps because the amyloid deposits were white and glistening. Virchow believed incorrectly that amyloid was made of starch because of the iodine-sulfuric acid reaction; Rokitansky believed it was a fatty substance ([4]). Matthias Schleiden, a German botanist, coined the term “amyloid” in 1838 to describe a normal constituent of plants ([5], [6] and [7]). It was 1859 when Friedreich, Nikolau, and Kekule recognized that the waxy spleen described by Virchow did not contain any starchlike substances and was probably derived from modified proteins. Kekule was famous in his own right at the time for describing the structure of benzene from his dream of a serpent biting its own tail. Friedreich also gave the first description of a form of ataxia that now bears his name ([8], [9]).

George Budd (1808–1882) analyzed the liver of a patient with amyloidosis and found that it had a low fat content and was not lardaceous; he also made original descriptions of rickets and scurvy ([10]). The first reported case of primary amyloidosis (AL) (“idiopathic” from the terminology of the day) was probably made by Sir Samuel Wilks, who reported on a 52-year-old patient with lardaceous change unrelated to an obvious cause ([11], [12] and [13]). Wilks was the first to use bromide for the treatment of epilepsy and made an original description of myasthenia gravis. The amino acid composition of amyloid was first described by Schmiedeberg in 1920 ([14]). The amyloid strongly resembled serum globulin and was therefore neither fat nor carbohydrate. The first description of Congo red as the specific stain for the detection of amyloid was made in 1922 by Hermann Bennhold ([15]). In 1927, green birefringence of amyloid-laden material under polarized light was reported by Divry and Florkin in the brain of a patient with Alzheimer disease ([16], [17]). The recognition that the neurodegeneration of Alzheimer disease was associated with amyloid was forgotten for nearly 50 years. Magnus-Levy postulated that the Bence Jones protein was a precursor of the amyloid substance, noting a relationship among amyloid, the Bence Jones protein, and multiple myeloma ([18]).

The finding that amyloid represented a fibril is credited to Cohen and Calkins in 1959 ([4]). They found that all forms of amyloid were nonbranching and fibrillar. The fibril length varied and had a width of 9.5 nm. Apitz claimed that amyloid in the tissues was analogous to the excretion of immunoglobulin light chain proteins by the kidneys ([19], [20]). Apitz coined the term “paraprotein” to describe monoclonal immunoglobulins. The Bence Jones proteins were reported to have a direct role in the pathogenesis of AL by Osserman in 1964 ([21]). Normal proteins are configured as an a helix. Using x-ray defraction, Eanes and Glenner ([22]) in 1968 reported that amyloid formed the alternate configuration of a ß-pleated sheet, a configuration found in silk ([23]). Silk is highly resistant to solvents. The resistance of amyloid to solubilization is used in its purification. Amyloid is repeatedly homogenized in saline, and the supernatant, which is soluble, is discarded. The residual pelleted material contains the amyloid and, when suspended in distilled water, yields a relatively pure preparation of amyloid fibrils. Pras first described the purification of amyloid in 1968 ([24]). Levin sequenced the first amyloid protein and labeled it amyloid A ([25]). Earl Benditt independently reported the same structural finding ([26], [27]). The first sequence reported of an immunoglobulin light-chain form of amyloid was in 1970 by Glenner ([28]). It was recognized to be a fragment of the N-terminus of the immunoglobulin light chain and not the intact immunoglobulin light chain ([28], [29], [30], [31] and [32]).

CLASSIFICATION

The diagnosis of amyloid requires tissue biopsy proof of deposits that stain positively for Congo red ([33]). With hematoxylin and eosin staining, amyloid deposits are hyalin appearing. The deposits are always extracellular and appear amorphous. Apple-green birefringence is seen when Congo red–stained material is viewed under polarized light ([34]). False-positive results can occur, however, particularly if the stain is not used regularly. The Congo red stain can be technically difficult to use, for example, and can form precipitates, yielding false-positive results ([35]). All forms of amyloid have a fibrillar appearance under the electron microscope and are rigid and nonbranching, but all fibrils so identified do not represent amyloid ([36], [37] and [38]). The finding of fibrils on the electron microscope is strongly suggestive, but in the absence of a positive Congo red stain and apple-green birefringence, the diagnosis remains unconfirmed.

The classification of amyloidosis has undergone revisions as the understanding of the pathophysiology of the disease has improved. In the nineteenth century, anatomic involvement of the liver, spleen, and kidneys was incorrectly thought to represent secondary amyloidosis (AA); amyloid that would involve the heart, tongue, and peripheral nerves was classified as primary amyloidosis (AL), or idiopathic in the nomenclature of the era. Later, amyloid was classified by the site of first deposition and was referred to as *pericollagenous* or *perireticular* ([39], [40]). Familial amyloidosis (AF) was recognized generally by the presentation of progressive painful peripheral neuropathy with an autosomal-dominant inheritance pattern ([41], [42]). Families with inherited renal amyloidosis were also described ([43], [44]). In the nineteenth century, when tuberculosis, leprosy, syphilis, and chronic infections were prevalent, the secondary form of amyloidosis was regularly seen. In the postantibiotic era, chronic inflammatory polyarthritis, including ankylosing spondylitis and juvenile rheumatoid arthritis, are more commonly associated with AA. Crohn disease and chronic osteomyelitis are also responsible for a small number of AA patients in the West ([45]). One hundred years ago, when “primary amyloid” referred to idiopathic amyloid and included all cases that were neither familial nor secondary, cases of unrecognized familial amyloid and secondary amyloid for which a cause could not be established were mistakenly labeled primary. AL now refers only to patients whose amyloidosis is immunoglobulin light-chain derived. A clonal plasma

cell disorder exists in all instances, part of a spectrum extending from patients who have a small plasma cell clone to those with frank overt multiple myeloma ([46]). A classification of the various forms of amyloid is given in Table 99.1.

TABLE 99.1. Nomenclature of Amyloidosis

Protein	Precursor	Clinical
AL or AH	Immunoglobulin light or heavy chain	Primary or localized; myeloma or macroglobulinemia association
AA	SAA	Secondary or familial Mediterranean fever
ATTR	Transthyretin	Familial and senile
A fibrinogen	Fibrinogen	Familial renal amyloidosis (Ostertag)
Aß $_2$M	ß $_2$-Microglobulin	Dialysis-associated carpal tunnel syndrome
Aß	AßPP	Alzheimer disease
ApoAI, AII	Apolipoprotein	Renal, nephrotic syndrome
Lysozyme	Lysozyme	Renal, hepatic rupture

AA, secondary amyloidosis; AßPP, amyloid ß protein precursor; AH, immunoglobulin heavy chain amyloid; AII, apolipoprotein AII amyloid; AL, primary amyloidosis; ApoAI, apolipoprotein AI amyloid; ATTR, amyloid transthyretin; SAA, serum amyloid A.

From Gertz MA, Lacy MQ, Dispenzieri A. Immunoglobulin light chain amyloidosis (primary amyloidosis). In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:157–195. By permission of Mayo Foundation.

Human monoclonal immunoglobulin light chains can be converted to amyloid fibrils by digestion with pepsin *in vitro* ([30]). Amyloid fibrils can be produced synthetically by breaking the disulfide bonds of intact immunoglobulins. Originally, all forms of amyloid were thought to be related to misfolding of the fragments of immunoglobulin light chains, but heavy-chain fragments have also been found to produce amyloid and have been given the designation AH ([47]). AL patients have immunoglobulin light chains that have an abnormal tertiary structure and an abnormal amino acid sequence ([48] , [49]). Generally, they tend to have a higher ß-pleated sheet content than an a-helical structure. If mice are injected with purified immunoglobulin light chains derived from the urine of patients with multiple myeloma who do not have amyloid, no renal dysfunction is seen ([50]). If light chains purified from the urine of patients with AL are injected, the mice develop deposits of human AL. In AL, three-fourths of the immunoglobulin light chains are of the ? group. In multiple myeloma and monoclonal gammopathy of undetermined significance, two-thirds of the light chains are of the ? group ([45]). The implication is that ? immunoglobulin light chains have a greater tendency to form a ß-pleated sheet. The ? $_{VI}$ subgroup of immunoglobulin light chain is always associated with amyloid, suggesting that there are unique amino acid sequences that result in amyloidogenic proteins ([51]).

The distinction between amyloidosis and amyloidosis associated with multiple myeloma is somewhat arbitrary. Significant overlap exists. Finding a patient with amyloidosis who has widespread lytic bone disease, rib fractures, or lumbar spine compression fractures is uncommon ([52]). Renal insufficiency in an amyloid patient almost never owes to the formation of light-chain casts, as is the case in multiple myeloma. In patients with amyloid, the renal failure owes to tubular atrophy, a consequence of long-standing albuminuria ([53] , [54]). Often the distinction among multiple myeloma associated amyloid and amyloid AL has been made on the basis of the percentage of plasma cells in the bone marrow ([55]). Serial bone marrow biopsies in patients with AL do not demonstrate a progressive increase in the plasma cell percentage. In amyloid, the process is clonal but is not typically proliferative, and the unrestrained growth associated with malignancy is not present. Patients with AL who have 10 to 30% plasma cells do not go on to develop multiple myeloma if it is not present at diagnosis. Less than one-half of 1% of amyloid patients go on to develop multiple myeloma ([46]). The authors have established an arbitrary threshold of 30% plasma cells to fulfill the criteria of multiple myeloma–associated amyloid if no other clinical features of multiple myeloma are present. In patients who have greater than 30% plasma cells in the bone marrow, the clinical course is dominated by their AL and not by myeloma bone disease or myeloma-induced anemia.

The incidence of AL is 8 per million per year and has been stable for more than 50 years ([56]). Multiple myeloma is four times more prevalent than amyloidosis ([57]). The incidence of amyloidosis, although considered rare, is similar to that of Hodgkin disease (nodular sclerosing variant), chronic granulocytic leukemia (Philadelphia chromosome–positive), and polycythemia rubra vera ([58] , [59] and [60]). Bone marrow plasma cells from AL patients typically show chromosomal abnormalities ([61]). Trisomies of chromosomes 7, 9, 11, 15, and 18 were seen in 42%, 52%, 47%, 39%, and 33%, respectively. Fifty-four percent of men and 13% of women showed trisomy X; 72% of AL patients have deletion of chromosome 18. The finding of aneuploidy in the monoclonal plasma cells supports the neoplastic nature despite the fact that these plasma cells are nonproliferative and are present in small numbers (median, 5% plasma cells) ([62]). An early pathogenetic event in the development of multiple myeloma is translocation at the immunoglobulin heavy-chain locus (band 14q32) ([63] , [64]). Sixteen of 29 AL patients showed definite translocations at the immunoglobulin heavy-chain locus (55%). An additional 17% demonstrated a pattern compatible with a possible immunoglobulin H (IgH) translocation ([65]). Overall, an IgH translocation was seen in 21 of 29 patients by fluorescent *in situ* hybridization analysis. Of the 21, 16 were t(11;14)(q13;q32). Fifteen of the 16 patients demonstrated 11;14 translocations, with cyclin D1 overexpression accounting for 76% of all IgH translocations.

Light-chain amyloid AL is a monoclonal immunoglobulin plasma cell disorder. AL may be misdiagnosed as multiple myeloma because both have a monoclonal immunoglobulin, a high prevalence of proteinuria, and bone marrow plasmacytosis. AL should always be in the differential diagnosis when a patient is seen with monoclonal gammopathy of undetermined significance or is suspected of having multiple myeloma.

SUSPECTING PRIMARY AMYLOIDOSIS

Weight loss, paresthesias, edema, dyspnea, and fatigue are the most common symptoms associated with AL ([66]) (Fig. 99.1). These complaints are nonspecific and provide little help to a clinician trying to evaluate patients. Patients with extreme degrees of weight loss frequently undergo an evaluation for an occult malignancy. The fatigue, which is usually caused by early cardiac involvement with AL, is generally not associated with overt congestive heart failure and can easily be diagnosed incorrectly as being stress related or functional ([67]). The authors have seen scores of patients undergo coronary angiography because of fatigue and breathlessness, and when the angiogram is normal, the evaluation frequently is stopped ([68]). Lightheadedness occurs frequently but is nonspecific because it is such a common complaint in the primary care setting. In AL, the etiology of lightheadedness is multifactorial ([69]). Patients with nephrotic syndrome developed dizziness owing to hypoalbuminemia and a significant intravascular volume contraction, which leads to orthostatic hypotension ([70]). Patients with cardiac AL have a low end-diastolic volume owing to restriction to filling during diastole ([71]). Cardiac AL patients have a low cardiac output but maintain a normal ejection fraction until late in the course of the disease. The echocardiographic finding of the normal ejection fraction can be highly misleading in recognizing AL. Patients can have orthostatic hypotension as a consequence of autonomic neuropathy, and syncope is not unusual ([72] , [73]). The physical findings of amyloidosis are specific and diagnostic; however, they are present in only 15% of patients and may easily be overlooked. Amyloid purpura is seen in only one patient in six (Fig. 99.2) ([74]). Purpura may be periorbital but also can occur in the face, webbing of the neck, and upper chest. Purpura on the arms is not characteristic of AL, but petechial lesions on the eyelids should not be overlooked.

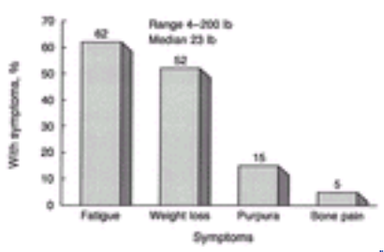

Figure 99.1. Prevalence of symptoms in patients with primary amyloidosis evaluated within 1 month before or after diagnosis at the Mayo Clinic, 1981–1992. (From Kyle RA, Gertz MA. Primary systemic amyloidosis. Clinical and laboratory features in 474 cases. Semin Hematol 1995;32:45–59, with permission.)

Figure 99.2. Classic truncal purpura in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211–1233, with permission.)

The liver is palpable 5 cm below the right costal margin in only 10% of patients. Splenomegaly, if present, is usually of modest degree. Overall, any degree of hepatomegaly is present in one-fourth of patients ([75]).

Macroglossia is the most specific finding in AL (Fig. 99.3). In the authors' experience, enlargement of the tongue is never found in AF, AA, or senile systemic amyloidosis ([76]). Tongue enlargement is seen in one patient in eleven with AL and can be overlooked easily unless dental indentations are sought for on the underside of the tongue. Patients presenting with fatigue, edema, breathlessness, or paresthesias would not immediately alert the physician to examine the tongue. Tongue enlargement is almost always accompanied by concomitant enlargement of the submandibular salivary glands ([77]). This involvement of salivary glands with amyloid should not be misinterpreted as submandibular lymphadenopathy. Salivary gland involvement, major and minor, is responsible for the sicca syndrome that these patients frequently demonstrate. Sjögren syndrome has been reported with AL ([78]). Vascular involvement with amyloid without visceral organ dysfunction has been reported. Vascular involvement produces occlusion and ischemic symptoms, including jaw claudication when the temporal arteries are involved ([79]), and calf and limb claudication when microvasculature supplying the extremities is involved ([80]). The presence of a monoclonal protein in the serum can elevate the sedimentation rate, and it is not unusual for amyloid patients with jaw claudication to be misdiagnosed as having polymyalgia rheumatica ([81]). If a temporal artery biopsy is performed, amyloid deposits are found, but Congo red staining is not typically performed on temporal artery biopsy specimens ([80], [82]). The shoulder-pad sign is a consequence of periarticular infiltration with amyloid and may produce pseudohypertrophy. Although the musculature and the shoulder and hip girdles are enlarged, these patients present with diffuse muscular weakness ([83], [84]) and may have muscular atrophy owing to chronic vascular occlusion.

Figure 99.3. Tongue enlargement in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211–1233, with permission.)

DIAGNOSING PRIMARY AMYLOIDOSIS

When should a clinician suspect AL and begin a diagnostic algorithm to confirm the diagnosis? The symptoms and physical findings of AL are nonspecific and generally not helpful to the clinician. There are seven critical clinical syndromes commonly associated with amyloid that should trigger screening: (a) gastrointestinal tract symptoms of pseudoobstruction or steatorrhea, (b) tongue enlargement, (c) carpal tunnel syndrome, (d) hepatomegaly, (e) peripheral neuropathy, (f) nephrotic-range proteinuria, and (g) infiltrative cardiomyopathy with restrictive hemodynamics. The diagnosis of AL must be considered when any one of these syndromes is seen (Table 99.2). Any patient in whom the diagnosis of multiple myeloma is being considered and who has associated, unexplained weight loss or fatigue or a percentage of plasma cells in the bone marrow that does not meet the criteria of multiple myeloma must be investigated for AL.

TABLE 99.2. Syndromes in Primary Amyloidosis

Syndrome	Patients (%)
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22
Carpal tunnel	21
Neuropathy	17
Orthostatic hypotension	12

From Gertz MA, Lacy MQ, Dispenzieri A. Immunoglobulin light chain amyloidosis (primary amyloidosis). In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:157–195. By permission of Mayo Foundation.

The most important screening test in a patient with cardiomyopathy, neuropathy, hepatomegaly, or proteinuria is immunofixation of the serum and urine ([85]). A clonal population of plasma cells was seen in all AL patients ([86]). The insoluble, fibrillar ß-pleated sheet of amyloid is derived from the monoclonal immunoglobulin light chains produced by a clonal population of plasma cells. In any patient with a compatible clinical syndrome that has a monoclonal gammopathy, the diagnosis of AL should be pursued aggressively. Electrophoresis of the serum is an inadequate screening test. To screen for AL, immunofixation of urine and serum is necessary. The urine must be evaluated because one-fourth of patients with AL fail to demonstrate a monoclonal light chain in the serum (Fig. 99.4). Serum electrophoresis is inadequate because the light chains in AL are frequently present in trace amounts in the serum and do not produce a spike on an electrophoretic pattern. Monoclonal proteins in the urine are frequently difficult to detect because the majority of patients have significant degrees of proteinuria, which can obscure small amounts of light chains (Fig. 99.5). If amyloid is being considered, immunofixation of serum or urine, or both, is essential.

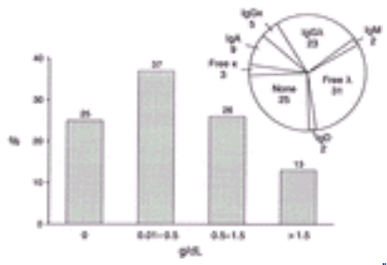

Figure 99.4. Amount of serum monoclonal protein in patients with primary amyloidosis and immunofixation results. Ig, immunoglobulin. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002:445–463, with permission.)

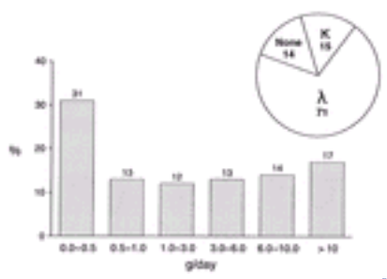

Figure 99.5. Distribution of 24-hour urine total protein and immunofixation results in primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002:445–463, with permission.)

A monoclonal light chain can be detected in the serum or urine, or both, of nearly 90% of AL patients. In a patient with a suggestive clinical syndrome, immunofixation is the single best noninvasive screening test. In patients who do not have light chains in the serum or urine, the bone marrow demonstrates a clonal population of plasma cells by flow cytometry, immunofluorescence, or immunohistochemistry ([87], [88]). Such patients have light chains below the threshold of detection by immunofixation ([89]). This can occur because the levels are low or because the light chain fragments do not express antigenic determinants that are recognizable by commercially available antisera. In patients with confirmed AL who did not have a detectable monoclonal protein in the serum or urine, 94% had a clonal population of plasma cells in the bone marrow with a slide-based immunofluorescence test to detect the expression of clonal cytoplasmic immunoglobulin. If the patient has neither a monoclonal protein in the serum or urine nor a clonal population of plasma cells in the bone marrow, the diagnosis of AL is in question. If amyloidosis is present, it is likely not immunoglobulin light chain–derived, and further evaluation for familial, secondary, or localized amyloidosis should be performed.

The nephelometric assay for serum free light chains has improved the authors' ability to recognize AL; it detects free immunoglobulin light chains not associated with an intact immunoglobulin molecule ([90], [91]). This test was performed in 100 consecutive AL patients. In patients with known ? amyloid, the free light chain assay had a sensitivity of 90%. In patients with known ? AL, a similar sensitivity was seen. In patients who had a known urinary light chain but did not have a detectable monoclonal protein on serum immunofixation, the free light chain assay found free light chains in the serum of 85% of patients with ? and 80% of patients with ? AL. In patients with AL who were carefully evaluated and had no monoclonal protein in the serum or in the urine by immunofixation, the nephelometric light chain assay found a free ? light chain in 86% of ? AL and 30% of ? AL. The free light chain assay is particularly important in patients who do not have light chains detectable by immunofixation. The serum assay is convenient and adds an important diagnostic tool for classifying and potentially monitoring AL patients.

All forms of amyloid contain the amyloid P component. Amyloid P component is structurally related to C-reactive protein, but is not an acute-phase reactant in humans ([92]). Amyloid P component is a pentagonal glycoprotein that can comprise as much as 10% of the amyloid fibril by weight. Amyloid P component is in dynamic equilibrium with the amyloid fibril and is not irreversibly bound. P component maintains a relatively stable plasma concentration throughout one's life and is found in all vertebrates. Because serum amyloid P (SAP) exchanges readily with the amyloid P component, amyloid deposits can be demonstrated visually via 123-iodine-labeled SAP scanning ([93], [94]). In addition, the clearance of the radiolabeled P components (125-iodine-labeled SAP) in the plasma can be used to assess the total body burden of amyloid and to evaluate the impact of therapy ([95]). Patients with high burdens of amyloid clear the radiolabeled P component quickly. Patients with only trace amounts of systemic amyloid have plasma clearances close to those of normal adults. The P component scan can be performed serially to assess whether patients are having increasing depositions of AL or improvement. The technique does not determine whether the amyloid is AL, AF, AA, or localized. The technique is not sensitive in detecting cardiac amyloid and is generally used in conjunction with echocardiography ([96]). Uptake is seen in the spleen, liver, and kidneys in 87%, 60%, and 25% of patients, respectively. Rapid plasma clearance of amyloid P component is associated with a shorter survival. Imaging does not regularly demonstrate deposits in the carpal tunnel, the kidney, and the gastrointestinal tract. In normal adults, there is 50 to 100 mg of amyloid P component in the extravascular and intravascular compartments, whereas patients with amyloid can have as much as 20,000 mg. There is a poor correlation between imaging and the extent of organ dysfunction assessed clinically. Amyloid distributes heterogeneously within individual organs. Iodine-labeled SAP scanning is not available in the United States.

The diagnosis of amyloidosis must always be confirmed by tissue biopsy ([97]). In patients who have neuropathy, nephrotic syndrome, cardiac failure, or hepatomegaly, the diagnosis could be established by direct biopsy of these organs ([97]), but an invasive visceral biopsy is usually not required to confirm AL. Because amyloid is widespread at diagnosis, and extensive vascular involvement is seen ([98]), less invasive biopsies can establish the diagnosis at lower risk and lower cost. When the authors see a patient with a syndrome consistent with AL and the patient is confirmed to have a monoclonal protein, their diagnostic evaluation begins with a subcutaneous fat aspirate and bone marrow biopsy ([99]). The subcutaneous fat aspirate is a risk-free procedure performed by registered nurses ([100]) and has a sensitivity of 75%. Results are available within 24 hours (Fig. 99.6). Amyloid deposits are seen in one-half of the bone marrow biopsies performed in patients with AL, generally in blood vessels ([101]). Bone marrow biopsy is justified in any patient who has a monoclonal immunoglobulin light chain to exclude the diagnosis of multiple myeloma. Knowledge of the percentage of bone marrow plasma cells is prognostically important ([102]). Table 99.3 gives the results when bone marrow biopsy and fat aspiration are performed in AL patients. With Congo red studies of fat and bone marrow, the diagnosis is established in 87%. In the remaining 13%, the diagnosis can be established by biopsy of the affected organ.

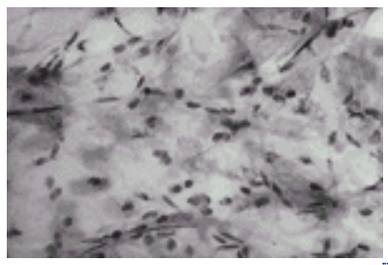

Figure 99.6. Subcutaneous fat aspirate demonstrates amyloid. (×100.) (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. In: Mehta J, Singhal S, eds. Myeloma. London: Martin Dunitz, 2002:445–463, with permission.)

Modified from Gertz MA, Lacy MQ, Lust JA, et al. Prospective randomized trial of melphalan and prednisone versus vincristine, carmustine, melphalan, cyclophosphamide, and prednisone in the treatment of primary systemic amyloidosis. J Clin Oncol 1999;17:262–267. By permission of the American Society of Clinical Oncology.

Other less invasive biopsies can establish a diagnosis of AL. It is recognized that xerostomia in amyloidosis owes to salivary gland infiltration, and lip biopsies have a high sensitivity ([103], [104]). In one study, this ranged as high as 87%. Subcutaneous blood vessels can be accessed via skin biopsy and may demonstrate AL deposits ([105], [106]). Amyloid was regularly confirmed by rectal biopsy in the 1970s and 1980s ([107]). Rectal biopsy is an outpatient procedure, although occasionally it could result in bleeding. Endoscopic biopsies are frequently inadequate because submucosa is essential for specimen adequacy.

A typical clinical example of a patient coming to the Mayo Clinic would be a referral to a nephrologist for evaluation of nephrotic syndrome. Nephrologists there perform immunofixation of serum and urine as a screen in all nephrotic syndrome patients. If positive, a fat aspiration is performed, and this eliminates the need for a diagnostic renal biopsy in 70% of patients. The net result is a reduced risk of bleeding, hospitalization, and expense.

The Congo red stain is not easily done and interpreted. Congo red can precipitate in tissue, and this overstaining, particularly in subcutaneous fat, can produce a false-positive result ([108]). Skin and subcutaneous fat have a high content of elastin and collagen, which binds Congo red and can also be interpreted as positive ([109]). Rectal biopsy specimens containing amyloid can be misinterpreted as collagenous colitis if stained only with hematoxylin and eosin ([110]). With hematoxylin and eosin, renal amyloid can be misinterpreted as glomerular hyalinization. To recognize amyloid in the myocardium, our cardiac pathologists prefer a sulfated Alcian blue stain ([111]). The Peripheral Nerve Laboratory at the Mayo Clinic stains sural nerve biopsy specimens with crystal violet as a screen and confirms the diagnosis subsequently with Congo red ([112]).

DIFFERENTIATING PRIMARY AMYLOIDOSIS FROM OTHER FORMS

It is important that the diagnosis of amyloid be confirmed as AL, AF, or AA because the therapy for the three syndromes is different ([113], [114]). Localized ([115]), familial ([116]), AA ([117]), and senile systemic forms of amyloid ([118]) are not associated with a plasma cell dyscrasia. Except in the rare instance of a patient with one of these forms of amyloid and an incidental monoclonal gammopathy of undetermined significance, only AL patients have monoclonal light chains in the serum and urine or clonal plasma cells in the marrow. Patients with localized amyloidosis can present with hematuria ([119]), respiratory difficulties ([120]), and visual disturbances ([121]) and can easily be confused with those who have the systemic form. The localized amyloid syndrome, usually involving the skin, tracheobronchial tree, or urogenital tract, never becomes systemic. The fibrils of localized amyloid are immunoglobulin light chain derived ([122]), but a plasma cell dyscrasia is not seen in the bone marrow. It is thought that the production of localized amyloid owes to plasma cells at the site producing the insoluble light chains.

The location of the amyloid is an important clue in recognizing the amyloid as being localized. The most frequent sites of localized amyloid are respiratory tract, genitourinary tract, and skin ([114], [123]). Pulmonary amyloid can be subdivided into nodular, tracheobronchial, or diffuse interstitial. Only the last represents a manifestation of systemic AL ([124]). The diagnosis of tracheobronchial amyloidosis is via bronchoscopy while evaluating a patient with obstruction, cough, dyspnea, wheezing, or hemoptysis. The usual treatment is yttrium-aluminum-garnet laser resection of the tissue ([125]). Tracheobronchial amyloid deposits are derived from immunoglobulin light chains ([126]). The nodular forms of amyloid present as solitary pulmonary nodules or multiple nodules. This does not represent the systemic form of AL ([127]). These nodules are not calcified and often require resection to exclude a diagnosis of malignancy. The diagnosis is made at thoracotomy or a video thoracoscopic surgical procedure. Amyloid can involve the vocal cords and false vocal cords, causing traction on the structures and leading to hoarseness. This form of laryngeal amyloid is always localized ([128]). Obstructive ureterovesicular amyloidosis is always localized. Patients present with hematuria. The prebiopsy diagnosis is cancer. Amyloid is found when cystoscopic biopsies are performed. Eighty-five percent of patients present with hematuria. Partial cystectomy, fulguration, and transurethral resection have all been used ([129]). Dimethylsulfoxide instillation in the bladder has been reported to improve these deposits ([130]). Colchicine has also been reported to be beneficial.

Amyloid involving the renal pelvis or ureter is a localized amyloid syndrome ([131], [132]). These patients present with colic owing to obstruction or hematuria. The deposits are found at surgery. Nephrectomy is commonly performed because of the concern that the ureteral mass would represent a transitional cell malignancy. The recognition of amyloid avoids nephrectomy. Amyloidosis can involve the urethra and present with dysuria and hematuria ([133]). The preoperative diagnosis is usually a urethral malignancy. Resection is the treatment of choice.

Three forms of cutaneous amyloidosis are recognized. The lichen and macular forms are localized ([134]). Nodular amyloidosis is associated with AL ([135]). The generated keratin fibrils are the source of macular and papular amyloid ([136]). Dermabrasion and other forms of local therapy are adequate for control. Lichen and macular amyloid usually is associated with a history of local skin trauma or inflammation. Lichen or macular amyloid is an innocuous condition. The nodular form, however, can be an important clinical clue to an underlying life-threatening process.

Carpal tunnel amyloidosis can be seen in systemic AL and AF and may be localized as well ([137], [138]). If a patient presents with carpal tunnel syndrome as the only manifestation of amyloid, the median survival is 12 years. Virtually all of these patients have localized disease, and only two of 124 patients with localized carpal tunnel amyloid developed AL ([139]). The amino acid composition of localized carpal tunnel amyloid tends to be transthyretin (TTR). The conjunctiva and orbits are sites where localized amyloidosis is also seen. The best treatment is surgical excision. Amyloid has also been localized to the breast ([140]), mesenteric lymph nodes, colonic polyps, thyroid ([141]), retroperitoneum, and ovary. Localized deposits of amyloid are commonly seen in trace amounts within the cartilage on the hip surface after a total hip arthroplasty ([142]). A localized deposit is similarly found in resected knee arthroplasty specimens. These deposits are not associated with systemic disease ([143]).

AA is a consequence of long-standing systemic inflammation that is poorly controlled. AA is more common than AL in underdeveloped countries because of the persistence of tuberculosis ([54]), syphilis, malaria, and leprosy. AA, when seen in the United States, is not easily distinguished from AL. AA is not associated with a monoclonal protein or clonal marrow plasma cells. AA most commonly presents with nephrotic-range proteinuria ([144]). From a simple syndrome standpoint, it is quite similar in its presentation to AL. At the Mayo Clinic, AA accounts for only 2% of the patients seen ([145]). The underlying etiology of AA most commonly includes ankylosing spondylitis ([146]), juvenile rheumatoid arthritis ([147]), psoriatic arthritis ([148]), and rheumatoid arthritis ([149]). The underlying cause in most instances of AA is clear because the arthritis is disabling and is present a median of 15 years before the development of AA ([150]). Of patients with rheumatoid arthritis, 3.1% succumb to AA ([151]). Amyloidosis of the AA type is also seen in Crohn disease ([152]), bronchiectasis ([153]), and chronic osteomyelitis ([154]). These are conditions in which the infection is not amenable to surgical excision, and in which antibiotics result in poor control. In most patients, the inflammatory bowel disorder or infection has been present for decades. The first clinical manifestation is proteinuria. No monoclonal protein is detectable. AA has been described in individuals who subcutaneously inject contaminated illegal substances ([155], [156]). Skin abscesses develop at the site of injection and result in the inflammation that is necessary for the development of AA. Patients with Hodgkin disease ([157], [158]) and hypernephroma ([159], [160]) have been described as having AA. Paraplegic patients who develop chronic infected decubitus ulcers or chronic urinary tract infection ([161], [162]) have been reported to develop AA. One-half of all patients who have had a spinal cord injury for 10 years or longer have amyloid deposits at autopsy ([163]). AA from Castleman disease has been recognized. Surgical excision leads to remission.

Inherited amyloid is more common than AA in the United States. The presentations of AF are clinically indistinguishable from AL and include cardiomyopathy ([164], [165]), neuropathy ([166]), and nephrotic syndrome ([167]). The most common form of inherited amyloidosis is a result of *TTR* mutations. Amyloid neuropathy has been reported involving more than 60 different mutations in the *TTR* gene ([168]). A positive family history is not found in nearly one-half of the patients with AF seen at the Mayo Clinic. The absence of a family history is a poor screen for excluding AF ([169]). The presence of amyloid neuropathy in the absence of a monoclonal protein or clonal plasma cell disorder should raise suspicion. Mutations in the *TTR* gene as well as wild-type *TTR* can be the source of cardiac amyloid deposition ([170]). In people older than 80 years, cardiac amyloid deposits occur in 8 to 25% ([171]). These deposits are a result of the deposition of normal TTR. In this form of senile systemic amyloid, only cardiac symptoms are seen.

Inherited amyloid involving the heart in the absence of a peripheral neuropathy was first described in a Danish kindred ([172]). Familial amyloid cardiomyopathy has

been described throughout the world. Pedigrees in the United States usually develop symptoms after age 60 years. Familial amyloid cardio-myopathy presents with heart failure or arrhythmias, and the clinical picture is virtually indistinguishable from senile cardiac amyloid or AL. In patients older than 90 years, 21% were found to have senile systemic amyloid owing to normal sequence TTR deposition ([173]). The first description of a TTR Ile122 mutation was in an African-American man aged 68 years ([174]). The TTR Ile-122 allele is carried by 3.9% of African Americans, which translates to 1.3 million people in the United States ([175]). Ile122 is a major cause of an inherited cardiac amyloidosis in African Americans. The finding of cardiac amyloidosis in the absence of a monoclonal gammopathy should not be assumed to be AL, but could represent familial amyloid cardiomyopathy even without a positive family history ([176]).

Mutations in the fibrinogen ([177]), lysozyme ([178]), or apolipoprotein A-I and A-II ([179] , [180] and [181]) molecules can produce inherited forms of renal amyloidosis. The amyloidosis associated with these mutations carries a much better prognosis than renal AL. The authors have regularly seen patients with proteinuria for more than a decade without renal failure and with easily controlled hypertension. Because these patients present with proteinuria and the renal biopsy demonstrates amyloid, it is easily confused with AL. The absence of a monoclonal immunoglobulin disorder or the absence of serum free light chains is an important distinguishing feature. Only immunohistochemical staining or sequencing of the amyloid can differentiate these entities definitively, however.

The treatment of TTR-derived AF includes liver transplantation, making the distinction between AF and AL critical ([182]). TTR is produced in the choroid plexus and the liver. Regression of amyloid deposits has been reported ([183]) when liver transplantation is performed before the development of disabling peripheral or autonomic neuropathy or advanced cardiomyopathy. Patients with the Val30Met mutation appear to have the best outcome after liver transplantation ([184]). Progressive cardiac amyloidosis has been reported after liver transplantation in patients with other *TTR* mutations ([185]). Once mutant TTR is deposited in the myocardium, it can serve as a nidus for further deposition of native TTR produced by the transplanted liver. At autopsy, the heart demonstrates amyloid fibrils that contain both mutant and wild-type TTR ([186] , [187]).

In summary, any patient with amyloidosis who does not have a detectable monoclonal light chain in the serum or urine and does not have a clonal population of plasma cells in the bone marrow should be considered for AA, localized, or AF amyloid.

PRESENTATION AND CLINICAL FEATURES

The authors reviewed all patients diagnosed with AL between June 1, 1988, and June 30, 1998, at the Mayo Clinic. All patients were diagnosed within 30 days of presentation at Mayo. All had a clonal plasma cell disorder and histologic proof of amyloid. Patients who had overt multiple myeloma were excluded. The male to female ratio was 2:1 (male, 67.3%). The male preponderance of AL has been a constant at their institution for 40 years, and the authors believe this reflects a true higher prevalence of the disorder in men and not a reflection of referral bias. Multiple myeloma is more common in men, but the ratio is 55:45. The age range of amyloidosis patients was 39 to 89 years (median, 67; standard deviation, 10 years). The authors have seen patients with amyloidosis as young as 27 years. The median age of patients presenting with AL in Olmsted County, Minnesota, is 73 years ([56]). The age difference suggests that there is referral bias to amyloidosis treatment centers. Presumably, younger patients are more likely to seek a second opinion at a referral center than older patients. The most common clinical manifestation of amyloidosis is cardiac amyloid, seen in 37.4% of patients. Congestive heart failure is present in only one-half of these patients; in the other one-half, the presenting symptom of cardiac amyloid is fatigue and dyspnea. These patients have poor cardiac filling and a low cardiac output state, but a preserved ejection fraction. Syncope and arrhythmias may also be seen. Echocardiography has led to improved recognition of cardiac AL ([188] , [189]).

Renal amyloid is seen in 30% of presenting patients and is the second most common presentation. Nephrotic-range proteinuria is seen in 95% of patients with renal AL. The 5% who present with renal insufficiency have amyloid deposits only in the interstitium and mesangium, without glomerular deposits. Sensorimotor symmetric ascending peripheral neuropathy is present in 15.3% of AL patients ([24]); 17.7% of AL patients have palpable hepatomegaly, but amyloid presenting with a dominant hepatic syndrome is seen in only 4.6% of patients; 7.1% of patients present with intestinal bleeding, pseudo-obstruction, or diarrhea, a manifestation of gastrointestinal tract amyloid. The remaining 7.8% of patients have amyloid limited to the tongue, lung, joints, or soft tissues.

The exact classification of a dominant amyloid syndrome is sometimes arbitrary; 36.3% of patients present with two or more organs involved, and some judgment is required to determine which of the two organs is “dominant.” At the Mayo Clinic, 29.9% of patients had two or more organs involved; 6%, three organs; and 0.5%, four or more organs. When multiple organs were involved, the liver was the organ most likely to be associated. Significant bleeding (excluding purpura) was present in only 2.3% of the authors' patients ([190] , [191]). Congestive heart failure was seen in 22% of patients, and carpal tunnel syndrome was seen in 21% of patients ([192]). Edema was a sign in 44.8% and fatigue in 46.4%. Lower-extremity paresthesias, nephrotic-range proteinuria, orthostatic hypotension, and weight loss were seen in 34.9%, 21.0%, 12.5%, and 51.7%, respectively.

Amyloidosis is rarely associated with anemia ([193]). The hemoglobin value was greater than 100 and 120 g/L in 90% and 64.4% of patients, respectively. Only 1.5% had a hemoglobin value less than 90 g/L, and the cause was usually active gastrointestinal tract bleeding or renal failure. The platelet count in amyloid ranges from 46 to 809 × 10^{9}/L (median, 257). A platelet count greater than 500 × 10^{9}/L is seen in 5.5%. The most common cause of thrombocytosis in AL is hepatic involvement with associated hyposplenism ([194] , [195]). A serum creatinine value greater than or equal to 2 mg/dl was present in 13.6% of patients; 6.7% of patients had an alkaline phosphatase value greater than twice the normal value. This is close to the number of patients with clinical hepatic amyloid involvement. The bone marrow plasma cell percentage in AL ranges from 1 to 30% (median, 7%) (Fig. 99.7). Patients with more than 30% plasma cells were excluded from this analysis and diagnosed as having myeloma-associated amyloid. In 11.3% of patients with AL, more than 20% plasma cells were found in the bone marrow without other clinical evidence of multiple myeloma. Proteinuria is exceedingly common in AL, and the median 24-hour urine protein loss in all patients is 790 mg/24 hours (Fig. 99.5). A monoclonal ?, ?, and no light chain was found in 70.1%, 18.9%, and 11%, respectively, in the serum or urine. The serum heavy chain was IgG, IgA, and IgM in 58%, 10%, and 8.2%, respectively, in those patients who had complete monoclonal gammaglobulins. The presence of an IgM monoclonal protein in 8.2% is important because the authors have seen many patients referred with a diagnosis of Waldenström macroglobulinemia in whom the amyloid syndrome was overlooked ([196]).

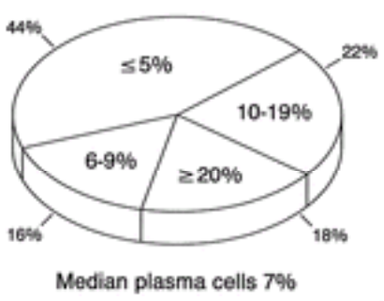

Figure 99.7. Distribution of bone marrow plasma cells in patients with primary amyloidosis. (From Gertz MA, Lacy MQ, Dispenzieri A. Amyloidosis. Hematol Oncol Clin North Am 1999;13:1211–1233, with permission.)

The use of echocardiography has dramatically increased the recognition of cardiac amyloidosis (see Cardiac). In a Cox statistical analysis, the variables that predict shortened survival include age, performance status, cardiac involvement as the dominant syndrome, and involvement of two or more organs. The median survival of our entire cohort was 12 months, with a 2- and 5-year survival of 33.6% and 14.9%, respectively.

Cardiac

Prognostically, the heart is the most important organ determining the outcome of AL and is the organ most frequently involved ([197] , [198] and [199]). Amyloid is deposited extracellularly and results in a noncompliant and thickened left ventricle ([200] , [201]). The clinical presentation is infiltrative cardiomyopathy with restricted diastolic ventricular filling (Fig. 99.8). Many patients present only with fatigue and unexplained weight loss. Early cardiac AL produces diastolic dysfunction without systolic dysfunction ([202] , [203]). In early AL, the chest radiograph shows no evidence of pulmonary vascular congestion or cardiomegaly. Moreover, the ejection fraction is preserved because this is an infiltrative process with diastolic dysfunction only ([204]). Indeed, owing to a low stroke volume, a hyperdynamic myocardium may develop with an elevated ejection fraction. This constellation of findings is frequently misinterpreted and the presence of amyloid is overlooked completely. By echocardiography, contractility is normal, but because of poor diastolic filling, there is a resultant reduced end-diastolic volume and low cardiac output. The

electrocardiogram shows low voltage, but this is also easily overlooked ([205]). The pseudoinfarction pattern of amyloid with loss of anterior forces in V_1 through V_3, seen in nearly two-thirds of patients ([205]), can be misinterpreted as ischemic heart disease. As a result of the electrocardiogram, patients invariably undergo coronary arteriography on a suspicion of silent ischemic disease. The coronary angiogram is generally normal ([206]), and an endomyocardial biopsy is not performed. A characteristic echocardiogram shows wall thickening, thickened valves, diastolic dysfunction, and a “sparkling” myocardium (Fig. 99.9). The median septal thickness in patients with AL was 14 mm. The septal thickness was less than 15 mm in 52.9% and greater than or equal to 15 mm in 47.1% ([188]). The wall thickening is frequently misinterpreted as concentric left ventricular hypertrophy or asymmetric septal hypertrophy rather than infiltrative cardiomyopathy ([207] , [208] and [209]). When ventricular hypertrophy is diagnosed from the thickened walls, the electrocardiogram typically shows low voltage and does not reflect hypertrophy, an important clinical clue ([210]). Screening for a monoclonal protein in the serum or urine should be done in any patient with diastolic heart failure, restrictive hemodynamics, or wall thickening.

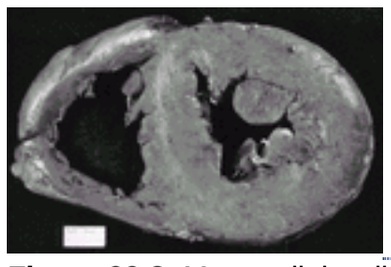

Figure 99.8. Myocardial wall diffusely thickened with amyloid. The whitish deposits represent the amyloid and are the lardaceous changes first recognized by Rokitansky. (From Gertz MA, Kyle RA. Amyloidosis [AL]. In: Wiernik PH, Canellos GP, Kyle RA, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003, with permission.)

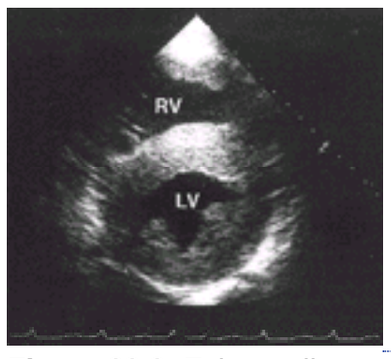

Figure 99.9. Echocardiographic demonstration of concentric thickening of the left ventricular (*LV*) wall from amyloid. RV, right ventricle. [From Gertz MA, Kyle RA. Amyloidosis (AL). In: Wiernik PH, Canellos GP, Kyle RA, et al., eds. Neoplastic diseases of the blood, 4th ed. New York: Cambridge University Press, 2003, with permission.]

Cardiac amyloid patients have restriction to blood inflow that is characteristic of the disease. Doppler studies are best for assessing myocardial function accurately in AL patients. The Doppler filling patterns closely relate to the extent of amyloid infiltration ([211]). In advanced cardiac amyloid, there is a short deceleration time consistent with restrictive physiology. In early cardiac amyloidosis, there is abnormal relaxation ([212]). Decreased fractional shortening combined with ventricular wall thickness is the best predictor of outcome in AL. A wall thickness greater than 15 mm with a fractional shortening of less than 20% is associated with a median survival of 4 months. An important measurement is the deceleration time. A short deceleration time by Doppler study reflects restrictive physiology. A deceleration time of less than 150 milliseconds is associated with poorer outcomes than a deceleration time of more than 150 milliseconds.

Thickening of the right ventricular wall, septum, and left ventricular free wall is the most common echocardiographic feature. The size of the left ventricular cavity is reduced. Roughly 20% of patients have congestive heart failure, but twice that number have cardiac amyloid by echocardiography. Patients regularly present with mild symptoms of fatigue and dyspnea on exertion who would not fulfill the clinical criteria of heart failure, but have overt cardiac amyloidosis. The survival of cardiac amyloid patients, determined by whether the septal thickness is greater than or equal to 15 mm or less than 15 mm at diagnosis, is 1 year and 4 years, respectively. Almost one-third of patients with cardiac AL develop syncope with exercise. A median survival of 2 months has been reported with exercise-induced syncope in AL ([213]). Immunofixation of the serum and urine is required in any patient presenting with cardiomyopathy or congestive heart failure that does not have an obvious ischemic etiology ([67]). The echocardiogram is the standard for recognizing amyloid cardiomyopathy; occasionally a patient has a nondiagnostic echocardiogram with amyloid subsequently proven via endomyocardial biopsy, but these occurrences are rare ([214]).

A poor prognosis is associated with right ventricular dilatation and atrial systolic failure ([215]). In patients who have thickening of the ventricular walls and are assumed to have hypertrophy, the finding of thickening of the mitral and tricuspid valves is common and also an important clue, because it is not found in hypertensive cardiomyopathy ([216]). Valvular regurgitation is commonly seen by Doppler echocardiography but does not appear to be clinically significant in altering myocardial performance ([216]). Atrioventricular sequential pacing does not benefit cardiac hemodynamics ([211]). Distinguishing pericardial disease from restrictive cardiomyopathy may be difficult ([217]). It is rare for surgical pericardiectomy to provide clinical benefit to patients with AL. The hazards of surgery in these AL patients are well established ([217] , [218]). As discussed, bone marrow biopsy and fat aspirate provide the diagnosis of cardiac amyloid in the overwhelming majority, but when infiltrative cardiomyopathy is recognized, endomyocardial biopsy provides the correct diagnosis in 100% of patients when at least three endomyocardial specimens are obtained ([219]).

Ventricular thrombi can develop in AL patients owing to stasis of blood within the cardiac chambers. Embolism can result, and the first manifestation of AL may be a stroke ([220]). AL patients in sinus rhythm can develop atrial thrombi ([221]). Anticoagulation therapy is indicated for AL patients with atrial standstill. Most patients present with cardiac muscle infiltration and pump failure. Rarely, patients present because of deposition of amyloid in the coronary arteries, resulting in symptoms of exertional angina and myocardial infarction ([222]). Angiographic findings are normal because the epicardial coronary arteries are spared. In these patients, standard exercise testing reveals ischemia ([206]), but the diagnosis of intracoronary amyloid is difficult to establish before death. Right ventricular myocardial biopsy may demonstrate amyloid deposits in small intramural vessels. The authors have reported on 11 AL patients presenting with angina or an unstable coronary syndrome ([223]). A classic low-voltage electrocardiogram was seen in only two patients. The median survival after symptom development was 18 months. Virtually all patients were diagnosed at autopsy, reflecting the difficulty in recognizing small-vessel coronary arteriolar amyloid.

All patients with cardiac amyloid do not have AL. Familial amyloid cardiomyopathy, particularly in elderly African-American men, must be distinguished from AL ([176]). The clinical presentations are similar ([224]). Patients with AF do not have a monoclonal protein in the serum and urine, and the most common mutation in the United States is *TTR* Ile-123. Senile cardiac amyloidosis must also be distinguished from AL ([225]). This syndrome results from the deposition of normal TTR. The echocardiographic features of AL, AF, and senile cardiac amyloidosis are indistinguishable. All the amyloid deposits are Congo red positive and exhibit apple-green birefringence under polarized light. The main distinguishing clinical feature is the presence of the monoclonal protein in patients with AL, lacking in the TTR forms of cardiac amyloid ([171]). The mechanism of deposition of amyloid in senile systemic amyloid is not understood. A quarter of patients older than 90 years have cardiac amyloid deposits. One must keep in mind that all forms of cardiac amyloidosis are not immunoglobulin light chain derived ([173]).

Renal

When a patient has free monoclonal light chains in the urine, the differential diagnosis is cryoglobulinemia ([226]), amyloidosis, Randall-type light chain deposition disease ([227]), and myeloma cast nephropathy ([228]). The presence of proteinuria does not always equate with albuminuria. All patients presenting with proteinuria should have immunofixation of the urine performed on the first evaluation to exclude one of these light chain–associated syndromes. The kidney is affected in 28% of AL patients. The Italian group has reported that amyloid affects the kidney in one-half of their patients ([229]). In nondiabetic adults with the nephrotic syndrome,

amyloidosis is seen in 12% of renal biopsies ([230]); 2.5 to 2.8% of all kidney biopsy specimens contain amyloid.

The serum creatinine value at diagnosis is important in predicting outcome. Patients with a creatinine value less than 1.3 mg/dl versus those with a creatinine value greater than 1.3 mg/dl have a median survival of 25.6 versus 14.9 months, respectively. Urinary protein loss has no impact on survival. Patients with higher levels of albumin loss have a shorter time from diagnosis to the development of end-stage renal disease ([231]). The presenting serum creatinine value exceeds 2 mg/dl in 14% of patients. The median urinary protein excretion for all AL patients is 0.75 g/24 hours. Thirty percent have more than 3 g of protein in the urine over 24 hours. Only 5% of AL patients have a urinary protein loss in the normal range. Patients with no protein in the urine generally have amyloid cardiomyopathy or neuropathy. Roughly two-thirds of patients have a detectable light chain in the urine, and two-thirds have a detectable light chain in the serum. A monoclonal light chain is more likely to be found if the urinary protein loss is high. If the urinary protein loss exceeds 1 g/day, a monoclonal light chain is found in 85%.

The ratio of patients with ? to ? light chains in the urine changes as the urinary protein excretion rises. The ratio of patients who have underlying ? clones compared to ? clones is 5:1 among those with nephrotic-range proteinuria. Urinary protein loss in ? amyloid is a median of 1.1 g/day. Median urinary protein loss in ? amyloid is 4.6 g/day. The presence of a ? light chain appears to predispose to a higher prevalence of renal involvement. There is no difference in the frequency of renal failure in ? or ? amyloid. The median survival in patients who have a urinary ?, urinary ?, or no urinary light chain is 1 year, 2.5 years, and 2.5 years, respectively. Severe hypoalbuminemia is the result of nephrotic-range proteinuria ([70]). Intravascular oncotic pressure decreases as the serum albumin decreases. Edema is a consequence of plasma transuding into the extracellular space. Diuretics are typically required to control edema, but diuretics further aggravate intravascular volume contraction, increase hypotension, and decrease renal blood flow. Bilateral catheter embolization of the renal arteries has been reported to reduce the loss of urinary protein and increase the serum total protein in patients with advanced anasarca ([232]).

Continuous urinary protein loss results in tubular damage, and the principal long-term complication is end-stage renal disease ([233]). Patients destined to develop end-stage renal disease are predicted by the presenting serum creatinine value and the 24-hour urinary protein loss. The median time from the diagnosis of AL nephrotic syndrome to dialysis is 14 months. After the initiation of dialysis, the median survival is 8 months. Most deaths in dialysis patients with AL owe to cardiac amyloid. There is no recognizable survival difference between patients who have hemodialysis and those who have peritoneal dialysis ([234]). The 1-year survival from the start of dialysis is 68%.

Patients younger than 45 years have a better survival. The use of chemotherapy does slow progression to end-stage renal disease, and there is a trend to improved survival with the use of chemotherapy. In addition to age, serum calcium and creatinine concentrations at presentation favor longer survival. Heart failure, cardiac arrhythmias, and refractory hypotension are the key extrarenal complications of AL. Cardiac amyloid associated with renal failure regularly results in dialysis complicated by severe hypotension and represents a major management problem. The amount of protein in the urine and the extent of amyloid deposits seen on kidney biopsy correlate poorly ([235]). Severe nephrotic syndrome can be seen with small amyloid deposits. All patients with nephrotic syndrome undergo ultrasonography, and the kidneys in AL are virtually always normal size ([236]) and not enlarged as suggested in prior literature. The urine in AL shows fat or fatty acid crystals but no casts or red blood cells ([237]). Of 118 patients with a monoclonal gammopathy undergoing renal biopsy, AL was found in 30% ([238]). In this cohort, the median time from diagnosis to dialysis was 15 months, the median overall survival was 24 months, and the main cause of death was cardiac amyloid.

Only 2% of patients with amyloid develop proteinuria if it is not present at presentation. After cardiac transplantation and antirejection therapy for cardiac AL, the authors have seen two patients who developed the nephrotic syndrome. One can speculate whether these patients in the past would not have survived to develop renal amyloid nephrotic syndrome. Amyloid deposits penetrate the glomerular basement membrane and result in proteinuria ([239]). Adult Fanconi syndrome ([240]), renal vein thrombosis ([241]), and retroperitoneal fibrosis have all been reported with renal amyloid. Fibrillary (immunotactoid) glomerulopathy is a deposition that occurs in the kidney and can be confused with AL ([242]). The fibrils of fibrillary glomerulopathy are twice the width of amyloid fibrils on electron microscopy ([243]). Fibrillary glomerulopathy patients do not develop extrarenal disease. The deposits are Congo red negative. A monoclonal protein is typically not seen in the serum or in the urine. Randall-type light chain deposition disease represents granular deposition of nonamyloid immunoglobulin light chain along the glomerular basement membrane ([244]). It produces nephrotic syndrome and renal insufficiency. Light chain deposition and amyloid have been reported in the same patient ([245]). Electron microscopy in light chain deposition disease does not demonstrate fibrils.

Fifteen patients with systemic amyloid who had undergone renal transplantation had serum amyloid P scintigraphy studies ([246]). Abnormal uptake was seen in the transplanted kidney in four of ten patients. In all of these patients, treatment had not resulted in a reduction in the fibril precursor protein. Renal amyloidosis patients have a high prevalence of adrenal dysfunction. Of 22 patients with renal amyloid, poor cortisol reserve was found in seven and hypoadrenalism resulting in death in four. Amyloid deposits are regularly found at autopsy in the adrenal glands.

Hepatic

One-fourth of patients with AL have hepatomegaly on physical examination ([247]). Hepatomegaly is not synonymous with hepatic involvement, because the high prevalence of right-sided heart failure can produce congestive hepatomegaly. A hepatic amyloid syndrome that is symptomatic is found in one-sixth of patients. Typically, an increased serum alkaline phosphatase or ?-glutamyltransferase value is found with unexplained hepatomegaly. Most clinicians suspect that the unexplained hepatomegaly owes to hepatic metastases; they perform scanning and find homogeneity by radionuclide imaging, computed tomography, or magnetic resonance imaging. A high proportion of patients with hepatic amyloid also has renal involvement.

Proteinuria in excess of 1 g/24 hours is present in one-half of the patients with hepatic amyloidosis. If a patient presents with an increased serum alkaline phosphatase value with proteinuria, this may suggest that the liver dysfunction owes to a systemic disorder such as amyloid. There are four key clues that are helpful in making the diagnosis of hepatic amyloidosis: (a) hepatomegaly out of proportion to the degree of liver function test abnormality; (b) presence of Howell-Jolly bodies in a peripheral blood film suggesting reduced splenic function, a consequence of splenic replacement with amyloid deposits; (c) a monoclonal protein by immunofixation in the serum or urine; and (d) proteinuria. Biochemically, hepatic amyloidosis patients tend to have low levels of aspartate aminotransferase and alanine transaminase, almost always less than twice normal at diagnosis. The bilirubin value is also virtually always normal. It is the increased alkaline phosphatase concentration that directs the clinician. Hyperbilirubinemia, when present, is usually a preterminal finding.

Splenic rupture is well recognized in patients with hepatic amyloid ([248] , [249]). Hepatic rupture is rare, but results in massive intraabdominal hemorrhage and is generally fatal. Computed tomography is useful in diagnosing hepatic rupture with subcapsular hematoma ([250]). The median extent of the liver below the right costal margin at diagnosis of hepatic AL is 7 cm. Hepatomegaly is not present in one-tenth of patients with biopsy-proven liver AL involvement. These patients are diagnosed because of an increased alkaline phosphatase value. When patients have hepatic AL, splenomegaly is present in 11%. Thirty-six percent of patients with hepatic AL have a urinary protein excretion greater than 3 g/day. At diagnosis, the median increase of the serum alkaline phosphatase value is 2.3 times the upper limit of normal. When an AL patient is evaluated, the serum alkaline phosphatase value represents the most important screen in assessing whether clinically important hepatic involvement is present. Hepatic AL patients also have higher levels of C-reactive protein than patients without hepatic involvement ([251]). The proportion of hepatic AL patients whose amyloid is derived from ? clones is identical to that of patients with other organ involvements. It has been suggested by others that there is a higher incidence of ? light chain in hepatic AL, but this is not supported by the authors' data.

Although symptomatic hepatic amyloid is found in only 16% of AL patients, serum amyloid P scanning makes it clear that hepatic amyloid is present in virtually all AL patients ([252]). Cholestatic jaundice is a preterminal finding ([253]). In hepatic AL, portal hypertension with varices and bleeding is rare ([254]). Presumably, patients succumb to hepatic or extrahepatic complications of AL before portal hypertension can develop ([255]). It is common to see ascites in patients with hepatic AL, but the majority of these patients have nephrotic-range proteinuria, hypoalbuminemia, or congestive heart failure, which are more likely causes of ascites, given the low incidence of portal hypertension. Amyloid deposits are found on liver biopsy specimens distributed in the portal tract and perisinusoidally ([256]). At autopsy, involvement of the portal triad vasculature is seen frequently but is not clinically important ([257]). After liver biopsy diagnosis of AL, the median survival is 1 year.

Scintigraphy is generally not useful in hepatic AL. The findings are nonspecific and include irregular distribution of the radionuclide, and occasionally splenic uptake is absent ([258] , [259] and [260]). Sinusoidal amyloid deposits can compress branches of the hepatic artery, which results in the angiographic appearance of luminal irregularity and abrupt changes in vascular caliber ([261]).

Amyloidosis is not a contraindication to liver biopsy. Although spontaneous hepatic rupture is described, rupture after a percutaneous liver biopsy has not been reported. The risk of complications from liver biopsy ranges from 0.31 to 3.00%. It should be kept in mind that biopsy of the subcutaneous fat or the bone marrow

demonstrates amyloid deposits in 90%; if amyloid is appropriately suspected, most liver biopsies are not required despite their relative safety.

In statistical analysis, the presence of hepatomegaly has a significant impact on survival within the first year after diagnosis. Part of the prognostic impact may be reflected by the fact that hepatomegaly may owe to congestive heart failure rather than hepatic infiltration. In an autopsy series of nine patients with amyloid and hepatomegaly, three did not have anatomic evidence of deposits, and the enlargement of the liver owed to passive congestion ([262]). In a second autopsy study, 20% of patients with palpable hepatomegaly and amyloid did not have deposits histologically.

In patients with AL, the finding of Howell-Jolly bodies is highly specific for splenic involvement. Hyposplenism is not a sensitive marker of splenic involvement, however ([263]). In a review of 12 patients with autopsy-proven diffuse splenic involvement, Howell-Jolly bodies were not found. Scanning of the spleen does not correlate well with the presence of Howell-Jolly bodies on the peripheral blood film.

In summary, the four cardinal features of hepatic AL are (a) hyposplenism, (b) a monoclonal protein in serum or urine, (c) proteinuria, and (d) increase of the alkaline phosphatase value with minimal increase in transaminases.

Gastrointestinal Tract

There is no correlation between the presence of gastrointestinal amyloid and liver amyloid. Only 15% of the authors' gastrointestinal amyloid patients have hepatomegaly, and fewer than one-third have any elevation of the alkaline phosphatase value ([264]). When routine screening biopsies are performed on the rectum or intestinal tract, amyloid deposits are found in the majority of patients ([107]). Generally, deposits are vascular; occasionally, they are in the submucosa of the bowel but produce symptoms in only a minority of patients ([265]). Few patients with AL have symptoms (e.g., steatorrhea, nausea, vomiting, abdominal pain, hematemesis, or hematochezia) referable to their gastrointestinal tract. Bowel dysfunction in AL can result from direct infiltration of the bowel lining or from a motility disturbance related to damage to the regulatory nerves of the intestinal tract ([266]). The high prevalence of anorexia and weight loss does not correlate with the presence of gastrointestinal tract amyloid. Typically, there is a delay between the onset of symptoms and the histologic recognition of AL. The median delay in patients with intestinal involvement was 7 months to a confirmed diagnosis, but in one patient, the diagnosis required 4 years. In 4 of the authors' 19 patients, a laparotomy was performed to evaluate the intestinal symptoms. In three of the four, the diagnosis was delayed because Congo red stains were not routinely performed on the surgical specimen ([264]).

Steatorrhea with increased fecal fat and low serum carotene is seen in less than 5% of patients. These patients are not clinically distinguishable from those with celiac sprue, Whipple disease, or bacterial overgrowth. A small bowel biopsy was performed and demonstrated deposits of AL in 19 patients seen at the Mayo Clinic. This constitutes only 1% of the authors' AL population ([264]), but does not include patients who had clinical evidence of malabsorption for whom a small bowel biopsy was not done because of evidence of widespread amyloid in other organs. Diarrhea, anorexia, dizziness, and abdominal pain were the most common symptoms. The median weight loss was 30 lb, and weight loss was seen in all patients. One-half of the patients had orthostatic hypotension. A prolongation of the prothrombin time primarily owing to malabsorption of vitamin K was present in one-fourth. Factor X deficiency was seen in one-fourth, but only 1 of the 19 patients had factor X activity below 30%. A multivariate analysis shows that the degree of weight loss and the hemoglobin value at diagnosis have an influence on survival. The median survival was 10 months in patients presenting with a weight loss in excess of 20 lb. Ten of the authors' 19 patients died as a consequence of nutritional failure, and one-fourth died of heart failure.

Barium studies demonstrate esophageal dysmotility or gastroesophageal reflux of the upper gastrointestinal tract ([267]). Multiple reports exist of patients who had surgical intervention for obstruction, only to have amyloid demonstrated histologically ([268]). The most frequent symptoms of pseudo-obstruction are nausea and vomiting ([269]). It is common to find abdominal distention and pain ([270]). The nausea is present even while fasting. Dilatation of small-bowel loops is rare ([271]). The typical findings on a barium study when intestinal amyloid is present include increased fluid accumulation in the small bowel, loop dilatation with delayed transit, and thickening or nodularity. Computed tomography may show mild splenomegaly or lymphadenopathy but is generally not helpful. Esophagitis, duodenitis, and gastritis are commonly found on endoscopic procedures ([272]). It is rare for these changes to cause symptomatic bleeding.

Rarely, ischemic colitis is the presenting feature of AL ([273]). The amyloid deposits under these circumstances obstruct the vessels of the muscularis mucosa and lamina propria. The obstructed blood supply leads to mucosal ischemia with sloughing of the bowel lining and hemorrhage ([274]). Barium studies demonstrate luminal narrowing, mucosal fold thickening, and ulcers. The most common location of ischemia is the rectosigmoid and descending colon ([275]). Vascular obstruction from AL has been reported to cause duodenal perforation. Hematemesis and hematochezia occur only rarely outside the transplant setting. The authors have not seen treatment of the underlying AL result in recovery of motility once pseudo-obstruction develops. In patients with pseudo-obstruction, extensive replacement of the muscularis propria by amyloid is prominent ([276]).

Nervous System

In 1938, the first description of peripheral nerve amyloid was published ([277]). Fifteen percent to 20% of AL patients have paresthesias and neuropathy symptoms ([278]). The clinical picture is often dominated by cardiac or renal involvement, and the peripheral neuropathy is minimally symptomatic. Echocardiographic abnormalities are found in 44% of patients presenting with AL neuropathy. When a predominant neuropathy is seen in a patient with biopsy-proven amyloid, consideration of the possibility of AF should be given. The absence of a monoclonal protein in the serum or urine is a useful distinguishing clinical feature between AL and AF ([279]). Paresthesias, pain, numbness, muscle weakness, impotence, urinary retention, and orthostatic symptomatology are the most frequent symptoms of amyloid neuropathy ([280]). Twelve percent of patients have syncope. Dysesthesia manifest by distal burning is present in one-fourth of the patients. Autonomic neuropathy is seen in two-thirds of those patients with peripheral neuropathy, and lower-extremity involvement precedes upper-extremity involvement in nearly 90%. Involvement of the cranial nerves in AL is rare but is reported ([281] , [282]). In patients with amyloid peripheral neuropathy, carpal tunnel syndrome, a soft tissue manifestation of amyloid, coexists in one-half of the patients. Frequently, it is difficult to distinguish electrodiagnostically between upper-extremity neuropathy and carpal tunnel syndrome. Weight loss was recognized in one-third.

An important clue to the diagnosis of amyloid neuropathy is its association with autonomic neuropathy ([283]). Peripheral neuropathy associated with significant autonomic dysfunction is most commonly seen in diabetes and amyloidosis. When patients present with peripheral neuropathy, however, amyloid is usually not considered in the differential diagnosis. The delay between onset of paresthesias and biopsy proof of amyloid is a median of 29 months. The time between symptoms and diagnosis exceeds the median time from diagnosis to death.

Amyloid preferentially causes loss of small myelinated and unmyelinated fibers. Electromyography is not good at detecting changes in small unmyelinated fibers. As a consequence, patients can have symptomatic amyloid neuropathy with a normal electromyogram. As it progresses, the neuropathy of amyloid is axonal and demyelinating. The loss of myelin results in an elevation of cerebrospinal fluid protein in one-third of patients. Axonal degeneration is detected on the electromyogram in 96% of patients so afflicted. Typical electromyogram changes consist of reduced amplitude of compound muscle action potentials, decreased or absent sensory responses, mild slowing of nerve conduction velocity, and fibrillation potentials on needle examination ([284]).

Although the sural nerve biopsy is the standard for the diagnosis of amyloid neuropathy, electromyogram nerve conduction velocities and less invasive biopsies like fat or bone marrow can confirm the diagnosis of amyloid neuropathy ([280]).

On sural nerve biopsy, amyloid deposits are found in the endoneurial capillaries or in the epineurium ([285]). Examination of teased fibers demonstrates axonal degeneration and a marked decrease in myelin fiber density. Although in the experience of the Mayo Clinic a sural nerve biopsy is the standard for diagnosis, it is not 100% sensitive. Nine patients were reported with amyloid neuropathy, of whom six had a negative sural nerve biopsy ([286]). One hypothesizes that amyloid has deposited at the level of the nerve root, which results in demyelination distally without recognizable deposits in the sural nerve. Amyloid deposits in the nerve are focal, and multiple sections of the sural nerve need to be examined to confirm the diagnosis.

In AL patients who present with a dominant neuropathy, the median survival is 25 to 35 months ([287] , [288]). Clinical improvement in peripheral neuropathy is rare with traditional chemotherapy and is infrequent even with high-dose therapy. The clinical course for most is progressive neuropathy over time. One-third of patients are ultimately bedridden, and three-fourths of the patients develop marked restriction in their mobility and a reduced ability to perform the activities of daily living. The serum albumin value is the only prognostic factor that is associated with survival in patients presenting with a dominant neuropathy. In neuropathy patients with an

albumin value greater than 30 g/L, the median survival was 31 months compared to only 18 months in those whose serum albumin at presentation was less than 30 g/L (Fig. 99.10).

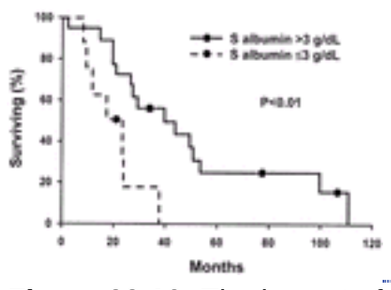

Figure 99.10. The impact of serum (*S*) albumin on the survival of patients with isolated amyloid peripheral neuropathy. (From Rajkumar SV, Gertz MA, Kyle RA. Prognosis of patients with primary systemic amyloidosis who present with dominant neuropathy. Am J Med 1998;104:232–237, with permission.)

All patients presenting with a peripheral neuropathy should be screened with immunofixation of serum and urine. A patient with a peripheral neuropathy and a monoclonal light chain has a restricted differential diagnosis that includes (a) amyloid; (b) cryoglobulinemia; (c) the polyneuropathy, organomegaly, endocrinopathy, M protein, and skin change syndrome (POEMS-osteosclerotic myeloma); and (d) a monoclonal gammopathy of undetermined significance–associated neuropathy.

Respiratory Tract

The authors' experience with pulmonary deposition of amyloid has been reviewed ([124]). Most patients presenting with amyloid involving the respiratory tract only have localized tracheobronchial or nodular pulmonary amyloid deposits. Neither is associated with systemic disease and both have a good prognosis ([196], [289], [290]). In contrast, patients presenting with systemic amyloid may have diffuse, interstitial pulmonary involvement, most commonly with concomitant cardiac involvement that overshadows any respiratory symptoms ([291]). Gas exchange is preserved until amyloid deposition in the alveolar interstitial space is advanced ([292]). Diffuse alveolar septal amyloid can rarely cause hemoptysis ([293]). Skeletal muscle and diaphragmatic involvement can produce muscular weakness and ventilatory failure ([294], [295] and [296]). Rarely, pleural effusions owing to pleural deposits of amyloid have been reported ([297], [298]). Occlusive amyloid deposits in the pulmonary circulation can occasionally cause pulmonary hypertension with resultant right-sided cardiac failure ([299], [300]). After a diagnosis of diffuse interstitial pulmonary amyloidosis, the median survival was 16 months; in the small number of patients with pulmonary hypertension, the median survival was 2.8 years.

Amyloidosis associated with an IgM monoclonal protein or Waldenström macroglobulinemia has a higher prevalence of pulmonary amyloid ([196]). A monoclonal protein is not seen in nodular, pulmonary, or tracheobronchial amyloid; only interstitial pulmonary amyloid is associated with free immunoglobulin light chains in serum or urine.

Pulmonary involvement as part of a systemic immunoglobulin light chain amyloid syndrome ([301]) manifests radiographically as an interstitial or reticulonodular pattern; the radiographic findings are not specific ([302]). Pleural effusion is uncommon. The diagnosis is easily obtainable with a transbronchial lung biopsy, which is not associated with excessive bleeding.

Minor salivary gland involvement is common in AL ([303]). It can be demonstrated in a high proportion of patients histologically, and xerostomia is reported by many ([294], [304]). AL patients have been misdiagnosed as having Sjögren syndrome.

Autopsy studies of pulmonary amyloid have been published ([305]). In one study, 11 of 12 patients had histologic deposits in the lung. Deposition was seen in blood vessel walls and the alveolar septum ([306]). In this autopsy study, only 4 of the 12 had clinical dyspnea, and pulmonary amyloid was responsible for the death of only one patient.

Patients with unexplained dyspnea or fluid overload who have normal left ventricular diastolic and systolic function should be evaluated for pulmonary hypertension owing to AL.

Coagulation System

Amyloidosis can be complicated by serious hemorrhage ([191]) or thrombosis. The most common manifestation of hemorrhage is purpura, a consequence of fragile blood vessels owing to infiltration of the vessel wall. A prolonged thrombin time is the most commonly seen abnormality in amyloid ([307]), and has been attributed to the presence of an inhibitor of fibrin polymerization in the plasma or the effects of prolonged nephrotic-range proteinuria with severe serum hypoalbuminemia.

Acquired factor X deficiency is an uncommon but well documented complication of AL amyloidosis ([74], [190], [309], [310]), although bleeding is unlikely if factor X levels are higher than 25% of normal. Fewer than 5% of patients have a serious deficiency of factor X ([74], [190]), and patients with cardiac and renal involvement in the absence of hepatic involvement do not demonstrate significant reductions in factor X levels. Serious bleeding complications can occur, however, especially in patients with ischemic colitis owing to vascular occlusions ([309], [310]). Bleeding disorders due to low levels of a $_2$ plasmin inhibitors, increased levels of plasminogen activators, and abnormal platelet aggregation also have been reported ([308]).

In one study 36 AL patients underwent a coagulation workup (310a). Severe bleeding was seen in only one and mild to moderate hemorrhage in nine. The most common abnormalities were prolongation of the reptilase and thrombin times. A severe factor X deficiency was seen in only one patient. The activated partial thromboplastin time was prolonged in 25 and the prothrombin time in eight. A lupus anticoagulant was not detected in any patients.

The authors also reported on patients with amyloid who had documented episodes of thromboembolism (310b). Of 2132 patients, 40 were so identified. Patients with myocardial infarction, peripheral vascular disease, and stroke were excluded. There were 19 women and 21 men who had a documented thromboembolus (median age, 65 years). In 11 of the 40, thromboembolism preceded a diagnosis of amyloid. In 9 of the 11, the event occurred 1 month or more before the diagnosis of amyloid. In 20 of the 40 patients, the thromboembolism occurred 1 month or more after the diagnosis of AL. The thrombosis was venous in 29 of the 40 and involved vessels in the calf, subclavian, popliteal, inferior vena cava, common femoral, and atrioventricular fistula, in decreasing order of frequency. Arterial thrombosis was seen in 11, involving femoral, popliteal, or multiple arteries, as well as the atria in two patients. Of the 40 patients, 37 had additional risk factors for thrombosis, including nephrotic syndrome in 20, immobilization in 13, tobacco use in six, heart failure in eight, estrogens in one, obesity in four, aortic aneurysm in one, prosthetic material in four, and disseminated intravascular coagulation in two. Five patients had activated protein C resistance. Eight patients died within a month of the thrombosis, and 18 of the 40 died within the first year. Thus, thrombosis appears to represent a significant predictor of imminent death within the first month and perhaps the first year after the event in patients with AL. The type of heavy or light chain and the organ distribution of amyloid did not predict the development of a thromboembolic event.

PROGNOSTIC FEATURES

Once amyloid has been confirmed histologically with fat aspiration or bone marrow biopsy in a patient presenting with a compatible clinical syndrome and with a monoclonal protein in the serum or urine, the patient needs to be advised of his or her prognosis. Congestive heart failure caused by progressive cardiomyopathy or sudden death caused by asystole or ventricular fibrillation is the most common cause of death in AL. The most important determinant of clinical outcome is the extent of cardiac involvement. Recognized adverse predictors of survival include referral status, heart failure, a hyposplenic peripheral blood film, free urinary light chains, elevated serum creatinine, a bone marrow plasmacytosis greater than 30%, circulating plasma cells in the peripheral blood, an elevated bone marrow plasma cell labeling index, and increased ß $_2$-microglobulin levels.

Congestive heart failure is associated with a median survival of approximately 6 months ([66], [311]). Exertional syncope is a harbinger of early death ([213], [312]). More

subtle cardiac findings are also prognostic. Echocardiography is an important tool in assessing the prognosis of all patients with AL. In echocardiographic studies, two-dimensional and Doppler, 40% of AL patients have cardiac involvement. Only 17% actually have symptoms of heart failure, however. In a Mayo Clinic study of 64 patients ([313]), relaxation was abnormal in early amyloidosis, but in advanced amyloidosis there was restricture filling and a shortened deceleration time ([314]). Doppler echocardiography can be performed serially to monitor diastolic dysfunction in cardiac AL. The 1-year survival of patients who by Doppler echocardiography have a deceleration time of greater than 150 milliseconds is 92%, in contrast to 49% for those with a deceleration time of less than 150 milliseconds. The Doppler-derived left ventricular diastolic filling parameters ([313] , [315]) are also important independent prognostic features. Doppler studies of right ventricular diastolic function demonstrate filling abnormalities that correlate with the degree of amyloid infiltration measured by right ventricular free wall thickness ([316] , [317]). Patients with elevations of serum cardiac troponin levels have a shortened overall survival ([318]).

When Howell-Jolly bodies are detected on a peripheral blood film, it reflects advanced splenic involvement usually associated with advanced hepatic involvement, and the median survival is 4.4 months ([319]).

The findings on renal biopsy provide prognostic information ([320]). Patients with a lower percentage of glomerular capillary wall thickening and a higher incidence of amyloid deposits in vessels but not in glomerular capillaries, as well as deposits of IgG and C3 in mesangial and glomerular capillary walls, have a better prognosis. The serum creatinine value at diagnosis and the presence of a urinary light chain are both important prognostic indicators. If the serum creatinine value at diagnosis is abnormal, the median survival is 15 months. Patients who have a free light chain in the urine have a shorter survival than those who do not, at 12 versus 35 months, respectively.

In a multivariate analysis, heart failure and orthostatic hypotension were associated with a median survival of less than 1 year in a cohort of 229 patients ([66]). An analysis was performed for the presence of cytoplasmic immunoglobulin-positive plasma cells by a sensitive slide-based immunofluorescent technique on 147 AL patients. The percentage of circulating cytoplasmic immunoglobulin-positive cells was calculated on circulating monoclonal plasma cells. Circulating blood plasma cells were seen in 16% of AL patients. The median survival of patients with and without circulating cells was 10 and 29 months, respectively ([321]). Independent prognostic factors for survival included the presence of peripheral blood plasma cells and the serum ß $_2$-microglobulin value. When AL patients with coexisting multiple myeloma and dominant cardiac amyloidosis were excluded, the test was of independent prognostic value.

The plasma cell labeling index is a slide-based immunofluorescent test capable of assessing the proliferative potential of the bone marrow plasma cells in patients with AL. More than 95% of patients with AL have clonally aberrant plasma cells in the bone marrow. Patients with AL and a labeling index of 0, reflecting no plasma cells in the S phase of the cell cycle, had a median survival of 30 months. If the labeling index exceeded 0, indicating plasma cells that were actively synthesizing DNA, the median survival decreased to 15 months ([322]).

When AL patients were compared for the level of serum ß $_2$ microglobulin, patients with normal values and patients with elevated values had median survivals of 33 and 11 months, respectively ([323]). The value of ß $_2$ microglobulin in assessing prognosis was independent of the presence of renal failure or heart failure. The median survival of patients who have normal renal function and an elevated ß $_2$-microglobulin value was 9 months compared with 39 months for those patients with a normal ß $_2$-microglobulin value. The presence of congestive heart failure and the serum ß $_2$-microglobulin value remain important predictors of outcome (Fig. 99.11) ([311]).

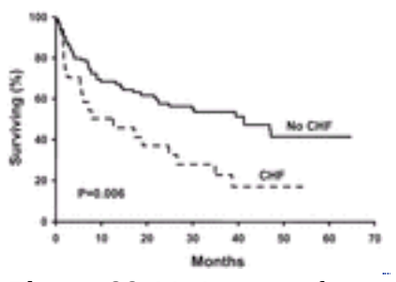

Figure 99.11. Impact of congestive heart failure (*CHF*) on survival in patients with amyloidosis. (From Gertz M. Multiple myeloma and amyloidosis. In: Straus D, ed. 2002 Educational review manual in medical oncology. New York: Castle Connolly Graduate Medical Publishing, 2002, with permission.)

In a cohort of 153 patients with AL, the median survival of the entire group was 20 months; the 5-year survival was 20% ([324]). In these patients presenting with congestive heart failure, the 5-year survival was 2.4%, with a median survival of only 8 months. If peripheral neuropathy was the sole manifestation of the AL, the median survival was 40 months; the 5-year survival was 32%. When assessing the long-term prognosis, it is useful to classify patients into four groups: heart failure, peripheral neuropathy, nephrotic syndrome, and other. Women have a slightly longer survival than men.

Referral bias definitely exists at large amyloid treatment centers. To be seen at a distant center, the patient *a priori* must be physically able to travel. This type of information is important when attempting to interpret the results of clinical trials reported from a single center. In patients with amyloidosis evaluated at the Mayo Clinic, the median survival was 2 years. If the cohort is limited to patients who are evaluated within 30 days of diagnosis, however, the median survival decreases to 13 months ([192]).

When uniform statistical criteria were applied to a large cohort of patients with AL, the median survival of the entire group was 12 months. The range was 50 months for those with peripheral neuropathy to 4 months for those with congestive heart failure ([311]). Within the first year after diagnosis, the key prognostic factors that achieved statistical significance included heart failure, a urinary light chain, the presence of multiple myeloma, and hepatomegaly ([311]). After the first year, the predictors of poor outcome were an increased serum creatinine value, the presence of multiple myeloma, a monoclonal serum protein, and orthostatic hypotension. When studies of treatment outcomes are compared, stratification for variables that have an impact on survival is important.

All patients being assessed for AL should undergo echocardiography, including Doppler studies of diastolic performance, ejection fraction, and mitral deceleration time.

TREATMENT

Supportive Therapy for Primary Amyloidosis

HEART AMYLOID Diuretics are the mainstay of therapy for cardiac AL. Diuretic therapy is complicated because many patients have orthostatic hypotension and intravascular volume contraction, a consequence of the nephrotic syndrome ([325] , [326]). Diuretic therapy may precipitate a decrease in renal blood flow with an associated rise in serum creatinine concentration and can precipitate syncope ([327]). Loop diuretics are typically used for control of edema. Doses of furosemide may range as high as 120 mg three times a day. When loop diuretics fail to control edema, metolazone can be beneficial. Patients with recurrent syncope have received permanent pacemakers ([328] , [329]). Those patients with exertional syncope should be considered for the placement of an implantable defibrillator because most patients die within 2 months ([213] , [312]). The standard of management of patients with heart failure includes the use of orally administered angiotensin-converting enzyme inhibitors. Whether these agents have a role in the treatment of cardiac AL and result in similar survival benefits is unknown ([330] , [331]). Their use is difficult in AL patients because of the high incidence of associated hypotension. Because systolic dysfunction is seen only late in the course of cardiac AL, digoxin is not generally helpful ([332] , [333]). Digoxin does not appear to have any beneficial effect on the reduced diastolic filling and restrictive physiology seen in AL ([334]). In addition, the literature suggests that digoxin is contraindicated in the management of amyloid heart disease ([335]) because of a perceived association with a high prevalence of sudden cardiac death. Sudden cardiac death is also well recognized ([336]), however, and common in cardiac amyloid patients who do not receive digoxin ([337] , [338] and [339]). It is therefore unclear whether the risk of sudden death is actually increased by this drug. Digoxin is effective in producing rate control when atrial fibrillation is present ([340]). Congestive heart failure may be precipitated by calcium channel blockers such as nifedipine and diltiazem in patients with cardiac AL. Amyloid fibrils selectively bind nifedipine, which could result in high intracellular levels of the drug ([341] , [342]). Fludrocortisone acetate in doses of 0.1 mg orally two

to three times per day can be used to treat AL orthostatic hypotension ([343]). The dose has been escalated from 0.4 to 2.0 mg daily ([344]). Side effects of fludrocortisone include supine hypertension, increased fluid retention with aggravation of heart failure, severe hypokalemia, and edema ([345]). Fludrocortisone is not well tolerated in elderly AL patients. Midodrine is a second agent that has been used to treat hypotension in AL patients ([346]). Midodrine is started at 2.5 mg three times a day at 4-hour intervals. Supine hypertension is a side effect of midodrine, and the dose is normally given only during waking hours ([347]). The drug is rapidly absorbed from the intestinal tract, and peak serum levels are attained within 30 minutes. The initial dose can be increased, based on therapeutic endpoints. The maximum recommended daily dose for midodrine is 40 mg. Active metabolites of midodrine are excreted by the kidney, and the agent should be started at a reduced dose in patients with renal insufficiency. The toxicity of midodrine includes restlessness, supine hypertension, and tachycardia. Patients with cardiac AL have received donor hearts. Seven patients who received cardiac allografts had a mean age of 46 years ([348]). Five patients were alive a mean of 32 months after transplantation. Recurrent amyloid was reported in the allograft in two at 3.5 and 4.0 months. One of these two died 13 months posttransplantation. There was one operative death. One patient who had transplantation was functional class I at 1 year, but amyloid deposits were seen by posttransplantation endomyocardial biopsy 14 weeks after transplantation. A successor report of ten patients noted that only four of nine patients survived more than 1 month and a high prevalence of recurrent amyloid was found in the transplanted heart. One patient with amyloid has been reported as having survived 9 years after cardiac transplantation ([349]), and the authors have personal experience with a patient who is now 11 years post cardiac transplantation and doing well. A report on ten patients receiving cardiac transplants from 1984 to 1997 indicated a 20% perioperative mortality; the remaining eight patients were followed for up to 50 months ([350]). Endomyocardial biopsy demonstrated recurrent amyloid in the grafted heart in five of the eight at 5, 11, 12, 28, and 30 months. None of these biopsies were associated with echocardiographic evidence of amyloid. Overall, seven of the ten patients died 3 to 116 months posttransplantation (median, 32 months). Four of the seven who died developed extracardiac amyloid. The 1- and 5-year survival was 60% and 30%, respectively. The operative mortality of 20% was attributable to extracardiac amyloid. Heart transplantation is technically feasible, but treatment to eliminate the underlying plasma cell proliferative disorder is necessary for a favorable outcome ([350]). A patient with IgG ? cardiac AL was hospitalized with heart failure. At age 47 years, she received a heart allograft followed 6 months later by a stem cell transplant with melphalan at 200 mg/m ^{2}. A hematologic response occurred with a reduction in the G ? monoclonal serum protein, but a complete response was not achieved. Engraftment was poor, and the platelet count persisted at 25 × 10 ^{9}/L. The patient died 2 years after stem cell transplantation, and at autopsy amyloid deposits were found in the myocardium. Thirteen Mayo Clinic patients have received a heart transplant ([351]). The actuarial 5-year survival was 50%, which is inferior to patients transplanted for primary cardiomyopathy. Four cardiac transplant recipients have received stem cell transplants at Mayo. Two of the four remain alive.

KIDNEY AMYLOID Diuretics, compressive support hose, low-sodium diets, and selective use of albumin diuresis are the mainstays of renal therapy for amyloid. Angiotensin-converting enzyme inhibitors can reduce proteinuria in nephrotic syndrome patients. The mechanism appears to be postglomerular vasodilatation. Toxicity of angiotensin-converting enzyme inhibitors includes hyperkalemia and hypotension. Enalapril and lisinopril have been reported to decrease proteinuria and steroid-resistant nephrotic syndrome when owing to focal segmental glomerulosclerosis. The possibility that angiotensin-converting enzyme inhibitors may be active in amyloid nephropathy has not been explored ([352] , [353]). The results of hemodialysis in AL patients are inferior to those seen in patients with primary kidney disorders. The 2-year survival for all dialysis patients was 76% compared with 53% for renal AL ([354]). The first report of continuous ambulatory peritoneal dialysis appeared in 1984; all three patients were alive from 10 to 18 months ([355]). One of these three received a renal transplant and survived 57 months. This patient died, and autopsy demonstrated widespread amyloid. In a review of 61 AL patients receiving dialysis, 18 died within a month of starting dialysis ([356]). At a median of 61 months after dialysis, 15 of the 43 remaining patients were alive. Hemodialysis and chronic ambulatory peritoneal dialysis had identical long-term survivals. Younger patients had a superior outcome. Patients most commonly succumb to the development of extrarenal amyloid in the gastrointestinal tract and heart. In the Mayo Clinic experience, two-thirds of the deaths of dialysis patients with AL are a result of extrarenal progression, the majority being cardiac. Most reports on the outcome of dialysis in renal amyloid are in patients with AA ([246] , [357] , [358]). In one report of 12 patients—two of whom had AL—only 4 of the 12 were alive 2 years after transplantation; and in two of the four survivors, renal biopsies demonstrated amyloid deposits. The development of amyloid in a transplanted kidney is well recognized ([359]). Eleven amyloid patients were followed after renal transplantation ([360]). Three amyloid recurrences were seen at 11, 28, and 37 months. After renal transplantation in two AL patients, one died as a result of renal failure owing to redepositing of amyloid into the grafted kidney. The second patient developed cardiac amyloidosis and died with stable renal function. Another 45 patients with amyloid were reported after kidney transplantation ([361]). The 3-year survival of these patients was 51%. Age older than 40 years is the major determinant of a poor outcome. The median age of AL patients is 62 years. Recurrent amyloid in the allograft was established histologically in four. The estimate was that after transplantation the chance of recurrence at 1 year was 20%. Two AL patients had renal biopsies demonstrating amyloid after transplantation ([362]). No factors predicted recurrence. Two additional AL patients receiving renal transplants were reported. Glomerular amyloid developed in one, resulting in renal failure and death. The second patient died of cardiac amyloid. Pasternack et al. ([361]) reported inferior survival of patients with renal AL.

HEPATIC AND GASTROINTESTINAL TRACT AMYLOID No specific supportive care measures are required for hepatic amyloid. As mentioned, the ascites seen in these patients is more commonly associated with concurrent right-sided heart failure or nephrotic syndrome. Diuresis and, on occasion, paracentesis are the mainstays of support. Patients with hepatic AL have been treated with transjugular intrahepatic portal systemic shunting ([363]). This has been reported to result in resolution of ascites and hydrothorax. In a patient with renal and hepatic amyloid, bilateral nephrectomy resulted in marked improvement in liver function, with normalization of a markedly increased bilirubin value ([364]). Amyloid deposits are commonly seen in the gastrointestinal tract. Intestinal symptoms include diarrhea and constipation that alternate within the same patient. Bowel disturbances can result from massive deposits in the gastrointestinal tract, with a malabsorption syndrome or dysmotility as a consequence of autonomic involvement. The therapy for diarrhea has included diphenoxylate, tincture of opium, loperamide, or paregoric but variable results are seen. Octreotide (a somatostatin analog) has been reported to reduce diarrhea. In the short-acting form, the dose is 200 to 300 µg/day divided into two or three doses. A long-acting depository form of octreotide, which comes in 10-, 20-, and 30-mg doses, exists. An intergluteal dose can be given on a monthly basis for 2 months and then adjusted according to the response of the patient's diarrhea. Patients who are disabled as a result of diarrhea and fecal incontinence can be managed with a diverting colostomy, which can result in excellent patient satisfaction. Patients with intestinal AL can sometimes have such severe nutritional failure that long-term total parenteral nutrition is required. Cisapride has been reported to be effective for treating amyloid intestinal pseudo-obstruction, but the authors have not found cisapride, metoclopramide, or cholinergic agents to be effective.

RESPIRATORY AMYLOID For these patients with localized tracheobronchial or laryngeal amyloidosis, neodymium:yttrium-aluminum-garnet laser therapy is standard treatment. Low-dose radiation has been reported to benefit obstructive symptoms ([125]). Nodular pulmonary amyloid can be treated with surgical excision. For patients with diffuse interstitial pulmonary amyloid with true disruption of the alveolar arterial gradient, low doses of prednisone produce symptomatic, although not radiographic, benefit. The therapy for pulmonary hypertension is vasodilators and calcium channel blockers. Many patients with amyloidosis are intolerant of these medicines because of associated orthostatic hypotension.

FACTOR X DEFICIENCY Therapy for factor X deficiency has included the use of oral melphalan and prednisone as well as stem cell transplantation ([365]). For a suitable patient, splenectomy results in improvement in factor X levels ([366]), and infusion of activated factor VII can temporarily normalize the coagulation factors to permit safe splenectomy ([367]).

Nonchemotherapy Treatment

DIMETHYL SULFOXIDE *In vitro*, dimethyl sulfoxide (DMSO) can solubilize amyloid deposits ([368]). DMSO fed to mice who were stimulated to develop AA had decreased development of amyloid deposits ([369]). The best results reported with DMSO have been as topical applications in patients with cutaneous amyloid ([370]) and after cystoscopic treatment in patients with bladder amyloidosis ([130] , [371]). DMSO is rarely used in the management of AL today ([372]).

COLCHICINE Familial Mediterranean fever (FMF) is associated with the development of AA amyloidosis with an autosomal-dominant inheritance pattern. Clinical features of FMF are pleuritis, peritonitis, synovitis, and migratory skin rash ([373]). This disorder is rarely seen in the West, affecting Sephardic Jews, Armenians, Arabs, and Turks. Recurrent attacks of polyserositis are not required for the development of amyloidosis. Fully one-fourth of patients in whom AA develops do not have any history of arthritis or polyserositis. In the Middle East, one-fourth of renal amyloid cases are related to FMF ([70]). With the introduction of colchicine, the median survival of FMF patients has improved from a dismal 25 months, with a 5-year survival of 20%. The clinical manifestation of AA in the setting of FMF is proteinuria, nephrotic syndrome, and dialysis-dependent renal failure. Colchicine has been shown to be effective in preventing attacks of familial amyloidosis in two double-blind placebo-controlled studies ([374]). In the two studies, the frequency of attacks was reduced by 82% and 78% ([375]). Colchicine decreased the incidence of renal amyloidosis by nearly two-thirds ([376] , [377]). When patients were compliant with colchicine therapy, the development of amyloidosis was rare. Occasionally, colchicine in FMF can reverse the proteinuria associated with established renal amyloid. When 350 children younger than 16 years were given prophylactic colchicine, amyloidosis developed in none. After renal failure develops from AA in FMF, colchicine prevents recurrent amyloid deposition in the grafted kidney. Colchicine is safe in pregnancy and children ([378]). Colchicine has been used in the treatment of AL. One patient treated with colchicine showed a reduction in 24-hour urine protein loss from 6.7 to 1.4 g/day ([379]). A case-control study was performed comparing colchicine to historical controls for the treatment of AL ([380]). Female sex and the time from diagnosis to initiation of colchicine did correlate with survival. The median survival for colchicine-treated patients was 17 months, compared with 6 months for non–colchicine-treated patients. Subsequent randomized studies ([381] , [382]) did not show any benefit for colchicine in the treatment of AL, however. Colchicine is rarely used today in patients with AL.

Measuring Responses in Primary Amyloidosis

Surrogate measurements are typically used to assess responses in amyloidosis. Responses to treatment in amyloidosis can be defined by clinical improvement in organ dysfunction or by reduction of the amyloid precursor protein. The latter involves measuring the monoclonal protein component and using criteria that have been established for patients with multiple myeloma. The third method of defining response is via the serum amyloid P scan, but this technique is not widely available. All patients who have a serum or urine monoclonal protein need to have this variable monitored after any therapeutic intervention. A reduction in the size of the M peak suggests a reduction in amyloid precursor protein production. For those patients who have only a free light chain that cannot be quantified, immunofixation is performed to determine whether the monoclonal protein is present or absent. The use of the immunoglobulin free light chain nephelometric assay has been invaluable in allowing quantification of monoclonal proteins that previously could be classified only as present or absent. When M components are measurable by electrophoresis or by the free light chain assay, a response requires a 50% reduction in the size of the serum or urine monoclonal protein, criteria conventionally accepted for response in multiple myeloma. When the free light chain assay is negative and the M component is not measurable, a response requires disappearance of the light chain by immunofixation ([383]). A bone marrow specimen that demonstrates less than 5% plasma cells is supportive of a response. The median number of plasma cells at diagnosis is only 5%, however, making the estimation of plasma cell reductions difficult. In addition, even when the percentage of plasma cells is 1 or 2%, sophisticated studies including immunofluorescent studies for cytoplasmic immunoglobulin or gene rearrangement studies detect a clonal population, suggesting that true complete responses are rare ([384]).

Ideally, a response in amyloidosis should be accompanied by an improvement in the function of a previously involved organ. Organ response criteria have been defined. A 50% reduction in the 24-hour urine albumin excretion with no increase in serum creatinine and no decrease in serum albumin concentration is generally accepted in defining a response in renal amyloid nephrotic syndrome. A 50% reduction in the serum alkaline phosphatase with no increase in transaminase or bilirubin is considered an organ response for hepatic AL. An actual reduction in the size of the liver is less common. It is difficult to document echocardiographic regressions of amyloid in the heart. A reduction in wall thickness of 2 mm by two-dimensional echocardiography needs to be seen to confirm a response. There is significant interprocedural variability, however, and caution is required before confirming response or progression when based on echocardiographic criteria only. Although rare, a response in amyloid peripheral neuropathy should be documented by an improvement in nerve conduction velocities on electromyogram.

Chemotherapy for Primary Amyloidosis

The successful use of cytotoxic chemotherapy to produce regression of AL was reported in 1972 ([385]). The use of alkylating agents to suppress the plasma cell clone in the bone marrow of AL patients followed the recognized success of these agents in the management of multiple myeloma ([386]). More recently, high doses of chemotherapy with peripheral blood support have been applied ([387]). Unlike multiple myeloma, recognizing a response in AL can take as long as 1 year. In the case of intermittent low-dose chemotherapy, it therefore becomes quite difficult to distinguish those patients who are destined to respond but need longer exposure to therapy from those who are destined to fail therapy and should be offered an alternative therapeutic approach ([388] , [389]). *In vitro* studies of the plasma cells from AL patients demonstrate aberrant light chain synthesis. In one study ([390]), the cytoplasm of the plasma cells contained light chain tetramers. After successful alkylating agent–based chemotherapy, light chain synthesis was suppressed, and a clinical response was demonstrated.

The three earliest reports of melphalan and prednisone therapy demonstrated responses and prolongation of survival in a minority of patients. Patients with renal, cardiac, or liver AL appeared to benefit, but ß $_2$M levels and cardiac involvement were predictors of failure of response ([391] , [392]).

Although melphalan-based therapy has been shown repeatedly to benefit a subgroup of patients with AL, the majority of patients fail to respond. Even with subset analysis, no cohort has been shown to have a response rate that exceeds 40%, and this includes patients who have single-organ renal involvement with a completely normal serum creatinine value. There was one case report of a patient with chronic polyarthritis unrelated to any hematologic problem who received melphalan and subsequently developed amyloidosis, demonstrating that melphalan could not prevent disease development. Moreover, even when patients demonstrated organ response, follow-up tissue biopsy demonstrated persistent deposits of amyloid ([393]). Because follow-up biopsies are done so infrequently, it is unclear whether clinical improvement is regularly associated with histologic regression. SAP scanning suggests, however, that these deposits can be mobilized and the total amyloid body burden reduced.

When the Mayo Clinic experience with melphalan and prednisone was reviewed, the overall response rate was only 18%. In patients in whom the serum creatinine value at the initiation of therapy exceeded 3 mg/dl, responses did not occur. Serum creatinine concentration also has an adverse impact on survival. The highest response rate was seen in the small group of patients with nephrotic syndrome, no extrarenal involvement, a normal serum creatinine, and a completely normal echocardiogram. In this group, the response rate was 39%. Responses were seen in patients with amyloid cardiomyopathy, suggesting a trial of therapy is warranted. The response rate, however, was only 15% ([324]). Clinical regression of neuropathic symptoms such as pain, paresthesias, and numbness is rare after melphalan-based chemotherapy. Although only 18% of patients responded to melphalan, their median survival was 89 months. The 5-year survival of this small subgroup was 78%. The median time to response was 1 year. Nonresponders had a median survival of 15 months. Therefore, it is difficult to know when to abandon low-dose melphalan-based therapy as a failure. If alternate therapies like high-dose chemotherapy with peripheral blood support are not viable, a trial of alkylating agent-based chemotherapy for AL can be beneficial and is a reasonable consideration for virtually any patient.

Long-term survival is seen in AL. Over a 21-year period, 841 patients with AL were reported ([394]). The actuarial survival for the patients at 1, 5, and 10 years was 51%, 16%, and 4.7%, respectively. The thirty 10-year survivors all had been treated with melphalan and prednisone. Fourteen had a documented hematologic response with an eradication of the M protein from the serum and urine. There were ten patients with nephrotic-range proteinuria, and four had a greater than 50% reduction in the urinary protein excretion. Unfavorable prognostic features for 10-year survival included heart failure, older age, creatinine value of greater than 2 mg/dl, bone marrow plasma cells greater than 20%, and platelet count greater than 500 × 10 ^{9}/L. In a report of ten patients with AL, eight were treated with cyclophosphamide and melphalan. Responses were seen in none ([395]). Four of these patients received treatment with infusional vincristine, doxorubicin, and dexamethasone (VAD) over 96 hours. Two patients showed a 50% reduction in the serum M component. The use of infusional VAD is an option for patients with AL. The use of vincristine in patients with amyloid neuropathy and doxorubicin in patients with cardiomyopathy, however, may limit its applicability.

In a prospective study of melphalan, prednisone, and placebo, 55 patients with biopsy-proven AL were randomized to melphalan and prednisone therapy or placebo in a double-blind fashion ([396]). There was no survival difference between the two groups, but patients who received melphalan and prednisone for a longer time and received larger doses had a superior survival. Nephrotic syndrome disappeared in two, and proteinuria decreased by greater than 50% in eight additional patients. There were no such responses in the placebo arm. There were 13 AL patients who received 12 months of therapy with melphalan and prednisone; six improved, three were stable, and four progressed.

A subsequent randomized crossover study of melphalan and prednisone versus colchicine was reported ([397]). The 101 eligible patients were stratified by their clinical manifestation: heart failure, neuropathy, nephrotic syndrome, and other. Patients were also stratified by age. One-half received melphalan and prednisone, and eight crossed over to colchicine. The other one-half received colchicine, and 35 crossed over to melphalan and prednisone owing to progression. In the crossover study, there was no difference in survival; however, when patients receiving only one regimen were analyzed or when survival was analyzed from the time of study entry to death or progression, there were significant differences that favored melphalan and prednisone.

There have been two prospective, randomized noncrossover studies evaluating the value of melphalan and prednisone in AL. In one, 219 patients received (a) colchicine 0.6 mg twice daily with increasing doses (N = 72); (b) melphalan 0.15 mg/kg/day with prednisone 0.8 mg/kg/day for 7 days every 6 weeks, with melphalan dose escalation to produce mild mid-cycle myelosuppression (N = 70); or (c) the two regimens combined (N = 69) ([381]). Stratification was by age, gender, and clinical manifestation. One-half had nephrotic-range proteinuria, and 20% had heart failure. The median survival was significantly superior in the melphalan- and prednisone-containing groups compared to the colchicine group: 17 versus 8.5 months. Melphalan is a superior therapy in the treatment of AL.

The second study randomized 100 patients (50 to colchicine and 50 to a combination of melphalan, prednisone, and colchicine) ([382]). Stratification was a function of gender, time from diagnosis to study entry, and dominant organ system involvement. The overall survival of the patient group was 6.7 months in the colchicine group and 12.2 months in the melphalan group. A survival advantage was seen particularly for those patients presenting with peripheral neuropathy or “other” (e.g., nonrenal, noncardiac, nonhepatic). In a multivariate analysis, melphalan had a significant impact on survival when heart failure was not present.

The frequency of response with melphalan is low, however, and the treatment itself is potentially leukemogenic. Of 153 patients receiving melphalan, cytogenetic

abnormalities were recognized in ten. All ten cytogenetic changes were consistent with damage to the hematopoietic stem cell. Eight of these ten died of pancytopenia and one of progressive renal amyloid, and one was alive. Morphologically, four had acute leukemia and five had myelodysplasia. Overall, bone marrow damage consistent with alkylator-induced toxicity was seen in 7% of the total patient population. The actuarial risk for developing myelodysplasia or acute leukemia in patients at 42 months after therapy was initiated was 21%. The median survival after the diagnosis of leukemia or myelodysplasia was 8 months ([398]).

Sixteen patients were treated with vitamin E because of an animal study suggesting that vitamin E could inhibit amyloid production ([399]). There were no objective responses in this cohort. The median survival was 19 months. A cohort of 15 patients was treated with subcutaneous injections of interferon a-2b 3 times a week. No responses were seen in this cohort. Interferon is not a useful agent in the treatment of AL ([400]). VAD chemotherapy resulted in an objective response in a 45-year-old man with myeloma-associated amyloidosis proven with biopsies of the rectum and lip ([401]). A second patient received four cycles of VAD chemotherapy for renal amyloid nephrotic syndrome proven by kidney biopsy. The proteinuria rapidly diminished during chemotherapy. VAD was given to four patients with AL nephrotic syndrome. Three of the four obtained a partial response and were alive at 4.1, 6.5, and 9.3 years ([402]).

In view of the toxicities of vincristine and doxorubicin in AL patients, nine consecutive patients were treated with dexamethasone alone, given 40 mg on days 1 to 4, 9 through 12, and 17 through 20 every 5 weeks for 3 to 6 cycles, followed by maintenance interferon in a dose of 3 to 6 million units 3 times per week. Three of these patients received maintenance dexamethasone 40 mg days 1 through 4 monthly for 1 year. AL organ improvement was reported in eight of nine patients. Of seven with nephrotic-range proteinuria, six had a 50% reduction in proteinuria with a median time to response of only 4 months. Organ function improvement was reported in amyloid neuropathy, hepatic involvement, and gastrointestinal involvement. Both patients with heart failure did not improve ([403]). Dexa-methasone has no tendency to cause leukemia. The responses are faster than melphalan and could be effective. When we treated 19 patients with high-dose dexamethasone in an identical regimen without interferon, only 3 of 19 showed an objective organ response. The median survival of the entire group was 11.2 months. When cardiac amyloid is not present, high-dose dexamethasone can produce benefit in some patients with AL. The authors have used dexamethasone as well when melphalan and prednisone therapy failed ([404]). Twenty-five patients received high-dose dexamethasone; three objective responses with organ-specific improvement were seen. The median survival of the entire group was 13.8 months. Dexamethasone can be beneficial in the treatment of a melphalan failure ([405]), but toxicity can be formidable, including fluid retention, gastrointestinal bleeding, and colonic perforation.

Because melphalan and prednisone produces survival benefit, a prospective randomized study of melphalan, prednisone, and vincristine versus carmustine, melphalan, cyclophosphamide, and prednisone was performed ([406]). One hundred one patients were randomized and were stratified by age, clinical manifestation, and the presence or absence of heart failure. The median overall survival for the entire group was 26.4 months, and of the 101, 77 have died. The median follow-up of survivors was 98 months (N = 24). There was no difference between the arms. It should be kept in mind that a median survival of 26 months is superior to the overall amyloid population, which has a survival of only 12 months. This suggests that those patients who enroll in chemotherapy treatment studies of AL have an inherently better outcome, presumably by virtue of their eligibility to participate in a clinical trial. The same holds true for patients who are eligible to receive stem cell transplant, as discussed in the following section. Of the 101, 18 patients ultimately received dialysis, and all but two have died. The most common cause of death while receiving dialysis was intractable hypotension related to cardiac involvement. Myelodysplasia was documented in eight, and all have died, including one who died after nonmyeloablative allogeneic transplant following diagnosis of myelodysplasia. All deaths were related to the myelodysplasia or acute leukemia, and the median survival from diagnosis of amyloid was 43 months.

4'-Iodo-4'-deoxydoxorubicin has been reported in the treatment of AL ([407]). Patients with visceral amyloid deposits have a lower response rate than those who have soft tissue amyloid ([408] , [409]). Of 45 patients treated with deoxydoxorubicin, the response rate was 15% ([410]).

Stem Cell Transplantation

Hematopoietic stem cell transplantation in AL is inherently different from transplantation in other hematologic malignancies ([411]). Patients with lymphoma, multiple myeloma, and leukemia typically have significant bone marrow abnormalities manifested by multiple cytopenias. In general, however, these patients have excellent cardiac, hepatic, and renal function and a performance status of 0 or 1. AL patients have opposite findings. Hematologic abnormalities such as anemia, leukopenia, or thrombocytopenia are uncommon. AL patients generally have significant visceral organ dysfunction, which puts them at a high risk for complications after high-dose chemotherapy.

Syngeneic transplantation was reported in the treatment of AL in 1995 ([412]). The patient received standard conditioning with cyclophosphamide (120 mg/kg) and total body irradiation (1200 cGy) ([413]). Monoclonal light chain synthesis disappeared from the serum and urine in this 32-year-old, who also had resolution of nephrotic syndrome and autonomic neuropathy. An amyloid P component scan showed a reduction in amyloid deposits. There have been two AL patients who had full-dose allogeneic bone marrow transplantation ([414] , [415]). The first who had purpura, macroglossia, and proteinuria of 1.4 g/day received 6 cycles of cyclophosphamide, vincristine, doxorubicin, and methylprednisolone. This patient had a hematologic response and then had an allogeneic transplant after melphalan 110 mg/m ^{2} and total body irradiation (1200 cGy). The patient continued a complete hematologic response and was alive at 29 months. The second patient received a sibling human leukocyte antigen identical transplant after melphalan 140 mg/m ^{2} and 800 cGy of total body irradiation. The urinary protein loss decreased from 9.15 to 1.3 g/day. This patient developed chronic graft-versus-host disease of the skin and liver but was alive at 18 months. It is unlikely that allogeneic or nonmyeloablative allogeneic transplantation will be applicable to a significant number of AL patients given the age restrictions and the need for good performance status and adequate renal function.

The majority of reported experiences using myeloablative chemotherapy involve progenitor cell replacement with peripheral blood stem cells. This occurs because of the ease of collection, reduced rate of tumor contamination, and faster engraftment seen with blood stem cells. Most AL patients who receive blood stem cells do demonstrate clonotypic cells in the apheresis product. CD34 cell selection to eliminate the clonotypic stem cells can be performed, but whether this has an impact on outcome is unknown ([416]). It is known that positive CD34 selection in multiple myeloma patients who are candidates for stem cell transplantation yields no survival benefit ([417]). There is no reason to believe the outcome would be different in AL transplants. Boston University first reported five patients with AL receiving stem cell transplants, and all five showed a clinical response ([418]). When expanding the cohort to 25 patients, a hematologic response was reported in 62% and an organ response in 65% of surviving patients ([419]). A report covering 250 patients receiving melphalan doses ranging from 100 to 200 mg/m ^{2} was published recently ([420]). The median age was 57 years; 53% had amyloid by echocardiography. The 3-month transplant-related mortality was 14%; 11% who initiated stem cell collection did not go on to transplantation owing to death or mobilization toxicities that would preclude safe transplantation. During mobilization, 23 patients experienced major morbidities, and 18 of them did not go on to stem cell transplantation. There were four reported cardiac arrests during stem cell infusion and six additional cardiac arrests during the weeks after transplantation. Sixty-two patients had febrile neutropenia; 17, gastrointestinal tract hemorrhage; and 12, progressive renal failure requiring dialysis. With a mean follow-up of 23 months, 66% of the patients were alive. The best responses were seen with isolated renal amyloid. Lower toxicities were observed in patients who received lower conditioning doses of melphalan (100 mg/m ^{2}).

Multicenter surveys reporting the outcome of transplantation were first published in 1998 ([421]). In France, 21 patients received transplants, 18 with melphalan alone and three with total body irradiation-containing regimens. The death rate was 43%, with 9 of 21 dying within 1 month after transplantation. All nine deaths owed to multiorgan failure, including one case of intractable bleeding. Of the 12 survivors, 10 achieved a response. Patient selection clearly had a role because the median time from diagnosis to transplantation was 11 months. This suggests that patients who would be destined to die early from AL would not survive to the time of transplantation. Outcome was predicted by the number of organs involved at the time of transplantation. For patients with two or more clinical manifestations, the 4-year survival was 11%. The risk of a toxic death when two organs were involved was 75%, reflecting the need for careful patient selection. In the United Kingdom, 27 patients received high-dose melphalan. There were eight treatment-related deaths (30%) ([422]). These deaths owed to multiorgan failure in four, gastrointestinal tract hemorrhage in two, and sepsis and cardiac complications in one each. In spite of this high death rate, a clonal response of the bone marrow plasma cells was seen in 64% and organ regression in 57% of surviving patients. Seventeen of the 27 patients are alive. In nine patients who received a transplant, four died within a year of transplantation, for a treatment-related mortality of 44% ([423]). Five were alive, but the median follow-up was only 12.6 months. Of the five, four were responders and one patient progressed. Three of the four deaths were related to cardiac amyloid. The fourth death involved the kidney, nerve, and intestinal tract. Multiorgan failure and gastrointestinal tract bleeding are far more common in AL than in transplantation for any other indication. Gastrointestinal tract bleeding appears to be highly specific for AL.

When the authors reviewed the first 45 patients who received transplants for AL, 11 had died at a median of 2 months posttransplantation ([424]). Gastrointestinal tract bleeding was seen in nine (20%). The median day of onset of bleeding was transplant day +9; median platelet count was 22 × 10 ^{9}/L. Bleeding was seen in the upper gastrointestinal tract in two, lower tract in three, and both in four. Endoscopy was performed in five, and all demonstrated an inflamed friable gastric and esophageal

mucosa. Four of the nine patients in whom bleeding developed died, three of multiorgan failure. Gastrointestinal tract bleeding was associated with female sex and poor engraftment of platelets. During the first 100 days posttransplantation, the median number of red blood cells administered was 20 in those with gastrointestinal tract bleeding. The exact mechanism underlying the bleeding in AL patients after stem cell transplantation is unknown. The widespread vascular deposits of amyloid can render the vessels rigid and friable, however. After high-dose chemotherapy, which causes significant mucosal damage, bleeding may result. In the authors' cohort, abnormalities of the coagulation system were not involved in the bleeding.

The authors have reported on three patients who did not proceed to stem cell infusion because of complications related to mobilization ([425]). Two of these three died of progressive amyloid at 1 and 3 months after mobilization. The authors have, in the past, used two different mobilization schemes. One was filgrastim alone (10 µg/kg/day), commencing apheresis on day 5. The second was cyclophosphamide 1.5 g/m ^{2} on 2 consecutive days followed by sargramostim (5 µg/kg/day), with apheresis beginning when the white blood cell count exceeded 1000/µl. The median overall CD34 yield was 6.4 × 10 ^{6} cells/kg. In the patients mobilized with cyclophosphamide, the median number of aphereses was three. In patients receiving filgrastim alone, the median number of aphereses was two, a statistically significant difference (Fig. 99.12). The authors now use filgrastim alone.

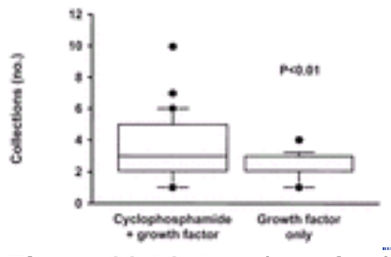

Figure 99.12. Number of aphereses required to achieve the target stem cell numbers, using two mobilization schemes. (From Gertz MA, Lacy MQ, Dispenzieri A, et al. Stem cell transplantation for the management of primary systemic amyloidosis. Am J Med 2002;113:549–555, with permission.)

Of our first 20 patients who went on to transplantation, renal, cardiac, nerve, and liver amyloid were seen in 14, 12, 3, and 1, respectively. Five of the 20 died posttransplantation. Two additional patients died of progressive amyloid and 13 were alive, with 12 of them showing a hematologic or organ response. The authors recently reported our results in 66 patients; renal, cardiac, nerve, hepatic, and autonomic amyloid were present in 68%, 48%, 17%, 17%, and 6%, respectively. Fourteen percent of these patients had an ejection fraction of less than 60% at transplantation. One patient who died on day +6 was not evaluable for granulocyte engraftment. The median time to achieve 500 granulocytes in the remaining 65 patients was 12 days. There were six patients who died without achieving a platelet count of 20 × 10 ^{9}/L. One patient is alive with a platelet count of 10 to 20 × 10 ^{9}/L untransfused. Fifty-nine patients achieved a platelet count in excess of 20 × 10 ^{9}/L by a median of day 14. Patients who had received oral melphalan chemotherapy before stem cell collection have slower engraftment of their platelets. The treatment-related mortality was 14% and included cardiac arrhythmias, gastrointestinal tract bleeding with multiorgan failure, pulmonary embolus, disseminated fungus infection, pneumonia, and aspiration.

Nine of the patients required dialysis posttransplantation. Seven of them died. One had complete recovery, and one is alive on dialysis. Eight of the nine patients had recognized renal amyloid before transplantation. The median serum creatinine value was 1.7 mg/dl in those who ultimately required dialysis and 1.1 mg/dl in those who did not. The authors have seen one myelodysplastic syndrome develop posttransplantation. This patient had previously received melphalan therapy and died of pancytopenia. The median hospital duration was 14 days, and 15 patients were hospitalized for more than 1 month. Neutropenic bacteremia is common. The most frequently isolated organism was staphylococcus, seen in 35 patients. The fraction of patients surviving at 2 years with one-, two-, and three-organ involvement was 91%, 82%, and 31%, respectively (Fig. 99.13).

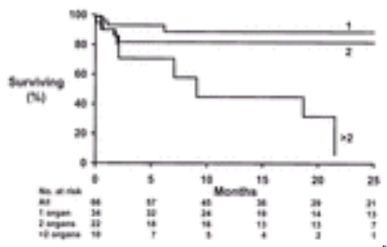

Figure 99.13. Survival of 66 patients who received transplants for amyloidosis, stratified by number of organs involved pretransplantation. (From Gertz MA, Lacy MQ, Dispenzieri A, et al. Stem cell transplantation for the management of primary systemic amyloidosis. Am J Med 2002;113:549–555, with permission.)

In spite of the high morbidity and mortality, a hematologic or an organ response was seen in 42 of the 66 patients. The responses were renal in 19; hepatic in five; cardiac in three; renal and cardiac in two; renal and hepatic in one; cardiac, renal, and nerve in one; and autonomic in one. There were 26 patients with kidney amyloid who achieved a response overall. The median urinary protein loss decreased from 7.10 g/day to 1.44 g/day. Twelve patients had their urinary protein loss decrease below 1 g/day. The median time to response was 3.6 months, but in six, response took more than 1 year. The serum creatinine value and the number of organs involved pretransplantation were the most important predictors of survival (Fig. 99.13).

The authors have now completed transplantation in 125 patients with AL, 94 of whom are alive. Hematologic responses have been documented in 67. Organ responses were seen in 52. Nineteen of the 125 died before day 100 (15%).

The toxicities associated with high-dose chemotherapy are listed in Table 99.4. The response rate that the authors have observed exceeds their previous experience with conventional-dose chemotherapy. Patients, however, are highly selected to begin with, and one cannot be certain what the response rate or survival would be in an age- and organ-matched population. The most common type of response is the resolution of nephrotic syndrome. Table 99.5 summarizes reported data on stem cell transplantation in nearly 300 patients.

TABLE 99.4. Toxic Responses (Southwest Oncology Group =Grade 2)

Toxic Response	Frequency, % (N)	
	200 mg/m ^{2} (N = 23)	100 mg/m ^{2} (N = 27)
Nausea/vomiting	83 (19)	52 (14)
Diarrhea	65 (15)	48 (13)
Mucositis	91 (21)	37 (10)
Pulmonary edema	35 (8)	26 (7)
Peripheral edema	48 (11)	15 (4)
Non-GI bleeding	17 (4)	0 (0)
GI bleeding	22 (5)	7 (2)

Comenzo and Gertz ([433]) published a risk-adapted strategy for selecting patients and assigning melphalan dose in AL patients. On review of four single-center studies, the day-100 mortality was 21%. The guidelines for selection of candidates for stem cell transplantation are given in Table 99.6 and the risk-adapted approach in Table 99.7.

TABLE 99.6. Guidelines for Selection of Stem Cell Transplant Recipients

Absolute contraindication
- Clinical congestive heart failure
- Total bilirubin >3.0 mg/dl
- Echocardiographic ejection fraction <45%

Relative contraindication
- Serum creatinine >2.0 mg/dl
- Interventricular septal thickness >15 mm
- Age >65 yr
- More than two visceral organs involved

From Gertz MA, Lacy MQ, Dispenzieri A. Immunoglobulin light chain amyloidosis (primary amyloidosis). In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders. Berlin: Springer-Verlag, 2004:157–195. By permission of Mayo Foundation.

TABLE 99.7. Risk-Adapted Approach

Good risk (all of the following)
- One or two organs involved
- No cardiac involvement
- Creatinine clearance =51 ml/min
- Any age

Intermediate risk (all of the following)
- Age younger than 61 yr
- One or two organs involved
- Asymptomatic cardiac or compensated cardiac
- Creatinine clearance <51 ml/min

Poor risk (one of the following)
- Three organs involved [a]
- Advanced cardiac involvement

Melphalan dosing (mg/m ^{2}): based on risk group and age (yr)

Good risk	Intermediate risk	Poor risk
200 if age =60	140 if age =50	Standard therapy
140 if age 61–70	100 if age 51–60	Clinical trials
100 if age =71	—	—

[a] Organ involvement includes heart, kidney, nerve, liver, vascular, or soft tissue; does not include bone marrow, skin, tongue, or gastrointestinal tract involvement.

Modified from Comenzo RL, Gertz MA. Autologous stem cell transplantation for primary systemic amyloidosis. Blood 2002;99:4276–4282. By permission of the American Society of Hematology.

It must be kept in mind that transplant patients with AL are highly selected because of age, number of organs involved, the absence of advanced heart failure, and performance status. Therefore, a true control group is lacking for comparison. Dispenzieri et al. ([434]) reviewed 1288 AL patients seen at the Mayo Clinic from 1983 to 1997 to identify those eligible for stem cell transplantation using the criteria in Table 99.6. Patients had to have symptomatic amyloid, no multiple myeloma, age younger than 70 years, and an echocardiographic septal thickness less than or equal to 15 mm with an ejection fraction greater than 55%. In addition, the serum creatinine value had to be less than 2 mg/dl, and a direct bilirubin value had to be less than 2 mg/dl as well. Among the patients, only 229 (18%) were eligible for transplantation. The median survival of this nontransplantation cohort was 42 months, with 5- and 10-year survivals of 36 and 15%. Clearly, patients who are eligible for transplantation have much better outcomes than patients who are not eligible. The predictors of survival included the size of the M protein in the 24-hour urine measurement and the number of organs involved (Fig. 99.14). The alkaline phosphatase value, performance status, and weight loss were also factors that influenced survival. Patients eligible for stem cell transplantation are an inherently good risk population, and they will do well with oral melphalan and prednisone. Certainly, their anticipated median survival far exceeds the 18 months published for other cohorts of patients receiving melphalan and prednisone. The value of hematopoietic stem cell transplantation for amyloid will not be known until a randomized phase 3 study is completed.

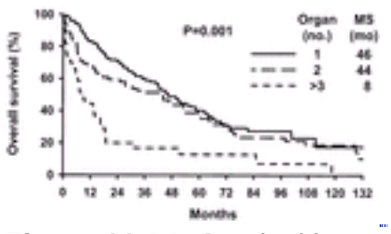

Figure 99.14. Survival by number of organs involved in patients eligible for stem cell transplantation but treated with melphalan and prednisone. (From Dispenzieri A, Lacy MQ, Kyle RA, et al. Eligibility for hematopoietic stem-cell transplantation for primary systemic amyloidosis is a favorable prognostic factor for survival. J Clin Oncol 2001;19:3350–3356, with permission.)

CONCLUSION

Amyloidosis should be considered in the differential diagnosis of any patient with nephrotic-range proteinuria, heart failure, neuropathy, or hepatomegaly. The symptoms of amyloid are vague and not useful in targeting a diagnosis. The pathognomonic physical findings are seen in fewer than one-fifth of patients and therefore are not sensitive. When a patient is seen with a compatible clinical syndrome, immunofixation of the serum and urine is the best screening test. Ninety percent of light chain amyloidosis patients have a monoclonal light chain in the serum or urine. Noninvasive studies such as the fat aspiration and bone marrow biopsy confirm the diagnosis of AL in 90% of patients. In a patient with biopsy-proven amyloidosis without a detectable monoclonal protein, a nonimmunoglobulin form of amyloid should be considered. The prognosis should be assessed by two-dimensional echocardiography with Doppler. Systemic therapy is appropriate for most patients. Treatment with melphalan and prednisone provides marginal survival benefit in a minority of patients. The more aggressive plasma cell ablative approach can offer the potential for long-term benefit. Response rates with stem cell transplantation can approach 60%, and responders have the potential for long-term survival. High-dose dexamethasone therapy can offer benefit to a subset of patients. The role of thalidomide is investigational. Firm evidence-based data do not exist to prove the survival benefit of stem cell transplantation.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia (WM) is a pleomorphic lymphoproliferative disorder that is characterized by the production of a mono-clonal immunoglobulin M (IgM) protein and a lymphoplasmacytic infiltrate in the bone marrow ([1], [2] and [3]). Classic features include anemia, hepatosplenomegaly, lymphadenopathy, and hyperviscosity ([1], [2] and [3]). This chapter reviews the published literature on the biology and management of WM. Because WM is uncommon, research focused on its etiology, prognosis, and management is sparse.

HISTORY

Waldenström (Fig. 100.1) first described the entity that bears his name in 1944 when he described two patients with bleeding from the mouth and nose, severe anemia, lymphadenopathy, an elevated serum concentration of a high-molecular-weight ?-globulin, and low fibrinogen ([4]). He noticed that the abnormal serum protein sedimented with a coefficient of 7S and distinguished this entity from multiple myeloma. Waldenström is well known for his description of this condition, but he also made the very important observation that ?-globulin elevations can be monoclonal or polyclonal.

Figure 100.1. Photograph of Jan Gosta Waldenström (1906–1996). (From Kyle RA, Anderson KC. A tribute to Jan Gosta Waldenström. Blood 1997;89:4245–4247, with permission.)

EPIDEMIOLOGY

WM is a rare disorder, with approximately 1500 cases per year in the United States ([5], [6]). This incidence is approximately one-sixth that of multiple myeloma ([7]). The median age at presentation is 63 years. Of all patients found to have a monoclonal IgM protein at Mayo Clinic, 17% had WM, and the remaining patients had IgM–monoclonal gammopathy of undetermined significance (IgM-MGUS) or other lymphoproliferative disorders ([8]). It is difficult to estimate the true prevalence of WM in the general population because of the rarity of the disease, lack of clear diagnostic criteria, and incomplete reporting. WM appears to be more common among whites and is rare in people of African or Mexican-mestizo descent ([1], [5], [6], [9]). Incidence and prevalence studies also suggest that the disease is slightly more common in men than in women ([5]). Age-adjusted incidence rates for WM (per 1 million person-years) have been reported at 3.4 for men and 1.7 for women, with the rates increasing sharply with age ([5]). Other studies have reported an age-standardized annual incidence rate of 6.1 per million in white men and 2.5 per million in white women ([6]).

Although WM is believed to be sporadic for the majority of patients, several reports in the literature suggest that some cases may have a familial component ([10], [11], [12], [13], [14], [15], [16], [17] and [18]), implying a single gene defect capable of producing the observed phenotype. In some reports, several family members were affected, and in others, monozygotic twins were both affected. Other reports describe family members of WM patients affected by other lymphoproliferative disorders associated with an elevated serum IgM level.

DIAGNOSIS

The diagnosis of WM is based on the presence of classic signs and symptoms in association with the monoclonal proliferation of mature lymphocytes or plasmacytoid cells in the marrow and a monoclonal IgM protein in the serum ([1], [3]). Standardized diagnostic criteria have not yet been established ([19], [20]). The treating physician needs to consider the entire clinical and pathologic presentation to differentiate IgM-MGUS from WM or other B-cell lymphoproliferative disorders. The mere presence of a lymphoplasmacytic infiltrate of the bone marrow or a monoclonal IgM protein does not prove the diagnosis of WM, because other B-cell neoplasms may also have plasmacytic differentiation and associated monoclonal proteins (M proteins) ([8], [21]).

Routine Laboratory Tests

Patients with suspected WM should have baseline laboratory tests consisting of a complete blood count and determination of creatinine, bilirubin, aspartate transaminase, alkaline phosphatase, and calcium in serum. Serum ß $_2$-microglobulin should also be measured, because it is a useful prognostic factor (see below) ([22], [23]). Patients with WM typically do not have peripheral blood lymphocytosis ([19], [23], [24], [25], [26] and [27]).

Monoclonal Protein Determination

The monoclonal IgM can be quantified by serum protein electrophoresis (SPEP) or by nephelometry. Immunofixation is required to characterize the abnormal protein detected by SPEP (Fig. 100.2). It is also recommended that quantitative serum Igs be measured by nephelometry to quantify levels of IgG, IgA, and IgM at the time of initial diagnosis. Occasionally, there can be discrepancies in IgM quantitation between nephelometry and SPEP, especially with larger monoclonal spikes. This is due to underestimation of the true concentration of the paraprotein by SPEP. To monitor the disease status, the same test should be used consistently. Serum viscosity determination is helpful at baseline and in situations in which symptoms of hyperviscosity are present (see below); however, it is not required at each subsequent visit.

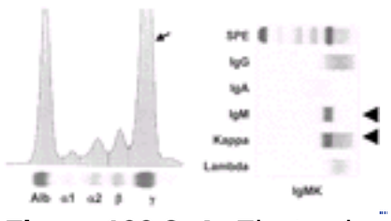

Figure 100.2. A: Electrophoretic pattern from a serum protein electrophoresis (SPE) showing a prominent M spike in the ? region (*arrow*). **B:** Immunofixation documenting that the M spike on SPE is a monoclonal immunoglobulin (Ig) M ? protein.

It has been proposed that a fixed minimum concentration of the serum M protein is needed to fulfill diagnostic criteria of WM. However, this would exclude patients early in the course of the disease who have a lower concentration of paraproteins but are symptomatic. Many consider a serum monoclonal IgM that exceeds 15 g/L as characteristic of WM and useful in differentiating WM from other lymphoid neoplasms with plasmacytoid differentiation ([21]). The serum IgM in symptomatic patients (i.e., those needing therapy) is typically high; for example, the median was 42 g/L in a recent large clinical trial in patients with previously untreated WM ([28]).

A 24-hour urine collection for protein electrophoresis and immunofixation should be performed to determine the presence and quantity of urine Bence Jones protein and to quantify total urinary protein. Approximately 40 to 80% of patients with WM have Bence Jones light chains in the urine (Bence Jones proteinuria) ([8]).

Bone Marrow Pathology and Immunophenotype

A unilateral bone marrow aspirate and biopsy for the estimation of clonal involvement are routinely obtained at diagnosis and subsequently whenever there are changes in clinical status ([23]). The primary abnormality in WM is a clonal proliferation of IgM-producing lymphoplasmacytic cells infiltrating the bone marrow. Typically, the predominant infiltrate is lymphoplasmacytoid, with a small percentage of mature plasma cells; however, the morphologic features can range from predominantly lymphocytic to lymphoplasmacytoid or to overt plasma cells ([29], [30] and [31]) (Fig. 100.3). Mast cells are usually present and associated with the clonal lymphoplasmacytes ([30], [31] and [32]). Although the predominant site of the disease is the bone marrow, extensive infiltrates are possible in lymph nodes, spleen, and liver ([21]).

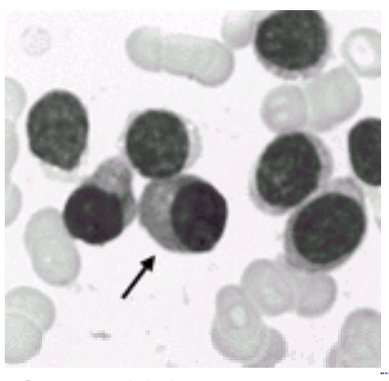

Figure 100.3. Bone marrow aspirate showing the malignant cells from a patient with Waldenström macroglobulinemia. The cells exhibit lymphoid and plasmacytoid morphology. The arrow indicates the monoclonal spike. See Color Plate.

Flow cytometric studies can be performed on cells from the marrow aspirate to document monoclonality of the B cells and determine their immunophenotype. Extensive immunophenotyping is not necessary in classic cases of WM but is helpful in difficult cases to differentiate WM from B-cell chronic lymphocytic leukemia, mantle cell lymphoma, and other lymphoproliferative disorders ([32], [33] and [34]) (Table 100.1). The typical surface marker profile for patients with WM is defined by the presence of pan–B-cell surface markers (CD19, CD20, CD22), in association with monoclonal light-chain expression on the cell surface and in cytoplasm ([2], [32], [33], [34] and [35]) and CD79a ([24]). CD10 and CD23 are usually absent. Although limited data are available, CD138 (syndecan-1) can be detected on the plasma cell compartment ([2], [32], [33], [34] and [35]). Most pathologists believe that the malignant cells in WM do not express the T-cell marker CD5; however, some cases reported in the literature and cases observed at our institution (E. Remstein, personal communication, 2002) fulfill the criteria for the diagnosis of WM but express CD5 on the cell surface ([2], [32], [33], [34] and [35]). The proportion of patients with expression of CD5 has not been defined but is unlikely to exceed 10%, and in many of the CD5 $^+$ cases, expression is limited to subpopulations of the clone.

TABLE 100.1. Pathologic Features of Waldenström Macroglobulinemia Compared with Other Lymphoproliferative Disorders

Pathologic Feature	MCL	B-cell CLL	FL	MZL	WM	MM
Paraprotein	None	Small IgG or IgM	Usually none	± Small IgM	IgM (large)	IgA, IgG [a]
Morphology	Centrocyte-like; small-to-medium-sized lymphocytes	Small lymphocyte with clumped chromatin	Follicle center cells (follicular pattern)	Monocytoid B cells, heterogeneous	Plasmacytoid lymphocytes and plasma cells	Plasma cells
Surface Ig	+	+	+	+	+	+
Cytoplasmic Ig	–	–	–	–	++	+++
CD19	+	+	+	+	+	–
CD20	++	+	++	+	+	15% CD20 $^+$
CD23	–	+	±	–	–	–
CD22	+	–	–	+	+	–
CD38	–	±	–	–	+	++

CD138	–	–	–	–	+	++
CD5	+	+	–	–	Usually CD5 $^{-}$	–
CD10	±	–	+	–	–	–
Cytogenetic aberrations	t(11;14)(q13;q32), *cyclin D1* $^{+}$	13q $^{-}$, 6q $^{-}$, +12, 11q23 $^{-}$	t(14;18)(q32; q21), *bcl-2* $^{+}$	t(11;18)(q21; q21), +3	6q $^{-}$	t(4;14)(p16.3;q32), t(11;14)(q13;q32), t(14;16)(q32;q23), other +14q32, 13q $^{-}$, aneuploidy
Somatic hypermutation	—	+, 50%; -, 50%	++	++	+++	+++
Bone marrow involvement (%)	25	~100	85	50	>90	100
Bone lytic lesions	No	No	No	No	5%	70%

CLL, chronic lymphocytic leukemia; FL, follicular B-cell lymphoma; Ig, immunoglobulin; MCL, mantle cell lymphoma; MM, multiple myeloma; MZL, marginal zone B-cell lymphoma; WM, Waldenström macroglobulinemia; +, presence; -, absence.

[a] Unusual but can have IgD or IgE and IgM.

Modified from Winkler JM, Fonseca R. Waldenström macroglobulinemia. In: Gertz MA, Greipp PA, eds. Handbook of multiple myeloma and related cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag (*in press*).

The plasma cell labeling index determined by immunofluorescence microscopy ([36]) usually shows the clonal cells to be nonproliferating (0% in >80% of patients) (R. Fonseca, unpublished observations, 2002). The plasma cell labeling index is useful in determining monoclonal cytoplasmic light-chain expression by the lymphoplasmacytoid cells; however, this can also be performed by immunohistochemical techniques on biopsy material.

There is no known reason for performing standard cytogenetic studies at the time of diagnosis of WM, except when the diagnosis is in doubt. Karyotype analysis should be done in subsequent bone marrow samples if the patient has cytopenia(s) and has had exposure to alkylator drugs, because myelodysplasia can occur ([28]).

Pathology and Differential Diagnosis

Because of its morphologic and immunophenotypic features, WM has been assigned the pathologic designation *lymphoplasmacytic lymphoma* (LPL) in the Revised European-American Lymphoma Classification ([21]). However, LPL is not always associated with paraproteinemia; thus, LPL without paraproteinemia appears to be distinct from WM as a pathologic entity. Indeed, in a recent study of patients with WM, those with a low paraprotein concentration fared worse, suggesting different biologic mechanisms ([22]) (Table 100.1).

Occasionally, it may be difficult to differentiate WM from marginal zone lymphomas on the basis of examination of bone marrow morphology. A key factor is the size of the IgM protein. Patients with higher-concentration (>30 g/L) M proteins likely have WM, whereas those with small M proteins more likely have marginal zone lymphomas. In addition, plasmacytoid morphology is more consistent with WM than marginal zone lymphoma.

The differentiation of WM from mantle cell lymphoma and B-cell chronic lymphocytic leukemia is usually straightforward, because both of these entities consistently express CD5 and have absent or low serum levels of monoclonal IgM. In addition, mantle cell lymphoma is usually associated with *cyclin D1* positivity on immunohistochemical analysis. With fluorescent *in situ* hybridization (FISH), a t(11;14)(q13;q32) translocation should always be present. Follicular B-cell lymphomas can be readily differentiated from WM by the architectural patterns on light microscopy, the strong positivity in the cells for *bcl-2*, cell surface expression of CD10, and the presence of a t(14;18)(q32;q21) translocation. Evolution of WM to more aggressive lymphoproliferative disorders has been reported previously ([37], [38]).

A rare entity was described in 2000 in which patients have features of WM but produce an excess amount of monoclonal IgG paraproteins rather than IgM, suggesting that the clonal cells have undergone isotype class switching ([39]). Although such patients may have hyperviscosity associated with clonal IgG or IgA M proteins, they are not normally considered to have WM. Likewise, cases of IgM myeloma have been reported ([40], [41] and [42]). The difference between IgM myeloma and WM has been difficult to discern. Recent information indicates that patients with WM almost never have IgH translocations ([43]), whereas those with IgM myeloma frequently do ([44]). Renal failure is reportedly more common among patients with IgM myeloma ([40], [41] and [42]).

Radiologic Studies

At baseline, it is useful to obtain a computed tomographic scan of the chest, abdomen, and pelvis to assess adenopathy and spleen and liver size. In contrast to myeloma, lytic bone disease is unusual in WM; therefore, routine skeletal radiographs or bone scans are not needed unless the patient reports bone pain ([40], [41] and [42]).

PATHOPHYSIOLOGY

Normal Counterpart to Waldenström Macroglobulinemia Clonal Cells

Although a precise definition of the normal counterpart of the malignant cell in WM has not been established, it is currently believed that the cells most resemble postgerminal center B cells without evidence of isotype class switching or memory B cells (Fig. 100.4). There is evidence of somatic hypermutation in the clonal cells of WM and little intraclonal heterogeneity ([45], [46], [47], [48] and [49]). Southern blot analysis shows no rearrangements at the switch µ regions, indicating the lack of isotype class switching consistent with the IgM isotype of the paraprotein in this disease ([43]). Studies using lymphoplasmacytoid cells from patients with WM demonstrate that they differentiate *in vitro* to mature IgM-secreting plasma cells ([50]).

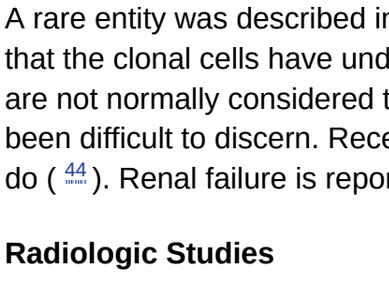

Figure 100.4. Diagram of B-cell development. The malignant cells in Waldenström macroglobulinemia (WM) are believed to be either postgerminal center B cells before isotype class switching or memory B cells. VDJ, variable diversity joining.

Relation to Monoclonal Gammopathy of Undetermined Significance

There is an ill-defined continuum between IgM-MGUS and active WM ([34], [51]) (Table 100.2). The prevalence of IgM-MGUS is fourfold that of WM. IgM-MGUS is more likely to evolve to WM than to myeloma or amyloidosis ([51]). In fact, patients with IgM-MGUS have a 46-fold higher relative risk of WM than the general population. Therefore, it is believed that some patients with IgM-MGUS actually represent early stages of WM. Identification of the patients in whom IgM-MGUS will

eventually transform to WM is not currently possible but is the subject of research. It is unclear how best to classify patients with paraprotein-associated complications such as demyelinating polyneuropathies or amyloid deposition.

TABLE 100.2. Relationship between Immunoglobulin M–Monoclonal Gammopathy of Undetermined Significance (IgM-MGUS), Smoldering Waldenström Macroglobulinemia (SWM), and Waldenström Macroglobulinemia (WM)

	IgM-MGUS	SWM	WM
Monoclonal serum protein concentration	Usually <15 g/L	Usually >15 g/L	Usually >30 g/L
Anemia	Not seen	Common but mild	Common
Other cytopenia	Not seen	Rare (15%)	Rare (15%)
Organomegaly	None	May be present	~15–20% of patients
Hyperviscosity	None	None	~15% of patients
Constitutional symptoms	None	None	Present
Bone marrow clonal cells	Usually <5–10%	Usually >20%	Usually >20%
Therapy	Not needed	Not needed	Indicated

Cytogenetics

Early reports described various cytogenetic abnormalities in WM patients, including the so-called W chromosome, but none of the abnormalities were specific for the disease, and most studies were done before G-banding analysis was available ([52], [53], [54], [55], [56], [57], [58], [59], [60], [61], [62], [63], [64], [65], [66], [67], [68] and [69]). In the majority of WM cases, the karyotype analyses are normal. Multicolor metaphase analysis in WM has been noncontributory so far ([43]). The only recurrent abnormality described in sporadic reports and small series is deletion of the long arm of chromosome 6 ([68], [69] and [70]). Interphase FISH is a useful technique for detecting chromosomal abnormalities in malignancies with low cellular proliferation rates such as WM. In a large cohort of WM patients studied by interphase FISH, a deletion of the long arm of chromosome 6 was observed in 40 to 60% of cases ([43]).

It is now believed that WM clonal cells lack IgH translocations. It has been reported that at least 50% of patients with LPL have a t(9;14)(p13;q32) translocation ([71]). The t(9;14)(p13;q32) results in up-regulation of *PAX-5* ([72], [73]), implicating this gene as a putative oncogene in the pathogenesis of LPL ([74], [75] and [76]). In the original series, none of the LPL patients with t(9;14) (p13;q32) had paraproteinemia. This finding is biologically plausible because up-regulation of *PAX-5* prevents expression of the high levels of Ig that result in paraproteinemia. Using interphase FISH, we were able to demonstrate absence of IgH translocations and t(9;14)(p13;q32) in a large cohort of patients with WM ([43]). This translocation should be readily detectable by karyotype analysis ([43]), and it has not been reported in studies of abnormal karyotypes of WM ([43], [67], [68]). Furthermore, these series failed to observe IgH translocations ([43], [67], [68]).

There are also sporadic reports of WM cases with the t(11;18)(q21;q21) translocation ([77], [78]), which is known to occur in extranodal marginal zone lymphomas ([77], [78]). This abnormality was not found in a large cohort of WM patients studied ([43]). In contrast to patients with multiple myeloma, those with WM rarely have 13q14 and 17p13.1 deletions at the time of diagnosis ([79]). The clonal cells of WM are usually diploid ([43]), and this has been confirmed by DNA content analysis in a small subset of patients ([57]).

Molecular Genetics

Little is known about the molecular genetic nature of WM. Methylation of the tumor suppressor gene *p16* and mutations of *TP53* are rare (R. Fonseca, unpublished observations, 2002). Ongoing studies are addressing the role of gene expression profiles in patients with WM.

CLINICAL FEATURES

The clinical features (Table 100.3) associated with WM can be divided into characteristics that are related to compromise of the bone marrow and other organs and those that are secondary to the clonal proliferation, hyperviscosity, other effects of the paraprotein on peripheral blood, and paraneoplastic phenomena ([3], [8], [23], [25]).

TABLE 100.3. Clinical Features of Patients with Waldenström Macroglobulinemia

Modified from Winkler JM, Fonseca R. Waldenström macroglobulinemia. In: Gertz MA, Greipp PA, eds. Handbook of multiple myeloma and related cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag (*in press*).

Anemia is the most common cause for initiation of therapy in patients with WM and is due to clonal expansion in the bone marrow, increased plasma volume, and hyperviscosity. In patients previously treated with chemotherapy, myelosuppression is an additional cause of anemia. The anemia can vary from mild to severe and results in fatigue proportional to the level of anemia. Anemia (hemoglobin, <100 g/L) has been reported in 27 to 38% of patients (19, 23). Successful treatment of WM should lead to an improvement in hemoglobin, a reduced need for transfusions, and an improvement in performance status. If myelosuppressive chemotherapy is used, the hemoglobin does not achieve maximum improvement until after the chemotherapy is stopped. If anemia is the only symptom, it may be correctable with erythropoietin (87) (see cautionary note under Hyperviscosity Syndrome). Increased viscosity reduces erythropoietin production and contributes to the anemia of WM (88).

In addition to anemia caused by ineffective erythropoiesis and peripheral destruction, patients with WM may have hemodilution because large amounts of pentameric IgM in the blood result in a hemoglobin level that is lower than would be expected on the basis of the red cell mass (1, 3). Patients may thus be asymptomatic (and not require transfusions) at hemoglobin levels that would typically result in symptoms in other patients.

Because of the M protein, rouleaux formation of red cells is characteristically observed on peripheral blood smear examination (29). Likewise, the M protein increases the Westergren erythrocyte sedimentation rate (ESR), making the ESR useless for the evaluation of infection or systemic inflammation in these patients. The influence on ESR seems to be independent of the protein concentration, and large increases may be seen even with small quantities of M proteins. Occasionally, patients we evaluate have been treated for presumed polymyalgia rheumatica or temporal arteritis, although in fact the high ESR could be simply attributed to the M protein.

Clinically significant thrombocytopenia is unusual in patients with WM despite the extensive marrow involvement and is usually not encountered until late in the disease. The median platelet count in the series of Kyle and colleagues (28) was within normal range, and only 9% of patients had a platelet count less than 100 × 10^9/L. Facon and associates (19) reported a thrombocytopenia prevalence of 22%. Other causes for thrombocytopenia include myelosuppressive chemotherapy and splenomegaly. In patients who have been previously treated, the possibility of myelodysplasia should be kept in mind. Thrombocytopenia, whenever present, potentiates the bleeding diathesis associated with hyperviscosity.

Organomegaly is seen in approximately one-third of patients with WM and includes hepatomegaly (20%) and splenomegaly (15%) (1, 8, 19, 23). The splenomegaly can produce hypersplenism and hence contribute to cytopenias. The liver involvement is usually not symptomatic and does not typically interfere with therapy. Fifteen to twenty percent of patients have lymphadenopathy ranging from mild to bulky (1, 8, 19, 23). Lung involvement in WM is unusual (89, 90).

Hyperviscosity Syndrome

FEATURES One characteristic feature of WM is the hyperviscosity syndrome (91, 92 and 93), which is seen in approximately 15% of cases. The dominant features of the hyperviscosity syndrome include oronasal bleeding, retinal hemorrhage, and neurologic abnormalities (Table 100.4). *Viscosity* is defined as the intrinsic resistance of a fluid to flow. Hyperviscosity is believed to be more common in association with IgM paraproteins because of the difference in length and width of the pentamer, compared with that of IgG and IgA antibodies. The viscosity of normal plasma, compared with that of water, is 1.8. For further details regarding the rheology of hyperviscosity, the reader is referred to Gertz and Kyle (91).

The syndrome does not necessarily correlate with the serum concentration of the M protein or serum viscosity ([91], [92] and [93]). Increased viscosity is not, in and of itself, an indication for plasmapheresis or treatment ([91], [92] and [93]). Some patients have no symptoms despite a high viscosity level, whereas others have prominent symptoms at similar levels. It is uncommon to see symptoms of hyperviscosity at values less than 4 cP. Most patients with a viscosity level of 5 to 8 cP are symptomatic, and nearly all patients with a viscosity greater than 8 cP are symptomatic ([91], [92] and [93]). Routine screening of viscosity in patients with an IgM less than 40 g/L is not recommended ([91]). Once a protein level at which symptomatic hyperviscosity occurs is determined, it can be used as a reference point at which symptoms of hyperviscosity may develop in the future ([91]). It is important to remember that viscosity can greatly increase if correction of anemia with red blood cell transfusions is overzealous; therefore, transfusions and erythropoietin therapy must be used with caution in patients at high risk for hyperviscosity syndrome. If a patient with hyperviscosity is in immediate need of blood transfusions, pretransfusion plasmapheresis may be necessary.

NEUROLOGIC AND RETINAL COMPLICATIONS ASSOCIATED WITH HYPERVISCOSITY Patients with WM and hyperviscosity may have neurologic symptoms. Focal neurologic deficits, including facial nerve paralysis, deafness, and other cranial neuropathies, were originally described by Waldenström ([94]). The combination of a neurologic syndrome and WM has been referred to as the *Bing-Neel syndrome*. Hyperviscosity can manifest as profound fatigue, mental confusion, obtundation, stroke ([95]), or dementia ([96]); therefore, the presence of neurologic symptoms or signs in a patient with WM should result in an urgent investigation for hyperviscosity. Even milder symptoms, such as headache or light-headedness, can also be due to hyperviscosity ([94]). In this circumstance, there should be a low threshold for emergent plasmapheresis, and the subsequent clinical improvement can be immediate and dramatic. There are several peripheral nerve complications associated with WM, including demyelinating polyneuropathy with anti–myelin-associated glycoprotein (anti-MAG) antibodies, demyelinating neuropathies not associated with anti-MAG antibodies ([97], [98]), polyneuropathies with IgM not reactive to known epitopes, cryoglobulin-associated symptoms, and, last, neuropathies associated with amyloidosis. Patients with WM can develop IgM-associated peripheral neuropathies and other syndromes, as described in Chapter 98, and such conditions have been reported in approximately 5% of cases. In many of these patients, the M protein has anti-MAG activity. This results in the binding of the M protein to the binding sheath and consequent demyelination ([99]). In one study, antimyelin activity of the monoclonal IgM was found in one-half of cases with neuropathy associated with WM ([100]). Patients with demyelinating polyneuropathies of the MAG type present with sensory deficits, including proprioception abnormalities that result in weakness and ataxia ([101], [102]). Treatments used for the control of WM, such as chlorambucil, may also be effective in controlling associated syndromes such as peripheral neuropathy, and cases of sustained neurologic improvement have been reported ([103]). Retinal complications include venous engorgement, retinal hemorrhage, cotton-wool spots, and, in extreme cases, retinal vein occlusion ([104], [105]).

Paraneoplastic and Other Manifestations

Patients with WM can develop clinical features of light-chain–associated amyloidosis ([8], [106], [107]). Such patients appear to have a stronger tendency to develop amyloid-associated cardiomyopathy than do other patients with amyloidosis (44% vs. 27%), and they have a higher incidence of pleural and pulmonary amyloidosis ([106]). In cases of WM-associated amyloidosis, the therapy should be designed to control the WM.

PROGNOSIS

The prognosis of WM is quite variable. The median survival is approximately 5 years ([28], [80]), but approximately 10% of patients remain alive after 15 years ([28]). Other series have reported a median survival of 108 months ([81]).

Because the disease is indolent and predominantly affects the elderly, few data are available on disease-related survival and mortality that exclude other causes of death. Better information is needed. Furthermore, because of the wide range of survival, prognostic factors are important. By updating the series studied originally by Facon et al. ([19]), Morel and colleagues ([80]) developed a prognostic model (Table 100.5) for WM based on age, serum albumin, and blood count data from 232 patients treated before 1989 with alkylator agents (no purine nucleoside analogs). Age greater than 65 years, albumin less than 40 g/L, and presence of at least one cytopenia (hemoglobin, <120 g/L; platelet count, <150 × 10^9/L; or white blood cell count, <4 × 10^9/L) were determined to be important for prognosis. Patients with one cytopenia were assigned one point; those with two or more cytopenias were assigned two points. Patients were then grouped into three prognostic categories: low risk (zero to one point, 27% of patients), intermediate risk (two points, 27% of patients), or high risk (three to four points, 46% of patients). The proportion of patients alive at 5 years was 87% for the low-risk, 62% for the intermediate-risk, and 25% for the high-risk group (Table 100.5). The median actuarial overall survival was 61 months, and there was no difference in overall survival between the patients who were initially observed without therapy versus those who received immediate treatment.

TABLE 100.5. Prognostic Models for Patients with Waldenström Macroglobulinemia

Model (Reference)	Prognostic Factors		5-Year Patient Survival (%)	
Morel (80): Categories	Points [a]		Overall	
Low risk	0–1		87	
Intermediate risk	2		62	
High risk	3–4		25	
Dhodapkar (22): Stages	**ß $_2$-microglobulin (mg/L)**	**Hemoglobinx and IgM**	**Progression-free**	**Overall**
A	<3	Hemoglobin =120 g/L	83	87
B	<3	Hemoglobin <120 g/L	55	64
C	=3	Serum IgM =40 g/L	33	53
D	=3	Serum IgM <40 g/L	12	22

Ig, immunoglobulin.

[a] Criteria for points in Morel model: age 65 or older, 1 point; albumin <40 g/L, 1 point; one cytopenia (hemoglobin, <120 g/L; platelet count, <150 × 10^9/L; or white blood cell count, <4 × 10^9/L), 1 point; two or three cytopenias, 2 points.

Modified from Winkler JM, Fonseca R. Waldenström macroglobulinemia. In: Gertz MA, Greipp PA, eds. Handbook of multiple myeloma and related cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag (*in press*).

Other prognostic factors in a univariate model were ß $_2$-microglobulin concentration greater than 3 mg/L, serum IgM, and plasma volume greater than 50 ml/kg. Factors not found to be prognostic were the presence of Bence Jones protein, splenomegaly, B symptoms, light-chain type, cryoglobulinemia, pattern of marrow involvement, and other cytologic features. When the analysis was restricted to patients younger than 65 years, only the presence of two cytopenias was important. Kyrtsonis and colleagues ([81]) confirmed the prognostic importance of the Morel scoring system.

The prognostic scoring system developed by Gobbi and colleagues ([20]) uses weight loss, cryoglobulinemia, anemia (hemoglobin, <100 g/L), and age older than 60 years. Low-risk patients have no or one adverse feature; high-risk patients have more than one. Last, Dhodapkar and colleagues ([22]) evaluated prognostic factors in a group of 182 patients who were treated with fludarabine. Serum ß $_2$-microglobulin of 3 mg/L or greater, hemoglobin less than 12 g/dl, and IgM less than 40 g/L were significantly associated with shorter survival. The investigators used these three factors to develop a prognostic system that estimated 5-year treatment-free and

overall survival (Table 100.5).

TREATMENT OPTIONS

Observation

Because WM is currently an incurable malignancy, the objectives of treatment should be to provide relief of symptoms and to prevent hyperviscosity and end-organ damage. The situation is analogous to that of smoldering myeloma ([110]), because patients who are asymptomatic can be carefully observed without immediate treatment. Waldenström himself raised the question regarding the need for therapy in asymptomatic patients ([111]). If a patient is asymptomatic and the disease incurable, then early treatment may result in side effects that reduce the patient's quality of life. Although observation is often an appropriate choice, it is important that all patients with WM be followed up at regular intervals with a history and physical examination, along with appropriate laboratory tests, to detect active disease before damage to vital organs. Treatment initiation must be dictated by symptoms and the trend of laboratory values, not merely the laboratory values alone.

Alkylating Agent–Based Therapy

SINGLE ALKYLATING AGENTS Oral alkylating agents have been used as the mainstay of treatment for WM for 40 years ([112]) (Table 100.6). In 167 patients with WM treated with oral chlorambucil (0.1 mg/kg/day), the median survival was 5 years ([19]). Tumor burden did not predict response to therapy; therefore, neither a high degree of bone marrow involvement nor lymphadenopathy was a predictor of response to therapy. Kyle and colleagues ([28]) have reported the only prospective randomized trial assessing the use of chlorambucil for the treatment of WM in symptomatic patients. Patients were randomly assigned to receive oral chlorambucil continuously (0.1 mg/kg/day) or in intermittent 7-day cycles every 6 weeks (0.3 mg/kg/day). Response rates were similar between the two treatment arms (79% of the continuous group vs. 68% of the intermittent group, not significant). The median overall survival from start of treatment was identical in the two arms at 5.4 years. Lessons learned from this trial were that responses may occur late and that a therapy period of at least 6 months is required to fully evaluate response ([28]). Because of myelosuppression, patients started on oral chlorambucil at 0.1 mg/kg/day usually require dose reductions. Others have also demonstrated the effectiveness of chlorambucil ([81]). Oral cyclophosphamide has also been used to treat WM ([113]).

TABLE 100.6. Alkylating Agents in the Treatment of Waldenström Macroglobulinemia

Author (Reference)	Regimen	Patients (No.)	Response Rate (%)	Median Response Duration (mo)	Median Overall Survival (mo)	Median Event-Free Survival (mo)

MULTIPLE ALKYLATING AGENTS Because of its activity in the treatment of multiple myeloma ([114]), the VBMCP regimen (vincristine, carmustine, melphalan, cyclophosphamide, and prednisone) has been used in WM in an attempt to improve survival. In the initial report of 14 patients, all patients responded, with two attaining a complete response. No patients required plasma exchange. A subsequent trial accrued 33 patients and used VBMCP every 5 weeks for 2 years, followed by VBMCP maintenance every 10 weeks ([108]). Twenty-one partial responses and six minor responses were observed, with a projected survival of 58% at 10 years. In another study of 34 patients, melphalan, cyclophosphamide, and prednisone were given for 12 months, followed by continuous chlorambucil maintenance. An overall response rate of 74% (26% complete response) was observed ([109]). The toxicity was minimal, and the overall median event-free survival was 66 months. Leblond and colleagues ([82]) studied 92 patients with WM who were either resistant to (N = 42) or had relapsed after (N = 50) treatment with alkylating agents. The patients were randomly assigned to receive fludarabine, 25 mg/m ^{2} (days 1 through 5), or six cycles of cyclophosphamide, doxorubicin (Adriamycin), and prednisone (CAP). The overall response rate was 30% with fludarabine versus 11% with CAP ($p = .019$), and all responses in both arms were partial. The duration of response was 19 months with fludarabine versus 3 months for CAP ($p < .01$); however, there was no difference in overall survival. There was also no difference in hematologic or infectious toxicity between the two arms, but patients receiving CAP had more mucositis and alopecia.

Purine Nucleoside Analogs

FLUDARABINE Purine nucleoside analogs have been demonstrated to be highly effective in the management of low-grade lymphomas and B-cell chronic lymphocytic leukemia and hence were also tested in the treatment of WM. The use of fludarabine (Table 100.7) was first reported in 1990 by Kantarjian and colleagues ([115]). Eleven patients (ten previously treated) were treated, and five responded, with a median time to response (50% reduction in M protein concentration) of 5.2 months and a median duration of response longer than 1 year. Dimopoulos and colleagues ([83]) treated 28 patients (26 previously treated) with fludarabine, achieving a response rate of 36% (31% in previously treated patients). Responses were durable, with a median duration of response of 38 months. In a study of 12 previously treated WM patients, five achieved a partial response with fludarabine ([116]). With a mean follow-up of 10 months, only one responding patient had relapsed. The Macroglobulinemia French Cooperative Group reported on fludarabine treatment in 71 previously treated patients ([84]). The median number of courses of fludarabine was six. Twenty-one patients (30%) responded, and the overall median survival of all treated patients was 23 months. The time to treatment failure for responders was 32 months.

[a] Four of five responders still in remission at study termination.

[b] No significant difference compared with CAP (cyclophosphamide, doxorubicin, and prednisone) as salvage.

[c] No difference between pretreated and naïve patients.

[d] Median follow-up only 6 months.

Modified from Winkler JM, Fonseca R. Waldenström macroglobulinemia. In: Gertz MA, Greipp PA, eds. Handbook of multiple myeloma and related cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag (*in press*).

In another study, seven patients with WM (six previously untreated and one minimally treated) received fludarabine at 25 mg/m ^{2} daily for 5 days on a monthly schedule (117). The median time from recognition of the M protein to the initiation of chemotherapy was 32.6 months. Most patients received six cycles of fludarabine. Six patients showed a marked reduction in IgM value and normalization of the hemoglobin, with a median time to response of 5.4 months. It is interesting that the maximum response was observed 17.3 months after the end of treatment. In six patients, the responses were sustained (from 20.8 to 55.2 months). Foran and colleagues (118) studied fludarabine administered at 25 mg/m ^{2} daily for 5 days every 4 weeks in 19 patients with previously untreated WM. The response rate was 79% (15% complete response), with a median response duration of 30 months. The treatment-related mortality was 5% due to fludarabine-induced pancytopenia and infection in patients with reduced marrow reserve. The largest study of fludarabine in WM enrolled 231 patients, of whom 167 were previously untreated and 64 had received prior therapy (22). Forty-nine of the previously untreated patients were observed because they were asymptomatic. A total of 182 patients were treated with four to eight cycles of fludarabine at a dose of 30 mg/m ^{2} daily for 5 days, repeated monthly. The overall response rate was 36% (2% complete response). Patients older than age 70 years were significantly less likely to respond to fludarabine therapy. There was no difference in response rates between previously untreated patients and those with prior therapy. The primary toxicity was myelosuppression, and mortality from infections was 4%.

2-CHLORODEOXYADENOSINE The purine nucleoside analog 2-chlorodeoxyadenosine (2-CDA; cladribine) is structurally similar to fludarabine and has also been studied in the treatment of WM (Table 100.8). Dimopoulos and colleagues (121) treated 29 WM patients with a continuous intravenous infusion of 0.1 mg/kg/day of 2-CDA for 7 days for a total of two courses. They reported an overall response rate of 59% (100% in previously untreated patients; 40% in relapsed patients). Delannoy and colleagues (122) reported similar results in 18 patients treated with 2-CDA with either 4.0 mg/m ^{2}/day for 7 days by continuous intravenous infusion (N = 5) or 5.6 mg/m ^{2} infused over 2 hours per day for 5 days (N = 13), with partial responses in 39% of patients (7 of 18). Grade 4 neutropenia developed in four patients (22%), and grade 4 thrombocytopenia developed in six patients (33%). In another study, 25 patients were treated with 2-CDA at a dose of 0.14 mg/kg/day for 5 consecutive days as a 2-hour intravenous infusion. The overall response rate was 64% (4% complete response) (125).

TABLE 100.8. 2-Chlorodeoxyadenosine (Cladribine) in the Treatment of Waldenström Macroglobulinemia

Author (Reference)	2-Chlorodeoxyadenosine Regimen	Patients (No.)	Response Rate (%)	Median Response Duration (mo)	Median Overall Survival (mo)

Liu and colleagues (119) reported on the use of 2-CDA (0.12 mg/kg over 2 hours each day for 5 days per month), obviating the need for an intravenous central catheter. They treated 20 patients and found an overall response rate of 55% (one complete response and ten partial responses). The median duration of response was 28 months. As in other series, myelosuppression was the main toxicity, with grade 3 or 4 neutropenia seen in 60% of patients. Two patients had herpes zoster due to cellular immunosuppression. Hellmann and colleagues (86) treated 22 WM patients with a similar 2-hour infusion of 2-CDA for three cycles and achieved an overall response rate of 41% (all partial). Neutropenia occurred in 77% of patients and thrombocytopenia in 32%, including one fatal hemorrhage. It appears that when 2-CDA is used to treat WM, it should be limited to two cycles to avoid profound myelosuppression. In another study, 2-CDA was administered to ten previously untreated patients (0.12 mg/kg over 2 hours every day × 5 days per month × 4 cycles), followed by interferon maintenance (120). The overall response rate was 100% (one response was complete, eight were partial, and one was minor). To assess long-term 2-CDA use, a multiinstitutional trial was reported in which 25 previously treated patients received 2-CDA subcutaneously (0.1 mg/kg/day for 5 days) every month for a maximum of six cycles. The median number of cycles administered was three, and the overall response rate was 40% (all partial responses) with a median remission duration of 8 months. Grade 2 or greater infections developed in 16% of patients. As first-line treatment for WM, 2-CDA is effective but is also associated with myelosuppression and T-cell immunodeficiency (126). Attempts to assess whether 2-CDA and fludarabine are non–cross-resistant have been published (123). In one study, 14 patients who did not respond to fludarabine therapy were treated with two courses of 2-CDA. Only one of ten patients with fludarabine-resistant disease responded. Three of four patients who had progressed after a previous response to fludarabine responded. In another study, six patients who were resistant to 2-CDA were treated with fludarabine, and two responded (127). This suggests that, for patients resistant to one purine nucleoside analog, limited benefit is obtained from switching to another purine nucleoside analog.

Rituximab

Because the majority of malignant cells in WM express surface membrane CD20, the recent availability of the anti-CD20 monoclonal antibody rituximab has allowed targeted immunotherapy (Table 100.9). Initial reports showed improvements in cytopenias (131) and neurologic symptoms (132) and disappearance of CD20 $^+$ B cells from the bone marrow and peripheral blood (133). Byrd and colleagues (129) treated seven relapsed patients with either four or eight weekly infusions of rituximab. The medication was well tolerated without myelosuppression or infections. Partial responses were noted in three patients, with a median progression-free survival of

6.6 months.

TABLE 100.9. Rituximab in the Treatment of Waldenström Macroglobulinemia

Author (Reference)	Rituximab Regimen	Patients (No.)	Response Rate (%)	Median Response Duration (mo)	Median Overall Survival (mo)	Median Event-Free Survival (mo)
Dimopoulos (128)	375 mg/m^2 IV × 4 wk, repeated × 1 for responders	27	44	NR	NR	NR

IV, intravenous; NR, not reported.

Modified from Winkler JM, Fonseca R. Waldenström macroglobulinemia. In: Gertz MA, Greipp PA, eds. Handbook of multiple myeloma and related cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag (*in press*).

[a] Includes partial and minor responses.

Treon and colleagues (130) treated 30 patients with previously treated WM with single-agent rituximab. Forty-seven percent (14 of 30) of patients had previously received a purine nucleoside analog. The median IgM values for all patients declined from 2403 to 1525 mg/dl. In addition, 63% of patients (19 of 30) had an increase in hematocrit, and 50% (15 of 30) had an increase in platelet count. Six of seven patients who were previously transfusion-dependent became independent after rituximab treatment. The overall response rate was 60% (18 of 30); 27% (8 of 30) were partial responses (>50% decline in the IgM), and 33% (10 of 30) were minor responses (>25% decline in the IgM). When repeat bone marrow examinations were performed after rituximab treatment (N = 17), the lymphoplasmacytic infiltration had decreased from 60% to 15%. The median time to treatment failure for responding patients was 8 months (5 months for stable patients).

Dimopoulos and associates (128) recently reported a prospective trial in 27 patients (15 untreated, 12 relapsed) treated with rituximab at 375 mg/m^2 weekly for 4 weeks. Patients who did not progress received an additional 4-week course 3 months after the first course. The overall response rate was 44%, with no difference between previously untreated and treated patients. The median time to response was 3.3 months, and the median time to progression was 16 months.

Because of these positive treatment responses, its acceptable toxicity profile, and the lack of therapy-associated myelosuppression and myelodysplasia, rituximab use has increased rapidly (134). Clearly, it is the most important new agent for WM. It is important to recognize that clinically meaningful responses to rituximab may occur several months after completion of therapy (personal communications, S. Treon, May 2002; M. Gertz, May 2002). In fact, the M protein concentration may initially increase at the end of rituximab administration or at the first evaluation point. These patients should be observed, if possible, because late responses can occur (128, personal observations). Currently unresolved questions regarding rituximab use in WM relate to its role in front-line therapy, in combination with myelosuppressive chemotherapy, and in maintenance therapy. These questions need to be addressed in future clinical trials.

Anti-CD20 radioimmunoconjugates have shown superior overall response rates in relapsed low-grade non-Hodgkin lymphoma when compared with rituximab; however, they have not been tested in WM.

Combination Therapy

Attempts have been made to combine alkylating agents with purine nucleoside analogs. Laurencet and associates (124) combined 2-CDA administered subcutaneously at 0.1 mg/kg/day for 3 consecutive days with intravenous cyclophosphamide at 500 mg/m^2 and oral prednisone monthly for up to six courses. The overall response rate was 88%, with grade 4 neutropenia seen in 11% of patients (2 of 19) but no treatment-related deaths. A subsequent dose-escalation study of the combination was performed. 2-CDA was given at 5.6 mg/m^2/day as a 2-hour intravenous infusion followed by a 1-hour infusion of cyclophosphamide on each of 3 days (135). The dose of cyclophosphamide, which was 200 mg/m^2 initially, was escalated in 100-mg/m^2 increments. After 2-CDA at the 5.6-mg/m^2 dose, the maximal tolerated dose of cyclophosphamide was 300 mg/m^2. The overall response rate was 58%. Dose-limiting toxicity was due to neutropenia, and severe infections were seen in 4% of cycles. Repeated cycles could not be given in 31% of patients because of prolonged thrombocytopenia.

Corticosteroids

Although, historically, WM has not been considered a steroid-responsive malignancy, some reports suggest that steroid treatment alone can be beneficial in WM, particularly in patients with severe pancytopenia who are not candidates for cytotoxic therapy. Gomez and colleagues (136) treated two WM patients with vincristine at 0.25 mg/m^2 and bleomycin at 5 units, given for 4 consecutive days, together with prednisone at 1000 mg/m^2, given orally on alternate days. Both patients had a greater than 50% decrease in the M protein and a 50% decrease in bone marrow tumor cell infiltration (remission duration, 4 to >35 weeks). In another report, two patients with resistant WM demonstrated marked decreases in total M protein and viscosity after short periods of high-dose dexamethasone (137). Because of its antiinflammatory properties and effect on immune complex vasculitis, steroid treatment has been reported to be particularly useful in patients with WM who have an associated cryoglobulin (138).

Interferon

Interferon treatment has been used in other lymphoproliferative disorders and therefore has been attempted in WM as well (139, 140). In one study, three patients with WM were treated with recombinant human interferon-a-2b (3 × 10^6 units three times a week) (141). After 4 months of treatment, a greater than 50% reduction of serum IgM was seen in all patients, with good tolerance. Low-dose interferon (1 × 10^6 units three times a week) was studied in 14 patients with WM (142). The median duration of treatment was 10.3 months. Forty-three percent of patients (6 of 14) had an increase in their hemoglobin concentration of 9 g/L or more, and 29% (4 of 14) had a substantial decrease in the M component of more than 20%. The median response duration was 6 months. Treatment had to be discontinued because of toxicity in three patients.

A phase II trial was conducted using interferon in 88 patients whose IgM M protein was higher than 10 g/L. Forty-three percent (38 of 88) had an M component higher than 30 g/L and were classified as having WM. The treatment consisted of 3 × 10^6 units/day for 1 month and then three times a week as maintenance. The M component was reduced by more than 50% in 12 of 38 patients (32%) and by 25 to 50% in an additional six patients (16%), for an overall response rate of 50%. Hyperviscosity symptoms improved, hemoglobin concentration increased, and the bone marrow lymphoplasmacytic infiltration decreased. Thus, interferon can produce meaningful clinical benefit in some patients (143).

Thalidomide

Thalidomide is an immunomodulatory and antiangiogenic agent that has been found to be effective in salvage therapy of multiple myeloma (144). Dimopoulos and colleagues (145) reported the results of a phase II trial of thalidomide in 20 patients (ten untreated, ten previously treated). Patients received thalidomide at doses of 200 to 600 mg/day. Five of 20 patients (two previously treated) responded, for an overall response rate of 25%. The time to progression was less than 3 months. It therefore appears that thalidomide as a single agent has limited activity in WM.

Stem Cell Transplantation

There have been few reports of the efficacy of autologous or allogeneic stem cell transplantation in WM. In one report, six patients with WM were treated with high-dose chemotherapy and stem cell support ([146]). The median age was 52 years. Four patients had relapsed after purine nucleoside analog therapy. In two of the purine nucleoside analog–treated patients, mobilization failed initially and required repeating. The conditioning regimens included single-agent melphalan (200 mg/m ^{2}) in five patients, including one tandem transplant, and melphalan (140 mg/m ^{2}) with total body irradiation in one patient. There were no treatment-associated deaths, and all six patients achieved a partial response. Five of the six patients were alive and four were event free 2 to 52 months after receiving the transplant.

In another study, seven patients received two to three cycles of combined chemotherapy with dexamethasone, carmustine, etoposide, cytarabine, and melphalan (Dexa-BEAM) and stem cell collection, followed by high-dose cyclophosphamide and total body irradiation ([147]). There were no treatment-related deaths. All patients had decreased serum IgM values, but five had persistently positive detection of M protein after transplantation. All patients were alive without progression 3 to 30 months after receiving the transplant. An additional report described a patient who achieved a complete response persisting for more than 12 months ([148]).

There are even fewer reports of allogeneic transplantation ([149] , [150]). Because the median age of patients at onset of WM is 65 years, the overwhelming majority may not be eligible to be treated with this method. Two patients who underwent an allogeneic transplantation procedure were alive and disease free at 3 and 9 years ([151]). One report of a successful nonmyeloablative allogeneic transplant has been published ([152]).

Transplantation remains an experimental therapy for WM. If autologous stem cell transplantation is being considered, stem cells should be harvested early in the disease course before significant exposure to purine nucleoside analogs and alkylating agents.

Other Therapeutic Interventions

SPLENECTOMY Although splenectomy does not address the bone marrow infiltration associated with WM, some patients with hypersplenic syndromes or spleen-dominant disease benefit from splenectomy ([153]). Splenectomy corrected a factor VIII deficiency associated with WM in one patient ([154]). In two patients with WM and massive splenomegaly refractory to chemotherapy, splenectomy was followed by disappearance of the monoclonal IgM from the serum. One patient was free of disease at 12 years; the other, at 13 years ([155]). Another patient with massive splenomegaly and WM underwent splenic irradiation, which transiently reduced the IgM level. After splenectomy, serum IgM values decreased, and peripheral blood cell counts normalized. The patient remained in remission at 6-year follow-up ([156]). In another patient, who underwent a Richter transformation of WM limited to the spleen, splenectomy led to disease control persisting at 45 months ([157]).
PLASMA EXCHANGE Plasmapheresis with total plasma exchange is very useful for treatment of the symptoms of hyperviscosity syndrome but has no impact on the tumor burden. When acute hyperviscosity symptoms develop, usually with a viscosity value above 4 cP, exchange of a small volume of plasma can produce large reductions in serum viscosity. Serum viscosity is not linearly correlated with IgM. Thus, IgM reductions of as little as 20% can result in viscosity reductions of as much as 50% ([158]). Even small reductions in serum viscosity can have dramatic effects on symptoms. In a Canadian survey, WM was among the top five indications for plasma exchange from 1981 to 1997 ([159]). Plasma exchange has also been used as a long-term maintenance treatment in patients who become resistant to cytotoxic drugs ([160]).

THERAPY-RELATED COMPLICATIONS

Patients with WM have baseline immunosuppression because of low levels of uninvolved Igs and treatment-related granulocytopenia. This increases the risk of infection. In addition, treatment with purine nucleoside analogs reduces levels of circulating CD4 $^+$ T cells, increasing the risk of opportunistic infections such as *Pneumocystis carinii* pneumonia ([161]). Other infections, such as opportunistic viral enteric infections ([162]) and *Cryptococcus* meningitis ([163]), have been reported in patients with WM treated with fludarabine. 2-CDA interferes with lymphocyte proliferation and activity, with associated fever and infection ([164]). It is interesting that, as a result of the suppression of T-lymphocyte function, the emergence of autoimmune phenomena in patients exposed to 2-CDA is possible. Four patients with WM have been reported in whom immune-mediated hemolysis developed after 2-CDA therapy (median, 40 months after initial administration). One patient responded to oral corticosteroids, and two died ([165]). Renal, neurologic, and local skin reactions have also been reported ([166]).

Alkylating agents are well known to be mutagenic and to induce chromosomal changes. The development of myelodysplasia in acute myelogenous leukemia is clearly the greatest risk factor associated with alkylating agent therapy, but fortunately it occurs in a small minority of patients. Shortly after the introduction of alkylating agents for the management of WM, reports of acute erythroleukemia appeared ([167] , [168] and [169]). In a study of 46 patients, acute leukemia or refractory anemia developed in four patients ([28]). Acute myelomonocytic leukemia has also been reported with chlorambucil treatment ([170]). Two patients have been reported with myelodysplastic syndrome and chromosomal abnormalities monosomy 5 and monosomy 7 without any prior exposure to alkylating agents ([171]). A metabolite of cyclophosphamide, acrolein, is toxic to the urinary bladder, and bladder cancer has been reported in patients treated with oral cyclophosphamide (50 to 100 mg/day) ([172]).

CONCLUSION

The mainstays of therapy for WM are alkylating agents and purine nucleoside analogs, usually administered singly and in sequence. The ultimate role of rituximab in the management of this disease remains to be defined, but rituximab is increasingly being considered as front-line treatment, particularly in younger patients. It is likely that a combination of rituximab with chemotherapy will be the next regimen to be tested in clinical trials for WM. Clear-cut guidelines for newly diagnosed, untreated patients with active disease cannot be provided because of the lack of randomized phase III studies. Data that permit selection of one method over the other do not exist. Whether combinations of therapies will be shown to be superior to sequential single agents is not known.

Cryoglobulinemia, Heavy Chain Diseases, and Monoclonal Gammopathy–Associated Disorders

This chapter addresses two types of immunoglobulin (Ig)-based orphan diseases: cryoglobulinemia and heavy chain disease (HCD). These diseases are characterized by lymphoproliferative, lymphoplasmacytic proliferative, or plasmaproliferative disorders and specific serum Ig findings that serve as markers to define each entity. As understanding of the pathologic mechanisms progresses, the similarities between a-HCD and cryoglobulinemia may prove to be greater than those among a-HCD, µ-HCD, and ?-HCD. Each entity is discussed separately in this chapter, with cryoglobulinemia discussed first and HCD second.

INTRODUCTION TO CRYOGLOBULINEMIA

In 1933, Wintrobe and Buell ([1]) originally reported observing cryoglobulins in a serum sample from a patient with multiple myeloma. These cold precipitable Igs are observed in some patients who have vasculitis, viral infection, or lymphoproliferative disorders and are byproducts of lymphoid dysfunction—unchecked and misdirected stimulation and proliferation that cause dysfunction and pathologic changes. An understanding of cryoglobulins and the cells that produce them, along with their interaction with tissue matrix, systemic cytokines, and the remainder of the immune system, may provide insight into basic control pathways and the earliest steps of malignant transformation.

The term *cryoglobulin* was coined by Lerner and Watson ([2]) in 1947. Precipitation of cryoglobulins is dependent on temperature, pH, cryoglobulin concentration, and weak noncovalent factors ([3]). Meltzer and others delineated a distinct syndrome of purpura, arthralgias, asthenia, renal disease, and neuropathy—often occurring with immune complex deposition, vasculitis, or both ([4], [5]). Brouet et al. ([6]) popularized a system of classifying cryoglobulinemia on the basis of the components of the cryoprecipitate: type I, isolated monoclonal Igs; type II, a monoclonal component, usually IgM, possessing activity toward polyclonal Igs, usually IgG; and type III, polyclonal Igs of more than one isotype. This classification provided a framework by which clinical correlations could be made. Associated conditions, such as lymphoproliferative disorders, connective tissue disorders, infection, and liver disease, were observed in some patients (Table 101.1) ([13], [16]). In several large series, 34 to 71% of cryoglobulinemia cases were not associated with other specific disease states and were termed *essential* or *primary cryoglobulinemia* ([6], [13], [17]). In 1990, hepatitis C virus (HCV) was recognized as an etiologic factor for the majority of these cases ([18], [19]) (Fig. 101.1).

TABLE 101.1. Cryoglobulinemia: Clinical and Experimental Associations

Infectious diseases	Autoimmune diseases
Viral	Systemic lupus erythematosus
Epstein-Barr virus	Nephritis, hypocomplementemia
Cytomegalovirus	Drug-induced lupus (procainamide)
Hepatitis B virus	Rheumatoid arthritis
Hepatitis A virus	Extraarticular disease, Felty syndrome, synovial fluid
Adenovirus	Polyarteritis nodosa (positive or negative for hepatitis B surface antigen)
Hepatitis C virus (7, 8)	Kawasaki syndrome (± macroglobulinemia)
Human immunodeficiency virus (9, 10 and 11)	Sjögren syndrome
Bacterial	Scleroderma
Subacute bacterial endocarditis (± nephritis)	Sarcoidosis
Lepromatous leprosy (± erythema nodosum)	Thyroiditis
Acute poststreptococcal nephritis	Henoch-Schönlein purpura
Syphilis	Behçet syndrome
Lyme disease (± erythema chronicum migrans)	Polymyositis
After intestinal bypass with arthritis	Inflammatory bowel disease
Q fever (12)	Celiac disease, ulcerative colitis, regional enteritis
Fungal	Endomyocardial fibrosis
Coccidioidomycosis	Pulmonary fibrosis
Parasitic	Cutaneous vasculitis
Kala-azar	Pemphigus vulgaris
Toxoplasmosis	Erythema elevatum diutinum
Tropical splenomegaly syndrome	Cold-induced urticaria
Echinococcosis	Epidermolysis bullosa acquisita
Malaria	Erythema multiforme
Schistosomiasis	POEMS syndrome
Trypanosomiasis	Pyoderma gangrenosum
Lymphoproliferative disorders	Liver diseases
Macroglobulinemia (primary and secondary) (6, 13, 14 and 15)	Cirrhosis (Laënnec, postnecrotic)
Lymphoma (Hodgkin and non-Hodgkin) (6, 13, 14 and 15)	Biliary cirrhosis

Chronic lymphocytic leukemia	Chronic hepatitis
Immunoblastic lymphadenopathy	Essential
Hairy cell leukemia	Experimental
Renal disease	Pneumococcal vaccines
Proliferative glomerulonephritis	Streptococcal (A and C) hyperimmunization
Familial (symptomatic, asymptomatic)	NZB/NZW, MRL/1, BXSB mice

POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

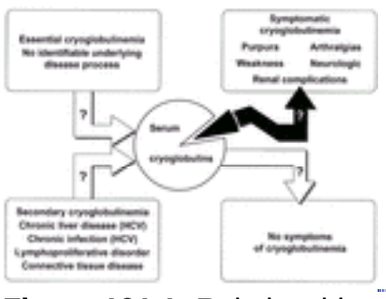

Figure 101.1. Relationship among underlying diseases, cryoglobulins, and symptoms of cryoglobulinemia. Question marks represent unknown contributing factors. HCV, hepatitis C virus. Dark arrows, symptomatic; light arrows, asymptomatic. [From Dispenzieri A, Gertz MA. Cryoglobulinemia. In: Gertz MA, Greipp PR, eds. Hematologic malignancies: multiple myeloma and related plasma cell disorders (primary amyloidosis, AL). Berlin: Springer-Verlag, 2004:53–109, with permission.]

EPIDEMIOLOGY OF CRYOGLOBULINEMIA

The prevalence of cryoglobulinemia is difficult to estimate because of its clinical polymorphism and because of the necessity of separating the laboratory finding of cryoglobulins from the symptomatic disease state. Although only a minority of patients with serum cryoglobulins have symptoms referable to them, cryoglobulins may be found in patients with cirrhosis (up to 45%), alcoholic hepatitis (32%), autoimmune hepatitis (40%), subacute bacterial endocarditis (90%), rheumatoid arthritis (47%), IgG myeloma (10%), and Waldenström macroglobulinemia (19%) ([6], [13], [14], [15] and [16]). In some situations, cryoglobulins serve as harbingers of undiagnosed chronic infections such as subacute bacterial endocarditis, Lyme disease, and Q fever ([16]). Case reports describe cryoglobulinemia associated with hepatitis A virus, hepatitis B virus, Hantavirus, cytomegalovirus, Epstein-Barr virus, human T-cell lymphotropic virus type I, hepatitis G virus, and human immunodeficiency virus ([9], [16]). An association with HCV was reported in 1990 and 1991 ([18], [19]), and it has become apparent that many patients (42 to 100%) with mixed cryoglobulinemia (MC) are infected with HCV ([19], [20], [21], [22], [23], [24], [25], [26] and [27]). By 2002, fewer than 10% of cryoglobulinemia cases were classified as “essential.”

Results of most studies show that the median age at diagnosis lies in the early to mid 50s. In some studies, the female predominance for cryoglobulinemia is greater than 2:1 (Table 101.2). No racial preference has been noted, but the incidence is higher in regions where HCV occurs at higher frequencies (e.g., southern Europe). The most common causes of death include renal failure, infection, lymphoproliferative disorders, liver failure, cardiovascular complications, and hemorrh age ([6], [13], [17], [29]).

TABLE 101.2. Clinical Features of Cryoglobulinemia (Cryo) at Diagnosis

Authors (Reference) [a]	No. of Patients	Female to Male Ratio	Patients (%)

[a] Publications are listed chronologically, from oldest to most recent.

[b] Cryo without any identified predisposing condition. These values do not represent actual incidence but rather the make-up of the population analyzed for symptoms.

[c] Patients with abnormal liver function tests, hepatomegaly, or both.

[d] Value is for types II and III combined.

[e] Symptoms of the essential mixed cryo (types II and III) population only.

[f] Series restricted to patients with renal involvement.

[g] Patients with multiple myeloma, Waldenström macroglobulinemia, and infection were excluded from this study by design.

[h] Only patients with a cryocrit =1% were included. The percentages were calculated on the basis of the 206 symptomatic patients described by the authors.

[i] In this study, 12% of the patients were not typed.
Modified from Dispenzieri A, Gorevic PD. Cryoglobulinemia. Hematol Oncol Clin North Am 1999;13:1315–1349.

ETIOLOGY OF CRYOGLOBULINEMIA

Cryoglobulinemia is driven primarily by four classes of disease: liver disease (predominantly HCV), infection (again, predominantly HCV), connective tissue disease, and lymphoproliferative disorders. These diseases induce a seemingly nonspecific stimulation of B cells, frequently resulting in polyclonal hypergammaglobulinemia. When these various antibodies are produced, antibodies to autoantigens may also result. In animal models, a strong B-cell stimulus disrupts the sequential order of idiotype–antiidiotype interactions, resulting in both immunosuppression and idiotype–antiidiotype immune complexes ([34]). Furthermore, poorly regulated production

and clearance of IgM rheumatoid factor (RF) contribute to immune complex formation ([3], [13]) and pathologic conditions, which include vasculitis, nephritis, and vascular occlusion.

Complement components, fibronectin, and lipoproteins have been found along with antigen–antibody complexes within cryoprecipitates. Although hepatitis B virus, Epstein-Barr virus, and bacterial products may also be present, by far the most common pathogen within cryoprecipitates is HCV ([35]). HCV RNA, HCV-specific proteins, and anti-HCV antibodies are found in the supernatant of the cryoprecipitate and in the cryoprecipitate itself in 42 to 98% of patients with essential MC ([21], [22], [23], [24], [25], [26] and [27]). Cryoprecipitates contain 20 to 1000 times more HCV RNA than is present in the supernatant ([36]). The IgG component to which the IgM-RF fraction binds is directed against the HCV proteins ([37]).

Relationships among Predisposing Conditions and Cryoglobulinemia

HEPATITIS C VIRUS The exact relationship between HCV and cryoglobulinemia is unknown. It is clear, however, that (a) HCV serves as a chronic stimulus, (b) cryoglobulins are present in up to 50% of HCV-infected patients ([38], [39], [40] and [41]), (c) HCV is associated with autoimmune phenomena even in the absence of cryoglobulinemia, and (d) HCV may predispose patients to lymphoma ([16], [42], [43] and [44]). Predisposing factors for cryoglobulinemia in HCV patients are female sex, alcohol consumption, detectable serum HCV RNA, longer duration of hepatitis, higher serum ?-globulin levels, higher RF levels, and extensive liver fibrosis or cirrhosis ([16], [27], [38], [39], [45], [46] and [47]).
CONNECTIVE TISSUE DISEASE The incidence of cryoglobulinemia—most commonly type II or III—associated with specific connective tissue disease is quite variable ([5]). Among patients with systemic lupus erythematosus, 25% have detectable cryoglobulins ([48]), and cryoglobulins have been found in 12.5% of patients with systemic sclerosis ([14], [49]). Measurable amounts of cryoglobulins, usually polyclonal, can be found in up to 46% of patients with active rheumatoid arthritis ([50]). Among patients with Sjögren syndrome, 16 to 37% have serum cryoglobulins ([14], [51], [52]); conversely, 5 to 15% of patients with MC have Sjögren syndrome ([6], [13], [17]). Patients with Sjögren syndrome who have mixed cryoglobulins have a sevenfold increased risk of developing lymphoma, compared with patients without cryoglobulins (86.0% vs. 12.5%) ([51]).

Lymphoproliferative Disorders

The relationship between cryoglobulinemia and lymphoproliferative disorders is complex; cause can be difficult to distinguish from effect. At a minimum, approximately 31% of all secondary cases of symptomatic cryoglobulinemia already carry a diagnosis of lymphoproliferative disorders when cryoglobulinemia is diagnosed ([17]). Higher percentages are found in series in which bone marrow biopsies, flow cytometry, Southern blot tests, and polymerase chain reaction are performed routinely ([53], [54], [55], [56] and [57]). In another 6 to 28% of patients, symptomatic lymphoma develops at follow-up ([43], [56], [58], [59]); 50% of these are intermediate- or high-grade lymphoma ([59]). The most common histologic diagnoses among the remaining low-grade lymphomas are immunocytoma ([53], [60]) followed by mucosa-associated lymphoid tissue and centrocytic follicular lymphoma ([61]). Among patients whose condition transforms to overt lymphoma, the malignant clone is derived from one of the dominant baseline B-cell clones in only a minority of patients ([55]), implying a predisposition for clonal production and evolution.

Associations among Cryoglobulinemia, Hepatitis C Virus, Connective Tissue Disease, and Lymphoma

A recognized model for progression from chronic antigenic stimulation to benign or malignant lymphoproliferation is provided by *Helicobacter pylori*–associated and mucosa-associated lymphoid tissue lymphomas ([62]). HCV, Sjögren syndrome, cryoglobulinemia, and immunocytoma may follow a similar pattern. There is remarkable conservation of and homology among the antigen-combining sites (variable regions) of the IgM-? RFs in patients with HCV, HCV-associated lymphoma, or cryoglobulinemia ([63], [64], [65], [66], [67], [68] and [69]). Similar degrees of homology are seen between the Ig receptors in the lymphoproliferation of patients with Sjögren syndrome and those in the lymphomas of HCV-infected patients with or without type II MC ([70]). This finding supports the concept that the combination of chronic antigenic stimulation, ineffectively regulated autoreactive B cells (which make restricted RF), and continued B-cell proliferation may predispose B cells to subsequent oncogenic mutation and transformation to malignant lymphoma.

Among HCV-positive patients with MC, HCV RNA is detected in peripheral blood mononuclear cells in up to 81% of patients ([71]) and in bone marrow cells in up to 100% of patients ([56], [72], [73], [74], [75] and [76]). Clonal Ig gene rearrangements can be detected by reverse transcriptase polymerase chain reaction in all HCV-positive patients with type II MC and in 24% of HCV-infected patients without cryoglobulinemia ([57]). Productive t(14;18) translocations with resultant Bcl-2 overexpression occur in approximately 12 to 26% of HCV-positive patients without symptomatic cryoglobulinemia and in 39 to 86% of their cryoglobulin-positive counterparts ([77], [78] and [79]). Patients with cryoglobulinemia in whom lymphoma develops have been found to have genomic sequences of HCV in their lymphoma specimens ([61], [80], [81] and [82]). The non-Hodgkin lymphoma (NHL) subgroup most commonly observed in patients with HCV is a lymphoplasmacytoid lymphoma/immunocytoma ([83]). An increased rate of HCV infection (8 to 50%) has also been reported in idiopathic B-cell NHL by many investigators ([16], [42], [43] and [44]).

CLINICAL PRESENTATION OF CRYOGLOBULINEMIA

Involvement of the skin, peripheral nerves, kidneys, and liver is common (Table 101.2). Lymphadenopathy is present in approximately 17% of patients ([5], [13]). On autopsy, widespread vasculitis involving small and medium vessels in the heart, gastrointestinal tract, central nervous system, muscles, lungs, and adrenal glands may also be seen ([13], [84]). The interval between the onset of symptoms and the time of diagnosis varies considerably (range, 0 to 10 years) ([13]). Type I cryoglobulinemia is usually asymptomatic. When symptomatic, it most commonly causes occlusive symptoms rather than the vasculitis associated with types II and III ([5], [6], [13]). Symptoms of hyperviscosity may occur (Fig. 101.2). Type II cryoglobulinemia is more frequently symptomatic (61% of patients) than type III (21% of patients) ([85]). The most common causes of death include renal failure, infection, lymphoproliferative disorders, liver failure, cardiovascular complications, and hemorrhage ([6], [13], [17], [29], [33]).

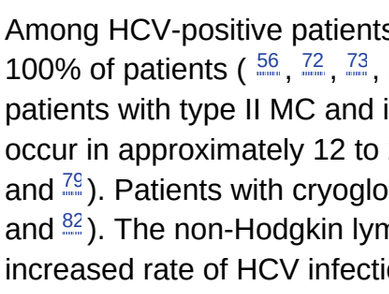

Figure 101.2. Cryoglobulin-associated physical findings. **A:** Hyperviscosity manifested as retinopathy with venous engorgement and hemorrhage. **B:** Purpura. **C:** Gangrene.

Skin

Purpura is the most frequent symptom of MC, found in 55 to 100% of MC patients ([6], [13], [17], [29]) (Table 101.2 and Fig. 101.2). The incidence varies from 15 to 33% in type I, from 60 to 93% in type II, and from 70 to 83% in type III ([86]). Petechiae and palpable purpura are the most common lesions, although ecchymoses, erythematous spots, and dermal nodules occur in as many as 20% of patients. Bullous or vesicular lesions are distinctly uncommon ([6]). Successive purpuric rashes, which may be preceded by a burning or itching sensation, occur most commonly on the lower extremities, gradually extending to the thighs and lower abdomen. Occasionally, the arms are involved, but the face and trunk are generally spared ([6]). Head and mucosal involvement, livedoid vasculitis, and cold-induced acrocyanosis of the helices of the ears are more frequently observed in type I; infarction, hemorrhagic crusts, or ulcers occur in 10 to 25% of all patients with MC ([87]). Showers of purpura last for 1 to 2 weeks and occur once or twice a month. Exposure to cold precipitates these lesions in only 10 to 30% of patients ([6], [87]). Raynaud phenomenon occurs in approximately 19 to 50% of cases ([6], [13], [17], [29]); in one-fourth of these, the symptoms may be severe, including necrosis of fingertips ([6]). Skin

necrosis, urticaria, and livedo, all of which are rare, are more commonly associated with exposure to cold.

Arthralgias

Arthralgias are common, affecting 35 to 92% of patients with cryoglobulinemia, with the highest incidence in type III cryoglobulinemia (Table 101.2). The small distal joints are affected more frequently than the larger proximal joints. Symmetric poly-arthralgia is often exacerbated by exposure to cold. Frank arthritis is rare ([6], [13], [17], [29], [32]).

Nervous System

Peripheral neuropathy is the most common presentation, although central nervous system involvement may occur. In the largest clinical series, peripheral nerve involvement is described in 12 to 56% of patients ([6], [13], [17], [29], [30], [32]) (Table 101.2). Signs and symptoms of sensory neuropathy usually precede those of motor neuropathy ([6]). The presentation may be an acute or subacute distal symmetric polyneuropathy or a mononeuritis multiplex ([88], [89]) with a chronic or chronic-relapsing evolution ([90]). The neuropathy in essential MC is most often characterized by axonal degeneration. Epineurial vasculitis is a common finding on sural nerve biopsy ([88], [89], [91], [92] and [93]).

Kidney

Approximately 21 to 39% of patients with MC have renal involvement ([6], [31], [32]) (Table 101.2). The incidence of renal injury is highest in patients with type II cryoglobulins ([17], [94]). Although renal and extrarenal manifestations may occur concurrently, renal involvement usually follows the onset of purpura by approximately 4 years ([13], [95]). Proteinuria greater than 0.5 g/day and hematuria are the most common features of renal disease at diagnosis (present in 50% of patients) ([96]); nephrotic syndrome affects approximately 20% of patients, and acute nephritic syndromes occur in approximately 25% of patients ([95], [96]). Although the diagnosis of a cryopathic membranoproliferative glomerulonephritis portends a poor prognosis ([13], [14], [94], [96], [97]), progression to end-stage renal failure due to sclerosing nephritis is uncommon ([96]). Among patients with MC-associated membranoproliferative glomerulonephritis followed up for a median of 11 years, 15% had disease progression to end-stage renal failure, and 43% died of cardiovascular, hepatic, or infectious causes ([96]).

Liver

Approximately 39% of patients with symptomatic cryoglobulinemia ([17]) and as many as 77% with MC ([13], [98]) have documented liver abnormalities at the time of diagnosis (Table 101.2). Furthermore, hepatomegaly is present in up to 70% of patients, and splenomegaly is present in up to 52% of patients ([4], [13], [28]). Among patients with symptomatic cryoglobulinemia, liver failure has been identified as the cause of death in 5.6 to 29.0% of individuals succumbing to the disease ([13], [30], [96]).

Histologic findings include portal fibrosis, chronic persistent hepatitis, chronic active hepatitis, chronic active hepatitis with cirrhosis, and postnecrotic cirrhosis ([98]). Most specimens are characterized by a diffuse lymphocytic infiltrate ranging from minimal periportal to extensive infiltration with nodule formation. These changes correlate with the severity of other pathologic findings. Plasma-cell infiltration also has been noted in several specimens ([85], [96]). The lymphoid population in the liver may show the histologic and immunophenotypic findings of lymphoplasmacytoid lymphoma/immunocytoma, and, frequently, the lymphoid elements are arranged in pseudofollicular structures in the liver with morphologic features similar to those previously reported in chronic HCV without cryoglobulinemia ([59]). These liver lymphoid nodules contain B cells predominantly with a $CD5^{+}/Bcl\text{-}2^{+}/Ki67^{-}$ phenotype associated with low apoptotic and proliferative rates ([99]).

DIAGNOSIS OF CRYOGLOBULINEMIA

By definition, all patients with cryoglobulinemia have serum cryoglobulins. The collection and processing of the specimens are critical because these cold-induced reversible precipitates can be lost with improper handling ([16], [100]). A minimum of 10 ml of blood is required, and the specimen must be allowed to clot at 37°C for 30 to 60 minutes before centrifugation. The serum supernatant is stored at 4°C for up to 7 days and inspected daily for the appearance of cryoprecipitates. Methods to evaluate the composition of the cryoglobulin include immunoelectrophoresis, immunofixation, immunoblotting, and capillary electrophoresis.

Concentrations of cryoglobulins tend to vary by type: type III, less than 1 mg/ml; type II, 1 mg/ml or greater; and type I, greater than 5 mg/ml ([6], [101]). The type or quantity does not reliably predict the presence or nature of symptoms. On serum protein electrophoresis, polyclonal hypergammaglobulinemia is the most common finding, although normal patterns or hypogammaglobulinemia may also be seen ([5], [13]). Even among patients with type II cryoglobulinemia, only 15% have a visible monoclonal spike on serum protein electrophoresis ([13]). Frequently, serum IgM levels are elevated; cryoprecipitable IgM may comprise up to one-third of the total serum IgM concentration ([13]). Hyperviscosity occurs only occasionally ([4]). Marked depression of complement CH50, C1q, and C4 in the presence of relatively normal C3 levels is usual ([13], [32], [102]). Neither C4 concentrations nor cryoglobulin levels correlate with overall clinical severity, although for individual patients, the cryoglobulin level can sometimes serve as a marker for disease activity ([13], [102], [103] and [104]). RF activity (i.e., anti-Fc activity) is detectable in the sera in 87 to 100% of patients with MC ([5], [6], [30]), and levels may decrease with response to therapy ([105]). An elevated erythrocyte sedimentation rate and a mild normochromic, normocytic anemia are fairly common ([13], [104]), but cryoglobulins with a high thermal amplitude may be associated with very low erythrocyte sedimentation rates. Cytopenias ([4]) have been described, as have pseudoleukocytosis and pseudothrombocytosis ([106]). Among patients with cryoglobulinemia, the antinuclear antibody results may be positive in as many as two-thirds of patients and in as many as one-third of HCV-positive patients ([32]). Because HCV is frequently concentrated in cryoglobulins ([21]), serial measurements of plasma or serum HCV RNA levels in these patients are not reliable ([47]).

TREATMENT OF CRYOGLOBULINEMIA

It is well recognized that cryoglobulinemia has a fluctuating course with spontaneous exacerbation and remission. This feature makes controlled clinical trials essential in evaluating the response to therapy. However, such studies are rare in the field of cryoglobulinemia. With the exception of the interferon (IFN)-a trials of the 1990s (Table 101.3) ([107], [108], [109], [110] and [111]) and the small low-antigen diet trial performed in the 1980s ([112]), the remainder of the information about the treatment of symptomatic cryoglobulinemia is anecdotal. Most “accepted” or “standard” treatments are not based on the results of randomized trials, and several reported strategies have questionable, if any, benefit (Table 101.4) ([16], [134]). Finally, therapies, such as the use of H_1- and H_2-blockers and penicillamine, are based on sound scientific principles but have shown no clear clinical benefit ([13], [16]). Figure 101.3 outlines a strategy for managing symptomatic cryoglobulinemia.

TABLE 101.3. Use of Interferon in Randomized Trials

Authors (Reference)	No. of Patients	Therapy			Comments
		Duration	Induction Dosage	RR (%) [a]	
Ferri et al. (107)	26	Crossover at 6 mo	IFN (2 MU/d × 1 mo, then qod × 5 mo)	77	Rebound after IFN was d/c.
		Pred (stable dosage; maximal, 10 mg/d)		0	
Misiani et al. (108)	53	5.5 mo	IFN (1.5 MU/d × 1 wk, then 3 MU 3×/wk)	60	Relapse occurred in all patients when IFN was d/c.
		Prior Rx [b]		0	
Dammacco et al. (109)	65	12 mo	nIFN (3 MU 3×/wk)	66	Most rapid and durable RR was with IFN/pred.

		nIFN/pred (nIFN, 3 MU 3×/wk; pred, 16 mg/d)		71	
		Pred (16 mg/d)		22	
		No Rx		13	
Lauta and De Sangro (110)	33	Indefinitely	Pred (10 mg/d)	27	
		IFN/pred (pred, 10 mg/d ± IFN, 3 MU/d until response, then 3 MU 3×/wk) [c]		83	
Mazzaro et al. (111)	36	6 mo	IFN (3 MU 3×/wk)	78	Duration of 12 mo provided better RR and better long-term response (22% vs. 11%).
		12 mo	IFN (3 MU 3×/wk)	89	

d/c, discontinued; IFN, interferon-a; nIFN, natural interferon-a; pred, prednisone; RR, response rate; Rx, treatment.

[a] All responses are based on *clinical responses*, which refer to symptomatic responses as defined by both clinical symptoms/signs and laboratory results known to correlate with symptomatic disease. Hepatitis C virus response is an antiviral response that is frequently measured in IFN trials.

[b] No therapy or stable low-dose therapy with pred (=0.2 mg/kg/day).

[c] Patients began receiving a maintenance dose of interferon when they achieved a complete response or when they achieved at least a minor response at 6 months.
Modified from Dispenzieri A, Gorevic PD. Cryoglobulinemia. Hematol Oncol Clin North Am 1999;13:1315–1349.

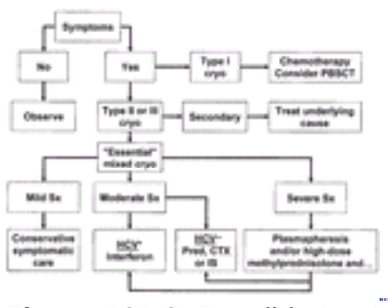

Figure 101.3. Possible treatment schema. If interferon therapy fails, combination therapy with interferon-a and ribavirin may help; however, contraindications for ribavirin should be considered. Cryo, cryoglobulin; CTX, cyclophosphamide; HCV, hepatitis C virus; IS, immunosuppressant; PBSCT, peripheral blood stem cell transplantation; pred, low-dose therapy with prednisone; Sx, symptoms.

TABLE 101.4. Treatment Strategies for Symptomatic Cryoglobulinemia

Reference	Treatment	Response	Quality of Data
See Table 101.3	Interferon	Effective	RCT
113	Ribavirin	PU	A
112	Low-antigen diet	PU (mild disease)	RCT
104, 114, 115, 116, 117, 118 and 119	Plasmapheresis, plasma exchange, cryoapheresis, and cryofiltration	PU	A
4, 13, 14, 28, 120, 121	Prednisone (1 mg/kg)	PU	A
122, 123	Methylprednisolone IV (1 g/wk or 1 g/d × 3 d)	PU	A
114	Chlorambucil	PU	A
119, 124, 125 and 126	CTX IV (750 mg/m ^{2}/mo); CTX orally (1–2 mg/kg/d)	PU	A
120	Melphalan	PU	A
13	Azathioprine orally (100 mg/d)	PU	A
59, 127	Cyclosporine (2.5 mg/kg/d)	PU	A
128	Colchicine (1 mg/d)	PNU	A
129, 130	Immunoglobulin IV	V [a]	A
131, 132	Cladribine and fludarabine	V	A
4, 124	Splenectomy	V	A
4	Chloroquine	PNU	A
13	H_1- and H_2-blockers	PNU	A
13	Penicillamine	PNU	A

A, anecdotal or single-armed trial; CTX, cyclophosphamide; PNU, probably not useful; PU, probably useful; RCT, randomized controlled trial; V, variable.

[a] One case report of precipitating acute renal failure (129) and another of systemic vasculitis (133).
Modified from Dispenzieri A, Gorevic PD. Cryoglobulinemia. Hematol Oncol Clin North Am 1999;13:1315–1349.

For years, the standard treatment of mild symptomatic cryoglobulinemia (purpura, asthenia, arthralgia, and mild sensory neuropathy) has included bed rest, analgesics, low-dose corticosteroid therapy, low-antigen content diet, and protective measures against cold; the treatment of severe disease (glomerulonephritis, motor neuropathy, and systemic vasculitis) has included plasmapheresis, high-dose corticosteroid therapy, and cytotoxic chemotherapy. Since the association between HCV and MC was established, immunosuppressive therapy has been viewed less favorably, and IFN is generally considered to be first-line therapy for HCV-positive patients who are in nonemergent situations (107, 108, 109, 110 and 111, 135). For patients with symptomatic type I cryoglobulinemia, cytotoxic therapy appropriate for the lymphoproliferative disorder remains the therapy of choice. Similarly, treatment of underlying connective tissue disease or infection would be first-line therapy in appropriate situations. The importance of not overtreating patients must be emphasized. Clinical trials are needed to clarify these issues.

Treatment of Life-Threatening Disease

The use of cytotoxic therapy, high-dose corticosteroid therapy, and plasmapheresis for patients with cryoglobulinemia with “uncontrolled features” has been the dogma, although no randomized clinical trials support this strategy. Plasma exchange or plasmapheresis alone can reverse serious complications, but most authors have recommended use of these procedures in combination with cytotoxic agents or corticosteroids for more durable responses (103, 114, 115 and 116). According to case reports, responses may be seen in 60 to 100% of patients (98, 114, 115 and 116). Skin manifestations and arthralgias usually respond most quickly, whereas the degree of neural and renal responses depends on the acuity of their occurrence, with poorer responses occurring in chronic cases (115). With combination immunosuppressive therapy and plasma exchange, reversal of catastrophic complications, such as encephalopathy and acute glomerulonephritis, has been documented (103, 115, 134). High-dose pulse therapy with methylprednisolone is also a favored therapeutic intervention for acute events, with 90% response rates reported in rapidly progressive glomerulonephritis (122, 136).

Interferon-a

Five randomized trials evaluating the efficacy of IFN therapy in HCV-positive patients with symptomatic type II MC have documented clinical responses in 60 to 89% of patients ([107], [108], [109], [110] and [111]) (Table 101.3). However, a majority of patients relapse within 6 months after discontinuation of therapy ([108], [109], [110] and [111], [135]). If no response occurs after 3 to 4 months of therapy, it is unlikely that further therapy will be successful ([135]). Factors associated with a poor response to therapy or a rapid relapse include liver cirrhosis, advanced age ([111]), male sex ([135]), and high levels of HCV RNA at the onset of therapy ([109], [138]). Purpuric lesions and liver function abnormalities tend to respond rapidly (within weeks), but neuropathy and nephropathy respond more slowly ([135], [137]). Although no randomized trial data exist for treatment of acute nephritis, most authors suggest initially supplementing IFN therapy with corticosteroids or plasmapheresis ([95]). Both peripheral neuropathy (*personal observation*, 137) and ischemic manifestations may be exacerbated by IFN ([139]).

More frequent doses (daily instead of three times weekly) ([137], [140]) and longer duration of therapy (at least 1 year) may result in more rapid ([137], [140]) and durable responses, respectively ([107], [108], [135]). The use of prednisone as part of the induction strategy also may result in quicker and more durable responses, but care must be taken because serum HCV RNA levels may increase with the use of prednisone ([109]). If relapse occurs during therapy, resistance may result from antibodies to IFN; reinduction may be possible with natural IFN ([137]). Use of combination therapy, including IFN-a and ribavirin, may be another strategy for patients with symptomatic cryoglobulinemia ([141], [142]). More than 60% of patients with symptomatic MC who do not respond to IFN therapy alone respond to combined therapy, and 80% of patients who relapse with IFN-a therapy alone respond to combined therapy ([141]).

Other Therapies

Although not formally studied, high-dose therapy with autologous stem cell transplantation may be considered for patients with symptomatic, refractory cryoglobulinemia associated with a plasmaproliferative disorder. There is an increased risk of lethal venoocclusive disease in patients with chronic HCV who are undergoing stem cell transplantation ([143]); for these patients, there are no data to support implementation of this therapy.

Dramatic reductions in the cryocrit and the cryoglobulinemic symptoms, including membranoproliferative glomerulonephritis, have been reported in several patients who underwent splenectomy for hypersplenism ([124], [144], personal observation). In contrast, in the series reported by Meltzer and Franklin ([4]), the patient who underwent splenectomy died of acute renal failure. Because this intervention has not been studied thoroughly, and because of the high risk involved, this intervention should not be considered as standard therapy but rather as a potential intervention for patients without cirrhosis who have disease that is difficult to manage because of cytopenias resulting from hypersplenism.

HEAVY CHAIN DISEASE

The HCDs are a rare group of disorders with diverse clinical presentations. The three conditions (a-, ?-, and µ-HCD) are discussed together because they are lymphoproliferative or plasmaproliferative disorders that share the generation and secretion of an isolated heavy chain fragment (Table 101.5). a-HCD (Mediterranean lymphoma or immunoproliferative small intestinal disease) is the most common and has the most uniform presentation; ?- and µ-HCD have variable clinical presentations and histopathologic features. In the majority of cases, the heavy chain fragment is not secreted in large quantities, and immunofixation or immunoelectrophoresis is required to detect the abnormality. Screening the serum and urine of patients with lymphoplasmacytoid NHL would most likely identify more patients with ?- or µ-HCD. Cases of ?- and µ-heavy chain monoclonal gammopathy of unknown significance have been reported ([149], [150]).

TABLE 101.5. Features of Heavy Chain Diseases

Feature	Type of Heavy Chain Disease		
	a	?	µ
Monoclonal heavy chain	IgA	IgG	IgM
Year described (reference)	1968 (145)	1964 (146)	1970 (147, 148)
Incidence	Rare	Very rare	Very rare
Median age	Young adults	61 yr	57 yr
Associated diseases	Bacterial overgrowth, malabsorption	Autoimmune diseases	—
Site	Small intestine, mesenteric lymph nodes	Lymph nodes, bone marrow, and spleen	Liver, spleen, lymph nodes, and bone marrow
Pathologic features	Extranodal marginal zone lymphoma (MALT or IPSID)	Lymphoplasmacytoid lymphoma	Small lymphocytic lymphoma/chronic lymphocytic leukemia
Therapy	Antibiotics, chemotherapy	Chemotherapy	Chemotherapy

Ig, immunoglobulin; IPSID, immunoproliferative small intestinal disease; MALT, mucosa-associated lymphoid tissue.

a-Heavy Chain Disease

Mediterranean lymphoma, originally described in the 1960s as a condition in young adults, is a primary small intestinal lymphoma coupled with intestinal malabsorption ([151]). An isolated IgA heavy chain fragment was recognized in association with this condition. Because some patients had benign-appearing lymphocytes in their small bowel, the term a *-HCD* was preferred over *Mediterranean lymphoma* by some authors ([152]). A consensus panel in 1976 concluded that a-HCD and Mediterranean lymphoma represented a spectrum of disease with benign, intermediate, and overtly malignant stages, and the term *immunoproliferative small intestinal disease* came into use ([153]).

The majority of reported patients with a-HCD are from northern Africa, Israel, and surrounding Middle Eastern or Mediterranean countries, with fewer patients from central and southern Africa, eastern Asia, and South and Central America ([154]).

Patients present with malabsorption syndromes, weight loss, and abdominal pain. On physical examination, peripheral edema, clubbing, and abdominal masses are not uncommon findings ([153], [154] and [155]). On endoscopy of the small intestine, one may find thickened mucosal folds, nodules, ulcers, a mosaic pattern, or submucosal infiltration. Intestinal parasites and bacterial overgrowth in the small intestine are common. Anemia, vitamin deficiencies, and hypogammaglobulinemia are also seen frequently. The IgA level is generally not increased, but on immunofixation or immunoelectrophoresis, a monoclonal component is present, especially in the earlier phases of the disease, and can be identified as an IgA heavy chain without associated light chains. The monoclonal IgA fragment may be found in jejunal secretions as well as in the blood and urine ([155]). In patients with a-HCD, the monoclonal protein belongs to the a1 subclass and consists of multiple polymers. The length of the basic polypeptide subunit is typically between one-half and three-fourths that of a normal a-heavy chain; the shortening results from an internal deletion involving most of the V_H and the C_H1 domains ([156]). In approximately one-half of the cases, the electrophoretic pattern of a-HCD protein consists of a broad band extending from the a2 region to the ß-globulin region, a reflection of the tendency of these chains to polymerize. The remainder of the patients may have a normal serum protein electrophoretic pattern.

The histologic findings have been classified into three distinct stages: Stage A includes a diffuse, dense, compact, and apparently benign lymphoplasmacytic infiltration of the mucosal lamina propria. Stage B has the features of stage A but has the additional finding of an “immunoblastic” lymphoma pattern in intestinal or

mesenteric lymph nodes. Stage C comprises a diffuse “immunoblastic” lymphoma with or without the benign-appearing lymphoplasmacytic infiltration seen in stage A ([153]). Villous broadening or effacement and shortened sparse crypts are also observed. These histopathologic findings can be distinguished from those of celiac sprue because celiac sprue includes total villous atrophy, hyperplastic and elongated crypts, intraepithelial lymphocytosis, and surface epithelial flattening. The lymphoma that arises from celiac sprue is a T-cell lymphoma ([157]) rather than a B-cell lymphoma, as in the case of a-HCD.

The hypothesis that chronic antigenic stimulation by intestinal organisms is the cause of this disorder is credible and can be modeled after the mucosa-associated lymphoid tissue lymphoma paradigm. This hypothesis is further supported by the fact that a-HCD (or immunoproliferative small intestinal disease) is most common in patients who live in areas with poor sanitation and who also have a high prevalence of intestinal microbial infestation, although the particular offending organisms have not been identified.

Although no data exist from randomized prospective studies, the standard accepted treatment for the early stage is broad-spectrum antibiotics with or without corticosteroids. This protocol has resulted in a clinical or histologic remission (in 33 to 71% of cases) that is generally short-lived but occasionally is durable ([154]). In the absence of a documented parasite or an intestinal bacterial overgrowth, therapy with tetracycline or metronidazole and ampicillin is appropriate ([158] , [159]). Any documented parasite should be eradicated. Treatment of *H. pylori* has led to complete remission in two patients with a-HCD ([160]), one of whom was unresponsive to prior combination chemotherapy. Response to antibiotics usually occurs promptly; however, a minimum 6-month trial of tetracycline (1 to 2 g/day) is recommended for establishing the responsiveness of the disease ([161]). In patients with more advanced disease or with unresponsive disease in its early stages, total abdominal radiation, combination chemotherapy, or both have been used (remission rate, 64%) ([162] , [163] , [164] , [165] , [166] and [167]). The overall 5-year survival rate is 60 to 70%. Immunotherapy with rituximab, an anti-CD20 monoclonal antibody, has been a major advance in the treatment of indolent NHL ([168]), but to date, there have been no reports of the use of rituximab in patients with a-HCD.

µ-Heavy Chain Disease

First described in 1970, µ-HCD is a rare condition ([147] , [148]). The median age of patients with µ-HCD is approximately 57 years, and equal numbers of males and females are affected ([149] , [169]). Common clinical presentations include splenomegaly and hepatomegaly. Lymphadenopathy is less common. Approximately one-third of patients have chronic lymphocytic leukemia. Some patients with µ-HCD have features resembling those of lymphoma or multiple myeloma with amyloid arthropathy ([170]). Hypogammaglobulinemia is present in approximately one-half of the patients, and a free monoclonal IgM fragment is found in the serum of all patients. The µ-heavy chain is missing most, if not all, of its V_H region ([171]). A free monoclonal light chain has been described in the urine in approximately one-half of the cases ([149] , [172]). Lytic bone lesions or osteoporosis occurs in a minority of patients. Bone marrow plasma cells tend to be vacuolated. Survival ranges from less than 1 month to 11 years (median, 24 months) ([149]). There is no standard treatment for this disorder, but it is generally treated as a low-grade lymphoproliferative disease with observation alone for asymptomatic patients and low-intensity chemotherapy for symptomatic patients.

?-Heavy Chain Disease

First described in 1964 by Franklin et al. ([146]), ?-HCD has a diverse clinical phenotype. The median age of patients with ?-HCD is 61 years, with 54% of the patients being male ([169] , [173]). Originally, ?-HCD was considered to be merely a lymphomalike illness; Kyle et al. ([173]) challenged this concept. Although most patients present with weakness, fatigue, fever, lymphadenopathy (62%), hepatomegaly (58%), splenomegaly (59%), and lymphoma, other features, such as autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura, may also be seen ([173]). Cutaneous and subcutaneous involvement is not uncommon ([174]). Several cases have arisen in patients with long-standing connective tissue disorders such as rheumatoid arthritis ([175] , [176] and [177]), lupus ([178]), keratoconjunctivitis sicca ([179] , [180]), vasculitis ([180]), and myasthenia gravis ([178]). A normochromic anemia is a presenting feature in approximately 79% of patients. Approximately 10% have either an autoimmune Coombs-positive or a Coombs-negative hemolytic anemia ([173] , [180]). Lymphopenia and lymphocytosis each occur in less than 10% of patients. Thrombocytopenia may be present in as many as 22% of patients ([173]).

The ?-chain in this disorder is truncated with deletions at the C_H1 domain ([169] , [181]). The mobility pattern of the Ig fragment on protein electrophoresis is quite variable, with the band found anywhere between the a1-globulin region and the slow ?-globulin region; most commonly, however, it runs in the ß region ([173]). The subclass distribution is IgG1 in 76%, IgG2 in 19%, and IgG4 in 5% of cases. In a normal distribution of subclasses, one would expect to find 66% IgG1, 23% IgG2, 7% IgG3 and 4% IgG4 molecules; the absence of IgG3 ? heavy chains is noteworthy. Proteinuria can range from none to 20 g/day.

Bone marrow demonstrates an increase of plasma cells, lymphocytes, or plasmacytoid lymphocytes; occasionally, eosinophilia is seen. The lymph node is not uniform morphologically: Well-differentiated plasma cells and lymphocytes are most commonly described ([182]). Lytic bone disease occurs rarely. Amyloid deposits may be present ([173]).

The median survival is 12 months, with a range of 1 month to more than 264 months ([173]). Treatment is not standardized. Single-agent therapy with prednisone and combination chemotherapy with cyclophosphamide, vincristine, and prednisone have been used with benefit. Patients with aggressive lymphomas should receive a regimen containing anthracyclines.

	VPRC: micro (5)		
	RBC: electronic	88	80–96
	VPRC: micro (5)		
	Coulter model STKS (10)	91	78.5–98.0
Mean corpuscular hemoglobin (pg/cell)	RBC: hemacytometer (4)	29	26–32
	Coulter model STKS (10)	31	27–34
Mean corpuscular hemoglobin concentration (g/dl RBC)	VPRC: macro	34	32–36
	VPRC: micro (5)	33	31–35
	Coulter model STKS (10)	34	33.5–36.0

RBC, red blood cell; VPRC, volume of packed red cells.

TABLE A.6. Effect of Altitude on Volume of Packed Red Cells (VPRC) in Normal Men

Altitude			
Feet	Meters	N	VPRC (L/L) [a]
0	0	721	0.47
4400	1340	744	0.495
7457	2280	100	0.51
12,240	3740	40	0.54
14,900	4540	32	0.61
17,800	5430	10	0.69

[a] Mean values in males.
From reference 9.

TABLE A.7. Effect of Pregnancy, with and without Iron Supplementation, on Values for Volume of Packed Red Cells and Hemoglobin

	Volume of Packed Red Cells (Mean, L/L)			Hemoglobin (Mean, g/dl)		
Wk of Gestation	No Supplement	Intramuscular Supplement [a]	Oral Supplement [b]	No Supplement	Intramuscular Supplement [a]	Oral Supplement [b]
0	0.420	—	—	13.4	—	—
12	0.383	0.406	0.357	12.5	13.1	11.4
16	0.395	0.379	0.363	12.4	12.1	11.4
20	0.364	0.370	0.371	11.7	11.8	11.8
24	0.356	0.363	0.371	11.4	11.8	11.8
28	0.346	0.369	0.368	11.0	11.8	11.8
32	0.341	0.372	0.370	10.6	12.1	11.8
36	0.343	0.375	0.375	10.7	12.1	12.0
40	0.349	0.385	0.387	10.9	12.7	12.4
Days Postpartum						
2	0.336	0.371	0.373	10.4	12.2	11.9
6	0.349	0.389	0.401	10.7	12.4	12.8
21	0.381	0.420	0.411	11.6	13.6	13.0
42	0.391	0.415	0.398	11.9	13.1	12.6
180	0.392	0.401	0.408	12.1	12.4	12.9

NOTE: Approximately 20 individuals were in each group.

[a] 1000 mg Fe as iron dextran administered IM.

[b] 39 mg elemental iron twice daily.

From reference 11.

TABLE A.8. Estimation of Red Cell, Plasma, and Total Blood Volume in Adult Men and Women

	Men	Women

Volume	a	b	SD (ml)	a	b	SD (ml)
Red blood cell volume [a]	490	21.4	200	409	18.3	139
Plasma volume [b]	1050	19.6	260	455	28.9	213
Total blood volume [b]	1530	41.0	400	864	47.2	319

SD, standard deviation.

NOTE: Instructions for use of table: For a subject of given weight [*w* (kg)], a normal mean red blood cell, plasma, or total blood volume [*V* (ml)] can be calculated from the following formula: $V = a \pm bw$ (using a and b values from the table). For example, in a 70-kg man, the mean red blood cell volume is 490 ± (21.4 × 70) ± 1988 ml ± 2 SD, and the range is 1988 ± 400, or 1588 to 2388 ml. The expected normal range can be calculated from the following formula: range = mean ± 2 SD.

[a] Measured by ^{51}Cr method.

[b] Calculated from the red cell volume and volume of packed red cells without correction for trapped plasma or “body hematocrit” differences.

From references 12 and 13.

TABLE A.9. Basic Ferrokinetic Measurements

Measurement	N	Mean	95% Range
Half-life ^{59}Fe (min)	66	87.5	38–137
Plasma iron transport			
mg/day	35	32.2	13–50
mg/kg/day	10	0.56	0.46–0.75

TABLE A.10. Reference Ranges [a] for Porphyrins and Porphyrin Precursors in Feces, Urine, and Erythrocytes

Porphyrin or Precursor	Feces	Urine	Erythrocytes
Aminolevulinic acid	—	1.5–7.5 mg/24 h 11.2–57.2 µmol/24 h	—
Porphobilinogen	—	<1.0 mg/24 h <4.4 µmol/24 h	—
Uroporphyrin	0–0.06 mg/24 h	10–30 µg/24 h	0
Coproporphyrin	0–500 µg/24 h	50–160 µg/24 h	0–500 µg/24 h
Protoporphyrin	0–600 µg/24 h	—	0–60 µg/24 h
Total porphyrin	4 mg/24 h	<0.2 mg/24 h	—

[a] 95% confidence limit.

From reference 2.

TABLE A.11. Measures of Hemoglobin Destruction

Measurement	95% Limits
Icterus index (units) (4)	5.0–7.5
Bilirubin, total (mg/dl)	0.1–1.0
Bilirubin, direct (mg/dl)	0.01–0.12
Urobilinogen, urine (Ehrlich units/day)	0.5–4.0
Urobilinogen, fecal	
Ehrlich units/day	80–280
mg/day	40–200
Bilirubin production (mg/kg/day) (18)	2.6–5.0
Serum hemoglobin (mg/dl)	0.5–5.0
Serum haptoglobin (mg/dl)	60–270
Urine iron (mg/day)	<0.1

Unless otherwise indicated, values derived from reference 2.

TABLE A.12. Normal Values for Osmotic Fragility

	% Hemolysis	
Sodium Chloride (Concentration in g/dl)	Before Incubation	After Incubation
0.85	0	0
0.75	0	0–5
0.65	0	0–10
0.60	0	0–40
0.55	0	15–70
0.50	0–5	40–85
0.45	5–45	55–95

0.40	50–90	65–100
0.35	90–99	75–100
0.30	97–100	85–100
0.20	97–100	95–100
0.10	100	100

TABLE A.13. Automated Leukocyte Differential Counts and Reference Values in Normal Male Adults

	Coulter S + STKR (80 Men)		Technicon H1 (64 Men)	
Percentage	**Mean**	**Central 95% Range**	**Mean**	**Central 95% Range**
Lymphocytes	36.1	22.3–49.9	31.3	18.3–44.2
Monocytes	4.1	0.7–7.5	5.5	2.6–8.5
Granulocytes	59.7	45.5–74.0	—	—
Neutrophils	—	—	58.8	45.5–73.1
Eosinophils	—	—	1.9	0.0–4.4
Basophils	—	—	0.7	0.2–1.2
LUCs	—	—	1.8	0.0–4.9
Absolute numbers				
Lymphocytes (×10 ^{9}/L)	2.4	1.2–3.5	2.06	0.9–3.22
Monocytes (×10 ^{9}/L)	0.3	0.0–0.5	0.37	0.12–0.62
Granulocytes (×10 ^{9}/L)	4.9	1.4–6.6	—	—
Neutrophils (×10 ^{9}/L)	—	—	4.01	1.31–6.71
Eosinophils (×10 ^{9}/L)	—	—	0.13	0.00–0.30
Basophils (×10 ^{9}/L)	—	—	0.05	0.01–0.09
LUCs (×10 ^{9}/L)	—	—	0.12	0.00–0.31

LUC, large unstained cell.

NOTE: Data based on measurements from healthy male students, 23 to 31 years of age, at an altitude of 4500 ft.

TABLE A.14. Scoring Criteria for Leukocyte Alkaline Phosphatase

		Precipitated Azo Dye in Cytoplasm		
Cell Rating	**Amount** [a]	**Granule Size**	**Staining Intensity**	**Background of Cytoplasm**
0	0	None	—	No staining
±1	50	Small	Faint to moderate	Colorless to very pale pink
±2	40–80	Small to medium	Moderate to strong	Colorless to pale pink
±3	80–100	Medium to large	Strong	Colorless to pink
±4	100	Medium and large	Brilliant	Nonvisible

[a] Percentage of volume of cytoplasm occupied by dye precipitate.

From reference 20, with permission of Williams & Wilkins.

TABLE A.15. Leukocyte Alkaline Phosphatase Scores in Normal Subjects

Group	Number	Mean	95% Limits
Male	51	73	22–124
Female	50	91	33–149
Total	101	82	25–139

12 to 18 yr												
Female	14.0	12.0	41	36	4.6	4.1	90	78	30	25	34	31
Male	14.5	13.0	43	37	4.9	4.5	88	78	30	25	34	31
18 to 49 yr												
Female	14.0	12.0	41	36	4.6	4.0	90	80	30	26	34	31
Male	15.5	13.5	47	41	5.2	4.5	90	80	30	26	34	31

SD, standard deviation.

These data were compiled from several sources. Emphasis is on recent studies using electronic counters and on the selection of populations that are likely to exclude individuals with iron deficiency. The mean ±2 SD can be expected to include 95% of the observations in a normal population.

From Dallman PR. In: Rudolph A, ed. Pediatrics, 16th ed. New York: Appleton-Century-Crofts, 1977; and Lubin BH. Reference values in infancy and childhood. In: Nathan DG, Oski FA, eds. Hematology of infancy and childhood, 4th ed. Philadelphia: WB Saunders, 1993 (22).

TABLE A.18. Full-Term Infants: Normal Values of Hemoglobin, Hematocrit, Erythrocyte Count, Mean Corpuscular Hemoglobin, Mean Corpuscular Volume, and Mean Corpuscular Hemoglobin Concentration

	Age (mo)						
	0.5 (N = 232)	**1 (N = 240)**	**2 (N = 241)**	**4 (N = 52)**	**6 (N = 52)**	**9 (N = 56)**	**12 (N = 56)**

Mean corpuscular hemoglobin concentration (mean ± SE) (g/L)	314 ± 1.1	318 ± 1.2	318 ± 1.1	327 ± 2.7	350 ± 1.7	349 ± 1.6	343 ± 1.5
±2 SD	281	281	283	288	327	324	321

SD, standard deviation; SE, standard error.

NOTE: These values were obtained from a selected group of 256 healthy term infants followed at the Helsinki University Central Hospital who were receiving continuous iron supplementation and who had normal values for transferrin saturation and serum ferritin. Values at the ages of 0.5, 1, and 2 months were obtained from the entire group, and those at the later ages were obtained from the iron-supplemented infant group after exclusion of iron deficiency.

From references 22 and 23.

NOTE: Percentages of cell types [means ± standard deviation (SD)] in tibial bone marrow of infants from birth to 18 months of age. Data were obtained from normal American infants of black, white, and Asian racial origin. The changes in the marrow during the first 18 months of postnatal life are based on differential counts of 1000 cells classified on stained smears on each of ten serial marrow samples aspirated from the same population of infants. Criteria for including bone marrow data in this study consisted of absence of any clinical evidence of disease, normal rate of growth, and normal serum proteins and transferrin saturations. N values are expressed in round figures for facilitating comparison. Means ± SD were calculated from values obtained in individual infants, and statistical comparisons were performed.

N, number of infants studied at each stage.

TABLE A.22. Iron and Copper in Plasma

Measurement	Mean	Lower Limit of Normal [a]	Upper Limit of Normal [a]
Plasma iron			
µg/dl	122 (men)	71 (43–112)	201 (112–276)
	109 (women)	60 (28–101)	173 (130–202)
µmol/L	21.8 (men)	12.7 (7.7–20.0)	35.9 (20.0–49.3)
	19.5 (women)	107 (5.0–18.0)	30.9 (23.2–36.1)
Plasma total iron-binding capacity			
µg/dl	340	250 (224–306)	400 (429–472)
µmol/L	60.7	44.8 (40.0–54.6)	71.6 (66.6–84.3)
Transferrin saturation (%)	35	20	55
Plasma copper			
µg/dl	114	70	155
µmol/L	18.1	11	24

[a] Range of values from several laboratories given in parentheses.

From references 2 and 25, 26 and 27.

TABLE A.23. Serum Folate, Vitamin B $_{12}$, and Related Determinations

Measurement	Mean	Lower Limit of Normal [a]	Upper Limit of Normal [a]
Serum vitamin B $_{12}$ (ng/L)	450	160 (100–270)	950 (750–1200)
Serum folate (µg/L)	8.1	±5 (2.3–7.5)	25 (9–28)
Erythrocyte folate (µg/L)	274	166 (50–325)	640 (300–875)
Urinary methylmalonate (mg/day)	—	—	9
Urinary formiminoglutamate (mg/day)	—	0.1	3

[a] Range of values from several laboratories given in parentheses.

From references 2 and 28.

TABLE A.24. Vitamin B $_{12}$ Absorption by Urinary Excretion Method (Schilling Test)

Oral Vitamin B $_{12}$ Dose (µg)	Urinary Vitamin B $_{12}$ Excretion (%)	
	24 h [a]	48 h [b]
0.5	26 (16–40)	37 (21–48)
1.0	22 (11–39)	29 (14–46)
2.0	11 (5–17)	17 (11–34)

[a] With 24-hour collections, one injection of 1000 µg “cold” B $_{12}$ was administered.

[b] With 48-hour collections, two injections of 1000 µg “cold” B $_{12}$ were administered at 24-hour intervals.

From references 26 and 28.

TABLE A.25. Human Erythrocyte Enzymes in Normal Adults

Enzyme (Synonym)	Enzyme Activity (IU/g Hemoglobin)
Acetylcholinesterase	36.9 ± 3.83
Adenosine deaminase	1.11 ± 0.23
Adenylate kinase	258 ± 29.3
Bisphosphoglyceromutase (2,3-diphosphoglyceromutase)	4.78 ± 0.65
Catalase	15.3 ± 2.39 × 10 ^{4}
Fructose-bisphosphate aldolase (aldolase)	3.19 ± 0.86
Galactokinase	0.079 ± 0.006
	0.029 ± 0.006
Galactose-1-phosphate uridylyl-transferase	28.4 ± 6.94
Glucose-6-phosphate dehydrogenase	8.34 ± 1.59
Glucose phosphate isomerase (phosphoglucose isomerase)	60.8 ± 11.0
?-Glutamyl-cysteine synthetase	0.43 ± 0.04
Glutathione peroxidase	31.4 ± 2.97

Glutathione reductase [nicotinamide adenine dinucleotide (phosphate)]	7.18 ± 1.09
Glutathione synthetase	0.19 ± 0.03
Hexokinase	1.16 ± 0.17
Hypoxanthine phosphoribosyltransferase (hypo-xanthine guanosine-phosphoribosyltransferase)	1.72 ± 0.3
Methemoglobin reductase	2.60 ± 0.71
6-Phosphofructokinase	11.0 ± 2.33
Phosphogluconate dehydrogenase (decarboxylating)	8.78 ± 0.78
Phosphoglycerate kinase	320 ± 36.1
Pyrimidine 5'-nucleotidase	0.11 ± 0.03
Pyruvate kinase	15.0 ± 1.96
Triosephosphate isomerase	2111 ± 397
Uroporphyrinogen I synthase	2.52

From references 22 and 26.

TABLE A.26. Concentrations of Immunoglobulins in Serum of Normal Subjects at Different Ages

		Level of ?G [a]		Level of ?M [a]		Level of ?A [a]		Level of Total ?-Globulin [a]	
Age	Number of Subjects	mg/dl (range)	% of Adult Level	mg/dl (range)	% of Adult Level	mg/dl (range)	% of Adult Level	mg/dl (range)	% of Adult Level
Newborn	22	1031 ± 200 (645–1244)	89 ± 17	11 ± 5 (5–30)	11 ± 5	2 ± 3 (0–11)	1 ± 2	1044 ± 201 (660–1439)	67 ± 13
1–3 mo	29	430 ± 119 (272–762)	37 ± 10	30 ± 11 (16–67)	30 ± 11	21 ± 13 (6–56)	11 ± 7	481 ± 127 (324–699)	31 ± 9
4–6 mo	33	427 ± 186 (206–1125)	37 ± 16	43 ± 17 (10–83)	43 ± 17	28 ± 18 (8–93)	14 ± 9	498 ± 204 (228–1232)	32 ± 13

25–36 mo	33	892 ± 183 (419–1274)	77 ± 16	61 ± 19 (28–113)	62 ± 19	71 ± 37 (19–235)	36 ± 19	1024 ± 205 (419–1418)	65 ± 14
3–5 yr	28	929 ± 228 (569–1597)	80 ± 20	56 ± 18 (22–100)	57 ± 18	93 ± 27 (55–152)	47 ± 14	1078 ± 245 (730–1771)	69 ± 17
6–8 yr	18	923 ± 256 (559–1492)	80 ± 22	65 ± 25 (27–118)	66 ± 25	124 ± 45 (54–221)	62 ± 23	1112 ± 293 (640–1725)	71 ± 20
9–11 yr	9	1124 ± 235 (779–1456)	97 ± 20	79 ± 33 (35–132)	80 ± 33	131 ± 60 (12–208)	66 ± 30	1334 ± 254 (966–1639)	85 ± 17
12–16 yr	9	946 ± 124 (726–1085)	82 ± 11	59 ± 20 (35–72)	60 ± 20	148 ± 63 (70–229)	74 ± 32	1153 ± 169 (833–1284)	74 ± 12
Adults	30	1158 ± 305 (569–1919)	100 ± 26	99 ± 27 (47–147)	100 ± 27	200 ± 61 (61–330)	100 ± 31	1457 ± 353 (730–2365)	100 ± 24

[a] Mean is ±1 standard deviation.

From reference 29, with permission.

TABLE A.27. Reference Values for Tests of Hemostasis and Blood Coagulation

Test	Normal Range (±2 Standard Deviations)
Partial thromboplastin time	
Standard	68–82 sec [a]
Activated	32–46 sec [a]
Plasma prothrombin time	11–15 sec [a]
Plasma thrombin time	10–16 sec [a]
Fibrinogen assay	150–350 mg/dl
Euglobulin clot lysis time	>2 h
Fibrin degradation products	>8 µg/dl
Plasminogen activity	74–124%
Antithrombin III activity	85–122%
Antithrombin III antigen	27–35 mg/dl
Protein C	60–150%
Protein S	66–122%
Ristocetin cofactor activity	0.5–1.6 U/ml
von Willebrand factor antigen	43–150%
Specific assays for individual coagulation factors	50–150% of normal

NOTE: References to methods used are included in Chapter 51.

[a] Significant variations depend on reagent used.

APPENDIX B: Comparative Hematology

According to Hawkey ([1]), there are over 4200 living species of mammals. Adequate hematologic characterization of these mammals has generally been done only for humans and, to a lesser extent, the common laboratory animals and domestic species. Despite voluminous databases for these three categories, the age (young or adult), prandial state, blood collection procedures, and, for nonhuman species, the housing and environmental conditions and the strain of the species are rarely stated in literature reports.

Table B.1 and Table B.2 list some hematologic variables reported by different investigators in a variety of vertebrate species. The tabulated data are representative but certainly are not exhaustive; an attempt was made to primarily include reports describing studies involving a large number of animals, but this limitation was not always possible. Many references for the various species are not cited in the text or tables but are presented unnumbered under each species to offer valuable information on additional data, techniques, or procedures. Also included in the References section are several extensive monographs on comparative hematology, including those of Archer and Jeffcott ([2]), Feldman et al. ([3]), Harvey ([4]), Hawkey and Dennett ([5]), Jain ([6]), Meyer et al. ([7]), Mitruka and Rawnsley ([8]), Reagan et al. ([9]), Sanderson and Phillips ([10]), Wintrobe ([11]), and Wolford et al. ([12]). Some of these references contain good descriptions and illustrations of the blood cells of various species. Because mean corpuscular volume is more commonly determined in clinical and toxicologic studies than red cell diameter, the latter is not reported in these tables. However, some of the older literature and many of the monographs referenced contain this information for various species.

TABLE B.1. Hematologic Values in Selected Species of Mammals

Species	Author	RBC (×106/µl)	HGB (g/dl)	VPRC (ml/dl)	MCV (fl)	MCH (pg)	MCHC (g/dl)	Retics (%)	WBC (×103/µl)	Neutro (×103/µl)	Lymph (×103/ul)	Mono (×103/µl)	Eos (×103/µl)	Baso (×103/µl)	Platelets (×103/µl)	No. Animals

[a] Leukocyte values in percent.

For those interested in the use of laboratory animals in regulated toxicity and safety studies, a joint international committee from ten scientific organizations was formed to provide recommendations for harmonization of clinical pathology testing ([13]).

Much of the tabular data is from animals kept under laboratory conditions (e.g., nonhuman primates, dogs, miniature swine, rats, mice, and hamsters) and generally should not be considered representative of values that one may encounter from all “normal” animals of that species. Controlled environmental conditions in laboratories vary and may have a profound influence on the hemogram. Even animals from the same supplier, but from different shipments, may manifest very significant differences in hematologic values. Therefore, except in the clinical setting, use of hematologic data from intracurrent control animals is imperative for comparison with data from treated experimental groups, rather than relying totally on historical data. Clinically, however, a database of expected normal values for the sex and age of each species should be established by individual laboratories or clinics.

With the exception of the elliptical, nucleated red cells of birds, fish, reptiles, and amphibians, circulating erythrocytes of most vertebrates are discoidal, nonnucleated, and quite similar cytologically to those of humans. However, tremendous variation is noted in the diameter and volume ranges of the red cells when interspecies comparisons are made, and the erythrocyte count tends to vary inversely with the mean corpuscular volume. Some unique species differences may also be present such as the refractile bodies noted as inclusions in cat erythrocytes. Polychromasia of the red cells is a common finding in rats and, particularly, in mice and may become evident with even minimal bone marrow stress. Values for red cell mass and red cell lifespan, although not included in the tables, may be found in many of the references. Several in-depth studies concerning hemoglobins of various animals have been performed, and references are present in the Suggested Readings for the appropriate species.

The cytologic and staining characteristics of the various leukocytes often are unique for a given species, and, in some cases, they differ considerably from those in humans, but their functions are similar to those of comparable human cells. For instance, in rabbits, guinea pigs, and birds, neutrophils have rather large eosinophilic granules that Ehrlich named *pseudo-eosinophils* or *heterophils*, and the blood of guinea pigs contains a large number of mononuclear cells with peculiar inclusions called *Kurloff corpuscles*. Neutrophils are commonly doughnut- and U-shaped in the blood of mice and some other rodents, and those in rabbits are hypersegmented. Elephant blood contains an unusual type of white cell that has a bilobed nucleus and cytoplasmic staining characteristics intermediate between those of lymphocytes and monocytes. Enzyme cytochemical analysis also reveals differences in reactivity among the mammalian species. In some species, such as rats, mice, rabbits, hamsters, pigs, and cattle, the neutrophil to lymphocyte ratio is reversed from that of humans. Leukocyte differential values in the tables are reported as absolute values when the original reports contained these data or if the conversion could validly be made; otherwise, they are cited as relative values or, in some cases, as ranges as in the original papers.

Platelet cytology in the common laboratory and domestic species is similar to that in humans, but the blood of some species may commonly manifest “giant” platelets. Further, mean platelet counts in rats and mice are normally approximately two to four times those in humans. In birds and amphibians, thrombocytes (i.e., nucleated cells) are present that have an appearance similar to normoblasts. The response of platelets and thrombocytes to various aggregating agents varies considerably with the species, and results should be extrapolated to humans with caution when using animal models in coagulation studies. Several of the references contain values for coagulation parameters in various species. In addition, there are some comparative coagulation studies on multiple species, including the proceedings of a Workshop on Animal Models of Thrombosis and Hemorrhagic Diseases, which contain many pertinent references for nonhuman species ([14]), a monograph by Lewis ([15]) on comparative hemostasis, and studies by Didisheim et al. ([16]) and Rowsell and Mustard ([17]).

For valid results, obtaining good-quality blood samples and then handling them appropriately before and during processing are imperative. Blood collection from animals may often be left to inexperienced or inadequately trained personnel who proceed under the misconception that getting “something red” in the collection tube is adequate. Blood collection techniques often are unique for a given species and vary considerably depending on the species. The Suggested Readings section contains numerous citations regarding blood collection procedures for various species. Finally, rigid quality control procedures must be instituted and followed at each laboratory or clinic. A study that is otherwise well conducted may easily be invalidated if sampling techniques and quality control procedures are ignored. The last section of the Suggested Readings contains several general publications on quality control methods in the clinical pathology laboratory.

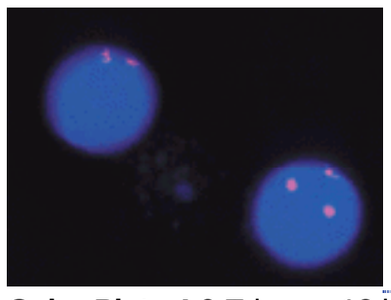
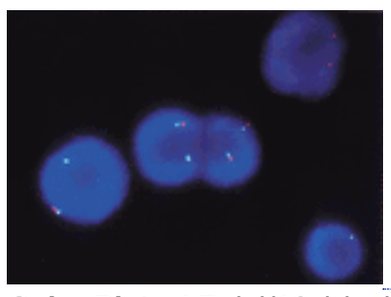
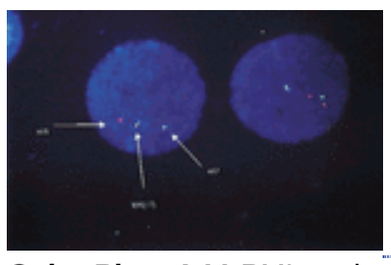
Color Plate



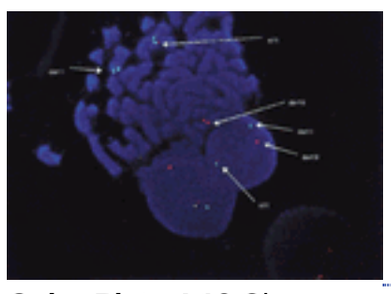
Color Plate 4.6 Trisomy 12 in an interphase cell (*right*) demonstrated by fluorescence *in situ* hybridization with a chromosome 12 centromeric probe. An interphase cell with two chromosome 12 signals is also seen (*left*). (This figure is printed in black and white as Figure 4.6.)



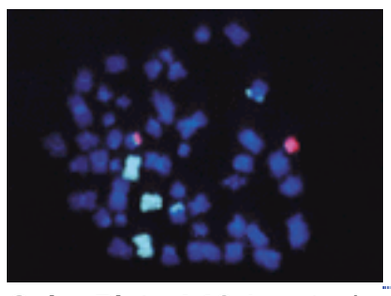
Color Plate 4.7 del(13q) is demonstrated by fluorescence *in situ* hybridization with locus-specific probes to two regions of chromosome 13q in two cells (*left* and *center*). A normal cell is also seen (*right*). (This figure is printed in black and white as Figure 4.7.)



Color Plate 4.11 PML–retinoic acid receptor (RAR)-a fusion demonstrated in an interphase cell (*left*) by fluorescence *in situ* hybridization with locus-specific probes for the PML and RAR-a genes. A normal cell is also seen (*right*). (This figure is printed in black and white as Figure 4.11.)

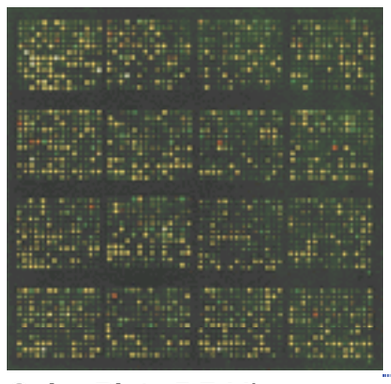


Color Plate 4.12 Chromosomal translocation involving the MLL gene on chromosome 11 (11q23) demonstrated by fluorescence *in situ* hybridization with a locus-specific probe for MLL. The normal MLL gene is seen as overlapping or adjacent red and green signals. When MLL is involved in a translocation, the red and green signals separate. (This figure is printed in black and white as Figure 4.12.)

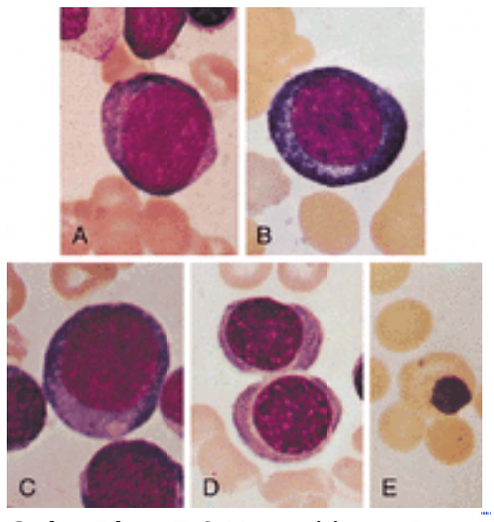


Color Plate 4.13 A metaphase spread showing the use of whole chromosome paints to confirm the origin of marker chromosomes. Chromosome 11 (*green*) is present as three intact chromosomes and as two translocation regions. Chromosome 20 (*red*) is seen as one intact chromosome and as a translocation region. (This figure is printed in black and white as Figure 4.13.)

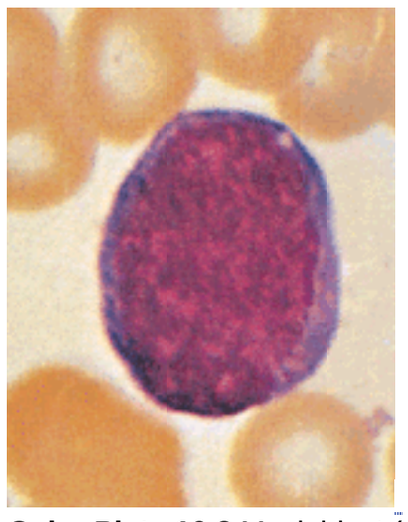
Color Plate 4.14 Spectral karyotype of a normal male cell **(A)** and of a cell with marker chromosomes **(B)**. (This figure is printed in black and white as Figure 4.14.)



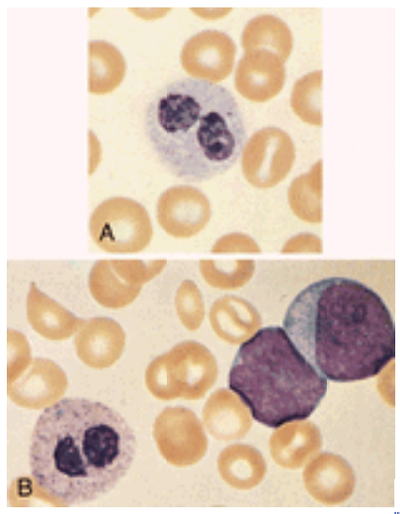
Color Plate 5.7 Microarray analysis. Shown is a portion of a complementary DNA (cDNA) microarray that has been competitively hybridized with cDNA made from human leukemic cell RNA and labeled with the fluorochrome Cy3 and cDNA prepared from a pool of human RNAs (reference RNA) and labeled with a different fluorochrome, Cy5. Each spot corresponds to one of a total of 11,000 cDNAs affixed on this array. Its color (red, green, or yellow) on laser-scanning analysis provides information about the abundance of specific RNAs in the leukemic blasts. (This figure is printed in black and white as Figure 5.7.)



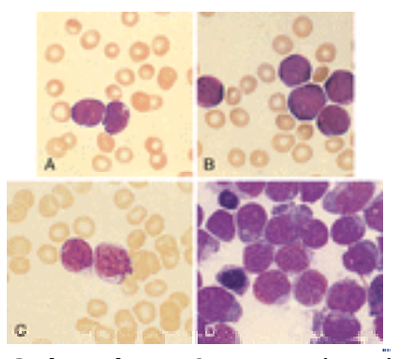
Color Plate 7.6 Normoblasts. Pronormoblast **(A)**; basophilic normoblast **(B)**; early **(C)** and late **(D)** polychromatophilic normoblasts; orthochromatic normoblast with stippling **(E)**. Magnification, ×1000; Wright stain. (This figure is printed in black and white as Figure 7.6.)



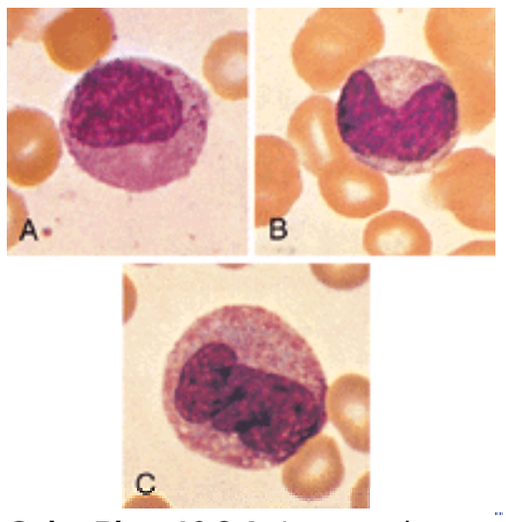
Color Plate 10.2 Myeloblast (×1000, Wright stain). (This figure is printed in black and white as Figure 10.2.)



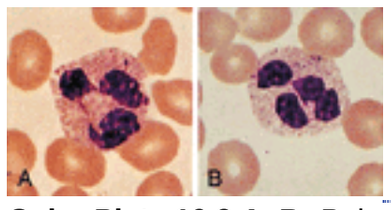
Color Plate 10.4 A, B: Pseudo–Pelger-Huët cells, the latter from the blood of a patient with acute myeloblastic leukemia (×1000, Wright stain). (This figure is printed in black and white as Figure 10.4.)



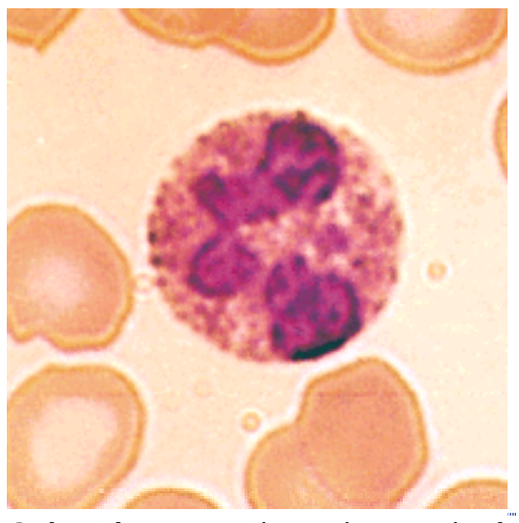
Color Plate 10.5 A: L1 lymphoblastic leukemia, blood. **B:** L2 lymphoblastic leukemia, blood. **C:** Acute leukemia, M1 blood (×1500). **D:** Acute leukemia, M1 marrow (×1500). (This figure is printed in black and white as Figure 10.5.)



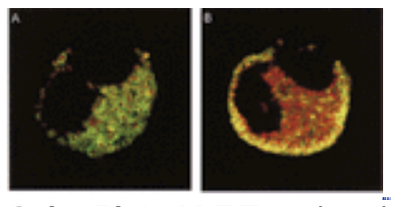
Color Plate 10.8 A: Late myelocyte or early metamyelocyte. **B:** Metamyelocyte. **C:** Monocyte (×1000, Wright stain). (This figure is printed in black and white as Figure 10.8.)



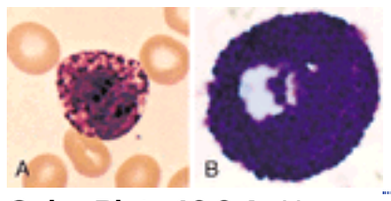
Color Plate 10.9 A, B: Polymorphonuclear neutrophils. (This figure is printed in black and white as Figure 10.9.)



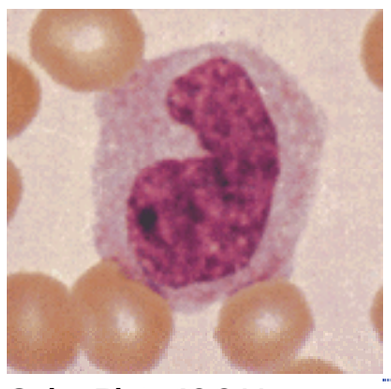
Color Plate 11.1 Photomicrograph of a peripheral blood eosinophil stained with May-Grünwald-Giemsa. (This figure is printed in black and white as Figure 11.1.)



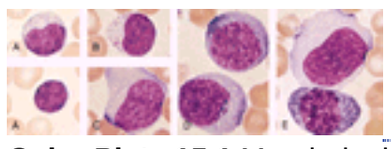
Color Plate 11.7 Translocation of the chemokine RANTES (regulated on activation, normal T-cell expressed and secreted) in human eosinophils activated by interferon-? *in vitro*. Immunoreactivities for RANTES (*green fluorescence*) and eosinophil major basic protein (MBP) (*red fluorescence*) are shown in control **(A)** and IFN-?–stimulated (10 minutes, 500 U/ml) **(B)** cells. The yellow color **(B)** resulted from co-localization of green and red immunofluorescence stains. Note that immunoreactivity for MBP remained associated with the cores of the crystalloid granules in both cells, whereas the green label for RANTES translocated toward the cell membrane. RANTES was proposed to be released from eosinophils by piecemeal degranulation. (Experimental conditions described in Lacy P, Mahmudi-Azer S, Bablitz B, et al. Rapid mobilization of intracellularly stored RANTES in response to interferon-gamma in human eosinophils. Blood 1999;94:23–32.) (This figure is printed in black and white as Figure 11.7.)



Color Plate 12.2 A: Human peripheral blood basophil stained with Wright. (From Lee G, Bithell T, Foerster J, et al., eds. Wintrobe's clinical hematology, 9th ed. Philadelphia: Lea & Febiger, 1993, with permission.) **B:** Rat peritoneal mast cell stained with May-Grunwald Giemsa. (This figure is printed in black and white as Figure 12.2.)

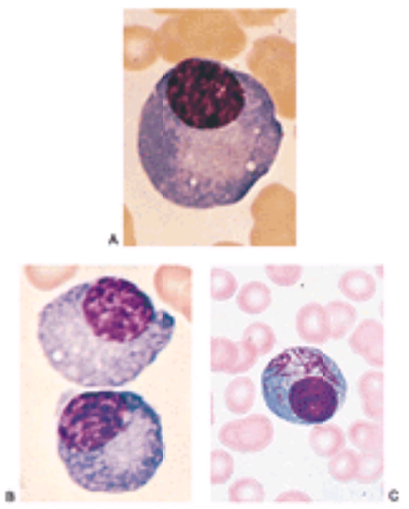


Color Plate 13.3 Monocyte ×1000 (approximately). Wright stain. (This figure is printed in black and white as Figure 13.3.)

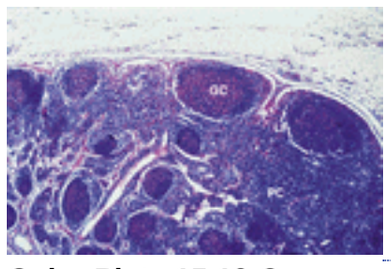


Color Plate 15.1 Morphologic heterogeneity of human peripheral blood lymphocytes. **A:** Giemsa-stained blood smears: small and large lymphocytes. **B:** Large

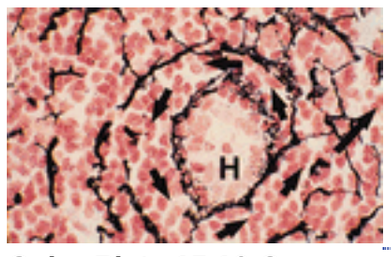
granular lymphocyte with azurophilic granules. **C:** Atypical lymphocyte. **D:** Lymphocytes resembling plasma cells (plasmacytoid) from the blood of a patient with viral pneumonia. **E:** One atypical lymphocyte and one plasmacytoid lymphocyte from peripheral blood. (This figure is printed in black and white as Figure 15.1.)



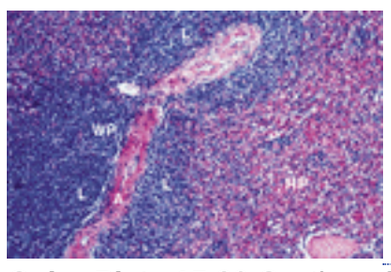
Color Plate 15.7 Plasma cells. **A:** Normal plasma cell. **B:** Plasmacytes with vacuoles from the bone marrow of a patient with infection and arthritis. **C:** Needle type of inclusions in plasma cell. (**C** used by permission of the American Society of Hematology Slide Bank, 3rd ed, 1990.) (This figure is printed in black and white as Figure 15.7.)



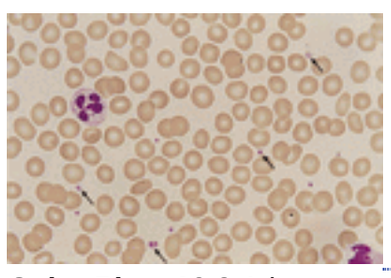
Color Plate 15.12 Cross-section of a normal lymph node. GC, germinal centers; LF, lymphocytic follicles; MC, medullary cords; PC, paracortical lymphoid areas. (This figure is printed in black and white as Figure 15.12.)



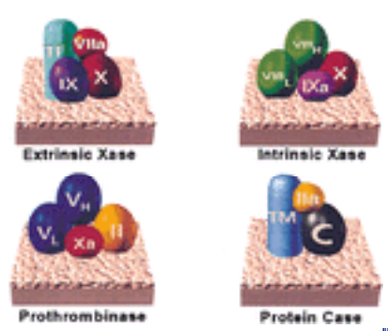
Color Plate 15.16 Cross section of a paracortical cord showing the corridor, outlined by reticular fibers stained by Gomori stain. The corridor encircles the high endothelial venule in the center *(H)*. (From Gretz JE, Anderson AO, Shaw S. Cords, channels, corridors, and conduits: critical architectural elements facilitating cell interactions in the lymph node cortex. Immunol Rev 1997; 156:11–24, with permission.) (This figure is printed in black and white as Figure 15.16.)



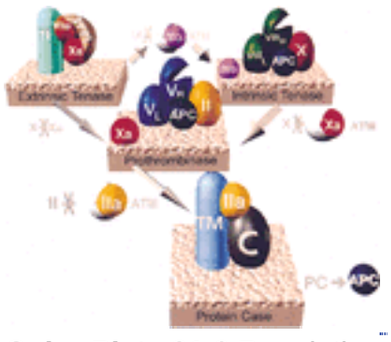
Color Plate 15.20 Section of the spleen. White pulp (*WP*): lymphocytes (*L*) packed around an arteriole (*A*). Red pulp (*RP*) surrounds the white pulp and consists mainly of sinuses, the cords, and cordal spaces. (This figure is printed in black and white as Figure 15.20.)



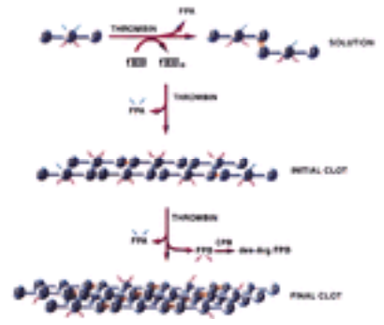
Color Plate 19.2 A human peripheral blood smear stained with Wright-Giemsa. Platelets, indicated by arrows, are interspersed between erythrocytes and a few leukocytes. The pale, grayish-blue cytoplasm contains purple-red granules. Original magnification of 35-mm slide = ×100. (This figure is printed in black and white as Figure 19.2.)



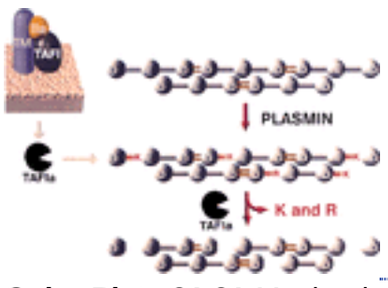
Color Plate 21.4 Vitamin K–dependent complexes. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. (From Mann KG. Coagulation explosion. Vermont Business Graphics, 1977, with permission.) (This figure is printed in black and white as Figure 21.4.)



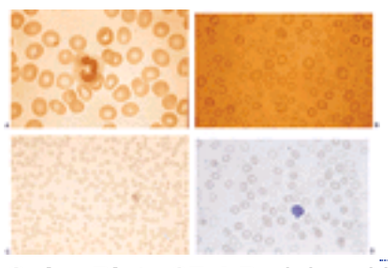
Color Plate 21.6 Regulation of the procoagulant response. Four vitamin K–dependent complexes are illustrated: the extrinsic tenase, the intrinsic tenase, prothrombinase, and protein Case. (From Mann KG. Coagulation explosion. Vermont Business Graphics, 1997, with permission.) (This figure is printed in black and white as Figure 21.6.)



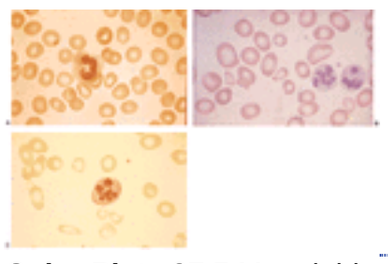
Color Plate 21.15 Schematic representation of whole blood fibrin formation. (From Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. J Biol Chem 1999;274:22862–22870, with permission.) (This figure is printed in black and white as Figure 21.15.)



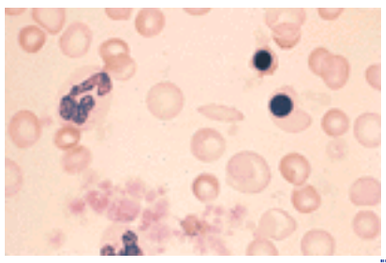
Color Plate 21.21 Mechanism of thrombin-activatable fibrinolysis inhibitor (TAFI) effects toward fibrinolysis. (From Mann KG. Coagulation explosion. Vermont Business Graphics, 1997, with permission.) (This figure is printed in black and white as Figure 21.21.)



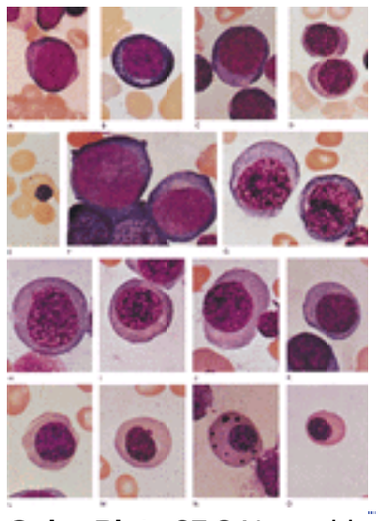
Color Plate 27.4 Peripheral blood smear of erythrocytes in a variety of hypochromic microcytic anemia. **A:** Normal red cells. **B:** Dimorphic population of cells in iron deficiency anemia responding to treatment. **C:** Thalassemia minor. The cells are thin and appear pale but nearly normal in diameter. Note the basophilic stippling in one red corpuscle. **D:** Sideroblastic anemia. A hypochromic, microcytic population of cells is mixed with a slightly macrocytic one. (This figure is printed in black and white as Figure 27.4.)



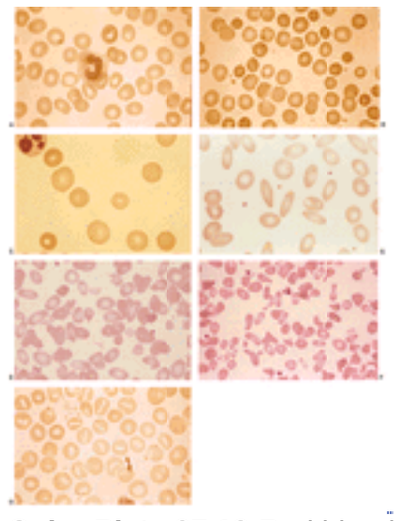
Color Plate 27.5 Megaloblastic anemia. **A:** Normal red cells. **B:** Macro-ovalocytes in pernicious anemia. **C:** Hypersegmented neutrophiles seen in patient with megaloblastic anemia. (This figure is printed in black and white as Figure 27.5.)



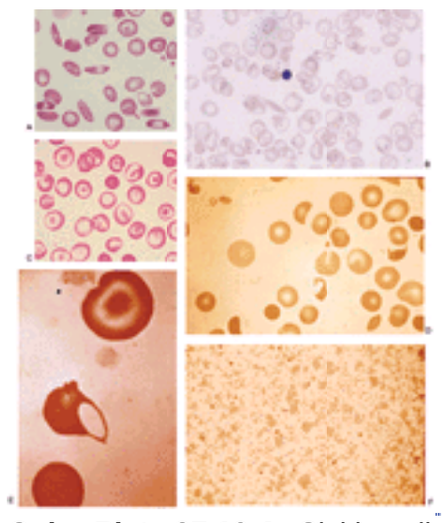
Color Plate 27.6 Peripheral blood smear. A leukoerythroblastic response seen in patient with myeloid metaplasia. (This figure is printed in black and white as Figure 27.6.)



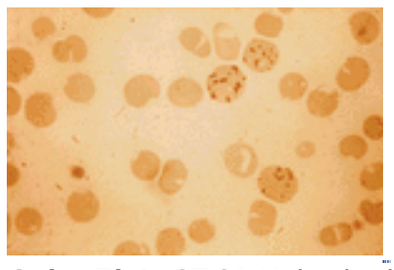
Color Plate 27.8 Normoblasts and megaloblasts contrasted (Wright stain ×1000). **A–E:** Normablasta. **A:** Pronormoblast. **B:** Basophilic normoblast. **C:** Early phlychromatophilic normablast. **D:** Late polychromatophilic normoblast. **E:** Orthochromatic normablast with stippling. **F–O:** Megaloblasts. **F:** Promegaloblast (*left*) and basophilic megaloblast (*right*). **G–K:** Polychromatophilic megaloblasts. **L–O:** Orthochromatic megaloblasts. (This figure is printed in black and white as Figure 27.8.)



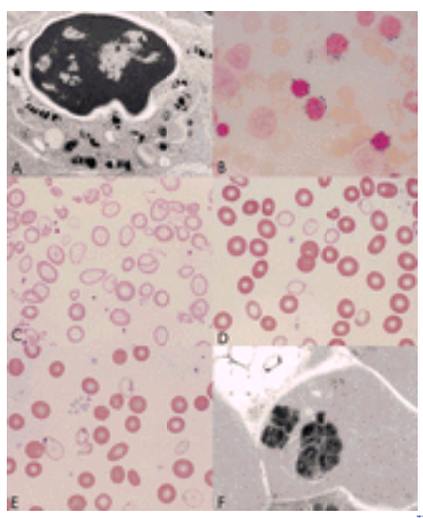
Color Plate 27.18 Red blood cell abnormalities associated with hemolysis. **A:** Normal red blood cells for comparison. **B:** Microspherocytes from patient with hereditary spherocytosis. **C:** Spherocytes from patient with autoimmune hemolytic anemia. **D:** Hereditary elliptocytosis—common variant with minimal or no hemolysis. **E:** Hereditary elliptocytosis—hemolytic variant. **F:** Hereditary elliptocytosis—pyropoikilocytosis variant. **G:** Hereditary stomatocytosis. (This figure is printed in black and white as Figure 27.18.)



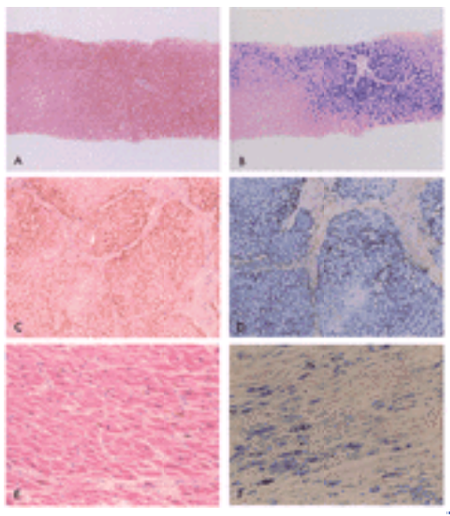
Color Plate 27.19 A: Sickle cell anemia. **B:** Sickle ß-thalassemia. **C:** Target cells in hemoglobin C disease. **D:** Schistocytes in patient with thrombotic thrombocytopenic purpura. **E:** Blister cell from oxidative assault in patient with glucose-6-phosphate dehydrogenase deficiency. **F:** Autoagglutination in cold agglutinin disease. (This figure is printed in black and white as Figure 27.19.)



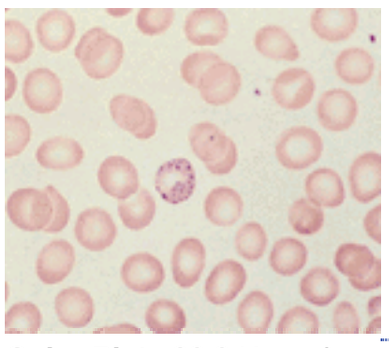
Color Plate 27.21 Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes). (This figure is printed in black and white as Figure 27.21.)



Color Plate 29.1 Morphologic features of sideroblastic anemia. **A:** Electron micrograph of an erythroblast with iron-laden mitochondria. **B:** Bone marrow smear (Prussian blue stain) with ring sideroblasts. **C,D:** Blood smears (Wright stain) of severe and mild sideroblastic anemia. **E:** Siderocytes (Wright stain). **F:** Electron micrograph of a Pappenheimer body in a peripheral red blood cell. (This figure is printed in black and white as Figure 29.1.)

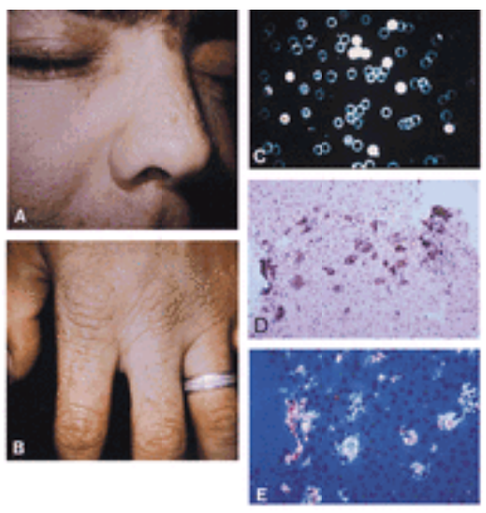


Color Plate 29.4 Histopathology of the iron overload in hereditary sideroblastic anemia. **A,B:** Liver section of a 26-year-old man with moderate hemochromatosis. **C,D:** Autopsy liver section of a 45-year-old man with micronodular cirrhosis and hemochromatosis. **E,F:** Section from the heart of the latter patient with marked hemosiderosis. (**A**, **C**, and **E:** hematoxylin stain; **B**, **D**, and **F:** Prussian blue stain.) (This figure is printed in black and white as Figure 29.4.)

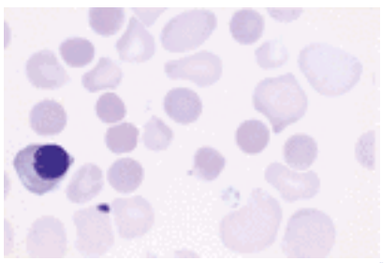


Color Plate 29.9 Hypochromia and red cell stippling in lead poisoning. (This figure is printed in black and white as Figure 29.9.)

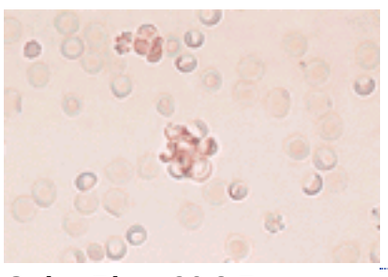
Color Plate 31.3 Porphyria cutanea tarda in a 60-year-old man. Note denuded skin areas over the fingers, an erosion, blisters, and milia. (This figure is printed in black and white as Figure 31.3.)



Color Plate 31.4 Protoporphyria. **A** and **B:** In a 29-year-old man. Note cobblestonelike, flesh-colored, lichenoid papules over the nose and dorsum of the hand joints. **C:** Dilute suspension of erythrocytes under the fluorescence microscope. Note a fraction of fluorescing cells. (Courtesy of Dr. Maureen Poh-Fitzpatrick, Columbia University, NY.) **D** and **E:** Needle biopsy section of liver. Note deposits of protoporphyrin pigment in the parenchyma and a portal triad **(D)**, and birefringence of the deposits, including a dark Maltese cross figure near the left center **(E)**. (This figure is printed in black and white as Figure 31.4.)

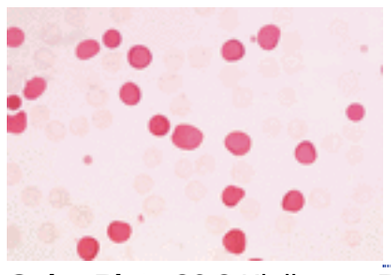


Color Plate 36.1 ABO hemolytic disease of the newborn (HDN). Peripheral blood from an infant with ABO HDN, with numerous spherocytes, occasional nucleated red cells, anisocytosis, and polychromasia (Wright-Giemsa stain). (©American Society for Clinical Pathology. Used with permission.) (This figure is printed in black and white as Figure 36.1.)

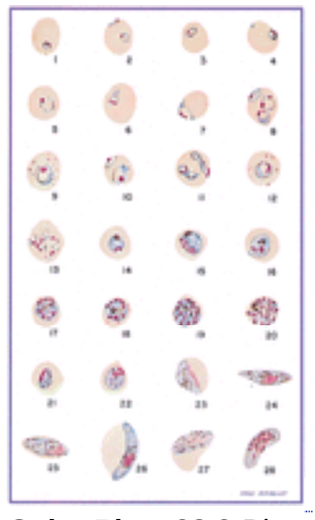


Color Plate 36.2 Rosette assay for fetal-maternal hemorrhage (FMH). D-positive red cells are identified in a background of D-negative red cells by the formation of rosettes in this screening test for FMH. There are two rosettes in this field—a large one in the center and a smaller one above it; unagglutinated red cells appear as

refractile, biconcave (unstained) disks. (This figure is printed in black and white as Figure 36.2.)

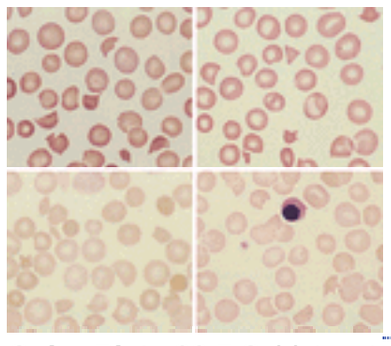


Color Plate 36.3 Kleihauer-Bethke acid elution for fetal hemoglobin (Hb). Cord blood was mixed with blood from a healthy adult to simulate fetal-maternal hemorrhage, and a Kleihauer-Bethke was performed. Red cells containing HbF are deeply stained red; red cells containing HbA appear as pale pink ghosts. (This figure is printed in black and white as Figure 36.3.)

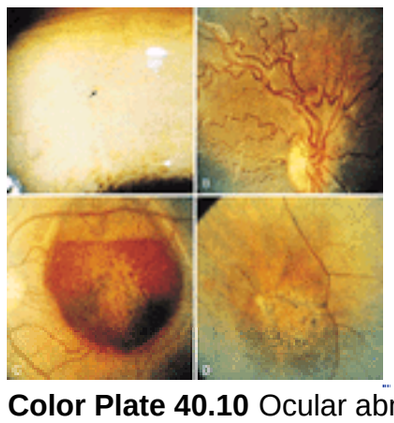


Color Plate 38.3 *Plasmodium falciparum*. **1:** Very young ring form trophozoite. **2:** Double infection of single cell with young trophozoites, one a marginal form, the other a signet ring form. **3, 4:** Young trophozoites showing double chromatin dots. **5–7:** Developing trophozoites. **8:** Three medium trophozoites in one cell. **9:** Trophozoite showing pigment in a cell containing Maurer spots. **10, 11:** Two trophozoites in each of two cells, showing variation of forms that parasites may assume. **12:** Almost mature trophozoite showing haze of pigment throughout cytoplasm. **13:** Aestiveo-autumnal slender forms. **14:** Mature trophozoite, showing clumped pigment. **15:** Parasite in the process of initial chromatin division. **16–19:** Various phases of the development of the schizont. **20:** Mature schizont. **21–24:** Successive forms in the development of the gametocyte, usually not found in the circulation. **25:** Immature macrogametocyte. **26:** Mature macrogametocyte. **27:** Immature microgametocyte. **28:** Mature microgametocyte. (From Wilcox A. Manual for the microscopical diagnosis of malaria in man. National Institutes of Health Bulletin No. 180, with permission.) (This figure is printed in black and white as Figure 38.3.)

Color Plate 38.4 Morphologic findings characteristic of hemolytic anemia caused by oxidant drugs and chemicals. **A:** Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes). **B:** “Bite cells” (seen in routine Wright-stained blood smear) as erythrocytes that look as if a semicircular bite has been taken from one edge. **C:** “Blister cells” or hemighosts (seen in routine Wright-stained blood smear) appear as if hemoglobin has shifted to one side of the cell, leaving the other side clear. These blister red blood cells contain a coagulum of hemoglobin that has separated from the membrane, leaving an unstained non-hemoglobin–containing cell membrane. [See Arese P, De Flora A. Pathophysiology of hemolysis in glucose-6-phosphate dehydrogenase deficiency. Semin Hematol 1990;27(1):1–40.] (**C** courtesy of Dr. Lawrence Naiman, M.D.) (This figure is printed in black and white as Figure 38.4.)

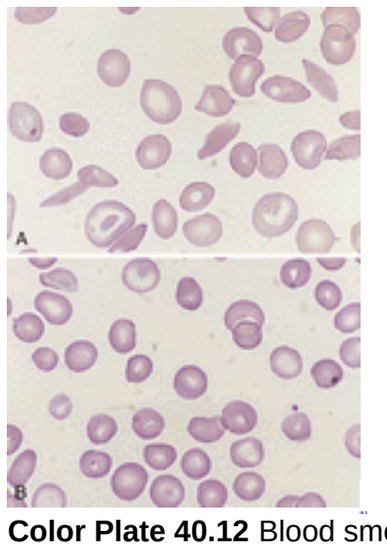


Color Plate 38.5 Schistocytes in patients with **(A)** thrombotic thrombocytopenic purpura, **(B)** disseminated intravascular coagulation, **(C)** aortic valve replacement, and **(D)** hemolytic uremic syndrome. (This figure is printed in black and white as Figure 38.5.)

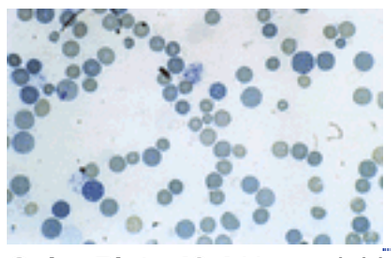


Color Plate 40.10 Ocular abnormalities in sickle cell anemia. **A:** “Comma” vascular sign: superficial conjunctival vessel that contains densely packed sickled cells (*arrow*). **B:** Widened veins and tortuous large vessels of the retina. **C:** Large preretinal hemorrhage of approximately 2 weeks' duration. There is partial resorption and

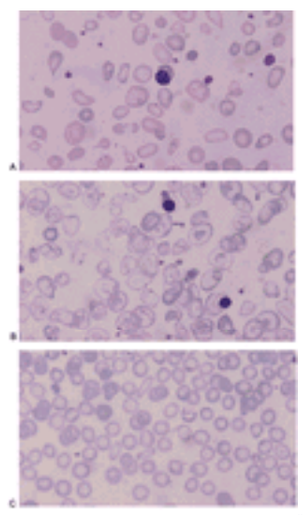
exposure of a darkened area that was the probable site of intraretinal hemorrhage. **D:** Old pigmented chorioretinal scar. (Photographs by Professor Mansour Armaly, The George Washington University Medical Center.) (This figure is printed in black and white as Figure 40.10.)



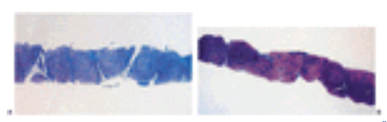
Color Plate 40.12 Blood smears of patients with hemoglobin (Hb) SS **(A)** and Hb SC (B) disease. (This figure is printed in black and white as Figure 40.12.)



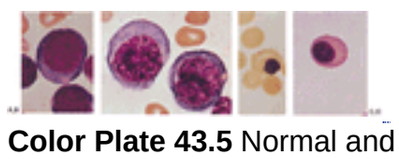
Color Plate 42.4 Hemoglobin H inclusion bodies. (This figure is printed in black and white as Figure 42.4.)



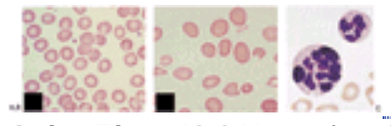
Color Plate 42.7 Peripheral blood smears in ß-thalassemia major **(A)** and intermedia **(B)** and in heterozygous ß-thalassemia **(C)**. (This figure is printed in black and white as Figure 42.7.)



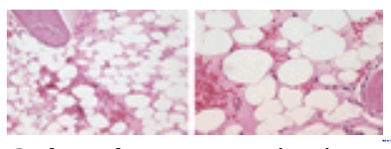
Color Plate 42.10 Liver biopsies before **(A)** and after **(B)** bone marrow transplantation demonstrating reversal of liver cirrhosis. (From Muretto P, Angelucci E, Lucarelli G. Reversibility of cirrhosis in patients cured of thalassemia by bone marrow transplantation. Ann Intern Med 2002;136:669, with permission.) (This figure is printed in black and white as Figure 42.10.)



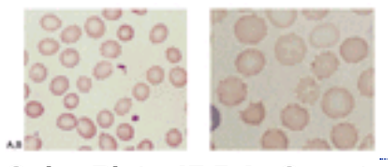
Color Plate 43.5 Normal and megaloblastic precursor cells in the bone marrow. **A:** Pronormoblast. **B:** Megaloblastic equivalent of cell in **A**. **C:** Late normoblast. **D:** Megaloblastic equivalent of cell in **C**. (From Lee RG, Foerster J, Lukens J, et al., eds. Wintrobe's clinical hematology, 10th ed. Philadelphia: Lippincott Williams & Wilkins, 1999: 913, with permission.) (This figure is printed in black and white as Figure 43.5.)



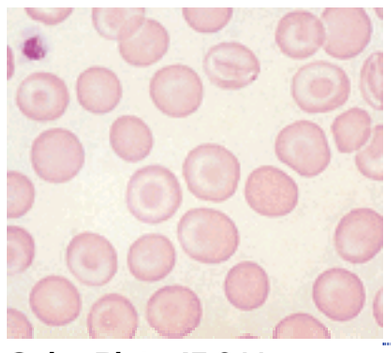
Color Plate 43.6 Normal peripheral blood cells compared with megaloblastic cells. Normal red blood cells **(A)**; macroovalocytic red blood cells with poikilocytosis **(B)**; and a normal neutrophil with a larger, hypersegmented one **(C)**. (From Lee RG, Foerster J, Lukens J, et al., eds. Wintrobe's clinical hematology, 10th ed. Philadelphia: Lippincott Williams & Wilkins, 1999: 910, 1895, with permission.) (This figure is printed in black and white as Figure 43.6.)



Color Plate 44.1 Aplastic anemia bone marrow histology. A bone marrow biopsy obtained from a child with aplastic anemia shows the characteristic hypocellularity. Note the abundance of fat. The few cellular elements are comprised primarily of lymphocytes. (This figure is printed in black and white as Figure 44.1.)

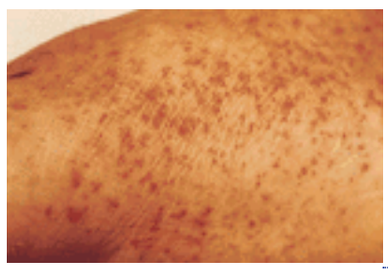


Color Plate 47.5 A: Crenated cells in renal disease (×1500). **B:** Burr cells in renal disease (×3000). (This figure is printed in black and white as Figure 47.5.)

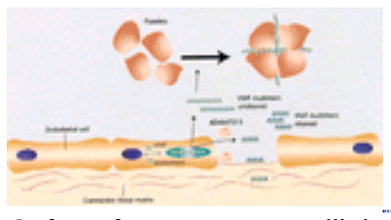


Color Plate 47.6 Macrocytes and target cells in liver disease (×1500). (This figure is printed in black and white as Figure 47.6.)

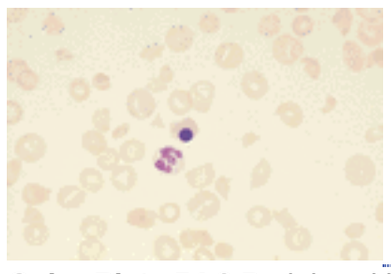
Color Plate 51.2 Large dissecting hematoma of thigh in a patient with hemophilia A. The lesion resulted from a slight bump to the inguinal area and spread to involve the entire thigh. (Courtesy of Dr. John Lukens.) (This figure is printed in black and white as Figure 51.2.)



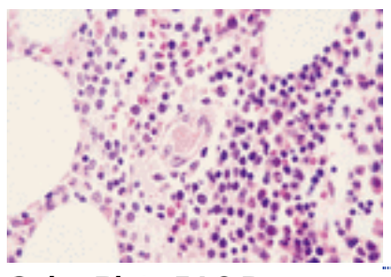
Color Plate 53.4 Petechiae. Pinpoint, nonblanching erythematous capillary bleeding sites are most common in dependent body areas or pressure points. (This figure is printed in black and white as Figure 53.4.)



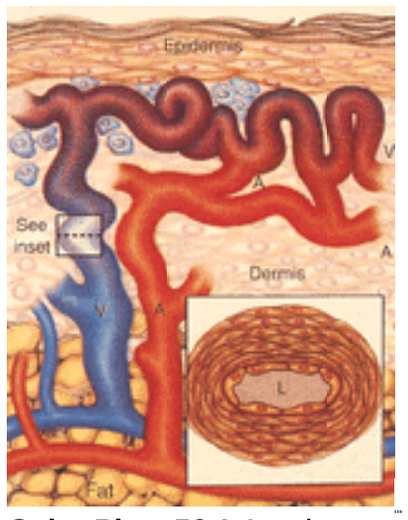
Color Plate 54.1 von Willebrand factor (VWF) is synthesized in endothelial cells as a monomer that is subsequently made into multimers that are secreted. Large multimers best support platelet adhesion to collagen, but the largest multimers have high affinity for platelets and may cause platelets to agglutinate. It is hypothesized that ADAMTS13, a metalloprotease, cleaves secreted VWF to limit the size of the multimers and prevent platelet agglutination in the circulation. (This figure is printed in black and white as Figure 54.1.)



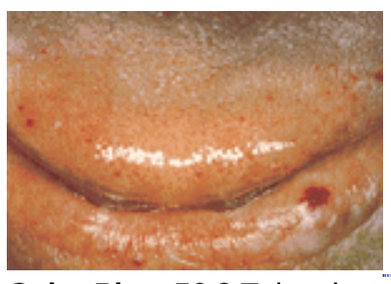
Color Plate 54.2 Peripheral blood smear from a patient with acute thrombotic thrombocytopenic purpura. Polychromasia, a nucleated red blood cell, and numerous schistocytes are present (×1000; Wright-Giemsa stain). (This figure is printed in black and white as Figure 54.2.)



Color Plate 54.3 Bone marrow biopsy in a patient with acute thrombotic thrombocytopenic purpura. There is a hyaline thrombus within one of the arterioles in the bone marrow (×1000; hematoxylin and eosin stain). (This figure is printed in black and white as Figure 54.3.)



Color Plate 56.1 Arteriovenous malformations in hereditary hemorrhagic telangiectasia. In a fully developed cutaneous telangiectasia, the venule (*V*) and its branches have become dilated and convoluted throughout the dermis. The connecting arterioles (*A*) have also become dilated and communicate directly with the venules without intervening capillaries. A perivascular infiltrate is present. The thickened wall of a dilated postcapillary venule is also shown. L, lumen of the vessel. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.) (This figure is printed in black and white as Figure 56.1.)

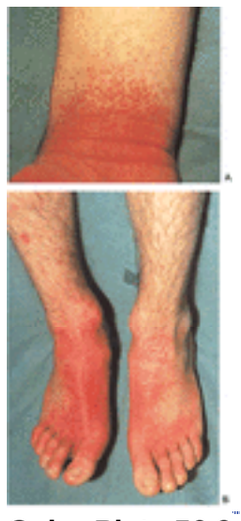


Color Plate 56.2 Telangiectasias of the tongue and lower lip in a patient with hereditary hemorrhagic telangiectasia. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918–924, with permission.) (This figure is printed in black and white as Figure 56.2.)

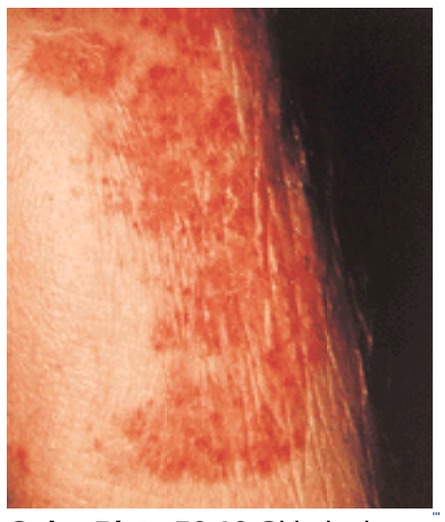
Color Plate 56.3 Periorbital purpura in a 58-year-old female with immunoglobulin A ? plasma cell dyscrasia associated with secondary amyloidosis. This photograph was kindly provided by Drs. Theresa Scholz and Pamela Nemzer (Department of Dermatology, University of Utah Health Sciences Center). (This figure is printed in black and white as Figure 56.3.)

Color Plate 56.7 Senile purpura (also known as *Bateman purpura*) in a 70-year-old man. This photograph was kindly provided by Dr. Kappa Meadows (Department of Dermatology, University of Utah Health Sciences Center). (This figure is printed in black and white as Figure 56.7.)

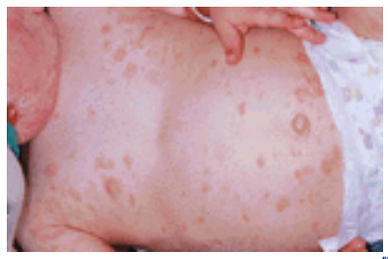
Color Plate 56.8 Lower extremity palpable purpura in a patient with Henoch-Schönlein purpura. (From Van Hale HM, Gibson LE, Schroeter AL. Henoch-Schönlein vasculitis: direct immunofluorescence study of uninvolved skin. J Am Acad Dermatol 1986;15:665–670, with permission.) (This figure is printed in black and white as Figure 56.8.)



Color Plate 56.9 Skin lesions of hands and feet associated with papular-purpuric gloves **(A)** and socks syndrome **(B)**. (From Harms M, Feldmann R, Saurat J-H. Papular-purpuric “gloves and socks” syndrome. J Am Acad Dermatol 1990;23:850–854, with permission.) (This figure is printed in black and white as Figure 56.9.)

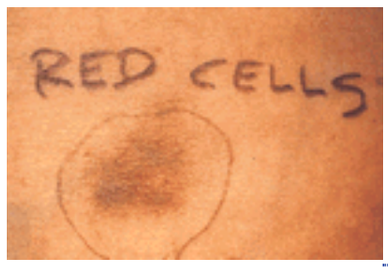


Color Plate 56.10 Skin lesions associated with Schamberg progressive pigmentary dermatosis. Note the irregular patches of punctate hemorrhagic lesions with yellow-brown discoloration of hemosiderin deposits. (From Sherertz EF. Pigmented purpuric eruptions. Semin Thromb Hemost 1984;10:190–195, with permission.) (This figure is printed in black and white as Figure 56.10.)

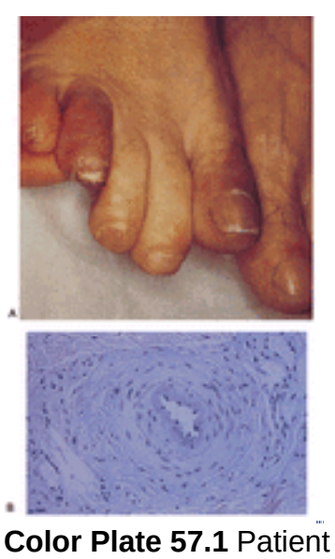


Color Plate 56.11 Pigmented purpura in a child. This photograph was kindly provided by Drs. Payem Tristani-Firouzi and Sheryll Vanderhooft (Department of Dermatology, University of Utah Health Sciences Center). (This figure is printed in black and white as Figure 56.11.)

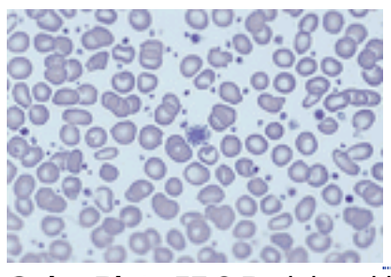
Color Plate 56.12 A fixed drug eruption lesion. This 30-year-old woman developed this thigh lesion after taking ibuprofen. This photograph was kindly provided by Dr. Pamela Nemzer (Department of Dermatology, University of Utah Health Sciences Center). (This figure is printed in black and white as Figure 56.12.)



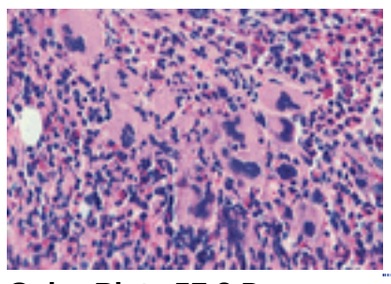
Color Plate 56.13 Skin lesion of psychogenic purpura (autoerythrocyte sensitization) induced by administration of intradermal autologous blood. A saline control elicited no response. [From Berman DA, Roenigk HH, Green D. Autoerythrocyte sensitization syndrome (psychogenic purpura). J Am Acad Dermatol 1992;27:829–832, with permission.] (This figure is printed in black and white as Figure 56.13.)



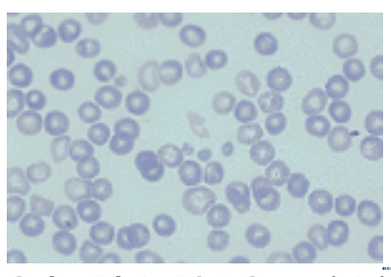
Color Plate 57.1 Patient with erythromelalgia secondary to essential thrombocythemia. **A:** There are painful, erythematous toes on both feet. **B:** Biopsy of affected region demonstrates smooth muscle cell hyperplasia of the arteriole (×430; hematoxylin and eosin stain). (From Naldi L, Brevi A, d'Oro LC, et al. Painful distal erythema and thrombocytosis. Arch Dermatol 1993;129: 105–106,109, with permission.) (This figure is printed in black and white as Figure 57.1.)



Color Plate 57.2 Peripheral blood smear from a patient with newly diagnosed essential thrombocytosis and a platelet count of 2 million/µl. A significant increase in platelets and one giant platelet can be seen in this field (×1000; Wright-Giemsa stain). (This figure is printed in black and white as Figure 57.2.)

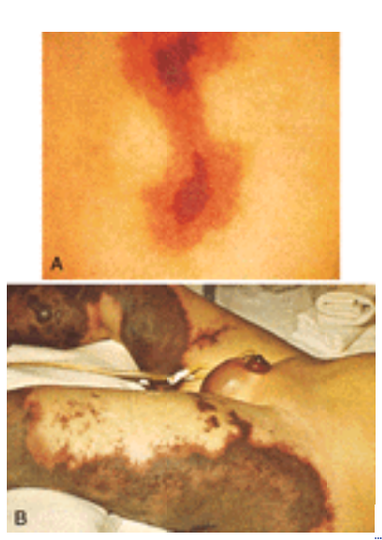


Color Plate 57.3 Bone marrow biopsy from the patient with newly diagnosed essential thrombocythemia and a platelet count of 2 million/μl presented in Color Plate 57.2. Megakaryocytes are increased in number and present in clusters (×1000; Wright-Giemsa stain). (This figure is printed in black and white as Figure 57.3.)



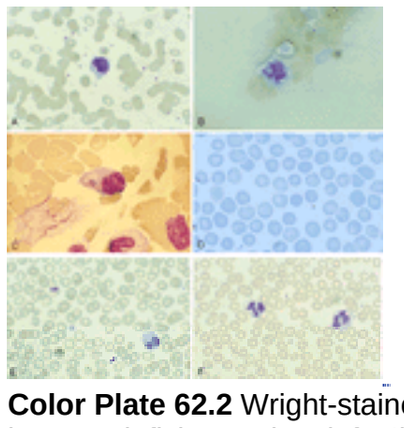
Color Plate 58.4 Gray platelet syndrome platelets. Giant platelets in the gray platelet syndrome (×1200, Wright stain). (This figure is printed in black and white as Figure 58.4.)

Color Plate 59.3 Hemophilic arthropathy. This figure illustrates the sequelae of recurrent joint bleeding. (This figure is printed in black and white as Figure 59.3.)



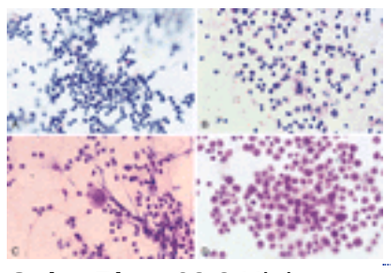
Color Plate 60.4 Purpura fulminans in infection-associated disseminated intravascular coagulation. Early lesions **(A)** are circumscribed; progressive lesions **(B)** may become necrotic. (From Dudgeon DL, Kellogg DR, Gilchrist GS, et al. Purpura fulminans. Arch Surg 1971;103:351–358; copyright 1971, American Medical Association, with permission.) (This figure is printed in black and white as Figure 60.4.)

Color Plate 60.6 Soft-tissue hemorrhage in a 76-year-old man with a high-titer factor VIII inhibitor. This patient has a history of ischemic cardiomyopathy and diabetes and developed spontaneous extremity bruising as shown. The antihuman factor VIII antibody titer was 10 Bethesda units. (Courtesy of Alan Grosset.) (This figure is printed in black and white as Figure 60.6.)

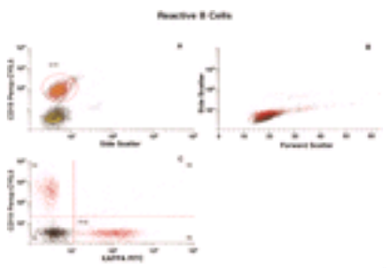


Color Plate 62.2 Wright-stained peripheral blood smears demonstrating **(A)** *Mycobacteria tuberculosis* as negative staining rods in monocyte from patient with human immunodeficiency virus infection, **(B)** *Histoplasma capsulatum* with three intracellular yeast forms in monocyte at feather edge of smear in patient with acquired immunodeficiency syndrome, **(C)** *Ehrlichia chaffeensis* as single basophilic cytoplasmic inclusion (photomicrogram courtesy of Dr. Charles Coleman, University of Missouri), **(D)** Babesia as single intracellular ring forms in two erythrocytes (photomicrograph courtesy of Dr. Ahn Dao, Vanderbilt University), **(E)** *Malassezia furfur* as extracellular budding yeasts (one of which is overlying an erythrocyte) in an infant on total parenteral alimentation, **(F)** intracellular bacteria in neutrophil with adjacent

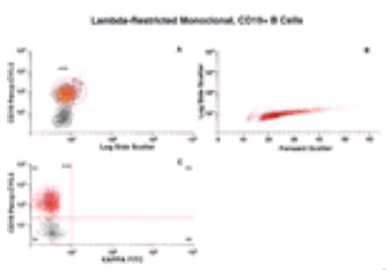
vacuolated neutrophil in patient with septicemia. (This figure is printed in black and white as Figure 62.2.)



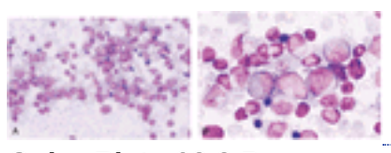
Color Plate 62.3 High power of hematoxylin eosin–stained touch preps of lymph node biopsies demonstrating **(A)** predominance of small lymphocytes in an adult with a small B-cell lymphoma; **(B)** mixed pattern of small and large lymphocyte macrophages, plasma cells, and neutrophils in a child with reactive adenitis; **(C)** mixed population of small and large lymphocytes with occasional large dysplastic cells in a patient with Hodgkin disease; and **(D)** predominance of large lymphocytes (many with polylobate nuclei) in a patient with large B-cell lymphoma of the mediastinum. (This figure is printed in black and white as Figure 62.3.)



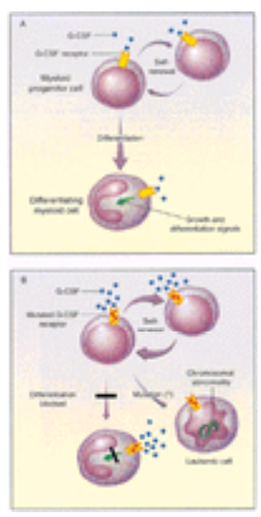
Color Plate 62.4 Flow cytometry of reactive B cells. **A:** Histogram (picture) of anti-CD19 antibody expression versus log side scatter (signal of cellular complexity), which is used to define and identify the B-cell lymphocytes. The CD19 $^{+}$ population is then focused on by using an isolation mechanism or *gate* (*R1*) to further describe this population. **B:** Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal (cell complexity or granularity). The red population represents the CD19 $^{+}$ B cells and their location in relation to the CD19 $^{-}$ population (*black dots*). **C:** A two-parameter histogram of fluorescein isothiocyanate (FITC) a light-chain found on the antibody molecule, versus anti-Lambda phycoerythrin, another light-chain found on the antibody molecule. Red dots are the CD19 $^{+}$ B cells from histogram **A**; the black dots represent the CD19 $^{-}$ population. The pattern shown includes statistics of each population. The *R2 area* represents the anti-Lambda, CD19 $^{+}$ population and equals approximately 16.5% of the total cells present. The *R3 area* represents the anti-Kappa positive, anti-Lambda positive CD19 $^{+}$ population. This population is usually negative. The *R5 area* represents the anti-Kappa, CD19 $^{+}$ population and equals approximately 27.7% of the total cells present. *R4* represents the anti-Kappa– and anti-Lambda–negative population. Percp, peridinin chlorophyll protein. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.) (This figure is printed in black and white as Figure 62.4.)



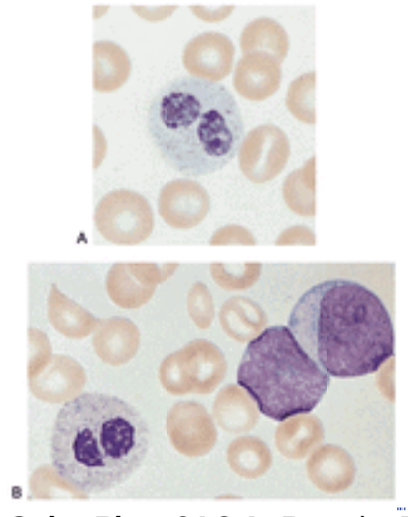
Color Plate 62.5 Flow cytometry of monotypic B cells. This set of pictures demonstrates CD19 $^{+}$ B cells that have a dominant expression of one particular light chain and is an example of monoclonal light-chain restriction. **A:** Histogram (picture) of anti-CD19 antibody expression versus log side scatter (signal of cellular complexity), which is used to define and identify the B-cell lymphocytes. The CD19 $^{+}$ population is then focused on by using an isolation mechanism or *gate* (*R1*) to further describe this population. Subsequent R1+ events are shown as red dots. Black dots represent CD19 $^{-}$ non-B cells. **B:** Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal (cell complexity or granularity). The red population represents the CD19 $^{+}$ B cells and their location in relation to the CD19 $^{-}$ population (*black dots*). **C:** A two-parameter histogram of anti-Kappa fluorescein isothiocyanate (FITC) versus anti-Lambda phycoerythrin. Red dots are the CD19 $^{+}$ B cells from histogram **A**; the black dots represent the CD19 $^{-}$ population. The pattern shown includes statistics of each population. The *R2 area* represents the anti-Lambda, CD19 $^{+}$ population and equals approximately 80% of the total cells present. The *R5 area* represents the anti-Kappa, CD19 $^{+}$ population and in this case is <1% of the total cells present. Percp, peridinin chlorophyll protein. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.) (This figure is printed in black and white as Figure 62.5.)



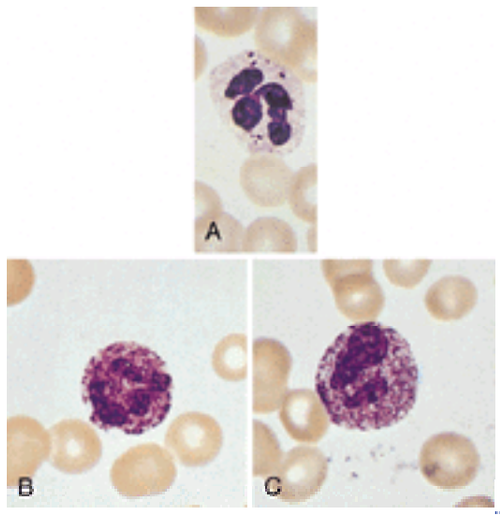
Color Plate 63.3 Bone marrow findings in severe congenital neutropenia (Kostmann neutropenia). Shown are a low-power view (×40) **(A)** and a high-power view (×100) **(B)** of a bone marrow aspiration from a child with severe congenital neutropenia. Note a cellular specimen with an apparent maturation arrest of myeloid differentiation at the promyelocyte stage. (Photomicrographs courtesy of David Kelly, M.D.) (This figure is printed in black and white as Figure 63.3.)



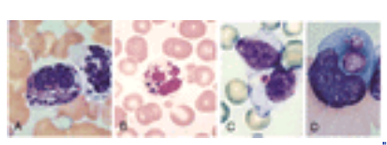
Color Plate 63.4 Possible mechanism for leukemic transformation. During normal, steady-state hematopoiesis **(A)**, only a small proportion of myeloid progenitors renew themselves. The majority differentiate into mature granulocytes. Granulocyte colony-stimulating factor (G-CSF) plays a major part in the process through an interaction with the G-CSF receptor that transmits the growth and differentiation signals. In cells with mutated G-CSF receptors **(B)**, more G-CSF is needed to activate the receptor. Abnormal proliferative signaling causes an accumulation of immature cells that do not differentiate. One such cell, constantly stimulated by G-CSF, may undergo a random mutation and acquire neoplastic properties. (From Naparstek E. G-CSF, congenital neutropenia and acute myeloid leukemia. N Engl J Med 1995;333:517, with permission.) (This figure is printed in black and white as Figure 63.4.)



Color Plate 64.2 A: Pseudo–Pelger-Huët cells. **B:** From a patient with acute myeloblastic leukemia. (This figure is printed in black and white as Figure 64.2.)

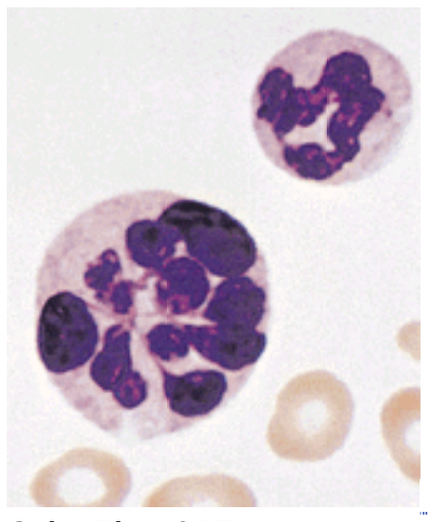


Color Plate 64.3 Neutrophils with Alder-Reilly bodies **(A)** compared with neutrophils exhibiting toxic granulation **(B,C)**. (This figure is printed in black and white as Figure 64.3.)



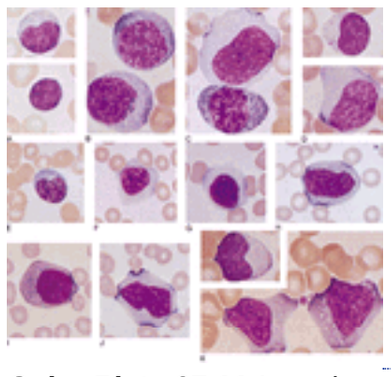
Color Plate 64.5 Inclusion bodies in Chédiak-Steinbrinck-Higashi anomaly. **A** and **B** in neutrophils; **C** in a lymphocyte; **D** in a monocytoid cell. (This figure is printed in black and white as Figure 64.5.)

Color Plate 64.6 The characteristic silver-gray hair of a child *(left)* with Chédiak-Steinbrinck-Higashi anomaly contrasted with that of her mother. (Courtesy of Dr. Dorothy Windhorst, National Institutes of Health.) (This figure is printed in black and white as Figure 64.6.)

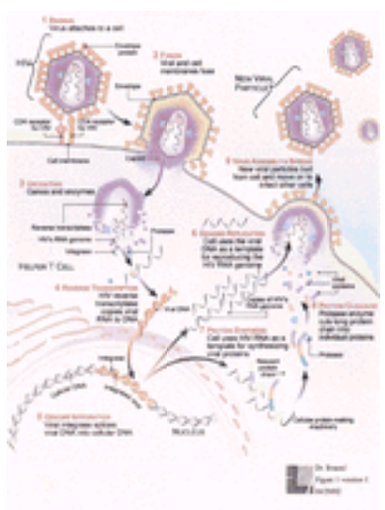


Color Plate 64.7 Hypersegmented neutrophil. (This figure is printed in black and white as Figure 64.7.)

Color Plate 66.5 Erythematous maculopapular rash in a boy with disseminated Langerhans cell histiocytosis. (From Esterly NB, Maurer HS, Gonzalez-Crussi F. Histiocytosis X: a seven year experience at a children's hospital. J Am Acad Dermatol 1985;13:481–496, with permission.) (This figure is printed in black and white as Figure 66.5.)

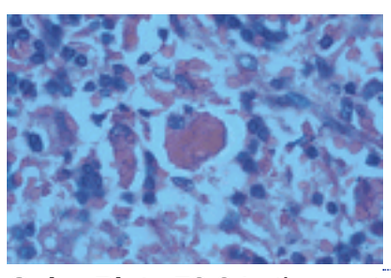


Color Plate 67.11 Lymphocytes and cells of infectious mononucleosis. **A:** Large and small lymphocytes from the blood of normal subjects. **B:** Lymphocytes resembling plasma cells (“plasmacytoid” cells) in the blood of a patient with viral pneumonia. **C:** Somewhat atypical lymphocyte and plasmacytoid lymphocytes in blood. **D:** Lymphocytes from the blood of a patient with viral infection; azurophilic granules are clearly seen in one of the cells. **E–J:** Infectious mononucleosis; lymphocytes showing increasing levels of atypia. **E:** Downey type I. **F, G:** Downey type II. **H–J:** Downey type III. **K:** Lymphocytes from blood of patient with infectious mononucleosis. (This figure is printed in black and white as Figure 67.11.)



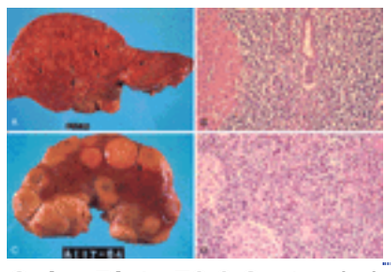
Color Plate 69.1 Human immunodeficiency virus (*HIV*) life cycle, deciphered with the help of genomic analyses, is unusually complex in its details, but all viruses undergo the same basic steps to infect cells and reproduce. (This figure is printed in black and white as Figure 69.1.)

Color Plate 70.5 Gross photograph of spleen in 35-year-old woman with marked splenomegaly from splenic hemangioma. The arrow demonstrates central hemangioma with surrounding uninvolved splenic parenchyma. This benign tumor had caused significant thrombocytopenia resulting in spontaneous bleeding before splenectomy. (This figure is printed in black and white as Figure 70.5.)

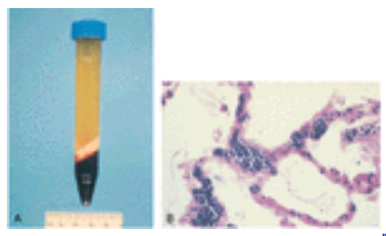


Color Plate 72.2 In the center of the field, two macrophages are stuffed with red blood cells (hemophagocytosis) in this high magnification view of spleen involved by a hepatosplenic ?d T-cell lymphoma (hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.) (This figure is printed in black and white as Figure 72.2.)

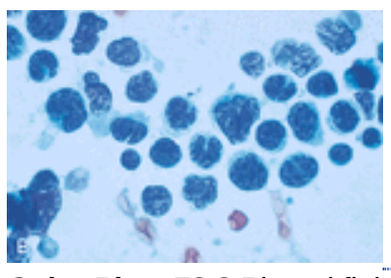
Color Plate 70.6 Large symptomatic splenic pseudocyst developing after blunt trauma to the spleen. (This figure is printed in black and white as Figure 70.6.)



Color Plate 72.3 Systemic involvement of lymphoma at autopsy. **A:** Pale nodules of follicular small cleaved cell are present on the cut surface of the liver. **B:** Microscopically, the liver shows a pronounced periportal lymphocytic infiltrate that surrounds a residual bile duct (hematoxylin and eosin stain) (*upper center*). **C:** Numerous lymphomatous nodules are also present on the external surface of the kidney. **D:** Extensive interstitial lymphocytic infiltrates obliterate the renal tubules, whereas two residual glomeruli can be seen on the left (hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.) (This figure is printed in black and white as Figure 72.3.)



Color Plate 72.4 Hyperleukocytosis and leukostasis. **A:** An elevated leukocrit is present in this tube of centrifuged peripheral blood from a patient with T-cell acute lymphoblastic leukemia who had a peripheral blood blast count of 250,000/µl. **B:** Pulmonary alveolar capillaries are expanded by leukocyte aggregates indicative of leukostasis in a patient with acute myeloid leukemia (hematoxylin and eosin stain). (This figure is printed in black and white as Figure 72.4.)

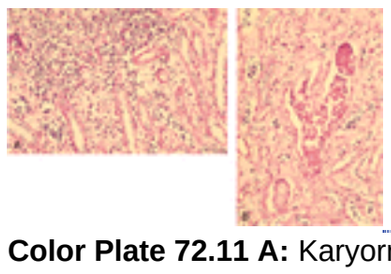


Color Plate 72.8 Pleural fluid cytology (Papanicolaou stain) shows numerous convoluted lymphoblasts characteristic of T-cell lymphoblastic lymphoma, a diagnosis confirmed by flow cytometric phenotypic analysis of the effusion. (Courtesy of Dr. Michael T. Lomis, Department of Pathology, Vanderbilt University School of Medicine, Nashville, TN.) (This figure is printed in black and white as Figure 72.8.)

Color Plate 72.9 A large mass near the ileocecal valve produced symptoms of intestinal obstruction in a patient with small noncleaved cell (Burkitt) lymphoma. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.) (This figure is printed in black and white as Figure 72.9.)

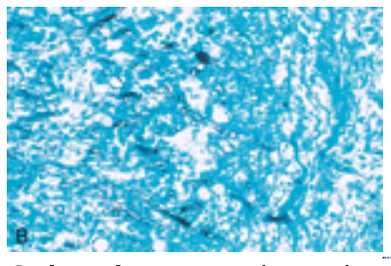
Color Plate 72.10 Spontaneous rupture of this friable spleen caused exsanguination of a patient with acute lymphocytic leukemia. (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.) (This figure is printed in black and white as Figure 72.10.)

Color Plate 75.2 *Fusarium* sepsis, manifesting as fever and a nodular, erythematous skin rash in an autologous bone marrow transplant recipient. (Photograph courtesy of S. Antony.) (This figure is printed in black and white as Figure 75.2.)

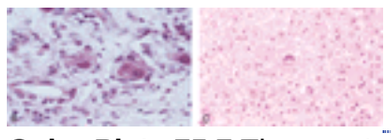


Color Plate 72.11 A: Karyorrhectic lymphoblast nuclei are present throughout the kidney in a patient with acute tumor lysis syndrome in whom cytolysis was initiated by administration of corticosteroids. **B:** Renal tubules contain calcium phosphate precipitates that contributed to acute tumor lysis–associated renal failure

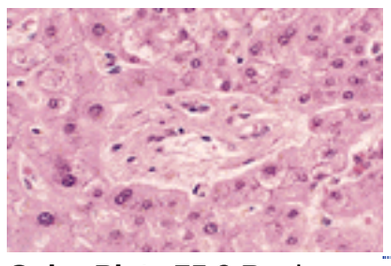
(hematoxylin and eosin stain). (Courtesy of Dr. William R. Macon, Department of Pathology, Mayo Medical Center, Rochester, MN.) (This figure is printed in black and white as Figure 72.11.)



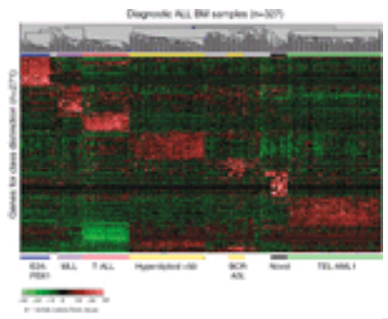
Color Plate 75.5 Photomicrograph of characteristic 45-degree-angle branching of septate hyphal forms of *Aspergillus* invading lung parenchyma (Gomori methenamine silver stain, ×400). (Courtesy of M. Scott.) (This figure is printed in black and white as Figure 75.5.)



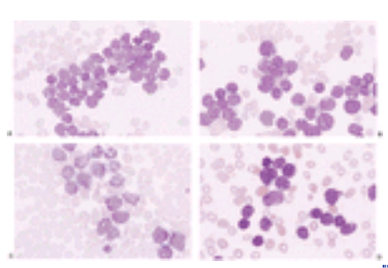
Color Plate 75.7 The spectrum of cytomegalovirus *(*CMV *)* disease in the abnormal human host. **B:** CMV inclusion disease of the colon. Typical infected cells show cellular ballooning with dense primary nuclear inclusions surrounded by a thin, cleared rim; secondary inclusions appear as cytoplasmic granules after the nucleus has filled with virions. **C:** CMV hepatitis demonstrated on liver biopsy. Viral cytopathic effect may be difficult to establish, but rare viral inclusions with surrounding parenchymal changes are diagnostic of CMV. Hematoxylin/eosin stains, ×400. (Photomicrographs courtesy of M. Scott.) (This figure is printed in black and white as Figure 75.7.)



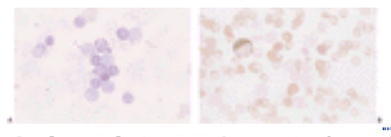
Color Plate 75.9 Regimen-related organ toxicity. Vasoocclusive disease of the liver with nonthrombotic fibrous occlusion of central veins and small venules (Hematoxylin/eosin stain, ×400). (Photomicrograph courtesy of M. Scott.) (This figure is printed in black and white as Figure 75.9.)



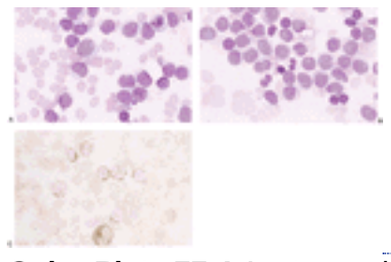
Color Plate 76.9 Microarray analysis of pediatric acute lymphocytic leukemia (ALL). Hierarchical clustering of 327 diagnostic ALL samples (columns) versus 271 genes (rows). The genes used in this analysis are the top 40 genes chosen by a chi-square statistic that are most highly correlated with the seven specific class distinctions. The normalized expression value for each gene is indicated by a color, with red representing high expression and green representing low expression, with the scale shown at the bottom. (From Yeoh E-J, Ross ME, Shurtleff SA, et al. Classification, subtype discovery, and prediction of outcome in pediatric acute lymphoblastic leukemia by gene expression profiling. Cancer Cell 2002;1:133–143, with permission.) (This figure is printed in black and white as Figure 76.9.)



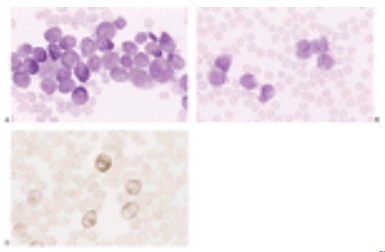
Color Plate 77.2 Acute lymphoblastic leukemia (ALL) cytologic appearance, Wright stain. **A:** French/American/British (FAB) L1 lymphoblasts, marrow. The blasts are small with folded or clefted nuclei, fine to condensed chromatin, and scant cytoplasm. Nucleoli are inconspicuous. **B:** FAB L2 lymphoblasts, marrow. The blasts are larger with more cytoplasm. Most nuclei are irregular or folded and chromatin is dispersed. Nucleoli are prominent. **C:** FAB L3 lymphoblasts, marrow. The blasts are medium to large with abundant vacuolated basophilic cytoplasm. The nuclei are round with dispersed chromatin and prominent nucleoli. **D:** ALL with cytoplasmic granules, marrow. These granules were Sudan black negative with this stain, and had a typical ALL immunophenotype (CD19 $^{+}$, CD10 $^{+}$, CD34 $^{+}$, TdT $^{+}$). (This figure is printed in black and white as Figure 77.2.)



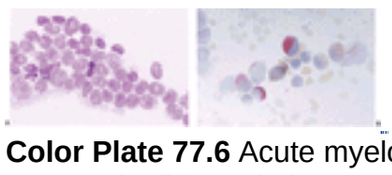
Color Plate 77.3 Acute lymphoblastic leukemia (ALL) cytochemical studies. **A:** Precursor B ALL. Blasts have coarse granular and block periodic acid–Schiff positivity. **B:** Precursor B ALL. Blasts are Sudan black negative. A residual normal myeloid cell is positive. (This figure is printed in black and white as Figure 77.3.)



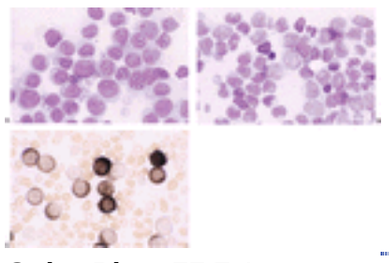
Color Plate 77.4 Acute myeloid leukemia, minimally differentiated [French/American/British (FAB) M1] and differentiated (FAB M2), marrow. Wright stain and cytochemical studies. **A:** FAB M1. Myeloblasts predominate with few maturing myeloid elements. **B:** FAB M2. Blasts show maturation beyond the blast stage. Numerous Auer rods are present. **C:** FAB M2. Blasts are Sudan black positive. (This figure is printed in black and white as Figure 77.4.)



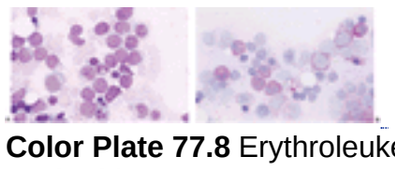
Color Plate 77.5 Acute promyelocytic leukemia (APL), French/American/British (FAB) M3, M3v. Wright stain and cytochemical studies (**A**, marrow; **B** and **C**, blood). **A:** Typical hypergranular APL (FAB M3h) has hypergranulated promyelocytes. **B:** The microgranular variant, FAB M3v has promyelocytes with folded, indented, or U-shaped nuclei and abundant cytoplasm with scant, fine, pink granules. These may be confused with myelomonoblasts. **C:** FAB M3v. The promyelocytes are strongly Sudan black positive and chloroacetate esterase positive. (This figure is printed in black and white as Figure 77.5.)



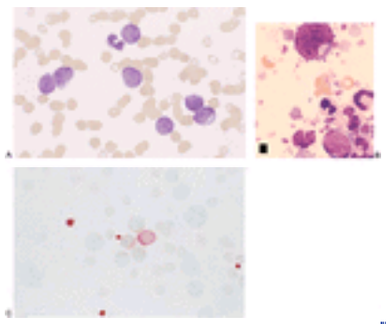
Color Plate 77.6 Acute myelomonocytic leukemia, French/American/British (FAB) M4, marrow. Wright stain and cytochemical studies. **A:** The blasts have myeloid and monocytic differentiation. **B:** Combined esterase stains show chloroacetate esterase reactivity (*red*) in myeloblasts and nonspecific esterase reactivity (*black*) in monoblasts. (This figure is printed in black and white as Figure 77.6.)



Color Plate 77.7 Acute monocytic leukemia, French/American/British (FAB) M5, marrow. Wright stain and cytochemical studies. **A:** FAB M5a. Predominant cell is a monoblast. **B:** FAB M5b. Blasts show differentiation to promonocytes and monocytes. **C:** FAB M5a. Nonspecific esterase is strongly positive. The reaction is inhibitable with fluoride treatment (not shown). (This figure is printed in black and white as Figure 77.7.)



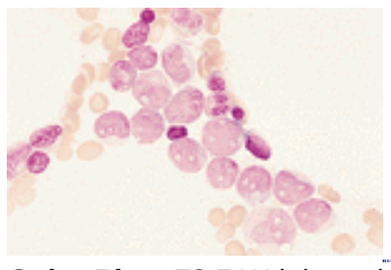
Color Plate 77.8 Erythroleukemia, French/American/British (FAB) M6, marrow. Wright stain and cytochemical studies. **A:** FAB M6 has a mixture of myeloblasts and erythroid precursors. Auer rods are present. Erythroid cells have dysplastic features, including megaloblastic change, lobated nuclei, and cytoplasmic vacuolization. **B:** The pronormoblasts have strong, coarse, blocklike periodic acid-Schiff staining and later stage erythroids are diffusely positive. (This figure is printed in black and white as Figure 77.8.)



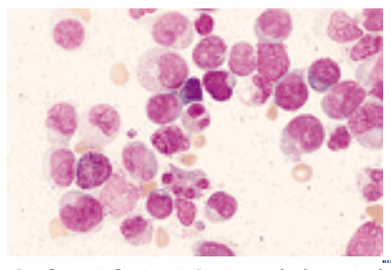
Color Plate 77.9 Megakaryocytic leukemic French/American/British (FAB) M7, marrow. Wright stain and immunoalkaline phosphatase staining. **A:** Megakaryoblasts often have dense chromatin and little cytoplasm, as shown here. **B:** Some megakaryoblasts have cytoplasmic blebs. **C:** The megakaryoblastic origin is confirmed by demonstrating CD41 expression using immunoalkaline phosphatase staining. (This figure is printed in black and white as Figure 77.9.)

Color Plate 79.3 Leukemia cutis manifesting as subcutaneous nodules. (Courtesy of Dr. Michael Smith, Department of Dermatology, Vanderbilt University Medical Center.) (This figure is printed in black and white as Figure 79.3.)

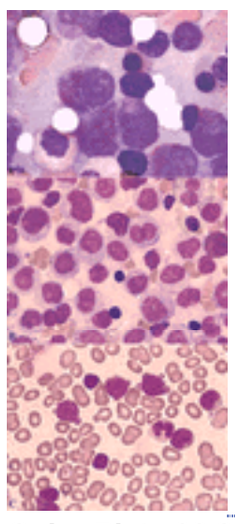
Color Plate 79.4 Swollen and spongy gums in a patient with acute leukemia. (Courtesy of Dr. Stuart Salmon, Department of Hematology/Oncology, Vanderbilt University Medical Center.) (This figure is printed in black and white as Figure 79.4.)



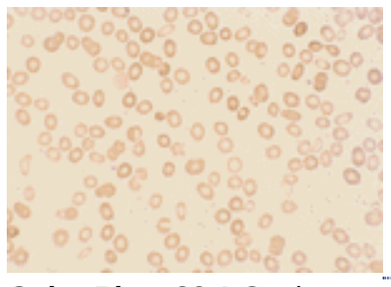
Color Plate 79.5 Wright-stained marrow smear from acute myeloid leukemia–M2 with t(8;21). Blasts are associated with maturing myeloid elements and numerous eosinophils with salmon-colored granules. (This figure is printed in black and white as Figure 79.5.)



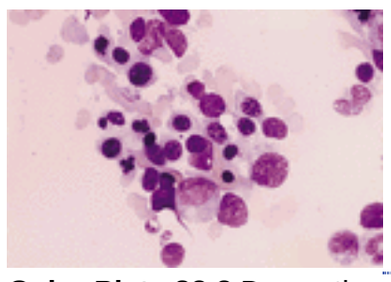
Color Plate 79.7 Wright-stained marrow smear from patient with M4Eo and an inv(16). Myeloblasts, monoblasts, and abnormal eosinophils with large basophilic granules, as illustrated here, are typically present in this variant. (This figure is printed in black and white as Figure 79.7.)



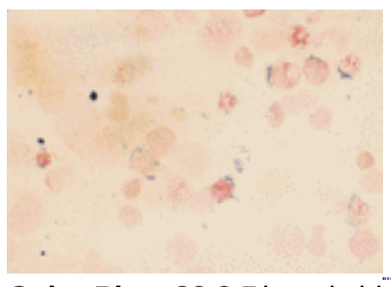
Color Plate 82.2 Morphologic subtypes of acute promyelocytic leukemia. **A:** "Classic" M3 is characterized by heavily granulated promyelocytes with abundant Auer rods. **B:** Microgranular variant (M3v) has fine granulation with a bilobed, folded nucleus. **C:** Hyperbasophilic variant has few granules, intense basophilia, and small cytoplasmic projections or buds reminiscent of micromegakaryocytes (100×, MacNeal Tetrachrome). (This figure is printed in black and white as Figure 82.2.)



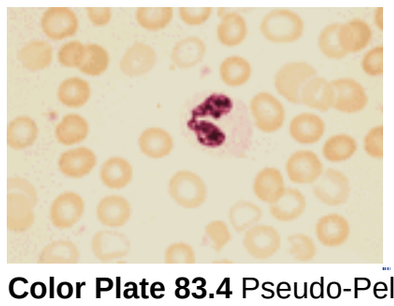
Color Plate 83.1 Oval macrocytes, hypochromic cells, and acanthocytes in refractory anemia with ringed sideroblasts (hematoxylin and eosin stain, ×1250). (This figure is printed in black and white as Figure 83.1.)



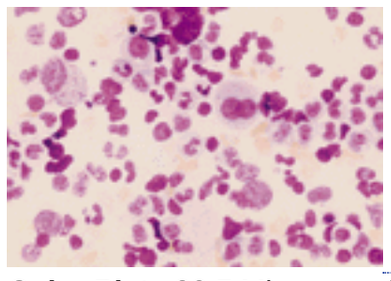
Color Plate 83.2 Dyserythropoiesis with nuclear budding and megaloblastoid erythropoiesis in refractory anemia (Wright-Giemsa stain, ×1250). (This figure is printed in black and white as Figure 83.2.)



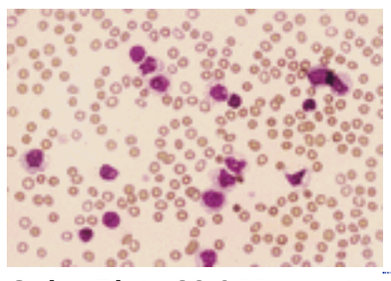
Color Plate 83.3 Ringed sideroblasts in refractory anemia with ringed sideroblasts (Prussian blue stain, ×1250). (This figure is printed in black and white as Figure 83.3.)



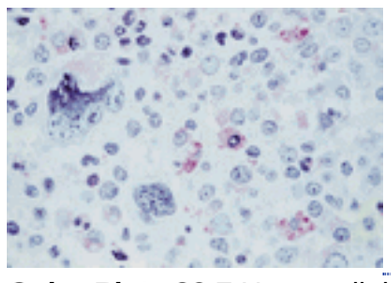
Color Plate 83.4 Pseudo-Pelger–Hüet anomaly in a patient with refractory anemia (hematoxylin and eosin stain, ×1250). (This figure is printed in black and white as Figure 83.4.)



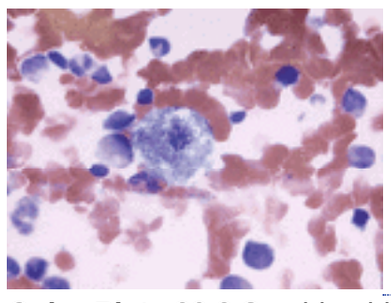
Color Plate 83.5 Micromegakaryocytes in a patient with refractory anemia with excess blasts (Wright-Giemsa stain, ×1250). (This figure is printed in black and white as Figure 83.5.)



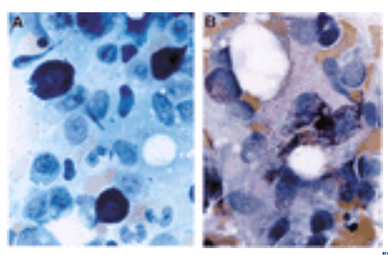
Color Plate 83.6 Monocytes in a patient with chronic myelomonocytic leukemia (hematoxylin and eosin stain, ×1250). (This figure is printed in black and white as Figure 83.6.)



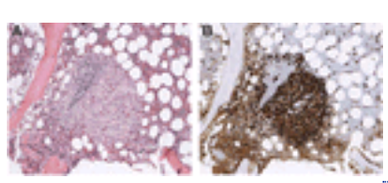
Color Plate 83.7 Hypercellular core biopsy with trilineage dysplasia in refractory anemia with excess blasts in transformation. Note atypical megakaryocytes (periodic acid-Schiff stain, ×1250). (This figure is printed in black and white as Figure 83.7.)



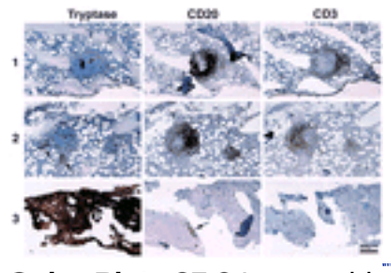
Color Plate 83.8 Sea blue histiocyte in refractory anemia (Wright-Giemsa stain, ×1250). (This figure is printed in black and white as Figure 83.8.)



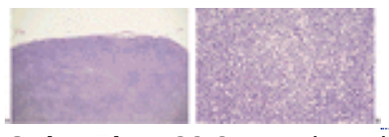
Color Plate 87.1 Morphologic features of mast cells from normal versus mastocytosis bone marrow aspirate. Panel **A** shows staining of a control bone marrow aspirate from an individual with aplastic anemia using toluidine blue stain (magnification, 40×). Panel **B** shows a hematoxylin and eosin stain of a bone marrow aspirate acquired from a patient with indolent systemic mastocytosis and illustrates representative spindle-shaped mast cells with an eccentric nucleus (magnification, 40×). (Provided courtesy of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health.) (This figure is printed in black and white as Figure 87.1.)



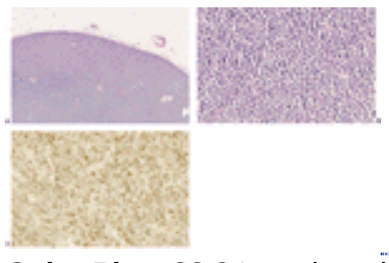
Color Plate 87.2 Bone marrow histopathology showing focal mast cell infiltrates in a bone marrow biopsy taken from a patient with indolent systemic mastocytosis. Panel **A** shows staining of a representative mast cell lesion with hematoxylin and eosin stain (magnification, 10×), and panel **B** shows staining of the same section with antitryptase antibody (magnification, 10×). (Provided courtesy of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health.) (This figure is printed in black and white as Figure 87.2.)



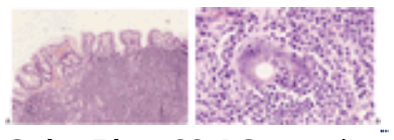
Color Plate 87.3 Immunohistochemical staining of lymphoid aggregates in two patients with a focal (**1** and **2**) and one patient with a diffuse (**3**) increase in mast cells. Antibodies are shown on top of each column. Nodular lesions shown in **1** and **2** contain a central core of mast cells (*arrows*) surrounded by B cells (CD20) and a peripheral rim of T cells (CD3). Diffuse mast cell infiltrates (**3**) are seen in association with a small B-cell collection (*arrow*) and scattered single T cells. The bar represents 200 µm. (From Akin C, Jaffe ES, Raffeld M, et al. An immunohistochemical study of the bone marrow lesions of systemic mastocytosis. Am J Clin Pathol 2002;118:242–247, by permission of Dr. Cem Akin, National Institute of Allergy and Infectious Diseases, National Institutes of Health and the *American Journal of Clinical Pathology*.) (This figure is printed in black and white as Figure 87.3.)



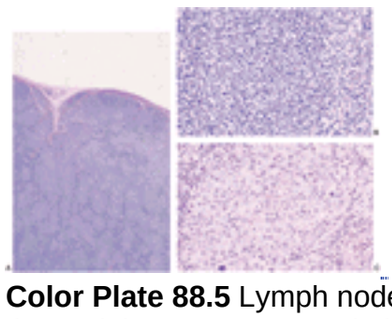
Color Plate 88.2 Lymph node: small lymphocytic lymphoma/chronic lymphocytic leukemia. **A:** Low magnification showing diffuse alteration of architecture with pale areas corresponding to mounds or proliferation centers. **B:** A higher power of a growth center composed of intermediate-sized cells with small nucleoli surrounded by small round lymphocytes. (This figure is printed in black and white as Figure 88.2.)



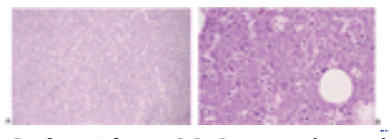
Color Plate 88.3 Lymph node: mantle cell lymphoma **A:** Low magnification showing diffuse architectural effacement, which, on higher magnification in **B**, is composed of sheets of small irregular lymphocytes with few large cells. **C:** Small lymphocytes exhibit nuclear staining for cyclin D1. (This figure is printed in black and white as Figure 88.3.)



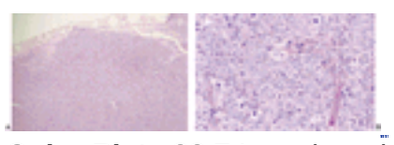
Color Plate 88.4 Stomach: extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue. **A:** The submucosa contains a diffuse infiltrate of small lymphocytes. **B:** Centrocyte-like cells with moderate amounts of clear cytoplasm invade gastric glands, producing lymphoepithelial lesions. (This figure is printed in black and white as Figure 88.4.)



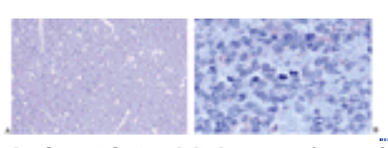
Color Plate 88.5 Lymph node: follicular lymphoma. **A:** Low magnification demonstrating effacement of architecture by a nodular process. **B:** In a higher magnification, the nodules are composed almost entirely of small cleaved cells (follicular lymphoma grade 1), whereas, in **C** from another patient, the nodules are dominated by large cells (follicular grade 3). (This figure is printed in black and white as Figure 88.5.)



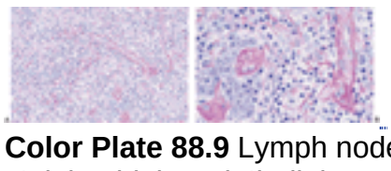
Color Plate 88.6 Lymph node: Burkitt lymphoma. **A:** The architecture is totally effaced by a diffuse infiltrate with a “starry sky” appearance. **B:** High power showing a monotonous population of small transformed or noncleaved lymphocytes with round to oval nuclei and variable cytoplasm. Mitotic figures are frequent. Numerous tingible body macrophages are present. (This figure is printed in black and white as Figure 88.6.)



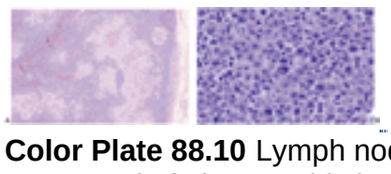
Color Plate 88.7 Lymph node: diffuse large B-cell lymphoma. **A:** On low magnification, the architecture is replaced by neoplastic process with a diffuse growth pattern. **B:** On high magnification, the tumor cells have large nuclei with dispersed chromatin, small nucleoli, and a variable amount of cytoplasm. Mitotic figures are easily identified. (This figure is printed in black and white as Figure 88.7.)



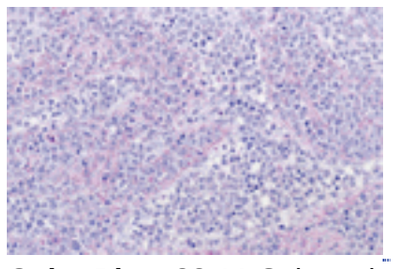
Color Plate 88.8 Lymph node: precursor T-cell lymphoblastic lymphoma. **A:** The nodal architecture is completely effaced by a diffuse lymphoid infiltrate. The interspersed macrophages help impart a “starry sky” appearance. **B:** The neoplastic cells are intermediate in size, have delicate chromatin characteristic of blasts, indistinct nucleoli, and scant cytoplasm. Frequent mitoses are present (*center*). (This figure is printed in black and white as Figure 88.8.)



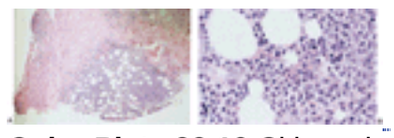
Color Plate 88.9 Lymph node: angioimmunoblastic T-cell lymphoma. **A:** There is a diffuse lymphoproliferation associated with prominent periodic acid-Schiff (PAS) staining high endothelial venules (HEVs). **B:** Perivascular clusters of “clear cell” immunoblasts (*left*) are admixed with small lymphocytes and PAS staining HEVs. (This figure is printed in black and white as Figure 88.9.)



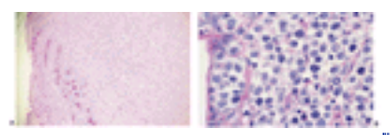
Color Plate 88.10 Lymph node: anaplastic large cell lymphoma. **A:** Pale staining tumor cell infiltrates with a cohesive appearance fill the sinuses. **B:** The lymphoma is composed of pleomorphic large lymphocytes, some of which have the characteristic horseshoe- or doughnut-shaped nuclei (*center*) characteristic of “hallmark” cells of anaplastic large cell lymphoma. (This figure is printed in black and white as Figure 88.10.)



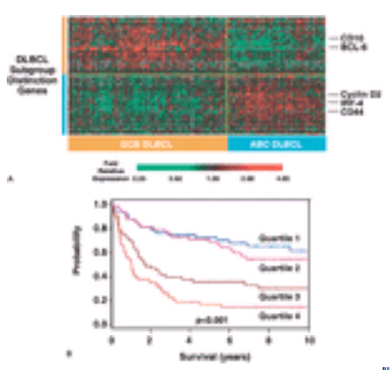
Color Plate 88.11 Spleen: hepatosplenic T-cell lymphoma. Intermediate-size lymphocytes are present throughout the splenic red pulp and markedly expand its sinuses. (This figure is printed in black and white as Figure 88.11.)



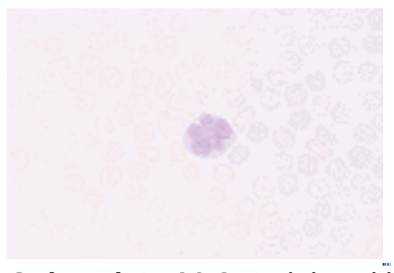
Color Plate 88.12 Skin: subcutaneous panniculitis-like T-cell lymphoma. **A:** There is a lobular panniculitic lymphocytic infiltrate that is confined to the subcutaneous tissue with complete sparing of the dermis. **B:** Pleomorphic tumor cells fill the interstitium and rim some of the fat spaces. (This figure is printed in black and white as Figure 88.12.)



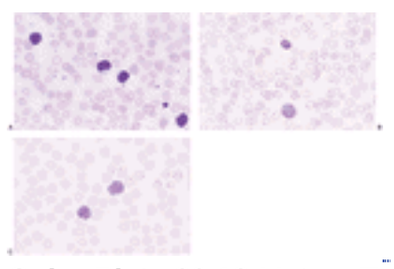
Color Plate 88.13 Small intestine: enteropathy-type T-cell lymphoma. **A:** The small intestinal features are markedly distorted by a lymphomatous infiltrate. There is also loss of the villous pattern at the luminal surface (*left*). **B:** Pleomorphic tumor cells with clear cytoplasm fill the mucosa and replace the glandular epithelium. (This figure is printed in black and white as Figure 88.13.)



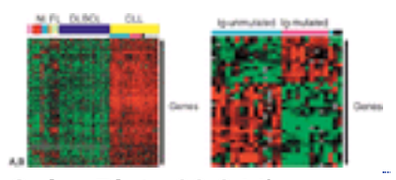
Color Plate 89.4 A: Subgroups of diffuse large B-cell lymphoma (DLBCL) defined by gene expression profiling. Hierarchical clustering of 188 lymph node biopsies from DLBCL patients, according to the gene expression levels of 100 selected genes. Shades of red indicate higher expression, shades of green indicate lower expression, and black indicates median expression. Each column represents one tumor sample, and each row represents a single gene. The germinal center B-cell–like DLBCLs (GCB DLBCLs) (see text) show high expression of genes that are characteristically expressed in germinal center B cells (e.g., CD10 and BCL6), whereas activated B-cell–like DLBCLs (ABC DLBCLs) express genes normally induced during *in vitro* activation of B cells (e.g., cyclin D2, IRF4, and CD44). **B:** A gene expression–based outcome predictor in 240 DLBCL patients. Each case of DLBCL was assigned an outcome predictor score calculated from gene expression averages of the model components (see text for details). Patients were ranked according to their scores and divided into quartiles. The 5-year survival rates for these quartile groups are shown in the Kaplan-Meier plot. (Adapted from Rosenwald A, Wright G, Chan WC, et al. The use of molecular profiling to predict survival after chemotherapy for diffuse large-B-cell lymphoma. N Engl J Med 2002;346:1937–1947, with permission.) (This figure is printed in black and white as Figure 89.4.)



Color Plate 90.2 Peripheral blood, adult T-cell leukemia/lymphoma. A neoplastic lymphocyte shows the cloverleaf nuclear lobations that are characteristic of circulating adult T-cell leukemia/lymphoma cells. [From Robert-Guroff M, Gallo RC. Establishment of an etiologic relationship between the human T cell leukemia/lymphoma virus (HTLV) and adult T cell leukemia. Blut 1983;47:1–12, with permission.] (This figure is printed in black and white as Figure 90.2.)



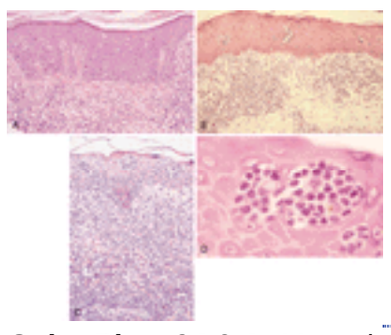
Color Plate 90.12 Mature T-cell and natural killer–cell leukemias. **A:** Peripheral blood, T-cell granular lymphocytic leukemia. Two lymphocytes that have oval-shaped nuclei, condensed chromatin, inconspicuous nucleoli, and abundant pale cytoplasm that contains azurophilic granules are in the center of the field. These lymphocytes have the characteristic morphology of large granulocytes that are normal constituents of the peripheral blood or that can be seen in large granular lymphocytic leukemia or in some reactive states. **B:** Peripheral blood, peripheral T-cell lymphoma of cytotoxic (natural killer–like) T-cell phenotype. A neoplastic large lymphocyte that has clumpy chromatin, a discernible nucleolus, and a modest amount of basophilic cytoplasm that contains a few azurophilic granules is associated with a smaller peripheral blood lymphocyte. The lymphoma had a $CD56^{+}$ and perforin+ T-cell phenotype. **C:** Peripheral blood, T-cell prolymphocytic leukemia, small ("knobby") cell variant. Small lymphocytes with markedly irregular ("knobby") nuclear profiles, coarse chromatin, variably discernible nucleoli, and scant agranular cytoplasm are characteristic of the small cell variant of T-cell prolymphocytic leukemia ("T-cell chronic lymphocytic leukemia"). (Courtesy of William Macon, Mayo Clinic, Rochester, MN.) (This figure is printed in black and white as Figure 90.12.)



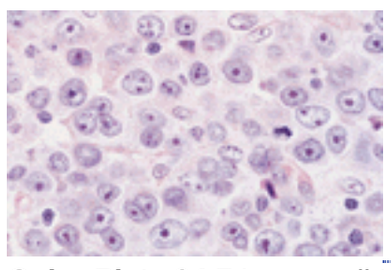
Color Plate 92.3 Microarray analysis in chronic lymphocytic leukemia (*CLL*). **A:** The expressions of Ç 247 "signature" genes differentiates CLL cells from diffuse

large B cell lymphoma (DLBCL), follicular lymphomas (*FLs*) and most normal (*Nl*) lymphocytes. The “signature” genes are expressed by CLL cases with or without *IgV* gene mutations. **B:** CLL patients can be differentiated into those with or without mutations of the *IgV* gene by the expressions of 56 genes (see Abraham RS, Clark RJ, Bryant SC, et al. Correlation of serum immunoglobulin free light chain quantification with urinary Bence Jones protein in light chain myeloma. Clin Chem 2002;48:655–657). Ig, immunoglobulin. (From Staudt LM. Gene expression profiling of lymphoid malignancies. Annu Rev Med 2002;53: 303–318, with permission.) (This figure is printed in black and white as Figure 92.3.)

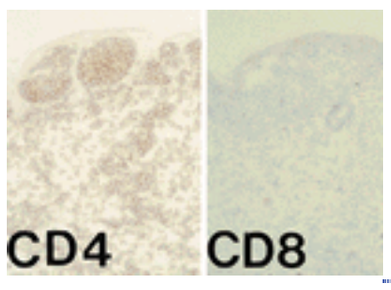
Color Plate 94.5 A–E: The cutaneous phases of cutaneous T-cell lymphoma (CTCL). **A:** Early patch stage lesions in a sun-protected region. **B:** Hyperpigmented diffuse patches on the back of a dark-skinned patient. **C:** Scattered thin and thick plaques on the back. **D:** Early keratoderma of the sole. **E:** Ulcerated tumor within a plaque on the posterior leg. **F:** Coalescing nodules and tumors with dermal thickening, forming “leonine facies” in this patient with transformed CTCL. See text for full description. (This figure is printed in black and white as Figure 94.5.)



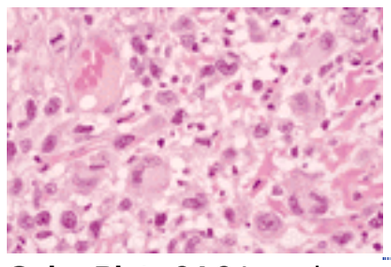
Color Plate 94.6 A: Mycosis fungoides (MF), patch stage. A bandlike lymphocytic infiltrate occupies the superficial papillary dermis with single-cell epidermotropism by atypical, “haloed” cerebriform T cells, preferentially involving the basal layer (hematoxylin and eosin, ×50). **B:** MF, plaque stage. A bandlike lymphocytic infiltrate occupies the papillary dermis with epidermotropism by atypical cerebriform T cells, focally forming small Pautrier microabscesses (hematoxylin and eosin, ×25). **C:** MF, thick plaque. A dense, bandlike lymphocytic infiltrate fills the papillary dermis and extends into the reticular dermis. Prominent epidermotropism by atypical, enlarged cerebriform T cells creates large Pautrier microabscesses (hematoxylin and eosin, ×25). **D:** MF, Pautrier microabscess. High magnification of a Pautrier microabscess shows characteristic small to medium cerebriform T cells with highly convoluted nuclear folding. The Pautrier microabscess recapitulates normal interactions between components of the skin-associated lymphoid tissue [i.e., cutaneous T cells, Langerhans histiocytes (two cells with large, pale nuclei in the center), and keratinocytes] (hematoxylin and eosin, ×500). (This figure is printed in black and white as Figure 94.6.)



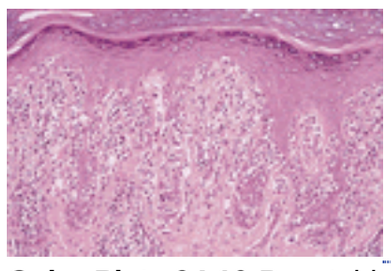
Color Plate 94.7 Large cell transformation of cutaneous T-cell lymphoma. This represents secondary transformation of low-grade mycosis fungoides to high-grade immunoblastic large-cell lymphoma. This tumor is composed of sheets of large transformed cells or immunoblasts with round to oval nuclei, dispersed chromatin, and prominent nucleoli. Several mitoses are present (hematoxylin and eosin, ×500). (This figure is printed in black and white as Figure 94.7.)



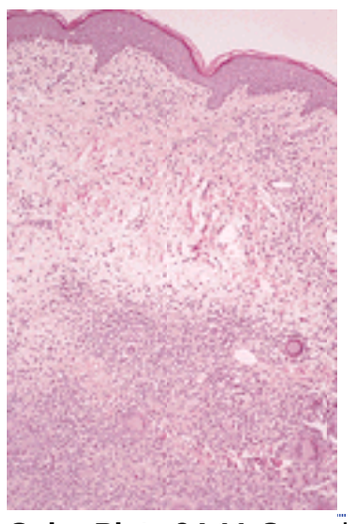
Color Plate 94.8 Frozen-section immunohistochemistry of a cutaneous plaque in a patient with mycosis fungoides shows a marked predominance of $CD4^{+}$ T-helper cells within Pautrier microabscesses and within the dermis. CD8 is essentially negative (diaminobenzidine and hematoxylin, ×50). (This figure is printed in black and white as Figure 94.8.)



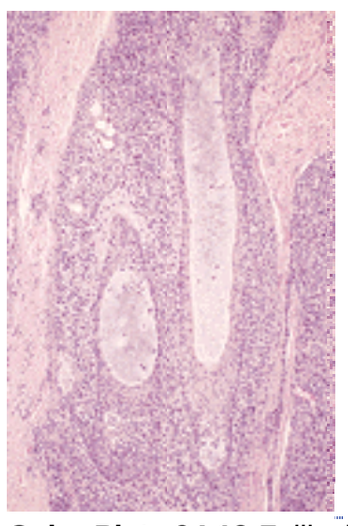
Color Plate 94.9 Lymphomatoid papulosis, type A. Anaplastic large cells with abundant cytoplasm, reniform nuclei, and prominent nucleoli are scattered among small lymphocytes and eosinophils. Note occasional binucleate Reed-Sternberg–like cells (hematoxylin and eosin, ×250). The large cells were strongly positive for CD30 (not shown). (This figure is printed in black and white as Figure 94.9.)



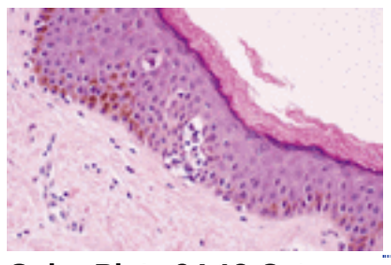
Color Plate 94.10 Pagetoid reticulosis. Note the pronounced pagetoid pattern of epidermotropism by enlarged, atypical, cerebriform T cells (hematoxylin and eosin, ×50). (This figure is printed in black and white as Figure 94.10.)



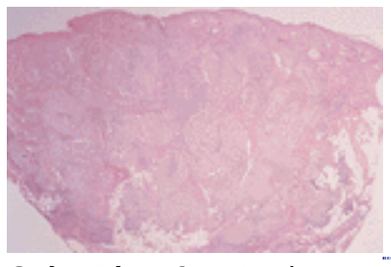
Color Plate 94.11 Granulomatous slack skin. This variant of mycosis fungoides shows a deep lymphocytic infiltrate with dermal edema, disruption of elastic fibers, and numerous foreign body giant cells (hematoxylin and eosin, ×10). (This figure is printed in black and white as Figure 94.11.)



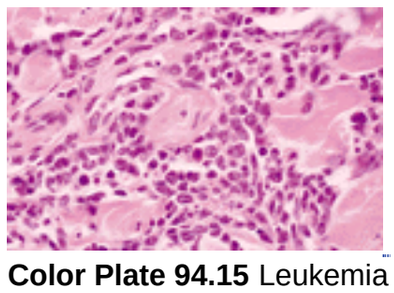
Color Plate 94.12 Folliculotropic mycosis fungoides with follicular mucinosis. Note the preferential pattern of perifollicular infiltration by atypical cerebriform T cells with prominent folliculotropism forming small Pautrier microabscesses. Also note the bluish pools of mucin within the hair follicles (hematoxylin and eosin, ×25). (This figure is printed in black and white as Figure 94.12.)



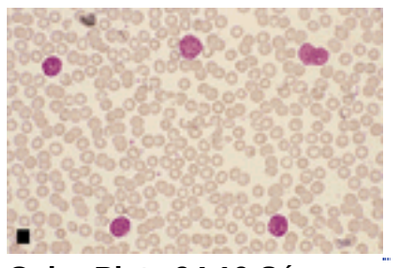
Color Plate 94.13 Cutaneous involvement by human T-cell leukemia virus type 1 (+) adult T-cell leukemia/lymphoma showing epidermotropism and formation of a Pautrier microabscess (hematoxylin and eosin, ×50). (This figure is printed in black and white as Figure 94.13.)



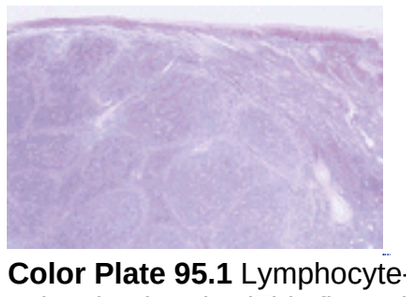
Color Plate 94.14 Primary cutaneous follicular large-cell lymphoma. Note the back-to-back nodular pattern. The infiltrate extends from the superficial reticular dermis to the superficial subcutis in a “bottom-heavy” pattern sparing the papillary dermis and epidermis (hematoxylin and eosin, ×2). (This figure is printed in black and white as Figure 94.14.)



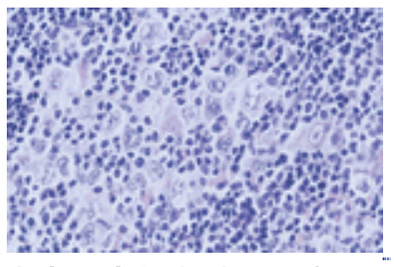
Color Plate 94.15 Leukemia cutis. Clusters of myeloblasts with fine chromatin and scant cytoplasm infiltrate between collagen bundles in the reticular dermis (hematoxylin and eosin, ×250). (This figure is printed in black and white as Figure 94.15.)



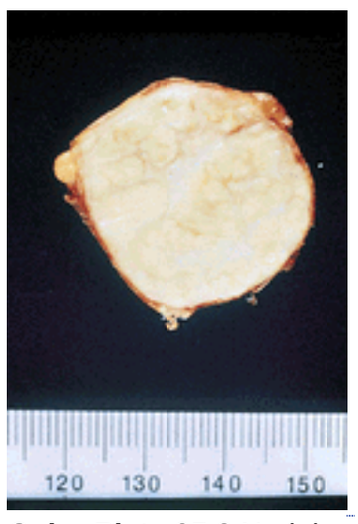
Color Plate 94.16 Sézary syndrome. The peripheral blood shows lymphocytosis. Most lymphocytes are Sézary cells with enlarged, highly convoluted nuclei and scant cytoplasm (hematoxylin and eosin, ×250). (This figure is printed in black and white as Figure 94.16.)



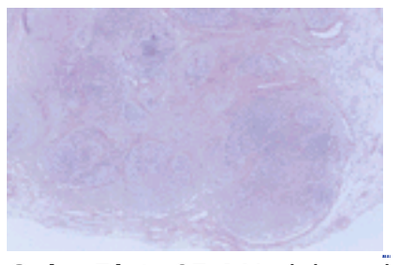
Color Plate 95.1 Lymphocyte-predominant Hodgkin disease, nodular type. Low magnification demonstrates a nodular growth pattern that compresses a rim of uninvolved node. (This figure is printed in black and white as Figure 95.1.)



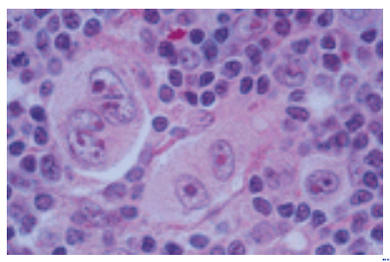
Color Plate 95.2 Lymphocyte-predominant Hodgkin disease. High magnification shows variant lymphocytic and histiocytic cells (L and H cells), which have “popcorn” nuclei. A background of small lymphocytes and histiocytes is present. (This figure is printed in black and white as Figure 95.2.)



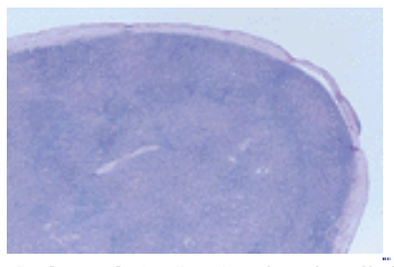
Color Plate 95.3 Nodular sclerosing Hodgkin disease. Gross appearance of the cut surface of a resected node shows a thickened capsule, white fibrous bands, and yellow parenchymal nodules. (This figure is printed in black and white as Figure 95.3.)



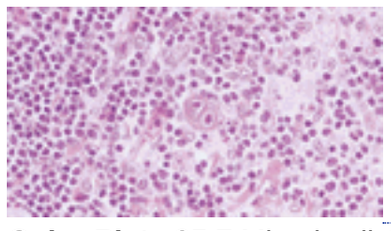
Color Plate 95.4 Nodular sclerosing Hodgkin disease. Low magnification shows a fibrous capsule and bands of sclerosis circumscribing abnormal lymphoid nodules. (This figure is printed in black and white as Figure 95.4.)



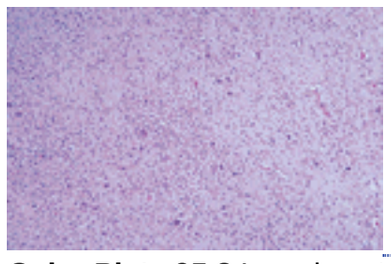
Color Plate 95.5 Nodular sclerosing Hodgkin disease. High magnification shows Reed-Sternberg cells and lacunar variants in B5 fixed material. (This figure is printed in black and white as Figure 95.5.)



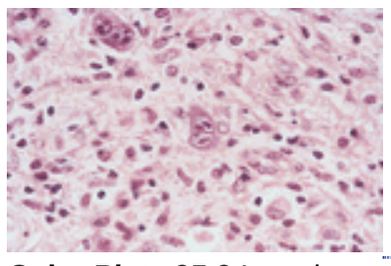
Color Plate 95.6 Mixed cellularity–type Hodgkin disease. Low magnification shows obliteration of nodal architecture. (This figure is printed in black and white as Figure 95.6.)



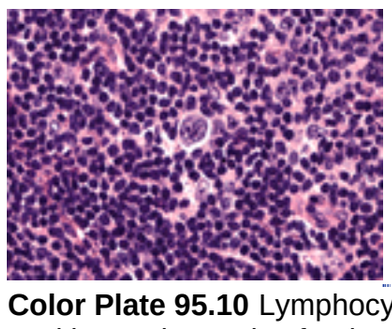
Color Plate 95.7 Mixed cellularity–type Hodgkin disease. High magnification shows a classic Reed-Sternberg cell in a mixed background of small lymphocytes, plasma cells, and eosinophils. (This figure is printed in black and white as Figure 95.7.)



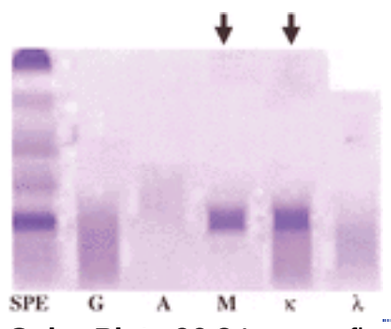
Color Plate 95.8 Lymphocyte-depleted type Hodgkin disease, diffuse fibrosis subtype. Low magnification shows depletion of cellularity of node and scattered large dysplastic cells. (This figure is printed in black and white as Figure 95.8.)



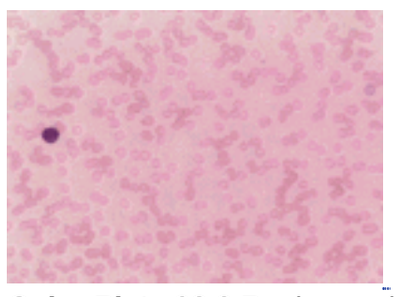
Color Plate 95.9 Lymphocyte-depleted type Hodgkin disease, diffuse fibrosis subtype. Reed-Sternberg cells are easily found, and the background is depleted of cellularity and composed of amorphous eosinophilic connective tissue. (This figure is printed in black and white as Figure 95.9.)



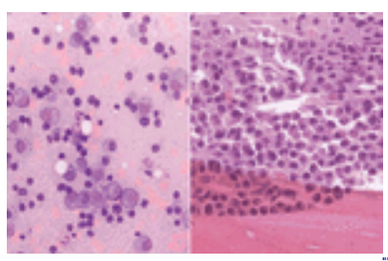
Color Plate 95.10 Lymphocyte-rich “classic” Hodgkin disease. The background is primarily lymphocytes, and the Reed-Sternberg cells are usually CD15 and CD30 positive and negative for the B-cell marker CD20. (This figure is printed in black and white as Figure 95.10.)



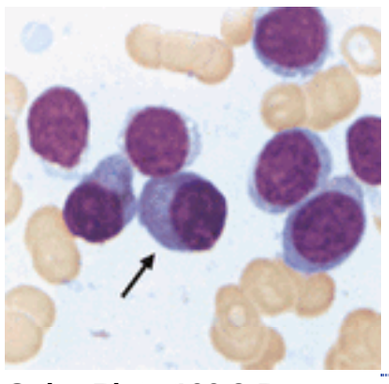
Color Plate 96.2 Immunofixation study done to characterize the monoclonal protein as a monoclonal immunoglobulin M ? protein. The arrows indicate the lanes that show reactivity with the specific antibodies. The reactivity is consistent with the same migration seen in the extreme left column that shows the electrophoresis (*SPE*). Thus, in this assay, the nature of the monoclonal protein seen in the electrophoresis is elucidated: isotype M and light chain ?. (This figure is printed in black and white as Figure 96.2.)



Color Plate 98.3 Rouleaux. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. handbook of multiple myeloma and related cell disorders. Berlin: Springer-Verlag, *in press*. By permission of the publisher.) (This figure is printed in black and white as Figure 98.3.)



Color Plate 98.6 Bone marrow. Plasma cells on aspirate and biopsy specimen. (From Dispenzieri A, Lacy MQ, Greipp PR. Multiple myeloma. In: Gertz MA, Greipp PR, eds. handbook of multiple myeloma and related cell disorders. Berlin: Springer-Verlag, *in press*. By permission of the publisher.) (This figure is printed in black and white as Figure 98.6.)



Color Plate 100.3 Bone marrow aspirate showing the malignant cells from a patient with Waldenström macroglobulinemia. The cells exhibit lymphoid and plasmacytoid morphology. (This figure is printed in black and white as Figure 100.3.)
