
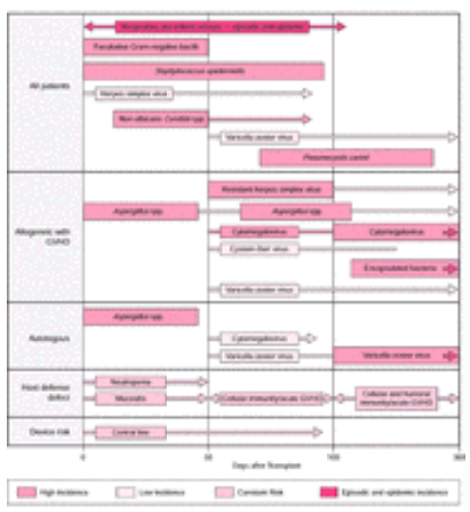

Figure 25.8. Periods of risk for opportunistic infections with standard prophylaxis after hematopoietic stem cell transplantation. Standard prophylaxis includes broad-spectrum antibiotics for neutropenia in the early posttransplant period, fluconazole to day 75, acyclovir early posttransplantation for herpes simplex virus and up to 1 year for prevention of reactivation of varicella-zoster virus, and trimethoprim and sulfamethoxazole for *Pneumocystis carinii* pneumonia. Strategies for preemptive treatment of cytomegalovirus still result in a significant incidence of viral reactivation but in a low incidence of cytomegalovirus disease. GVHD, graft-versus-host disease. (Adapted from D Armstrong, J Cohen. Infectious diseases. London: Harcourt Publishers Ltd., 1999.)

Bacterial Infections

During the last part of the 1980s, gram-positive organisms, especially streptococcus or enterococcus species, accounted for 60% of all bacteremias in neutropenic patients who received HSCT ([359], [360] and [361]). Previously, most infections had been due to gram-negative organisms ([362]). Most fevers in neutropenic patients are infectious in origin and potentially life-threatening. After a careful evaluation of the neutropenic patient with fever, empiric broad-spectrum antibiotic therapy should be initiated promptly and directed against the most likely causative organisms. If fever persists or recurs 4 to 7 days after initiation of antibiotics, empiric antifungal therapy should be considered ([363], [364] and [365]). In neutropenic patients with severe infections, transfusion of neutrophils from donors stimulated with G-CSF plus dexamethasone can restore a severely neutropenic patient's neutrophil counts, which may contribute to the resolution of infections ([366]). Further studies are required to characterize the potential benefits and costs of this form of therapy in neutropenic patients. After engraftment, patients with intestinal GVHD are at risk for recurrent bacteremias. Patients with chronic GVHD are at risk for recurrent bacteremias with highly encapsulated bacteria and sino-pulmonary infections. Strategies for prevention of bacterial infections beyond day 80 after HSCT include the daily use of either penicillin or trimethoprim-sulfamethoxazole (TMP-SMX) until immunosuppressive therapy is discontinued ([367]). Ig repletion should be considered in patients with documented Ig deficiency ([329]). Infrequent bacterial infections that should also be considered, especially in the presence of a pulmonary infiltrate or nodule, are those caused by *Legionella* (e.g., *L. pneumophila* and *L. micdadei*), *Nocardia*, *Mycobacterium tuberculosis*, and the atypical *Mycobacteria* ([368], [369], [370] and [371]).

Candidal Infections

Before the routine administration of antifungal prophylaxis to patients, candidal infections were reported to occur in 11.4% of patients during the first 100 days after HSCT ([372]). The mortality associated with candidemia was 39%. In one report, *Candida albicans* caused 71% of documented cases of fungemia in cancer patients (

[373]). Other *Candida* species are emerging as important pathogens ([374]). Often, blood cultures lack sensitivity in establishing a diagnosis of deep infection with *Candida* species ([375]). Fluconazole prophylaxis decreases the incidence of invasive and superficial *C. albicans* infections and may decrease the 100-day mortality from HSCT ([376], [377]). In addition, it was shown that 8 years after completion of the phase 3 studies, survival was significantly better in fluconazole recipients compared with placebo recipients ([378]). Fluconazole has limited activity against *Candida krusei*, *Torulopsis glabrata*, and *Aspergillus* species. Some, but not all, centers have reported an increase in the incidence of these resistant infections in patients on fluconazole ([379], [380]).

Treatment for systemic *Candida* infection consists of ampho-tericin B, although other newer antifungal agents are now available including voriconazole, posaconazole, and caspofungin ([381], [382]). Hepatosplenic candidiasis is not a contraindication to transplantation if antifungal therapy is given during the period of neutropenia ([383]).

Aspergillus Infections

In some transplant centers, invasive aspergillosis is emerging as the most frequent cause of mortality from infection ([379]). Risk factors for the development of aspergillosis are older age, acute and chronic GVHD, treatment with prednisone, and secondary neutropenia. Use of peripheral blood stem cells instead of marrow was associated with a decreased risk of aspergillosis ([384]).

The respiratory tract is the portal of entry, and the most common clinical manifestations are pneumonia and sinusitis. *Aspergillus* is the most common cause of brain abscesses in patients after HSCT ([385]). Isolation of *Aspergillus* from bronchoalveolar lavage fluid of transplant patients is highly suggestive of pulmonary infection, but negative studies do not rule out *Aspergillus* ([386], [387]). High-efficiency particulate air filtration systems can reduce the risk of nosocomial *Aspergillus* infections ([388]).

Hyphal invasion in tissue specimens and a positive culture for *Aspergillus* species from the same specimen are required for the definitive diagnosis of invasive aspergillosis. The detection of circulating fungal antigens and DNA seems to be a promising, rapid, and sensitive diagnostic tool for early diagnosis of aspergillosis. The current antifungals available for the treatment of invasive aspergillosis include voriconazole, amphotericin B deoxycholate and lipid formulations, posaconazole, and caspofungin acetate ([389], [390]).

Herpes Infections

CYTOMEGALOVIRUS INFECTIONS CMV is an important viral pathogen after HSCT. Infection occurs from reactivation of latent virus or is newly acquired from donor marrow or blood transfusions. Before the introduction of effective prevention strategies, CMV infection occurred in 70% of CMV-seropositive recipients and in 32% of CMV-seronegative recipients who received seronegative donor marrow and unscreened blood transfusions. Patients with CMV infections may be asymptomatic, but those with viremia are at high risk of developing CMV pneumonitis or gastroenteritis. In patients with CMV pneumonia, treatment is with a combination of ganciclovir and IVIg ([391]). The mortality associated with CMV pneumonitis remains greater than 50% ([392]). Treatment of CMV gastroenteritis may not require the administration of IVIg ([393], [394]). Foscarnet can be used in patients with ganciclovir-resistant CMV or during severe neutropenia. Cidofovir and foscarnet can be considered as second-line therapy for CMV disease failing other antiviral therapy ([395]). Because treatment of established CMV disease with antiviral agents has not been satisfactory, strategies for prophylaxis have been emphasized. The incidence of CMV infection was reduced in CMV-seronegative recipients to 3 to 6% when screened seronegative blood products were used ([396], [397]). Leukocyte depletion of blood products has also been effective in reducing the transmission of the virus ([398]). Ganciclovir was effective in preventing progression to disease at the time of first excretion of CMV as detected by culture of throat, blood, or urine ([399], [400]). Survival was improved in the group treated with ganciclovir in one study ([399]). However, disease was present at the time of first excretion in 12 to 30% of patients. When ganciclovir was given at the time of engraftment to CMV-seropositive recipients as early prophylaxis, CMV infection and disease were reduced, but there was no significant reduction in mortality ([401], [402]). Ganciclovir prophylaxis was associated with a higher incidence of neutropenic events and a delay in the reconstitution of CMV-specific T-cell immunity ([337]). Early treatment with ganciclovir or foscarnet strategies based on detection of CMV viremia by polymerase chain reaction technique or antigenemia by immunofluorescent studies was an effective strategy for preventing CMV disease ([403], [404] and [405]). Treatment of GVHD with doses of prednisone greater than 1 mg/kg was associated with rising CMV antigenemia levels during preemptive therapy ([406]). Continued induction dosing or reinduction may protect against early breakthrough CMV disease and CMV-related death among patients with rising antigenemia on preemptive therapy. The incidence of CMV disease late after transplantation has increased because the early use of ganciclovir blunts the recovery of CMV-specific immunity. Among seropositive patients who survive to day 80, approximately 18% develop late CMV disease. For those who receive treatment for GVHD, the incidence may exceed 30%. In view of this, high-risk patients require monitoring for reactivation for 1 year or longer after transplantation. The optimal strategy for prevention of CMV disease is likely to include prolonged surveillance and preemptive therapy or prophylaxis. Investigational strategies include enhancing the early restoration or the adoptive transfer of CMV-specific T-cell immunity ([347]).

OTHER HERPES INFECTIONS Without acyclovir prophylaxis, HSV infections occur in 80% of seropositive patients ([407]). Oral mucositis, cutaneous infections, esophagitis, genital herpes, and pneumonia are the most common clinical manifestations. Acyclovir is very effective for the prevention and treatment of HSV ([379]). Acyclovir is well tolerated immediately after transplantation with no effect on the recovery of neutrophil counts. HSV resistance to acyclovir can be managed with foscarnet. VZV infections occurred in 17% of VZV-seropositive patients ([408]). Median time to onset of infection was 5 months, with 85% occurring within 12 months of HSCT. VZV infections may manifest as herpes zoster only (84%) or as skin and visceral dissemination. Treatment with acyclovir within 24 to 48 hours of the onset of infection prevents dissemination and shortens the course of cutaneous disease ([408], [409]). The case-fatality rate for untreated VZV infection is 35%. Primary herpes virus 4 [Epstein-Barr virus (EBV)] does not cause significant disease in HSCT patients ([410], [411] and [412]). Lympho-proliferative disorders after allogeneic HSCT, however, are associated with herpes virus 4 infection of B lymphocytes and loss of herpes virus 4–specific T-cell immunity ([413]). Risk factors for the development of EBV-associated lymphoproliferative disorders are the severity of acute GVHD, type of treatment of acute GVHD, HLA disparity between donor and recipient, and T-cell depletion of the marrow graft. Although this is an infrequent complication, it is often fatal. Patients at high risk for reactivation of herpes virus 4 should be monitored prospectively and considered for preemptive therapy ([414], [415]). Reports of the successful use of B-cell–specific antibodies as prevention after EBV reactivation or induction of remissions of EBV-associated lymphoproliferative disorders have been published ([416], [417]). Reconstitution of EBV-specific cell-mediated immunity may induce remissions in some patients ([418], [419], [420] and [421]). Human herpesvirus 6 (HHV-6) infections have been described more recently in stem cell transplant patients ([422]). HHV-6 DNA can be detected in approximately 60% of patients after HSCT ([423]). Detection of HHV-6 DNA after HSCT is more frequent in patients with moderate and severe acute GVHD. Many patients with reactivation remain asymptomatic ([424]). Primary HHV-6 infections have been associated with self-limited clinical symptoms including fever and rash. HHV-6–associated pneumonitis and encephalitis have been reported ([425], [426] and [427]). However, it is still uncertain if HHV-6 causes pneumonitis. Ganciclovir and foscarnet appear to be effective therapy, but *in vivo* response of HHV-6 to treatment is not well characterized ([427], [428]).

Pneumocystis and Toxoplasmosis Infections

The incidence of *Pneumocystis* pneumonia without prophylaxis is 6.8% ([429]). The incidence may be as high as 28% between 41 to 80 days after HSCT. The mortality rate is 89% for patients who develop *Pneumocystis* pneumonia within 6 months of HSCT. TMP-SMX reduces the incidence of *Pneumocystis* pneumonia to 0.15%. If there is a history of an allergy to TMP-SMX, desensitization of patients should be attempted ([429]). Pentamidine (aerosolized and intravenous) and three times per week dapsone are ineffective for second-line prophylaxis ([430], [431]). Daily dapsone has been shown to be equivalent to TMP-SMX in human immunodeficiency virus–infected patients. Atovaquone may also be effective second-line prophylaxis, but there is still limited experience ([432]).

Toxoplasma infection occurred by reactivation in 1 to 2% of serologically positive allogeneic transplant recipients ([433], [434] and [435]). It was estimated that 15% of patients were seropositive before transplant, but this varies with the geography of the transplant program. The brain, heart, and lungs were the sites most commonly infected. *Toxoplasma* serology should be done routinely before HSCT to identify patients at risk for reactivation. Larger studies of seropositive patients are required to establish effective prophylaxis regimens ([435], [436]).

Immunizations

After the first year, those patients without chronic GVHD are likely to have good responses to influenza, pneumococcal polysaccharide, inactivated polio virus, diphtheria, pertussis, tetanus toxoid, *Haemophilus influenzae* type B conjugate vaccines, and hepatitis B ([437], [438]). Patients who are being treated with

immunosuppressive medications to control chronic GVHD may have an inadequate response after vaccinations, but there may still be a potential benefit, and many transplantation programs are recommending this approach. In patients without chronic GVHD, immunization with a live attenuated measles, mumps, and rubella vaccine can be given safely when administered 2 years after transplantation ([439]).

Gene Therapy for Hematologic Disorders, Human Immunodeficiency Virus Infection, and Cancer

The molecular characterization of a number of congenital and acquired human diseases has stimulated scientists and clinicians to envision genetic therapy as a new and exciting possibility ([1]). The technology has progressed sufficiently to offer real hope for successful widespread clinical application ([2], [3] and [4]). The first replication-defective retroviral vector was described in 1983, offering a safe and feasible route for transfer of exogenous genes to nontransformed human cells ([5]). By 1989 to 1990, clinical studies using gene transfer began ([6], [7] and [8]). Hundreds of clinical trials have been completed or are in progress and are summarized in Table 26.1. However, it is important not to exaggerate the current status of the field, especially to patients. In 1996, an expert panel convened by the Director of the National Institutes of Health (NIH) was critical of the premature initiation of clinical gene therapy trials and the subsequent overselling of results by investigators and the media ([9]). At the time of the report, no clinical gene “therapy” trial had shown unequivocal efficacy. The NIH report and a number of subsequent editorials stressed the need for rationally designed, small-scale clinical trials in diseases for which the pathophysiology is well understood, as well as the more important need for continued basic science investigations into vector systems and target cell biology ([10], [11] and [12]).

TABLE 26.1. Characteristics of Active or Completed Human Clinical Studies

	No. of Protocols	Percent	No. of Patients	Percent
Protocol type				
Cancer	403	63.4	2392	68.5

Laboratory and clinical hematologists have been critical to the development of gene transfer technologies, studying diseases that were early and obvious targets for therapeutic intervention. Hematopoietic stem cells (HSCs) and lymphocytes remain attractive target cell populations for two major reasons: First, they are relatively easy to manipulate *ex vivo*, and, second, many acquired and congenital diseases are potentially curable by their genetic correction ([13], [14]). As shown in Table 26.1, a significant fraction of ongoing human clinical trials target hematopoietic cells or are designed to treat congenital or acquired diseases of the hematopoietic or immune system. Moreover, many important experimental advances in our understanding of hematologic physiology have resulted from the application of gene transfer techniques in animal models or *in vitro* ([15], [16], [17], [18], [19], [20] and [21]). For instance, retroviral tagging has allowed tracking and quantitative analysis of murine and nonhuman primate stem cell behavior, and experiments overexpressing oncogenes or cytokines in primary hematopoietic cells using similar techniques have helped elucidate the *in vivo* role of these proteins. Significant advances in gene transfer technology have occurred since the NIH report, and, through systematic preclinical testing in large animal models, clinically relevant gene transfer levels have now been achieved. These results predict success in humans, at least in disorders for which modest transfer rates of genes not requiring complex regulation could be curative, and unequivocal efficacy has since been realized in a study in which children with X-linked severe combined immunodeficiency (SCID) were treated with autologous bone marrow that had been modified to carry the corrective gene ([22]). A second successful trial in patients with adenosine deaminase (ADA)–deficient SCID was reported soon thereafter, along with an update of the study in X-linked SCID ([23]). These long-anticipated results represented a significant advance for the field, providing not only restoration of immunity in children with this disorder but proof of principle in the context of a human disorder, and a great deal of enthusiasm for returning to the clinic for these and other disorders quickly developed. However, two serious adverse events that appear to be direct results of the transferred gene were reported in the larger trial and resulted in a temporary halt of all such trials to allow full understanding of these events, development of additional safeguards, and adjustment of the risk-benefit assessment in the informed consent process. Thus, it is particularly important for hematologists to have a general understanding of the field, even if widespread clinical applications may be a decade or more in the future. This chapter reviews the fundamental features of gene transfer technologies and their applications in preclinical and early clinical trials. The pace of the field is rapid, and many details may become obsolete, but the central concepts should remain relevant to any future gene therapy applications.

OVERVIEW OF BASIC CONCEPTS

Gene therapy can be defined as the transfer of a gene or genetic material (DNA or RNA) into a cell with therapeutic intent. The *genotype* of the cell is thus altered, with subsequent gene expression altering the *phenotype* of the cell. The therapeutic agent is the gene product, generally a protein or, less frequently, RNA (e.g., ribozymes or antisense molecules). This is in contrast to conventional therapies that act by directly altering the phenotype, even if the congenital or acquired defect is a genetic one. Three examples illustrate the conventional approach to underlying genetic disorders. Dietary avoidance of phenylalanine can prevent the consequences of phenylketonuria by circumventing the genetic deficiency of phenylhydroxylase. Cancer chemotherapy acts by preferentially killing tumor cells based on their cell cycle characteristics, thus removing cells with an acquired genetic defect. And factor replacement in hemophilia directly replaces the defective or missing gene product by infusion of an exogenously manufactured or isolated protein.

The identification and cloning (isolation) of genes responsible for many congenital disorders, as well as of the cellular genes mutated in acquired disorders such as cancer, have led to the concept of genetic correction of affected cell populations. Ideally, actual substitution of a defective gene with a therapeutic gene would be the most desirable method for returning target cells to a normal genotype and phenotype (*gene replacement*). However, this goal requires *homologous recombination*, a complex and inefficient process, and current gene transfer methods instead either randomly insert new genes into the chromosomes or rely on extrachromosomal (episomal) maintenance of a newly introduced gene (*gene addition*) ([24], [25] and [26]). To date, efforts have focused on *somatic* (non–germ cell) therapy, with genotypic alteration of only the diseased target tissue. Manipulation of germ cells, with transmission of altered genetic material to subsequent generations, is not yet feasible in humans, but the profound ethical and societal implications need to be addressed through the political process before the technology progresses much further ([27]).

The vehicle for transferring new genetic material into a target cell is called a *vector*. At a minimum, a vector contains the gene or genes of interest along with regulatory elements such as promoters or enhancers, which govern expression of the gene product. A vector may be a simple particle consisting of a fragment of DNA encapsulated within a liposome or conjugated to proteins that facilitate uptake into cells, or it may be a more complex viral vector, capitalizing on the ability of viruses to enter cells easily and express genes robustly. Characteristics of the major vector systems are summarized in Table 26.2 and Figure 26.1 and are detailed in subsequent sections. The successful interaction of a vector with a target cell, leading to an alteration in that cell's genotype, is termed *transduction*.

TABLE 26.2. Gene Transfer Vector Systems

Vector System	Integration	Cell Cycle Dependence	Insert Size Limit	Clinical Experience	Advantages	Disadvantages	Major Applications
Murine retrovirus	Yes	Yes	8–10 kb	Extensive	Stable producer lines, no viral genes in vector, low immunogenicity, well-understood biology, efficient entry and integration in many cell types, proven clinical safety	Low-titer, fragile vector; requirement for cycling; erratic expression; insertional mutagenesis	*Ex vivo*: stem cells, lymphocytes, tumor cells, hepatocytes, myoblasts. *In vivo*: producer cell or vector injection into tumors.

HIV-based lentivirus	Yes	No	—	None	Faithful delivery of complex genes, well understood, efficient entry and integration, pseudotyping allows broad tissue range	Labor-intensive production, erratic expression, insertional mutagenesis, recombination with wild-type HIV	*Ex vivo*: stem cells, lymphocytes, tumor cells, nondividing cells.
Adenovirus	No	No	8–10 kb	Moderate	High-titer, stable vector; transgene expression; efficient entry into many cell types	No stable producer lines; potential for recombination and replication-competent virus; multiple viral genes expressed from vector; high immunogenicity (may be advantage as a vaccine vector!); preexisting immunity; inflammatory responses	*In vivo*: pulmonary epithelium, tumor cells, muscle, liver.
Adeno-associated virus	Yes, but inefficient	Yes, but controversial	4.5 kb	Minimal	High-titer, stable vector, extra- and intracellularly; high-level transgene expression; no expressed viral genes in vector	No stable producer cell lines, high percentage of defective particles, requirement for helper adenovirus during production, very limited insert size, preexisting immunity	Undefined.
Naked DNA	No	No	No limit	Moderate	Ease of production, high level of safety, no extraneous expressed vector genes, no immunogenicity of vector	Inefficient cell entry and uptake into nucleus, poor stability within cell, low-level expression	*In vivo*: Tissues accessible to injection, for transient expression or vaccination.
Facilitated DNA (liposomes, polylysine conjugates, inactivated adenovirus, etc.)	No	No	No limit	Moderate	Same as naked DNA, plus can be targeted to specific cell types, more efficient uptake and intracellular stability	No mechanism for persistence	Same as naked DNA, plus *in vivo* tumor cells, vascular endothelium.

HIV, human immunodeficiency virus.

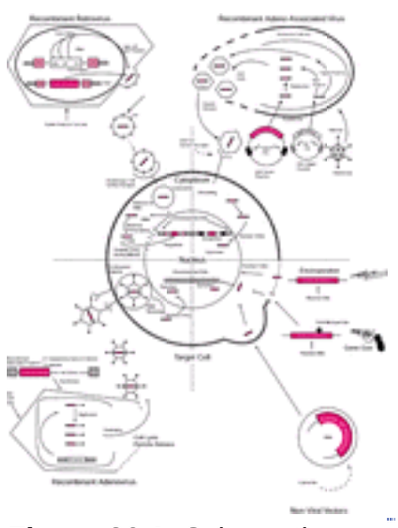

Figure 26.1. Schematic representation of transduction of a generic target cell by the four major gene transfer vector systems. The same “gene of interest” is shown being transferred with each vector. AAV, adeno-associated virus; Ad, adenovirus; ITR, inverted terminal repeat; LTR, long terminal repeat.

Vector production procedures are unique to each system, but a number of considerations are common to all, especially those being developed for actual clinical use. A clinical vector must be easy and inexpensive to produce safely at pharmaceutical grade ([28], [29]). To prevent indiscriminate spread of viral genomes, viral vectors must be rendered *replication-defective*: Once a viral vector enters a target cell, the cell will produce no new viral particles. High-titer vector preparations, containing a high concentration of functional vector particles, are also very important, allowing exposure of target cells to the highest possible *multiplicity of infection*, defined as the ratio of vector particles to target cells; this increases the probability of successful vector–cell interaction.

Exposure of target cells to vectors can occur either *ex vivo* or *in vivo*. Autologous hematopoietic targets, such as stem cells or lymphocytes, are generally transduced *ex vivo*, because these cells can be easily collected, manipulated in culture, and then reinfused intravenously. *Ex vivo* transduction allows for a controlled exposure of only the desired target cells to large concentrations of vector and is less likely to generate an inflammatory or immune response or be hindered by vector inactivation by complement. Other cellular targets for *ex vivo* transduction have included hepatocytes, keratinocytes, tumor cells, and muscle progenitor cells.

In vivo gene transfer has been used for applications involving cells that cannot successfully or easily be harvested and manipulated *ex vivo* such as airway epithelium, vascular endothelium, differentiated muscle cells, and neurons. The ideal *in vivo* system would allow intravenous injection of a vector followed by rapid and safe specific transduction of target cells around the body.

A number of important steps must occur between exposure of a target cell to a vector and successful transduction of that cell, with persistence of the transferred genetic material in the correct cellular compartment and expression of the gene of interest or *transgene*. The vector must cross the plasma membrane efficiently and without damaging the cell. Viral vectors enter cells via specific cell-surface receptors, and an important consideration is the number of functional receptors on the proposed target cell for the vector being used ([30]). A process called *pseudotyping* can be used to redirect viral vectors to different cell-surface receptors by substituting alternative viral envelope proteins during the vector production process ([31], [32], [33] and [34]). Nonviral vectors may cross the plasma membrane without need for a specific receptor.

After crossing the plasma membrane, the vector must then travel through the cytoplasm and cross the nuclear membrane to enter the nucleus and use the cell's transcriptional machinery for expression of the transgene. Nuclear entry of some vectors may be dependent on mitosis, with temporary breakdown of the nuclear membrane; others carry nuclear localization determinants that result in specific conveyance across the intact membrane. The transferred genetic material may integrate permanently into the target cell's own chromosomal DNA, ensuring passage of the new gene to all daughter cells with every cell division. The need for integration depends on the target cell and therapeutic application: It is absolutely required for gene transfer into HSCs in which the transgene must be transmitted to all progeny cells but is superfluous for cellular targets such as neurons or muscle cells that are not mitotic.

Current vector systems insert new genes randomly or semi-randomly within cellular chromosomes, but integration at a specific site would be more desirable ([35], [36] and [37]). Random integration has the potential to alter the function or expression of endog-enous cellular genes, a process termed *insertional mutagenesis* ([38]). The insertion of new DNA could interrupt a critical cellular gene, although this is unlikely because of the relative rarity of actual coding compared to noncoding sequences in the genome and because of the presence in each cell of two copies of all genes except those on the sex chromosome. More worrisome, instead, is inappropriate activation of a cellular gene involved in growth control. For instance, cellular oncogenes such as *c-myc* can be transcriptionally activated due to the insertional event. In the mouse, this is the mechanism of leukemia induction by the murine viruses that are used as backbones for gene transfer vectors ([39]).

Alternatively, the gene may remain *episomal*, or nonintegrated. Some vectors are very stable as nuclear episomes, with prolonged persistence of transgene expression as long as the cell does not undergo mitosis. Unless the episome can reproduce itself, cell division eventually dilutes out episomal DNA, limiting the

application of nonintegrating vectors to nonmitotic tissues or to situations requiring only transient expression.

The level of transgene expression and the ability to restrict expression to specific target cell types are also important factors to consider. Expression of the transduced gene is dependent on both vector and target cell determinants. Transcriptional promoters must be included along with the actual transgene protein coding sequences in the vector, and often *lineage* or *tissue-specific* promoter and enhancer elements are used to limit expression to a particular cell lineage derived from a target cell population ([40], [41] and [42]). For instance, hemoglobin gene regulatory sequences can be used to drive transgene expression specifically in erythroid cells. In other situations, *constitutive* control elements that can drive transcription continuously in most cell types can be used. Genetic control elements that are *inducible*, or turned on by some exogenous manipulation, such as the administration of an antibiotic, are also under development for inclusion in gene transfer vectors ([43], [44]). Endogenous cellular factors may shut off expression of transferred genes in some situations ([45], [46]). These factors have not been fully elucidated and vary from vector to vector. Silencing of transferred genes via methylation of vector sequences is one possible mechanism ([47]). The level of expression necessary for the desired therapeutic effect is very important to determine during *in vitro* and animal experiments and varies greatly depending on the target cell type and the proposed clinical application.

NONVIRAL VECTORS

The simplest approach to gene transfer is to use only the DNA of the transgene, with the necessary control sequences, as the vector ([29], [48]). Recombinant DNA production in bacteria can result in purified plasmids containing the gene(s) of interest along with regulatory elements. For over two decades, scientists have introduced purified DNA into target cells *ex vivo* by a variety of physical and chemical means. The least complex technique is direct microinjection into individual cells, which has little clinical utility due to the impossibility of injecting enough cells to produce most of the desired effects. One exception is the recent observation that direct DNA injection into muscle or skin can stimulate a very potent immune response against antigens introduced as plasmid transgenes ([49], [50]). This has led to rapid preclinical and recent clinical development of a genetic vaccination strategy against bacterial and viral pathogens ([51]).

A number of other methods have been explored for getting plasmid DNA into cells. Liposomes, composed of phospholipid bilayers enclosing an aqueous space loaded with DNA, can directly fuse with the plasma membrane, releasing DNA into the cytoplasm ([52]). The *gene gun technique* involves bombardment of the cell membrane with gold microparticles complexed to DNA ([53], [54], [55], [56] and [57]). Electroporation and calcium phosphate precipitation are generally too toxic and inefficient for use in gene transfer strategies aimed at primary human cells ([58], [59] and [60]).

All of these methods lack mechanisms to stabilize intracellular vector DNA, nor do they allow transport into the nucleus; they therefore rarely result in chromosomal integration or long-term persistence and expression. The development of *cationic liposomes* has improved cellular uptake of plasmid DNA and has circumvented cytoplasmic degradation ([61], [62]). In aqueous solution, these positively charged liposomes bind with up to 100% of negatively charged DNA without size restrictions and can deliver DNA to the cell nucleus, albeit inefficiently, where it remains primarily episomal ([63]). If administered *in vivo*, liposomes demonstrate no target cell tropism and are rapidly cleared by the reticuloendothelium system. However, after intravenous injection of cationic liposomes, long-term low-level persistence of vector sequences in many murine organs has been demonstrated ([64], [65]).

Nonviral plasmid DNA transfer has been improved by conjugation of vector DNA to substances that improve cellular transport and allow target cell specificity via cell-surface receptors ([66], [67]). For example, adenoviral capsid elements (especially the penton base protein) help disrupt endosomes, releasing DNA more efficiently into the cytoplasm, and inclusion of transferrin or other ligands in DNA-polylysine conjugates allows specific uptake via cell-surface receptors ([68], [69], [70], [71] and [72]).

Manufacturing nonviral vectors is much simpler than manufacturing viral vectors and cannot generate potentially dangerous replication-competent infectious particles ([29], [73]). Transduction is not dependent on target cell cycling, and no viral proteins are present to induce an antivector immune response. There are no size constraints. Limitations include a generally lower transduction efficiency than that of viral systems. Most important is the fact that transgene integration is poor and persistent expression is rare, limiting utility to situations allowing transient transgene expression.

VIRAL VECTORS

Viral vectors are Trojan horses, taking advantage of the viral capsid or envelope and of the viral machinery to deliver nonviral transgene sequences efficiently to target cells ([74]). In general, the external capsid or envelope of the virus is unaltered in a viral vector, but the genome of the virus is in large part replaced by a transgene or genes. This strategy is limited by the space available in a viral particle for new genetic material. Viral vectors also depend on the presence of a specific viral receptor on target cells. The efficiency of gene transfer is the main advantage when compared to some of the physical and chemical cell entry methods described above. Furthermore, the relatively low toxicity of certain viral vectors [e.g., retroviruses, lentiviruses, and adeno-associated viruses (AAVs)] is another advantage when compared to physical or chemical methods. To modify a virus into a vector system, detailed understanding of the viral genome and life cycle is necessary to retain viral genome sequences required for packaging of vector nucleic acids into viral particles and for appropriate trafficking in the target cell, while removing sequences that might allow production of replication-competent viral particles.

Retroviral Vectors

The murine retroviruses exemplified by the Moloney murine leukemia virus were the basis of the first practical viral vector system ([75], [76] and [77]). These retroviruses consist of two single strands of linear viral RNA bound to protein core and coated by a lipid envelope that is acquired from the plasma membrane of the infected cell on viral release. The linear RNA genome can contain 2 to 9 kb of coding and regulatory sequences, flanked on each end by sequences termed *long terminal repeats* (LTRs) that permit integration into chromosomes. These retroviruses contain only three genes necessary for viral replication and packaging: *gag*, *pol*, and *env*. The retrovirus enters a cell after binding to a specific cell-surface receptor via the *env* gene product. These receptors are large, widely expressed proteins involved in phosphate transport and other cellular homeostatic functions ([30]). The *amphotropic receptor* is found on both rodent and primate cells and is the entry site for most murine retroviral vectors directed at human cells ([78], [79] and [80]).

After cell entry, the viral RNA is reverse transcribed via the *pol* gene product into *proviral* complementary DNA (cDNA) and enters the nucleus. The LTR sequences allow random integration of the viral cDNA into the host chromosomes. The integrated retroviral genome, or *provirus*, relies on the host cell's transcriptional machinery for expression of proviral genes and production of full-length viral RNA. The *gag*, *pol*, and *env* gene products are packaged along with the new viral RNA into viral particles, dependent on the presence of a *packaging* (?) sequence in the viral RNA, and viral particles are released from the cell via budding through the plasma membrane without damaging the infected cell.

Recombinant retroviral vectors are constructed by removing the *gag*, *pol*, and *env* gene sequences from the viral nucleic acid backbone and replacing them with up to 7 to 8 kb of a gene or genes of interest, retaining only the LTRs and the ? signal ([5]). The resulting recombinant viral vector can integrate and express the gene or genes of interest but cannot replicate and produce new retrovirus once within a target cell because of the lack of *gag*, *pol*, and *env* genes within its genome. Thus, it is termed *replication defective*. Figure 26.1 diagrams the steps involved in making a retroviral vector. A *packaging cell line* is created by introducing a plasmid containing *gag*, *pol*, and *env* sequences but no ? sequence into an immortalized cell line such as NIH3T3. The lack of the ? sequence prevents these helper genes from being packaged into viral particles. A second plasmid containing the recombinant vector sequences (LTRs flanking the transgene or genes) is then introduced into these cells to create a *producer cell line*. Full-length vector RNA is transcribed from the vector plasmid sequences and packaged into viral particles using the *gag*, *pol*, and *env* proteins encoded by helper plasmid sequences. In this way, producer cell lines release helper-free, replication-defective vector particles containing the recombinant genome into cell culture media at a titer of up to 10^7 particles per ml. These particles contain the full-length vector RNA, consisting of the viral LTRs flanking the transgene or genes and the *env*, *gag*, and *pol* proteins, but, because they do not contain any actual gag, pol, or env viral gene sequences, no further infectious virus can be made once the vector infects the target cell.

The potential for generation of replication-competent virus through recombination events between the vector and helper sequences in the producer cell line is a significant safety concern ([28], [81]). To allow packaging of replication-competent viral particles, these recombination events must result in the transfer of an intact ? packaging sequence being transferred into the helper sequences containing the gag, pol, and env genes. The presence of replication-competent virus could allow spread of vector and helper particles indiscriminately to nontarget cells *in vivo*, thus greatly increasing the risk of insertional mutagenesis by repeated infection of susceptible cell populations ([38], [81]). The absolute need for avoidance of replication-competent viral particles in clinical vector preparations was inadvertently demonstrated when high-grade lymphomas occurred in rhesus monkeys transplanted with HSCs transduced with a vector preparation contaminated with high levels of

replication-competent virus ([82]). Over the next several years, a number of modifications in the organization of genetic sequences included in the packaging cell lines have greatly decreased the risk of recombination events, and sensitive systems for detecting replication-competent virus have been developed ([28] , [83] , [84] and [85]). A number of investigators have used packaging cell lines derived from human instead of murine cells to make producer cell lines, in hopes that lower levels of endogenous retroviral sequences in human cells would also decrease recombination events and thus replication-competent viral contamination ([86] , [87]).

As described below, retroviral vectors are capable of stable integrated transduction of a large number of cell types, including repopulating stem cells, but have a number of important limitations. Stable transduction and integration require passage of the target cell through the S-phase of the cell cycle, preventing transduction of quiescent cells ([88]). The amphotropic receptor density on certain target cell types may be too low to allow efficient transduction ([89]). Thus, redirection of receptor specificity via pseudotyping with alternative envelope proteins has been explored, with some success ([32] , [90] , [91] , [92] , [93] and [94]).

Biophysical considerations may also limit vector–target interactions. Vector particles are very fragile and degrade quickly in solution or within cells if cell division allowing nuclear entry and integration does not occur. A number of investigators have tried to increase the likelihood of successful transduction by flowing vector solution continuously over target cells or by co-localizing vector and target cells using culture dishes coated with fibronectin fragments ([95] , [96]). New methods of concentrating and stabilizing vector preparations are also under development ([33] , [91] , [97]).

Alternative Retroviral Vectors

Over the past several years, there has been real progress toward the development of alternative retroviral systems that may overcome some of the limitations of the murine leukemia virus vectors. Human immunodeficiency virus (HIV)–derived lentiviral vectors have been most actively pursued. Relatively high-titer vectors have been reported using production strategies with numerous safeguards against recombination events that could result in generation of wild-type HIV ([98] , [99] and [100]). Vectors retaining the HIV gp120 envelope protein could be used to transduce CD4 $^{+}$ T cells, monocyte/macrophages, or glial cells, whereas pseudotyping with alternative envelope proteins, such as vesicular stomatitis virus (VSV) or amphotropic leukemia virus envelope proteins, could be used for transduction of a wider range of cells. Lentiviral vectors can traverse an intact nuclear membrane, requiring the HIV *gag* protein and an accessory VpR protein, thus allowing transduction of nondividing cells ([101] , [102]). Although the promise for more efficient HSC transduction using lentiviral vectors remains an attractive feature, other features of HIV-based vectors have also stimulated interest. Specifically, the faithful delivery of nonrearranged genes with complex regulatory elements appears superior, and success in delivering the human ß globin gene along with large portions of the locus control region has finally been achieved with HIV-based vectors ([103]). A number of additional safety modifications have been used, the first clinical trial using lentiviral vectors for the treatment of HIV was proposed to the Recombinant DNA Advisory Committee, and additional concerns were raised to the investigators before approval ([104]). The protocol has now been granted permission to proceed, and the first patients to receive lentiviral vector–transduced cells are now accruing. Despite the many safety modifications built into these systems to avoid generation of replication-competent HIV virus, the development of vectors based on nonhuman or less pathogenic lentiviruses would be much more desirable ([105]).

The other member of the Retroviridae under consideration as a gene transfer vector is the human foamy virus (HFV). HFV, a poorly characterized retrovirus, has three potential advantages. It has never been associated with pathology in animals or humans, it infects a wide variety of primate cell types, and it has the capacity to package longer transgene(s) ([106]). It does not appear, however, to transduce nondividing cells, although it may be more stable than conventional retroviruses within a target cell, tolerating a more prolonged period before cell division and then integration ([107]). Virologists are trying to define the packaging signal and other important elements necessary for engineering a replication-incompetent HFV vector ([108] , [109]), and a method for the production of helper-free vector stocks has recently been described ([110]). These foamy virus vectors appear efficient for transducing HSCs, with high gene transfer rates observed in human cord blood *in vitro* and in murine bone marrow *in vivo* after a single, overnight vector exposure ([111]).

Adenoviral Vectors

Adenoviruses (Ad) are nonenveloped, double-stranded, large DNA viruses ([112]). The linear Ad genome contains 36 kb with an inverted terminal repeat (ITR) of 100 to 165 bp at each terminus. A set of early genes encodes for regulatory proteins that serve to initiate cell proliferation, DNA replication, and down-modulation of host immune defenses, whereas the late genes encode for structural proteins. The Ad readily cross the plasma membrane of many cell types, whether replicating or not, via receptor-mediated endocytosis ([113]) through the receptor that is common to two distinct viral pathogens, coxsackie B and Ad 2 and 5, and termed the *coxsackie and adenovirus receptor* ([114]). The adenovirus escapes the endosome by altering the pH and then enters the nucleus, where it remains as a linear episome. In permissive cells, the Ad replicate and then enter a lytic cycle, destroying the host cell and releasing daughter viral particles. Of the 42 Ad serotypes, most are known to cause mild respiratory, gastrointestinal, and conjunctival infections in immunocompetent humans; no associated malignancies in humans have been reported, although some serotypes can transform cells in culture.

Recombinant Ad vectors have been engineered from adenovirus (usually serotype 5) by the removal of the E1 and E3 genes (regulating replication and immune recognition) and replacement by the gene or genes of interest, with space for 7 to 8 kb of new genetic material ([115] , [116] , [117] , [118] and [119]). High-titer Ad vector, up to 10^{12} plaque-forming units per ml, can be reliably packaged through the use of a human embryonic kidney transformed cell line ([293]), which provides the helper or replication E1 genes, followed by purification and concentrating procedures. The final product is a replication-defective Ad vector that is free of helper- or wild-type virus that can efficiently transduce nondividing cells ([117]). These vectors do not integrate into the target cell genome, avoiding insertional mutagenesis and resulting in only transient transgene expression in proliferative tissues. Because of the tropism of Ad for epithelial cells, these vectors were initially investigated for the treatment of pulmonary diseases and diseases in which liver gene transfer is desirable ([120] , [121]).

Transient transgene expression also may result from host cellular and humoral immune responses directed at either transgene-encoded antigens or adenovirus proteins expressed from the large portions of the Ad genome retained in these vectors ([122] , [123]). Another concern is inflammation resulting from *in vivo* transduction of certain cell types, especially airway epithelium ([124]). *In vivo* use may also be compromised by preexisting or new antiviral neutralizing antibodies, limiting the efficacy of repeated dosing, which may be required for applications directed at mitotic tissues ([125]). Nonessential adenoviral sequences are being gradually eliminated from the vectors ([126] , [127]). Specific dosage schedules (e.g., neonatal or embryonic exposure) or coadministration of immune modulators such as cyclosporine or interleukin (IL)-12 may also prevent sensitization ([128] , [129] , [130] , [131] and [132]).

In initial clinical trials, Ad vectors were used to transfer a normal cystic fibrosis transmembrane conductance regulator gene into airway cells (bronchial or nasal) of patients with cystic fibrosis ([133] , [134] and [135]). Despite the demonstration that airway cells could be transduced with these vectors *in vivo* with correction of the chloride transport defect, clinical utility has been precluded by the harmful immune and inflammatory responses noted above. However, the active immune response induced by adenoviral vectors is also being explored as a possible advantage when Ad vectors are used to transduce tumor cells with cytokines or other immune modulators for tumor vaccine protocols ([136] , [137] and [138]). The fact that most adenoviral gene transfers result in transient transgene expression (in contrast to retroviral-mediated gene transfer) has limited their use for congenital diseases in which permanent expression of a missing protein is desirable, such as hemophilia, ornithine transcarbamoylase (OTC) deficiency, or a $_{1}$-antitrypsin inhibitor deficiency. Nevertheless, because removal of most (if not all) adenovirus genes seems to prolong transgene expression, repeat administration might become feasible should the interval be sufficiently long to allow practical clinical application.

Adeno-Associated Viral Vectors

AAVs are small, nonenveloped, single-stranded DNA viruses in the parvovirus family, Dependovirus subfamily, that require a helper virus (adenovirus or herpes simplex virus) for production of new viral particles ([139] , [140] and [141]). The linear AAV genome is approximately 4.7 kb long and consists of two homologous ITRs of 145 bp flanking two groups of genes: the *rep* or nonstructural genes and the *cap* or structural genes. The AAV cell-surface receptor has not been identified, but AAV is known to bind to and infect a wide variety of human cell types ([142]). There are at least five serotypes of AAV, of which AAV-2 is the best characterized. AAV has oncoprotective and HIV-suppressive properties and is not known to cause disease in humans or other animals ([143] , [144] and [145]). Prior infection with AAV in humans is common: Seroepidemiologic studies demonstrate that 80% of the adult population has antibodies ([140] , [146]).

In the absence of helper virus, internalization occurs via interaction with heparan sulfate on the surface of the target cell and the capsid protein. Subsequently, AAV integrates within the host chromosome ([147]). Integration of multiple copies in tandem occurs in a site-specific manner within a relatively small area on chromosome

19; this site specificity appears to require rep protein ([148], [149]). Specifics of replication and integration are less well understood than for retroviruses.

Recombinant AAV vector DNA contains the AAV ITRs flanking a gene of interest, replacing the *rep* and *cap* genes. This plasmid is introduced into a cell line permissive for adenovirus, along with a helper plasmid containing the AAV *rep* and *cap* genes but no ITRs. On exposure to adenovirus or transfection with adenovirus genes such as E4 (particularly open reading frame 6), the cell line packages the recombinant vector sequences using the *rep* and *cap* gene products produced by the helper plasmid, and recombinant vector particles are released as the producer cell lyses ([150], [151], [152], [153] and [154]). Recombinant AAV vectors have size constraints: Vector sequences longer than 115% of the wild-type length are not packaged or encapsidated efficiently. Very high titers of recombinant AAV particles can be produced, but often a significant percentage are empty capsids or otherwise defective vector particles.

The need for live adenovirus during AAV vector production complicates the manufacturing and safety issues, because the adenovirus must be inactivated or removed before use. Some progress is being made toward introducing only the specific adenovirus genes necessary for AAV replication into producer cell lines, avoiding live adenovirus. The inability to harvest AAV vector without actual lysis and death of the producer cells also complicates production of pure and defined vector preparations. Generation of stable packaging cell lines is also hindered because the AAV *rep* gene product harms most cell types, but, recently, producer cell lines expressing *rep* from an inducible promoter have been isolated ([155]).

Integration of the recombinant vectors into target cell chromosomes appears to be very inefficient, and thus these vectors prove more useful in situations not requiring integration, because they have been shown to be stable as episomes for long periods ([154], [156], [157]). Site-specific integration in chromosome 19, which is very desirable to avoid random insertional mutagenesis, does not occur with the recombinant AAV vectors, presumably due to lack of rep protein in the vector particle ([157]). Many cell types can be efficiently transduced, including nondividing cells such as neurons, but integration and increased efficiency of transduction still appear to depend on cell division or other DNA-disrupting events, although this conclusion is very controversial ([158], [159], [160], [161] and [162]).

It is possible that a number of other parvoviruses can be developed as vectors, including AAV-3, nonpathogenic strains of B19, or novel autonomous parvoviruses isolated from nonhuman primates or other animal species ([163], [164] and [165]). These viruses are similar to AAV, but some, such as B19, never integrate.

Miscellaneous Other Vectors

Herpes viruses are large DNA viruses with marked neurotropism and are generating intense interest in their potential as vectors targeted at the nervous system ([166], [167], [168] and [169]). They can accommodate very large DNA sequences (up to 30 kb). More recently, these vectors have been reported to transduce some types of hematopoietic cells, including monocytes, leukemic blasts, and progenitor cells ([170], [171]). However, these vectors result in only transient expression in dividing cells and cause cytotoxicity, limiting clinical utility, at least for hematologic applications.

Vaccinia virus, a large DNA virus that replicates cytoplasmically, has also been considered for gene therapy applications ([172], [173]). It can accommodate very large transgenes (up to 30 kb) and expresses these genes at very high levels, but expression is transient, and production of replication-incompetent vectors has not yet been possible. Very high immunogenicity limits most clinical applications but may be advantageous for *in vivo* vaccination with vaccinia-transduced tumor cells ([173], [174], [175] and [176]).

HEMATOPOIETIC STEM AND PROGENITOR CELLS AS TARGETS FOR GENE TRANSFER

After the development of helper-free retroviral gene transfer technology more than two decades ago, the HSC has been a primary target for gene therapy applications. The curative potential of HSCs carrying corrective genes has been well established through the use of allogeneic bone marrow transplantation (BMT) in genetic disorders whereby an individual carrying a normal genotype serves as the stem cell donor, yet procedural toxicities and finite donor availability limit this approach. The prospect of a curative, one-time therapy using genetically modified autologous stem cells for the treatment of a wide variety of congenital disorders such as hemoglobinopathies, immunodeficiencies, or metabolic storage diseases and of a new weapon against malignancies and HIV infection has proven irresistible ([13], [14], [177], [178], [179] and [180]). Gene therapy directed at the HSC must use an integrating vector, because ongoing self-renewal or proliferation/differentiation would rapidly dilute out an episomal vector in daughter cells. Thus, the vast majority of preclinical and clinical research in this field has used retroviral vectors. Some of the alternative vector systems described above, including HIV and AAV, continue to be developed and tested in hematopoietic cells.

Although efficient, reproducible gene transfer to long-term repopulating stem cells in rodents has been achieved, studies in larger animals and humans have been largely disappointing ([14], [180]). Clearly, better knowledge of stem cell biology and perhaps development of alternative vector systems may be necessary for clinical progress on a large scale. Diseases such as SCID, in which modest correction levels can revert the phenotype, have appropriately remained a focus, yet application to conditions such as sickle cell anemia, which require higher levels of regulated, lineage-specific gene expression, remains further from reach. Nevertheless, progress has been achieved at all levels of gene transfer, and promise remains.

Preclinical Studies and Predictive Models

First reported in 1984, retroviral gene transfer into murine hematopoietic repopulating stem cells has become routine in many laboratories ([181], [182] and [183]). The isolation and availability of various hematopoietic growth factors have allowed *ex vivo* maintenance and increased retroviral gene transfer into hematopoietic target cells. Several different combinations of growth factors have been successful, including at least two or three cytokines active on primitive cells such as IL-3, IL-6, and stem cell factor (SCF). Their mechanism of action probably includes both induction of cell cycling, a necessity for retroviral transduction and integration, and up-regulation of retroviral cell-surface receptors ([89], [184], [185], [186], [187] and [188]). Other manipulations found to increase gene transfer efficiency to murine stem cells include co-culture of target cells directly on a layer of retroviral producer cells, use of high-titer (>10^5 viral particles per ml) vector, induction of stem cell cycling by pretreatment of donor mice with 5-fluorouracil, and co-localization of vector and target cells using fibronectin-coated culture dishes ([96], [186], [189], [190] and [191]). Using these techniques, successful gene transfer can now be achieved in virtually all mice transplanted with transduced syngeneic bone marrow stem cells, with long-term persistence of the vector sequences in 10 to 100% of cells from all hematopoietic lineages ([186], [187], [189], [190], [192]). The continued presence of vector sequences in short-lived granulocytes for the lifespan of the mouse and in multiple lineages of the blood of serial transplant recipients indicates that murine repopulating stem cells can be successfully modified with retroviral vectors ([15], [17], [187], [193], [194] and [195]). Insertion site analysis documenting the shared single-cell ancestry of gene-modified cells from different lineages has also supported this contention.

Despite the ability to produce mice with a high percentage of gene-modified circulating hematopoietic cells, actual levels of expression from the transgenes have often been quite low. Although high-level production of clinically relevant gene products, such as glucocerebrosidase, has been demonstrated for over 12 months in multiple lineages, other genes and retroviral vector constructs have resulted in extinction of vector-encoded gene expression over time, despite the persistence of the proviral sequences in the genome ([187], [192], [196], [197], [198] and [199]). Gradual methylation of transcriptional control sequences in the vectors has been found to correlate with decreased expression in some mouse cell types and may be overcome by use of stronger promoters within the vector, instead of relying on the viral LTR for transcription ([47], [200], [201]).

Selection for more primitive cell populations by exposure of whole bone marrow to antibodies directed against cell-surface antigens found only on primitive cells, such as CD34, followed by flow cytometric sorting or immunoabsorption allows isolation of the 1 to 5% or less of total cells that are $CD34^+$. This procedure greatly enriches for progenitor cells while retaining reconstituting activity in clinical transplantation protocols ([202], [203], [204] and [205]). Purification of $CD34^+/CD38^-$ or $HLA\text{-}DR^-$ populations may further enrich for stem cells ([206], [207]). However, some stem cells may be $CD34^-$, calling into question the use of purified cells for gene transfer and other applications ([208], [209] and [210]). The use of purified target cells permits more practical *ex vivo* transduction culture volumes and higher vector particle to target cell ratios (multiplicity of infection), possibly improving transduction efficiency ([46], [211], [212], [213] and [214]). Given their phylogenetic proximity to humans, nonhuman primates have been used most extensively for the preclinical testing of promising gene therapy strategies ([215]). The cross-reactivity of reagents used for human application adds to the practicality of these models. Long-term persistence of vector sequences in the nonhuman primate was first demonstrated in 1989 after infusion of marrow cells transduced with a very high-titer retroviral vector producer cell line secreting greater than 10^8 to 10^9 viral particles per ml of culture media ([216]). However, recombination between vector and helper sequences in the producer line resulted in the generation of replication-competent helper virus, and high-grade T-cell lymphomas arose due to insertional mutagenesis in three of the recipient animals, underscoring the importance of large animal preclinical testing ([82], [217]). This

setback led to a reassessment of safety issues and increased regulatory oversight of human clinical trials, with consensus that it is absolutely necessary to use producer cell lines and vector stocks that have been confirmed to be helper-free in any clinical application ([82]). In subsequent rhesus studies using helper-free vectors, two laboratories showed long-term genetic modification of multiple hematopoietic lineages using a number of different retroviral vectors. These successful transductions were all carried out in the presence of hematopoietic cytokines, using unpurified or CD34-enriched target marrow or mobilized peripheral blood cells. Much lower levels of gene-modified circulating cells than in the murine experiments were reported, generally less than 0.01 to 1.00% ([216] , [218] , [219] and [220]). Transduction in the presence of a cell line engineered to express a transmembrane form of human SCF resulted in animals with long-term levels of up to 4% gene-modified cells ([216]). Prolonged expression of vector-encoded murine ADA at 3 to 5% of endogenous rhesus ADA activity was also documented. Long-term expression of vector human glucocerebrosidase RNA in rhesus recipients has been reported ([220]). Subsequently, peripheral blood progenitor cells mobilized by granulocyte colony-stimulating factor (G-CSF) and SCF or bone marrow cells collected 2 weeks after a short G-CSF/SCF treatment period showed improved retroviral susceptibility, with over 5% positive circulating cells confirmed for the first time in a large animal by genomic Southern blotting as opposed to the less quantifiable polymerase chain reaction (PCR) analysis ([221]).

Optimization of retroviral gene transfer techniques using primary human hematopoietic cells has largely relied on *in vitro* progenitor cell assays, including short-term progenitors such as colony-forming units (CFU) or even more primitive cell populations such as long-term culture-initiating cells, yet these assays proved to be inadequate surrogates for true stem cell activity ([222] , [223] , [224] and [225]). Despite efficient gene transfer to these progenitor cell populations, circulating levels of vector-containing cells in early trials in humans undergoing autologous transplantation with bone marrow– or peripheral blood–derived progenitor cells genetically modified using marker genes were too low to predict clinical benefit, requiring highly sensitive PCR-based techniques for detection ([226] , [227] , [228] and [229]). Indeed, early human clinical gene therapy trials for disorders such as SCID and Fanconi anemia (FA) also produced only modest levels of engraftment, and clinical benefit could not be convincingly ascribed to the use of genetically modified cells in either setting ([230] , [231]). A number of important plausible explanations for the poor results include loss of stem cell activity by forced *ex vivo* division, immune recognition of cells expressing foreign transgene products, and toxicity from the constitutive expression of the transferred gene products on HSC differentiation *in vivo*, along with the lack of conditioning in the clinical settings; these were among the questions to be addressed before returning to the clinic.

Large animal models thus became a focus, but outbred animals introduce significant experimental variability, and the high costs limit the breadth of experiments that can be performed. For this reason, a competitive repopulation model in which each animal serves as its own control has been used for the majority of subsequent comparative studies. In this model, hematopoietic progenitors are isolated and divided equally for transduction under two (or more) distinct experimental conditions using marking vectors that can be distinguished *in vivo* after reconstitution. Loss of stem cell activity during the *ex vivo* culture required to achieve gene transfer was a major concern generated by the early human clinical trials, a concern supported by studies in the mouse in which *ex vivo* culture of HSCs resulted in a significant engraftment defect ([232]). Competitive experiments in the nonhuman primate tracking genetically modified cells subjected to either short or extended *ex vivo* culture supported this notion ([233]). The advent of newly characterized hematopoietic growth factors, however, allowed improved gene transfer rates to cells in short-term culture, especially with the inclusion of Flt-3 ligand. The use of autologous stroma or extracellular matrix proteins, such as the CH-296 fibronectin fragment, was associated with further improvements, allowing even extended culture and *ex vivo* division without apparent loss of stem cell activity ([233] , [234] , [235] and [236]). The low-level expression of the amphotropic receptor required for standard retroviral vectors on HSCs ([89]) has stimulated interest in exchanging or pseudotyping with alternative envelope proteins, including the gibbon ape leukemia virus (GALV) ([94]), VSV-G ([237]), and the feline endogenous retrovirus (RD114) ([93]), as a means to further increase gene transfer efficiency. By systematically comparing these and other modifications to retroviral transduction methods, clinically relevant levels of genetically modified cells have been reached, with stable levels of 5 to 10% or higher now achievable ([233] , [234] and [235]).

Establishing that transduction of the true HSC has been achieved, however, requires further evidence: rescue from lethal irradiation and long-term contribution by and pluripotency of the genetically modified product. The long-term persistence of vector in short-lived granulocytes along with the presence of vector in multiple hematopoietic lineages suggested successful stem cell transduction. The finding of common integration sites among myeloid and erythroid colonies as well as in peripheral blood T- and B-cell populations along with the prolonged contribution of some clones to myeloid progeny, however, satisfied the more strict criteria for transduction of the HSC, providing further optimism for eventual clinical application ([238] , [239] and [240]).

The canine autologous transplantation model has also been used to test retroviral gene transfer strategies. Successful transduction of G-CSF–mobilized peripheral blood engrafting cells was first demonstrated in the dog, as was the importance of partially or fully ablative conditioning radiation or chemotherapy for detectable engraftment with transduced primitive hematopoietic cells ([241] , [242] and [243]). Cross-reactivity of human reagents has proven more problematic in the dog model, yet continued progress in this model has led to clinically relevant gene transfer techniques ([244] , [245]). The value of the dog model as a large animal model is further strengthened by the presence of several disease states that mimic those in humans, which could allow stringent preclinical testing.

Although results from the large animal models have better correlated with results from early human clinical trials, the rhesus and canine experiments are expensive, slow, and technically difficult, not allowing large-scale testing of new approaches. Recently, xenograft models have gained in popularity, in part due to access, and investigators have begun to use engraftment of transduced human hematopoietic cell populations in immunodeficient mice as an alternative experimental model ([246] , [247] , [248] and [249]). This approach was initially limited by very low-level engraftment with human cells, but modifications including co-transplantation of stromal cells secreting human IL-3 and transplantation into immunodeficient transgenic mice expressing human cytokines have resulted in increased levels of human cell engraftment ([246] , [247]). In one study, common integration sites of a retroviral vector were demonstrated in human myeloid and T-cell clones isolated from a mouse 7 to 9 months after transplantation, suggesting that a very primitive pluripotent human cell had been transduced and could contribute to both myeloid and lymphoid human lineages ([250]). The long-term engraftment of human cells in the xenograft model was improved when transduced in the presence of an autologous stromal cell layer ([251]). Examples of the way in which the murine xenograft model has since been used include the comparison of stem cell sources or vector systems, investigation of the expression of therapeutic genes in marrow-derived cells from individuals with specific genetic disorders, and the determination of copy number for new vector systems ([252] , [253] , [253a] , [254]). The predictive value of these xenograft models, however, remains to be proven by direct comparison with human clinical trial results, tracking the same gene-modified cell population in both a patient and an immunodeficient mouse.

Human Clinical Trials

GENETIC MARKING The first human clinical gene transfer trials used retroviral vectors carrying nontherapeutic marker genes and were critical for establishing proof of principle and allaying safety concerns ([7] , [255]). In the case of HSC targets, patients already undergoing autologous transplantation as therapy for an underlying malignancy received genetically marked cells ([256]). Only a fraction of their graft was transduced, and the patient received no clinical benefit from the gene marking procedure. Genetic marking with an integrating vector is a unique method to track transplanted autologous cells and their progeny *in vivo*. Many patients have now been enrolled in clinical gene marking protocols in the setting of autologous transplantation. Several studies used retroviral marking to determine whether reinfused tumor cells contribute to relapse after autologous transplantation ([257] , [258]). In two pioneering studies involving pediatric patients with acute myeloid leukemia or neuroblastoma at St. Jude Children's Research Hospital, unpurged autologous marrow was briefly exposed to a retroviral marking vector carrying the bacterial neomycin phosphotransferase gene (Neo) ([229]). Genetically marked tumor cells were unequivocally demonstrated in several patients at the time of relapse, suggesting that the reinfused marrow had contributed to progression and that investigation of purging strategies was worthwhile ([259] , [260] and [261]). A smaller study of adult acute leukemia patients did not detect any marked tumor cells at the time of relapse, but overall transduction efficiencies in this study were much lower ([262]). Marked relapses after autologous transplantation have also been reported in chronic myelogenous leukemia (CML). Individual bcr/abl+ marrow CFU-culture (CFU-C) were shown to contain the retroviral marker gene ([263]). No marked relapses have been detected in adult patients with multiple myeloma and breast cancer transplanted with genetically marked bone marrow and mobilized peripheral blood cells, but the target marrow and blood cells had been CD34-enriched before transduction, probably purging at least 2 logs of tumor cells ([204] , [264]). The other major objective of these gene-marking studies was to assess the efficiency of retroviral gene transfer into human long-term repopulating cells. In the pediatric St. Jude study, a fraction of the harvested bone marrow harvest was briefly exposed to retroviral supernatant without growth factors or supporting stroma ([229]). Although animal experiments and *in vitro* assays predicted poor marking using this transduction protocol, as high as 5 to 20% of nonleukemic CFU grown out of the marrow between 6 and 18 months after transplant contained the marker gene and were neomycin-resistant, indicating ongoing transgene expression. Only 0.1 to 1.0% of circulating mature cells were marked. The surprisingly high levels of stable marking of marrow progenitors may be explained in part by beneficial cell cycle kinetics of the primitive hematopoietic cells from these patients, because of their young age or ongoing hematopoietic recovery from high-dose induction chemotherapy just before bone marrow harvesting. An NIH trial treated adults undergoing autologous bone marrow and mobilized peripheral blood stem cell transplantation for multiple myeloma and breast cancer ([226]). In this marking trial, the transduction was for 3 days in the presence of the cytokines IL-3, IL-6, and SCF. Bone marrow and peripheral blood CD34-selected cells were transduced with different Neo-marking vectors (distinguishable by PCR) to assess the relative contribution to marking and engraftment of marrow and peripheral blood populations. Circulating marked cells were detected after engraftment in all patients; in three of nine, marked cells were detected for over 18 months. Although granulocytes, B cells, and T

cells were all positive for the transgene, the efficiency of gene transfer was much lower than that reported by the St. Jude group: Less than 0.1% of circulating cells were marked long term ([226], [265]). Because both the bone marrow and peripheral blood grafts contributed to long-term marking, mobilized peripheral blood grafts can produce durable multilineage engraftment. This source of primitive cells should be useful in the allogeneic setting. These investigators have gone on to test the brief single transduction protocol that seemed more effective in the St. Jude pediatric study, but no persistent marking has been detected in these adult patients ([266]).

THERAPEUTIC GENES Despite the low efficiencies of gene transfer into long-term repopulating stem cells achieved in large animal models and early human marking trials, several phase I/II clinical trials investigating the transfer of potentially therapeutic genes were initiated. Important information has been obtained on safety and on the feasibility of stem cell engraftment without ablation, and, although these initial trials were largely disappointing, there were glimmers of hope regarding clinical benefit. SCID due to ADA deficiency has been a prototype target disease for gene therapy since the initial development of retroviral vectors in the 1990s ([267]), and children with ADA-deficient SCID were the subjects of the first clinical trial using a vector carrying a therapeutic gene directed at T-lymphocyte targets ([267]). HSCs are theoretically preferable to T cells as gene correction targets in this and other immunodeficiency disorders, due to the potential for permanent and complete reconstitution of the T-cell repertoire. To directly address this hypothesis, two ADA-deficient children received autologous bone marrow and mature lymphocytes transduced with two different retroviral vectors carrying the ADA gene and the Neo gene and then repeatedly reinfused without conditioning ([231]). In the first year after initiation of these infusions, vector-containing T cells originating from the transduced T cells were observed, but, with time, there was a shift to vector-containing T cells originating from transduced bone marrow cells. The proportion of gene-corrected clonable T cells was 2 to 4%, and analysis of T-cell receptor gene rearrangements indicated a wide repertoire of corrected clones. A surprisingly high number of marrow myeloid colonies resistant to neomycin was also reported, despite lack of conditioning, and an *in vivo* selective advantage for gene-corrected cells of all lineages was hypothesized. For genetic disorders diagnosed *in utero*, the use of cord blood cells as targets for gene transduction represents an exciting alternative approach ([268], [269]). Cord blood may contain greater numbers of primitive reconstituting cells with higher proliferative potential that may prove more susceptible to retroviral transduction. Moreover, early treatment is crucial in diseases that progress to irreversible damage before a child is old enough to allow collection of mobilized peripheral blood or bone marrow cells ([270]). Three infants diagnosed *in utero* with ADA deficiency allowed the testing of this concept, and cord blood was collected at the time of delivery. The cells were CD34-enriched, transduced with an ADA/Neo retroviral vector, and infused in the absence of conditioning ([271]). Vector sequences were detected in circulating myeloid and lymphoid cells at low levels of less than 0.05% in all three children for longer than 18 months. Four to six percent of individual colonies grown from bone marrow aspirates at 1 year contained vector, and semiquantitative PCR performed on bone marrow mononuclear cell and on sorted $CD34^+$ cell samples suggested a higher contribution in the $CD34^+$ fraction. The finding of higher transduction levels in the more primitive population of cells was not explained but could be due to toxicity of either Neo or ADA to mature but not to primitive cells, protection by the marrow microenvironment of more immature cells from immune destruction, or a differential contribution of transduced cell populations to colony-forming progenitor cells as compared to those producing the actual circulating cell populations. The children remain clinically well but continue on ADA enzyme replacement therapy. Clonality analysis performed after 10 years shows that, although a single vector integrant was predominant in the T cells of one patient, a broad T-cell repertoire was represented, indicating transduction of a prethymic stem or progenitor cell ([272]). A gradual withdrawal of the exogenous ADA has been initiated. If corrected lymphocytes have an *in vivo* selective advantage as hypothesized, the level of corrected T lymphocytes would be expected to increase over time ([273]). The long-term results of the original gene therapy trial were also recently reported, with 20% of lymphocytes in one patient still carrying the ADA gene more than 10 years after the infusion of transduced mature lymphocytes ([274]). FA is another genetic disorder of the hematopoietic system that appears to be an excellent candidate for gene therapy. This congenital syndrome is characterized by bone marrow failure, physical anomalies, and an increased susceptibility to marrow failure and leukemias. Cells from these patients are abnormally sensitive to chemically induced DNA cross-linking. Many of the complementation groups have been cloned and sequenced, making a genetic approach feasible for this disorder ([275]). The bone marrow failure seen in patients with FA parallels the poor *in vitro* growth of their CFU. Phenotypic correction of this abnormality in cells from one patient group was successful after transduction with viral vectors carrying the Fanconi complementation group C gene ([276], [277]). A possible *in vivo* survival advantage for gene-corrected primitive cells and their progeny has made FA an attractive candidate disease for stem cell gene therapy. Even a very low efficiency of transduction might result in gradual *in vivo* expansion of corrected progenitor and stem cell populations. A clinical trial testing this hypothesis using G-CSF–mobilized peripheral blood $CD34^+$ cells as targets yielded disappointing results, in part due to the very poor mobilization in these subjects ([278]), yet engraftment with corrected CFU-C was demonstrated ([230]). Despite the numerous hurdles encountered in these early clinical gene transfer trials, efforts in the clinic have continued largely uninterrupted, with SCID remaining a prototype target disease. The parallel development of improved techniques in small and large animal models continued to fuel the clinical effort. Appropriately, the first definitive evidence for efficacy of any gene therapy trial was reported in children with SCID in 2000 ([22]). In this landmark trial, children with the X-linked form of SCID received autologous bone marrow $CD34^+$ cells transduced with a ?c-encoding vector under optimal conditions, and these cells were then infused in the absence of conditioning ([22]). T and natural killer cells reached normal levels in the blood within 4 months in four of the five treated patients. These long-awaited results have been duplicated by another group in children with the ADA-deficient form of SCID ([23]). In contrast to the first study, patients received genetically modified cells after conditioning with low-dose intravenous busulfan. Whereas the initial reports described relatively short follow-up in only a few patients, longer term follow-up is now available for the recipients of ?c-corrected bone marrow. Phenotypic and functional studies, including analysis of the T-cell repertoire and *in vitro* and *in vivo* T-cell function, appear nearly normal. Furthermore, thymopoiesis was documented, and thymic development appeared normal. Although B-cell numbers were low, serum immunoglobin levels were sufficient to avoid intravenous immunoglobulin treatment. Furthermore, antibody production was observed after immunizations. Most important is the fact that the patients were able to leave the hospital and lead a normal life outside of the protection of a sterile environment. These results definitively established the therapeutic potential of HSC-based gene transfer and ushered in a great deal of enthusiasm for moving toward the clinic for other disorders such as the hemoglobinopathies, which have also remained a major focus for gene therapy application.

Gene Therapy for Globin Disorders

The thalassemias and hemoglobinopathies represent a heterogeneous group of anemias characterized by absent/reduced or abnormal production of one or more of the globin-molecule subunits, respectively, and strategies that aim to replace the absent or defective globin gene have long been envisioned as potentially curative. Progress in the field suggests that this goal may one day be achievable. Indeed, retroviral vectors carrying globin genes were among the first to be tested in murine models ([184], [279], [280]). Attaining erythroid-specific gene expression, however, has remained a seemingly insurmountable barrier. The incorporation of ß-globin promoters and enhancers within vector constructs directs erythroid-specific expression but at very low levels ([184], [279], [280], [281], [282], [283], [284] and [285]). The finding that DNA sequences important in globin gene regulation are located upstream of the human ß globin gene was crucial to the further development of this potential therapy ([286], [287], [288] and [289]). The region, designated the *locus control region* or *LCR*, is unfortunately too large to incorporate into standard retroviral vectors, and smaller fragments do not confer full LCR activity ([290], [291], [292], [293], [294], [295], [296], [297], [298], [299], [300] and [301]). As a result, other approaches to improve human ß-globin expression, such as the use of alternative erythroid-specific control elements ([302], [303] and [304]) or preselection of transduced stem cells that express the vector at high levels ([305], [306]), have been pursued in parallel.

The development of vector systems that allow stable transmission of larger segments of the LCR and other transcriptional elements would theoretically improve on the results achieved to date. To test this approach, May et al. produced vectors derived from HIV-1 based on its unique properties, which allow regulated RNA splicing in ways that oncoretroviruses lack ([307], [308]). Using a modified HIV-1–derived vector ([309]), May et al. succeeded in stably transmitting the human ß globin gene along with the promoter and enhancer and large segments of the LCR ([103]). This vector proved effective in a murine transplantation model, with sustained, high-level human ß-globin expression achieved ([103]). Furthermore, human ß-globin expression was sufficient to ameliorate the phenotype in mice with a form of ß-thalassemia similar to human ß-thalassemia intermedia. Equally encouraging results were subsequently reported in a novel human ß-thalassemia major murine model ([310]). An HIV-1–based vector expressing a mutant, antisickling human ß globin has also demonstrated efficacy in two different models of human sickle cell anemia ([311]). The results have set the stage for large animal, preclinical testing and predict eventual success in the clinic.

LYMPHOCYTES AS TARGETS FOR GENE TRANSFER

The first human clinical gene transfer trial to be approved and accomplished involved marking tumor-infiltrating lymphocytes (TILs) ([7], [255]). Lymphocytes have several features that make them more attractive than HSCs as targets for gene therapy. They are easily harvested and circulate in large numbers and can be cultured *ex vivo* without major perturbation of phenotype, immune responsiveness, or proliferative potential ([312]). Lymphocytes may be repeatedly harvested, and ablative conditioning is not necessary for persistence of infused cells. These advantages have stimulated investigators to pursue lymphocytes as potential targets for many gene therapy applications. Recent *in vivo* human trials have yielded very important and often surprising information on the lifespan of these “terminally” differentiated cells in the body but also worrisome evidence of strong immune responses against exogenous genes expressed by these cells.

Preclinical Studies

Using a retroviral vector containing both the neomycin resistance (Neo) and human ADA genes, investigators showed stable, long-term expression of transgenes in

both murine and human T lymphocytes in culture ([313]). Transduced murine lymphocytes could be selected by growth in neomycin and subsequently expanded without changing their antigenic specificity. Infusion into nude mice demonstrated the persistence of Neo-resistant cells, which continued to produce human ADA for several months ([313]).

Further *in vitro* optimization of lymphocyte transduction protocols has involved the pseudotyping of vector particles with a GALV envelope ([314] , [315] and [316]). Lymphocytes have more GALV receptors than amphotropic receptors. Other technical improvements during transduction have included centrifugation to increase target–virus interactions, phosphate depletion to up-regulate the amphotropic or GALV receptors, and low-temperature incubation to stabilize vector particles. These methods have resulted in reports of successful transduction of up to 50% of cultured lymphocytes with preservation of viability, phenotype, and expansion capability ([316]). In a subsequent *in vivo* marking experiment using these optimized conditions, rhesus peripheral blood lymphocytes were transduced with a vector encoding the Neo gene and HIV-1 TAT/REV antisense sequences. After reinfusion, 3 to 30% of circulating $CD4^+$ cells contained the vector for at least several months, and lymph node sampling demonstrated that these cells could traffic normally ([317]).

Clinical Studies

GENE MARKING STUDIES The first human gene transfer study used gene marking to monitor the fate of TILs *in vivo.* Persistence of low-level gene-marked cells was demonstrated, including in tumor deposits, although marking levels were too low to assess any preferential trafficking of TIL cells to residual tumor ([7]). More recently, gene marking studies in humans undergoing allogeneic BMT have helped to further characterize the behavior of lymphocytes that have been cultured *ex vivo*. Epstein-Barr virus (EBV)–specific T cells from patients at high risk for postallogeneic BMT EBV lymphoproliferation were isolated, expanded, and gene marked *ex vivo* in culture with EBV-transformed donor lymphoblasts ([318] , [319]). After BMT, the T cells were infused, and marked cells were detectable at levels suggesting expansion of two to three orders of magnitude. EBV-specific cytotoxicity in the peripheral blood was greatly enhanced after the infusions. Although circulating marked cells fell below the limit of detection by 4 to 5 months after infusion, the continued presence of memory cells derived from the infusion product was inferred in one patient who had detectable marked lymphocytes in the blood after reactivation of latent EBV ([319]).

SUICIDE GENE STUDIES A second group is using a similar approach in patients with EBV lymphoproliferation but has incorporated the herpes thymidine kinase (tk) gene into the retroviral vector ([320]). This *suicide gene* converts the nontoxic prodrug ganciclovir to a toxic metabolite that kills the tk-expressing cell by interfering with DNA synthesis ([321]). The inclusion of this gene in vectors allows postinfusion destruction of transduced cells simply by treating the patient with ganciclovir. For instance, ganciclovir treatment could abrogate graft-versus-host disease in allogeneic BMT recipients if most of the allogeneic T cells contain the tk gene ([320] , [322]). This strategy depends on inclusion of a cell-surface marker gene in the vector to allow positive selection of transduced cells by flow cytometry before reinfusion, so that almost all infused cells will contain the tk gene ([320] , [323]). With this approach, it may be feasible to transplant patients with T-depleted marrow grafts and then infusions of large numbers of tk gene–transduced T cells, specifically stimulated *ex vivo* to respond to viral infections or neoplastic cells ([312] , [324]). The benefits of antiviral and antitumor immunity could be retained while allowing for immediate control of graft-versus-host disease by ganciclovir administration. Further, the inclusion of an *ex vivo* selectable marker with a suicide gene could enhance engraftment while providing protection from graft-versus-host disease ([325]). Another group grew HIV-specific autologous cytotoxic T-lymphocyte clones from patients with HIV disease. Because the safety of infusing these cells was unknown, the clones were transduced with a vector containing the tk gene (along with a hygromycin resistance gene allowing *in vitro* selection) to allow *in vivo* ablation of transduced cells if toxicity developed. Analysis of this adoptive immunotherapy strategy was precluded by the appearance of vigorous cell-mediated immunity to gene products encoded by the vector, including the tk protein and the hygromycin resistance gene product, despite the patients' immunosuppression from their active HIV disease ([326]). Vector sequences were detectable soon after the first infusion of transduced cells but rapidly disappeared, especially after subsequent infusions, and active cell-mediated immunity against the hygromycin resistance gene protein was demonstrated. This observation serves as an important caution that foreign proteins introduced via lymphocytes may stimulate immune recognition and rejection.

THERAPEUTIC GENES T lymphocytes were the targets in the first human study using a potentially therapeutic gene, initiated in 1990 ([8] , [327]). Two children with SCID due to ADA deficiency received multiple infusions of autologous T cells transduced with a retroviral vector encoding human ADA ([6]). Both patients showed improvements in circulating T-cell numbers and cellular and humoral immunity. In one child, over 30% of the circulating T cells were positive for the transgene, and ADA levels approached the normal range for more than 2 years. The persistence and continued expression of the transgene indicate that the extinction of transgene expression seen in some mice may not apply to immunodeficient humans. The second child had only 0.1 to 1.0% of circulating T cells containing the vector even after multiple infusions, clouding interpretation of how much of her clinical improvement was due to the gene transfer and how much to other factors, including the *ex vivo* lymphocyte expansion.

GENE THERAPY FOR HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The lack of effective, nontoxic, and practical conventional pharmacologic therapies for HIV infection and the current bleak outlook for the rapid development of a vaccine have made the gene therapy approach an attractive alternative ([179] , [328] , [329]). A number of ongoing and completed human clinical trials have already involved patients with HIV disease, and this activity is certain to increase over the next several years because so many gene therapy biotechnology companies have focused on HIV disease. After intensive investigation into the molecular biology of the HIV virus, scientists have identified a number of potential targets for genetic intervention ([330]). The concept of *intracellular immunization* against HIV, conceived over a decade ago, hypothesizes that an effective gene therapy strategy for HIV could be designed to confer nonimmunologic HIV resistance to mature cell populations by introducing a gene that interferes with the HIV life cycle into HSCs or lymphocyte precursors ([331]). A second approach uses gene transfer to introduce genes that result in the killing of infected cells, either directly or via enhanced immunity, and thus destroy the HIV viral reservoir. All strategies under current development will treat patients who are already HIV infected and involve one or more of the approaches listed in Table 26.3.

TABLE 26.3. Gene Therapy Strategies for Human Immunodeficiency Virus (HIV) Infection

Interference with HIV replication or infection by gene transfer of an inhibitory transgene into target cells
Transdominant negative mutant proteins
Tat mutants
Rev mutants
Gag mutants
Env mutants
Intracellular single-chain antibodies
Anti-env antibody
Anti-rev antibody
Anti–reverse transcriptase antibody
Antisense RNA
Complementary to critical HIV RNA sequences
Ribozymes
Complementary to critical HIV RNA sequences
RNA decoys
Trans-activating response element
Rev-responsive element
Destruction of HIV-infected cells by increased immunity
Genetic delivery of HIV gene products
Env
Universal receptor introduction into effector cells
CD4/T-cell receptor-? chimera
Direct destruction of HIV-infected cells
Conditional genes expressed from HIV-dependent sequences

Diphtheria toxin
Herpes thymidine kinase

Potential target cell populations for a strategy of conferring intracellular resistance to HIV include lymphocytes and HSCs. As already discussed in the previous two sections, gene transfer into lymphocytes has been more efficient than transfer into repopulating stem cells. For HIV disease, however, stem cells would be better targets. T cells, macrophages, or glial cells would be protected from HIV if they developed from stem cells successfully transduced with a gene or genes preventing HIV infection, integration, or replication. In time, the immune system could be reconstituted, despite the presence of replicating HIV in unprotected cells.

Stem cell gene therapy for HIV also makes more sense if stem cells are not already infected. Most investigators believe that primitive $CD34^{+}$ cells are not actually infected with HIV, although maturing cells of the monocyte-macrophage lineage can be infected ([332], [333] and [334]). The use of mature T cells as targets may be useful for testing specific genetic manipulations, but therapeutic benefit would probably require repeated infusions, and a lymphocyte strategy alone would not prevent HIV disease of the central nervous system. Because of the probable deleterious immune response against exogenous gene products expressed in lymphocytes, even in patients immunosuppressed by HIV infection, a stem cell approach may be absolutely necessary if the anti-HIV moiety is an expressed protein as opposed to an RNA decoy or antisense sequence ([326], [335]).

A number of gene therapy approaches to HIV are being tested in a unique clinical model at the NIH. A cohort of syngeneic twins has been identified in which one twin is infected with HIV and the second twin is not. T cells from the uninfected twin are collected by apheresis and then transduced with vectors encoding potential anti-HIV genes. Comparison of survival of these transduced cells with survival of cells transduced with a control vector may prove to be a very rational way to test the *in vivo* efficacy of various strategies ([336]). A preliminary gene marking study was initiated and followed by testing of several of the most promising anti-HIV vectors ([337]). In one report, transduced T cells were infused without incident and persisted long term, although no improvement in disease could definitively be ascribed to the infused cells ([338]).

Transdominant Proteins

One promising strategy has been to express transdominant mutant proteins that interfere with the HIV life cycle, either by inactivating regulatory proteins such as Tat and Rev or by interfering with structural proteins such as gag, env, or reverse transcriptase ([339], [340] and [341]). These proteins are designed to interfere with the function of wild-type HIV proteins. Most transdominant mutant proteins work by complexing with the wild-type protein and interfering with normal function or by binding to the target of the wild-type protein and preventing normal function of the target. The HIV Tat protein is essential for high-level expression from the HIV LTR because it interacts with the region of the LTR in transcripts termed the trans *-activating response* element or *TAR* ([330], [342]). Mutant Tat proteins or peptides have been reported to decrease transcription from the HIV LTR, possibly through formation of inactive heterodimers with wild-type Tat, but the desired effect occurred only with large molar excess of mutant Tat, tempering enthusiasm for this approach ([343]). A number of subsequent studies described more potent inhibition, however ([344], [345]).

The investigation of transdominant Rev mutants has been more encouraging. Rev acts to increase expression of full-length HIV transcripts, specifically, facilitating transport of these transcripts to the cytoplasm ([330], [342], [346]). Rev binds to a target sequence of RNA termed the *Rev-responsive element*, or *RRE*. Mutant Rev proteins have been reported that interfere with Rev function, either by binding to and inactivating wild-type Rev or by competitively blocking binding of the wild-type Rev to the RRE ([60], [347]). Expression of one mutant, termed *Rev M10*, has been extensively studied *in vitro* and was used in a preliminary clinical trial ([55], [348], [349]). Production of HIV either from normal lymphocytes exposed to HIV in culture or from HIV-infected lymphocytes from patients was decreased after either retroviral or gene gun particle-mediated transduction with a vector expressing the Rev M10 mutant, compared to a nontranslated inactive control Rev mutant ([55]). A clinical trial used the gene gun to transduce autologous lymphocytes from HIV-infected patients with either the active Rev M10 vector or the inactive control Rev vector. These cells were then expanded *in vitro* and reinfused. The lymphocytes containing the active Rev M10 sequences survived preferentially *in vivo*, suggesting that the Rev M10 transgene improved T-cell survival in infected individuals ([348]). In another protocol, individuals with HIV infection and a refractory hematologic malignancy were offered allogeneic peripheral blood stem cell transplantation, and an aliquot of the allogeneic graft was CD34-selected, transduced with a transdominant Rev-encoding vector, and infused with the unmanipulated allograft. Although overall marking was low in the only recipient of genetically modified cells, rising vector copy number and nondetectable HIV over extended follow-up were encouraging ([350]).

In another approach, the oligomerization of gag protein is inhibited by a transdominant mutant form of gag; to date, there is *in vitro* evidence for decreased viral production from T-cell lines but not from primary T cells ([351]). The envelope protein is also a potential target. One mutant form of the gp41 subunit, which contains the fusion domain, interferes with HIV spread in culture ([352]). HIV-infected cells containing this transgene release virus that is unable to fuse normally with target cells. Another mutant lacking the CD4-binding domain of the gp120 subunit of HIV-2 interferes with production of infectious virus from a wild-type HIV genome ([353]). All the transdominant protein anti-HIV strategies share some common limitations. The mutant expressed proteins may induce an antitransgene immune response, and the anti-HIV effect follows integration of HIV, which is, of course, less desirable than preventing infection of cells altogether.

Intracellular Anti–Human Immunodeficiency Virus Antibodies

An alternative gene therapy approach for prevention of HIV release from cells is to introduce genes that code for antibody fragments binding to critical HIV proteins ([354]). The gene for a single-chain antibody recognizing the CD4-binding region of HIV gp120 was introduced into HIV-infected cells, and production of infectious virus decreased ([355]). The antibody fragment was shown to bind gp120 and to retain it in the endoplasmic reticulum, at least partially preventing release of infectious HIV virus. A similar approach was used to express a single-chain antibody fragment against Rev ([356]). The highly conserved Rev sequences were believed to be a logical target, especially because very high levels of intracellular Rev are necessary for HIV replication. The cells expressing the anti-Rev antibody sequences sequestered Rev in the cytoplasm, where it was unable to chaperone full-length HIV genomes out of the nucleus, thus decreasing viral production.

Another group has targeted single-chain antibodies to the HIV reverse transcriptase ([357]). This approach has the theoretic advantage of preventing infection altogether, because reverse transcriptase protein entering an HIV-susceptible cell with the HIV particle is necessary for synthesis of cDNA and integration. The investigators showed that expression of this transgene in susceptible T-cell lines made them resistant to infection. Testing of these antibody strategies using T-cell clones, primary T-cells, and even $CD34^{+}$ cells differentiated *in vitro* demonstrates their potential for *in vivo* use ([358], [359], [360] and [361]).

Anti–Human Immunodeficiency Virus Nucleic Acids

In theory, introducing DNA sequences that encode anti-HIV RNA sequences but not proteins may have several advantages, the most important of which is the decreased immunogenicity of the gene product. A number of different strategies have been explored. Antisense RNAs or RNA sequences complementary to expressed messenger RNA (mRNA) decrease gene expression either by preventing normal translation of mRNAs or by interfering with RNA processing ([362], [363] and [364]). Decreased HIV production has been the reported result of transduction with an AAV vector expressing antisense RNA sequences to part of the HIV LTR that includes the TAR sequence and the polyadenylation signal ([365]). However, a nonspecific effect of AAV vector transduction on HIV production was not ruled out by this study. A number of other studies using other HIV antisense sequences transfected into stable cell lines have also been reported ([366], [367]).

A related strategy involves the use of anti-HIV ribozymes ([368], [369]). Ribozymes are antisense RNA molecules that not only bind to complementary RNA sequences but actually catalytically cleave and thus inactivate target RNAs ([179], [370]). Thus, one ribozyme molecule can destroy many target HIV RNAs, whereas a standard antisense molecule can bind to and inhibit expression from only one HIV RNA molecule. Also, ribozymes can cleave full-length viral RNA before reverse transcription and actual infection of a susceptible cell. A ribozyme that targeted gag RNA sequences was shown to reduce gag p24 levels ([371]). Since then, many other ribozymes targets have been explored ([179], [372], [373], [374] and [375]).

A third nucleic acid strategy uses *decoy sequences* to sequester viral regulatory proteins such as Tat and Rev. Transduction of cells with retroviral vector containing either TAR or RRE sequences results in decreased HIV replication ([376], [377] and [378]). The combination of ribozymes and decoy elements has also been pursued ([379], [380] and [381]). A clinical trial testing this approach in children infected with HIV was recently completed, although overall engraftment levels of genetically modified cells

were too low to expect benefit ([382]).

Another strategy involves the use of defective interfering viruses, which are known to interfere with wild-type replication and spread. The application of defective interfering HIV vectors may result in competition with wild-type HIV and decrease viral load ([383]). A protocol using an HIV vector system mobilized via rescue by wild-type HIV has been proposed as the first gene transfer trial in humans using lentiviral vectors. This “defective interfering strategy” introduced additional concerns over the possibility of creation of a replication-competent recombination between the vector and the packaging sequences or inadvertent transfer of a mobilized vector to others by the research subject, requiring further development of sensitive replication-competent retrovirus testing before clinical use ([104]).

Destruction of Human Immunodeficiency Virus–Infected Cells

Many investigators have taken the approach of using introduced transgenes to destroy HIV-infected cells, instead of trying to make living cells resistant to infection or productive HIV replication. Vectors have been developed that express the herpes simplex tk gene from genetic regulatory elements that are active only in HIV-infected cells. Exposure of a population of cells to ganciclovir would then kill only those transduced cells that are also infected with HIV ([384]). For instance, a vector expressing the tk gene from an HIV-2 promoter and the HIV TAR region was used to transduce human cell lines. Cells infected with HIV or expressing the HIV Tat gene were preferentially killed by ganciclovir exposure ([385] , [386]). However, some cells not expressing HIV Tat were also killed, showing that the current promoters are not completely inactive in the absence of Tat protein. Other groups have used toxin genes, such as the diphtheria toxin, expressed from HIV-dependent control sequences, to kill HIV-infected cells ([387]). The large number of HIV-infected cells and the huge viral load present even in asymptomatic individuals make strategies dependent on direct killing less appealing, unless new T cells developing from stem cells could also be rendered resistant to infection. An alternative suicide gene has recently been developed for HIV-directed gene therapy ([388]).

Genetic vaccination approaches are also under development as a potentially more effective way to raise anti-HIV immunity ([389]). Fibroblasts transduced with a retroviral vector expressing the gp160 HIV envelope gene induced HIV-specific cell-mediated and humoral immunity in mice ([390]). Early clinical trials are using this approach in patients, either by direct injection of the vector into muscle or by *ex vivo* transduction of autologous fibroblasts that are then reimplanted ([391]). Another approach is to introduce a *universal receptor* transgene into cytotoxic T cells taken from patients infected with HIV. The extracellular portion of the chimeric gene product is the HIV gp120-binding moiety from CD4, and the intracellular portion is the ?-chain–transducing portion of the T-cell receptor complex. Cytotoxic T cells and other effector cells expressing this molecule specifically kill gp120-expressing HIV-infected cells ([392]). A current clinical trial uses a vector expressing this molecule to transduce T cells from a non–HIV-infected syngeneic twin before infusion into the infected twin ([337]).

GENE THERAPY FOR BLEEDING DISORDERS

The primary bleeding disorders most commonly result from genetic deficiencies of specific clotting factors. Classic hemophilia, or hemophilia A, results from a deficiency of factor VIII, which is normally produced by hepatocytes and vascular endothelial cells. Hemophilia B results from a deficiency of factor IX, which is normally made by hepatocytes. Thus, both diseases are hematologic disorders resulting from deficiencies of soluble plasma proteins synthesized by nonhematopoietic cells. Each of these coagulation factors may be found in circulating platelets' storage granules ([393]), but the megakaryocyte is not likely a site of synthesis, and storage is likely to occur after uptake of the protein from plasma.

Hemophilia A and B have attracted a significant amount of attention from those interested in gene therapy for a variety of reasons. First, they are monogenic diseases for which numerous mutations are known ([394] , [395]), and the cDNAs have been cloned ([396] , [397]). The factor VIII and factor IX genes may be expressed in nearly any cell type as long as the appropriate posttranslational modifications are made and the protein is secreted into the circulation. The amount of circulating factor VIII or factor IX required to mediate an improvement in the bleeding phenotype can be as little as 1% of normal plasma levels. Furthermore, there may be a substantial margin for error with regard to overexpression due to regulation of the “tenase” (factor VIII/factor IX) enzyme complex and “prothrombinase” (factor V/factor X) complex by the protein C/protein S anticoagulant proteins and antithrombin III. Recent epidemiologic analysis suggests that elevated factor VIII or factor IX levels may be a risk factor for thrombotic diseases ([398] , [399]), but, thus far, it seems unlikely with current gene transfer practices that these supraphysiologic levels of factor VIII or factor IX would be sustained for prolonged periods of time (years). Preclinical testing of hemophilia gene therapy has been facilitated by the presence of several animal models of hemophilia, including factor VIII and factor IX knock-out mice ([400] , [401] , [402] and [403]) and spontaneous hemophilia A and B dog colonies ([404] , [405] , [406] , [407] and [408]). Furthermore, it has proved possible to detect epitope-tagged human factor VIII ([409]) or normal human factor IX ([410] , [411] , [412] and [413]) in normal rhesus macaques after gene transfer with various vectors, which permits not only safety testing of gene transfer but also some assessment of gene expression *in vivo*.

von Willebrand disease is a relatively common bleeding disorder that is due to a deficiency of von Willebrand factor, which is a cytoadhesive protein synthesized by endothelial cells. von Willebrand factor–deficient swine and dogs are known and could be used for testing of von Willebrand factor gene transfer *in vivo*. As a practical matter, more effort has been focused on gene therapy to correct deficiencies of factor VIII or factor IX than on von Willebrand disease because the von Willebrand factor cDNA is substantially larger than factor VIII or factor IX, and, unlike factor VIII, there does not appear to be any portion of the von Willebrand factor protein/cDNA that is dispensable for coagulant factor activity. In contrast to hemophilia A and B, von Willebrand disease is unlikely to be ameliorated by expression of protein levels as low as those that seem to ameliorate hemophilia A or B. For these reasons, little progress has been made in the development of clinical protocols for von Willebrand factor gene therapy.

Potential targets for gene transfer that have been addressed in preclinical studies *in vivo* include skin fibroblasts or keratinocytes, myocytes, hepatocytes, and bone marrow. Skin fibroblasts or keratinocytes are readily propagated in tissue culture and can be transduced by vectors that may include selectable markers. Cells selected *in vitro* can be reintroduced to the host, where the secreted protein enters the bloodstream. Preclinical studies using fibroblasts or keratinocytes transduced with factor IX or factor VIII retroviral vectors ([414] , [415] , [416] , [417] , [418] and [419]) in rodents have indicated that therapeutic levels of factor IX or factor VIII (>1% of normal) could be achieved by this approach. A recurring issue is lack of sustained expression of the desired transgene, which may be due to loss of transduced cells due to cell-mediated immunity or promoter shutdown in implanted cells that remain viable ([420]). One clinical trial has been performed in which factor VIII–transfected skin fibroblasts were reimplanted in the omentum. The peak levels achieved were marginally therapeutic but not sustained ([421]). The need for customized (autologous) tissue culture of an individual patient's skin fibroblasts/keratinocytes might be addressed through the use of a standardized cell line expressing factor VIII or factor IX encapsulated in an immunoisolation chamber or device for use in multiple recipients as protected allografts ([422]), yet this approach has not been used in humans.

Gene transfer to muscle cells can be performed using appropriate muscle-specific promoters, nonspecific promoters, or both to direct gene expression. The engineered cells may be implanted in the host organism under the appropriate conditions. Factor IX has been expressed in mice using transduced primary myocytes or cell lines propagated as myotubes then induced to differentiate into myocytes before reimplantation ([423] , [424] and [425]). Alternatively, differentiated myocytes or myoblasts have been encapsulated (e.g., in alginate compounds) before implantation to provide some degree of immunoisolation for the modified cells *in vivo* to express human factor IX in immunocompetent mice ([426] , [427]). The latter approach in immunodeficient (nude) hemophilia B mice has been complicated in one study by the development of tumors of myoblast origin ([428]), raising concerns about using this method for hemophilia B gene therapy in humans. The lack of suitable human myoblast/myotube cell lines that could be used in immune-competent humans makes it much more practical to transduce myocytes *in vivo*. Appealing aspects of *in vivo* gene transfer to muscle as compared to *ex vivo* approaches include the relatively simple methodology (intramuscular injection), the ability to use one vector for various patients, and the lack of cumbersome *ex vivo* cultivation of individual patient myocytes. The most extensively studied and successful application of this approach has been through gene transfer with AAV vectors. AAV vectors are limited to gene transfer of DNA with a total length of approximately 4.5 kb or less, which is appropriate for factor IX gene transfer but of limited use for factor VIII gene transfer. *In vivo* preclinical studies with AAV vectors in hemophilia B knock-out mice and hemophilia B dogs have shown that it is possible to achieve clinically relevant levels of factor IX in the plasma for significant periods of time using this approach ([429] , [430] , [431] , [432] , [433] , [434] , [435] and [436]). A key problem directly related to the use of muscle as a target for gene transfer is poor delivery of recombinant factor IX by muscle into plasma due to binding of factor IX by type IV collagen, mediated by epidermal growth factor–like domain on factor IX ([437]). Further, it appears that AAV gene transfer efficiency into skeletal muscle is significantly greater in type X (slow-twitch) fibers as compared to type Y (fast-twitch) fibers, which appears to be a consequence of the much higher density of AAV receptors on the cell surface for the former muscle fiber type. Clinical trials of AAV–factor IX gene transfer *in vivo* targeting muscle have been performed and have demonstrated therapeutically significant plasma factor IX levels (~1% of normal) at doses of 2×10^{11} vector genomes per kg ([438]). Although the trial was an open-label study and a placebo effect cannot be ruled out, there was a lower frequency of joint bleeds as reported by patients ([438]). However, higher doses of the vector do not result in a greater therapeutic effect, perhaps due to binding of factor IX to type IV collagen that is present in muscle ([439]).

Non–viral-mediated factor IX gene transfer methods to muscle in mice and dogs using electroporation of plasmid DNA *in vivo* to facilitate gene transfer have been studied ([440]). Using these methods, it has been possible to establish transient expression of human factor IX to levels of approximately 1% of normal, the duration of which was limited by the expected antibody response to foreign factor IX. This technique requires confirmation of factor IX activity in hemophilia B animals to establish its efficacy.

Factor VIII expression in muscle has thus far not proven to be a promising avenue for delivery of factor VIII to the circulation, and other targets warrant investigation. Liver hepatocytes synthesize most of the plasma proteins, including factors VIII and IX, and synthesize some proteins (e.g., albumin) in tremendous quantities. Hepatocytes are readily transduced by various vectors (especially Ad), and gene transfer to liver is an important avenue under investigation for gene therapy of hemophilia. Hepatocytes are not easily obtained and propagated *ex vivo*, but *in vivo* gene transfer has been successfully pursued in animal models using adenovirus, AAV, and retrovirus vectors. Adenovirus vectors are capable of near-quantitative gene transfer to hepatocytes *in vivo* when administered intravenously. It is not surprising that adenovirus vectors have been used for *in vivo* gene transfer of factor VIII or factor IX to liver cells in various animal models, including mice ([131], [441], [442], [443], [444], [445], [446], [447], [448], [449], [450], [451] and [452]), monkeys ([409], [410], [412]), and hemophilic dogs ([453], [454], [455], [456] and [457]). Unfortunately, adenovirus-mediated gene transfer is typically characterized by gradual loss of gene expression, and the presence of the adenovirus vector proteins in immune-competent animals induces the cytokine cascade ([458]) and has a significant adjuvant effect that may induce antibodies to the expressed gene ([410], [454], [455], [459]). Based on the observation that deletion of adenovirus vector genes may result in longer periods of gene expression and a decreased immune response ([459]), efforts have been made to create and test vectors with most or nearly all of the adenovirus genes removed for gene therapy of hemophilia ([446], [449], [460], [461] and [462]). Technical problems with production of large quantities of these highly deleted vectors have impeded the translation to clinical trials; however, there is at least one clinical trial under way in which a highly deleted adenovirus vector is being tested for *in vivo* factor VIII gene transfer in patients with hemophilia A. Any clinical use of adenovirus vectors will be limited by neutralizing antibodies to most common serotypes that are routinely present in most humans and which would be boosted substantially with administration of an adenovirus vector ([463]).

Although there are reports of AAV-mediated factor VIII gene transfer to liver *in vivo* ([464], [465] and [466]), gene transfer to liver hepatocytes using AAV vectors has focused largely on factor IX due to the previously noted size constraints of vector DNA packaging. *In vivo* gene transfer of factor IX by intravenous, portal vein, or hepatic artery injection of AAV vectors has resulted in gene transfer to liver and expression of factor IX in mice ([47], [467], [468], [469], [470], [471], [472], [473], [474] and [475]), dogs ([231], [468], [476], [477]), and nonhuman primates ([478]). The results of these preclinical studies have shown persistent expression of sufficient amounts of factor IX to justify clinical trials, one of which is under way in patients with hemophilia B. This trial was temporarily put on hold due to vector shedding in the semen of the first subject enrolled ([479]). After demonstration that the AAV vector was not incorporated in germ-line DNA, the trial was resumed; however, data on factor IX gene transfer and expression are not yet available.

Although typical Moloney-based retroviral vectors are not particularly effective at *in vivo* gene transfer to hepatocytes due to the relatively low rate of cell division, lentivirus vectors (which do not require cell division for gene transfer) may prove to be useful for hemophilia gene therapy. Several groups have used pseudotyped lentiviral vectors to transfer the factor VIII cDNA to liver ([480], [481] and [482]).

Cells of hematopoietic origin are logical targets for *ex vivo* gene transfer and reintroduction by marrow transplantation due to the fact that these cells circulate in the blood and, in the case of platelets, are concentrated at the site of vascular injury. Gene transfer to hematopoietic cells has been attempted as an experimental approach to hemophilia A and hemophilia B. *Ex vivo* retroviral gene transfer of the (B domain–deleted) human factor VIII gene into hemophilia A knock-out mouse bone marrow did not result in detectable plasma levels of human factor VIII after transplantation with myeloablation; however, there was the remarkable effect of conferring immune tolerance to human factor VIII in recipients of transduced bone marrow ([483]). Because the marrow was transduced with a nonspecific viral (LTR) promoter, which could in theory direct expression in any differentiated cell type, along with the suggestion that bone marrow cells may contribute to many nonhematopoietic cell lineages, it is tempting to speculate that expression of factor VIII in hematopoietic cells, nonhematopoietic cells, or both might mediate the immune tolerance response acquired during marrow reconstitution.

Bone marrow stromal cells are readily obtained by modestly invasive methods (marrow aspiration) and are readily propagated and transduced by retroviral vectors *in vitro* ([484]). Human marrow stromal cells have been transduced *ex vivo* with a GALV-pseudotyped Moloney retroviral vector containing a (B domain–deleted) factor VIII expression cassette and reimplanted in the spleen of NOD-SCID mice. Clinically significant (6% of normal) factor VIII levels were obtained in these immu-nodeficient mice; however, expression of human factor VIII ceased after approximately 4 months due to promoter inactivation ([484]). Reinfusion of factor IX–expressing bone marrow stromal cells in canines after conditioning of marrow by irradiation led to detectable levels of factor IX in plasma ([485]). Analysis of hematopoietic cell lines transduced with lentivirus vectors containing factor VIII expression cassettes showed that erythroid and megakaryocytic cell lines secrete significantly higher levels of factor VIII than do B- or T-cell lines. Little effect on factor VIII expression was noted with the use of cytokines; however, differentiating agents such as phorbol myristic acid, which activates protein kinase C, induce two- to threefold greater factor VIII expression ([486]).

Factor IX has been expressed *in vitro* in human myeloid leukemia (HL-60) cells after transduction by various Moloney retroviral vectors under control of different viral promoters; expression from the cytomegalovirus promoter is increased with phorbol myristic acid (a monocytic differentiating agent) or dimethylsulfoxide (a granulocytic differentiating agent) ([487]). Factor IX has been expressed *in vitro* under the control of a megakaryocyte-specific (gpIIb) promoter in human erythroleukemia cells, suggesting that platelets might store the expressed protein in granules that might be released at the site of platelet aggregation ([488]). As in previous work with myelomonocytic leukemia cells ([487]), induction of differentiation resulted in increased levels of factor IX expression *in vitro*. Thus far, factor IX has not been expressed at clinically significant levels *in vivo* by hematopoietic cells.

Future issues to be addressed in the field of hemophilia gene therapy include minimizing the risk of inhibitors, developing vectors with the ability to direct sustained high levels of coagulation factor expression, and avoiding unintentional germ-line transmission of vector sequences. Novel (mainly viral) vectors continue to be discovered, and their suitability for clinical gene therapy is being assessed ([435], [436], [489]). Novel strategies for expression of the relatively large factor VIII cDNA in fragments (e.g., “split vectors”) may permit hemophilia A gene therapy with AAV vectors ([490], [491]). Vector constructs that may mediate integration by novel methods (e.g., “sleeping beauty” transposon approach) have been described ([492], [493] and [494]). Novel targets, such as intestinal epithelial cells that have been transduced by viral or nonviral vectors *in vitro*, need to be studied *in vivo* ([495]). These fertile areas are being addressed by many hemophilia investigators throughout the world.

GENE THERAPY FOR CANCER

In contrast to heritable genetic disorders in which the genetic abnormality involves a single, identified, and well-studied gene, the genetic abnormalities in cancer are often acquired, multiple, and more poorly understood; they may also require delivery of a therapeutic gene to virtually every malignant cell. Despite these hurdles, a considerable amount of enthusiasm for the use of gene transfer strategies in the treatment of human malignancies has evolved over the past several years ([48], [496], [497], [498], [499], [500], [501] and [502]). As shown in Table 26.1, the majority of clinical gene therapy trials involve patients with cancer, and the most frequent target cell is the tumor cell itself. These trials, at the very least, should offer considerable insights into cancer biology. Investigators have used a number of different conceptual approaches to the genetic treatment of cancer, including abrogation of oncogene function in cancer cells, restoration of tumor-suppressor gene function, enhancement of tumor cell drug sensitivity, enhancement of non–tumor cell drug resistance (e.g., bone marrow progenitor cells) to allow more intensive chemotherapy, and improvement of immune responses to tumor cells by genetically altered tumor cell vaccines or modified effector cells. Many of these approaches apply primarily to nonhematopoietic target cells or diseases but are briefly discussed here because the concepts involved may have future applications in hematologic malignancies.

Antioncogene or Pro–Tumor-Suppressor Gene Therapy

The causal relationship between the expression of a mutated or chimeric and dysregulated oncogene and certain malignancies has stimulated the search for a way to specifically turn off the expression of these genes ([498], [503]). The expression of a gene product may be disrupted by small DNA sequences (“antisense” oligonucleotides) synthesized as exact reverse complements of the mRNA target responsible for the abnormal gene product ([504], [505], [506] and [507]).

The potential application of this strategy in CML became apparent when a pathogenic role for the *bcr/abl* gene was proven in mice that developed a syndrome similar to human CML after expression of the p210 *bcr/abl* gene product in primitive hematopoietic cells ([18]). Preliminary studies reported inhibition of malignant

hematopoietic progenitor colony growth after *in vitro* exposure of the cells to antisense oligonucleotides specific to the *bcr/abl* junction, correlating with decreased expression of the *bcr/abl* gene product ([508]). However, subsequent *in vitro* studies have not shown a specific effect from antisense oligos directed to the *bcr/abl* junction, and one group has reported more promising and specific results using antisense oligos directed at the *c-myb* oncogene, which also appears to be abnormally expressed in malignant CML cells ([509], [510] and [511]). A phase I clinical protocol using *c- myb* antisense oligonucleotides to purge autologous CML marrow before reinfusion was recently reported, and although the effect of purging in this manner could not be definitively assessed in this pilot trial, a 50% reduction in *bcr/abl*-positive long-term culture-initiating cells was achieved before infusion ([512], [513]).

In vivo gene delivery of antisense oligos complementary to other oncogenes has also been explored in acute leukemia, but poor stability of these small DNA sequences has been problematic ([514], [515]). Efficacy *in vivc* is also limited by the need to successfully inhibit and kill virtually every leukemic cell, a limitation that may restrict this approach to the adjuvant setting ([504], [516], [517]).

p53 is a nuclear phosphoprotein that acts as a tumor-suppressor gene, and its protein product can arrest the replication of a cell that has undergone DNA damage, allowing either repair or apoptosis ([518]). A cell deficient in p53 may continue to replicate even after DNA damage has occurred, allowing expansion of abnormal cell populations. Mutation of p53 was first described in colorectal cancer and has subsequently been found in many other human tumors ([519]). Strategies to deliver the p53 gene to tumors have largely relied on adenovirus-mediated gene transduction. In an animal model of human non–small cell lung cancer, tumor formation was prevented in a high proportion of inoculated animals that received tumors transduced with recombinant adenovirus p53 ([168]). Similar results were seen in nude mice models of human head and neck cancer using adenoviral vectors. As a result, clinical gene therapy protocols for lung and head and neck cancer in humans have been initiated ([137], [520]). Preliminary results from a lung cancer treatment protocol using *in vivo* delivery of retroviral vectors have been published, and high-efficiency delivery of p53 was documented, along with some evidence for antitumor efficacy ([521]). The combination of gene transfer with radio- or chemotherapy has also been explored ([522], [523]). Applications for these strategies in hematopoietic malignancies are difficult to imagine unless an *in vivo* injectable vector that targets tumor cells can be developed.

“Suicide” Cancer Gene Therapy

The introduction of a *suicide gene* into a tumor offers another potential treatment approach. A tumor can be rendered sensitive to a particular agent by the expression of a gene product that converts nontoxic drugs into a toxic compound that can then kill the tumor cell ([384], [524], [525] and [526]). One example is the herpes virus tk gene. Nucleoside analogs such as ganciclovir are relatively nontoxic to human cells; however, after phosphorylation by tk, ganciclovir can be incorporated into the DNA of dividing cells, acting as a chain terminator and killing them efficiently.

In a glioblastoma model in the rat and subsequent primate studies, a novel approach using suicide gene transfer was developed ([527]). A retroviral producer cell line releasing a vector containing the herpes virus tk gene was injected directly into brain tumor masses. Dividing tumor cells specifically took up and integrated the vector, whereas nondividing normal neural cells did not. Tumor cells were then specifically killed by systemic administration of ganciclovir. It is interesting that a “bystander” effect was documented: Even tumor cells that had not been transduced with the vector were killed, as long as a significant fraction of the tumor cells was successfully transduced. Evidence for passage of the phosphorylated ganciclovir from transduced tumor cell to contiguous tumor cells has been found ([528]). Some of the killing of nontransduced cells may also be caused by destruction of vector-infected vascular endothelial cells within the tumor, as well as by an induced immune response against the tumor cells stimulated by the death of the vector-transduced cells ([529], [530] and [531]). A clinical trial in humans evaluating this strategy for brain tumors demonstrated tumor reduction in 5 of 15 treated patients, but response was confined to patients with small tumors, indicating the need for further progress ([532]). Other potential suicide genes, such as cytosine deaminase, which converts 5-fluorocytosine to 5-fluorouracil, are in development ([530], [533]). These cytosine deaminase suicide genes can also be targeted using tumor-specific antigens ([534], [535], [536] and [537]). Application of this strategy to hematologic malignancies would be limited to lymphomas and other solid tumors into which one can inject directly.

Enhanced Antitumor Immune Response

A number of investigators have focused on gene transfer as a means to increase the immunogenicity of tumor cells ([538], [539], [540], [541], [542] and [543]). Various cytokines are effective in increasing T-cell immune responses against tumors, but systemic delivery may not be optimal due to short cytokine half-life, toxicity, and low intratumor concentrations. Investigators have attempted to increase both nonspecific and cytotoxic T-cell responses to tumor cells by transducing the tumor with retroviral vectors carrying granulocyte-macrophage colony-stimulating factor, IL-2, interferon-?, or other cytokines ([138], [176], [544], [545]). Efficacy has been demonstrated in murine models, both against transduced tumor cells expressing the cytokine and against nontransduced distant tumor deposits ([546]). Early clinical trials are in progress in melanoma, neuroblastoma, and renal cell carcinoma, which are tumors that other studies have implicated as possibly responsive to antitumor immunotherapy, as well as others such as prostate carcinoma. Primary autologous tumor cells or HLA-matched allogeneic tumor cell lines are first transduced *ex vivo* with a vector containing a cytokine gene, irradiated, and then used to vaccinate the patient ([500], [547]). In one completed human gene therapy trial, eight patients received irradiated autologous tumor vaccines engineered to secrete granulocyte-macrophage colony-stimulating factor by *ex vivo* retroviral transduction of surgically harvested tumor cells, with evidence for induction of both a T- and B-cell response *in vivo* ([548]).

A second approach is to introduce either HLA molecules or co-stimulatory molecules, such as B71 or B72, into tumor cells to increase their immunogenicity ([175]). Tumor cells may escape immune surveillance by down-regulation of major histocompatibility complex molecules or co-stimulatory molecules. Expression of these molecules in tumor cells can allow an immune response to be generated against the tumor cells, even against those that do not express high levels of these molecules. This approach has been used in animal models of a number of different tumors. One early clinical trial involved patients with melanoma ([549]). Foreign HLA class I genes were expressed in tumor cells by direct injection of plasmid DNA–liposome complexes into melanoma nodules. Locally, lymphocyte migration into the lesions was enhanced, as was local TIL cytotoxic activity. Several patients had regression of the injected nodules. TIL cells could be grown from these lesions and, in one patient, were effective in generating a systemic antitumor response. The applicability of these types of approaches to hematologic malignancies is being tested with good results in animal lymphoma and leukemia models ([550]). Another exciting approach involves the use of vectors encoding fusion receptors that would allow T cells to be directed toward a target tumor antigen ([502]). The use of such an approach allowed the generation of T cells expressing fusion receptors directed against prostate-specific membrane antigen containing T-cell signaling elements that were able to specifically lyse tumors expressing this antigen, even after a greater than 2-log expansion ([551]).

APPROACHES TO IMPROVING GENE THERAPY

Engraftment without Ablation

For disorders such as SCID, a growth advantage conferred on genetically corrected cells enables engraftment without conditioning, yet for the majority of disorders in which HSC gene transfer may be applicable, no such advantage to the modified cells is conferred, and most investigators have relied instead on toxic myeloablative conditioning to permit engraftment of genetically modified cells. In the context of clinical trials, however, the potential complications arising from aggressive conditioning are not unacceptable. Chimerism can be achieved in mice in the absence of conditioning by using extremely large bone marrow grafts ([552], [553], [554], [555] and [556]). Improved engraftment with reduced-intensity conditioning can be achieved when hematopoietic growth factors precede conditioning ([557], [558] and [559]). Studies in the nonhuman primate support this notion but point out that some degree of conditioning is required ([560], [561] and [562]). The further extension of studies focused on the development of nonmyelo-ablative conditioning regimens with even lower toxicity in large animals with the aim of reaching clinically relevant levels of engraftment of genetically modified cells will be required to allow widespread clinical application.

Although specific tolerance to foreign transgenes can be obtained by introduction through the HSC population after ablative conditioning ([563]), host immune responses to cells expressing new or foreign transgenes may also be limiting in the absence of such ablative conditioning ([564]). The degree and type of conditioning required to prevent rejection of HSC progeny expressing foreign transgenes are currently being evaluated in both murine and nonhuman primate models, and results suggest that low-intensity conditioning may suffice ([565], [566]).

The ability to attain significant engraftment of genetically modified cells without eliciting host immunity using low-intensity conditioning would allow the pursuit of gene transfer strategies for disorders such as the thalassemias and hemoglobinopathies. Indeed, stable gene transfer levels of 10% or more now achievable in the nonhuman primate with conditioning, if achievable in humans, might suffice for some disorders. Disease amelioration has been achieved after allogeneic

transplantation for both thalassemia and sickle cell anemia even when only partial donor marrow chimerism is attained ([567], [568], [569] and [570]). Altogether, these observations suggest that the establishment of stable hematopoietic chimerism without aggressive cytoreduction may be feasible and that such chimerism resulting from transplantation of genetically corrected cells could be therapeutic for disorders of human globin.

In Vivo Selectable Markers

One strategy to increase the efficiency of gene transfer entails the inclusion of selectable genes in vectors to confer an *in vivo* advantage to transduced cells ([571], [572]). The prototype for this approach is the inclusion of the human multidrug resistance (MDR1) gene, which codes for a transmembrane glycoprotein (p-glycoprotein), an energy-dependent toxin efflux pump ([573], [574]). Cells expressing this protein can extrude many of the chemotherapeutic agents derived from natural products, including the anthracyclines, Taxol, and vinca alkaloids, thereby revealing a drug-resistant phenotype. Mice engrafted with bone marrow cells transduced with an MDR-containing vector and subsequently treated with the cytotoxic drug paclitaxel showed substantial stable increases in the proportion of hematopoietic cells containing the vector, suggesting *in vivo* selection at a very primitive progenitor/stem cell level ([190], [195], [575]).

There are at least two possible applications for this *in vivo* drug selection strategy. Bicistronic vectors capable of coexpression of both a gene of interest (e.g., glucocerebrosidase) and an *in vivo* selectable gene such as MDR have been developed ([65], [576], [577]). If initial *ex vivo* retroviral transduction results in only low-efficiency correction of stem cells, post-BMT treatment with even low doses of MDR-effluxed drugs could result in an increase in the percentage of gene-modified cells to a therapeutically beneficial range. Second, transfer of drug resistance genes to normal marrow progenitor/stem cells has been developed as an approach for decreasing toxicity and increasing dose intensity in patients with nonhematologic malignancies ([178]). Mice engrafted with MDR-transduced marrow cells become increasingly resistant to the marrow-suppressive effects of MDR-effluxed drugs, allowing significant dose intensification ([178], [195], [578]). Based on these results, three human clinical trials piloting this marrow-protective approach were initiated for patients undergoing autologous BMT for solid tumors such as ovarian and breast cancer ([579], [580] and [581]). Modest levels of engraftment were obtained with some evidence for selection after chemotherapy in one trial ([582], [583]). In the interim, however, a direct toxicity from the transfer of the human MDR1 gene into hematopoietic cells, which were expanded *ex vivo*, was noted when murine recipients of such cells developed a myeloproliferative syndrome ([584]). Although experiments conducted in the nonhuman primate to determine the risk of this complication in large animals failed to document its occurrence, the low level of MDR1 expression attainable in the nonhuman primate, in which vector copy number is generally low, may not have been sufficient to produce the phenotype observed in the mice, in which high copy number and high MDR1 expression were seen ([236]).

A number of alternative drug resistance genes have been studied *in vitro* and in murine models, including O6-alkylguanine-DNA-alkyltransferase or glutathione S-transferase, which confer protection against alkylating agents, and mutant dihydrofolate reductases that confer resistance to trimetrexate and other antimetabolites ([585], [586], [587], [588] and [589]). When used as dose-intensification strategies in cancer patients, the dose-limiting toxicity of the treatment regimen must very clearly be bone marrow suppression or no benefit will ensue. Many of these drug resistance gene strategies have begun to show promise for their ability to allow selection at the level of the true HSC in both primary and secondary transplant experiments ([590], [591], [592], [593] and [594]).

Ex Vivo Selection

Positive selection of transduced cells *in vitro* before reinfusion is another strategy to increase repopulation with gene-modified cells. Vectors containing genes for various cell-surface proteins have allowed flow cytometric sorting of successfully transduced cells. A number of studies have used the human cell-surface protein CD24 or heat stable antigen, the murine homolog. There is limited sequence homology between the murine and human forms, and non–cross-reactive antibodies are available. Their small size means that they take up little space in the vector construct. Murine marrow cells transduced with a vector containing human CD24 and sorted before reinfusion result in greatly increased long-term reconstitution with vector-containing cells ([595]). A vector expressing the murine equivalent, heat stable antigen, allows enrichment for transduced human progenitor cells ([596]). However, CD24 and heat stable antigen are glucose phosphate isomerase–linked surface proteins, a class of proteins that has been shown to be transferred from cell to cell both *in vitro* and *in vivo*, clouding the specificity of this marker and raising concerns about ectopic expression of these genes *in vivo* ([156], [595], [596]).

Retroviral vectors carrying a truncated, nonfunctional form of the human nerve growth factor receptor have also been developed as a selectable marker for use on hematopoietic targets, because hematopoietic cells do not express endogenous nerve growth factor receptor. Transduction and sorting of lymphocytes using this system are sensitive and specific; clinical trials using cells sorted for this transduction marker have begun ([320], [323]). The introduction of new cell-surface proteins has the theoretic disadvantage of altering trafficking or cell–cell interactions on infusion of transduced cells. Alternative cytoplasmic markers, such as green fluorescent protein and mutated murine protein, are naturally fluorescent, avoiding the need for preselection antibody staining ([597]). However, prolonged stable expression of these proteins has proved difficult, and there is evidence that these proteins are toxic to primary mammalian cells ([598], [599]). The use of selection for green fluorescent protein after retroviral-mediated transduction in the nonhuman primate model to increase engraftment by genetically modified cells results in increased short-term engraftment only, raising another concern that expression of transferred genes may be more efficient in differentiated cells than in stem cells, effectively enriching for progenitors with only short-term potential ([600]).

Ex vivo selection strategies using these types of vectors have already been shown to be very useful for lymphocyte targets, where expansion of transduced cells does not appear to affect phenotype or *in vivc* function ([320]). However, low transduction efficiency of primitive human HSCs may preclude posttransduction sorting for a marker gene if, after sorting, too few stem cells remain to allow safe and rapid hematopoietic reconstitution; this is especially problematic after ablative chemotherapy. A potential solution to this problem would be *ex vivo* expansion of selected transduced cells before reinfusion, although it is unknown whether true long-term repopulating cells can be expanded or even maintained *ex vivo* using current culture conditions ([233], [236], [601], [602] and [603]). Most of the murine studies have assessed engraftment into lethally irradiated or genetically stem cell–deficient animals. When, however, *ex vivo* cultured cells compete against endogenous stem cells in a nonablative model, a significant engraftment defect is evident ([232], [604]). Moreover, when an *ex vivo* transduction protocol that routinely yielded high levels of marked cells after myeloablation was used in nonablated mice, very low levels of vector-containing cells were detected ([605]).

A number of alternative genetically based approaches aiming to enhance hematopoietic reconstitution have also been described ([606]). For example, mouse HSCs transduced with the homeobox gene, HOXB4, possess more than tenfold greater repopulating ability than nontransduced bone marrow ([607]). Furthermore, transgenic overexpression of the antiapoptotic protein Bcl-2 results in increased HSC numbers ([608]), and expression of a truncated form of the human erythropoietin (Epo) receptor can augment HSC engraftment through the use of exogenous Epo ([609]). Blau and colleagues have used inactive monomeric signaling domains derived from receptors such as Epo or thrombopoietin to permit controlled growth of genetically modified cells through the use of chemical inducers of dimerization ([610], [611]). Another approach involves selective enrichment of genetically modified cells using vectors encoding a fusion protein between the growth signaling portion of the G-CSF receptor and the hormone-binding domain of the estrogen receptor. This approach allows controlled growth of genetically modified cells using exogenous estrogen, and preclinical testing in the nonhuman primate has demonstrated the feasibility of this approach ([612], [613]). The optimization of such approaches could enable one to control the overall level of contribution toward hematopoiesis by genetically modified cells *in vivo* after transplantation such that therapeutic efficacy could be achieved in disorders in which no selective advantage is conferred on the corrected cells. The theoretic potential for accelerating HSC exhaustion and concern for an increased risk for leukemogenesis by applying such pressure on hematopoiesis require further safety testing.

Alternative Vectors

Alternative vector systems continue to be explored given the overall low transduction efficiencies of human hematopoietic cells with standard retroviral vectors. *Pseudotyping*, or the replacement of the Moloney murine leukemia virus envelope protein with an alternative protein, has been developed as an approach to changing target cell specificity or the physical properties of the vector particle. The presence of the VSV envelope protein results in increased viral stability and ability to concentrate vector preparations but no increase in transduction efficiency of hematopoietic progenitor cells ([31], [86], [614]). Pseudotyping with gibbon-ape leukemia virus envelope protein improves the transduction efficiency of primate lymphocytes and may confer increased efficiency to HSCs when compared to standard amphotropic vectors ([94], [214], [316]). Amphotropic or ecotropic envelope proteins made chimeric by the addition of a ligand, such as SCF, have been explored as a mechanism for targeting vectors to specific cell types such as primitive hematopoietic cells expressing the SCF receptor *c-kit*. Despite some encouraging reports and clear evidence of production of vectors containing modified envelope proteins that can bind specifically to receptor-bearing target cells, intracellular processing can be disrupted, with inefficient or nonexistent actual transduction and integration ([34], [90], [615], [616]). The low-level expression of the amphotropic receptor required for standard retroviral vectors on HSCs ([89]) has stimulated interest in pseudotyping with alternative envelope proteins, including the GALV ([94]), VSV-G ([237]), and the feline endogenous

retrovirus (RD114) ([93]), as a means to further increase gene transfer efficiency.

A major limitation to the efficiency of retroviral gene transfer is the requirement for active cell cycling of the target cell at the time of, or very soon after, exposure to the viral vector. Optimal gene transfer would be accomplished by vectors capable of integrating into the host genome without cell division. As described earlier, this property is shared by HIV and other lentiviruses. Pseudotyping of HIV-based vectors with VSV or amphotropic envelope protein could allow transduction of hematopoietic progenitor and stem cells, whereas use of the HIV envelope would be applicable only to $CD4^+$ target cells ([100]). Indeed, lentiviral vectors have proven efficient in transducing nonhuman primate cells in the baboon model after a brief exposure *ex vivo*, yet significant marking levels were only observed when cells were cultured in the presence of multiple hematopoietic growth factors ([617]). HFVs have been shown to infect human hematopoietic progenitor cells but do not have clear advantages over standard retroviral vectors for hematopoietic applications, although HFV receptors may be more ubiquitous and highly expressed ([109]). Moreover, the problems encountered in the production of replication-competent, retrovirus-free vector have been overcome. The nonpathogenic nature of HFV makes vectors based on this virus more palatable.

Despite a great deal of initial enthusiasm for the use of AAV as a clinical gene transfer vector, more recent data argue against the use of AAV for most applications requiring stable integration in hematopoietic cells and their progeny. Several laborato-ries have reported high transduction efficiency of both human and murine hematopoietic progenitors, as assayed by PCR or transgene expression analysis on individual CFU-C ([157], [618], [619]). These results are difficult to interpret, however, given the stability of the AAV vector DNA and the very high efficiency of transient expression of transgenes for days to weeks without integration ([156], [618], [619]). Although p studies indicate no advantage over retroviral vectors in terms of gene transfer into repopulating stem cells, efficient transfer to hematopoietic cells can be obtained using AAV vectors ([620], [621]). The need for integration has precluded extensive investigation of nonviral delivery systems for hematopoietic applications requiring long-term expression.

Gene Correction

All the current vectors and protocols have attempted phenotypic correction or modification by gene addition, generally randomly in the genome. A different process, gene correction by homologous recombination in hematopoietic tissues, has been proposed as an alternative ([35]). Although correction of the genetic defect in lymphoblastoid cell lines derived from patients with sickle cell disease was described ([36]) using an RNA-DNA oligonucleotide, the general applicability of this approach has not been validated.

An alternative corrective approach for some disorders, including a sizable fraction of the human thalassemias, which result from aberrant RNA splicing, has recently been described. Constructs targeting aberrant splice sites in the form of oligonucleotides, morpholinos, or U7 small nuclear RNAs lead to increased levels of correctly spliced ß-globin mRNA by effectively blocking the aberrant splice site through the use of sequences complementary to the corrected sequence ([622], [623] and [624]). A major problem with this approach remains the difficulty in delivering such constructs *in vivo* with sufficient efficiency to correct the phenotype, and, recently, lentiviral vectors designed to permanently deliver modified U7 small nuclear RNAs have been tested in cell lines and in primary cells from individuals with thalassemia with encouraging early results ([625]).

Immune Responses to Vectors and Transgenes

Immune responses against vector proteins or the transgene-encoded protein itself have only recently become the focus of intensive investigation. For *in vivo* vector administration, preexisting immunity to a vector such as adenovirus is at least a theoretic concern. Repeated *in vivo* administration of complex vectors clearly stimulates an active immune response to vector proteins and greatly hinders success. The expression of viral genes remaining in the vector sequences could also stimulate an immune response against transduced target cells. This is not a problem for retroviral vectors; as well, newer modifications of adenoviral vectors have been developed that no longer contain or express residual adenoviral genes ([126], [127]). Nonhuman marker genes, such as the neomycin resistance gene, or viral suicide genes, such as tk included in vectors for positive or negative selection, may also induce an immune response ([326]). Finally, the therapeutic gene itself may induce an immune response if the patient completely lacks the endogenous gene product ([122]).

Rejection of the foreign transgene itself can be the primary problem, even when highly immunogenic adenoviral vectors are used. Recombinant adenoviral vectors encoding either murine or human Epo genes or a control vector without an expressed gene were injected into murine muscle, and the mice were followed up for several months for Epo expression and presence of the vector sequences in muscle ([122]). Mice expressing either human or murine Epo transgenes developed high hematocrits, but the effect was transient in those expressing human Epo, as profound anemia, surprisingly, developed after the transient polycythemia. Immune responses to both the vector-expressed human Epo and endogenous murine Epo were documented in these animals, indicating that the active immune reaction against the human Epo had also generated cross-reactivity toward endogenous Epo. Adenoviral genomes were detectable long-term in the muscles of the murine Epo mice and the control mice but not in the human Epo mice. This suggests that the immune response was elicited by expression of the foreign transgene, not by viral proteins.

In a murine model of allogeneic skin graft survival, foreign genes expressed by HSCs and their progeny may be capable of inducing tolerance even across major histocompatibility complex barriers ([626]). This evidence and documentation in mice of very long-term persistence of expression of completely xenogeneic genes such as human glucocerebrosidase have led some to believe that immune responses against genes introduced via repopulating stem cells will not induce immune responses ([187], [627]). On the other hand, immune responses to a retroviral vector–introduced transgene in the canine MPS-1 autologous transplantation model have been shown to limit efficiency ([628]).

In the murine model, tolerance to xenogeneic genes can be achieved by introduction through the hematopoietic compartment ([629]). Long-term persistence of genetically modified cells at clinically relevant levels can be achieved even after very low-dose irradiation with 100 cGy, even when highly immunogenic genes are transferred. Large animal testing in the nonhuman primate confirms these observations, with equivalent levels of long-term engraftment of cells transduced with a vector encoding the neomycin phosphotransferase (neo) and with a vector carrying but not expressing this gene product, but the overall levels of engraftment were much lower ([562]). Transduction of lymphocytes in the absence of conditioning, however, resulted in rapid clearance of the neo-expressing cells. However, if HSCs were transduced and transplanted first, long-term persistence of lymphocytes transduced with the neo-expressing vector was observed ([563]).

Various methods of immunosuppression have been at least partially successful in avoiding immune rejection of transduced cells. Neonatal exposure to vector has allowed repeated treatments with adenoviral vectors ([630]). Treatment with cyclosporine, cyclophosphamide, or IL-12 has been reported to prolong survival of transduced cells ([128], [129], [130], [131] and [132]). But these general pharmacologic approaches are not desirable or practical for most gene therapy applications, which are attractive only if they prevent life-long reliance on toxic pharmacologic agents. Instead, improved vector design and possible inclusion of antirejection mechanisms in the vectors themselves are more attractive approaches.

SAFETY CONSIDERATIONS

The number of individuals who have safely received genetic material in the form of vectors or vector-modified cells is now in the thousands (Table 26.1), suggesting that current approaches carry a low risk to subjects; however, safety remains the primary goal of the majority of published or in-progress studies. Although clinical benefit is the ultimate goal of all such endeavors, early studies exploring new strategies are appropriately designed around safety endpoints. Pharmacokinetic principles dictate that drug toxicity is related to bioavailability, volume of distribution, clearance, and half-life, and these principles can also be applied in the setting of gene therapy. Considering that the overwhelming majority of gene therapy trials conducted thus far have not even approached the therapeutic window along with the general rule that toxicity often lies somewhere beyond the therapeutic threshold, it remains appropriate to conduct all current trials at the phase I/II level. Side effects of gene transfer can result from all levels of the process, including those inherent to the vector system, vector production, target cell manipulation, vector integration, transgene expression, or selective pressure applied after transfer ([631]).

The first reported serious complication of gene therapy occurred when an 18-year-old patient with OTC deficiency volunteered for a dose-escalation gene therapy trial and received a catheter-directed infusion of a high dose of an adenoviral vector encoding the corrective OTC into the hepatic artery. Within hours of the infusion, signs and symptoms of a systemic immune response syndrome appeared, and soon thereafter, the patient required extracorporeal membrane oxygenation for life support. Two days later, the patient died from multiorgan system failure.

Since his death, the case has been studied extensively, and many experiments have been performed to determine the exact mechanism for his death. Other patients on the study experienced liver toxicity at similar doses of the adenovirus-OTC vector, but the toxicity was mild and reversible. Preclinical studies of the vector in nonhuman primates have shown evidence for activation of the innate immune response attributable to the adenovirus capsids as well as a vigorous IL-6 response ([410] , [412]). Thrombocytopenia and abnormal blood coagulation parameters (with or without evidence for damage to endothelial cells and disseminated intravascular coagulation) have also been seen in nonhuman primates ([410] , [412] , [632]). The induction of IL-6 and other acute phase reactants was anticipated from the preclinical data in nonhuman primates; however, the severity and duration of the fatal reaction observed were not expected at the dose level reached. It remains unclear even now whether the toxicity represented an idiosyncratic reaction to the adenovirus vector or whether the patient was at the leading edge of a toxic dose-response curve. Whether the catabolic state induced by the adenovirus vector caused his OTC deficiency to decompensate remains another unresolved issue.

As a result of the death, many clinical gene therapy trials were temporarily put on hold, and the maximum doses of adenovirus (or other) vectors to be given to humans were scaled back as a precautionary measure. Furthermore, a number of issues with respect to the pace of clinical gene therapy trials, the informed consent process, subject eligibility, reporting of adverse events, and oversight of clinical gene therapy trials were raised, and measures to increase the protection of research subjects were uniformly instituted across all gene therapy trials.

Soon after the first unequivocal demonstration of clinical efficacy in a human gene therapy trial, in which 10 of 11 children with SCID who received retrovirally transduced autologous bone marrow cells were apparently cured ([22]), two patients developed a complication that appears to be directly related to the gene transfer. Both received retrovirally transduced bone marrow CD34 $^{+}$ cells at a very young age and experienced rapid and complete immune reconstitution. Three years after the successful infusion, a precipitous rise in T-cell counts was observed, which progressed to overt leukemia ([633]). Retroviral integration site analysis demonstrated an insertion in or near the Lmo-2 gene, a transcription factor required for fetal hematopoietic development and already linked to spontaneous childhood T-cell leukemia ([634]), in both patients, suggesting that this complication arose as a direct result of insertional mutagenesis ([633]).

These events resulted in a rapid response from investigators and regulatory agencies worldwide, most initially stopping all accrual to gene therapy trials using integrating retroviral vectors in hematopoietic targets. Since that time, a number of U.S. Food and Drug Administration and Recombinant DNA Advisory Committee meetings have occurred to analyze and respond to these events. Clearly, further investigation is required, both of patients in clinical trials and of experimental models, to better understand the etiology of the leukemias observed. Although fatal malignancies were observed in the nonhuman primate model after retroviral gene transfer complicated by inadvertent contamination with replication-competent virus, no cases of insertional mutagenesis had been observed in human recipients of replication-competent retrovirus–free retrovirally transduced hematopoietic cells. However, 1 day after the report of the successful trial in humans, such a complication was reported in the mouse model ([635]). The observed leukemias were a direct result of insertional mutagenesis but were noted only in secondary transplant recipients who were followed up long term. These observations in both the patients and in preclinical models stressed the need for long-term toxicity assessment in preclinical models.

Integration in or near Lmo-2 in both patients has also challenged conventional dogma with respect to retroviral integration, which is generally believed to be random or semirandom. One recent report demonstrated an approximately twofold preference of HIV for chromosomal regions containing active genes. It is likely that several factors were required to result in leukemias in the children, including increased activity of Lmo-2 in the target cell population, the constitutive expression of a growth factor receptor (IL2R?) in hematopoietic cells perhaps at all levels of development, expansion of a target lymphoid progenitor population, marked *in vivo* expansion of corrected cells due to the underlying immune deficiency increasing the likelihood of a second hit, and, finally, rescue of a malignant phenotype by transfer of the corrective gene. These and a number of other issues remain to be investigated to better assess the potential of retrovirally mediated HSC gene therapy.

Although these examples of serious toxicity with gene transfer are the exception, both have occurred in trials that either approached or reached therapeutic efficacy and point out that there may be a narrow therapeutic index with certain approaches or clinical settings. One must also consider that the absence of toxicity in protocols that fail to achieve significant gene transfer rates may not be sufficient to establish safety, in much the same way that one could not establish the safety of a new drug delivered orally if the drug was either not absorbed or absorbed at a very low level. Small and large animal preclinical models along with carefully constructed phase I/II clinical trials in humans in the appropriate setting remain the priority for this young, promising field of medicine.

CONCLUSIONS

The wide variety of imaginative approaches involving genetic manipulation of hematopoietic targets and other novel approaches to hematopoietic diseases, such as leukemia or hemophilia, are certain to eventually revolutionize therapy for a number of currently fatal or disabling conditions, but further basic scientific investigation of target cell biology and vector systems will be necessary before these goals can be realized on a large scale.

Anemia: General Considerations

This introductory chapter focuses on the general concepts of anemia, the classification of the most common types of anemia, the approach to patients with hemolysis, and the assessment of posthemorrhagic anemia. Anemia rarely is a disease by itself; almost always it is a consequence of another acquired or genetic abnormality. The various medical conditions that result in anemia encompass nearly the full spectrum of human disease.

DEFINITION OF ANEMIA

Red blood cells (RBCs) circulate in the peripheral blood for 100 to 120 days, and approximately 1% of the body's red cells are lost and replaced each day. Red cells recognized as being old are removed from the circulation by macrophages in the spleen, liver, and bone marrow (Chapter 9). An erythropoietic feedback loop ensures that the total red cell mass remains constant (Chapter 7).

Anemia is functionally defined as an insufficient RBC mass to adequately deliver oxygen to peripheral tissues. For practical purposes, any of the three concentration measurements are used to establish the presence of anemia: hemoglobin (Hb) level (g/dl), hematocrit (%), RBC number (10^{12}/L).

In the past, these parameters were measured using manual physical and chemical techniques, but now these assays are determined by electronic cell counters and Hb analyzers (Chapter 1). In most of the current analyses, RBC number, Hb concentration, and mean corpuscular volume (MCV) are directly measured; these values are used to calculate the hematocrit, the mean corpuscular Hb (MCH), and the MCH concentration (MCHC). The electronic counters also generate an index of red cell size, the red cell distribution width (RDW). The RDW is a quantitative measure of the variation in red cell size, and the higher the values, the more heterogeneous the RBC population size. The mean normal Hb and hematocrit value and the lower limits of the normal range depend on the age and gender of the subjects, as well as their altitude of residence (Appendix A).

Anemia in Adults

Most references consider Hb concentrations of 14 g/dl and 12 g/dl as the lower limits of normal, at sea level, in adult men and women, respectively ([1]). These values have received wide acceptance and often are used in population surveys ([2]). However, data from a large, diverse, and carefully selected sample suggest that these values are somewhat high. The sample studied during the second National Health And Nutrition Examination Survey (NHANES II), 1976–1980, was selected statistically as representative of the entire population of the United States ([3]). Age, gender, and race as well as geographic and socioeconomic factors were factored into the selection process. For the purpose of determining normal values, subjects were excluded if they were pregnant, if a hereditary hemoglobinopathy was detected, or if the transferrin saturation, MCV, or erythrocyte protoporphyrin value was abnormal. By these means, iron-deficient subjects were effectively excluded. The values of the remaining 11,547 subjects were used to calculate a 95% reference range. In adult subjects (age 10 to 44 years), the lower limit of normal was 13.2 g/dl in men and 11.7 g/dl in women (Fig. 27.1). Values for black subjects were approximately 0.5 to 0.6 g/dl lower than those of white subjects.

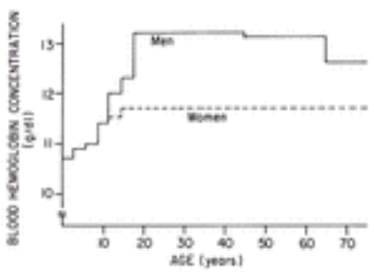

Figure 27.1. The lower limit of normal blood hemoglobin concentration in men and women of various ages. Values were calculated from a sample of 11,547 subjects selected to represent the population of the United States. Subjects with iron deficiency, pregnancy, or an abnormal hemoglobin value were excluded from the sample. [From Dallman PR, Yip R, Johnson C. Prevalence and causes of anemia in the United States, 1976 to 1980. Am J Clin Nutr 1984;39(3):437–445, with permission.]

Hemoglobin Values in the Elderly

From the NHANES II study, the normal Hb values decreased after the age of 65 years, but whether these lower levels of Hb in elderly subjects (especially men) represent a physiologic phenomenon or the development of a substantially increased prevalence of anemia in this age group is not known ([4]). By using 14 g/dl and

12 g/dl as the lower limits of normal in men and women, respectively, anemia was found in as many as 25% of apparently healthy individuals older than 65 years of age ([5], [6]). However, in most cases, careful clinical investigation did not uncover a specific cause of anemia. The lower levels therefore could result from decreased androgen secretion in men or from age-related decreases in stem cell proliferation ([7]). These results suggest that somewhat lower limits of normal might be used in evaluating the elderly. However, the too easy acceptance of mild anemia as a physiologic phenomenon in the elderly runs the risk of ignoring a potentially valuable, early clue to an important underlying disorder.

Hemoglobin Values in Infants and Children

At the other extreme of life, the definition of anemia in infancy and childhood is different from adults. The lower limit of normal Hb concentration at birth is 14 g/dl, and this decreases to 11 g/dl by 1 year of age. This Hb decrement, referred to as the *physiologic anemia of infancy*, occurs as part of the normal physiologic adaptation from the relatively hypoxic intrauterine existence to the well-oxygenated extrauterine environment (Chapter 48). Also, as fetal erythropoiesis is replaced, the MCV decreases from birth (100 to 130 fl) to 1 year of age (70 to 85 fl).

Even after the first year of life, normal childhood Hb and MCV values remain considerably lower than those occurring in adolescents and adults (Table 27.1). From the NHANES II study, the lower limit of normal Hb concentration in both male and female children, ages 1 to 2 years, was 10.7 g/dl, and the value rose with advancing age until adult levels were reached at age 15 to 18 years.

TABLE 27.1. Red Blood Cell Characteristics in Childhood

Age	Lowest Normal Hb (g/dl)	Normal Red Blood Cell Size Mean Corpuscular Volume (fl)	Fetal Hb (%)
Birth	14.0	100–130	55–90
1 mo	12.0	90–110	50–80
2 mo	10.5	80–100	30–55
3–6 mo	10.5	75–90	5–25
6 mo–1 yr	11.0	70–85	<5
1–4 yr	11.0	70–85	<2
4 yr–puberty	11.5	75–90	<2
Adult female	12.0	80–95	<2
Adult male	14.0	80–95	<2

Hb, hemoglobin.

There has been no completely satisfactory explanation for these differences in normal Hb values of children and adults, but it is not due to nutritional deficiencies. Of interest, it has been demonstrated that serum inorganic phosphate is 50% higher in children compared to adults, and this hyperphosphatemia is associated with elevated erythrocyte adenosine triphosphate and 2,3-diphosphoglycerate content, and thus, the erythrocyte oxygen affinity is decreased in children compared to adults. On this basis, it has been postulated that lower Hb values in children may be due to altered Hb-oxygen affinity and thereby represent a physiologic anemia of childhood ([8]).

At puberty, the Hb concentration in children reaches the same levels seen in adults. The higher Hb levels in males presumably are a reflection of the effects of androgens on erythropoiesis.

Limitations in the Use of Hemoglobin, Hematocrit, and Red Blood Cell Measurements in Defining Anemia

For practical purposes, the blood hemoglobin and hematocrit determinations are useful in assessing for anemia in most patients, but there are limitations that must be recognized:

1. Hb changes may reflect altered plasma volume, not a change in RBC mass (Table 27.2). In pregnancy, for example, the plasma volume increases, thereby decreasing the Hb concentrations, although, in fact, total RBC mass actually is increased, but to a lesser degree than the plasma volume ([9], [10], [11] and [12]) (Chapter 48). Similarly, individuals with massive splenomegaly may have some anemia because of hypersplenism (Chapter 38), but the degree of anemia may appear more severe because of an increased plasma volume. Conversely, burn patients lose plasma, not RBC, through the injured skin, leaving Hb concentrated at a higher level. Other causes of dehydration with depletion of intravascular space also produce a spuriously high Hb concentration. In chronically ill patients with a reduced red cell mass, the magnitude of anemia may be masked by an associated contraction of the plasma volume ([13], [14], [15], [16] and [17]).

TABLE 27.2. Conditions Associated with Discordance Between Hemoglobin Concentration and Red Cell Mass

Increase in plasma volume relative to RBC mass (Hb disproportionately low)
Hydremia of pregnancy
Congestive splenomegaly
Recumbency (vs. upright)
Decrease in plasma volume relative to RBC mass (Hb high, normal, or low; but high relative to RBC mass)
Dehydration
Protracted diarrhea (especially in infants)
Peritoneal dialysis with hypertonic solutions
Diabetic acidosis
Diabetes insipidus with restricted fluid intake
Burn patients
Stress erythrocytosis, spurious polycythemia
Decrease in both plasma volume and RBC mass (Hb normal, RBC mass low)
Acute blood loss
Chronic disease

Hb, hemoglobin; RBC, red blood cell.

2. Another consideration is that Hb changes may reflect underlying physiologic conditions with different oxygen needs. For example, an emphysematous patient, or one with right to left cardiac shunt, or in an Andes dweller, oxygen needs are increased, and these individuals often are polycythemic with elevated Hb levels. A normal Hb level in such a patient actually may represent anemia by the functional criterion of adequately meeting tissue oxygen requirements. Conversely, patients with hypothyroidism (decreased oxygen needs) may have low Hb levels, but yet have adequate oxygen delivery for the apparent oxygen needs.
3. Some abnormal Hb variants have an altered ability to bind and release oxygen, and this can be associated with changes in Hb concentration. For example, Hb Yakima has increased oxygen affinity with a low P50, and higher than normal Hgb levels are characteristic. Conversely, Hb Kansas has decreased oxygen affinity, high P50, and lower than normal Hgb levels. Despite the disparate Hb levels in these cases, both satisfy the criteria of appropriate oxygen delivery for tissue oxygen needs.
4. Acute blood loss is another example of the problem of denoting anemia by the Hb concentration. Immediately after loss of a liter of blood, the Hb level is normal,

because the initial response to acute hemorrhage is vasoconstriction. The shift of fluid from extravascular to intravascular space, and thus the decrease in Hb concentration, does not begin for 6 hours, and can continue for 48 to 72 hours. Reticulocytosis occurs after 24 to 48 hours.

5. Impaired partial synthesis of one globin-chain, as in thalassemia trait, may be reflected in a low Hb (10 g/dl) and a high RBC count (6.5 million/µl), thus giving anemia by one measure (Hb) and polycythemia by another (RBC).

In addition to the issues listed above, changes in posture also have effects on red cell concentration that can influence Hb and hematocrit measurements. When normal individuals assume a recumbent position, the hematocrit falls an average 7% (range, 4 to 10%) within 1 hour ([18]). When the upright position is resumed, the hematocrit increases by a similar amount within 15 minutes. These changes have been attributed to alterations in plasma volume as fluid moves between the circulation and the extravascular spaces in the lower limbs as a result of hydrostatic forces.

CLINICAL EFFECTS OF ANEMIA

Patients with anemia usually seek medical attention because of decreased work or exercise tolerance, shortness of breath, palpitations, or other signs of cardiorespiratory adjustments to anemia. At times, they feel fine, but their friends or family have noted pallor. It is not uncommon that anemia in a child is first recognized by a visiting relative, the process sometimes occurring so slowly as to not be noted by parents or other immediate family members.

Cardiovascular and Pulmonary Features of Anemia

The clinical manifestations of anemia depend on the magnitude and rate of reduction in the oxygen-carrying capacity of the blood, the capacity of the cardiovascular and pulmonary systems to compensate for the anemia, and the associated features of the underlying disorder that resulted in the development of anemia. The Hb concentration is not the only determinant of the observed symptoms. Coexistent cardiovascular or pulmonary disease, particularly in older individuals, may exaggerate the symptoms associated with a degree of anemia that would be well tolerated under other circumstances.

If the anemia has been insidious in onset and there is no cardiopulmonary disease, the patient's adjustment may be so good that the blood Hb concentration may fall to 8 g/dl or even lower before the patient experiences enough symptoms to appreciate the situation ([19]). In cases of iron deficiency anemia, pernicious anemia, or other types of slowly developing anemia, Hb concentrations may reach levels of 6 g/dl or lower before patients are motivated to seek medical attention ([20]). This is particularly true in children where no limitations of physical activity may be apparent despite the existence of very severe anemia ([21]). The physiologic adjustments that take place with a slowly falling red cell mass chiefly involve the cardiovascular system and changes in the Hb-oxygen dissociation curve.

In many patients, respiratory and circulatory symptoms are noticeable only after exertion; however, when anemia is sufficiently severe, dyspnea and awareness of vigorous or rapid heart action may be noted even at rest. When anemia develops rapidly, shortness of breath, tachycardia, dizziness or faintness (particularly upon arising from a sitting or recumbent posture), and extreme fatigue are prominent. In chronic anemia, only moderate dyspnea or palpitation may occur, but in some patients, congestive heart failure ([22]), angina pectoris, or intermittent claudication ([23]) can be the presenting manifestation. In patients with severe chronic anemia, tachycardia and postural hypotension may not be present because the total blood volume actually may be increased due to an expanded plasma volume. It is in these cases that rapid administration of a blood transfusion may precipitate congestive heart failure by aggravating an already expanded blood volume.

Heart murmurs are a common cardiac sign associated with anemia. They usually are systolic in time and best heard in the pulmonic area ([24] , [25] and [26]). Often, they are moderate in intensity, and at times may be rough in quality and raise suspicion of organic valvular heart disease.

Pallor

Pallor is a sign of anemia, but many factors other than Hb concentration affect skin color. These include the degree of dilation of peripheral vessels, the degree of pigmentation, and the fluid content of the subcutaneous tissues. Certain people routinely have pale-appearing skin without being anemic. Patients with myxedema may manifest pallor without anemia. In simple vasovagal syncope, pallor results from cutaneous vasoconstriction and is not a sign of anemia. Jaundice, cyanosis, racial skin pigmentation, and dilation of the peripheral vessels all can mask the pallor of anemia.

The pallor associated with anemia is best detected in the mucous membranes of the mouth and pharynx, the conjunctivae, the lips, and the nail beds. In the hands, the skin of the palms first becomes pale, but the creases may retain their usual pink color until the Hb concentration is less than 7 g/dl.

A distinctly sallow color implies chronic anemia. A lemon-yellow pallor suggests pernicious anemia, but it is observed only when the condition is well advanced. Definite pallor associated with mild scleral and cutaneous icterus suggests hemolytic anemia. Marked pallor associated with petechiae or ecchymoses suggests more generalized bone marrow failure due to acute leukemia, aplasia, or myelophthisis.

Skin and Mucosal Changes

Other changes in the integument occur with anemia. Thinning, loss of luster, and early graying of the hair may occur, the last especially in patients with pernicious anemia, in whom it may precede the development of anemia. The nails may lose their luster, become brittle, and break easily. This finding is especially noticeable in chronic iron deficiency anemia ([27]), in which the nails may actually become concave instead of convex (Chapter 28). Chronic leg ulcers may occur, especially in patients with sickle cell anemia and rarely in those with other hemolytic anemias. Glossitis occurs in association with pernicious anemia. When nutritional deficiency is associated with anemia, symmetric dermatitis may develop, fissures may be present at the angles of the mouth, glossitis may occur, and erythematous lesions on the face, neck, hands, or elbows may be found.

Neuromuscular Features

Headache, vertigo, tinnitus, faintness, scotomata, lack of mental concentration, drowsiness, restlessness, and muscular weakness are common symptoms of severe anemia. Paresthesias are common in pernicious anemia and may be associated with other symptoms and signs of peripheral neuropathy, and more especially with combined system disease (see Chapter 43).

Ophthalmologic Findings

A variety of ophthalmologic findings have been observed in anemic patients ([28] , [29] and [30]). Approximately 20% of such patients have flame-shaped hemorrhages, hard exudates, cottonwood spots, or venous tortuousness affecting the retina. The hemorrhages occur even in the absence of coexisting thrombocytopenia. Papilledema related solely to anemia has been described ([31] , [32]), and it clears when the anemia disappears.

Gastrointestinal Changes

Gastrointestinal symptoms are common in anemic patients. Some are manifestations of the underlying disorder (e.g., hiatal hernia, duodenal ulcer, or gastric carcinoma); others may be a consequence of the anemic condition, whatever its cause. Glossitis and atrophy of the papillae of the tongue commonly occur in pernicious anemia and less often in iron deficiency anemia. Painful, ulcerative, and necrotic lesions in the mouth and pharynx occur in aplastic anemia and in acute leukemia, usually reflecting the neutropenia accompanying these conditions. Dysphagia may occur in chronic iron deficiency anemia.

EVALUATION AND CLASSIFICATION OF ANEMIA

History and Physical Examination

All aspects of the history and clinical examination are important. The duration of the symptoms and their onset, whether insidious or acute, should be established. It is very helpful to know the most recent date at which a routine hematologic examination was normal.

The family history is important with respect to history of jaundice, gallstones, and splenectomy (see Approach to Hemolysis). A family history of any bleeding disorder also is important.

The patient's occupation, household customs, and hobbies must be ascertained because certain drugs, solvents, and other chemicals may produce hemolytic anemia or aplastic anemia, as well as granulocytopenia and thrombocytopenia. Also, social habits (alcohol use), travel history (to malarious or other infectious areas), and drug history are all important in attempting to ascertain the underlying etiology.

The dietary history is critical to the analysis, and questions regarding the diet must be specific (i.e., meal-by-meal) in the hope of obtaining quantitative information. A record regarding dietary idiosyncrasies and cooking habits may be valuable, especially with reference to folic acid intake. In very young children, those who obtain the bulk of their nutrition from cow's milk (good for calories, very low in iron) are at great risk for iron deficiency anemia. Changes in weight are most important in both adults and children.

The patient should be questioned about early graying of the hair, burning sensations of the tongue, sores about the angles of the mouth, and discomfort and brittleness of the fingernails, which are symptoms of the anemias caused by the deficiency of specific nutrients.

Change in stool habits may be an important clue to neoplasms of the colon and rectum underlying the anemia. The significance of tarry stools often is not appreciated by patients, and specific inquiry is necessary. The amount of blood lost from hemorrhoids may be overlooked or overestimated. In men, occult blood loss most often is from the gastrointestinal tract.

In women, additional important information includes an appraisal of the amount of blood lost during menstruation. Data about number of pads or tampons used and the presence or absence of clots should be obtained. Menstrual flow should be deemed excessive if more than 12 pads are used each period, if clots are passed after the first day, or if the period duration exceeds 7 days. The number of pregnancies and abortions and the interval since the most recent of these are also important, for each represents significant iron loss.

The presence or absence of fever must be known; its presence suggests infection, lymphoma, or other neoplasm or collagen disease. Pains in the limbs, paresthesias, and difficulty in walking suggest pernicious anemia. Abnormal color of the urine, suggesting blood or Hb, may signify urinary tract disease or hematologic problems. Bilirubin is not detected in the urine of people with uncomplicated hemolytic anemia, but a darker than normal color may result from the increased excretion of urobilinogen and its conversion to urobilin.

Bruises, ecchymoses, and petechiae are other important points in the history. Their presence indicates that the disorder producing anemia may also involve platelets or the liver. Alternatively, the anemia itself may be the consequence of blood loss resulting from a disorder of hemostasis.

In all instances, the presence or absence of symptoms suggestive of an underlying disease such as chronic renal disease, liver disease, chronic infection, endocrinopathy, or malignancy must be explored. Anemia can be the presenting feature of many of these disorders.

The physical examination can provide further clues to the cause of anemia. Scleral icterus suggests the presence of hemolytic anemia or ineffective erythropoiesis. Sternal tenderness near the middle or lower one-third of the sternum, of which the patient may have been unaware, is a useful sign in some patients with acute leukemia. Palpation of the liver and spleen and a systemic check for lymphadenopathy is necessary as a clue to infection, lymphoma, leukemia, or metastatic carcinoma.

The initial patient evaluation should include a urinalysis. Even when the color of the urine does not suggest blood, the routine urinalysis should be tested for occult blood. A positive reaction may be due to hematuria, hemoglobinuria, or even myoglobinuria. Hematuria may be differentiated from the other conditions by finding RBCs on microscopic examination of the urine, or by centrifuging a fresh urine specimen, thereby clearing the bloody color from the supernatant and depositing the RBCs in the bottom of the tube. Hematuria reflects disease of the kidneys or urinary tract. Sickle cell trait may be accompanied by innocuous hematuria. Hemoglobinuria implies intravascular hemolysis.

Evaluation of Basic Hematology Laboratory Data

To identify the cause of anemia, information from the medical history and physical examination must be integrated with some key laboratory tests. There is no one simple classification of anemia. A useful approach entails asking several questions, outlined in the following sections (Fig. 27.2).

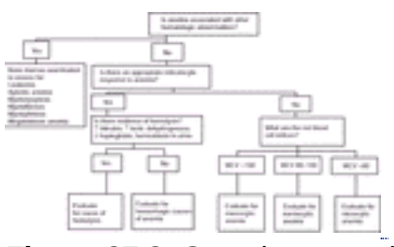

Figure 27.2. Questions to ask in the initial evaluation of anemia. MCV, mean corpuscular volume (fl); ?, increased; ?, decreased.

IS ANEMIA ASSOCIATED WITH OTHER HEMATOLOGIC ABNORMALITIES? Specifically, is the anemia associated with thrombocytopenia or abnormalities in white blood cell numbers or the presence of abnormal leukocytes? If the answer to this question is yes, consideration must be given to the possibility of bone marrow failure due to aplastic anemia, leukemia, or other malignant marrow disease. Alternatively, pancytopenia can be secondary to peripheral destruction or sequestration of cells as in hypersplenism. In most cases, these disorders can be differentiated by careful review of screening hematologic studies and close attention to the medical history and physical examination.

IS THERE AN APPROPRIATE RETICULOCYTE RESPONSE TO ANEMIA? The number of erythrocytes in the circulation at a given time is the result of a dynamic equilibrium between the delivery of red cells into the circulation on one hand and their destruction or loss from the circulation on the other. Each day, approximately 1% of the RBC pool is replaced by young erythrocytes released from the marrow. The homeostatic mechanisms of the body bring about recovery from anemia by accelerating erythropoiesis, and this response of the normal marrow is brought about through the release of erythropoietin. At maximum stimulation, the bone marrow is capable of producing erythrocytes at six to eight times the normal rate. The reticulocyte count provides an initial assessment of whether the cause of anemia is due to impaired RBC production or due to increased loss in the peripheral circulation (e.g., blood loss, hemolysis) (Fig. 27.2). The normal reticulocyte count is 0.5 to 1.5% of the total red cells. However, in the presence of anemia, this number must be corrected because it is spuriously elevated when it is related to the reduced number of RBC in an anemic patient. Moreover, an additional correction of this index needs to be made, because reticulocytes released under intense erythropoietin stimulation remain in the peripheral blood for approximately twice the usual 1-day survival time of nonstress reticulocytes.

$$\text{Reticulocyte count} = \%\ \text{reticulocytes in RBC population}$$

$$\text{Reticulocyte count corrected for anemia} = \%\ \text{reticulocytes} \times \text{patient hematocrit}/45$$

$$\text{Reticulocyte count further corrected for extended presence of reticulocytes in the circulation} = (\%\ \text{reticulocytes} \times \text{patient hematocrit}/45) \times 0.5$$

A practical alternative to the awkward construct of a corrected reticulocyte index is to assess the reticulocyte count in absolute numbers.

$$\text{Absolute reticulocyte count} = \%\ \text{reticulocytes} \times \text{RBC count}/L^3$$

Normal values for the absolute reticulocyte count are from 25 to 75 × 10^9/L. Any value greater than 100 × 10^9/L is considered evidence of an erythroid marrow compartment that is responding normally. An absence of an appropriate reticulocytosis in the setting of anemia indicates that RBC production is impaired.

IF ANEMIA IS ASSOCIATED WITH RETICULOCYTOSIS, IS THERE ANY EVIDENCE FOR HEMOLYSIS? The most characteristic presentation of hemolysis is

reticulocytosis with some degree of hyperbilirubinemia as a marker of increased heme catabolism. Other markers reflect direct red cell injury (e.g., increased serum lactic dehydrogenase) or increased excretion of Hb (e.g., low serum haptoglobin, hemoglobinemia, hemoglobinuria, and increased urinary hemosiderin). The evaluation and diagnostic considerations related to hemolytic anemia are complex and are considered separately elsewhere in this chapter (see Approach to Hemolysis).

IF ANEMIA IS ASSOCIATED WITH A LESS THAN APPROPRIATE RETICULOCYTE RESPONSE, WHAT ARE THE RED CELL INDICES? Anemia with low reticulocytes usually reflects some impairment of normal erythropoiesis, and this can be due to two kinds of defects. Erythropoiesis may be impaired because of a reduction in red cell precursors (hypogenerative). Alternatively, red cell production may be ineffective, a condition characterized by erythroid hyperplasia in the bone marrow, but with the production of essentially nonviable red cells, most of which do not reach circulation. There are numerous causes of anemia with low reticulocyte counts, and it is in this group that analysis of red blood cell indices is most helpful. Of these, the MCV tends to be the single most useful measurement ([33], [34] and [35]), although some clinicians prefer to use the MCH ([36]). The MCV and MCH almost always correlate closely ([37], [38]). An initial step in classification of anemias with low reticulocyte counts separates them into three groups on the basis of average cell size: the macrocytic, microcytic, and normocytic anemias (Fig. 27.2). Anemia is classified as macrocytic if MCV exceeds 100 fl. Usually, the MCH is also increased, whereas the MCHC remains within normal limits (Fig. 27.3). Microcytic anemia is identified when the MCV is less than 80 fl in adults. The anemia is normocytic when the indices are within normal limits, with an MCV between 80 and 100 fl. In children, MCV values vary as a function of age, and, correspondingly, the definition of microcytic, normocytic, and macrocytic differ accordingly (Table 27.1). As a practical matter for those who take care of children, it is important to know the age-related differences in RBC size, because many laboratory reports only contain adult normal values, often signaling the child's hematologic values as abnormal.

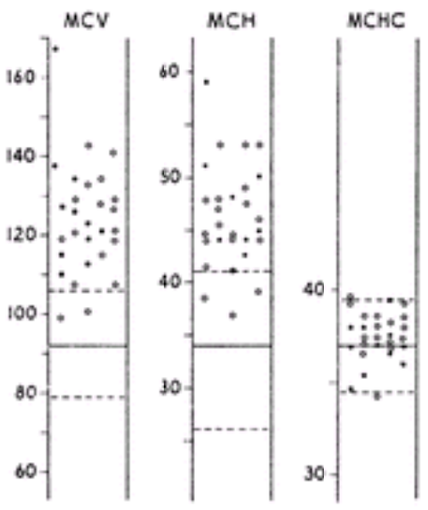

Figure 27.3. Erythrocyte indices in 28 patients with untreated or relapsed pernicious anemia. Dashed lines enclose the 95% confidence limits in normal subjects. Solid dots indicate males; open circles indicate females. MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume. (From Hallberg L. Blood volume, hemolysis and regeneration of blood in pernicious anemia. Scand J Clin Lab Invest 1965;7[Suppl 16], with permission.)

The MCHC is useful in detecting severe hypochromia, but it is rarely abnormal when the MCV is normal ([35], [36], [37], [38], [39] and [40]). A reduced value for MCHC is observed most often in association with iron deficiency, and this index tends to be the last to fall as iron deficiency worsens ([41], [42] and [43]). The changes in MCHC with iron deficiency were seen more frequently in the past when centrifugal methods were used to determine the hematocrit before the availability of electronic cell counting. Because of plasma trapping, centrifugal hematocrit methods overestimate the volume of packed red cells and, therefore, underestimate MCHC. Plasma trapping increases from 1 to 3% with normal blood to as much as 6% in iron deficiency, a consequence of anisocytosis and reduced cell deformability ([44]).

IS THE ANEMIA ASSOCIATED WITH A LOW RETICULOCYTE RESPONSE AND MICROCYTIC RED BLOOD CELLS? The large majority of patients in this category have defects in Hb synthesis due to either iron deficiency, thalassemia trait, or Hb E syndromes (see Approach to Microcytic Anemia).

IS THE ANEMIA ASSOCIATED WITH A LOW RETICULOCYTE RESPONSE AND MACROCYTIC RED BLOOD CELLS? In these patients, the anemia is characterized by reticulocytopenia with red cells having an increased MCV. Many of these disorders are due to megaloblastic anemia resulting in impaired nuclear development, and the formation of other blood cells is also affected (see Approach to Macrocytic Anemia).

IS THE ANEMIA ASSOCIATED WITH A LOW RETICULOCYTE RESPONSE AND NORMOCYTIC RED BLOOD CELLS? Normocytic anemia, low reticulocyte count, and normal bilirubin levels characterize a large number of anemias. The anemia of chronic disease usually is normocytic, although rarely may be slightly microcytic. In these cases, there usually is clinical evidence of rheumatoid arthritis or other chronic illness. The anemia of renal failure is normocytic and largely is due to reduced erythropoietin production. Acquired pure red cell aplasia (PRCA) is a normocytic anemia, which occurs in adults and children (see Approach to Normocytic Anemia).

IS THE ANEMIA ASSOCIATED WITH POPULATIONS OF RED CELLS OF DIFFERENT SIZE? The red cell indices represent mean values and do not reveal any variation that may exist within a population of cells. Also, the indices do not detect two or more populations differing in size or other characteristics. The MCV can be normal if there are combined abnormalities, such as when iron deficiency (decreased MCV) is accompanied by a megaloblastic anemia (increased MCV). For these purposes, it is important to examine the peripheral blood smear. Also, the electronically derived RDW allows for recognition of these phenomena because it quantifies the degree of heterogeneity of RBC size (i.e., anisocytosis) in a population of cells, and this has proven to be of value ([33], [45]). The upper limit of normal values for RDW is 14.6% ([33]). An increased RDW value is an early and pronounced finding in iron deficiency and most megaloblastic anemias; no differences from normal are seen in heterozygous thalassemia. In iron deficiency, the RDW value may become abnormal even before the MCV falls below the lower limits of normal.

IS THE ANEMIA ASSOCIATED WITH ABNORMALITIES SEEN ON THE BLOOD SMEAR? Despite the technical advances provided by current electronic complete blood cell count (CBC) measurements, review of the peripheral blood smear remains a critical aspect of the diagnostic evaluation for anemia. It confirms the electronically determined classification of RBC size. Most important, it also allows for recognition of the many variations in RBC size and shape that frequently are seen in patients with hemolysis. Microcytes and macrocytes can be detected on the blood smear on the basis of a change in red cell diameter. Normal red cells approximate the size of a small lymphocyte nucleus, and the area of central pallor is one-third to one-half of the diameter of the red cell (Fig. 27.4A). An increase in the area of central pallor of erythrocytes on the blood smear is indicative of hypochromia, and when the change is pronounced, little more than a faint ring of color in the periphery may be apparent (Fig. 27.4B). Hypochromia and microcytosis almost always occur together.

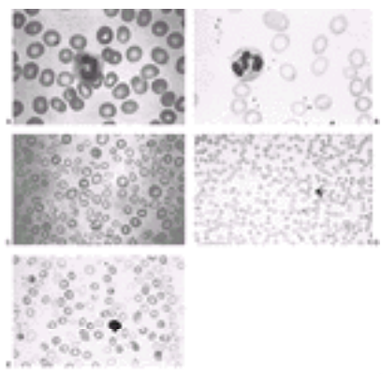

Figure 27.4. Peripheral blood smear of erythrocytes in a variety of hypochromic, microcytic anemia. **A:** Normal red cells. **B:** Iron deficiency anemia. Note the large area of central pallor. **C:** Dimorphic population of cells in iron deficiency anemia responding to treatment. **D:** Thalassemia minor. The cells are thin and appear pale but nearly normal in diameter. Note the basophilic stippling in one red corpuscle. **E:** Sideroblastic anemia. A hypochromic, microcytic population of cells is mixed with relatively normocytic red blood cell. See Color Plate.

The automated analysis of the blood has made the erythrocyte indices more accurate and reproducible ([46]). However, the evaluation of the blood smear still remains important because it may reveal abnormal cell populations too small to affect the erythrocyte indices. For example, as iron deficiency develops, some microcytic cells are produced while the RBC indices are still normal. Furthermore, as folic acid deficiency progresses, some characteristic oval macrocytes and hypersegmented neutrophils may appear long before there are MCV or Hb changes (Fig. 27.5B and Fig. 27.5C). Moreover, examination of the smear is important for detecting conditions characterized by two populations of cells, only one of which is of abnormal size. This dimorphic anemia is particularly characteristic of sideroblastic anemias (Fig. 27.4E) (see Chapter 29). It also is seen in iron deficiency after iron therapy is started (Fig. 27.4C).

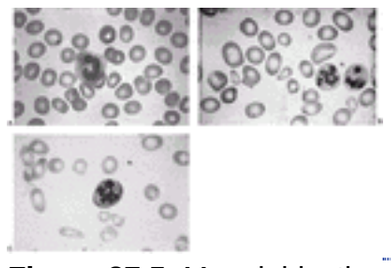

Figure 27.5. Megaloblastic anemia. **A:** Normal red cells. **B:** Macroova-locytes in pernicious anemia. **C:** Hypersegmented neutrophils seen in patient with megaloblastic anemia. See Color Plate.

Review of the blood smear may reveal underlying causes of the anemia. A leukoerythroblastic picture (teardrop RBC, nucleated RBC, early white blood cell precursors, or abnormalities in platelet shape) suggests marrow infiltration by hematologic or other malignant cells (Fig. 27.6). The marked elevation in serum proteins in multiple myeloma may result in a stacking of RBCs in rouleaux formation. The appearance of RBC in agglutinates (as opposed to their stacking into rouleaux) is seen with cold agglutinin disease. Also, probably one of the most valuable outcomes of reviewing the blood smear is that it often reveals abnormal red cell shapes characteristic of certain hemolytic anemias in particular. This assessment is discussed in detail in the section Approach to Hemolysis.

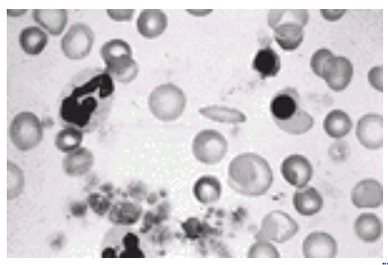

Figure 27.6. Peripheral blood smear. A leukoerythroblastic response seen in patient with myeloid metaplasia. See Color Plate.

IS A BONE MARROW EXAMINATION NEEDED TO CLARIFY THE CAUSE OF ANEMIA?Examination of the bone marrow is most useful in reticulocytopenic anemias, particularly when there is more than one hematopoietic cell line affected. Both hypoplasia and marrow infiltrative disease due to leukemia or tumor (myelophthisic anemia) may readily be demonstrated in the bone marrow aspirate and biopsy. Myelofibrosis can be recognized as a component of myeloid metaplasia. If the marrow is normocellular except for reduced erythropoiesis, the underlying cause may be red cell aplasia, renal disease, endocrinopathy, or certain chronic disorders. Examination of iron in bone marrow macrophages is considered the definitive way to demonstrate decreased iron stores. In most cases, however, the diagnosis of iron deficiency can be made by simple blood tests, thus obviating the need for an iron stain of the bone marrow. On the other hand, to make the diagnosis of sideroblastic anemia, a bone marrow examination is necessary to identify ringed sideroblasts. Megaloblastic anemias usually can be recognized by peripheral blood findings, but a marrow examination will confirm the diagnosis. In some anemias with low reticulocyte counts, marrow erythropoiesis surprisingly is quite active. This is referred to as *ineffective erythropoiesis*, and it occurs when developing red cells are defective and are destroyed before they leave the marrow or shortly thereafter. A very small fraction of erythropoiesis is ineffective, even in normal subjects; however, in certain conditions, especially megaloblastic anemias, thalassemias, and sideroblastic anemias, ineffective erythropoiesis becomes greatly exaggerated. The increased intramedullary destruction of erythroblast in these conditions is associated with accelerated heme catabolism, resulting in an elevated unconjugated bilirubin level in the plasma. Also, the serum lactic dehydrogenase level, a marker of cell destruction, is markedly elevated. Ineffective erythropoiesis can be confused with hemolytic anemia because signs of excessive red cell destruction and erythroid hyperplasia of the bone marrow are found in both conditions. However, the two conditions are distinguished from one another by the degree of reticulocytosis, which is increased in hemolytic anemia and reduced in ineffective erythropoiesis.

APPROACH TO MACROCYTIC ANEMIA

Macrocytosis is a common finding in clinical settings. In 1.7 to 3.6% of cases involving patients seeking medical care, MCV is increased, often in the absence of anemia ([47], [48], [49], [50], [51] and [52]). Mild macrocytosis (MCV of 100 to 110 fl) is particularly common and often remains unexplained, even after careful study ([47]). Even so, this finding should not be ignored, because it can be an important early clue to reversible disease. For example, it may appear 1 year or more before anemia develops in patients with pernicious anemia, and neurologic disease can progress during that interval ([53]).

Morphologic and biochemical criteria allow macrocytic anemias to be divided into two groups: the megaloblastic anemias and the nonmegaloblastic macrocytic anemias. The types of macrocytic anemias clinicians encounter vary considerably depending on the population served. If alcoholism is common in the population, it is likely to be the most common cause. If an institution specializes in the treatment of cancer, high MCVs are most likely due to chemotherapy. In hospitals largely serving the elderly, pernicious anemia and other nutritional anemias may predominate ([52]).

When confronted with a diagnostic problem involving macrocytic anemia, the physician should first distinguish between megaloblastic and nonmegaloblastic anemia (Fig. 27.7). The most useful steps for this purpose are morphologic examinations.

Figure 27.7. Diagnostic approach to a patient with macrocytic anemia.

Megaloblastic Anemias

The term *megaloblast* is a designation that was first applied by Ehrlich to the abnormal erythrocyte precursors found in the bone marrow of patients with pernicious anemia. Megaloblasts are characterized by their large size and by specific alterations in the appearance of their nuclear chromatin (Fig. 27.8). These distinctive cells are now known to be the morphologic expression of a biochemical abnormality: retarded DNA synthesis ([54]). RNA synthesis remains unimpaired while cell division is restricted ([55], [56]). As a result, cytoplasmic components, especially Hb, are synthesized in excessive amounts during the delay between cell divisions. An enlarged cell is the product of such a process. Megaloblastic anemias are defined by the presence of these cells or by other evidence of defective DNA synthesis.

Normoblasts and megaloblasts contrasted (Wright stain ×1000). **A–E:** Normoblast. **A:** Pronormoblast. **B:** Basophilic normoblast. **C:** Early polychromatophilic normoblast. **D:** Late polychromatophilic normoblast. **E:** Orthochromatic normoblast with stippling. **F–O:** Megaloblasts. **F:** Promegaloblast (*left*) and basophilic megaloblast (*right*). **G–K:** Polychromatophilic megaloblasts. **L–O:** Orthochromatic megaloblasts. See Color Plate.

A pathogenetic classification of the causes of megaloblastic anemias is presented in Table 27.3. Most often, megaloblastic anemia is the consequence of deficiency of vitamin B_{12} or folate, or both. Less commonly, megaloblastic anemia results from inherited or drug-induced disorders of DNA synthesis (Chapter 43).

TABLE 27.3. Pathogenetic Classification of Megaloblastic Anemia

Vitamin B_{12} deficiency
Dietary deficiency (rare)
Lack of intrinsic factor
Pernicious anemia
Gastric surgery
Ingestion of caustic materials
Functionally abnormal intrinsic factor
Biologic competition for vitamin B_{12}
Small-bowel bacterial overgrowth
Fish tapeworm disease
Familial selective vitamin B_{12} malabsorption (Imerslund-Gräsbeck syndrome)
Drug-induced vitamin B_{12} malabsorption
Chronic pancreatic disease
Zollinger-Ellison syndrome
Diseases of the ileum
Previous ileum resection
Regional enteritis
Folate deficiency
Dietary deficiency
Increased requirements
Pregnancy
Infancy
Chronic hemolytic anemia
Alcoholism
Congenital folate malabsorption
Drug-induced folate deficiency
Extensive intestinal resection, jejunal resection
Combined folate and vitamin B_{12} deficiency
Tropical sprue
Gluten-sensitive enteropathy
Inherited disorders of DNA synthesis
Orotic aciduria
Lesch-Nyhan syndrome
Thiamine responsive megaloblastic anemia
Methyl-tetrahydrofolate reductase
Formiminotransferase
Dihydrofolate reductase
Transcobalamin II deficiency
Homocystinuria and methylmalonic aciduria
Drug- and toxin-induced disorders of DNA synthesis
Folate antagonists (e.g., methotrexate)
Purine antagonists (e.g., 6-mercaptopurine)
Pyrimidine antagonists (e.g., cytosine arabinoside)
Alkylating agents (e.g., cyclophosphamide)
Zidovudine (AZT, Retrovir)
Trimethoprim
Oral contraceptives
Nitrous oxide
Arsenic
Chlordane
Erythroleukemia

HEMATOLOGIC FEATURES OF MEGALOBLASTIC ANEMIA Examination of the blood smear often reveals the two most valuable findings for differentiating megaloblastic from nonmegaloblastic anemia: neutrophil hypersegmentation and oval macrocytes. Neutrophile hypersegmentation is one of the most sensitive and specific signs of megaloblastic anemia (Fig. 27.5C). Normally, the nuclei of circulating, segmented neutrophils have fewer than five lobes. In megaloblastic anemia, neutrophils with six to ten or more lobes may be detected. In a large study, more than 98% of patients with megaloblastic anemia had at least one six-lobed neutrophil of the 100 cells examined, as compared with only 2% of normal control subjects ([57]). Hypersegmentation is among the first hematologic abnormalities to appear as

the megaloblastic state develops ([58]). It persists for an average of 14 days after institution of specific therapy ([59]). The main products of megaloblastic erythropoiesis are macrocytic erythrocytes with a distinctly oval shape. Such cells are well filled with Hb, and often central pallor is reduced or absent (Fig. 27.5B). The oval shape may be useful in distinguishing megaloblastic anemias from other causes of macrocytosis; the macroreticulocytes that characterize accelerated erythropoiesis tend to be round and distinctly blue or gray in Romanowsky dyes. Although oval macrocytes are prominent in megaloblastic anemia, the size and shape of the erythrocytes may vary considerably. Quantitative measures of anisocytosis, such as the RDW, are substantially increased, and the increase may precede the development of anemia ([60]). Morphologic changes on the blood smear, however, are most conspicuous when anemia is pronounced. Megaloblastic anemias usually develop gradually, and the degree of anemia is often severe when first detected. Hb values less than 7 or 8 g/dl are not unusual. Macrocytosis characteristically precedes the development of anemia ([53], [61], [62]) and may even do so by several years. The MCV usually falls between 110 and 130 fl but may reach as high as 160 fl with extreme degrees of anemia.

BONE MARROW A megaloblastic marrow is cellular and usually hyperplastic, with erythrocyte precursors predominating. The characteristic megaloblasts are distinguished by their large size and especially by their delicate nuclear chromatin. The chromatin has been described as particulate or sievelike, as distinguished from the normal denser chromatin of normoblasts (Fig. 27.8). This morphologic change may be detected at all stages of erythrocyte development; however, the identification of orthochromatic megaloblasts is particularly useful in the recognition of megaloblastic anemia because they differ so markedly from any cell found in normal marrow. In the orthochromatic megaloblast, the abundant cytoplasm appears mature (pink), whereas the nucleus appears immature as the result of the megaloblastic change. Leukopoiesis is also abnormal; extraordinarily large (up to 20 or 30 μm) leukocytes are found. These abnormalities of cellular development may occur at any stage in the myeloid series, but they are particularly common among the metamyelocytes. The nucleus of these giant metamyelocytes is enlarged, both absolutely and in relation to the total cell size; it may be bizarre in shape and in chromatin structure or staining properties. In general, megakaryopoiesis is less disturbed than that of either of the other two cell lines; however, when megaloblastic change is severe, megakaryocytes may be reduced in number and abnormalities of nuclear chromatin may be evident.

VITAMIN B_{12} AND FOLATE LEVELS IN SERUM AND ERYTHROCYTES Once it is established that a patient has megaloblastic anemia, serum vitamin B_{12} and folate levels are measured to distinguish between the two most common causes of this problem (Chapter 43). Vitamin B_{12} levels may be determined by microbiologic assay ([63], [64]) or by competitive-binding isotope techniques ([65]). Serum and erythrocyte folate concentrations may be determined microbiologically ([66]) or by isotope dilution ([67], [68] and [69]). Unlike serum vitamin B_{12}, serum folate is labile, being sensitive to short-term changes in folate balance. Thus, serum folate concentration may increase within a few hours after consumption of folate-containing food. Furthermore, a low intake of folate may result in reduced serum levels before true deficiency develops ([58]). The erythrocyte folate level is a better index of tissue folate stores, and its significance with respect to folate deficiency is more nearly equivalent to that of serum vitamin B_{12} levels in vitamin B_{12} deficiency. Erythrocyte folate levels are established during formation of the red cell and persist throughout its lifespan. Thus, it may take 3 to 4 months of folate deprivation before low values are obtained. Other blood studies (serum homocysteine, serum methylmal-onate, antibodies to intrinsic factor), urine studies (excretion of methylmalonic acid, excretion of formiminoglutamate), and vitamin B_{12} absorption studies (Schilling test) can further define the specific causes of these disorders (Chapter 43).

Nonmegaloblastic Macrocytic Anemias

Nonmegaloblastic anemias are not united by a common pathogenetic mechanism; they simply represent macrocytic anemias in which the RBC precursors appear normal without the characteristic nuclear and cytoplasmic findings of megaloblastosis. DNA synthesis is unimpaired. When macrocytosis is found, it tends to be mild; the MCV usually ranges from 100 to 110 fl and rarely exceeds 120 fl ([48]). Several causes of nonmegaloblastic macrocytosis are recognized (Table 27.4).

TABLE 27.4. Nonmegaloblastic Macrocytic Anemias

Associated with accelerated erythropoiesis
Hemolytic anemia
Posthemorrhagic anemia
Alcoholism
Liver disease (Chapter 47)
Myelodysplastic syndrome (Chapter 43)
Myelophthisic anemias
Aplastic anemia (Chapter 44)
Acquired sideroblastic anemia (Chapter 29)
Hereditary dyserythropoietic anemia (congenital dyserythropoietic anemia types I and III) (Chapter 46)
Diamond-Blackfan anemia (Chapter 45)
Hypothyroidism (Chapter 47)

ACCELERATED ERYTHROPOIESIS Mild to moderate macrocytosis often follows erythropoietin-mediated acceleration of red cell production, as may be induced by blood loss or hemolysis. In part, this increased cell size occurs because reticulocytes are approximately 20% larger than mature red cells ([70]). Also, under conditions of accelerated red cell production, a premature release of bone marrow reticulocytes (shift reticulocytes) occurs, and these cells are even larger and contain more RNA than normal circulating reticulocytes ([71]). Last, an erythroblast cell division may be skipped under this erythropoietic stress, a phenomenon that results in a macroreticulocyte that is approximately twice the normal size ([72]).

ALCOHOLISM Macrocytosis, usually mild, is evident in 40 to 96% of chronic alcoholics, many of whom have no anemia ([73], [74] and [75]). The finding is so characteristic of the condition that testing for macrocytosis has been used as part of the screening procedure for the early detection of alcoholism. Macrocytosis and anemia in alcoholic individuals have several causes. Folate deficiency can lead to megaloblastic anemia, and alcoholic cirrhosis may be associated with spur-cell hemolytic anemia. Most often, however, alcoholic macrocytosis is associated with none of these factors and instead results from poorly defined direct effects of alcohol on the bone marrow. There are no morphologic stigmata of megaloblastic anemia. Serum and erythrocyte folate levels are usually normal, and the macrocytosis does not respond to folate treatment. If the patient abstains from alcohol use, the MCV returns to normal levels after 2 to 4 months.

LIVER DISEASE The causes of anemia in liver disease are multifactorial, resulting from intravascular dilution due to hypervolemia, impaired ability of the marrow to respond optimally to the anemia, and in some patients, a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells) (Chapter 47). The anemia is usually mild to moderate. In cirrhotic patients, the Hb level averages approximately 12 g/dl, and remains above 10 g/dl in the absence of bleeding or severe hemolysis. The anemia of liver disease is mildly macrocytic: The MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow. In addition, liver disease is associated with thin macrocytes, defined as cells with increased surface area ([76]) but without a corresponding increase in volume ([77]). The increased surface area of thin macrocytes is the consequence of excessive membrane lipids, especially cholesterol ([76]), but also phospholipids. On the blood smear, thin macrocytes are characterized by an increased diameter and a visibly enlarged area of central pallor. The characteristic target cell of liver disease is a thin macrocyte. Because the volume of such cells is normal, their presence has no effect on the erythrocyte indices.

MISCELLANEOUS ANEMIAS Macrocytosis that accompanies various refractory anemias with low reticulocyte counts includes myelodysplastic and myelophthisic conditions (Chapter 83). The reason for macrocytosis in these disorders is not well understood. Evidence of disorders of the hematopoietic stem cell has been observed in elderly patients with unexplained macrocytosis ([78]). Congenital red cell hypoplasia or Diamond-Blackfan anemia (DBA) is a pure RBC aplasia in children that is due to impaired differentiation of developing erythroblasts (Chapter 45). This disorder is characterized by a life-long anemia that presents in the first few months of life. Many children with DBA have congenital abnormalities, including short stature and skeletal defects (usually affecting the thumb). The diagnosis of DBA is suggested by a macrocytic (although sometimes normocytic) anemia with reticulocytopenia presenting in the first 6 months of life. Bone marrow examination reveals decreased erythroid precursors. Congenital dyserythropoietic anemias (CDAs) are a group of anemias characterized by ineffective erythropoiesis and dys-erythropoiesis (Chapter 46). The term *dyserythropoiesis* refers to the presence of morphologically abnormal erythroblasts in the bone marrow with multinuclearity, karyorrhexis, or megaloblastic changes. Three major types of CDA have been distinguished on the basis of morphologic and serologic classification, and these have been designated CDA types I, II, and III. The degree of anemia encountered in the CDAs varies considerably. It may range from a mild to moderate anemia that is only discovered or diagnosed later in life to a severe anemia apparent in infancy. Morphologically, the anemia is generally mildly macrocytic in CDA types I and III and is normocytic in CDA type II. In all of the disorders, the bone marrow findings are consistent with ineffective erythropoiesis: There is erythroid hyperplasia along with morphologically abnormal precursors. An elevation in serum lactate dehydrogenase and indirect bilirubin levels may be observed. Spurious macrocytosis can result from laboratory artifacts. Cold agglutinins and marked leukocytosis can lead to a incorrect high MCV value ([49]). Care is needed so that these situations do not lead to a fruitless search for a disorder known to cause macrocytic anemia.

APPROACH TO MICROCYTIC ANEMIA

Most microcytic anemias are due to deficient Hb synthesis, often associated with iron deficiency or impaired iron use (Table 27.5). The differentiation of iron deficiency from the anemia of chronic disease and the differentiation of iron deficiency from thalassemia trait syndromes are both common clinical issues. Significant microcytosis is detected in nearly 3% of all patients who require admission to the hospital ([40], [79]).

TABLE 27.5. Pathogenic Classification of Microcytic Anemias

Disorders of iron metabolism
Iron deficiency anemia (Chapter 28)
Anemia of chronic disorders (Chapter 47)
Disorders of globin synthesis
Alpha and beta thalassemias (Chapter 42)
Hemoglobin E syndromes (AE, EE, E-ß-thalassemia) (Chapter 39)
Hemoglobin C syndromes (AC, CC) (Chapter 39)
Unstable hemoglobin disease (Chapter 41)
Sideroblastic anemias (Chapter 29)
Hereditary sideroblastic anemia
X-linked
Autosomal
Acquired sideroblastic anemia
Refractory anemia with ringed sideroblasts
Malignancies
Myeloproliferative disorders
Reversible acquired sideroblastic anemia
Alcoholism
Drugs (isoniazid, chloramphenicol)
Lead intoxication (usually normocytic)

The typical Hb levels seen in adults with a variety of microcytic anemias is depicted in Table 27.6. The laboratory evaluation of microcytic anemias focuses on screening hematologic studies, followed by more definitive tests to distinguish iron deficiency anemia, the anemia of chronic disease, hemoglobinopathies, or sideroblastic anemias (Fig. 27.9). A few commonly used studies are described below; others are described elsewhere in this text.

TABLE 27.6. Typical Hemoglobin and Mean Corpuscular Volume Values in Adults with Certain Anemias

Condition	Hb Concentration (g/dl)	MCV (fl)
Normal men	16 (14–18)	89 (80–100)
Normal women	14 (12–16)	89 (80–100)
Iron deficiency anemia	8 (4–12)	74 (55–85)
Anemia of chronic diseases	10 (8–13)	85 (75–95)
ß-Thalassemias minor	12 (9–14)	68 (55–75)
ß-Thalassemias major	(2–7)	(48–72)
Hemoglobin H disease	9 (7–11)	70 (53–88)
Hemoglobin E trait (AE)	14 (12–17)	73 (71–78)
Homozygous hemoglobin E (EE)	12 (11–15)	64 (58–76)
Hemoglobin C disease (CC)	10 (7–14)	77 (55–93)
Congenital sideroblastic anemia	6 (4–10)	77 (49–104)
Acquired sideroblastic anemia	10 (7–12)	104 (83–118)

NOTE: Values are means, with approximate range in parentheses.
Hb, hemoglobin; MCV, mean corpuscular volume.

Figure 27.9. Diagnostic approach to a patient with microcytic anemia. ?, increased; ?, decreased.

Iron Pathway Disorders

The principal source of iron for Hb production is that carried by transferrin, the iron-transport protein in plasma. Under normal circumstances, plasma iron levels are not rate limiting in erythropoiesis, and transferrin is able to supply all the iron required for normal or accelerated production rates. However, in iron deficiency anemia, the storage sites in macrophages are depleted of iron and the plasma iron concentration falls. When transferrin saturation with iron is less than 16%, the red cell production rate decreases, and hypochromic, microcytic cells are manufactured. This state is known as *iron-deficient erythropoiesis*.

In the anemia associated with chronic disorders (Chapter 47), the macrophage iron level is normal or increased, but flow to plasma and the bone marrow erythroblasts is partially blocked ([80], [81] and [82]). Thus, iron accumulates in the macrophage, whereas the plasma level falls, and the marrow is deprived of adequate supplies.

Together, iron deficiency anemia and the anemia of chronic disease are among the most common causes of anemia. Iron deficiency predominates in children and young women, but it also occurs in older individuals in whom it may reflect occult bleeding due to underlying pathology. The anemia of chronic disorders is most common among elderly people ([83]), but it also can occur in younger individuals affected by certain chronic inflammatory states.

Distinguishing typical iron deficiency anemia from the anemia of chronic disorders is usually not difficult. Anemia, hypochromia, and microcytosis are typically more pronounced in iron deficiency, as are the degrees of anisocytosis and poikilocytosis. The anemia of chronic disease is usually normocytic. However, when iron deficiency is early and mild, the morphologic findings in the two conditions may be similar.

MEASUREMENT OF SERUM IRON AND IRON-BINDING CAPACITY Serum iron levels are a measure of the amount of iron bound to transferrin. Total iron-binding capacity (TIBC) is an indirect measurement of transferrin in terms of the amount of iron it will bind. A limitation in the use of serum iron determinations is the considerable variability in values ([35], [46], [84], [85]). A technical problem relates to contamination of glassware and reagents with iron, although the use of disposable, plastic equipment has reduced such contamination considerably. Even if technical problems are eliminated, serum iron values in an individual can vary from 10 to 40% within a single day or from day to day ([86], [87]); and many normal subjects demonstrate a predictable diurnal variation, with highest values in the morning and lowest values in the evening ([35]). In contrast to serum iron, TIBC values show only slight day-to-day fluctuation or diurnal variation ([84]). It also must be recognized that serum iron levels are influenced by the recent ingestion and absorption of iron medication. The normal mean serum iron value for men is approximately 120 µg/dl (21.8 µmol/L). The composite normal range is approximately 70 to 200 µg/dl (13 to 36 µmol/L); as discussed previously, however, values vary substantially from one laboratory to another. The TIBC averages 340 µg/L (61 µmol/L) in both men and women, with a composite normal range of 250 to 435 µg/dl (45 to 78 µmol/L). Transferrin saturation is calculated with the following formula: transferrin saturation (%) = serum iron × 100/TIBC. The normal value is 20 to 45%. Values below 16% are noted in association with both iron deficiency and the anemia of chronic disorders (Fig. 27.10). The degree of reduction tends to be greater in iron deficiency than in chronic disorders, but considerable overlap exists between these two conditions. In both children and adults, however, a value of less than 5% is almost certainly due to iron deficiency anemia. In sideroblastic anemias, transferrin saturation invariably is increased and often approaches 100%.

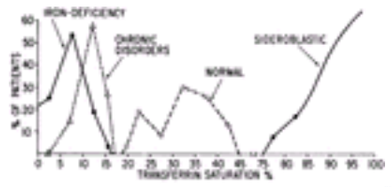

Figure 27.10. Transferrin iron saturation in patients with several types of anemia. The values are low (>16%) in iron deficiency anemia and the anemia of chronic disorders, with considerable overlap. Values of less than 5% are found only in iron deficiency. Transferrin saturation is increased in sideroblastic anemia.

The absolute value for TIBC may be helpful in distinguishing between iron deficiency and the anemia of chronic disorders. The TIBC often is increased in iron deficiency and decreased in chronic disease (Fig. 27.11), and some consider it to be the best test to distinguish these two disorders ([88]).

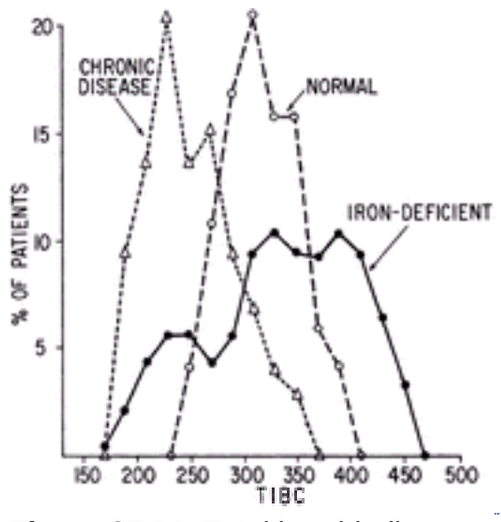

Figure 27.11. Total iron-binding capacity (*TIBC*) in patients with iron deficiency and in those with chronic disease. A high value indicates iron deficiency. Low values are found in chronic disease but may also occur in iron deficiency.

SERUM FERRITIN Determination of serum ferritin concentration also is used for evaluating iron stores in patients with iron deficiency ([89]). Ferritin is chiefly an intracellular iron storage protein, but trace amounts are also secreted into plasma. The serum protein differs from the intracellular protein in that it is glycosylated ([90]) and contains little or no iron ([89], [91], [92]). In most clinical circumstances, the serum ferritin concentration is proportional to total body iron stores. In contrast to serum iron measurements, ferritin values are not influenced by recent iron therapy ([93]). The mean ferritin value for normal adult men is 90 to 95 µg/L, with a range of approximately 20 to 500 µg/L. For women, mean values of approximately 35 µg/L are noted, with a usual range of 10 to 200 µg/L, when iron deficiency was excluded ([92]). In infants, values are high at birth but rapidly fall to approximately 30 µg/L, where they remain until puberty. Serum ferritin values in men tend to rise steadily with age. These levels show little or no diurnal variation. Day-to-day variation averages approximately 15%, mostly because of methodologic factors ([92]). In patients with uncomplicated iron deficiency, mean values of 3 to 6 µg/L have been reported. In patients with excessive iron stores, values are usually greater than 1000 µg/L and may reach 10,000 µg/L (Fig. 27.12) ([94]). Also, the serum ferritin level in patients with anemia of chronic diseases may increase disproportionately relative to the increase in iron stores, probably because ferritin is an acute-phase reactant. This phenomenon complicates the diagnosis of iron deficiency when it coexists with inflammatory disease. In some other illnesses, the serum ferritin level increases because of factors other than augmented iron stores. One such condition is liver disease, in which damage to the hepatic cell can cause the release of intracellular ferritin (nonglycosylated and iron-rich) ([94]). Serum ferritin values also may be inappropriately increased in association with various malignancies, especially hematologic malignancies ([92], [95], [96]).

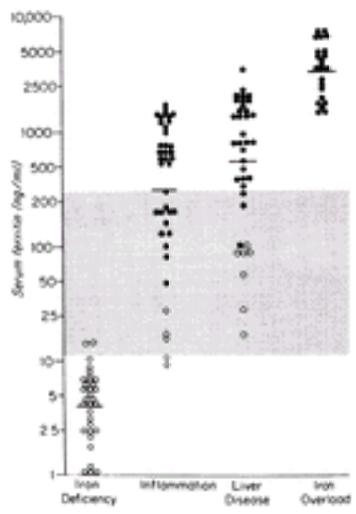

Figure 27.12. Measurements of serum ferritin in uncomplicated iron deficiency, inflammation, liver disease, and iron overload. Geometric mean values for each group (*horizontal line*). Patients with iron deficiency (total iron-binding capacity >400 µg/100 ml and transferring saturation below 16% or absent marrow iron or both) (*open circles*). Normal range (*shaded area*). (From Lipshitz D, Cook JD, Finch CA. A clinical evaluation of serum ferritin as an index of iron stores. N Engl J Med 1974;290:1213–1216, with permission.)

EVALUATION OF BONE MARROW IRON STORES In bone marrow aspirates, hemosiderin appears as golden-yellow refractile granules. More often, the specimen is stained by the Prussian blue method, which renders hemosiderin blue ([97]). Experienced observers can grade the marrow hemosiderin stores from 0 to 6+ (Table 27.7) ([98]). Normal marrow is graded 1+ to 3+. In iron deficiency, marrow hemosiderin is absent; in the anemia of chronic disorders, iron is always present, most often of grade 2 or 3+, but sometimes 4 or 5+. Iron stores are greatly increased (5 to 6+) in thalassemia major and in sideroblastic anemias. Nowadays the marrow assessment of iron is used much less, because serum ferritin provides a simple measurement that correlates with clinical iron states in the anemia of chronic disease and in iron deficiency states.

TABLE 27.7. Criteria for Grading Iron Stains in Bone Marrow Aspirates

Grade	Criteria	Iron Content (µg/g)

0	No iron granules observed	42 ± 23
1+	Small granules in reticulum cells, seen only with oil-immersion lens	130 ± 50
2+	Few small granules visible with low-power lens	223 ± 75
3+	Numerous small granules in all narrow particles	406 ± 131
4+	Large granules in small clumps	762 ± 247
5+	Dense, large clumps of granules	1618 ± 464
6+	Very large deposits, obscuring marrow detail	3681 ± 1400

Gale E, et al. The quantitative estimation of total iron stores in human bone marrow. J Clin Invest 1963;42:1076.

TRANSFERRIN RECEPTORS Transferrin receptors (TfRs) are disulfide-linked transmembrane proteins that facilitate the entry of transferrin-bound iron into cells (Chapter 48). A soluble, truncated form of the protein can be detected in plasma, and its immunologic quantification can be useful in detecting iron deficiency and distinguishing it from the anemia of chronic disease. Values in iron-deficient subjects are clearly increased, but, importantly, TfR values do not increase in the anemia of chronic disease (Fig. 27.13) ([99], [100] and [101]). Therefore, TfR determination is another test that may be useful in distinguishing iron deficiency from the anemia of chronic disease when serum ferritin levels are not definitive. Serum TfR levels also vary with the total mass of red cell precursors. Therefore, the value increases in hemolytic anemia, thalassemia, and polycythemia and decreases in hypoplastic anemia and renal failure ([60]).

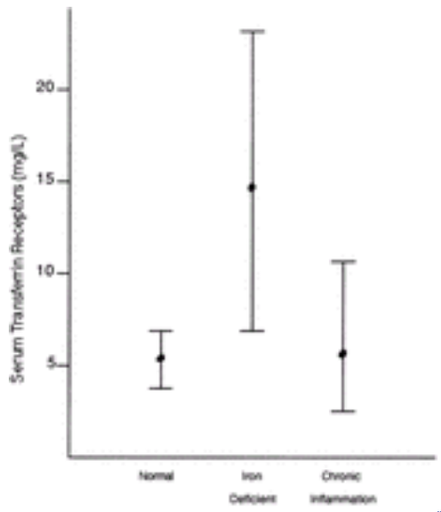

Figure 27.13. Serum transferrin receptors in patients with iron deficiency and the anemia of chronic disorders. Bars indicate the mean (*dot*) and ranges of values in the three groups. [From Ferguson BJ, et al. Serum transferrin receptor distinguishes the anemia of chronic disease from iron deficiency anemia. J Lab Clin Med 1992;119(4):385–390, with permission.]

OTHER TESTS TO ASSESS IRON METABOLISM

Erythrocyte Zinc Protoporphyrin Red cell precursors normally synthesize slightly more protoporphyrin than is needed for heme synthesis. The excess remains with the cell throughout its lifespan and has been called free erythrocyte protoporphyrin (FEP). When iron is not available for heme synthesis, protoporphyrin accumulates in excess as zinc protoporphyrin. Measurement of FEP is available as a screening test for iron deficiency, and the test requires only a drop of blood and 1 minute of processing ([35], [102]). The level of FEP increases dramatically in iron deficiency and is a sensitive laboratory abnormality in this condition ([35], [102], [103], [104] and [105]). The erythrocyte zinc protoporphyrin content also is greatly increased in lead poisoning but is normal in thalassemia ([102], [103]).

Liver Iron Stores Iron stores can also be estimated by liver biopsy using both histochemical and chemical methods of analysis ([106], [107]). Even gross inspection of a Prussian blue–stained biopsy specimen can provide a reasonably reliable estimate of iron stores ([108]). Criteria for grading the preparations from 1 to 4+ have been established ([106], [107], [109]), and these correlate well with chemical analysis. Chemical analysis is particularly important in evaluating hemochromatosis and transfusion-iron overload, because a disproportionate amount of iron is in parenchymal cells in the form of ferritin, which does not stain with Prussian blue ([110]). Measurement of hepatic iron stores is used mainly to assess iron overload states, because the correlation between serum ferritin and true tissue iron content is not as good when there is elevated tissue iron content.

Urinary Iron Excretion Storage iron has been evaluated by urinary excretion of iron after the administration of a chelating agent ([111], [112], [113] and [114]). The chelator most commonly used for this purpose is deferoxamine. A rough correlation exists between iron stores and urinary iron excretion after deferoxamine administration. The test is useful in detecting iron overload, but it is less reliable in assessing deficient stores, because the values found in normal and iron-deficient subjects overlap ([114], [115] and [116]).

Disorders of Hemoglobin Synthesis

The Hb disorders associated with microcytosis include the thalassemias and certain structural Hb variants.

The thalassemias are a group of inherited disorders in which synthesis of one of the normal polypeptide chains of globin is severely deficient (Chapter 42). In mild forms of the disease (thalassemia minor), hypochromia and microcytosis are prominent, whereas anemia is absent or mild. In other thalassemic disorders, including homozygous ß-thalassemia (ß-thalassemia major) and Hb E ß-thalassemia, hypochromic, microcytic anemia is usually quite severe.

Some structurally abnormal Hb also may be associated with moderate microcytosis. This is particularly characteristic of patients carrying a Hb E gene (Chapter 39). Heterozygotes for this hemoglobinopathy typically have microcytosis without anemia ([117], [118] and [119]). Homozygotes have a greater degree of microcytosis and either mild or no anemia ([37], [117], [118]). Like thalassemia, Hb E diseases are characterized by reduced ß-chain synthesis ([120]). Microcytosis also occurs in homozygous Hb C disease ([121], [122]).

The possibility of thalassemia minor is often raised by finding that the microcytosis is more severe than might be expected for the mild degree of anemia. In addition, basophilic stippling and target cells tend to be more prominent in thalassemia than in iron deficiency. An important feature of thalassemia trait–like conditions (which include the Hb E syndromes) is that the RBC count often is very high normal to elevated despite having anemia and small RBC. This characteristic has allowed several different measures for differentiating iron deficiency from thalassemia trait and Hb E disorders. One of the most useful is a modification of the Mentzer index ([123]), which is based on the MCV and RBC count:

MCV/RBC (10^6)>14 (suggestive of iron deficiency)
MCV/RBC (10^6) 12–14 (indeterminate)
MCV/RBC (10^6) <12 (suggestive of thalassemia trait disorders)

Measures of anisocytosis (RDW) derived from erythrocyte volume distribution also have been advocated for distinguishing iron deficiency from thalassemia minor ([33], [42], [45], [124]). Anisocytosis is an early and prominent finding in iron deficiency, often detectable before significant microcytosis, hypochromia, or even anemia is apparent. In contrast, anisocytosis tends to be absent or mild in thalassemia minor. The normal value for RDW is 13.4 ± 1.2% (mean, 2 SD), and the upper limit of normal is 14.6% ([33]). In iron deficiency, the value is 16.3 ± 1.8%, whereas in ß- or a-thalassemia minor, the value is normal (13.6 ± 1.6%). An increased RDW appears to be 90 to 100% sensitive for iron deficiency but only 50 to 70% specific ([125]). An increased value for RDW in an otherwise normal complete blood count most often represents early iron deficiency, but other nutritional deficiencies are also possible causes.

Homozygous hemoglobinopathies, especially Hb C ([118]) and Hb E ([37], [119]), tend to be microcytic and normochromic, and many target cells are apparent in the blood smear (Chapter 39).

Distinguishing homozygous ß-thalassemia (ß-thalassemia major) from ß-thalassemia minor is rarely a problem, because the former is accompanied by signs of

hemolysis and ineffective erythropoiesis; there also are characteristic findings on the blood smear, including nucleated red cells, extreme anisocytosis and poikilocytosis, and target cells (Chapter 42). However, it is a common diagnostic problem to distinguish patients with ß-thalassemia trait from those with iron deficiency. In almost all cases of ß-thalassemia trait, the fraction of Hb A_2 is increased, whereas the value for Hb A_2 is normal or decreased in iron deficiency ([126]).

a-Thalassemia syndromes result from decreased a-globin chain synthesis that is directed by four structural genes. Four different a-thalassemia syndromes have been recognized on chromosome 16. Silent carrier state (a-thalassemia II) individuals lack one a globin gene; the a,ß-globin chain synthetic ratio is decreased from unity, but these individuals are hematologically normal and have no clinical problems. a-Thalassemia trait (a-thalassemia I) individuals lack two a-globin genes, a-globin synthesis is impaired, and there is a mild hypochromic microcytic anemia. Hb H disease is caused by the deletion of three a-globin genes, and the consequence of this is a mild to moderate hemolytic anemia. Beyond the neonatal period, the unbalanced chain synthesis leads to an excess in ß-globin chains which form Hb H ($ß_4$ tetramers). Hb H is mildly unstable, particularly in the presence of oxidant stress, thereby causing intermittent hemolysis. Homozygous a-thalassemia (hydrops) is due to a deletion of all four a-globin genes, resulting in severe anemia due to the complete absence of a-globin chains. This disorder is incompatible with life, and fetuses are aborted early, are stillborn, or die within the first few hours of life.

A common clinical problem is to identify a-thalassemia trait, which has a similar presentation to ß-thalassemia trait and iron deficiency. The diagnosis often is a presumptive one, made after excluding iron deficiency, ß-thalassemia trait, and any other abnormal Hb. Specific DNA-based testing is available, but it is seldom used for routine diagnostic purposes. Its major value is in prenatal diagnosis, and the counseling of potential parents at risk for having children with homozygous a-thalassemia. The a-thalassemia syndromes occur primarily in those of Asian and African descent, and it is of interest that in Africans with a-thalassemia trait, the globin gene deletions occur on different chromosomes (i.e., trans deletions), whereas in Asians with a-thalassemia trait, the gene deletions occur on the same chromosome (i.e., cis deletion). As a consequence of these racial differences, Hb H disease and homozygous a-thalassemia occurs only in Asians. Moreover, virtually all Africans with a-thalassemia have a-thalassemia trait (Chapter 42).

Hb C, Hb E, and Hb H can be detected by electrophoresis; unstable Hbs are detected by the heat-denaturation test.

Sideroblastic Anemias

The sideroblastic anemias are due to acquired and hereditary disorders of heme synthesis (Chapter 29). A classic morphologic feature of this type of anemia, as seen in the peripheral blood smear, is the presence of erythrocyte dimorphism (Fig. 27.4E), with a microcytic population of cells mixed with a normal red cell population and the presence of occasional, heavily stippled, hypochromic cells. In hereditary (X-linked) sideroblastic anemia, the anemia and microcytosis are pronounced (Table 27.6), and these changes are accompanied by considerable anisocytosis and poikilocytosis. The serum iron concentration usually is elevated, and the TIBC is increased. In all cases of sideroblastic anemia, regardless of the specific etiology, impaired heme synthesis leads to retention of iron within the mitochondria. Morphologically, this is seen in marrow aspirates which reveal many nucleated red cells with iron granules (i.e., aggregates of iron in mitochondria) that have a perinuclear distribution ([127], [128]). These unusual cells, known as *ringed sideroblasts*, are found only in pathologic states and are distinct from the sideroblasts (erythroblasts with diffuse cytoplasmic ferritin granules) seen in 30 to 50% of normal red blood cell precursors in marrow. Most common sideroblastic anemias occur in middle age and later life, and these acquired disorders can be idiopathic, secondary to drugs, alcohol, or myeloproliferative disorders (Table 27.5). In addition, there are rare congenital sideroblastic anemias that conform to an X-linked pattern of inheritance, usually occurring in males, although skewed lyonization has resulted in affected females. Autosomal-dominant and sporadic cases also occur. Severe anemias are recognized in infancy or early childhood, whereas milder cases may not become apparent until early adulthood or later. Patients may present with pallor, icterus, moderate splenomegaly, or hepatomegaly. Iron overload is a major complication of this disorder. In some cases in which there is little or no anemia, there still may be clinical evidence of iron overload (i.e., diabetes mellitus and liver dysfunction).

APPROACH TO NORMOCYTIC ANEMIA

Normocytic anemias are those in which the values for MCV are within normal limits, between 80 and 100 fl in adults. At times, however, the anemias that fall into this category also may be macrocytic or microcytic. For example, the anemia associated with hypothyroidism and liver disease may be either normocytic or slightly macrocytic. Also, because of reticulocytosis, the anemia associated with acute hemorrhage or chronic hemolysis may be normocytic or slightly macrocytic. The anemia of chronic disorders, although most often normocytic, is sometimes microcytic, and its pathogenesis is best understood in the context of microcytic anemias, as described above. Last, iron deficiency early in the course of anemia may be normocytic before becoming microcytic.

The normocytic anemias are not related to one another by common pathogenetic mechanisms. In many instances, anemia is only of incidental importance, a minor manifestation of a systemic disease with other, more serious consequences. Importantly, however, sometimes anemia is the first evidence of disease and the sign leading to discovery of the underlying disorder.

Despite the varied etiologic background and the often incidental nature of the normocytic anemias, they can be classified in a way that forms a basis for diagnostic investigation (Fig. 27.14). As a first step, it should be determined whether the erythropoietic response is appropriate to the degree of anemia. When bone marrow function is unimpaired and the iron supply is ample, erythropoiesis can increase manyfold. In most cases, marrow examination is not necessary to determine that the erythropoietic response is adequate, because reticulocytosis may be prominent, and polychromatophilic macrocytes may be detected on routinely stained smears. These manifestations of appropriate marrow response are typical of hemolytic anemia and posthemorrhagic anemia. The history, physical examination, and signs of excessive erythrocyte destruction (e.g., hyperbilirubinemia) provide the information necessary to differentiate these two conditions. The diagnostic approach to anemias due to hemolysis and after acute hemorrhage are discussed separately below.

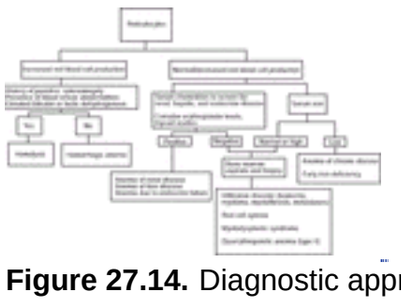

Figure 27.14. Diagnostic approach to a patient with normocytic anemia.

When anemia is apparent but the erythropoietic response is less than appropriate, most likely the underlying disorder directly or indirectly affects the bone marrow. Indirect effects should be investigated first, because often a diagnosis can be made without resorting to marrow aspiration and biopsy. For example, several disorders are associated with reduced secretion of erythropoietin (Table 27.8). In these conditions, screening tests usually uncover an underlying systemic disease, and for this purpose, renal function, liver function, and thyroid status should be assessed by use of appropriate biochemical tests. Although severe protein-calorie malnutrition is accompanied by reduced erythropoietin secretion and a mild normocytic anemia, such undernutrition is rare in temperate countries and thus is not likely to be confused with other systemic disorders. The anemia of chronic disease also can present as a normocytic anemia with low reticulocytes. This can be recognized by the underlying chronic illness and the previously described iron studies. One of the causes of this is thought to be a blunted erythropoietic response due to the presence of inflammatory cytokines (Chapter 47).

TABLE 27.8. Classification of the Normocytic Anemias

Anemia associated with appropriately increased erythrocyte production
Posthemorrhagic anemia
Hemolytic anemia
Decreased erythropoietin secretion
Impaired source

Renal: anemia of renal insufficiency (Chapter 47)
Hepatic: anemia of liver disease (Chapter 47)
Reduced stimulus (decreased tissue oxygen needs)
Anemia of endocrine deficiency (Chapter 47)
Protein-calorie malnutrition
Anemia of chronic disorders (Chapter 47)
Anemia with impaired marrow response
Bone marrow hypoplasia
Red blood cell aplasia (Chapter 45)
Acquired pure red cell aplasia in adults
Transient erythroblastopenia of childhood
Transient aplastic crises associated with hemolysis
Aplastic anemia (pancytopenia) (Chapter 44)
Bone marrow infiltrative disorders
Leukemia (Chapter 78, Chapter 79, Chapter 80, Chapter 81 and Chapter 82)
Myeloma (Chapter 98)
Other myelophthisic anemias
Myelodysplastic anemias (Chapter 83)
Dyserythropoietic anemias (congenital dyserythropoietic anemia type II) (Chapter 46)
Iron deficiency (early) (Chapter 28)

Normocytic anemia with marked reticulocytopenia also is a characteristic of RBC aplasia. Acquired PRCA in adults represents a relatively rare group of disorders usually occurring in the fifth to seventh decades of life (Chapter 45). The anemia can occur as a primary disorder or secondary to some other disease. Early studies suggested an association with thymoma, but more recent data indicate this is much less common. Most cases of PRCA are seen with a variety of hematologic malignancies (in particular chronic lymphocytic leukemia) and also with nonhematologic malignancies, rheumatoid arthritis, systemic lupus erythematous and in association with a variety of drugs and chemicals. Laboratory data reveals isolated anemia, reticulocytopenia, and a bone marrow almost completely void of erythroblasts. The remainder of the CBC is normal.

Transient erythroblastopenia of childhood (TEC) is a form of RBC aplasia occurring in young children, caused by transient antibody-mediated suppression of normal erythropoiesis that frequently follows a viral infection (Chapter 45). In contrast to Diamond-Blackfan syndrome, there are no congenital abnormalities and no abnormal RBC features. The natural history of transient erythroblastopenia of childhood is one of spontaneous recovery over a few weeks.

Aplastic crises with hemolytic anemia is a self-limiting form of red cell aplasia seen in patients with chronic hemolytic anemia. It is characterized by a rapid decrease in the steady-state Hb concentration and a very low reticulocyte count (see Approach to Hemolysis).

When the normocytic anemia with reticulocytopenia is associated with leukopenia and thrombocytopenia, there should be suspicion for intrinsic marrow disease due to aplastic anemia, leukemia, myelofibrosis or myelophthisis. Morphologic abnormalities suggestive of marrow infiltration found on the blood smear include nucleated red cells, teardrop poikilocytes, immature leukocytes, and large, bizarre platelets or megakaryocyte fragments (Fig. 27.6). When such changes are detected, as well as in any patient with anemia along with other cytopenias, marrow aspiration and biopsy should be performed.

Of the different congenital dyserythropoietic anemias (discussed in Approach to Macrocytosis), type II CDA is the most common, and it is the one that almost always presents as a normocytic anemia. This disorder is recognized by distinct multinuclearity of the marrow normoblasts (Chapter 46).

APPROACH TO HEMOLYSIS

Hemolytic disorders are characterized by signs of accelerated erythrocyte destruction together with those of vigorous blood regeneration. Under maximal stimulation, the normal marrow is capable of undergoing hyperplasia until its production rate increases approximately six to eight times ([129]). With optimal marrow compensation, the survival of red cells in the circulation can theoretically decrease from the normal 120 days to as few as 15 to 20 days without anemia developing. Such an increase in destruction and production of erythrocytes can result in a compensated hemolytic state without anemia being present. In this regard, it is of interest that a significant fraction of patients with hereditary spherocytosis patients are not anemic. However, when red cell survival is so short that anemia develops despite a vigorous erythropoietic response, the term *hemolytic anemia* is appropriate.

Pathogenesis and Classification

Disorders associated with hemolytic anemia have been classified in various ways, none of which is entirely satisfactory.

On clinical grounds, hemolytic anemias have been divided into acute and chronic forms, but such a division is of limited usefulness because acute episodes may develop during the course of chronic hemolytic disorders.

Of somewhat greater use is a classification based on the site of hemolysis: whether it is predominantly within the circulation (intravascular) or within tissue macrophages (extravascular). Most hemolytic diseases are characterized by extravascular red cell destruction. The intravascular hemolytic disorders are accompanied by unique manifestations, such as hemoglobinemia, hemoglobinuria, and hemosiderinuria, and this type of hemolysis is easily recognized (Table 27.9) ([130]).

TABLE 27.9. Hemolytic Anemias Characterized By Significant Intravascular Red Cell Destruction

Paroxysmal nocturnal hemoglobinuria
Erythrocyte fragmentation disorders
Transfusion reactions resulting from ABO isoantibodies
Paroxysmal cold hemoglobinuria
Acquired autoimmune hemolytic anemia (occasionally)
Associated with certain infections
Blackwater fever in falciparum malaria
Clostridial sepsis
Caused by certain chemical agents
Arsine poisoning
Snake and spider venoms
Acute drug reactions with glucose-6-phosphate dehydrogenase deficiency
Intravenous administration of distilled water
Thermal injury

Hemolytic disorders also may be considered to be caused by an intrinsic defect in the cell itself or caused by extrinsic agents acting on otherwise normal red cells. It is this classification which generally is most useful to the clinician (Table 27.10). Most intrinsic defects are inherited, whereas the extrinsic ones are acquired. Exceptions to this generalization are few; these include paroxysmal nocturnal hemoglobinuria (Chapter 37), an acquired disorder characterized by an intrinsic red cell defect. Also, certain inherited intrinsic defects [e.g., the most common form of glucose-6-phosphate dehydrogenase (G6PD) deficiency] are associated with no ill effects in the absence of an extrinsic agent, usually an infection or exposure to a drug (see Chapter 33).

TABLE 27.10. Etiologic and Pathogenetic Classification of the Hemolytic Disorders

- Inherited hemolytic disorders
  - Defects in the erythrocyte membrane (Chapter 32)
    - Hereditary spherocytosis
    - Hereditary elliptocytosis syndromes
      - Common hereditary elliptocytosis
      - Homozygous (doubly heterozygous) hereditary elliptocytosis
      - Hereditary pyropoikilocytosis
      - Spherocytic elliptocytosis
      - Southeast Asian ovalocytosis
    - Stomatocytic disorders
      - Hereditary stomatocytosis
      - Hereditary xerocytosis
      - Intermediate stomatocytic syndromes
      - Rh-null syndrome
    - Acanthocytic disorders
      - Abetalipoproteinemia
      - Macleod phenotype
    - Echinocytic disorders
    - Target cell disorders
      - Familial lecithin-cholesterol acyltransferase deficiency
  - Hereditary enzyme disorders (Chapter 33)
    - Disorders of hexose monophosphate shunt and glutathione metabolism
      - Glucose-6-phosphate dehydrogenase deficiency
      - Related disorders of hexose monophosphate shunt and glutathione metabolism
        - Defects in glutathione synthesis
        - ?-Glutamyl-cysteine synthetase deficiency
        - Glutathione synthetase deficiency
    - Disorders of glycolysis
      - Pyruvate kinase deficiency
      - Other glycolytic enzymopathies
        - Hexokinase deficiency
        - Glucosephosphate isomerase deficiency
        - Phosphofructokinase deficiency
        - Aldolase deficiency
        - Triose phosphate isomerase deficiency
        - Phosphoglycerate kinase deficiency
    - Disorders of erythrocyte nucleotide metabolism
      - Pyrimidine 5' nucleotidase deficiency
      - Adenosine deaminase excess
      - Adenylate kinase deficiency
  - Inherited disorders of hemoglobin or synthesis
    - Unstable hemoglobin disorders (Chapter 41)
    - Sickle cell anemia syndromes (Chapter 40)
    - Other homozygous hemoglobinopathies (CC, DD, EE; Chapter 39)
    - Thalassemia syndromes (Chapter 42)
  - Acquired hemolytic anemias
    - Immunohemolytic anemias (Chapter 34, Chapter 35)
      - Transfusion of incompatible blood
      - Hemolytic disease of the newborn (Chapter 36)
      - Autoimmune hemolytic anemia caused by warm-reactive antibodies
        - Idiopathic
        - Secondary or symptomatic
        - Drug-induced
      - Autoimmune hemolytic anemia caused by cold-reactive antibodies
        - Cold hemagglutinin disease
        - Paroxysmal cold hemoglobinuria
      - Traumatic and microangiographic hemolytic anemias (Chapter 38)
      - Prosthetic valves and other cardiac abnormalities
      - Hemolytic uremic syndrome
      - Thrombotic thrombocytopenic purpura
      - Disseminated intravascular coagulation
      - Cancer-induced
      - Chemotherapy/drug-induced
    - Infectious agents (Chapter 38)
      - Protozoa: malaria, toxoplasmosis, leishmaniasis, trypanosomiasis, babesiosis
      - Bacteria: bartonellosis, clostridial infection, cholera, typhoid fever, and others
    - Chemicals, drugs, and venoms (Chapter 38)
      - Oxidant drugs and chemicals
      - Nonoxidant drugs and chemicals
      - Associated with hemodialysis and uremia
      - Venoms
    - Physical agents

Thermal injury (Chapter 38)
Hypophosphatemia (Chapter 38)
Paroxysmal nocturnal hemoglobinuria (Chapter 37)
Spur-cell anemia in liver disease (Chapter 47)

Intrinsic and extrinsic abnormalities originally were defined by performing cross-transfusion erythrocyte survival studies (Table 27.11). When normal erythrocytes are transfused to patients with an extrinsic cause for hemolysis, the donated cells are destroyed as rapidly as the patient's own cells. On the other hand, when the patient's RBCs are removed from their unfavorable environment and transfused to a normal recipient, their survival time is normal. In contrast, when the disorder is due to an intrinsic red cell defect, the RBCs of the patient, when given to a normal recipient, are removed from the circulation more rapidly than those of the recipient; the normal erythrocytes, if transfused into the patient, maintain a normal lifespan. Such cross-transfusion experiments are not used in the study of hemolytic anemias nowadays, but, in the past, they played an important role in clarifying the pathogenesis of various hemolytic disorders.

TABLE 27.11. Cross-Transfusion Erythrocyte Survival Technique for Distinguishing Intrinsic and Extrinsic Erythrocyte Red Blood Cell Abnormalities

Donor Red Blood Cells	Recipient	Erythrocyte Survival	
		Intrinsic Abnormality	Extrinsic Abnormality
Patient	Normal subject	Reduced	Normal
Normal subject	Patient	Normal	Reduced

The intrinsic disorders of the erythrocyte are due to defects affecting the red cell membrane (Chapter 32), disorders of cell metabolism (Chapter 33), or various Hb abnormalities (Chapter 39, Chapter 40, Chapter 41 and Chapter 42) (Table 27.10).

The acquired hemolytic anemias are further subclassified on the basis of the extrinsic factors causing hemolysis. These include antibodies (Chapter 34, Chapter 35 and Chapter 36), and other nonimmune causes (Chapter 38) including physical trauma, infectious agents, physical agents, chemical agents, hypophosphatemia, and liver disease (spur cell anemia). A separate category is needed for paroxysmal nocturnal hemoglobinuria, which is unique among the acquired hemolytic anemias in that it is related to an intrinsic abnormality of the red cell (Chapter 37).

Each of these different hemolytic anemias is discussed in detail elsewhere in this book. The remainder of this section focuses on the general clinical and laboratory features that are common to most congenital and acquired hemolytic anemias.

Clinical Features of Congenital Hemolytic Anemia

DEGREE OF ANEMIA The severity of anemia varies greatly, even among patients with the same congenital disorder. Most commonly, the anemia with congenital hemolytic disorders is mild to moderate because the shortened erythrocyte survival is partially offset by increased activity of the bone marrow. Often, patients accommodate remarkably well to the anemia and may exhibit few signs or symptoms. Consequently, detection can be delayed until later in childhood and discovered incidentally. Moreover, some patients have no anemia at all. The disease may then remain unsuspected until late in adult life unless jaundice, a crisis, or complications of gallbladder disease draw attention to the condition. Sometimes, such cases are discovered only in the course of a family study. In some congenital hemolytic disorders, such as homozygous ß-thalassemia, the rate of red cell destruction far exceeds the erythropoietic capacity of the marrow, and these individuals usually have a very severe anemia, usually requiring life-long red cell transfusions.

JAUNDICE Jaundice often is first noted in the neonatal period ([131]), and phototherapy frequently is used to reduce the hyperbilirubinemia and, sometimes, exchange transfusions are required. In some older children and adults with congenital hemolytic anemia, icterus is absent or mild enough to pass unnoticed. Careful inquiry often elicits a history of episodes of jaundice or the passing of dark urine associated with trivial infections. In other cases, jaundice is persistent but never becomes intense. Often, slight scleral icterus is the only sign of hemolytic disease. The jaundice of hemolytic disease is acholuric; the bilirubin, being unconjugated, is not excreted in the urine. Furthermore, pruritus is absent. These features help to distinguish the icterus of hemolytic disease from that found with disorders of the hepatobiliary system.

APLASTIC CRISES Aplastic crises result from transient failure of red cell production (Fig. 27.15) caused by infection with the type B19 human parvovirus (HPV) ([132], [133], [134] and [135]). The same virus also causes erythema infectiosum (fifth disease, a common childhood exanthem) ([136], [137]) and may cause an acute polyarthropathy syndrome in adults as well as aseptic meningitis ([138]) and fetal death with hydrops fetalis ([139], [140]). HPV infection may occur sporadically but most often is an epidemic disease that can affect several family members simultaneously or multiple people in a large geographic area. School-age children (age 5 to 10 years) are most at risk for HPV infection ([135]), but cases have been reported of HPV infection in young adults ([135], [141]). Any patient with moderately severe chronic hemolytic disease who becomes infected with HPV is at high risk for a crisis. Blood Hb concentrations fall several grams, sometimes to life-threatening levels ([141]), and the reticulocyte count falls abruptly, usually to less than 1%. The magnitude of the crisis depends on the severity of the underlying hemolytic process. In most cases, leukocyte and platelet counts are unaffected, but neutropenia and thrombocytopenia can occur and, rarely, may be severe ([134]). The bone marrow is cellular, but erythroid hypoplasia is the characteristic finding; in particular, the more mature erythrocyte precursors tend to disappear. Giant pronormoblasts may be observed. Recovery is heralded by reticulocytosis. The entire episode, from onset of symptoms to reappearance of reticulocytes, lasts approximately 10 to 12 days in subjects with normal immunologic responses but may persist much longer in patients with defective or suppressed immune systems ([142]). HPV infection also produces erythroid aplasia in normal subjects, but the decrease in Hb concentration is minimal when erythrocyte survival is normal ([143]), and such small changes go undetected. During the acute phase of aplastic crisis, HPV particles often can be detected in the serum by polymerase chain reaction assays ([136]). The appearance of a specific immunoglobulin (Ig) M (IgM) antibody in serum is a marker of recent infection ([135]). It is replaced by an IgG antibody that persists for years and is found in 60% of normal subjects. A single infection apparently confers life-long immunity.

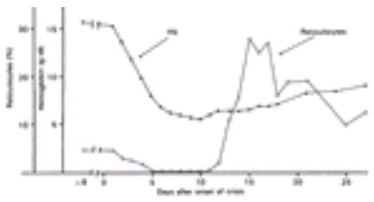

Figure 27.15. Severe aplastic crisis in a patient with hereditary spherocytosis who previously had well-compensated hemolysis. Note the profound reticulocytopenia during the early phases of the reaction, followed by reticulocytosis. Hb, hemoglobin. (Plotted from Owren P. Congenital hemolytic jaundice. The pathogenesis of the “hemolytic crisis.” Blood 1948;3:231–248, with permission.)

SPLENOMEGALY The spleen typically is enlarged in patients with congenital hemolytic anemias, except for individuals with sickle cell anemia older than 5 years of age (Chapter 40). Most often, the degree of enlargement is mild to moderate. At times, splenomegaly leads to discovery of the disease because the spleen is detected on a routine physical examination. It is not uncommon for children with hereditary spherocytosis to first be picked up by the finding of splenomegaly during a routine physical examination in an otherwise healthy child.

CHOLELITHIASIS Gallstones and its complications play a significant role in the clinical manifestations of congenital hemolytic anemias. Symptoms of gallbladder disease rarely may be the initial manifestations of a hemolytic process and the ones that bring the illness to the attention of a physician. Gallstones typical of hemolytic anemia are so-called black pigment stones ([144], [145]). They differ from brown pigment stones and cholesterol stones, neither of which is associated with hemolysis. The hepatic bile of patients with hemolytic anemia contains greatly increased amounts and concentrations of unconjugated bilirubin, decreased concentrations of bile acids ([145], [146]), and increased concentrations of ionized calcium ([147]). The prevalence of cholelithiasis in patients with hemolytic anemia increases with age and with the intensity of the hemolytic process. In a large study series involving Jamaican patients with sickle cell anemia, the prevalence ranged from 8% among patients 16 to 25 years old to 55% in patients older than age 35 years with reticulocyte counts greater than 15% ([148]).

LEG ULCERS Chronic ulcerations of the legs are peculiar and uncommon complications of chronic hemolytic disease. They are particularly characteristic of sickle cell anemia (Chapter 40) ([150]) but also occur in association with other hemolytic disorders ([151], [152] and [153]), such as hereditary spherocytosis ([149]) (Chapter 32). The ulcers often are bilateral and tend to involve the areas overlying or proximal to the medial or lateral malleoli. They tend to be chronic or recurrent and, upon healing, leave the skin indurated and pigmented.
SKELETAL ABNORMALITIES When hemolytic anemia is severe during active phases of growth and development, the pronounced expansion of erythroid bone marrow may lead to a tower-shaped skull, thickening and striation of frontal and parietal bones, maxillary and dental abnormalities, and other distortions of bony structures. Such abnormalities are particularly characteristic of severe thalassemia major, the so-called thalassemic facies (Chapter 42). Nowadays it is much less common to see these skeletal malformations, because patients with homozygous ß-thalassemia are transfused aggressively with red cells to maintain a higher Hb level, and this suppresses expansion of the erythroid marrow and its subsequent effects on bone structure. However, in patients with thalassemia intermedia, a slightly milder clinical variant not necessitating RBC transfusions, the characteristic bone changes may occur because of the expanded size of the erythroid marrow. The skeletal changes also may occur in patients with sickle cell anemia and in exceptional patients with other forms of congenital hemolytic anemia ([153]).

Clinical Features of Acquired Hemolytic Anemia

Hemolytic anemia sometimes develops acutely, such as after the transfusion of incompatible blood or the ingestion of an oxidant drug by patients with G6PD deficiency or in association with an acute febrile illness. Some instances of autoimmune hemolytic anemia, thrombotic thrombocytopenic purpura, and other hemolytic disorders may also begin abruptly ([154]). Aching pains in the back, abdomen, or limbs are common, as are headaches, malaise, vomiting, shaking chills, and fever ([154]). Abdominal pain may be severe, and the accompanying muscular spasm and rigidity may simulate the signs of an acute abdominal condition requiring surgical treatment. Pallor, jaundice, tachycardia, and other symptoms of severe anemia may be prominent.

Acquired hemolytic anemia also can begin insidiously, developing gradually over a period of weeks or months. Cardiovascular adjustments to the anemia may be adequate, and patients may have few symptoms. Pallor, scleral icterus, or a jaundiced complexion may be the first evidence of illness, and often, these signs are noticed by friends or associates before they are appreciated by the patient or the family. As in congenital hemolytic anemia, the course may be interrupted by aplastic crises ([133]).

In other instances, the clinical setting may be dominated by the manifestations of an underlying disease of which the hemolytic anemia is one manifestation. For example, signs and symptoms of lymphoma, lupus erythematosus, or mycoplasma pneumonia may overshadow those of the associated hemolytic process.

Laboratory Features of Hemolysis

The laboratory studies used to identify a hemolytic process include those related to the increase in erythrocyte destruction and those related to the compensatory increase in the rate of erythropoiesis. Once it is established that a patient has hemolysis, then more specific procedures are used to identify the precise cause. Some of these procedures are described in this section, and others are discussed elsewhere in the text.

SIGNS OF INCREASED RED BLOOD CELL DESTRUCTION

Serum Bilirubin The amount of bilirubin in the circulation depends in part on the rate at which the bilirubin is formed and in part on the efficiency with which it is excreted by the liver. Hyperbilirubinemia is a hallmark of hemolytic anemia (Fig. 27.16), although occasionally the serum bilirubin is within the normal range despite brisk hemolytic disease ([155]). The increased serum bilirubin level in hemolysis almost always consists of the unconjugated (indirect-reacting) pigment. The conjugated fraction remains within normal limits, and no bilirubin is evident in the urine. Except for during the neonatal period, values greater than 5 mg/dl are unusual in patients with hemolytic anemia and suggest coexisting hepatic dysfunction.

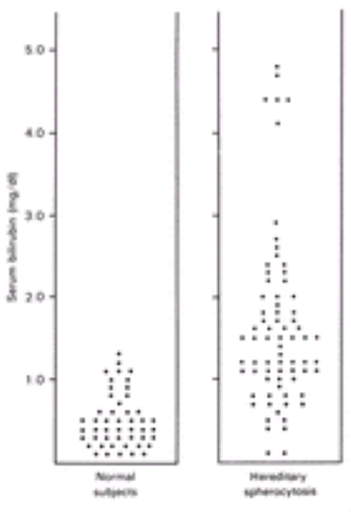

Figure 27.16. Total serum bilirubin values in 48 normal subjects and 72 patients with hereditary spherocytosis. (From Mackinney A, Norton NE, Kosower NS. Ascertaining genetic carriers of hereditary spherocytosis by statistical analysis of multiple laboratory tests. J Clin Invest 1962;41:554–567, with permission.)

Serum Lactic Dehydrogenase Serum lactic dehydrogenase (LDH) often is increased in patients with hemolytic anemia, although not to as great an extent as in megaloblastic anemia. The increase in LDH probably results from liberation of the erythrocyte enzyme into the plasma during hemolysis ([156]). Increased serum LDH is a nonspecific finding, because it also is elevated in other medical conditions associated with tissue injury.
Serum Haptoglobin When Hb enters the plasma, it binds to haptoglobin, and the complex is removed by hepatocytes (Chapter 9). As a result, serum haptoglobin decreases in individuals with hemolytic disease. Moreover, despite the intravascular site of haptoglobin function, this protein becomes depleted in association with both intravascular and extravascular hemolysis, such as sickle cell anemia ([157]), hereditary spherocytosis ([157], [158]), hereditary elliptocytosis ([159]), and pyruvate kinase deficiency ([153]). Haptoglobin also disappears in megaloblastic anemia and other conditions with intramedullary hemolysis (ineffective erythropoiesis) (Fig. 27.17) ([160]). In microangiopathic hemolytic anemias with intravascular hemolysis, low haptoglobin levels are the most sensitive marker of red cell destruction, and may be seen in the absence of anemia or hemoglobinemia (Chapter 38).

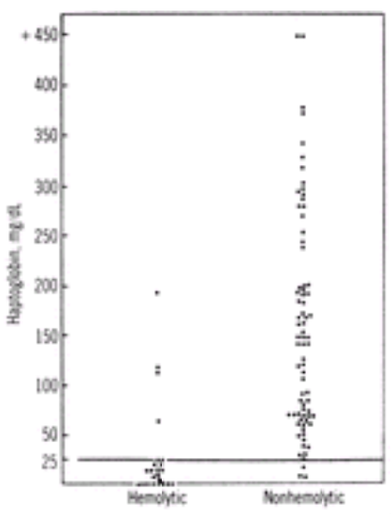

Figure 27.17. Serum haptoglobin in hemolytic and nonhemolytic disease. (From Marchand A, Galen RS, Van Lente F. The predictive value of serum haptoglobin in hemolytic disease. JAMA 1980;243:1909, with permission.)

The interpretation of haptoglobin levels sometimes is complicated by the fact that haptoglobin is an acute phase reactant, the synthesis of which increases in response to inflammatory, infectious, or malignant disease. Haptoglobin values also may fall in association with liver disease because of impaired synthesis and in hereditary deficiency of the protein.
Erythrocyte Survival The strictest definition of hemolysis requires demonstration that the red cell lifespan is reduced, using methods described in Chapter 9. From a practical perspective, however, erythrocyte lifespan determinations are rarely necessary, because they provide little additional information beyond what can be

assessed by more easily obtained data, such as serial observations of the degree of anemia, reticulocytosis, and jaundice. For these reasons, determination of red cell survival is reserved for use in evaluating patients with especially difficult diagnostic problems.

Rate of Carbon Monoxide Production Determinations of the rate of endogenous carbon monoxide production (Chapter 9) provide accurate assessments of the rate of heme catabolism. With these methods, values of approximately two to ten times the normal rate have been detected in small groups of patients with hemolytic disease. At the present stage of development, however, these methods are not available for routine clinical use.

Fecal Urobilinogen Excretion Quantitative measurements of fecal urobilinogen excretion (Chapter 9) provide a sensitive index of hemolysis; however, it necessitates the accurate collection and processing of timed fecal specimens. These tests are rarely ever used nowadays.

Glycosylated Hemoglobin Glycosylated Hbs (Hb A1c) are regularly reduced in people with hemolytic disease (161 , 162), and this reflects the young RBC age in these patients. From a practical perspective, this measurement is rarely used to assess hemolysis in clinical situations.

SIGNS OF INTRAVASCULAR HEMOLYSIS When erythrocytes are destroyed within the circulation, and also when extravascular destruction is so rapid that it exceeds the capacity of the macrophage system, Hb is released into the plasma. The disposal of Hb and its heme group occurs by several mechanisms (Chapter 9), and characteristic laboratory abnormalities are found (Table 27.12).

TABLE 27.12. Laboratory Signs of Hemolysis

Accelerated red cell destruction
Decreased erythrocyte lifespan
Increased heme catabolism
Increased serum unconjugated bilirubin level
Increased carbon monoxide production [a]
Increase rate of urobilinogen excretion
Increased serum lactate dehydrogenase [a]
Decreased serum haptoglobin [a]
Signs of intravascular hemolysis
Hemoglobinemia
Hemoglobinuria [a]
Hemosiderinuria [a]
Methemalbuminemia
Decreased serum hemopexin
Reduced glycosylated hemoglobin
Fall in blood hemoglobin level at a rate greater than 1.0 g/dl/wk [a]
Accelerated erythropoiesis
Complete blood count [a]
Reticulocytosis
Macrocytosis
Blood smear findings [a]
Polychromatophilia
Basophilic, stippling
Erythroblastosis
Abnormal red blood cell forms
Bone marrow (erythroid hyperplasia)
Ferrokinetic (increased plasma iron turnover)
Biochemical (increased erythrocyte creatine)

[a] Commonly used tests and observed laboratory features.

Hemoglobinemia At low concentrations, plasma Hb may be measured by means of the benzidine reaction, which allows detection not only of Hb but also of any other heme pigments that may be present. If special precautions are observed to avoid artifactual hemolysis during collection of blood, normal values of less than 1 mg/dl of plasma are found. Plasma usually appears visibly red when Hb exceeds 50 mg/dl. At levels greater than 100 mg/dl, Hb can be measured directly by the cyanomethemoglobin method. Plasma Hb levels are normal in most patients with hereditary hemolytic anemias, including hereditary spherocytosis, but can be increased in severe, acquired, immunohemolytic anemia, at times reaching 100 mg/dl (163). Particularly high values, up to 1000 mg/dl, are found only in patients with disorders associated with intravascular hemolysis (130).

Hemoglobinuria When plasma Hb exceeds the haptoglobin binding capacity, Hb dimers are excreted into the urine, resulting in hemoglobinuria. Urine that contains Hb ranges from faint pink to deeper red, or even to almost black, similar to a cola beverage. Hemoglobinuria can be distinguished from hematuria (whole RBCs in the urine) by microscopic examination of a freshly voided urine specimen. Urine also may appear red because of ingestion of certain drugs (Pyridium) or food (beets), or because of porphyrinuria (Chapter 31) or myoglobinuria. Of these various red urinary pigments, only Hb and myoglobin produce a positive reaction in the commonly available tests for occult blood, which are based on the benzidine or orthotolidine reactions (164). Hemoglobinuria must be distinguished from myoglobinuria, which occurs as the result of massive muscle injury (165 , 166 and 167). Myoglobin is a heme pigment of low molecular weight (17,000 d); it is not bound by haptoglobin and therefore does not accumulate to an appreciable extent in plasma. Thus, inspection of the plasma can help to distinguish myoglobinuria from hemoglobinuria, the presence of a red color in the plasma favoring the latter. More precise identification is accomplished by spectroscopic analysis.

Urine Hemosiderin and Urinary Iron Excretion Hb in the glomerular filtrate is partially reabsorbed by the proximal tubular cells, and the Hb iron is incorporated into ferritin and hemosiderin. Subsequently, the iron-containing tubular cells are sloughed into the urine. Hemosiderinuria, therefore, constitutes reliable evidence that hemoglobinemia has occurred in the recent past (130 , 163). After an acute episode of intravascular hemolysis, however, several days may pass before increased iron excretion can be detected. Moreover, the abnormality may persist for some time after the episode has terminated. In most conditions associated with chronic intravascular hemolysis, such as in some of the fragmentation hemolysis syndromes, increased iron excretion is a constant finding, whereas hemoglobinuria occurs only intermittently. Hemosiderinuria may be detected by means of a qualitative test based on the Prussian blue reaction (163). Urinary iron content can be determined spectrophotometrically after wet digestion of a measured urine specimen (168 , 169). The normal value for urinary iron excretion is less than 0.1 mg/day, but in a variety of disorders associated with intravascular hemolysis, urinary iron values increase to between 3 and 11 mg/day (168 , 169). Measurement of urinary iron excretion is rarely used in assessing intravascular hemolysis; however, it is frequently used to assess efficacy of chelation therapy in iron-overload patients receiving chronic transfusions.

Methemalbumin and Hemopexin Hb in plasma is readily oxidized to methemoglobin, from which the heme group easily detaches. The liberated heme binds to hemopexin and also to albumin, forming methemalbumin. Hemopexin-heme and methemalbumin impart a coffee-brown color to plasma. With either combination, a spectral absorption band is observed at 620 to 630 nm, which, unlike a similar band in methemoglobin, does not disappear if hydrogen peroxide is added. With the addition of ammonium sulfide, the 620- to 630-nm band disappears and a band at 558 nm forms (Schumm test) (170). Although hemopexin can be depleted in the course of serving its function (171), depletion occurs less regularly than occurs with haptoglobin. Low hemopexin values usually indicate that the hemolytic anemia is severe (157). Low hemopexin values are seen in thalassemia major, sickle cell anemia, and the fragmentation hemolytic anemia that follows cardiac surgical procedures. The measurement of hemopexin is seldom used to assess hemolytic anemia.

SIGNS OF ACCELERATED ERYTHROPOIESIS Laboratory signs of increased erythropoiesis are almost always present in patients with chronic hemolytic disease. In patients who have had an acute hemolytic episode, signs of increased red cell production appear after 3 to 6 days (Table 27.12). These same signs of increased RBC production also occur after hemorrhage and after specific therapy for anemia caused by iron, folate, or vitamin B_{12} deficiency.

Reticulocytosis An increased number of reticulocytes continues to be the most readily available and most often used index of accelerated erythropoiesis. In cases of hemolytic anemia, the erythrocyte production rate and the absolute reticulocyte count is usually greatly increased when hemolysis is severe enough to produce anemia. In most types of hemolytic anemia, the reticulocyte count consistently increases to levels that correlate fairly well with the severity of the process. Exceptions occur during aplastic crises. Also, some patients with idiopathic acquired immunohemolytic anemia may have normal reticulocyte counts, and in one report, values of less than 2% were found in 26% of 35 such patients (154). In these cases, it is thought that the autoantibodies are directed against marrow erythroid precursors as well as circulating erythrocytes.

Red Cell Creatine Creatine levels in young red cells are six to nine times higher than those in older cells, and the elevation persists for as long as 20 days of erythrocyte lifespan, compared to the reticulocyte maturation time of 1 to 3 days ([172], [173]). Erythrocyte creatine level correlates with the reticulocyte count, but the relationship is not linear. The former appears to be a more sensitive indicator of red cell age than is the latter, so it may be increased in people with mild hemolytic processes when the reticulocyte count remains equivocal. It is not a commonly used test.

Morphologic Findings in the Blood When reticulocytes are increased, polychromatophilia and fine basophilic stippling are apparent on routinely stained smears of blood. Macrocytosis is found in association with most hemolytic disorders because of erythropoietin-mediated stimulation of Hb synthesis and because prematurely released (shift) reticulocytes are larger than normal erythrocytes. Exceptions occur in hereditary spherocytosis and sickle cell anemia, diseases in which the intrinsic defect of the cell tends to decrease its size. When hemolysis is brisk, nucleated erythrocytes may be found in the blood (erythroblastosis), usually in numbers below 1% of all the nucleated cells. In infants, however, erythroblastosis may be more striking, especially in hemolytic disease of the newborn. Neutrophilic leukocytosis and thrombocytosis may accompany hemolytic anemia. These findings tend to be most common and most pronounced in patients with acute hemolytic anemias. Platelets are not only numerous but also large. The changes are less pronounced in chronic hemolytic processes.

Bone Marrow The major alteration in the bone marrow in hemolytic anemia is erythroid hyperplasia, as manifested by a reduction in the myeloid to erythroid ratio.

Ferrokinetic Studies The plasma iron transport rate is considered a measure of total erythropoiesis and correlates well with the degree of erythroid hyperplasia ([174]). The erythrocyte iron turnover rate is a measure of effective erythropoiesis and correlates well with the reticulocyte production index. In hemolytic anemia, the plasma iron transport rate reaches two to eight times the normal rate, and the erythrocyte iron turnover rate increases two to four times. These determinations provide accurate information regarding rates of erythropoiesis, but they are unnecessary for most patients because other easily obtained determinations are simpler, faster, considerably less expensive, and nearly as accurate.

Laboratory Tests Useful in the Differential Diagnosis of Hemolysis

SPECIFIC MORPHOLOGIC ABNORMALITIES Detection of certain distortions of red cell shape is of particular diagnostic use because their presence suggests only one or a few entities. Descriptive features of certain such abnormal red cells are presented in Table 27.13 and illustrated in Figure 27.18 and Figure 27.19.

TABLE 27.13. Morphologic Abnormalities in Hemolytic Anemia

Cell	Description	Clinical Disorders
Spherocyte	Spheric; appear microcytic with no central pallor	Hereditary spherocytosis Immunohemolytic anemia Burns
Elliptocytes	Oval cell	Hereditary elliptocytosis Megaloblastic anemia
Stomatocytes	Uniconcave red cell; slitlike rather than circular area of central pallor	Hereditary stomatocytosis Alcoholism
Acanthocytes	5–10 spicules of various lengths, irregular in spacing and thickness	Spur-cell anemia with liver disease Abetalipoproteinemia
Echinocytes	10–30 spicules evenly distributed over cell surface	Uremia
Sickle cells	Cell with sickle shape	Sickle cell anemia
Target cells	Solid area in center of central pallor	Thalassemia Hemoglobin C disorders Liver disease Lecithin-cholesterol acyltransferase deficiency Postsplenectomy
Schistocytes	Triangular, helmet-shaped, fragmented or greatly distorted cell; small	Microangiopathic anemia Turbulent blood flow Hemolytic uremic syndrome

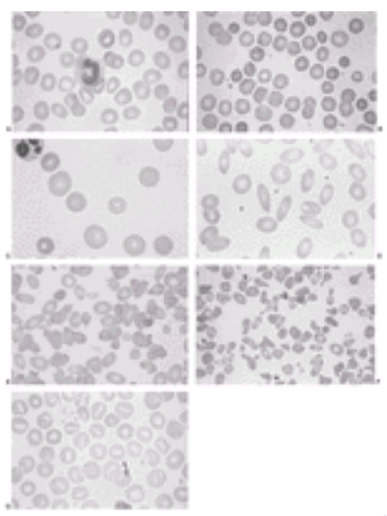

Figure 27.18. Red blood cell abnormalities associated with hemolysis. **A:** Normal red blood cells for comparison. **B:** Microspherocytes from patient with hereditary spherocytosis. **C:** Spherocytes from patient with autoimmune hemolytic anemia. **D:** Hereditary elliptocytosis—common variant with minimal or no hemolysis. **E:** Hereditary elliptocytosis—hemolytic variant. **F:** Hereditary elliptocytosis—pyropoikilocytosis variant. **G:** Hereditary stomatocytosis. See Color Plate.

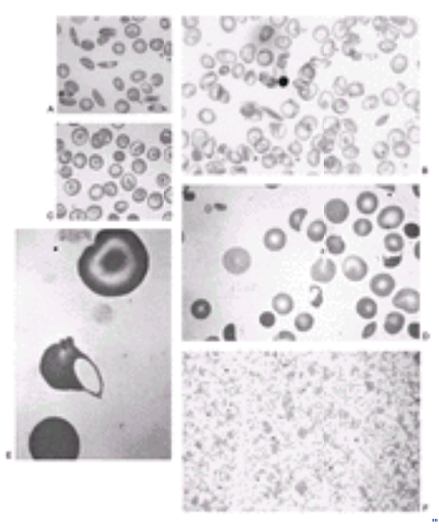

Figure 27.19. A: Sickle cell anemia. **B:** Sickle ß-thalassemia. **C:** Target cells in hemoglobin C disease. **D:** Schistocytes in patient with thrombotic thrombocytopenic purpura. **E:** Blister cell from oxidative assault in patient with glucose-6-phosphate dehydrogenase deficiency. **F:** Autoagglutination in cold agglutinin disease. See Color Plate.

Spherocytes, erythrocytes that lack an area of central pallor (Fig. 27.18B), are the hallmark of hereditary spherocytosis (Chapter 32). They are also found in most patients with acquired immunohemolytic anemias (Fig. 27.18C), thermal injury, hypophosphatemia, or certain kinds of chemical poisoning (Chapter 35 and Chapter

38). Oval cells or elliptocytes (Fig. 27.18D) are the *sine qua non* of common hereditary elliptocytosis which usually is a morphologic curiosity, but not associated with significant hemolysis (Chapter 32). However, some hereditary elliptocytosis variants are also associated with marked poikilocytosis (Fig. 27.18E and Fig. 27.18F), and these individuals have significant hemolytic anemia. Stomatocytes (Fig. 27.18G), which suggest a disturbance in red cell cation content, are found in association with a rare inherited hemolytic disease (see Chapter 32) and also in liver disease. Acanthocytes indicate disturbed erythrocyte lipid composition; they occur in association with abetalipoproteinemia and the spur cell anemia that occasionally accompanies hepatic cirrhosis (Chapter 32). Echinocytes (sea urchin cells) are a nonspecific abnormality and are also found in uremia. Sickle cell anemia was named after the unmistakable sickle-shaped red cells that characterize that disorder (Fig. 27.19A and Fig. 27.19B) (Chapter 40). Target cells (Fig. 27.19C) are characteristic of thalassemia (Chapter 42]), Hb E syndromes (Chapter 39) and Hb C disorders (Chapter 39). Target cells also occur in nonhemolytic states, such as obstructive jaundice and after splenectomy. Schistocytes, helmet cells, or other fragmented red cells (Fig. 27.19D) suggest hemolysis associated with physical trauma to the erythrocyte or with diseases affecting small blood vessels (Chapter 38). Bite cells are erythrocytes that look as if a semicircular bite has been taken from one edge. Hemighosts are red cells that look as if the Hb has shifted to one side of the cell, leaving the other side clear. These hemighosts also are referred to as *blister cells* and may appear to contain a coagulum of Hb that has separated from the membrane (Fig. 27.19E). These cells are seen in patients with oxidant-induced injury such as in G6PD deficiency (Chapter 33). Autoagglutination may be apparent in blood smears (Fig. 27.19F) or may even be visible to the naked eye when the blood is allowed to flow along the side of a glass container. The phenomenon is particularly characteristic of immunohemolytic disease caused by cold agglutinins. Autoagglutination must be distinguished from rouleau formation, a manifestation of multiple myeloma and related diseases and the phenomenon responsible for accelerated rates of erythrocyte sedimentation.

DIRECT ANTIGLOBULIN TEST The test used for detection of immunohemolytic anemia is the direct antiglobulin or Coombs test (see discussion in Chapter 34 and Chapter 35). Positive test results indicate that the red cells are coated with IgG or complement components, especially C3. However, 2 to 5% of patients with immunohemolytic disease have negative test results because the amount of globulin on the cell surface is below the detection limits ([175]). Rarely, patients have weakly positive test results and no clinical evidence of hemolysis. Positive tests are found in as many as 34% of patients with AIDS without other evidence of immunohemolytic disease ([176]).

OSMOTIC FRAGILITY TEST The osmotic fragility test is a measure of the resistance of erythrocytes to hemolysis by osmotic stress. The test consists of exposing red cells to decreasing strengths of hypotonic saline solutions and measuring the degree of hemolysis. A symmetric, sigmoidal curve is obtained in most subjects (Fig. 27.20). Increased fragility is indicated by a shift of the curve to the left, whereas osmotic resistance (reduced fragility) is signified by a rightward shift of the curve. Increased osmotic fragility is observed in conditions associated with spherocytosis. With prior incubation of sterile blood for 24 hours ([177]), the increased osmotic fragility of spherocytes is greatly accentuated, whereas normal cells become only slightly more fragile. The osmotic fragility of unincubated blood may be normal in some patients with hereditary spherocytosis, and for this reason, the test should be performed on incubated samples. Determination of osmotic fragility is of value chiefly in confirming important morphologic findings, especially the presence of spherocytes. In most cases, however, the osmotic fragility test does not provide information that was not already available from an expert examination of a well-prepared, stained blood smear. Osmotic gradient ektacytometry is more sensitive and specific than the osmotic fragility test for the diagnosis of hereditary spherocytosis but is not widely available ([152]).

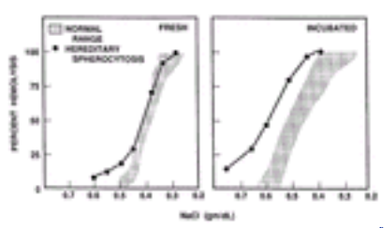

Figure 27.20. Osmotic fragility (as manifested by percent hemolysis) of normal and hereditary spherocytosis (HS) erythrocytes after incubation in salt solutions of varying tonicity. In fresh HS erythrocytes, note the "tail" of cells with increased sensitivity as a result of splenic conditioning (*left*). In the incubated red blood cell (RBC), note that the entire HS population of RBCs is more osmotically sensitive (*right*). (From Glader BE, Naumovski L. Hereditary red blood cell disorders. In: Rimoin DL, Connor JM, Pyeritz RE, Emery AE, eds. Principles and practice of medical genetics. New York: Churchill Livingstone, 1996, with permission.)

TESTS FOR HEMOLYTIC DISORDERS ASSOCIATED WITH HEINZ BODY FORMATION In certain disorders, the hemolytic process involves precipitation of Hb, with the formation of inclusions known as *Heinz bodies*. These inclusions are rapidly removed by the spleen. Heinz body formation is the principal mechanism of hemolysis in G6PD deficiency and related disorders (Chapter 33), in unstable Hb disease (Chapter 41), in the thalassemias (Chapter 42), and in certain kinds of chemical injury (Chapter 38). Heinz bodies are not observed when ordinary staining procedures are used, but require the use of special supravital stains (Fig. 27.21). Cells containing these inclusions may be found in the blood during an acute hemolytic episode in subjects with G6PD deficiency and also in splenectomized individuals with unstable Hb disease. When the spleen is intact, however, the inclusions are removed with such efficiency that the inclusion-containing cells often are not seen.

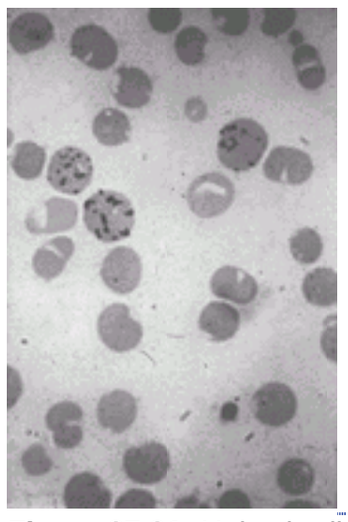

Figure 27.21. Heinz bodies (seen with brilliant cresyl blue supravital stains of blood during hemolytic episodes). See Color Plate.

Diagnostic Strategy to the Patient with Hemolytic Anemia

ESTABLISHING THE PRESENCE OF HEMOLYTIC ANEMIA The most common manifestations of chronic hemolytic anemia include anemia and reticulocytosis, often associated with various signs of excessive blood destruction. In contrast, an acute hemolytic anemia initially may not be accompanied by signs of accelerated red cell production. Such a diagnosis may be suspected because of the abrupt onset of hemoglobinuria or other signs of intravascular hemolysis or because of a rapid fall in blood Hb concentration from previously stable levels. As a rule, a decrease of more than 1.0 g/dl/week is indicative of hemolysis, hemorrhage, or hemodilution. If hemorrhage and hemodilution can be excluded, the presence of hemolytic anemia is established.

CONDITIONS SOMETIMES MISTAKEN FOR HEMOLYTIC ANEMIA Anemias associated with acute hemorrhage and those with partially treated deficiency states are characterized by transient anemia and reticulocytosis (Table 27.14). They usually can be distinguished from hemolytic disease by the absence of icterus and by a rising hematocrit on subsequent determinations.

TABLE 27.14. Conditions Sometimes Mistaken for Hemolytic Anemia

Associated with anemia and reticulocytosis
Hemorrhage
Recovery from iron, folate, or vitamin B_{12} deficiency
Recovery from marrow failure
Associated with jaundice and anemia
Ineffective erythropoiesis (intramedullary hemolysis)
Bleeding into a body cavity or tissue
Associated with jaundice without anemia
Defective bilirubin conjugation
Crigler-Najjar syndrome
Gilbert syndrome
Marrow invasion (myelofibrosis, metastatic disease)

Anemias caused by ineffective erythropoiesis often are accompanied by jaundice and erythroid marrow hyperplasia; however, the reticulocyte count usually is not increased. In equivocal situations, this may be one of the rare instances where the measurement of erythrocyte survival might be useful. In hemolytic disease, the red cell survival is distinctly shortened, whereas it is normal or nearly so in association with ineffective erythropoiesis. A particularly confusing situation may arise after occult hemorrhage into the retroperitoneal space or other tissue compartments; anemia develops rapidly, and reticulocytosis follows. Furthermore, indirect hyperbilirubinemia may occur as the result of reabsorption of the products of Hb breakdown at the site of hemorrhage. Thus, the picture of hemolytic anemia may be simulated in several ways. Diagnosis depends on detecting signs of the hemorrhage itself or the disease process leading to it. If occult hemorrhage is suspected, serial observations usually clarify the situation; once the hemorrhage ceases, the hematocrit, reticulocyte count, and bilirubin values return to normal. In individuals with acholuric jaundice but without anemia, the differential diagnosis lies between a compensated hemolytic state and Gilbert syndrome or other disorders of bilirubin catabolism. Reticulocytosis or morphologic abnormalities of erythrocytes are typical findings in the former. In mild compensated hemolytic disease, however, one cannot always be certain that the hematologic values will be abnormal. Fasting induces an exaggerated increase in bilirubin levels in patients with Gilbert syndrome ([178]), and this phenomenon may be useful in distinguishing Gilbert syndrome from hemolytic anemia. Anemia associated with marrow invasion may be accompanied by erythroblastosis and bizarre abnormalities of erythrocyte shape. Mild reticulocytosis may develop because of premature release of cells from the marrow. Usually, however, patients do not have jaundice, and evidence of the invasive disease may be detected by examination of the bone marrow.

DETERMINING THE SPECIFIC CAUSE OF HEMOLYSIS Information from the medical history and physical examination, careful review of the CBC and peripheral blood smear, and results from the direct antiglobulin test, taken together, form the basis of the initial diagnosis assessment of hemolysis. From these data, five groups of patients can be distinguished.

1. Those patients in whom the diagnosis is clear because of medical history such as obvious exposure to infectious, chemical, or physical agents (Chapter 38). Some infections, such as malaria, can cause hemolysis directly (Chapter 38), whereas in other cases it is more indirect, associated with an underlying G6PD deficiency (Chapter 33) or an unstable Hb, such as Hb H (Chapter 41, Chapter 42).
2. Those with a positive direct antiglobulin test. Such individuals may be presumed to have immunohemolytic anemia (Chapter 35, Chapter 36). The subsequent investigation requires a search for an underlying disease as well as a serologic study of the nature of the antibody.
3. Those with antiglobulin-negative, spherocytic hemolytic anemia. Such patients probably have hereditary spherocytosis (Chapter 32). It is appropriate to confirm the presence of spherocytes by the osmotic fragility test and also to attempt to establish the familial nature of the illness by studying family members. Immunohemolytic anemia may be associated with spherocytosis and is occasionally associated with a negative antiglobulin reaction. Exposure to chemical or infectious agents producing spherocytosis may not always be easy to establish.
4. Those with other specific morphologic abnormalities of erythrocytes. The significance of various types of abnormally shaped red cells was discussed previously. Some poikilocytes, such as elliptocytes and sickle cells, are virtually pathognomonic findings. Others, such as extensive red cell fragmentation, identify a category to which several diseases belong (Chapter 38).
5. Those with no specific morphologic abnormalities and a negative reaction to the antiglobulin test. These patients warrant a battery of screening tests, including Hb electrophoresis, the heat denaturation test for unstable Hb disease (Chapter 41), tests for common red cell enzymes such as G6PD and pyruvate kinase (Chapter 33), and a screening test for paroxysmal nocturnal hemoglobinuria (Chapter 37).

If all of these procedures yield normal results, making the diagnosis is likely to be difficult. One of the rarer erythrocyte enzyme deficiencies is possible, but these entities can be established only by using specific assays (Chapter 33).

APPROACH TO ACUTE POSTHEMORRHAGIC ANEMIA

When blood loss occurs in small amounts over a prolonged period, no anemia develops until iron stores are depleted. In such circumstances, the hematologic findings are those of iron deficiency anemia (Chapter 48). On the other hand, when larger amounts of blood are lost over shorter periods of time, anemia may develop, although iron stores remain adequate. This latter condition is called *acute posthemorrhagic anemia*.

The patient may be asymptomatic and appear to be in shock, or the entire situation might be confused with an acute hemolytic process.

The physiologic changes that occur with acute blood loss in otherwise healthy individuals are summarized in Table 27.15. The immediate effects of acute hemorrhage are primarily cardiovascular. The plasma volume and red cell mass are reduced in proportional amounts; consequently, no decrease is observed in the hematocrit ([179] , [180]). Because of the time required for extracellular fluid to restore the blood volume, the amount of blood loss tends to be underestimated by the degree of anemia, especially early in the disease course. The platelet count increases, often reaching levels above normal within 1 hour, and values greater than 1 million platelets/L can be observed. There also is a neutrophilic leukocytosis over 2 to 5 hours. Typically, the leukocyte count is between 10 and 20 10^9/L. The leukocytosis is explained in part by the effect of epinephrine on granulocyte demargination and release from the marrow granulocyte reserve.

TABLE 27.15. Clinical Features of Acute Hemorrhage in Healthy Young Adults

Volume of Blood Loss (ml)	Blood Volume (%)	Symptoms
500–1000	10–20	Few if any symptoms
1000–1500	20–30	Asymptomatic while at rest in a recumbent position; light-headedness and hypotension when upright; tachycardia
1500–2000	30–40	Symptoms present when subject is recumbent; thirst, shortness of breath, clouding or loss of consciousness; blood pressure, cardiac output, venous pressure decrease; pulse usually becomes rapid; extremities become cold, clammy, and pale
2000–2500	40–50	Lactic acidosis, shock; irreversible shock, death

When first detected, the anemia following acute hemorrhage is normocytic with few signs of erythrocyte regeneration. The hematocrit or Hb may not reach the minimum value until 3 days or more after the hemorrhage ceases.

Some increase in the number of reticulocytes is usually perceptible within 3 to 5 days, and maximal values are reached at 6 to 11 days ([181]). The degree of reticulocytosis is related to the magnitude of hemorrhage, but rarely exceeds 15%. Other signs of erythrocyte regeneration include polychromatophilia and macrocytosis, and the MCV may transiently increase. If the patient is seen for the first time during this stage, the findings may be mistaken for those of hemolytic anemia; however, signs of increased bilirubin production are conspicuously absent, unless there has been bleeding into a body cavity or tissue space.

An external hemorrhage of a magnitude sufficient to cause significant anemia is usually evident. Similarly, substantial bleeding from the gastrointestinal or female reproductive tract is likely to be a dramatic event with readily detected signs and symptoms. Internal bleeding, as from a ruptured aneurysm, may be less apparent but should be suspected when there is the abrupt onset of shock or unexplained hypotension and tachycardia. Often, these manifestations are accompanied by symptoms referable to the site of bleeding. Hemorrhage into the retroperitoneal space, a body cavity, or a cyst sometimes presents a diagnostic problem. There may be a rapid onset of anemia accompanied by hyperbilirubinemia arising from the breakdown and absorption of RBCs. Under such circumstances, the picture may be transiently confused with acute hemolytic anemia. In all cases, the onset of a sudden, unexplained anemia should lead to the suspicion of covert bleeding. The suspicion is strengthened if signs of regeneration, such as reticulocytosis, appear and no evidence of excessive blood destruction is found.

Elective surgery is a special circumstance in which hemorrhage is predictable. Surgical mortality is clearly increased when patients are severely anemic. In Jehovah's Witness patients who refuse transfusion, surgical mortality is approximately 60% at Hb values less than 6 g/dl and more than 30% at values between 6 and 8 g/dl ([182]). At values greater than 8 g/dl, no increased mortality is observed. An older guideline requiring preoperative transfusion if the Hb is less than 10 g/dl has been replaced by a lower trigger point, 7 g/dl, in otherwise healthy, younger patients ([183] , [184]). Surgeons and anesthesiologists use several techniques to avoid the need for allogeneic transfusions ([185]). These techniques include the use of autotransfusion of cells harvested during surgery ([186]) and preoperative harvesting of

autologous blood ([187], [188]). The preoperative or postoperative use of erythropoietin injection or iron medication has proved disappointing ([189], [190]) but may have a role with severely anemic Jehovah's Witness patients ([191]).

If hemorrhage ceases, the Hb concentration may reach normal levels after 6 to 8 weeks. In a study of patients who underwent coronary bypass surgery, Hb levels fell, on average, from a preoperative value of 14 to 15 g/dl to 9.5 g/dl on the sixth postoperative day. They rose to 13.6 g/dl by postoperative day 59 ([189]). Morphologic evidence of active red cell regeneration should disappear after 10 to 14 days if hemorrhage does not recur. The leukocyte count should be normal after 3 to 4 days. Sustained reticulocytosis is suggestive of continued bleeding. Persistent leukocytosis may result from the same cause, from hemorrhage into body cavities, or from complications. The latter, particularly infections, tend to delay the hematopoietic response.

ACKNOWLEDGMENT

The author wishes to acknowledge G. Richard Lee, MD, for the excellent previous chapters on anemia in the 10th Edition of *Wintrobe's Clinical Hematology*. These earlier contributions provided a substantial template for the current chapter in this 11th Edition of *Wintrobe's Clinical Hematology*.

Iron Deficiency and Related Disorders

Iron deficiency has been recognized since medieval times. *Chlorosis*, a term derived from the Greek word meaning *green*, was applied by Varandaeus ([1]) to a disorder that was first described in 1554 by Johannes Lange who called it " *De morbo virgineo*" ([2]). The disease became well known, not only in medical circles, but also in the general population, who called it the "green-sickness." It was depicted in many paintings by the Dutch masters and was alluded to by Shakespeare and other literary figures of the period.

Chlorosis occurred almost exclusively in girls between the ages of 14 and 17 years. A prominent manifestation was greenish pallor ([3]). Other clinical features were breathlessness, palpitations, slight ankle edema, and gastrointestinal complaints, including changes in appetite, flatulence, abdominal pain, and constipation. Emotional disturbances ("love sickness"), depression, irritability, and moodiness were common. Thrombophlebitis was a relatively frequent complication, and the incidence of cerebral sinus thrombosis was particularly striking.

Iron deficiency anemia undoubtedly played a prominent part in chlorosis. In the 1830s, anemia, hypochromia, and lack of iron in the blood were detected by Hoefer, Popp, and Foedisch, respectively ([4]). In 1832, Pierre Blaud described the response of chlorosis to his deservedly famous pills (ferrous sulfate plus potassium carbonate). He gave gradually increasing doses, from two pills on the first day to 12 pills on day 16. Many observers, including Nie-meyer and Osler, confirmed his findings ([5]). Ferrous sulfate remains a cornerstone of modern treatment of iron deficiency.

Today, most believe that chlorosis resulted from a combination of factors affecting adolescent girls: the demands of growth and the onset of menses, an inadequate diet, and a legacy of poor iron stores at birth from an iron-deficient mother. However, to reconcile this concept with observations on the fluctuations in the incidence of the disease is difficult ([1]). Chlorosis became especially common in the last decade of the nineteenth century. It then abruptly declined in incidence until only rare cases were observed after 1910. One prominent hypothesis offered to explain the changing incidence of chlorosis relates the disease to tight lacing of the body with a corset or similar garment, a hypothesis that continues to attract advocates ([1]).

In the late 1920s and early 1930s, a distinct hypochromic anemia was described, which corresponds to iron deficiency anemia as we know it today. Like chlorosis, chronic hypochromic anemia chiefly affected women; it differed from chlorosis in that it was detected later in life, especially in the fourth and fifth decades ([6]). Other distinguishing clinical features were epithelial changes involving the tongue and nails, as well as achlorhydria, which some believed was of specific differential diagnostic value. The anemia most often affected women with poor diets, multiple pregnancies, or menstrual irregularities. Today, menstruating women continue to be among the most likely individuals to develop iron deficiency, along with young children whose growth outstrips their iron supply. To best appreciate the varied causes of iron deficiency anemia, an understanding of normal iron physiology is essential.

NORMAL IRON PHYSIOLOGY

Total Body Iron

Iron endowment varies with age and sex. Full-term infants begin life with approximately 75 mg/kg body weight of iron, primarily acquired from their mothers during the third trimester of gestation. These abundant stores are rapidly depleted over the first few months of life, and most children are in rather tenuous iron balance, as their intake must keep pace with rapid growth. After adolescence, requirements decrease, and men have a small, gradual increase in iron stores throughout life. The body iron content of normal adult men is 50 mg/kg body weight or greater. In contrast, postpubertal women have continuous loss of iron until they cease to menstruate,

resulting in a body iron endowment averaging 35 mg/kg. After menopause, women accumulate iron linearly in parallel with adult men.

Most of the body iron is found in heme compounds, especially hemoglobin and myoglobin (Table 28.1). Very small amounts are incorporated into enzymes that use iron in electron transfer, including peroxidases, catalases, and ribonucleotide reductase. Some is used in enzymes containing iron-sulfur clusters. However, most nonheme iron (approximately 1 g in adult men) is stored as ferritin or hemosiderin in macrophages and hepatocytes. Only a tiny fraction (approximately 0.1%) is in transit in the plasma, bound to the carrier protein, transferrin.

TABLE 28.1. Important Fe-Containing Compounds in the Human

Protein	Function	Fe Oxidation State	Amount (g)	Percent of Total
Hemoglobin	Erythrocyte O_2 transport	2 (heme)	2.600	65.0
Myoglobin	Muscle O_2 storage	2 (heme)	0.130	6.0
Transferrin	Plasma Fe transport	3	0.003	0.1
Ferritin	Intracellular Fe storage	3	0.520	13.0
Hemosiderin	Intracellular Fe storage	3	0.480	12.0
Catalase, peroxidase	H_2O_2 degradation	2	—	—
Cytochromes	Electron transport	2/3 (heme)	—	—
Aconitase	Tricarboxylic acid cycle	4Fe•4S cluster	—	—
Ferrochelatase	Heme biosynthesis	2Fe•2S cluster	—	—
Duodenal cytochrome *b*–like protein	Intestinal Fe reduction	2 (heme)	—	—
Others	Other oxidases, enzymes	—	0.140	3.6

Iron Balance

Iron is not actively excreted through the liver or kidneys. It is lost from the body only when cells are lost, particularly epithelial cells from the gastrointestinal tract, epidermal cells of the skin, and, in menstruating women, red blood cells. Urinary iron amounts to less than 0.05 mg/day and is largely accounted for by sloughed cells.

Although iron is a physiologic component of sweat, only a tiny amount of iron (22.5 µg/L) is lost by this route ([7]). On the basis of long-term studies of body iron turnover, the total average daily loss of iron has been estimated at approximately 1.0 mg (range, 0.6 to 1.6 mg) in normal adult men and nonmenstruating women ([8]). Menstruating women lose an additional, highly variable amount averaging approximately 0.006 mg/kg/day prorated over the entire menstrual cycle. Occasionally, menstruation results in losses of more than 0.025 mg/kg/day ([9], [10]). In pregnant women, the rate of iron loss is approximately three and a half times as great as in normal men.

In the ideal situation, these losses are balanced by an equivalent amount of iron absorbed from the diet. However, only a fraction of dietary iron is absorbed. The bioavailability of iron in the American diet has been estimated to be approximately 16.6%, but the amount of bioavailable iron is lower in many parts of the world ([9]). Fractional absorption of dietary iron can increase up to three- to fivefold if iron stores are depleted. Conversely, the proportion absorbed decreases in states of iron overload. Thus, iron balance is primarily, if not exclusively, achieved by control of absorption rather than by control of excretion.

Intestinal Absorption

Iron is absorbed in the proximal small intestine, close to the gastric outlet ([11]). The site of absorption is determined both by local intraluminal factors such as pH and redox potential and by the fact that key proteins of intestinal iron absorption are expressed at highest levels in the first part of the duodenum (see below). The importance of gastric acidity is apparent because nonheme iron absorption is impaired in patients who have undergone gastrectomy or have achlorhydria ([12], [13] and [14]).

Humans and other omnivorous mammals have at least two distinct pathways for iron absorption: one for uptake of heme iron ([15]) and another for ferrous (Fe^{2+}) iron ([16]). Dietary iron must be converted to one of these two forms to be absorbed. Heme iron is derived from the hemoglobin, myoglobin, and other heme proteins in foods of animal origin. Exposure to acid and proteases present in gastric juices frees the heme from its apoprotein. This heme iron is probably oxidized to its ferric state, forming hemin. There is evidence that hemin enters the mucosal cell intact, probably by binding to an as yet unidentified receptor ([15]). In contrast, nonheme iron generally arrives in its ferric (Fe^{3+}) form, which must be converted to ferrous ion to be absorbed ([16]).

Approximately 10 to 15% of the iron in nonvegetarian, Western diets is in the form of heme ([17]). Less dietary heme is present in the food consumed in most of the rest of the world. Dietary nonheme iron is largely in the form of ferric hydroxide or loosely bound to organic molecules such as phytates, oxalate, sugars, citrate, lactate, and amino acids. Certain foods, including flour and infant formulas, are commonly fortified with iron, and these may be an important source of iron in the diet ([18]).

Absorption of heme iron is relatively unaffected by the overall composition of the diet ([17]). However, other dietary constituents may have profound effects on the absorption of nonheme iron, making the bioavailability of food iron highly variable ([17], [19]). Depending on various combinations of enhancing and inhibitory factors, dietary iron assimilation can vary as much as tenfold. Ascorbate ([20]) and animal tissues ([19], [21]) are major dietary enhancers of inorganic iron absorption. Ascorbate exerts its effects, at least in part, by aiding in the reduction of ferric iron to the absorbable ferrous form. Beef, lamb, pork, chicken, and fish considerably enhance nonheme iron absorption, but the exact nature of the meat factor remains unknown. It may be that low-molecular-weight intermediates of digested animal proteins bind iron in soluble complexes. For example, peptides containing cysteine have been shown to enhance nonheme iron absorption ([22]). Not all proteins enhance iron absorption, however. Vegetable proteins, notably soy protein, do not have this effect and may actually inhibit iron absorption, even when iron-binding plant substances are removed ([23]). It is interesting, however, to note that soy sauce and similar products that do not contain appreciable amounts of soy proteins appeared to enhance iron absorption in other studies ([24], [25]). Bovine milk proteins inhibit absorption ([26]), although substances found in human breast milk improve absorption ([27]). Other possible enhancers of nonheme iron absorption include certain keto sugars, organic acids, and amino acids that form soluble iron chelates.

Other ingredients in foods can significantly inhibit nonheme iron absorption. Phytates, present in grains and some other vegetable foods, form stable, poorly absorbable complexes with iron ([28], [29] and [30]). Bran ([31]) and other fibers ([32], [33]) inhibit iron absorption mainly because of their phytate content ([34], [35]). Polyphenols probably interfere with absorption of iron from legumes, tea, coffee, and wine ([28], [32], [36], [37], [38], [39] and [40]). Phosphates and phosphoproteins inhibit absorption of iron from egg yolks and milk. Calcium inhibits intestinal iron absorption ([41], [42] and [43]), and other metals, such as zinc ([44]), may compete for iron uptake.

Iron absorption must be considered as a process involving at least two distinct steps: (a) mucosal uptake, and (b) transfer of iron from the mucosal cell to the lamina propria, where it enters plasma. Both steps involve specific iron carriers and are discussed separately below.

Mucosal uptake begins at the brush border of the mucosal cell where it is mediated (in rodents and probably also in humans) by divalent metal ion transporter 1 (DMT1, also known as *Nramp2*, *DCT1*) ([45], [46], [47] and [48]). DMT1 is a protein with twelve predicted transmembrane segments, which is expressed on the apical surface of absorptive enterocytes. Levels of DMT1 are markedly increased in iron-deficient animals ([49], [50]) and in some animals with increased intestinal iron absorption

resulting from other causes ([51]). In addition to iron, DMT1 has been shown to transport a variety of divalent metal ions, including Mn^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+} ([50]). It appears to be a proton symporter; that is, there is evidence that protons accompany metal ions into the cell ([50]). This feature helps to explain why iron absorption takes place close to the gastric outlet. The acidic gastric fluid probably provides the required supply of protons for iron transport.

The importance of DMT1 in iron transport was shown by identification of a mutation in DMT1 in two rodent strains, microcytic mice and Belgrade rats, which have profound iron deficiency due to impaired apical transport of iron into their enterocytes ([47], [48]). Remarkably, microcytic mice and Belgrade rats have the same codon change, glycine 185 to arginine, disrupting a critical transmembrane helix of the protein. *In vitro* experiments have shown that this mutation markedly impairs DMT1 function ([52]), and immunohistochemistry has shown that this mutant form of DMT1 is mislocalized *in vivo* in villous enterocytes ([46]). The severe phenotype of microcytic mice and Belgrade rats strongly suggests that DMT1 is the major, if not the only, transporter for dietary nonheme iron that functions in rodents. Although not yet proven, it is likely that this is also true in humans. To date, no DMT1 mutations have been identified in human patients.

DMT1 has a strict requirement for divalent cations, and it will not transport the Fe^{3+} form of iron. As discussed above, most dietary nonheme iron arrives at the brush border as Fe^{3+} ion. A duodenal cytochrome *b*–like ferrireductase enzyme, Dcytb, is expressed at that site, and is induced in response to stimuli that increase iron absorption ([53]). Although not formally proven yet, it is likely that Dcytb serves the function of reducing dietary iron to make it a substrate for transport by DMT1. No human or mouse mutations in this protein have been reported to date.

When heme iron enters the cell, the porphyrin ring is enzymatically cleaved ([54]), probably by heme oxygenase ([55]). The liberated iron then probably follows the same pathways as those used by nonheme iron. A small proportion of the heme iron may pass into the plasma intact ([54]) and become bound to the heme-binding protein, hemopexin.

A variable proportion of iron taken into the cell is delivered to the plasma within a few hours. The remainder probably is incorporated into mucosal ferritin ([56]), an intracellular iron protein that is discussed in a later section. Iron retained in mucosal ferritin is not absorbed—rather, it is lost from the body when the senescent mucosal cells are sloughed into the intestine at the end of their 3- to 4-day lifespan ([57]). There seems to be regulated partitioning of iron between ferritin storage and serosal transfer, because a delayed phase of iron absorption has been observed that occurs between 3 and 24 hours and may represent later mobilization of iron from ferritin or other intracellular binding sites ([58]). In a sense, the retention of iron by mucosal cells represents a mechanism for loss of iron from the body that may, at least on some levels, be regulated.

The iron that is not stored in the absorptive enterocytes is transferred across the basolateral membrane of the cell to the lamina propria and ultimately to the plasma. This is most likely accomplished, at least in part, by the transporter ferroportin (also known as *IREG1*, *MTP1*), a multitransmembrane domain protein that has many of the features expected of the basolateral iron carrier ([59], [60] and [61]). Ferroportin was identified simultaneously by three groups of investigators. Donovan and co-workers found a mutation in the zebrafish ortholog of ferroportin in mutant zebrafish that were anemic due to a defect in transfer of iron from the yolk sac to the developing embryo ([60]). McKie and co-workers used a subtractive hybridization strategy to identify messenger RNAs (mRNAs) that were induced in iron-deficient animals ([61]). Abboud and Haile found the same mRNA using a selection for molecules containing RNA stem-loop structures termed *iron responsive elements* ([59]). All three groups showed that ferroportin is expressed in enterocytes, that it has features of an iron-responsive mRNA, and that it appeared to mediate the efflux of iron from cells. However, none of the iron export assays that have been published are robust enough for quantitative analysis, making it difficult to use them in the biochemical characterization of this protein.

Although ferroportin is undoubtedly important for iron transfer in developing fish embryos, mutations have not yet been described in mice or rats, in which much more is known about normal iron physiology. However, some insights have been gained from the identification of ferroportin mutations in human patients. Heterozygosity for missense mutations and in-frame deletion mutations in ferroportin results in an autosomal-dominant iron overload disorder, characterized by disproportionately elevated serum ferritin and a macrophage-predominant pattern of iron deposition ([62], [63], [64], [65] and [66]). Although initially attributed to a gain-of-function mutation in ferroportin that could increase intestinal iron absorption ([62]), it now seems more likely that the disease results from a loss-of-function mutation ([63]). Increased intestinal iron absorption appears to result, despite having only one normal copy of ferroportin present in the enterocyte. This paradox is probably explained by the fact that iron homeostasis is modulated at multiple levels. There is clear evidence for a block in macrophage iron release in patients with ferroportin mutations, and this impairment appears to limit the amount of iron available for erythropoiesis. The working hypothesis is that, as a consequence, the amount of dietary iron absorption increases to compensate. This interpretation has several implications for the role of ferroportin in basolateral iron transfer. First, it may be that the amount of functional ferroportin is not limiting at that step. Alternatively, there may be redundancy in basolateral iron transfer, and another molecule might help accomplish increased iron flux across the basolateral surface. A third, and relatively unlikely, possibility is that ferroportin does not play a significant role in normal basolateral iron transfer, despite its expression at that site. These questions will be answered in the near future through analysis of mice with targeted disruption of the gene encoding ferroportin in duodenal enterocytes.

Similar to apical iron uptake, basolateral iron efflux is aided by an enzyme that changes the oxidation state of iron. In this case, Fe^{2+} iron leaving the cell must be oxidized to its Fe^{3+} form to bind to transferrin. A membrane-bound multicopper oxidase, hephaestin, has been implicated in this process. Hephaestin closely resembles ceruloplasmin, which has been shown to be involved in efflux of iron from hepatocytes ([67]) and macrophages ([68], [69] and [70]). Sex-linked anemia mice, carrying a large deletion in the X-chromosomal hephaestin gene ([71]), have impaired placental iron transfer and decreased intestinal iron absorption ([72], [73]). Their iron deficiency results in anemia during the neonatal period, but affected animals generally recover and show only subtle evidence of iron deficiency as adults ([74]). The simplest interpretation is that hephaestin is important in placental iron transport but dispensable for intestinal iron uptake. The functional relationship between hephaestin and ferroportin has not yet been defined in detail. A model incorporating current knowledge of nonheme iron transport is shown in Figure 28.1.

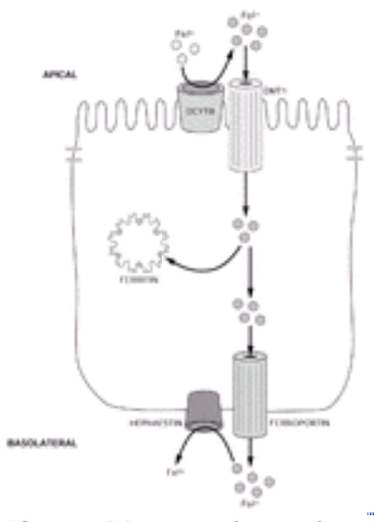

Figure 28.1. Nonheme iron absorption in the intestine. The figure shows a drawing of an absorptive enterocyte from the proximal duodenum. The apical brush border is at the top. Dietary nonheme iron enters the gut as the ferric (Fe^{3+}) ion and is converted to the ferrous (Fe^{2+}) ion by a surface reductase activity, probably mediated by the duodenal cytochrome *b*–like (DCYTB) protein. The Fe^{2+} iron enters the cell through the action of divalent metal ion transporter 1 (DMT1). Within the cell, some iron is stored, and some is transported across the basolateral membrane. Ferroportin is believed to function as a basolateral Fe^{2+} iron transporter. Hephaestin, a ferroxidase, facilitates basolateral iron export, possibly by oxidizing the iron as it exits the cell to the Fe^{3+} form to bind to plasma apotransferrin.

Because the total body iron content is largely determined by the absorption of iron, the mechanisms by which the rate of absorption is regulated have been of great interest for many years. Two factors are of prime importance in determining absorptive rate. The first is the amount of storage iron in the body. When storage iron is depleted, iron absorption is increased; when it is excessive, iron absorption is decreased. This has been termed the *stores regulator* ([75]). It is capable of changing iron absorption modestly—iron flux increases two- to threefold in iron deficiency ([76]). The molecular details of the stores regulator are not known, but it may sense

variations in the iron occupancy of plasma transferrin.

The second important factor is the overall rate of erythropoiesis and whether it is effective or ineffective. This *erythroid regulator* ([75]) mediates an increase in intestinal iron absorption when the red cell production rate is increased, if iron is limiting, or if erythroid precursors are destroyed relatively close to their site of origin in the bone marrow (ineffective erythropoiesis, as seen in thalassemia syndromes, congenital dyserythropoietic anemias, and sideroblastic anemias). It modulates iron absorption in response to erythropoietic need. It is logical that the erythron should have some influence on the rate of intestinal iron absorption, as it is the major consumer of body iron. Yet how it accomplishes this feat has remained mysterious. At the other extreme, iron absorption is decreased when erythrocyte production is decreased. The effect of accelerated erythropoiesis is especially evident when the erythropoietic rate exceeds the rate at which iron can be supplied to the marrow.

The potency of the erythroid regulator is dramatically demonstrated by studies of hypotransferrinemic (*hpx*) mice ([77], [78], [79], [80] and [81]) and atransferrinemic human patients ([82], [83]). In both cases, deficiency of plasma transferrin leads to the unusual combination of severely iron-limited erythropoiesis and massive tissue iron overload. The stores regulator should be acting to minimize intestinal iron absorption, but absorption is greatly increased, presumably in response to signals from the erythroid regulator. In homozygous *hpx* mice, expression of *Dmt1*, *Fpn*, and *Dcytb* mRNAs is markedly increased ([51], [53], [61]). It is likely that augmented production of these molecules plays a direct role in augmenting iron absorption.

In addition to these major influences, iron absorption also appears to be regulated in response to hypoxia ([84], [85] and [86]) and inflammation ([86], [87]), but even less is known about the molecular mechanisms in these situations.

It is not yet known how the stores and erythroid regulators act to modulate intestinal iron absorption. At the time they begin to differentiate in the intestinal crypts of Lieberkuhn, the intestinal mucosal cells appear to be programmed to a certain level of iron absorption. Endogenous iron is incorporated into these mucosal cells within the crypts ([88], [89]). It has been proposed that this iron helps to establish a cellular iron set point: more iron than normal being incorporated when iron stores are excessive or erythropoiesis is depressed, and reduced amounts being incorporated in iron deficiency states or during accelerated phases of erythropoiesis. Failure to demonstrate significantly reduced amounts of nonheme iron in mucosal epithelial cells in iron-deficient rats with increased iron absorption has been cited as evidence against the hypothesis ([90]). Other investigators, however, found mucosal iron to be reduced in a supernatant fraction of mucosal homogenate from both iron-deficient and hemolyzing animals ([56]).

Because the bone marrow, liver, and intestine are not contiguous tissues, it has been assumed that the erythroid and stores regulators must depend on soluble or cellular signals that circulate in the plasma. Some possible candidates, such as erythropoietin, have been definitively ruled out ([91]). Buys and co-workers tried to show evidence of a transferable factor by infusing normal animals with plasma from homozygous *hpx* mice, which, as discussed above, have marked activation of the erythroid regulator ([79]). They did not see any stimulation of iron absorption in the recipient animals, shedding doubt on the possibility that the erythroid regulator signal was a stable, soluble protein. It is important, however, that their experiment did not rule out the possibility that the erythroid regulator involved disappearance of a plasma protein rather than induction of a plasma protein. If a molecule normally functioned to suppress iron absorption, then plasma from anemic animals would not have it, and there would be no effect of transferring that plasma to another animal.

Recently, the discovery of a small peptide hormone has shed new light on possible mechanisms regulating intestinal iron absorption. *Hepcidin* is a small peptide of 20 to 25 amino acids, which is cleaved from a larger precursor. It is produced in the liver, but it is present in the plasma and excreted through the kidneys ([92], [93]). Hepcidin is structurally similar to antimicrobial peptides involved in innate immunity, and it has been shown to have antimicrobial properties ([94], [95]). Mice that inadvertently lost expression of hepcidin as a result of targeted disruption of the gene encoding upstream stimulatory factor 2 developed iron overload ([96]). This phenotype was clearly due to loss of hepcidin, rather than loss of upstream stimulatory factor 2, because a distinct upstream stimulatory factor 2 knock-out mouse with normal hepcidin expression did not develop iron overload ([95]). Hepcidin expression is increased in animals with iron overload induced by feeding of carbonyl iron, suggesting that its production might be part of a compensatory response to limit iron absorption ([94]). This conclusion is strongly supported by the recent finding that transgenic mice constitutively expressing hepcidin have severe iron deficiency anemia ([95]). Furthermore, expression of hepcidin is decreased in the setting of iron deficiency anemia, hypoxia, or inflammation ([86], [97]). Finally, human patients with inappropriate expression of hepcidin develop an iron-restricted anemia ([97]). Together, these observations make hepcidin an attractive candidate for a soluble regulator that acts to attenuate intestinal iron absorption ([98]). This interpretation is entirely consistent with the Buys experiment described above ([79]).

Iron Cycle

Most functional iron in the body is not derived from daily intestinal absorption but rather from recycling of iron already present (Fig. 28.2). The most important source and destination of recycled iron, by far, is the erythron. At the end of their 4-month lifespan, effete erythrocytes are engulfed by reticuloendothelial macrophages, primarily in the spleen, which lyse the cells and dissemble hemoglobin to liberate their iron. This process is poorly understood, but it appears to involve the action of heme oxygenase for enzymatic degradation of heme. Some of this iron may remain stored in macrophages as ferritin or hemosiderin, but most is delivered to the plasma, where it becomes bound to transferrin, completing the cycle. In normal men, approximately 30 mg of iron completes the iron cycle each day. An additional small amount of iron, probably less than 2 mg, leaves the plasma each day to enter hepatic parenchymal cells and other tissues. Here, the iron is stored or used for synthesis of cellular heme proteins, such as myoglobin and the cytochromes.

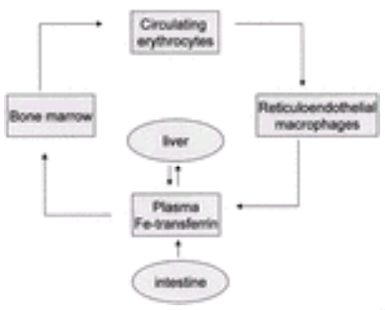

Figure 28.2. Iron cycle in humans. Iron (Fe) enters the body through the small intestine and travels in the plasma bound to transferrin. It is delivered to the erythroid bone marrow, where it is incorporated into hemoglobin and released into the circulation in mature erythrocytes. After a lifespan of approximately 120 days, erythrocytes are engulfed by macrophages in the reticuloendothelial system. There the Fe is extracted from hemoglobin and returned to plasma, where it becomes bound to transferrin, completing the cycle. Fe in excess of tissue needs is stored in the liver.

Plasma Transport

The plasma iron-binding protein, transferrin, is a glycoprotein with a molecular weight of approximately 80 kilodaltons ([99]). The transferrin gene is located on chromosome 3q21 near the genes for lactoferrin and ceruloplasmin. Transferrin is synthesized chiefly in the liver by parenchymal cells ([100]), but lesser amounts are made in other tissues, including the central nervous system, the ovary, the testis, and helper T lymphocytes (T4+ subset) ([101]). The rate of synthesis shows an inverse relationship to iron in stores; when iron stores are depleted, more transferrin is synthesized, and when iron stores are overfilled, the level of transferrin decreases. Transferrin is synthesized as a preprotein; a 19-amino acid leader sequence is removed and carbohydrate moieties are added to produce the mature, secreted protein. ([102]).

Studies with iodine 131–labeled transferrin have given insight into its distribution and kinetics ([103], [104]). The protein is almost equally distributed between plasma and extravascular sites, and exchange takes place between the two compartments at the rate of approximately 5% per hour. Transferrin turnover follows first-order kinetics with a half-clearance time of approximately 10 days or approximately 17 mg/kg/day. Transferrin catabolism is not well understood.

The normal concentration of transferrin in the plasma is approximately 2 to 3 g/L. Clinically, transferrin is quantified in terms of the amount of iron it will bind, a measure called the *total iron-binding capacity* (TIBC). In the average normal subject, the plasma iron concentration is approximately 18 µmol/L (100 µg/dl), and the

TIBC is 56 µmol/L (300 µg/dl). Thus, only approximately one-third of the available transferrin binding sites are normally occupied, leaving a large capacity to deal with excess iron. Plasma iron concentration varies over the course of the day, with the highest values in the morning and the lowest in the evening. This must be taken into account in interpreting transferrin saturation values. However, the levels of serum transferrin are more constant, and there is no apparent diurnal variation in TIBC. Data on normal values for plasma iron and TIBC are given in Appendix A.

Transferrin has two homologous iron-binding domains, each of which binds an atom of trivalent (ferric) iron. The iron atoms are incorporated one at a time and appear to bind randomly at either or both of the two sites. Thus, iron-loaded transferrin exists as either of two monoferric transferrins or as diferric transferrin. When binding is complete, the iron lies in a pocket formed by two polypeptide loops. Two tyrosine residues, a histidine residue, and an aspartic acid residue serve as metal ligands ([105]). One mole of anion, usually carbonate or bicarbonate, is taken up, and three moles of hydrogen ion are released for each mole of iron bound. There are functional differences between the two iron-binding sites ([106]), but it is not clear that these have physiologic importance.

The characteristic pink color of transferrin, with an absorption peak at a wavelength of 465 nm, results from the interaction between iron, bicarbonate, and the binding site. Under physiologic circumstances, ferric iron binds to transferrin with very high affinity, with an affinity constant of approximately 10^{20}/mol. The affinity of iron–transferrin interaction is pH dependent, decreasing as pH is lowered. Other transition metals, such as copper, chromium, manganese, gallium, aluminum, indium, and cobalt, can be bound by transferrin but with less affinity than iron.

The transferrin-mediated delivery of iron to erythroid precursors imparts direction to the flow of iron in the cycle shown in Figure 28.2. The biologic importance of transferrin in erythropoiesis is illustrated by the phenotype of patients and mice with congenital atransferrinemia ([77], [80], [82], [83], [107], [108] and [109]). When transferrin is severely deficient, red cells display the morphologic stigmata of iron deficiency. This occurs despite the fact that intestinal iron absorption is markedly increased, presumably in response to a perceived need for iron for erythropoiesis, and nonhematopoietic tissues avidly assimilate the nontransferrin-bound metal. Similarly, mutant mice lacking tissue receptors for transferrin die during embryonic development from severe anemia, apparently resulting from ineffective iron delivery to erythroid precursor cells ([110]).

Transferrin delivers its iron to developing normoblasts and other cells by binding to specific cell-surface receptors. Like many other receptors, the transferrin receptor (TFRC) is a disulfide-linked glycoprotein with a single membrane-spanning segment and a short cytoplasmic segment. It is a type II membrane protein, with its *N*-terminus located within the cell. The native molecular weight of TFRC is approximately 180,000 ([102]). The gene encoding TFRC is located on 3q29. Each TFRC homodimer can bind two transferrin molecules. Diferric transferrin is bound with higher affinity (association constant, 2 to 7 × 10^{-9} M) than monoferric transferrin. As a result, diferric transferrin has a competitive advantage in delivering iron to the erythrocyte precursors ([111]). Apotransferrin has little affinity for the receptor at physiologic pH but considerable affinity at lower pH, an important factor in intracellular iron release ([112]). There is a second, related molecule, TFR2, which shares approximately 45% homology with TFRC in its large extracellular domain ([113]). TFR2 binds transferrin with lower affinity, and its role in cellular iron uptake is unclear ([114]). It is highly expressed in the liver and in erythroid precursor cells ([113], [115]). It must have some function in iron metabolism, because patients carrying mutations in the *TFR2* gene develop an iron overload disorder that is clinically indistinguishable from classical hereditary hemochromatosis ([116], [117]).

The role of TFRC is relatively well understood. TFRC numbers are modulated during erythroid cell maturation, reaching their peak in intermediate normoblasts. Very few are found on burst-forming unit–erythroid cells, and only slightly greater numbers are found on colony-forming unit–erythroid cells. However, by the early normoblast stage, approximately 300,000 receptors are found on each cell, increasing to 800,000 at the intermediate stages. The rate of iron uptake is directly related to the number of receptors. The number decreases as reticulocytes mature, and late in maturation, erythroid cells shed all remaining receptors by exocytosis and by proteolytic cleavage ([118]). The shed receptors can be found in plasma in a concentration that correlates with the rate of erythropoiesis ([119], [120]). An increase in plasma TFRC is a sensitive indicator of erythroid mass and tissue iron deficiency ([120], [121]).

After ligand and receptor interact, iron-loaded transferrin undergoes receptor-mediated endocytosis, beginning with invagination of clathrin-coated pits (Fig. 28.3) ([122]). Specialized endocytic vesicles form, which are acidified to a pH of 5 to 6 by influx of protons, facilitating release of iron from transferrin and strengthening the apotransferrin–receptor interaction ([112]). Released iron is reduced by an as yet unidentified ferrireductase and transferred to the cytosol by DMT1 ([48]). Because DMT1 is believed to cotransport protons with iron atoms ([50]), vesicle acidification is also important for the function of this transporter. After the iron enters the cytosol, the protein components of the endosome return to the membrane surface where the neutral pH causes the release of apotransferrin to the plasma ([112]). Both transferrin and TFRC participate in multiple rounds of iron delivery.

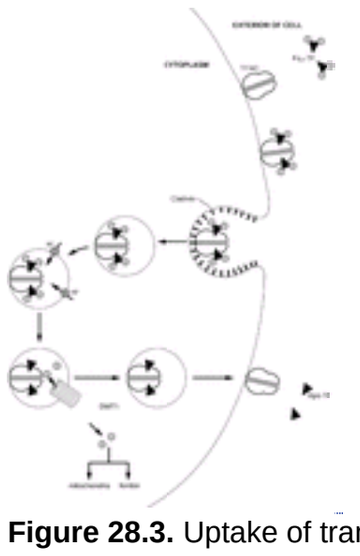

Figure 28.3. Uptake of transferrin (TF) by TF receptors (TFRC). Iron (*gray circles*) bound to plasma TF (*dark triangles*) is delivered to the cell by binding of Fe_2-TF to cell-surface TFRC. The ligand–receptor complex enters the cell through invagination of clathrin-coated pits to form specialized endosomes. The endosomes become acidified through the entry of protons, releasing iron from TF and strengthening the TF–TFRC complex at low pH. The iron exits the endosome through the divalent metal ion transporter 1 (DMT1) to go to sites of storage and use within the cell (ferritin, mitochondria). The TF–TFRC complex then returns to the cell surface, where it is externalized, and apo-TF is released. Both TF and TFRC participate in multiple rounds of iron delivery.

The rate of entry of iron into normoblasts is intimately related to heme biosynthesis ([123]). The addition of free heme inhibits reticulocyte iron uptake *in vitro* by reducing endocytosis of the TFRC complex. In less mature erythrocyte precursors, an optimal amount of heme may be necessary to sustain TFRC synthesis ([124]). Furthermore, a decrease in intracellular free heme concentration induced by inhibitors of heme synthesis (e.g., isoniazid) leads to increased iron uptake, and an increase in intracellular free heme induced by inhibitors of globin synthesis (e.g., cycloheximide) has the opposite effect. These phenomena appear to reflect a feedback inhibition system that regulates the supply of iron according to the needs of the cell for hemoglobin synthesis. This is part of a highly coordinated erythroid regulatory system that acts to balance the amounts of alpha and beta globin proteins and heme, avoiding toxic buildup of any intermediates of hemoglobin production ([125]).

Ferritin is found in plasma in small amounts (12 to 300 µg/L), and the serum ferritin concentration correlates roughly with the amount of iron in stores. Circulating ferritin differs from tissue ferritin not only in its low concentration, but also in its composition—it is a glycosylated protein, suggesting that it is actively secreted ([126]). It is predominantly made up of L-ferritin subunits, and it is relatively iron poor. Although erythroid cells are able to take up ferritin through an as yet unidentified receptor ([127], [128]), under normal circumstances, ferritin probably has little, if any, role in iron delivery to hemoglobinizing erythroid precursors.

Metabolism within Normoblasts

In the normal subject, approximately 80 to 90% of the iron that enters erythroid precursor cells is ultimately taken up by mitochondria and incorporated into heme. Most of the remainder is stored in ferritin ([129], [130]). Granules of ferritin in erythrocytes may sometimes be detected by means of the Prussian blue reaction ([131], [132]). Normoblasts with Prussian blue–positive (siderotic) granules are called *sideroblasts*, and, if the granules persist after denucleation, the mature cells are called

siderocytes. In normal individuals, approximately half of the normoblasts are sideroblasts, each containing less than five small granules ([132]). By electron microscopy, these normal siderotic granules are seen to be aggregations of ferritin, often surrounded by a membrane (siderosomes) ([133]). Isolated molecules of ferritin not surrounded by a membrane may also be seen by electron microscopy but not with light microscopy. Another kind of sideroblast, the ringed sideroblast, is found only under pathologic circumstances (sideroblastic anemias; see Chapter 29). In the ringed sideroblast, the siderotic granules form a full or partial ring around the nucleus, and electron microscopy reveals that the iron is deposited in mitochondria ([133]). The spleen plays an active role in the removal of the iron-laden mitochondria when cells enter the circulation. Although critically important in heme biosynthesis, details of erythroid mitochondrial iron metabolism are not yet well understood.

Macrophage Iron Recycling

Although there are many types of tissue macrophages, those that participate in the catabolism of red blood cells can be subdivided into two categories with respect to their role in iron metabolism. One type, exemplified by pulmonary alveolar macrophages and other tissue macrophages, is able to phagocytize erythrocytes and convert the iron they contain into storage forms, but it lacks the ability to return the iron to the circulation. This type of macrophage appears to retain the iron indefinitely within the tissues. The second type of macrophages, comprising the reticuloendothelial system, acquire iron in a similar fashion but are able to process it into a form that can be returned to the plasma. The latter macrophages, found especially in the sinuses of the spleen and the liver, play a primary role in the normal reutilization of iron from destroyed red cells. They acquire and store a relatively labile pool of iron, allowing completion of the iron cycle shown in Figure 28.2.

Macrophages acquire most of their iron by erythrophagocytosis. Circulating monocytes lack transferrin receptors; however, receptors appear when they are transformed to macrophages, probably to allow the cells to acquire iron needed for cellular functions, including oxidative killing. However, it is doubtful that receptor-acquired iron makes a major contribution to iron storage or reutilization.

After erythrophagocytosis by reticuloendothelial macrophages, the red cell membrane is destroyed, heme is released from hemoglobin, and iron is liberated by heme oxygenase. The subcellular localization of these events is not well defined. Subsequently, two phases of macrophage iron release are observed: an early phase, complete within a few hours after erythro-phagocytosis, and a later phase, taking place over a period of days ([134]). The early phase probably reflects immediate export of iron. The later phase probably results from storage of acquired iron and later mobilization in response to iron demand. Because there is a large iron flux through this system on a daily basis, approaching 30 mg, the partitioning of iron between immediate transport and storage functions is a critical determinant of the availability of iron for plasma transferrin and, consequently, for erythropoiesis. The *anemia of chronic inflammation*, characterized by macrophage iron retention, illustrates the deleterious effects of perturbing the delicate balance between macrophage iron storage and release.

Under equilibrium conditions (i.e., when the amount of iron that enters the macrophage approximates that which leaves it), relatively little interchange occurs between the newly liberated iron and the storage forms ([135]). Instead, iron from recently destroyed erythrocytes passes quickly through the macrophage and is presented to the plasma at the cell surface. The intermediate iron compounds in this process, if any, are not known. At the cell–plasma interface, however, the iron probably is in the form of ferrous iron, and its release is probably mediated by ferroportin ([59], [60], [136]). Released iron must be oxidized to be bound to transferrin. It has been proposed that the ferrous oxidation (ferroxidase) reaction is catalyzed by the plasma copper protein, ceruloplasmin ([137], [138]).

In nonequilibrium situations, iron either enters or leaves macrophage stores. When the red cell mass is expanding and erythrocytes are being produced more rapidly than they are being destroyed, iron is mobilized from macrophages. The amount of iron leaving the macrophages then exceeds that which enters. When red cell destruction exceeds production, iron is deposited in macrophage stores, and the amount of iron entering the macrophages exceeds that which leaves. Mechanisms must exist for coupling the rate at which iron leaves the macrophages to the rate of red cell production. The nature of the control mechanism remains unknown, although recent studies suggest that hepcidin, a small peptide hormone, may play a crucial role ([86], [97]).

Under normal circumstances, the rate at which iron leaves macrophages exhibits diurnal variation ([139]). The evening rate is approximately one-half of the morning rate. This phenomenon results in a well-known diurnal variation in plasma iron concentration.

Intracellular iron is stored in two compounds: ferritin and hemosiderin. Iron-free ferritin (apoferritin) exists as a sphere with a diameter of 13 nm ([140]). It has a hollow central cavity, 6 nm in diameter, which communicates with the surface by six channels through which iron and other small molecules can enter and leave. The protein shell is constructed of 24 molecules of two distinct ferritin subunits, designated *H* (for *heavy* or *heart*) and *L* (for *light* or *liver*). The molecular weights of the H and L subunits are approximately 21,000 and 19,000, respectively. The expressed gene for the H chain is located on chromosome 11, and that of the L chain is on chromosome 19 ([141]), but multiple copies of both genes, all but one (see below) of which are presumed to be pseudogenes, are found throughout the genome ([142], [143]). H and L ferritins are highly homologous, suggesting that they were derived from a common ancestral protein. However, there are functional differences between the two subunits. H chains contain a ferroxidase center not found in L chains and are able to oxidize iron ([144], [145]). Ferritins rich in H chains reflect this property and acquire iron more rapidly ([146]). Ferritins rich in L chains appear to be more stable and resistant to denaturation.

Fully assembled, iron-free apoferritin has a molecular weight of approximately 440 kilodaltons. When iron is incorporated into the molecule, it is deposited in the central core. Rather than a smooth sphere, the iron core is partially divided into four lobes by protein indentations, a form that may account for the characteristic tetrads seen in ultrastructural studies of ferritin. Theoretically, a single ferritin molecule could hold up to approximately 4500 iron atoms. The whole molecule would then have a molecular weight of more than 800 kilodaltons. Fully saturated ferritin is unusual, however. More often, molecules with 2000 or fewer iron atoms are found. The iron is a trivalent polymer of ferric hydroxide and phosphate.

At least 20 distinct isoferritin proteins, with varying proportions of L and H chains, have been isolated from human tissue ([147]). They differ from one another in surface charge; acid iso-ferritins contain a high proportion of H chains, whereas basic isoferritins are rich in L chains. The various isoferritins may differ in relative rates of synthesis and in the ability to bind and release iron. Each tissue has a characteristic isoferritin profile. Acidic isoferritins predominate in cardiac, placental, and renal tissues. They are also found in lymphocytes, monocytes, and erythrocyte precursors. Basic isoferritins are found in the liver and spleen. The isoferritin in serum is a basic protein containing negligible amounts of H chains ([148]). Some differences in iso-ferritin distribution have been detected in association with certain diseases. In idiopathic hemochromatosis, the acid isoferritins in heart, kidney, and pancreatic tissues disappear, and the pattern resembles that of the liver and spleen. In contrast, in many types of cancer, the malignant tissues are rich in acidic isoferritins.

Although H and L chains make up the abundant tissue ferritin molecules, a novel ferritin protein has recently been described in mitochondria. Mitochondrial ferritin has been reported to be transcribed from a distinct, intronless gene on human chromosome 5q23 ([149]). It appears to have a ferroxidase activity, making it most analogous to H-ferritin.

In a wide variety of cell types, the synthesis of apoferritin has been shown to be stimulated by exposure to iron ([150]). This effect of iron takes place at the translational level of protein synthesis. A transcribed but untranslated nucleotide sequence found at the 5' end of the mRNAs encoding ferritin chains is both necessary and sufficient for the iron effect ([151]). In red cell precursors, hemin rather than iron itself may exert a similar function ([124], [152]). The mechanisms for translational control are discussed in a later section.

Apoferritin is formed first, and iron is added later. Iron, in the form of Fe^{2+}, enters the molecule through one of the six penetrating channels. As it passes into the core, it is oxidized to the Fe^{3+} form by molecular oxygen, with apoferritin catalyzing the oxidative process ([153]). Iron is deposited irregularly and in varying amounts, forming microcrystals. The rate of iron deposition in each molecule is related in part to its iron content. Up to a point, perhaps 500 to 1000 iron atoms per molecule, iron uptake is stimulated by the presence of iron. At levels greater than 1000 atoms per molecule, iron uptake is slower. Mobilization of iron from ferritin depends on iron reduction or chelation.

Hemosiderin was formerly distinguished from ferritin on the basis of solubility and the Perls Prussian blue reaction. Ferritin was considered to be soluble and Prussian-blue negative; hemosiderin, insoluble and Prussian-blue positive. However, it is now clear that these distinctions are not reliable; ferritin can also be stained with Prussian blue and can exist in insoluble forms. Hemosiderin is not a precisely definable chemical entity ([154], [155]). It appears to be formed by incomplete degradation of ferritin and conglomeration of iron, ferritin proteins, and other subcellular constituents. It differs from ferritin in having a higher iron to protein ratio as well as being less soluble in aqueous solutions. Standard hemosiderin preparations may contain a variety of organic constituents, including proteins, lipids, sialic acid, and porphyrins. In most instances, hemosiderin appears to be derived from ferritin. From a physiologic viewpoint, hemosiderin appears to represent a more stable and less available form of storage iron than ferritin. Newly deposited or newly mobilized iron enters or leaves the ferritin compartment. Only after prolonged storage or

continued mobilization does the hemosiderin compartment change in size.

Metabolism in Other Tissues

Iron is required in small amounts by all tissues for the synthesis of iron-containing enzymes and proteins, including cytochromes, catalase, ribonucleotide reductase, ferrochelatase, and myoglobin. Like red cells, these tissues are generally thought to acquire their iron from transferrin through binding to cell-surface TFRC, although there is little experimental evidence that this is the major iron acquisition mechanism. Aside from erythroid precursors and tumor cells, iron uptake by hepatic parenchymal cells has been most extensively studied. Normally, approximately 5% of iron leaving plasma is accounted for by this pathway ([156]). This fraction increases markedly when transferrin saturation increases or when erythropoiesis is depressed. It is important to note that transferrin is not essential for iron assimilation by hepatocytes or most other nonhematopoietic cells, as demonstrated by atransferrinemic human patients and *hpx* mice, both of which develop marked iron overload in nonhematopoietic tissues ([77] , [80] , [82] , [83] , [107] , [108] and [109]).

The placenta also accepts iron from transferrin and may do so even at relatively low plasma iron levels, thus effectively competing with the maternal erythroid bone marrow. Under normal circumstances, efficient transfer of iron to the fetus occurs across the placenta, but some iron is stored within that tissue as ferritin and hemosiderin. The gut also accepts iron from transferrin, and this pathway has been thought to have a regulatory function in iron absorption ([157] , [158]). Skeletal muscle uses iron for myoglobin synthesis and also maintains an iron storage pool that, although large, is not easily mobilized for use by other tissues ([159]). Proliferating cells in many tissues have increased numbers of transferrin receptors compared to their quiescent counterparts, presumably reflecting their need for iron.

Regulation of Intracellular Iron Metabolism

Cells have developed mechanisms that make it possible for them to acquire the iron they need while avoiding the toxic effects of excess iron. This is accomplished, in part, by regulating production of transferrin receptors and apoferritin. Cells replete in iron synthesize apoferritin and inhibit synthesis of transferrin receptors, thereby limiting acquisition of iron and facilitating storage of any excess. In contrast, iron-depleted cells actively synthesize transferrin receptors and restrict the synthesis of apoferritin to optimize iron entry and utilization and to minimize diversion into stores. These effects are mediated at the translational level.

The noncoding portions of mRNAs for TFRC and ferritin subunits contain stem-loop structures that constitute iron-responsive elements (IREs; reviewed in reference 160). Five IREs are found in the 3' untranslated region of the mRNA encoding TFRC, and one each in the 5' untranslated regions of the mRNAs encoding L- and H-ferritins. The IREs bind iron regulatory proteins (IRPs). Currently, there are two known IRPs, designated *IRP1* and *IRP2*. IRP binding produces opposite effects on the different mRNAs: It stabilizes TFRC mRNA by protecting it from endonucleolytic cleavage, resulting in an increase in synthesis of TFRCs. In contrast, protein binding blocks translational initiation in ferritin mRNAs by preventing the interaction of the cap-binding complex eIF4F and the small ribosomal subunit ([161]), but it does not alter mRNA stability.

The two IRPs are structurally similar, but they are regulated differently. IRP1 contains a 4Fe•4S iron-sulfur cluster that, when saturated with iron, acts as a cytosolic aconitase and catalyzes the conversion of citrate to isocitrate ([162]). In the enzyme form, it has low affinity for IREs in mRNAs. When iron-poor, IRP1 loses its aconitase activity and greatly increases its affinity for IREs ([163] , [164]). This bifunctional property of the protein acts as a “ferrostat” to allow the cell to respond appropriately to its internal iron environment. IRP2 is less abundant than IRP1 and functions in a different manner. It does not have an identified enzyme function, and it is rapidly degraded in iron replete cells ([165] , [166]). The degradation is mediated by the ubiquitin-mediated proteasome pathway ([166] , [167]). By this means, its concentration and, therefore, its mRNA binding activity are increased when cellular iron concentration is low. In 2002, it was shown that IRP2 interacts with Y-box-binding protein YB-1, a molecule involved in chromatin modifications, alterations of mRNA translation, and RNA chaperoning ([168]). YB-1 may bind to the ferritin IRE independent of IRP2 and may act to modulate the effects of IRP2.

Pathogenesis of Iron Deficiency Anemia

Three pathogenetic factors are implicated in the anemia of iron deficiency. The first is impaired hemoglobin synthesis, a consequence of reduced iron supply. The second is a generalized defect in cellular proliferation. Third, there may be reduced erythrocyte survival, particularly when the anemia is severe.

When transferrin saturation falls below 16%, the supply of iron to the marrow is inadequate to meet basal requirements for hemoglobin production (generally approximately 25 mg of iron daily in average adults). As a result of this defect, the amount of free erythrocyte protoporphyrin increases, reflecting the excess of protoporphyrin over iron in heme synthesis. Each cell produced contains less hemoglobin, resulting in microcytosis and hypochromia.

In addition, cellular proliferation is restricted in iron deficiency, and red blood cell numbers fall. Although there is relative erythroid hyperplasia in the bone marrow, both the degree of erythroid hyperplasia and the reticulocyte count are low for the degree of anemia. There is a significant component of “ineffective erythropoiesis” in iron deficiency, and a proportion of immature erythroid cells in iron-deficient subjects are so defective that they are rapidly destroyed. This iron is reused within the bone marrow, making the interpretation of ferrokinetic studies more complicated ([169] , [170]).

In iron deficiency, survival of circulating erythrocytes is normal or somewhat shortened ([171] , [172] , [173] and [174]). Cross-transfusion studies indicate that the shortened survival results from an intracorpuscular defect. There is a strong correlation between the degree to which red cell survival is shortened and the proportion of morphologically abnormal cells on blood smear ([172]). The principal site of destruction is the spleen ([173]). The reduced erythrocyte viability is associated with decreased membrane deformability ([175]). This abnormality appears to result from oxidative damage to the membrane ([175] , [176]).

Other iron-containing proteins are also reduced in iron deficiency, and some of these may be responsible for clinical and pathologic manifestations. Iron is a component of various heme proteins, including cytochromes, myoglobin, catalase, and peroxidase. Proteins containing iron-sulfur clusters and metalloflavoproteins are important in oxidation-reduction reactions, especially those that take place in mitochondria. Furthermore, iron is a cofactor for some enzymes, including aconitase and tryptophan pyrrolase.

At one time, it was thought that depletion of tissue iron proteins was a late manifestation of prolonged iron deficiency. It is now believed that many of the enzymes are depleted in proportion to the degree of anemia ([177]). Among the iron proteins reduced in iron deficiency are cytochrome *c* ([177] , [178]), cytochrome oxidase ([179] , [180]), a-glycerophosphate oxidase ([181] , [182]), muscle myoglobin ([177] , [178]), succinic dehydrogenase, and aconitase. Because it is also a heme protein, it is possible (but not yet proven) that protein levels of the intestinal ferrireductase, Dcytb, are also decreased.

In iron-deficient rats, impaired exercise performance correlated with reduced levels of a-glycerophosphate oxidase in muscle ([181] , [182]). As a result, glycolysis was impaired, which led to lactic acidosis and, in turn, adversely affected work performance. Lactic acidosis was also noted in a patient with severe iron deficiency anemia ([183]).

Levels of catecholamines are increased in the blood and urine of iron-deficient patients and animals ([184] , [185]). The increase is explained in part by decreased tissue levels of monoamine oxidase ([186] , [187]). Conceivably, a disturbance in catecholamine metabolism may contribute to the behavioral disturbances seen in iron-deficient children ([188] , [189]).

As described below, there are several characteristic epithelial changes in iron deficiency. The pathogenesis of these abnormalities is not understood, but it is reasonable to assume that deficiencies in tissue iron enzymes are at fault.

Role of Copper in Erythropoiesis

It has long been known that copper deficiency is associated with abnormalities in iron metabolism and iron deficiency anemia. In recent years, it has become clear that this is due, at least in part, to the importance of the copper-containing ferroxidases ceruloplasmin and hephaestin. Ceruloplasmin is a plasma glycoprotein containing six to seven copper atoms. Ceruloplasmin acts as an oxidase for a variety of substrates ([190] , [191]), one of which is ferrous iron ([137]). There is evidence that ceruloplasmin is required for the optimal mobilization of iron from cells to plasma. When the gene encoding ceruloplasmin is disrupted in mice, macrophages fail to release their iron at a normal rate, and this leads to hypoferremia in the presence of normal iron stores ([138]). The abnormality was promptly corrected by

administering ceruloplasmin intravenously. A similar phenomenon was noted in aceruloplasminemic human subjects ([192]). Ceruloplasmin probably acts by catalyzing the oxidation of ferrous iron to the ferric form, which is a prerequisite for iron binding by apotransferrin.

The anemia of copper deficiency, however, is not completely explained by defective ceruloplasmin function. A second copper-containing ferroxidase, hephaestin, is expressed in the duodenal enterocytes responsible for iron absorption ([71], [193]). Mice carrying a deletion in the hephaestin gene, located on the X chromosome, have perinatal iron deficiency anemia and decreased intestinal iron absorption, due to defects in placental and duodenal iron transport, respectively ([72], [73]). Analogous to the function of ceruloplasmin in macrophage iron release, hephaestin probably oxidizes iron in concert with its transfer across the basolateral membrane to facilitate loading onto transferrin. However, the activity of hephaestin is not as well understood as that of ceruloplasmin.

CLINICAL FEATURES OF IRON DEFICIENCY

Stages in the Development of Iron Deficiency

When not due to major blood loss, iron deficiency is the end result of a long period of negative iron balance. As the total body iron level begins to fall, a characteristic sequence of events ensues. First, the iron stores in the hepatocytes and the macrophages of the liver, spleen, and bone marrow are depleted. Once stores are gone, plasma iron content decreases, and the supply of iron to marrow becomes inadequate for normal hemoglobin production. Consequently, the amount of free erythrocyte protoporphyrin increases, production of microcytic erythrocytes begins, and the blood hemoglobin level decreases, eventually reaching abnormal levels.

This progression corresponds to three recognized stages. The first stage, also called *prelatent iron deficiency* or *iron depletion*, represents a reduction in iron stores without reduced serum iron levels ([194], [195]). This stage is usually detected by a low serum ferritin measurement. Latent iron deficiency is said to exist when iron stores are exhausted, but the blood hemoglobin level remains higher than the lower limit of normal ([195], [196], [197], [198] and [199]). In this second stage, certain biochemical abnormalities of iron-limited erythropoiesis may be detected, including reduced transferrin saturation ([197]), increased TIBC ([200]), increased free erythrocyte protoporphyrin ([198]), increased zinc protoporphyrin ([201]), and increased serum TFRC ([202]). Other findings include subnormal urinary iron excretion after deferoxamine injection ([196], [203]) and decreased tissue cytochrome oxidase levels ([197]). The mean corpuscular volume usually remains within normal limits, but a few microcytes may be detected on a blood smear. Many patients report generalized fatigue or malaise, even though they are not yet anemic.

Finally, in the third stage, the blood hemoglobin concentration falls below the lower limit of normal, and iron deficiency anemia is apparent. Iron-containing enzymes, such as the cytochromes, also reach abnormally low levels during this period. Epithelial manifestations of iron deficiency occur very late in iron deprivation. This progression forms the basis for the stages of iron deficiency outlined in Table 28.2. It has been confirmed by experiments in which normal volunteers gradually were depleted of iron by phlebotomy ([204], [205]).

TABLE 28.2. Stages in the Development of Iron Deficiency

	Stage 1 (Prelatent)	Stage 2 (Latent)	Stage 3 (Anemia)
Bone marrow iron	Reduced	Absent	Absent
Serum ferritin	Reduced	<12 µg/L	<12 µg/L
Transferrin saturation	Normal	<16%	<16%
Free erythrocyte protoporphyrin, zinc protoporphyrin	Normal	?	?
Serum transferrin receptor	Normal	?	?
Reticulocyte hemoglobin content	Normal	?	?
Hemoglobin	Normal	Normal	Reduced
Mean corpuscular volume	Normal	Normal	Reduced
Symptoms	Fatigue, malaise in some patients		Pallor, pica, epithelial changes

?, increased; ?, decreased.

Prevalence

Iron deficiency is the most common nutritional deficiency in both developing and developed countries. Iron deficiency anemia may be defined by cutoff hemoglobin values of 11.7 g/dl in women and 13.2 g/dl in men. In the United States, the most comprehensive surveys for iron deficiency anemia have been the three National Health and Nutrition Examination Surveys (NHANES). According to data from NHANES III, covering the years 1988 to 1994, the prevalence of hypoferremia in the United States is less than 1% in adult men younger than 50 years of age, 2 to 4% in adult men older than 50 years of age, 9 to 11% in menstruating teenagers and women, and 5 to 7% in postmenopausal women ([206]). Anemia was noted in no more than 1% of adult men and in 2 to 5% of adult women ([206]).

Iron deficiency is particularly common in infants and pregnant women. Iron deficiency was detected in 9% of infants and toddlers, with anemia in approximately one-third of those children ([206]). In infancy, the occurrence of iron deficiency is equal in both sexes. It is usually detected between the ages of 6 and 20 months. The peak incidence is at a younger age in infants born prematurely than in those born at term, because premature infants do not have full opportunity to acquire maternal iron during the third trimester. The prevalence of iron deficiency is also higher among people living in chronic poverty ([207]). Iron deficiency tends to run in families, possibly as a result of economic factors. If an iron-deficient child is identified, the mother and siblings of that child are frequently also deficient.

Etiology

Iron deficiency occurs as a late manifestation of prolonged negative iron balance, as a result of major blood loss, or because of failure to meet an increased physiologic need for iron. The normal mechanisms for maintaining iron balance are discussed earlier in this chapter. Factors leading to negative iron balance, increased requirements, or inadequate iron for erythropoiesis are listed in Table 28.3. In many instances, multiple etiologic factors are involved. The association of a marginal diet with some source of blood loss, such as that associated with menstruation, is a common combination. Another example is hookworm infection, which produces anemia primarily in those people whose diets are marginally adequate.

TABLE 28.3. Etiologic Factors in Iron Deficiency Anemia

Negative iron balance
Decreased iron intake
Inadequate diet
Impaired absorption
Achlorhydria
Gastric surgery
Celiac disease
Duodenal bypass
Drugs that increase gastric pH
Tannins, phytates, bran

- Competing metals
- Increased iron loss
  - Gastrointestinal bleeding
    - Hookworm
    - Schistosomiasis
    - Trichuriasis
    - Hemorrhoids
    - Peptic ulcer
    - Gastritis
    - Hiatal hernia
    - Diverticulosis
    - Neoplasm
    - Inflammatory bowel disease
    - Arteriovenous malformation
    - Varices
    - Meckel's diverticulum
    - Milk-induced enteropathy (infants)
    - Salicylate use
    - Excessive menstrual flow
    - Gynecologic neoplasm
    - Bladder neoplasm
    - Epistaxis
    - Blood donation
    - Hemoglobinuria
    - Self-induced bleeding (autophlebotomy)
    - Pulmonary hemosiderosis
    - Tuberculosis
    - Bronchiectasis
    - Hereditary hemorrhagic telangiectasia
    - Coagulopathies
    - Chronic renal failure and hemodialysis
    - Runner's anemia
  - Increased requirements
    - Infancy
    - Pregnancy
    - Lactation
- Inadequate presentation to erythroid precursors
  - Atransferrinemia
  - Antitransferrin receptor antibodies
- Abnormal iron balance
  - Aceruloplasminemia
  - Autosomal-dominant hemochromatosis due to mutations in ferroportin

Diet

The total amount of iron in the diet roughly correlates with caloric content; in the United States, the diet contains approximately 6 mg of iron per 1000 kcal. The bioavailability of dietary iron in specific foods, however, varies considerably ([208]). Iron is absorbed either in the form of heme or as ferrous iron. Heme iron is well absorbed and unaffected by dietary composition and gastric acidity. Other forms of iron must be converted to ferrous iron, a process affected by gastric acidity, by dietary components that enhance absorption, such as ascorbate and meat ([209]), and by various dietary constituents that form insoluble complexes or chelates with iron, such as phosphates, phytates, and tannates.

The early stages of human evolution were characterized by hunter-gatherer food patterns and by diets rich in meat. In evolutionary terms, agriculture is a recent development to which humans have not fully adapted. Thus, individuals whose diets are rich in meat, a source of heme iron and an enhancer of the absorption of nonheme iron, usually absorb more iron from their diets than those who subsist on grains and vegetables. The increased prevalence of iron deficiency among the economically deprived and people in developing countries is explained in part by the fact that heme iron is almost totally absent from their diets.

Because many factors influence the bioavailability of iron, it is difficult to make recommendations about the optimal amount of iron in the diet. In the usual mixed diets of Western countries, adult men should consume 5 to 10 mg/day, and adult women should consume 7 to 20 mg/day ([195]). Because women are usually smaller and consume less food than men, and because their requirements are greater, their daily iron intake tends to be marginal. Iron deficiency is rarely seen in American men as a result of diet alone. Exceptions to this rule are sufficiently unusual to justify case reports ([210]).

In some countries, nutrient density of the diet is reduced because of poverty, war, unwise agricultural practices, or religious or social tenets. In many countries, foods are fortified to compensate for the insufficient amounts of iron in the diet ([18], [211]). Selection of the food to fortify and the iron compound to use in fortification requires consideration of a number of factors. The iron salt should be absorbable but should not affect appearance, taste, or shelf life. However, the most soluble and absorbable iron compounds are also the most chemically reactive. Salts such as ferric orthophosphate are used for fortification of flour in the United States because they are palatable and white, but they are so insoluble that they are of little nutritional benefit. Small-particle forms of elemental iron, NaFe ethylenediaminetetraacetic acid, and ferrous compounds each have their place as fortifying agents for particular foods. The salt must be chosen with consideration of the food to be fortified, and that choice must be individualized to the target population. In Western countries, wheat flour is a typical choice; its use is widespread, and highly available ferrous salts can be used in such products as bread because their shelf life is inherently short. Target foods in other countries include salt, sugar, rice, and condiments. For infants, fortified milk- or soy-based formulas and dry cereals are important sources of iron in the diet.

Impaired Absorption

Achlorhydria is common in iron-deficient subjects, both as a result of the deficiency and as a factor in its development ([14]). Gastric acid facilitates absorption of nonheme iron ([212]), and absorption of inorganic iron is profoundly impaired in patients with atrophic gastritis. Therapeutic measures used to reduce gastric acidity, such as the administration of antacids and drugs that block acid production, also impair iron absorption but usually not to a clinically significant degree.

Iron deficiency anemia is a common complication of gastric surgeries, including total gastrectomy ([213]), partial gastrectomy ([214], [215] and [216]), and vagotomy with gastroenterostomy ([217], [218]). Reduction in gastric acidity is only one factor in the impaired iron absorption that follows such operations. Other gastric secretions that aid in iron absorption may also be lost ([12]). Also, because most iron absorption takes place in the duodenum, the rapid intestinal transit that follows loss of the reservoir function of the stomach may lead to decreased absorption. For the same reason, iron deficiency is more common when the duodenum is surgically bypassed ([218]). Finally, recurrent bleeding, as well as increased sloughing of iron-containing epithelial cells, may contribute to the development of postgastrectomy anemia ([219]

).

In addition to gastrectomy, other defects in the gastrointestinal tract may lead to malabsorption of iron, contributing to the development of iron deficiency. The anemia associated with celiac disease (gluten sensitivity, sprue, idiopathic steatorrhea) is often hypochromic rather than megaloblastic ([220], [221] and [222]); in fact, iron deficiency anemia may be the initial and dominant manifestation of celiac disease, with steatorrhea detectable only by laboratory test analysis ([221], [223]). Both malabsorption and intestinal blood loss are factors in the development of iron deficiency ([222]). Most patients with tropical sprue are deficient in iron ([224]).

Although the efficiency of iron absorption is usually increased in iron-deficient individuals, severe deficiency can be associated with impaired iron absorption ([225]). This defect, correctable by iron repletion, has been attributed to reduced activity of mucosal iron enzymes, such as cytochrome oxidase. However, the recent discovery of the brush border ferrireductase Dcytb ([53]), a heme-containing enzyme, raises the possibility that iron-reducing activity is also impaired in severe iron deficiency.

Pica is a peculiar manifestation of iron deficiency. It is the habitual ingestion of nonnutritive substances, the most common of which are earth or clay (geophagia), laundry starch (amylophagia), and ice (pagophagia), but many other substances have been reported ([226]). Pica disappears when iron deficiency is effectively treated. Although a relatively specific sign of iron deficiency, pica has been described as a practice rooted in custom, folklore, or superstition among certain cultural groups. Furthermore, iron deficiency is a common complication of both clay-eating and starch-eating ([227], [228] and [229]). Clay can behave as an ion exchange resin in the gut, directly interfering with iron absorption. Normal subjects who absorbed 27% of a 5-mg iron dose absorbed only 2% when Turkish clay was ingested with the iron. Similarly, iron-deficient subjects absorbed 46% of the iron, and only 6% with Turkish clay ingestion ([230]). Other clays also inhibit absorption but to a lesser degree. In Iran, Egypt, and Turkey, geophagia is implicated in a syndrome consisting of iron deficiency anemia, zinc deficiency, hepatosplenomegaly, hypogonadism, and dwarfism ([231]).

Laundry starch may interfere with iron absorption ([232]). It is a nearly pure carbohydrate source that not only inhibits iron absorption but also has very low iron content. When it is consumed in large quantities to the exclusion of other foods, an extremely deficient diet results ([229]).

Blood Loss

Blood loss is a major cause of iron deficiency anemia. It is important not only because of its frequency, but also because the accurate detection, precise diagnosis, and proper management of the bleeding lesion may be of far greater importance to the ultimate well-being of the patient than repletion of iron stores. In individuals with normal hematocrits, each 1.0 ml of blood contains approximately 0.5 mg of iron. Thus, assuming the consumption of an average diet, chronic blood loss of as little as 3 to 4 ml/day (1.5 to 2.0 mg of iron) can result in a negative iron balance. Acute hemorrhage resulting in major blood loss is discussed later in this chapter.

GASTROINTESTINAL BLEEDING Gastrointestinal bleeding is the most common cause of iron deficiency in adult men and is second only to menstrual blood loss as a cause in women. Any hemorrhagic lesion of the alimentary tract may cause iron deficiency. Most commonly, the lesions cause occult bleeding or the steady loss of small amounts of blood. They may go unnoticed or may be tolerated until the symptoms of anemia supervene. The list of etiologies presented here is not meant to be comprehensive; many other, less common lesions have been reported to occur in association with isolated cases of iron deficiency anemia. Two-thirds of patients with hemorrhoids experience rectal bleeding, which is usually obvious to the patient because blood streaks the outside of the stool or is visible on toilet tissue or in the water in the toilet bowl. Nevertheless, a large majority of patients allow at least 1 year to elapse before seeking medical attention, and perhaps one-third wait for more than 10 years. Some of these patients become accustomed to the periodic loss of small amounts of blood, and gradual depletion of their iron stores occurs without their becoming unduly alarmed. Nevertheless, although hemorrhoids are frequently associated with iron deficiency anemia, the clinician should be reluctant to accept them as the only bleeding lesions; a careful investigation is warranted because hemorrhoids may divert attention from another, less obvious lesion elsewhere in the alimentary tract. Upper gastrointestinal bleeding is typically due to duodenal or gastric ulcers or gastritis, all of which can cause sufficient blood loss to result in iron deficiency. Certain drugs are associated with gastrointestinal bleeding. Of these, nonsteroidal antiinflammatory drugs, including aspirin, are the most important. Nonsteroidal antiinflammatory drug administration causes mucosal damage manifested by petechial hemorrhage, erosions, and ulcers. The problem is more likely to occur in elderly patients and women and with higher (“antiinflammatory”) doses than with lower (“analgesic”) ones ([233]). Studies with aspirin demonstrate that at a daily dose of 2 to 6 g, 70% of patients have gastrointestinal bleeding at an average rate of 5 ml/day ([234]). After 7 days of treatment with only two aspirin tablets per day, or an equivalent dose of other salicylate-containing medications, excessive blood loss (1.0 to 4.5 ml/day) occurs. Regular use of aspirin more often than four times weekly is associated with bleeding ([235]). The incidence of aspirin-induced bleeding has probably decreased as the pattern of analgesic use has changed. Between 1965 and 1975 in the United States, acetaminophen, which is not associated with gastrointestinal bleeding, became more popular than aspirin as an over-the-counter analgesic. Newer nonsteroidal antiinflammatory drug preparations are also less likely to cause significant gastrointestinal blood loss. The popularity of aspirin is on the rise again for prophylaxis of coronary artery disease but in low doses. Other drugs associated with gastrointestinal bleeding include stanozolol, anticoagulants, corticosteroids, and ethacrynic acid. Iron deficiency anemia occurs in approximately 15% of patients with esophageal hiatal hernia ([236]). Anemia is particularly common (30%) with the paraesophageal variety of lesion and is more common when the hernias are large ([237]). Anemia may be the presenting manifestation and may occur even in the absence of dyspeptic symptoms. The average daily blood loss in anemic patients with hiatal hernia is 15 ml. Reasons for the bleeding include reflux esophagitis and trauma to the gastric mucosa at the neck of the hernial sac ([236]). Colonic diverticuli can also bleed in patients with diverticulosis and diverticulitis. Usually, the blood loss is small and intermittent and may resemble the pattern of hemorrhoidal bleeding. As with the latter, a careful investigation for other sources of intestinal blood loss is warranted to exclude the possibility of a neoplasm. Intestinal bleeding can also result from the presence of adenomatous polyps. Iron deficiency anemia may be the first sign of a malignant neoplasm of the gastrointestinal tract, and the anemia may lead to its discovery at an operable stage. Carcinoma of the cecum is often clinically silent until anemia occurs. Less often, in carcinomas of other parts of the colon, as well as of the stomach and the ampulla of Vater, iron deficiency anemia may be the only initial symptom. In a survey of 32 patients with ulcerative colitis, 26 (81%) had iron deficiency anemia ([238]). Average fecal blood loss of 6 to 25 ml/day was noted in five patients who were moderately anemic with relatively mild symptoms of colitis. An important cause of gastrointestinal blood loss in tropical areas is infection with intestinal and genitourinary parasites ([239]), including whipworm, *Trichuris trichiura* ([240]); hookworm, *Necator americanus* or *Ancylostoma duodenale* ([241], [242]); and schisotosomes ([243]). Hookworm is particularly important, affecting some 20% of the world's population ([224]). It is endemic in a zone extending from the southern United States to northern Argentina in the Western hemisphere, as well as in Mediterranean countries, South Asia, and Africa. The worms attach to the upper small intestine and suck blood from the host. The amount of blood lost is proportional to the number of worms harbored, which in turn can be estimated by the fecal excretion of hookworm eggs. With *Necator* infections, each worm accounts for a loss of approximately 0.05 ml of blood per day. Female subjects harboring more than 100 worms (5 ml/day of blood loss) and male subjects harboring more than 250 worms (12.5 ml/day of blood loss) tend to become anemic ([241]). The daily blood loss may be as great as 250 ml. Even larger amounts are lost in *Ancylostoma* infections—approximately 0.2 ml/worm/day. Other factors affecting iron balance determine whether the mildly infected person becomes anemic. An iron-deficient diet, repeated pregnancies, and achlorhydria are contributory factors in development of hookworm anemia. Among hookworm carriers in Argentina, those who consumed meat in substantial quantities were not anemic. At one time, many people believed that hookworm anemia resulted from elaboration of a toxin, but this is not the case. The anemia has all of the characteristics of iron deficiency and can be relieved with iron therapy, whether or not the worms are removed. Conversely, removal of worms with an effective antihelminthic agent does not correct the anemia unless iron stores are replenished. Schistosomiasis and trichuriasis are other parasitic infections associated with iron deficiency ([239]). With *Schistosoma mansoni*, blood loss is from the intestine, whereas with *Schistosoma haematobium* the loss is from the urinary tract ([243]). *Trichuris* (whipworm) has caused iron deficiency in inhabitants of Central America ([240]).

MENSTRUATION Menstrual blood loss is the most common single cause of iron deficiency in women ([9], [10], [244], [245] and [246]). In healthy, hematologically normal women, menstrual blood flow averages approximately 35 ml per menstrual period, and the upper limit of normal is approximately 80 ml per period ([10], [244], [245]). Although flow varies considerably among different women, it is remarkably constant from one period to the next in the same person. In Swedish women with a dietary intake of approximately 10 mg of iron per day, 67% of women with menstrual blood loss exceeding 80 ml per period were anemic ([10], [245]). In another study, British women with iron deficiency anemia lost an average of 85 ml per period ([244]). In contrast, however, a better-nourished Canadian population tolerated flows greater than 80 ml per period without overt anemia or hypoferremia ([247]). Menstrual blood flow is increased by the use of certain intrauterine contraceptive devices ([248]) and is reduced by the use of oral contraceptives. Estimating menstrual blood loss from information obtained in interviews is difficult because few women have a basis for determining the normality of their flow. It is important to elicit a history including a detailed description of the events during each menstrual period. Any of the following findings are indications of excessive menstrual flow: (a) inability to control flow with tampons alone; (b) use of more than 12 pads per period or 4 per day, unless the patient is unusually fastidious; (c) passage of clots, especially if they are larger than approximately 2 cm in diameter or if they persist after the first day; and (d) period duration exceeding 7 days.

BLOOD DONATION Regular blood donation may be an important source of iron loss. Each unit of blood donated contains approximately 250 mg of iron. In most blood banks, blood hemoglobin concentration, a relatively insensitive determination, is the only index of donor iron status. As assessed by serum ferritin concentration, iron stores were reduced in 8% of male and 23% of female blood donors ([249]). Among donors, the prevalence of deficiency increased with the

frequency of donation. After five donations in 1 year, 8% of male and 38% of female donors had reduced stores. The use of iron supplements decreased the incidence of deficiency and should be recommended to people who choose to donate more than once or twice a year.

ALVEOLAR HEMORRHAGE Acute hemorrhage into the pulmonary alveoli may be severe enough to cause the blood hemoglobin level to fall 1.5 to 3.0 g/dl in 24 hours ([250]). Reticulocytosis and hyperbilirubinemia often accompany such episodes, leading to an incorrect diagnosis of hemolytic anemia. Iron in the shed blood is converted to hemosiderin by pulmonary macrophages, but it cannot be used for hemoglobin synthesis. Thus, repeated hemorrhages can lead to iron deficiency despite a normal total amount of body iron. Hemoptysis and alveolar infiltrates are the other prominent manifestations. However, if the hemorrhages are small, the hemoptysis may be unnoticed, making the diagnosis difficult without a chest x-ray examination. Patients may swallow the blood-containing sputum, rendering the stools positive for occult blood and resulting in further diagnostic confusion. Idiopathic pulmonary hemosiderosis, an illness of children and young adults, is characterized by alveolar hemorrhage that is not due to another form of lung disease ([251] , [252] , [253] and [254]). Iron deficiency anemia almost invariably accompanies the disease and may be the initial and only symptom. Hemoptysis and alveolar infiltrates, however, are common manifestations. Interstitial fibrosis may develop after repeated episodes, with dyspnea, clubbing, and even cor pulmonale. Anemia is also a common finding in antiglomerular basement membrane antibody disease (Goodpasture syndrome) ([254] , [255]). The presence of renal disease distinguishes this illness from other forms of pulmonary hemosiderosis, but kidney involvement may not be evident early in the course of the disease or the degree of proteinuria or microscopic hematuria may be modest. Eventually, however, most patients develop azotemia. Focal or diffuse glomerulonephritis is evident from renal biopsy, and linear deposits of immunoglobulins (Igs) are characteristic of, although not completely specific for, the disease. Detection of antibasement membrane antibodies in serum is approximately 80 to 85% sensitive and 98% specific for the diagnosis ([250]). Other illnesses associated with pulmonary alveolar hemorrhage include rapidly progressive glomerulonephritis, systemic lupus erythematosus, and certain other collagen vascular diseases and systemic vasculitides ([250]). The presence of antineutrophil cytoplasm antibodies or other autoantibodies is considered a particularly poor prognostic sign in patients with pulmonary hemosiderosis ([252]). Alveolar hemorrhage is also observed as a toxic reaction to trimellitic anhydride, D-penicillamine, or lymphangiography.

HEMOGLOBINURIA Paroxysmal nocturnal hemoglobinuria can result in urinary iron losses averaging 1.8 to 7.8 mg/day ([256]). Consequently, this rare disorder often is complicated by hypoferremia and hypochromic anemia ([256] , [257]). Hemoglobinuria in other disorders, such as the erythrocyte fragmentation syndromes associated with prosthetic cardiac valves, also may be complicated by iron deficiency ([258] , [259]).

FACTITIOUS ANEMIA Self-induced blood-letting (autophlebotomy) is an unusual cause of iron deficiency ([260] , [261] and [262]). In almost all reported instances, such anemia occurred in unmarried women in paramedical occupations. Blood was removed by venipuncture or injuring preexisting hemorrhoids, by laceration of the gastrointestinal tract with such instruments as knitting needles, or by means that remained obscure. In general, the women with this form of blood loss were described as hyperactive, obsessive, intelligent, and displaying unusual hostility or contempt toward the medical profession. A single case was reported in which an infant apparently developed severe iron deficiency as a result of deliberate parental action ([263]). The parent elected to remove all iron from the child's diet. This act was considered a covert form of child abuse, falling into the category of the Munchausen syndrome by proxy (i.e., a syndrome induced or fabricated by someone other than the patient).

HEREDITARY HEMORRHAGIC TELANGIECTASIA Hereditary hemorrhagic telangiectasia is an uncommon disorder characterized by recurrent hemorrhages from the nose, gastrointestinal tract, and other sites. Iron deficiency anemia, sometimes very difficult to control, is an important complication of the illness ([264]).

MASSIVE HEMORRHAGE When blood loss occurs in small amounts over a prolonged period, no anemia develops until iron stores are depleted. In such circumstances, the hematologic findings are those of iron deficiency anemia. On the other hand, when larger amounts of blood are lost over shorter periods of time, acute anemia may develop, even though iron stores remain adequate. The manifestations of acute hemorrhage depend on the rate and magnitude of the bleeding, the time elapsed since it took place, and whether the site is external or occult. In addition, the presence of complicating diseases and the cardiovascular status of the patient, as well as age, nutritional adequacy, and emotional stability, may modify the response to bleeding. After a single acute hemorrhage of brief duration, a characteristic sequence of events occurs, which may be divided into two phases. The first phase, lasting approximately 2 to 3 days, is dominated by manifestations of hypovolemia, with little or no anemia. Anemia and signs of active erythrocyte regeneration characterize the second phase, which follows restoration of the blood volume to near normal levels. When the hemorrhage is prolonged or recurrent, the two phases are not distinct, and manifestations of hypovolemia and regenerative anemia may occur at the same time. Most young, healthy subjects can tolerate the rapid loss of 500 to 1000 ml of blood (10 to 20% of the blood volume) with few, if any, symptoms ([265]). Approximately 5% of patients, however, experience a vasovagal reaction to blood loss of this magnitude ([266] , [267]). With the rapid loss of 1000 to 1500 ml of blood (20 to 30% of the blood volume), previously healthy subjects remain asymptomatic while at rest in a recumbent position, but they may experience lightheadedness and hypotension when upright. When 1500 to 2000 ml (30 to 40% of the blood volume) is lost, symptoms develop even when the subject is recumbent. Thirst, shortness of breath, clouding or loss of consciousness, and sweating occur. The blood pressure, cardiac output, and central venous pressure decrease ([268] , [269]). The pulse usually becomes rapid and low in volume (thin and thready); however, some patients experience bradycardia. When rapid blood loss exceeds 2000 to 2500 ml (40 to 50% of the blood volume), a severe state of shock ensues. Lactate acidosis results from inadequate tissue perfusion. At this stage, there is significant risk that the shock will become irreversible, leading to death. After a hemorrhage, physiologic mechanisms are brought into play to restore blood volume by an influx of fluid containing electrolytes and protein. The restoration occurs in two phases ([270]). The first is a partial restitution brought about in response to a fall in capillary pressure. This phase is followed by a slower restoration of both volume and protein that may take several days. As volume is restored and anemia develops, erythropoietin secretion increases. Under the influence of this hormone, proliferation of erythrocyte precursors in the marrow is increased. Erythroid hyperplasia of the marrow is usually perceptible within 3 to 5 days after hemorrhage ([271]). With hemorrhagic anemia, in contrast to hemolytic anemia, the rate of red cell production may be restricted by the availability of iron, even in the absence of iron deficiency. Iron must be drawn from ferritin and hemosiderin stored in macrophages, a slow process compared to mobilization of iron newly extracted from destroyed red cells. Marrow production after hemorrhage may be limited to approximately three times the normal level, compared with five or even eight times the normal level in chronic hemolytic states ([271]). Also, iron supply may be restricted by the effects of concurrent inflammation ([272]). Trauma and surgery often trigger the mechanisms leading to the anemia of chronic disorders and the disturbance in iron metabolism that accompanies it.

NOSOCOMIAL BLOOD LOSS Diagnostic phlebotomy can result in substantial iron losses in patients with chronic disorders and in hospitalized patients. In a study of 100 adult hospital inpatients in the 1980s, the average blood loss from diagnostic phlebotomy was 12.4 ml/day or 175.0 ml over the course of hospitalization on general wards ([273]). Patients in intensive care units lost an average of 41.5 ml/day or 762.0 ml during their stay. Of the 100 patients, 36 required blood transfusions, in part because of the losses from phlebotomy. Clearly, phlebotomy can contribute to a negative iron balance, and in patients with marginal iron stores, it may precipitate or aggravate iron deficiency anemia.

Chronic Renal Failure Treated with Hemodialysis

Iron deficiency affects a significant fraction of patients treated with hemodialysis when transfusions are restricted ([274]). Absolute iron deficiency may result from the loss of blood associated with the dialysis process and diagnostic tests. Gastrointestinal blood losses may also be substantial, averaging 6.27 ml/day in one study ([275]). Telangiectasias are among the most common bleeding gastrointestinal lesions in patients with renal failure. Other factors contributing to negative iron balance include reduced dietary iron intake and malabsorption of iron caused by the aluminum hydroxide used to control hypophosphatemia.

Administration of erythropoietin may result in a “functional iron deficiency” even when body iron stores are replete. The intense, periodic erythropoietic stimulus resulting from erythropoietin treatments can drive red blood cell production in such a way that adequate transferrin-bound iron is not available. For this reason, parenteral iron supplementation is typically provided as an adjunct to erythropoietin therapy (reviewed in reference 276).

Runner's Anemia

Iron deficiency anemia has been observed in long-distance runners ([277]). Over 50% of regular joggers and competitive runners become iron deficient ([278]). Three sources of blood loss appear to be of importance in this patient population. Mild mechanical hemolysis accompanies strenuous exercise, resulting in hemoglobinuria and hemoglobinemia (also called *march hemoglobinuria*). Gastrointestinal bleeding contributes to blood loss and iron deficiency ([278] , [279] and [280]). Fecal blood excretion increases substantially after a race or an intense training exercise and may reach 5 to 7 ml/day. Stress, intestinal ischemia, and the jarring effect of running have been advanced as possible explanations for the gastrointestinal blood loss.

Decreased Total Body Iron at Birth

Body iron concentration in normal neonates averages approximately 75 to 100 mg/kg weight. Similar concentrations are found throughout fetal development, resulting in a linear relationship between body iron and body weight. Newborn babies in the upper range of normal birth weights have more iron than those in the lower range. Premature infants are at higher risk of iron deficiency during the first year of life, because they have not had the full opportunity to accumulate iron stores during the third trimester of gestation.

Newborn iron levels can be influenced by the technique that the obstetrician uses to clamp the umbilical cord at delivery ([281]). As much as 100 ml of fetal blood may

remain in the placenta with early clamping of the cord. Cord clamping delayed for only 3 minutes can result in a 58% increase in red cell volume. If delayed clamping is impractical, as in cesarean section procedures, a similar effect can be achieved by clamping the cord at the placental end, raising the clamp, and allowing gravity to drain the cord ([282]). Although the newborn has no immediate need for these erythrocytes, the iron they contain can be used later to meet the demands of growth.

The fetus is an effective scavenger of maternal iron. Therefore, depletion of maternal iron has little or no effect on the body iron stores of the newborn ([283]). No difference was found between the hemoglobin values in infants of anemic mothers and those in infants of nonanemic mothers either at birth or later ([284]). Furthermore, iron supplementation during pregnancy has no effect on the subsequent development of iron deficiency in the infant, although it may be protective for the mother. Finally, as measured by serum ferritin levels, maternal iron stores bear no relation to fetal stores ([282]). These observations are consistent with results of studies in animals that demonstrate iron transported across the placenta against a gradient, even at the expense of maternal iron stores ([285]).

Growth

In the absence of disease, iron requirements of an adult man are relatively low and vary little. In contrast, in infancy, childhood, and adolescence, the requirements for iron are relatively great because of the increased needs of rapidly growing tissues. The most rapid relative growth rates in human development occur in the first year of life. Body weight and blood volume approximately triple, and the circulating hemoglobin mass nearly doubles. Still greater relative growth occurs in premature and low-birth-weight infants. Premature infants weighing 1.5 kg may increase their weight and blood volume sixfold and may triple the circulating hemoglobin mass in 1 year. To meet the demands imposed by growth, the normal-term infant must acquire 135 to 200 mg of iron during the first year of life. A premature infant may require as much as 350 mg in the same period ([286]).

The relatively slower rates of growth in children through the remainder of the first decade require a positive iron balance of approximately 0.2 to 0.3 mg/day. The growth spurt that occurs in the early teens requires a positive balance of approximately 0.5 mg/day in girls and 0.6 mg/day in boys ([195]). Toward the end of this period, the onset of menstruation occurs in girls, and their requirements then equal those of adult women.

Diet in Infancy and Childhood

Iron stores in the infant are typically depleted by 4 to 6 months of age as a result of the demands of growth. During this critical period, a normal full-term infant must absorb approximately 0.4 to 0.6 mg of iron daily from the diet. To achieve this level of absorption, an iron intake of 1 mg/kg/day is recommended for full-term infants, 2 to 4 mg/kg/day for preterm infants, and at least 6 mg (to a maximum of 15 mg) for preterm infants receiving erythropoietin therapy ([287]). These amounts may be difficult to achieve without supplementation.

Both human milk and cow's milk contain relatively small amounts of iron, but the infant more readily absorbs the iron in human milk. In one study, 49% of the iron in human breast milk was absorbed, compared with 10% of the iron in cow's milk ([27]). As a result, iron deficiency is relatively uncommon in the first 6 months of life in infants exclusively fed breast milk.

Formula-fed infants are likely to become iron deficient unless iron-supplemented formulas are used. In the United States, such formulas are often supplemented with iron (10 to 12 mg/L) as ferrous sulfate, of which a variable proportion is absorbed ([287]). Approximately 7 to 12% of the iron in cow's milk–based formulas is absorbed, with the lower percentage seen when formulas with higher iron content are given ([288]). Less iron is absorbed from soy-based formulas, but soy formulas containing 12 mg/L of iron appear to be adequate ([289]). Fortified dry cereals for infants are another important source of iron in the diet of both breast-fed and formula-fed infants. Currently, infant cereals are fortified with small-particle elemental iron at a concentration of 0.45 mg/g, from which approximately 4% is absorbed ([290]). Two servings per day will supply the needs of most infants.

Excessive intake of cow's milk is an important cause of iron deficiency in the first 2 years of life ([286] , [291]). Not only is cow's milk a poor source of iron, but it may cause gastrointestinal blood loss (see next section). Cow's milk should not be given to infants younger than 1 year of age. Some mothers allow their toddler children to use the bottle as a pacifier and constant companion, and the children become addicted (“milkoholics”). In one study, inadequate diet was considered the only factor in the development of iron deficiency in 20 of 55 infants ([291]); few patients in this series had iron deficiency resulting from defective stores at birth, unless the diet was also inadequate. A unique disorder termed *Bahima disease*, described in Uganda, was attributed to the practice of feeding children a diet of cow's milk almost exclusively ([292]).

Blood Loss in Infancy

Occult hemorrhage, often without obvious anatomic lesions, may be observed in some iron-deficient infants ([290] , [293] , [294]). The process is often accompanied by diffuse disease of the bowel with protein-losing enteropathy and impaired absorption of other nutrients ([295] , [296]). It probably results from hypersensitivity to a heat-labile protein in cow's milk ([297] , [298]). The daily loss of 1 to 4 ml of blood, along with increased serum albumin turnover, was observed while fresh cow's milk was consumed, and these abnormalities ceased abruptly with the substitution of heat-treated or soybean-protein feeding formulas. Furthermore, in infants in whom fresh cow's milk was introduced into the diet at age 2 months, iron deficiency was considerably more common than in those receiving prepared formulas during the entire first year of life ([297] , [298]).

In another group of infants, however, iron deficiency anemia appeared to be the primary abnormality, with intestinal disease occurring as a secondary phenomenon ([299]). The number of mucosal secretory IgA-producing cells was deficient in the jejunum, and the possibility that the iron deficiency led to a defect in local immune defense mechanisms with resulting hypersensitivity to components of the diet was considered. Some confirmation of this view was obtained from the results of studies in rats ([300]). Iron-deficient rats had significantly decreased mitotic indices in their intestinal crypts, and this was associated with reduced numbers of secretory IgA- and IgM-containing cells. The abnormality was reversed after iron repletion.

Pregnancy and Lactation

Pregnancy is a major drain on the limited iron reserves of young women. Each pregnancy results in an average loss to the mother of 680 mg of iron, the equivalent of 1300 ml of blood. An additional 450 mg of iron must be available to support the expanded blood volume during pregnancy. The latter amount of iron does not represent a net loss after delivery because the iron is returned to stores; it must be available, however, during the pregnancy or iron deficiency will supervene.

Prorated over the full term of pregnancy, the iron requirement amounts to approximately 2.5 mg/day (Table 28.4). Because most of the loss occurs during the third trimester, the requirement is small early in pregnancy and rises to as much as 3.0 to 7.5 mg/day in the third trimester. These amounts are greater than those that can be absorbed from even the best of diets, and stores may be insufficient to meet them. For this reason, iron supplementation is frequently recommended as a component of prenatal care. In the absence of supplements, maternal iron deficiency may occur, usually manifesting in the third trimester.

TABLE 28.4. Iron Balance in Pregnancy

Iron Fate	Mean Amount (mg)	Range (mg)
Lost to fetus	270	200–370
Lost in placenta, cord	90	30–170
Lost with bleeding at delivery	150	90–310
Normal body iron loss	170	150–200
Added to expanded red blood cell mass	450	200–600
Total	1130	670–1650
Returned to stores when red blood cell mass contracts after delivery	450	200–600
Net loss (over 9 mo)	680	470–1050

Lactation results in a daily iron loss of approximately 0.5 to 1.0 mg. The iron content of human breast milk is probably not affected by the maternal iron stores ([301]). Because normal menstruation is usually inhibited while breast-feeding continues, iron requirements in the lactating mother approximate those of the menstruating woman.

Signs and Symptoms of Iron Deficiency

Iron deficiency anemia, like all anemias, is not a disease but a manifestation of disease, and the clinical presentation may include features of the underlying disease process as well as those of the deficiency state. Many patients, however, seek medical attention because of symptoms of anemia alone. In a study from the 1960s, this mode of presentation was observed in 63% of 371 patients ([220]). Only 16% visited the physician because of symptoms of the disease causing the anemia. In the remaining 21%, anemia was discovered at the time of evaluation for an unrelated complaint.

The onset of iron deficiency anemia is usually insidious, and the progression of symptoms is gradual. As a result, patients accommodate remarkably well to advancing anemia and may delay a visit to their physicians for prolonged periods.

GROWTH Iron deficiency impairs growth in infancy, and the growth rate is restored when the deficiency is corrected ([188]). In one group, 78 of 156 iron-deficient children fell below the twenty-fifth percentile of expected weight.

FATIGUE AND OTHER NONSPECIFIC SYMPTOMS Iron deficiency anemia can be associated with irritability, palpitations, dizziness, breathlessness, headache, and fatigue. Fatigue is a particularly common complaint among patients. It is clear that even latent iron deficiency (i.e., iron deficiency without any anemia at all) may result in fatigue ([302]). A group of 44 nonanemic women reporting fatigue were treated both with iron and with placebo in random order. Symptomatic improvement in women receiving iron was significantly better than that of women given the placebo but only in women whose iron stores were depleted. Other investigators have been unable to confirm this observation ([303] , [304]), but many practitioners have cared for patients with recurrent iron deficiency who could tell when their stores became depleted because of symptoms that preceded anemia.

NEUROMUSCULAR SYSTEM Despite the lack of symptoms at rest, investigators have demonstrated that even mild degrees of iron deficiency anemia impair muscular performance, as measured by standardized exercise tests ([189] , [305] , [306]). Total exercise time, maximal workload, heart rate, and serum lactate levels after exercise are all affected adversely in proportion to the degree of anemia. Furthermore, work performance and productivity at tasks requiring sustained or prolonged activity are impaired in iron-deficient subjects and improve when iron is administered ([307] , [308]). As a result, measures directed toward iron nutrition of a work force can produce important economic dividends, more than offsetting the costs of the treatment program ([189] , [307]). Abnormalities in muscle metabolism are noted even when deficiency is mild ([309]). Blood lactate levels were measured in mildly iron-deficient female athletes after standardized exercise tests. Peak lactate levels fell significantly after 2 weeks of iron treatment. This observation led to the suggestion that iron deficiency forces the muscles to depend to a greater extent on anaerobic metabolism than occurs in normal subjects. In contrast, no abnormalities of muscle function were noted in six nonanemic patients with long-standing iron deficiency, induced for the treatment of polycythemia vera ([310]). Animal studies confirm that muscle function is disturbed in iron deficiency. The spontaneous activity level of iron-deficient rats decreased ([311]), and short-term exercise tolerance in treadmill running tests was reduced ([181] , [182] , [312] , [313]), even at mild degrees of deficiency ([314]). These abnormalities could not be explained by anemia alone, because they persisted after anemia was corrected by exchange transfusion ([181] , [182]). All were corrected promptly when iron was administered. A variety of behavioral disturbances has been observed in iron-deficient children ([188] , [315] , [316] , [317] , [318] and [319]). These children have been reported to be irritable and disruptive, with short attention spans and a lack of interest in their surroundings. Neurologic development in infants ([320]) and scholastic performance in older children ([321]) may be impaired. Cognitive performance is defective in iron-deficient rats ([322]). All of these behavioral abnormalities are ameliorated with the initiation of iron therapy. The ability to maintain body temperature on exposure to cold is impaired in iron-deficient patients ([323]) and animals ([324]). Occasional patients experience neuralgia pains, vasomotor disturbances, or numbness and tingling. In children, iron deficiency has been associated with neurologic sequelae, including developmental delay, ischemic stroke, increased intracranial pressure, papilledema, and the clinical picture of pseudotumor cerebri ([325]). The pathogenesis is probably complex, involving severe anemia, thrombocytosis, and reduced levels of tissue iron enzymes.

EPITHELIAL TISSUES Patients with long-standing iron deficiency may develop a constellation of symptoms characterized by defective structure or function of epithelial tissue. Especially affected are the nails, the tongue and mouth, the hypopharynx, and the stomach. These epithelial lesions tend to occur together in the same patients at the same time ([326] , [327]) but also may occur as isolated findings. In iron-deficient subjects, the fingernails may become brittle, fragile, or longitudinally ridged, but these findings are quite nonspecific. Alterations more typical of iron deficiency are nail thinning, flattening, and ultimately the development of koilonychia, concave or “spoon-shaped” nails (Fig. 28.4). Koilonychia is now rarely seen in clinical practice, but of 400 babies attending a well-baby clinic in West Virginia before 1970, 5.5% had koilonychia, and nearly all of these infants appeared to be iron-deficient ([328]). Koilonychia is a relatively nonspecific finding, which can also result from prolonged, repeated exposure to hot soapsuds and other caustic agents.

Figure 28.4. Koilonychia in a 11/2-year-old child with iron deficiency anemia.

Oral abnormalities, including atrophy of the lingual papillae, are the most common of iron deficiency–induced epithelial changes (Fig. 28.5, Table 28.5). These may present as soreness or burning of the tongue, either spontaneously or stimulated by food or drink, and by varying degrees of redness ([326]). The filiform papillae over the anterior two-thirds of the tongue are the first to atrophy and may disappear completely. In severe cases, fungiform papillae also may be affected, leaving the tongue completely smooth and waxy or glistening ([329]). These changes are generally reversed after 1 to 2 weeks of iron therapy. Angular stomatitis, characterized by ulcerations or fissures at the corners of the mouth, is a less specific sign of iron deficiency, and it also occurs in riboflavin and pyridoxine deficiencies.

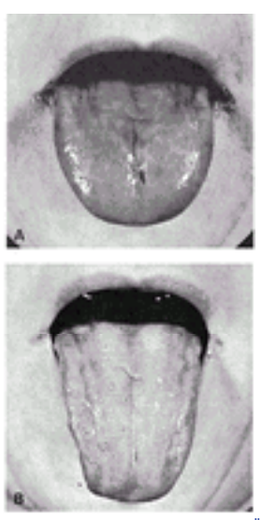

Figure 28.5. Tongue of a patient with iron deficiency anemia. Moderately severe papillary atrophy evident before therapy **(A)** and restoration after iron repletion **(B)**. (Courtesy of R.W. Monto, Detroit, MI.)

TABLE 28.5. Epithelial Lesions Associated with Iron Deficiency

Site	Finding
Nails	Flattening
	Koilonychia

Tongue	Soreness
	Mild papillary atrophy
	Absence of filiform papillae
Mouth	Angular stomatitis
Hypopharynx	Dysphagia
	Esophageal webs
Stomach	Achlorhydria
	Gastritis

The association of dysphagia, angular stomatitis, and lingual abnormalities with hypochromic anemia was reported as early as the beginning of the twentieth century. Dysphagia affects women more often than men and is relatively uncommon in patients younger than age 30 years. However, it has been observed in adolescents ([188], [326]) and even toddlers (*author's unpublished observations*). Patients with sideropenic dysphagia (also known as *Paterson-Kelly syndrome* and *Plummer-Vinson syndrome*) note a gradual onset of difficulty swallowing and describe discomfort localized to the area of the neck near the cricoid cartilage. They experience dysphagia with solid foods but have little problem with liquids. If not treated, the dysphagia worsens, and ultimately the diet is so restricted that it interferes with the maintenance of balanced nutrition. The most common anatomic lesion is a “web” of mucosa at the juncture between the hypopharynx and the esophagus ([330]). These webs, which may be multiple, usually extend from the anterior wall into the lumen of the esophagus, but they may encircle the lumen completely, forming a cufflike structure. In some patients, a benign stricture is noted, and the opening into the esophagus at the cricoid area may be reduced to the size of a pinhole or slit. Postcricoid webs may occur in the absence of documented iron deficiency, but nearly all affected patients were iron-deficient in one investigative series ([327]). Both webs and strictures may be demonstrated by radiographic examination (lateral view) of the neck after barium swallow (Fig. 28.6). Multiple exposures or cineradiography are required for optimal demonstration of these abnormalities.

Figure 28.6. Esophageal web (*arrows*) in Plummer-Vinson syndrome.

At biopsy, the webs appear to be constructed of normal epithelium with underlying loose connective tissue, sometimes showing a chronic inflammatory reaction. In a small percentage, hyperchromatic nuclei and increased mitotic activity are observed in the basal cell layer. Biopsy of the strictures demonstrates chronic, nonspecific inflammation and degeneration of striated muscle. Carcinoma in the postcricoid area has been noted as a late complication of the syndrome in 4 to 16% of patients ([326]). For relief of the dysphagia, clinicians often must rupture the webs, dilate the stenosis, or both, although treatment with iron supplements often relieves dysphagia in mild cases if the associated webs are small ([331], [332]). The variation in the prevalence of sideropenic dysphagia suggests that factors other than iron deficiency may contribute to oroesophageal abnormalities. Genetic factors may be important, as may some unrecognized coexisting nutritional abnormalities. Gastric biopsy demonstrates the presence of gastritis of varying severity in a substantial fraction of iron-deficient patients. These lesions are nonspecific and often asymptomatic and may be indistinguishable from those seen in association with pernicious anemia. Varying degrees of reduction in gastric secretion are associated with the gastritis. As gastric damage progresses, patients lose the ability to secrete acid, pepsin, and intrinsic factor. Achlorhydria has been reported to occur in infants and children as well as in adults ([188]). Antibodies to gastric parietal cells have been described in approximately one-third of patients with iron deficiency ([326], [333]). Although the mechanism of production of these antibodies is not understood, they appear to be a manifestation, rather than a cause, of gastritis.

IMMUNITY AND INFECTION The relationship between iron deficiency and infection is complex ([334], [335] and [336]). Iron deficiency clearly results in at least two abnormalities in the immune response: defective lymphocyte-mediated immunity and impaired bacterial killing by phagocytes. Evidence of defective cellular immunity includes as much as a 35% reduction in the number of circulating T cells. Both helper and suppressor T cells are affected ([337]). In addition, iron-deficient subjects do not respond as well as normal subjects to certain skin test antigens, such as to *Candida*, diphtheria, and *Trichophyton.* These abnormalities can be corrected by the administration of iron. No abnormalities have been noted in testing with tuberculin or dinitrochlorobenzene. Ribonucleotide reductase is an iron-containing enzyme required for the synthesis of DNA for cell division. Some authors have suggested that reduced levels of this enzyme might lead to impaired ability of the T cells to proliferate, thereby accounting for the defects in cell-mediated immunity, but others have reported changes in cytokine production in iron-deficient patients. The nitroblue tetrazolium dye test of phagocyte function yielded abnormal results in iron-deficient children, and the abnormality could be corrected by iron administration ([338], [339]). Furthermore, a decrease in the magnitude of the “oxidative burst” accompanying phagocytosis was observed ([340]). Finally, killing of several types of pathogenic bacteria by neutrophils was defective ([338], [341]). The sequence of changes in neutrophil function was studied as iron deficiency developed in rats. Myeloperoxidase activity was reduced to a greater extent and responded more slowly to iron therapy than did defects in the oxidative burst ([342]). Because the oxidative burst is considerably more important in bacterial killing than is myeloperoxidase, the observations suggest that the neutrophil conserves its most important function as the deficiency develops. The defect in the oxidative burst could be demonstrated only with the use of agents that induced phagocytosis; no defect was noted when the burst was stimulated by soluble agents. Thus, phagocytosis, rather than the oxidative burst itself, may be at fault. Taken together, these abnormalities provide a basis for an expectation that resistance to infection may be impaired in iron deficiency. Conversely, considerable data suggest that iron deficiency and iron sequestration by binding proteins protect against infection by depriving the invading organisms of the metal. Thus, optimal immune function is highly dependent on iron balance; both iron-deficient and iron-overloaded hosts are at higher risk for infection.

PICA Pica is a striking symptom of iron deficiency. Hippocrates wrote that a “craving to eat earth” was associated with “corruption of the blood.” Abnormal eating patterns were also a prominent manifestation of chlorosis. *Pagophagia*, defined as the purposeful eating of at least one tray of ice daily for 2 months, is a common form of pica. In one study, the ingestion of ice averaged nearly 2 kg/day, and some patients ate an astounding 4 to 9 kg/day ([343]). This dramatic symptom was relieved within 1 to 14 days after iron was administered. Another study found that pagophagia was a symptom of iron deficiency in 23 of 38 consecutive adult patients, and iron therapy was curative ([344]). Pica is especially striking when the patient consumes bizarre, nonfood substances ([226]). Crosby estimated the incidence of pica in his iron-deficient patients to be 50% ([345]). Approximately one-half of them ate ice; the rest experienced “food pica.” The latter consists of compulsively eating one food, often something that is brittle and makes a crunching sound when chewed ([346]). Because patients may be ashamed of this compulsive habit, they often do not volunteer the information during the medical interview. Direct, tactful inquiry is necessary to elicit the history of pica.

GENITOURINARY SYSTEM Disturbances in menstruation are common in iron deficiency, and not infrequently, iron deficiency results from, or is exacerbated by, excessive menstrual blood loss. *Beeturia*, the excretion of a pink to red pigment in the urine after the ingestion of beets, has been reported to be more common in iron-deficient patients than in normal subjects ([347]). However, it is likely that a significant fraction of the normal population also has this symptom ([348]).

SKELETAL SYSTEM Changes in the skull similar to those found in association with thalassemia or chronic hemolytic anemia have been reported in children with iron deficiency anemia of long duration ([349], [350]). The diploic spaces may be widened, and the outer tables thinned, at times with vertical striations producing a hair-on-end appearance. In addition, abnormalities of the long bones are noted, especially the metacarpals and phalanges, with expansion of the medulla and thinning of the cortices ([350]). These changes likely result from expansion of the erythroid marrow during bone growth and development.

LABORATORY FINDINGS IN IRON DEFICIENCY

Erythrocytes

The severity of anemia depends on the presenting circumstances of iron deficiency. If discovered when the patient is being evaluated for an underlying or unrelated

disease, the anemia may be mild. If symptoms of anemia are the presenting complaint, the blood hemoglobin level is usually 8 g/dl or lower.

The mean corpuscular volume and mean corpuscular hemoglobin values are reduced in most patients, and the mean corpuscular hemoglobin concentration is reduced in long-standing or severe disease. The degree of change in the red cell indices is related in part to the duration and in part to the severity of the anemia. In mild iron deficiency of short duration, the indices may be within normal ranges.

In contrast, the content of reticulocyte hemoglobin is an early, sensitive indicator of iron deficiency ([351]). The content of reticulocyte hemoglobin directly examines the hemoglobin endowment of the youngest circulating erythrocytes, allowing detection of iron deficiency before the bulk population shows evidence of an effect. Similarly, the content of reticulocyte hemoglobin can show a response to iron therapy approximately 4 days after it is begun, which is much earlier than other hematologic measurements. However, this value is not measured by all clinical laboratory blood cell analyzers; at present, it is only measured by the Technicon H*3 machine manufactured by the Bayer Corporation (Tarrytown, NY).

Anisocytosis is an important early sign in iron deficiency and one that has differential diagnostic value when quantified ([352], [353]). The red cell distribution width is increased in iron deficiency. Both the percentage and the absolute number of reticulocytes may be normal or slightly increased. In experimentally induced iron deficiency in certain animal species, including rats, mice, and pigs, reticulocytosis is pronounced. The chief finding on blood smear is hypochromia, observed as an increase in the size of the region of central pallor (Fig. 28.7). The more severe the anemia, the more severe the hypochromia and the greater the percentage of erythrocytes affected. When hypochromia is extreme, most of the red blood cells appear as mere rings. Tiny microcytes and a moderate number of poikilocytes, particularly tailed and elongated elliptical forms (pencil cells), are also found. In almost all instances, however, a variable number of well-filled red corpuscles are present, and some macrocytes, often polychromatophilic, can be distinguished. The number of such cells increases as iron is made available.

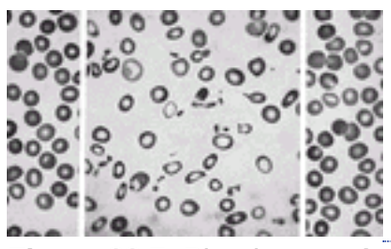

Figure 28.7. Blood smear from a patient with hypochromic microcytic anemia caused by iron deficiency. Normal red blood cells are shown on each side for comparison (Wright stain, ×900).

Leukocytes and Platelets

The leukocytes are usually normal in number, but mild granulocytopenia may occur in long-standing cases of iron deficiency. Recent large-volume hemorrhage may cause a slight neutrophilic leukocytosis, and occasional myelocyte may be found in peripheral blood. In iron deficiency due to parasitic infestation, eosinophilia may be present.

Thrombocytosis commonly accompanies iron deficiency ([354]). The platelet count usually increases to approximately twice the normal level, and values return to normal after iron therapy. The cause of the thrombocytosis of iron deficiency is unknown.

Bone Marrow

Macrophage iron is absent or severely reduced in the marrow (and liver) of iron-deficient subjects. Fewer than 10% of the marrow normoblasts are sideroblasts. In addition, the iron-deficient bone marrow is characterized by mild to moderate erythroid hyperplasia. There may be striking nuclear distortions, resembling those found in dyserythropoietic anemias ([355]). Karyorrhexis and nuclear budding are particularly common, but multinuclearity, nuclear fragmentation, and even intranuclear bridging may be observed. The individual normoblasts appear small and may have scanty cytoplasm, often with irregular, ragged borders. When therapy is given, erythroid hyperplasia initially increases, but as erythropoiesis is restored to normal, the cellularity of the marrow likewise becomes normal.

Iron Metabolism

Serum iron concentration is reduced in iron deficiency, and the TIBC is often increased, but it may be normal or even decreased. Patients with reduced TIBC values tend to have hypoalbuminemia, inflammation, or both as well. Saturation of transferrin is always reduced to less than 16%. At this level of saturation, iron delivery to erythroid precursors is limited.

Although they do not always show a linear relationship to iron stores, ferritin levels are the single best serum measure of storage iron. In iron deficiency anemia, the value is less than 12 µg/L in the absence of a complicating disease. When an infectious or inflammatory disease like rheumatoid arthritis is also present, the serum ferritin level is usually higher, but it is generally less than 50 to 60 µg/L. Of all the serum tests for iron deficiency, the serum ferritin determination is the most useful, and a low serum ferritin invariably signifies iron deficiency. However, the test lacks sensitivity, and a normal value does not reliably exclude iron deficiency.

Serum transferrin receptor (sTFR) fragments, as measured by immunologic methods, are substantially increased in iron-deficient patients ([202]). This determination is useful in distinguishing iron deficiency from the anemia of chronic disease, particularly when analyzed as the ratio of sTFR to the log of the ferritin value ([356]). When the ratio of sTFR to log ferritin is greater than 1.5, iron deficiency is usually present (with or without other processes); when it is less than 1.5, the patient most likely has impaired iron use due to the anemia of chronic inflammation, without frank iron deficiency. The sTFR values are also increased in conditions characterized by erythroid hyperplasia of the bone marrow with ineffective erythropoiesis ([357]).

Ferrokinetic Studies

Although no longer routinely performed, it is possible to follow the movement of iron in the iron cycle by using radioactive tracers to study ferrokinetics. Typically, transferrin is labeled with iron 59, and the radioactive iron is monitored as it moves from the plasma to the bone marrow and into the circulating red cells. Because the kinetics of iron are intimately related to hemoglobin synthesis, such a study makes it possible to assess rates and sites of erythropoiesis and to evaluate ineffective and effective erythropoiesis.

In most ferrokinetic studies, iron 59 is injected directly as ferrous citrate or is first bound to transferrin by incubation with fresh plasma. After administration of the labeled iron or plasma, serial samples of blood are taken at frequent intervals during the first several hours and daily thereafter. These samples are analyzed for plasma and red cell radioactivity, plasma iron concentration, and volume of packed red blood cells. For some calculations, a separate determination of plasma volume is made, or it may be calculated from the extrapolated zero-time plasma radioactivity and the total injected radioactivity. The basic measurements calculated from these data are given in Table 28.6.

TABLE 28.6. Basic Ferrokinetic Measurements

Measurement	Calculation	Average Normal Value
$t_{1/2}$	Graphically, from semilogarithmic plot of plasma radioactivity disappearance	86 min
PIT	$(0.693/t_{1/2}) \times$ plasma Fe (mg/ml) × plasma volume (ml) × 1440 min/d *or*	26 mg/d *or*
	[plasma Fe (µg/dl) × 100 – volume of packed red cells]/($t_{1/2} \times 100$)	0.7 mg/d/dl blood
RCU	(day 14 radioactivity/ml blood × 100)/(0 time radioactivity/ml blood) *or*	80%

	[(day 14 radioactivity/ml red blood cells) × red cell mass (ml) × 100]/total injected radioactivity	
Erythrocyte iron turnover rate	PIT × RCU	21 mg/d *or* 0.56 mg/d/dl blood
Marrow transit time	Graphically, from a semilogarithmic plot, the time at which 100 – RCU = 50%	3.5 d

PIT, plasma iron transport rate; RCU, red blood cell utilization; $t_{1/2}$, plasma Fe half-life.

The plasma iron transport rate (PIT) is a measure of the rate at which iron leaves the plasma. It may be expressed either as a total daily rate (milligrams of iron per day) or as a rate per volume (dl) of blood. The latter mode of expression eliminates the need for determining plasma volume and incorporates a built-in correction for body size. It assumes, however, that the blood volume is approximately normal. The PIT is generally considered a good index of total erythropoiesis, whether effective or ineffective. The PIT correlates with the total nucleated red cell mass and with the rate of red cell production induced by phlebotomy ([156]). Its value as a measure of erythropoiesis, however, is limited by two phenomena. First, some iron leaves plasma by entering the extravascular space, the extravascular flux ([358]). Second, the plasma iron pool includes two main species, monoferric transferrin and diferric transferrin. The latter has a fourfold advantage in affinity for receptors and also delivers twice as much iron per molecule of transferrin taken up. For these reasons, PIT tends to increase as the serum iron increases, even when total erythropoiesis is unchanged. A suggested improvement over PIT is erythron transferrin uptake ([359] , [360]). This measurement is calculated by subtracting extravascular flux from PIT and then converting iron uptake to transferrin uptake by correcting for the predictable distribution of iron between monoferric and diferric transferrin species.

The erythrocyte iron turnover rate (EIT) is a measure of the rate at which iron moves from marrow to circulating red cells. Like PIT, it may be expressed as a total daily rate or as a rate per deciliter of blood, and the same advantages and disadvantages of the two modes of expression apply. It is an index of effective erythropoiesis and correlates well with an appropriately corrected reticulocyte index.

The observation that red cell iron utilization (RCU) is usually less than 100%, and therefore PIT is greater than EIT, means that some of the iron leaving plasma does not make its appearance in circulating red cells. There are several possible fates for this nonutilized iron. It may enter nonerythroid tissues; it may be lost with hemoglobin when normoblast denucleation occurs; it may be lost with intramedullary destruction of defective red cells (ineffective erythropoiesis); and, finally, it may enter the extravascular space, as noted previously. When RCU is reduced and the difference between PIT and EIT is relatively large, one of these pathways accounts for a larger than normal proportion of plasma iron turnover.

The marrow transit time may be used to evaluate erythropoietin response. In general, this value decreases in proportion to the degree of erythropoietic stimulation. In situations characterized by an appropriate marrow response to anemia, the relation between the volume of packed red blood cells and marrow transit time is predictable ([156]).

In addition to these determinations on blood specimens, it is possible to monitor iron movements within the body by surface counting over the liver, spleen, and sacrum (marrow). This procedure may be particularly useful in detecting extramedullary hematopoiesis.

Variations of ferrokinetic measurements in representative disease states are listed in Table 28.7. When erythropoiesis is reduced, as in hypoplastic anemia, the PIT may be normal or only slightly reduced, but RCU and EIT are greatly reduced. Furthermore, iron appears early in the liver and is retained there. When erythropoiesis is accelerated in hemolytic anemia, both PIT and EIT are increased, and radioactivity accumulates at the sites of destruction (the spleen or liver). In states of ineffective erythropoiesis, such as thalassemia major, PIT is greatly increased, RCU is reduced, and EIT is relatively normal. Early iron uptake may occur over organs in which the defective cells are destroyed. The erythron transferrin uptake appears to be a more precise measure of erythropoiesis than PIT. As compared with a mean normal erythron transferrin uptake value of 60 µmol/day/L blood, the value in patients with aplastic anemia or pure red cell aplasia was 12, and that in patients with hemolytic anemia or ineffective erythropoiesis was over 400 ([360]).

TABLE 28.7. Ferrokinetic Data in Representative Clinical Situations

	Half-Life (min)	Plasma Iron Transport Rate (mg/d/dl)	Erythron Transferrin Uptake (µmol/d/L)	Red Blood Cell Utilization (%)	Erythrocyte Iron Turnover Rate (mg/d/dl)
Normal	86	0.70	60	80	0.56
Hypoplastic anemia	267	0.45	12	23	0.10
Hemolytic anemia (hereditary spherocytosis)	24	3.42	400	57	1.87
Ineffective erythropoiesis (thalassemia major)	21	6.87	474	18	1.24

NOTE: Values are means.

Data from Finch CA, Deubelbeiss K, Cook JD, et al. Ferrokinetics in man. Medicine (Baltimore) 1970;49:17–53; and Cazzola M, Pootrakul P, Huebers HA, et al. Erythroid marrow function in anemic patients. Blood 1987;69:296–301.

Iron does not leave the plasma at a single exponential rate. The early part of the plasma disappearance curve does, in fact, approximate a straight line on a semilogarithmic plot. After several hours, however, a significant change occurs in the slope of the line until another, much slower, exponential disappearance rate is established. This phenomenon is explained by the return to plasma of approximately 35% of the iron that leaves it ([156]).

MANAGEMENT OF IRON DEFICIENCY

Management is primarily focused on repletion of iron stores. Most of the time, this therapy is straightforward, simple, and inexpensive. The response to treatment is predictable and gratifying. There is, however, an important caveat: Correction of the iron deficiency is only part of the task confronting the clinician. Particularly in older adults, iron deficiency may be an early sign of a serious illness, such as an occult gastrointestinal malignancy. Clearly, correction of the anemia without recognition and treatment of a possible underlying disease is poorly practiced medicine. The cause of iron deficiency anemia can be defined in the great majority of cases. Once an etiologic diagnosis is made, appropriate therapy can begin.

Iron is highly effective in treating iron deficiency. It has no other legitimate therapeutic use. In particular, it is not beneficial for any of the numerous anemias that are not associated with iron deficiency. The practice of giving iron indiscriminately in undiagnosed anemia is questionable. Although this is often a reasonable approach in young children at high risk for iron deficiency and with no evidence of other pathology, it is harder to defend in adult populations.

Iron can be administered orally or intravenously. The oral route is the safest and least expensive. Importantly, therapeutic doses are quite different for oral and intravenous preparations. Most iron-deficient patients respond well to oral therapy, but intravenous administration of iron may sometimes be required.

Oral Iron Therapy

The most common preparation used orally is ferrous sulfate, which has been a mainstay of treatment for iron deficiency since it was first introduced by the French physician Pierre Blaud in the nineteenth century. It is effective, reasonably well tolerated, and inexpensive. If equivalent amounts of elemental iron are given, ferrous gluconate and ferrous fumarate are equally satisfactory and have approximately the same incidence of side effects. Although iron deficiency clearly promotes increased absorption, individual variations are great, and absorption may be vastly different at varying degrees of anemia and in the presence of complicating

illnesses.

The dose is best calculated in terms of elemental iron. For adults, the optimal response occurs when approximately 200 mg of elemental iron is given each day. Iron is absorbed more completely when the stomach is empty; when iron ingestion occurs after or with a meal, absorption decreases substantially ([361]). However, gastrointestinal irritation is common when the stomach is empty. Consequently, patients are frequently advised to take oral iron immediately after or even with a meal. The gain in patient acceptance may be more important than the reduced absorption of iron. However, it is important to remember that, whereas absorption is enhanced by the presence of orange juice, meat, poultry, and fish, other substances such as cereals, tea, and milk inhibit it. This is particularly important in toddlers, because administration of oral iron with milk often compromises therapy.

For iron-deficient children, the optimal dosage is 1.5 to 2.0 mg elemental iron per kilogram of body weight three times per day. Palatable elixirs and syrups are the most satisfactory pediatric preparations, although they can stain the teeth if not given carefully. Children usually tolerate this form of therapy on an empty stomach.

In adults, a 200-mg daily dose produces a maximal rate of hemoglobin regeneration. However, the maximal rate is not necessarily the only legitimate therapeutic goal. If the underlying disease has been corrected and the anemia is mild to moderate, a slower rate of response may be acceptable. Thus, if such patients cannot tolerate 200 mg/day of elemental iron, it is reasonable to reduce the dose to 100 mg/day ([362]). Because less iron is given, tolerance improves. In this circumstance, speed of response is exchanged for increased patient compliance, although it may be necessary to treat for longer. Regardless of the form of oral therapy used, treatment should be continued for at least 3 to 6 months after the anemia is relieved. If treatment does not continue, relapse is common. The continued therapy allows for repletion of iron stores.

Side Effects of Oral Iron Therapy

Some patients given oral iron report gastrointestinal symptoms, including heartburn, nausea, abdominal cramps, and diarrhea. However, functional gastrointestinal symptoms are common in the general population, and patients may incorrectly ascribe them to iron treatment. Many studies of gastrointestinal intolerance to iron have not included adequate controls. In one excellent double-blind study, ferrous sulfate, ferrous gluconate, ferrous fumarate, and placebo were administered in identically appearing tablets ([363]). No significant differences were found among the three iron salts. Approximately 12% of subjects had symptoms that could reasonably be ascribed to iron ingestion. Often, tolerance of iron salts improves when a small dose is given at first and increased over the course of several days to the full dose. Without such a gradual increase in dosage, gastrointestinal side effects are more likely to develop.

A polysaccharide–iron complex is marketed under the brand name Niferex. It is a ferric-polysaccharide polymer that is alleged to be as effective as ferrous sulfate while causing fewer side effects. The question of whether it is as well absorbed as ferrous sulfate has not been definitively resolved.

If given in sufficient quantities, both ascorbic acid and succinic acid increase absorption of ferrous iron. Ascorbate, however, also increases the side effects of iron therapy ([363]); thus, an increased dose of iron might achieve the same result at lower cost. Furthermore, many of the available iron and ascorbate preparations contain only small amounts of ascorbate.

Enteric-coated preparations are designed to reduce side effects by retarding dissolution of the iron. However, this effect may markedly decrease absorption, especially in achlorhydric individuals, whose gastric juice cannot dissolve the coating. Sustained release preparations also reduce side effects by retarding dissolution, but in so doing, the most actively absorbing regions of the intestine are bypassed. According to most ([364]) but not all ([365]) studies, absorption is therefore reduced.

Failure of Oral Iron Therapy

Clinicians often encounter patients said to have iron deficiency anemia unresponsive to oral therapy. The most common explanations for failure to respond to oral iron include (a) incorrect diagnosis, (b) complicating illness, (c) failure of the patient to take prescribed medication, (d) inadequate prescription (dose or form), (e) continuing iron loss in excess of intake, and (f) malabsorption of iron.

In managing a problem of alleged failure to respond to iron, it is important to review the data on which the diagnosis of iron deficiency anemia was based and to take note of any laboratory procedures that might have yielded erroneous information. At times, even though iron deficiency is present, a coexisting cause for anemia may impair response. Examples are iron deficiency as a complication of the anemia of chronic disorders in rheumatoid arthritis as well as so-called dimorphic anemia, in which iron deficiency and pernicious anemia coexist.

Even apparently intelligent and cooperative patients may not take medications as prescribed, and this possibility should be considered. In some patients, blood loss is so great that oral iron therapy cannot keep up with it. If this situation is not correctable (e.g., in the case of hereditary hemorrhagic telangiectasia) parenteral therapy must be given. Finally, rare patients may be unable to absorb iron. This is unusual; even patients with sprue or total gastrectomy are usually able to absorb adequate amounts of ferrous sulfate. Although it is formally possible that patients may not absorb iron because of genetic defects in the proteins involved in intestinal iron transport, mutations in the genes encoding these proteins have not yet been described in patients who do not respond to oral iron therapy.

Parenteral Iron Therapy

Parenteral iron therapy is highly effective, but it poses significant risks to some patients. Parenteral iron therapy may be indicated when the patient (a) has severe iron deficiency anemia; (b) is unable to tolerate iron compounds given orally; (c) repeatedly does not heed instructions or is incapable of accepting or following them; (d) loses iron (blood) at a rate too rapid for the oral intake to compensate for the loss, such as in hereditary hemorrhagic telangiectasia; (e) has a disorder of the gastrointestinal tract, such as ulcerative colitis, in which symptoms may be aggravated by iron therapy; (f) is unable to absorb iron from the gastrointestinal tract; (g) is unable to maintain iron balance on treatment with hemodialysis; or (h) has functional iron deficiency because of concurrent treatment with erythropoietin (e.g., in the anemia of renal failure, in the anemia of chronic disease, or for autologous blood donation).

Iron can be administered parenterally, but preparations must have certain properties to be both safe and efficacious. It must be possible to give substantial doses in a form that is avidly taken up by reticuloendothelial macrophages, minimally excreted into the urine, and does not cause iron deposition in liver parenchymal cells or renal tubular cells ([366]). There are currently three parenteral iron preparations in clinical use (Table 28.8). Iron–dextran complex, which contains 50 mg of iron per milliliter of solution, is the most stable, allowing the total dose to be given at one time ([367]). It has been in use for the longest period of time. However, there is a small but significant incidence of anaphylaxis associated with iron dextran, which has convinced many practitioners to use either of two alternative preparations that have recently become available in the United States—sodium ferric gluconate ([368]) and iron sucrose ([369]). Sodium ferric gluconate can be toxic in large doses, and it is safest to give no more than 62.5 mg as a daily dose to adult patients. Rare anaphylactic reactions have been reported with iron sucrose, but they appear to be less frequent than with iron dextran. The total dose is calculated from the amount of iron needed to restore the hemoglobin deficit plus an additional amount to replenish stores. The following is a useful formula:

TABLE 28.8. Parenteral Iron Preparations

Preparation	Concentration	Administration
Iron–dextran complex (INFeD)	50.0 mg iron/ml	Must give 0.5 ml test dose before each administration to check for anaphylactic reaction. In iron deficiency, total replacement dose can be given in 1 d. Small doses can be infused undiluted no faster than 1 ml/min. Larger doses should be diluted 5 ml iron dextran into 100 ml normal saline and infused at 20–60 gtts/min, beginning slowly.
Sodium ferric gluconate (Ferrlecit)	12.5 mg iron/ml	No more than 100 mg should be given per d; doses of 62.5 mg or less are recommended to avoid toxicity. Small doses can be infused undiluted no faster than 1 ml/min. Larger doses should be diluted 5 ml sodium ferric gluconate into 100 ml normal saline and infused over 1 hr.

Iron sucrose (Venofer)	20.0 mg iron/ml	Anaphylactic reactions are rare but have been reported. Some practitioners give a test dose of 2.5 ml diluted in 50.0 ml normal saline over 5–10 min. No more than 300 mg should be given per d. Small doses can be infused undiluted no faster than 1 ml/min. Larger doses should be diluted 5 ml iron sucrose into 100 ml normal saline and infused over 60–90 min.

$$\text{Iron to be injected (mg)} = \text{weight (kg)} \times [\text{normal hemoglobin value} - \text{actual hemoglobin value (g/dl)}] \times 2.4 + 500 \text{ mg}$$

Alternatively, a calculator is available on the Internet at http://www.globalrph.com/irondextran.htm. This site calculates a dose for milliliters of iron dextran; doses of other intravenous iron preparations can be determined taking into account the fact that the concentration of iron dextran is 50 mg/ml.

Parenteral iron preparations should be given intravenously, because experience with iron dextran complex shows that intramuscular injections can cause skin discoloration and formation of sterile abscesses and may predispose to local sarcomas ([370]). For iron dextran and possibly also iron sucrose, a small test dose should be given initially to test for hypersensitivity (Table 28.8). If this is well tolerated, the full dose may be given. Some practitioners prefer to give large doses of iron over several days, but a total dose infusion of iron dextran can be given to iron-deficient patients ([367]). Delayed reactions may be more common with total dose infusion; nevertheless, it has been used extensively in the United States, Great Britain, and continental Europe. The initial flow rate should be 20 drops per minute for 5 minutes. If no side effects are observed, the rate may be increased to 40 to 60 drops/minute.

Side Effects of Parenteral Iron Therapy

Side effects may be local or systemic. With intravenous injection, rates of administration greater than 100 mg/minute are associated with pain in the vein injected, flushing, and a metallic taste ([371]). Such reactions are brief in duration and relieved immediately by slowing the injection. Systemic reactions may be either immediate or delayed. Immediate side effects include hypotension, headache, malaise, urticaria, nausea, and rare anaphylactoid reactions, particularly to iron dextran. Delayed reactions include lymphadenopathy, myalgia, arthralgia, and fever. Most of the reactions are mild and transient, but the anaphylactoid reactions may be life-threatening ([371], [372]).

Reactions occurred after 13% of 2099 intravenous injections of iron dextran; the reactions affected 26% of 481 patients treated ([371]). Of those patients who reacted, 5.0% experienced a reaction serious enough to limit ordinary activity, and 0.6% had a life-threatening anaphylactoid reaction. Another 1.0% experienced severe, delayed reactions resembling serum sickness. The clinician should be prepared for the possibility of anaphylaxis by having epinephrine, oxygen, and facilities for resuscitation available. Sodium ferric gluconate and iron sucrose are generally better tolerated than iron–dextran complex, as long as the recommended dosages are not exceeded.

Formerly, use of intravenous iron was discouraged in patients with rheumatoid arthritis, because it was thought to induce disease flares. However, recent reports suggest that it is safe and effective when given with erythropoietin in the treatment of the anemia of chronic disease associated with that disorder ([373], [374]).

Response to Therapy

When specific iron therapy is given, patients often show rapid subjective improvement, with disappearance or marked diminution of fatigue, lassitude, and other nonspecific symptoms. This response may occur before any improvement in anemia is observed. Similarly, pica has been reported to be relieved within 1 week of therapy ([343]).

The earliest hematologic evidence of response to treatment is an increase in the percentage of reticulocytes. The reticulocytes attain a maximal value on the fifth to tenth day after institution of therapy and thereafter gradually return to normal. The maximal value usually ranges from 5 to 10% and is inversely related to the level of hemoglobin. The reticulocyte response may not be detectable in mild iron deficiency anemia.

The blood hemoglobin level is the most accurate measure of the degree of anemia in iron deficiency. During the response to therapy, the red cell count may increase temporarily to values above normal, but the hemoglobin value lags behind. The red cell indices may remain abnormal for some time after the normal hemoglobin level is restored. As recovery occurs, a normocytic cell population gradually replaces the microcytic cell population. When treatment is effective, hemoglobin reaches normal levels by 2 months after therapy is initiated, regardless of starting values.

Of the epithelial lesions in iron deficiency, those affecting the tongue and nails are the most responsive to treatment. After 1 to 2 weeks, small regenerating filiform papillae are observed. After 3 months, the tongue has usually returned to normal; however, in patients with severe anemia, some atrophy may persist. Koilonychia usually disappears in 3 to 6 months, with the concavity moving toward the end of the nail as the nail grows. Gastritis and the associated defects in gastric secretion often do not respond to therapy, especially in older adults. In patients younger than 30 years of age, gastric acid secretion and normal epithelial architecture may be restored ([333]).

Dysphagia may be relieved by iron therapy if the associated postcricoid webs are small or medium sized ([332]). The webs themselves are not altered, however, and relapse of the anemia is associated with recurring dysphagia. With more severe lesions, dilatation of the esophagus is required for relief.

Relapse occurs in a significant fraction of patients who respond to iron treatment, in part because of failure to complete the full course of therapy and in part because of recurrence (or continuation) of the predisposing condition or illness.

Preventive Treatment

Certain people are at such high risk for developing iron deficiency that prophylactic measures may be considered. These include infants, pregnant women, adolescents, regular blood donors, women with menorrhagia, and patients receiving continuous, high-dose aspirin therapy. Iron supplementation has been recommended for pregnant women for almost half a century. Although the advantages of this practice have not been definitively established ([375], [376]), the large iron cost of pregnancy and delivery to the mother (Table 28.4) suggest that it is warranted.

In 1999, the Committee on Nutrition of the American Academy of Pediatrics made recommendations for iron supplementation in infants ([287]). They believe that breast-feeding is preferable for the first 5 to 6 months of life if it is feasible, and beyond 6 months of age, breast-fed infants should receive supplemental iron at 1 mg/kg/day. Infants who are not breast-fed should be given formula supplemented with 12 mg/L of iron through the first year of life. The Committee recommends using iron-fortified cereal at the time that a solid diet is begun. Finally, fresh cow's milk should be avoided until after the first birthday.

Anemia after Acute Hemorrhage

Anemia after acute hemorrhage rarely requires specific therapy. If iron stores are adequate, the marrow is capable of replacing the lost red cells, and correction of anemia is not accelerated by the administration of iron, folate, or vitamin B_{12}. As a rule, no matter how great the blood loss, the rate of erythrocyte replacement is such that a level of approximately 4.5×10^{12} red cells/L is reached in approximately 33 days, with more accelerated erythropoiesis in subjects with more severe degrees of anemia ([377], [378] and [379]). If hemorrhage does not recur, the red cell count is usually restored entirely to normal in 4 to 6 weeks, although the hemoglobin value may lag behind, reaching normal levels only after 6 to 8 weeks.

Morphologic evidence of active red cell regeneration should disappear after 10 to 14 days, if hemorrhage does not recur. The leukocyte count should be normal after 3 to 4 days. Sustained reticulocytosis is suggestive of continued bleeding. Persistent leukocytosis may result from the same cause, from hemorrhage into body cavities, or from complications. The latter, particularly infections, tend to delay the hematopoietic response.

Acute Iron Intoxication

The accidental ingestion of iron compounds by children who have mistaken the tablets for candy is a common problem, particularly with toddlers whose mothers are taking iron-containing prenatal vitamin supplements ([380], [381], [382], [383], [384] and [385]). A few cases have also been reported in adults ([386]). At one time, the associated mortality rate was as high as 50%. Those persons who died had swallowed 3 to 10 g or more.

Symptoms of iron intoxication have been classified in four stages. In the first stage, gastrointestinal symptoms predominate (vomiting, diarrhea, and melena). Shock may ensue, followed by dyspnea, lethargy, and coma. These events occur in the first 6 hours after ingestion. In the second stage, lasting from 6 to 24 hours after ingestion, transient improvement occurs and may continue to recovery. In stage three, metabolic acidosis is present. Death may take place 12 to 48 hours after ingestion. Stage four consists of intestinal obstruction as a late complication caused by scarring of the intestine.

These ill effects are the consequence of the local irritative action of the iron, resulting in mucosal ulceration and bleeding. Capillary dilatation and diapedesis of red cells may occur. Many factors cause the shock, including the absorption of iron in amounts far above the binding capacity of the plasma. Serum iron values as high as 3000 µg/dl have been observed. Late coma is the result of hypoxia, metabolic disturbances, and hepatic damage.

The introduction of deferoxamine as a therapeutic agent has greatly modified the outlook ([383]). This hexadentate chelator, which has a high specific affinity for iron, can be given orally and intravenously. The molecular complex is small and is excreted quickly by the kidneys. Nonetheless, it is prudent to manage iron poisoning in consultation with an experienced toxicologist.

Sideroblastic Anemias

The sideroblastic anemias are a heterogeneous group of disorders ([1], [2]) with the unique characteristic of amorphous iron deposits in erythroblast mitochondria ([3], [4] and [5]) (Fig. 29.1A) that are housed within a distinct, mitochondrial ferritin ([6], [7]). The iron-laden mitochondria often assume a perinuclear distribution, particularly in the later stages of erythroblast maturation, and account for the so-called ring sideroblast, a nucleated red cell in which large Prussian blue–positive granules form a full or partial ring around the nucleus (Fig. 29.1B).

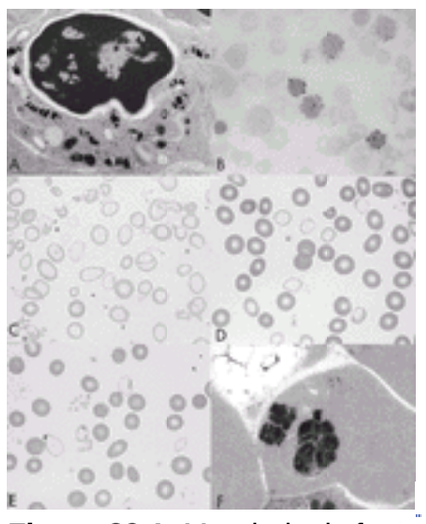

Figure 29.1. Morphologic features of sideroblastic anemia. **A:** Electron micrograph of an erythroblast with iron-laden mitochondria. **B:** Bone marrow smear (Prussian blue stain) with ring sideroblasts. **C,D:** Blood smears (Wright stain) of severe and mild sideroblastic anemia. **E:** Siderocytes (Wright stain). **F:** Electron micrograph of a Pappenheimer body in a peripheral red blood cell. See Color Plate.

The basis for the mitochondrial iron accumulation in the various sideroblastic anemias is considered to be insufficient generation of heme as a result of decreased production of protoporphyrin or impaired incorporation of iron into protoporphyrin in the erythroid cell, creating an imbalance between mitochondrial iron import and its utilization ([8]). Globin synthesis is also impaired, but this effect is secondary as it can be corrected *in vitro* by the addition of heme ([9], [10]). Iron delivery to the erythroid cell is not down-regulated in the face of the diminished heme synthesis, and iron continues to be transported normally to mitochondria, where it accumulates ([11], [12]).

Kinetically, the sideroblastic anemias are characterized by ineffective erythropoiesis, like other erythroid disorders with defective cytoplasmic or nuclear maturation ([13], [14], [15], [16] and [17]). Erythroid hyperplasia of the bone marrow is accompanied by a normal or only slightly increased reticulocyte count. The plasma iron turnover rate is increased, but iron incorporation into circulating red cells is reduced. Red cell survival, as measured with the usual random labels (see Chapter 9), tends to be normal or slightly reduced. Slight hyperbilirubinemia may be noted, as well as an increase in urobilinogen excretion, as a result of a raised erythropoietic component of the “early-label” bilirubin peak ([18]). Thus, it can be inferred that a substantial proportion of the developing ring sideroblasts are nonviable, and their destruction through enhanced apoptotic mechanisms within the marrow ([19], [20] and [21]) accounts for the kinetic abnormalities.

The progeny of the ring sideroblasts are hypochromic and microcytic erythrocytes, a finding that provides morphologic evidence of impaired hemoglobin formation as well as the initial clue to the diagnosis. The degree of hypochromia and microcytosis varies considerably from one form of sideroblastic anemia to another (Fig. 29.1C and Fig. 29.1D). Often, dimorphism is pronounced, with a hypochromic/microcytic population of cells existing side by side with a normal or even a macrocytic one; this morphologic heterogeneity may also be evident in a distinctive bimodal erythrocyte distribution in the Coulter cell volume distribution curve. The siderotic mitochondria of the developing cell may be retained in some circulating erythrocytes (Pappenheimer bodies) and are regularly found with concomitant hypofunction or absence of the spleen; these cells are the nearly pathognomonic siderocytes in the Wright-stained blood smear ([22], [23]) (Fig. 29.1E and Fig. 29.1F).

A constant feature of those sideroblastic anemias that are not reversible is an excess of total body iron. The serum iron concentration is increased, often to the point of complete saturation of transferrin, and the level of serum ferritin roughly reflects the degree of iron overload. The ineffective erythropoiesis mediates, in an unknown manner, increased intestinal absorption of iron ([24], [25] and [26]). The consequent iron overload state is called *erythropoietic hemochromatosis*, and its clinical and pathologic features and course are for the most part indistinguishable from those of hereditary hemochromatosis ([27], [28]) (see Chapter 30). The concomitant presence of an allele(s) for hereditary hemochromatosis likely accentuates the iron overload ([29], [30] and [31]), but its prevalence in patients with sideroblastic anemia does not appear to be greater than in the general population ([28], [32], [33], [34] and [35]).

Diverse mechanisms impairing erythroid heme synthesis are reflected in the various forms of sideroblastic anemia (Table 29.1), whether inherited or acquired. Within the hereditary group, X-linked transmission is the most frequent. In several kindreds, the disorder appeared to be inherited as an autosomal trait, and an increasing number of sporadic congenital cases are being found in children as well as in adults without other affected family members. Acquired sideroblastic anemia is more common than the inherited forms and occurs as a primary erythropoietic disorder or in association with myelodysplastic or myeloproliferative diseases. Several diverse factors, such as ethanol, certain drugs, copper deficiency, and hypothermia, produce a ring sideroblast abnormality that is fully reversible.

TABLE 29.1. Classification of the Sideroblastic Anemias (SAs)

Hereditary SA
X-linked (XLSA)
X-linked with ataxia (XLSA/A)
Presumed autosomal
Sporadic congenital
Associated with erythropoietic protoporphyria
Associated with thiamine-responsive megaloblastic anemia (TRMA)
Associated with mitochondrial cytopathy (Pearson syndrome)
Acquired idiopathic SA (AISA)
Pure sideroblastic anemia (PSA)
Refractory anemia with ring sideroblasts (RARS)
Associated with hematologic malignancies, myeloproliferative disorders
Reversible—associated with
Alcoholism
Certain drugs (isoniazid, chloramphenicol)
Copper deficiency (nutritional, copper chelation, ? malabsorption, zinc toxicity)
Hypothermia

HISTORICAL ASPECTS

Various clinical and morphologic features that characterize the sideroblastic anemias were described separately before their true relationship to these disorders was realized. Cooley reported the first family with X-linked hypochromic microcytic anemia in 1945 ([36]), recognizing its differentiating features from those of thalassemia, which he had described in 1925. In the following year, Rundles and Falls reported additional findings in the same family as well as in a second kindred ([37]). After spontaneous pyridoxine-responsive anemia was reported by Harris and colleagues in 1956 ([38]), a member of the family first described by Cooley was also shown to respond to pyridoxine administration ([39]). Many reports of familial and nonfamilial cases of pyridoxine-responsive anemia followed thereafter ([13] , [14]). The first patients (three brothers) said to have responded to pyridoxine, however, were given the vitamin during the 1940s ([40]).

Iron-positive granules in erythroblasts, including their perinuclear distribution, were described in 1947 ([41] , [42]). They were first associated with acquired sideroblastic anemia by Bjorkman ([43]) and were later also recognized as a constant finding in hereditary hypochromic microcytic anemia and in pyridoxine-responsive anemia ([1] , [25] , [44]). Electron microscopic studies revealed that the siderotic granules represented iron deposits in erythroblast mitochondria ([3]). Soon, ring sideroblasts were detected in numerous patients with refractory anemia of unknown cause, hereditary or acquired, and these observations formed the basis of a symposium in 1965, at which time the term *sideroblastic anemia* was adopted ([1]). By then, the iron overload of these disorders had also become fully appreciated ([25] , [45] , [46]).

The occurrence of sideroblastic anemia in patients receiving antituberculous agents with antipyridoxine properties indicated that erythroid heme synthesis can be impaired by depletion of active forms of vitamin B_6 in humans ([47] , [48]). The condition was then reproduced experimentally in animals ([49] , [50]). The spectrum of reversible sideroblastic anemia was widened further when other agents such as chloramphenicol ([51]) and alcohol ([52]) were found to produce it.

Investigations during the last three decades have defined the subcellular sites in which derangements impair the synthesis of erythroid heme in several sideroblastic anemia states. These include decreased production of 5-aminolevulinate (ALA) caused by mutant erythroid ALA synthase or by impaired metabolism of vitamin B_6; mitochondrial dysfunction of genetic, nutritional, and toxic causes; and clonal hematopoietic disorders in which the basis for the faulty heme synthesis remains least understood.

HEME SYNTHESIS IN ERYTHROID CELLS

Characterization of the cellular and molecular biology of the sideroblastic anemia syndromes is facilitated by evolving insights concerning the synthesis of heme in erythroid tissue. Developing erythroid cells have the greatest requirement of any cell type for heme for hemoglobin, and they produce more than 80% of the heme in the body. The expression and regulation of erythroid heme synthesis are unique in that they are linked (a) to the differentiation events after the action of erythropoietin when erythroid precursors acquire the machinery for hemoglobin synthesis, (b) to the availability of iron, and (c) to the production of globin during development of the red cell. As in hepatocytes, ALA synthase and porphobilinogen (PBG) deaminase have considerably lower relative activities than the remaining enzymes in the heme biosynthetic pathway (see Chapter 7) and are sites of pathway regulation ([53]). In contrast to the liver, the relative activity of ferrochelatase, the terminal enzyme in the pathway, appears also to be low in erythroid cells ([53]). Furthermore, developing red cells express erythroid-specific isozymes or messenger RNA (mRNA) transcripts of the first four enzymes of heme synthesis, namely ALA synthase, ALA dehydratase, PBG deaminase, and uroporphyrinogen III synthase.

ALA synthase is synthesized in the cytosol as a precursor protein with an *N*-terminal signal sequence that is proteolytically cleaved and processed on transport of the protein into the mitochondrial matrix ([54] , [55]). The mature mitochondrial protein catalyzes the formation of ALA from glycine and succinyl coenzyme A (CoA) and requires pyridoxal 5'-phosphate (PLP) as a cofactor. Two separate genes encode the ALA synthase isoenzymes ([56] , [57] , [58] and [59]). The housekeeping gene (*ALAS1*), located on chromosome 3 ([56] , [58] , [60]), is expressed ubiquitously ([61]), whereas the erythroid-specific gene (*ALAS2*) is on the X chromosome ([57] , [58] , [62] , [63]). Expression of the housekeeping gene, at least in hepatocytes, is increased by certain steroids, various drugs, and chemicals and is repressed by administration of heme, the end product of the pathway, so that heme levels tightly regulate transcription of its mRNA in a feedback manner ([61]). Expression of the erythroid gene is essential for hemoglobin production, and ALAS1 cannot compensate for ALAS2 deficiency ([64] , [65] and [66]). It is activated and transcribed in concert with other erythroid genes through the action of erythropoietin on erythroid transcription factors ([54] , [61]) (Fig. 29.2); it is not repressed by heme but is up-regulated by hypoxia ([67]). Cellular iron levels may also control ALAS2 mRNA expression or stability ([68]), whereas heme may inhibit translation of ALAS2 mRNA ([69]), although the mechanisms by which these occur are not known. In addition, the erythroid ALA synthase mRNA, but not the housekeeping form, has in its 5' untranslated region a *cis*-acting iron-responsive element (IRE) ([70] , [71]), so that cellular iron status modulates translation of the enzyme ([72] , [73] and [74]) and thus its activity (Fig. 29.2), analogous to the regulation of apoferritin synthesis by iron ([75]). A candidate cytosolic IRE-binding protein in the erythroid cell may be ferrochelatase, which possesses an iron-sulfur cluster ([76] , [77]) and binds to the IRE of ALAS2 ([78]), analogous to the IRE-binding protein cytosolic aconitase ([79]). Thus, protoporphyrin production can be coupled to iron availability for the formation of heme. The low ALA synthase activity observed in erythroid cells in iron deficiency is consistent with such a control mechanism ([80] , [81]). In addition, cellular levels of heme may influence mitochondrial import of ALA synthase in erythroid cells (Fig. 29.2) as in hepatocytes, in that the signal sequence of the ALAS2 precursor protein contains the two heme-binding motifs implicated in regulating translocation of ALA synthase isozymes into mitochondria ([82]), and heme interacts with these motifs ([83]). Within the mitochondrion, the ALAS2 isoform uniquely associates with the succinyl CoA synthetase ßA subunit, seemingly to stabilize the ALAS2, to control the generation of its substrate succinyl CoA, or both ([84]).

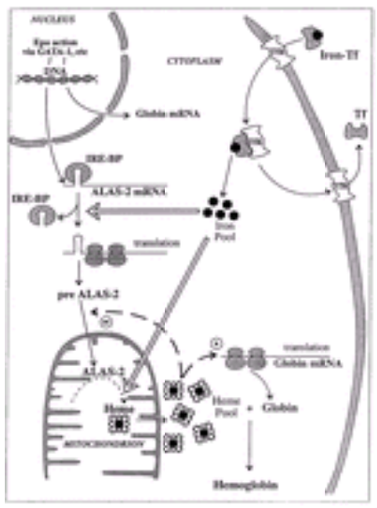

Figure 29.2. The postulated regulation of erythroid 5-aminolevulinate synthase (ALAS2). Epo, erythropoietin; IRE-BP, iron-responsive element–binding protein; mRNA, messenger RNA; Tf, transferrin; TfR, transferrin receptor; [circled dash] denotes inhibition; [circled plus] denotes stimulation. (Modified from May BK, Dogra SC, Sadlon TJ, et al. Molecular regulation of heme biosynthesis in higher vertebrates. Prog Nucleic Acid Res Mol Biol 1995;51:1–51.)

For ALA dehydratase, a cytosolic enzyme, two tissue-specific isozymes are produced by a single gene, which contains two promoter regions, generating housekeeping and erythroid-specific transcripts with alternative first noncoding exons (exons 1A and 1B) ([85], [86]). Although both transcripts encode identical polypeptides, the erythroid-regulated form would provide for the production of the large amounts of heme for hemoglobin. Not being a rate-limiting enzyme for heme biosynthesis, its expression in erythroid cells in manyfold excess amounts ([53]) may also serve as the proteasome inhibitor CF-2 to inhibit protein (hemoglobin) degradation ([87]).

In the case of PBG deaminase, which acts in the cytosol to form the linear tetrapyrrole hydroxymethylbilane from four molecules of PBG (see Chapter 7), two tissue-specific isoenzymes also are produced by a single gene. The gene has two overlapping transcription units, each with its own promoter: an upstream ubiquitous promoter and another downstream promoter active only in erythroid cells ([88]). Two mRNAs are generated by alternative splicing, one encoding the PBG deaminase isoenzyme found in all cells and the other encoding the isoenzyme found only in erythroid cells. To what extent the erythroid-specific enzyme has a regulatory role in the overall production of heme in erythroid cells is not known. In response to erythropoietin or hypoxia, bone marrow PBG deaminase activity increased 3.5-fold, apparently by *de novo* synthesis, whereas the steady-state activity of ALA synthase and ferrochelatase was not significantly affected ([89]). Further regulation of this enzymatic step may occur through PBG oxygenase, which oxidizes PBG to 5-oxopyrrolines ([90], [91]).

The gene for uroporphyrinogen III synthase likewise has two promoters generating housekeeping and erythroid-specific transcripts with unique 5'-untranslated sequences (exons 1 and 2A) ([92]). As for ALA dehydratase and PBG deaminase, the erythroid-promoter activity is increased during erythroid differentiation.

After translation, all three terminal enzymes of heme biosynthesis (coproporphyrinogen oxidase, protoporphyrinogen oxidase, ferrochelatase), like ALA synthase, are transported to their mitochondrial sites of action. Single genes encode these enzymes, and erythroid-specific transcription products are not known for them. However, erythroid-specific regulation of their expression is accommodated by the presence of promoter sequences in their genes for binding of erythroid transcription factors (e.g., GATA-1, NFE-2) ([93], [94] and [95]) to enhance production of these enzymes during erythropoiesis ([96]). Ferrochelatase, the last enzyme of the heme synthetic pathway, catalyzes the insertion of iron into protoporphyrin to form heme. A repressor sequence in the promoter region of its gene is believed to be involved in the regulation of the binding of the erythroid transcription factors GATA-1 and NFE-2 to their recognition sites ([95]). The activity of this enzyme relative to the activity of ALA synthase is in considerable excess ([53], [97]) and is known to become rate-limiting only as a defective protein in hereditary protoporphyria (see Chapter 31). Uroporphyrinogen decarboxylase, the fifth enzyme of the pathway with its site of action in the cytosol, is not known to have erythroid-regulatory features.

The large amounts of iron required for erythroid heme synthesis are delivered through transferrin receptor–mediated endocytosis of iron-transferrin (see Chapter 28), and iron availability ultimately limits the normal rate of heme synthesis in erythroid cells ([98]). High expression of transferrin receptors is also linked to erythropoietin-induced differentiation ([61], [98]), as well as to translational modulation by erythropoietin ([99]). Moreover, an erythroid-specific isoform of human transferrin receptor has been described ([100]), and erythroid-active elements have been identified in the promoter of the murine gene ([101], [102]). With erythroid maturation and the accumulation of cellular hemoglobin, the transferrin receptor number progressively decreases ([98]). Transferrin receptors and iron uptake are increased in iron-deficient erythroblasts ([103], [104]) but are not altered in states of impaired heme synthesis, such as in the presence of succinylacetone ([105]) or in erythroid cells from patients with sideroblastic anemia ([11]). High levels of heme, if such occur, appear to block iron release from transferrin after endocytosis ([98]). How the transfer of iron to mitochondria and to apoferritin is accomplished and regulated is not understood. A transient mitochondrion–endosome interaction may be involved in iron translocation to ferrochelatase ([106]).

The molecular events coordinating the production of globin chains with the rate of heme synthesis may occur at more than one level. Heme is required for initiation of globin mRNA translation and acts by inhibiting a protein kinase that inactivates the translational initiation factor 2 (eIF-2a) ([107]) (Fig. 29.2). Heme also appears to be necessary for the induction of globin synthesis during erythroid differentiation ([108]), and findings of several studies indicate that heme affects globin production at the transcriptional level ([109], [110] and [111]).

HEREDITARY SIDEROBLASTIC ANEMIAS

Inherited sideroblastic anemias are emerging as more common disorders than was previously believed and are clinically and genetically heterogeneous (Table 29.2). From descriptions of numerous families and of isolated cases that have been detected soon after birth or in early life, varied patterns of inheritance are apparent and indicate a spectrum of fundamental defects. Within the hereditary categories, severity of the anemia is also highly variable.

TABLE 29.2. Genetic and Hematologic Features of the Hereditary Sideroblastic Anemias

	Mode of Inheritance	Defective Enzyme/Protein	Gene/Chromosomal Location of Gene	Erythrocyte		Severity of Anemia
				Mean Corpuscular Volume	Protoporphyrin	
X-linked sideroblastic anemia	X-linked	ALAS2	*ALAS2*/Xp11.21	Decreased [a]	Decreased	Mild to severe
X-linked sideroblastic anemia with ataxia	X-linked	ABC7 mitochondrial transporter	*ABC7*/Xq13.1-q13.3	Decreased	Increased	Mild
Hereditary	Autosomal	?	?	Decreased	Normal/increased	Mild to severe
Hereditary [b]	Maternal	?	?	Increased	Increased	Mild
Congenital	Sporadic	?	?	Decreased	Normal/increased	Mild to severe
Thiamine-responsive megaloblastic anemia	Autosomal	Thiamine transporter	*SLC19A2*/1q23.3	Increased	Normal/increased	Mild to severe
Pearson syndrome	Sporadic/maternal	Respiratory chain components	Multiple/mitochondrial DNA	Increased	Increased	Severe

[a] Often normal or increased in females expressing the disorder.

[b] One family reported (reference 220).

Hereditary Patterns and Pathogenesis

X-LINKED SIDEROBLASTIC ANEMIA In many kindreds with sideroblastic anemia, inheritance is consistent with an X-linked pattern ([36], [37], [112], [113], [114], [115], [116], [117] and [118]). The anemia occurs primarily in males and their maternal uncles and cousins. Minimal expression of the erythroid abnormality is frequent but not uniform in carrier females and is consistent with variable X inactivation affecting the mutant locus of the disorder. However, in some kindreds, the anemia has occurred only in females and may have been lethal in hemizygous male conceptions ([115], [119], [120], [121] and [122]). Several earlier observations had implicated defects in ALA synthase as underlying the impaired heme biosynthesis in this form of sideroblastic anemia. In patients who respond to pyridoxine supplement, the incorporation of glycine, but not of ALA, into heme is reduced in reticulocytes ([40]). ALA synthase activity in bone marrow may be low before pyridoxine administration and returns to normal or supranormal levels after an erythropoietic response ([117], [123], [124] and [125]). Presumably, residual activity or stability of a defective erythroid ALA synthase is enhanced by additional supply of its coenzyme PLP [e.g., if the enzyme has a reduced affinity for the coenzyme ([124]) or is abnormally sensitive to proteolysis ([123])]. In two individuals, one-half the normal levels of erythroid ALA synthase mRNA were observed, whereas levels of the housekeeping ALA synthase mRNA were increased severalfold, perhaps in response to low levels of cellular heme, and contributing to the associated increased enzyme activity observed ([125]). Although the disorder closely resembles the experimental anemia of vitamin B_6 deprivation ([49], [50], [126], [127]), no dietary lack or altered metabolism of the vitamin is evident; usually, pharmacologic amounts of pyridoxine are required when an erythropoietic response occurs, but the response is variable and rarely complete. Not infrequently, individuals have presented with profound anemia only in adulthood or even late in life ([117], [128], [129] and [130]), suggesting that the disorder may progress with time. In some cases, prior additional dietary or medicinal intake of pyridoxine ([131]), possible changes in pyridoxine metabolism with advancing age ([132]), or initiation of hemodialysis ([133], [134]) can be factors in unmasking mild phenotypes that were not symptomatic at younger age. In female patients, skewed lyonization in hematopoietic tissue related to age ([135]), if leading to progressive inactivation of the X chromosome bearing the normal *ALAS2* allele, seems to play a significant role when symptomatic anemia develops in adulthood ([122]) or late in life ([136]). After the cloning and characterization of the erythroid ALA synthase gene ([70], [137]) (Fig. 29.3) and its localization to the X chromosome, linkage of the disorder to the *ALAS2* locus was established ([117], [138]), and many heterogeneous missense mutations involving invariant or highly conserved amino acid residues in the catalytic domain of the enzyme have been found to cause the disorder (Table 29.3). A nonsense mutation in one case ([122]) and a recently identified mutation in the promoter region of the *ALAS2* gene ([415]) have been the exceptions. Hence, in at least four families described up to 58 years ago ([36], [112], [116], [157]), the underlying molecular defect in ALAS2 could also be defined ([31], [142], [151], [152]). The majority of mutations identified to date reside in exon 9, which contains the PLP-binding lysine (K391) of the enzyme ([158]), although mutations are also frequent in exon 5 (Table 29.3). However, among the 40 distinct mutations so far encountered, only seven occurred in more than one unrelated family or proband. Sites of mutations and severity of anemia or extent of its responsiveness to pyridoxine supplements are not readily correlated. Moreover, marked variation in severity of anemia has been noted between some kindreds bearing the same mutation (Table 29.3) as well as among individuals within some kindreds ([117], [118], [155]), implicating modifying factors affecting penetrance. Activity of the recombinant enzyme is reduced for many, but not all, ALAS2 mutants so far examined and is variably enhanced by PLP ([117], [118], [130], [142], [153], [159]). How any one mutation affects the function of the enzyme would be determined by alterations in the structure of the mutant protein to affect its properties such as binding of substrates or cofactor, its stability, or even its processing to its site of action in the mitochondrion. Toward this end, a three-dimensional structure model of the human enzyme has been constructed, allowing predictions of any structural basis for altered enzyme activity or pyridoxine responsiveness in some of the naturally occurring mutants that give rise to X-linked sideroblastic anemia (XLSA) ([160]). For example, mutations located in the vicinity of the PLP-binding site exhibit a response to pyridoxine, whereas mutations involving substrate binding or catalytic amino acids are refractory to pyridoxine. One ALAS2 mutant (Asp190Val) was shown to lack the ability to associate with the adenosine triphosphate–specific ß subunit of the enzyme succinyl CoA synthetase ([84]), presumably a prerequisite for availability of the substrate succinyl CoA for the enzyme.

[a] Unpublished material.

In some kindreds with an X-linked inheritance pattern, examination of the exonic and promoter regions of the *ALAS2* gene has not revealed molecular defects, suggesting another locus for XLSA.

X-LINKED SIDEROBLASTIC ANEMIA WITH ATAXIA In a large kindred with XLSA with ataxia (XLSA/A) (161), linkage to the phosphoglycerate kinase locus at Xq13 was demonstrated (162) and linkage to ALAS2 was excluded using a highly polymorphic repeat sequence within intron 7 of the *ALAS2* gene (63). Cloning and chromosomal mapping to Xq13.1-q13.3 of the human *ABC7* gene (163 , 164 and 165), an ortholog of the *ATM1* gene in yeast that encodes a transporter protein required for mitochondrial iron homeostasis (166), led to identification of a mutation in this gene as the underlying defect in the kindred (167). Subsequently, distinct mutations in the *ABC7* gene have been identified in two additional families (168 , 169). All three mutations result in substitutions of conserved amino acids (Ile400Met, Glu433Lys, and Val411Leu) and affect a region of the protein involved in binding and transport of substrate. It is postulated that ABC7 participates in the export of iron-sulfur (Fe/S) clusters generated in mitochondria for assembly of cytoplasmic Fe/S cluster–containing proteins. Expression of wild-type ABC7, but not mutant ABC7, in Atm1p-deficient cells restores phenotypic defects as well as the production of cytosolic Fe/S proteins (168). As in yeast (170), a defective ABC7 protein leads to mitochondrial siderosis in the human disorder. How heme synthesis becomes impaired is not understood and may be a consequence of mitochondrial iron-mediated oxygen radical effects. Because free protoporphyrin and zinc protoporphyrin accumulate in erythrocytes (161 , 168 , 169), generation of ferrochelatase (171), an Fe/S-containing protein, and iron availability may be reduced. Neither ALA synthase nor ferrochelatase has been examined in erythroid cells with the XLSA/A defects. The mechanism for the neural dysfunction in this disorder also remains elusive. As in Friedreich ataxia (172), disrupted mitochondrial iron homeostasis in neural cells is likely involved in the pathogenesis.

PRESUMED AUTOSOMAL INHERITANCE Two families have been described in which sideroblastic anemia occurred in a vertical distribution, including father to son transmission, consistent with a dominant trait (173 , 174). In one kindred, the inheritance pattern appeared to be discordant for sideroblastic anemia and X-linked factor IX deficiency (175). In others, the disorder was found only in siblings and with equal severity (176 , 177 , 178 , 179 , 180 and 181), suggesting autosomal-recessive inheritance; a mutation in the *ALAS2* gene was excluded in one such family (179). Responsiveness to pyridoxine was not observed or documented in these reports. Studies of heme biosynthesis or DNA analysis have not been carried out to suggest the pathogenesis.

SPORADIC CONGENITAL CASES Over 20 young children, in whom molecular studies were not performed and who did not have other affected family members, have been reported with severe anemia since birth (182 , 183 , 184 , 185 , 186 , 187 , 188 , 189 , 190 , 191 and 192). These cases may represent autosomal-recessive defects or new mutations in the *ALAS2* gene in a parental germ cell. In two patients, bone marrow ALA synthase activity was decreased without an *in vivo* response to pyridoxine (182 , 184), and, in several, variable responses to pyridoxine were noted. More recently, at least 20 further child cases, as well as a number of isolated adult patients with the hereditary phenotype, have been encountered in whom *ALAS2* defects could not be found with DNA analysis (*unpublished data*).

ASSOCIATION WITH ERYTHROPOIETIC PROTOPORPHYRIA Deficiency of ferrochelatase underlies erythropoietic protoporphyria. It is manifested mainly, if not exclusively, in erythroid cells and leads to accumulation of protoporphyrin, the substrate of the enzyme. The protoporphyrin accumulates during the final stages of erythroid maturation when the defective ferrochelatase becomes rate-limiting for heme production (193). However, heme synthesis is compromised in less than 30% of patients as reflected in a mild hypochromic microcytic anemia (193 , 194), and bone marrow examination has generally not been performed in this disorder. Ring sideroblasts with typical mitochondrial iron deposits were observed in ten patients (195 , 196) but not in one sibling pair (193). The genetic heterogeneity in protoporphyria now established (see Chapter 31) may account for phenotypic differences, or another coexisting defect may be present when the ring sideroblast abnormality is found.

THIAMINE-RESPONSIVE MEGALOBLASTIC ANEMIA SYNDROME Thiamine-responsive megaloblastic anemia (TRMA) syndrome, also known as *Rogers syndrome*, is a recessively inherited autosomal disorder that was described in 1969 (197). It is characterized by megaloblastic anemia, diabetes mellitus, and progressive sensorineural deafness. Associated hematologic features include the ring sideroblast abnormality and, variably, neutropenia and thrombocytopenia (198). Pharmacologic doses of thiamine (vitamin B_1) ameliorate the anemia and diabetes. TRMA cells lack the high-affinity component of thiamine transport, and the gene, termed *SLC19A2*, encoding the transporter was recently mapped and cloned (199 , 200 , 201 and 202). Subsequently, distinct mutations have been described in many families (198) and lead to lack of the protein product or altered protein structure so that mutant proteins are not properly targeted to the cell membrane for their site of function (203 , 204). Whereas the pathogenesis of the megaloblastic change may involve disordered ribose 5-phosphate synthesis (205) via the nonoxidative transketolase pathway, which requires thiamine pyrophosphate as cofactor, the basis for the ring sideroblast abnormality is undefined. It may relate to the role of thiamine as cofactor for a-ketoglutarate dehydrogenase (206), which is involved in generation of succinyl CoA, a substrate of ALA synthase.

MITOCHONDRIAL DNA MUTATIONS In Pearson marrow-pancreas syndrome, a progressive, congenital multisystem mitochondrial disorder caused by sporadic major deletions, rearrangements, or duplications of mitochondrial DNA, an early feature is severe anemia associated with ring sideroblasts in the bone marrow (207 , 208 , 209 , 210 and 211) and pronounced abnormalities in the ultrastructure of erythroblast mitochondria (212). Although the specific deranged gene products resulting from the deletions of the mitochondrial genome are not yet defined, respiratory enzyme defects are postulated. Whether erythroid heme biosynthesis is compromised is also uncertain because the peripheral erythrocytes are macrocytic, and there is associated neutropenia and thrombocytopenia. Moreover, a spectrum of mitochondrial cytopathies is recognized, and heterogeneity of mutant mitochondrial DNA content among different tissues has been noted (213). The degree to which any given tissue contains abnormal mitochondria (heteroplasmy) determines the tissue-specific clinical expression of the disease (210). In the majority of cases so far described, the infants did not survive beyond 2 to 3 years of age. In others, the disorder evolved into the Kearns-Sayre syndrome (214 , 215 and 216). A milder form of mitochondrial cytopathy with myopathy, lactic acidosis, and sideroblastic anemia has been described in siblings in the second and third decades of life (217 , 218 and 219). In one family with apparent maternally inherited sideroblastic anemia manifested in both genders, a defect in mitochondrial DNA was postulated (220). The anemia is mild and is characterized by erythrocyte dimorphism and macrocytosis. The free erythrocyte protoporphyrin (FEP) was slightly raised.

ANIMAL MODELS OF SIDEROBLASTIC ANEMIA The first genetically designed animal model of hereditary sideroblastic anemia was developed in zebrafish, in which hematopoiesis resembles that of higher vertebrates also at the molecular level, as hematopoietic gene expression and function are conserved (221). The chemically induced mutant gene encodes the zebrafish ortholog of human ALAS2 and expresses embryonic hypochromic anemia with severe heme deficiency. The two mutation sites, predicting Val249Asp and Leu305Gln substitutions, are in exon 6 and exon 7, respectively, and represent conserved amino acids across large phylogenetic boundaries, including the human. However, the mutants' blood cells did not reveal ring sideroblasts, perhaps due to species differences in cellular iron metabolism. In a transgenic mouse model with homozygous deficiency of ALAS2, erythroid differentiation is arrested, and embryos die by day 11.5 (64). Mice chimeric for *ALAS2*-null mutant cells exhibit the phenotype of human XLSA, with severe anemia and typical ring sideroblasts in the marrow. The combination of isoniazid (INH) and cycloserine administered to guinea pigs produces sideroblastic anemia in a few weeks (49 , 50). Blood PLP concentrations become reduced, and bone marrow ALA synthase as well as ferrochelatase activity is diminished (50). The latter may be secondary to mitochondrial damage by the iron deposits. The flexed-tail (*f/f*) mouse has a transient embryonic and neonatal anemia associated with siderotic granules (iron-laden mitochondria) in erythrocytes and reduced heme synthesis, which coincides with the physiologic cessation of hepatic erythropoiesis (222 , 223). The defect is a frameshift mutation in the *f* gene (sideroflexin, *sfxn1*) that encodes a protein proposed to facilitate transport of a component required for iron utilization into or out of mitochondria (224).

Clinical and Laboratory Features

The clinical characteristics are similar in X-linked, autosomally inherited, and congenital forms but are most extensively known from the X-linked type. Severe forms of the anemia are recognized in infancy or early childhood. If milder or asymptomatic, the disorder may be discovered only in young adulthood or even in later life. Because severity of anemia can also vary within kindreds (117 , 118 , 155) (Table 29.3), diagnosis in family members may be delayed or overlooked unless complete pedigree studies or DNA analyses for an *ALAS2* mutation identified in the proband are performed.

In addition to symptoms and signs of anemia, all patients exhibit manifestations of iron overload that is not HLA-linked (28) and has been termed *erythropoietic*

hemochromatosis. *HFE* mutations were underrepresented in a series of patients examined ([33]). Mild to moderate enlargement of the liver and spleen is common, but liver function usually is normal or only mildly disturbed at presentation. In untransfused patients, liver biopsy reveals iron deposition that is indistinguishable from hereditary hemochromatosis ([25], [46]) (Fig. 29.4). The iron burden does not correlate with the severity of anemia, and, not infrequently, well-established but asymptomatic micronodular cirrhosis is discovered in the third or fourth decade ([28], [46], [121], [129], [225]); development of hepatocellular carcinoma has not been reported. Clinical diabetes or abnormal glucose tolerance may or may not be related to the iron overload process. Skin hyperpigmentation is uncommon. The most dangerous manifestations of the iron overload are cardiac arrhythmias and congestive heart failure, which usually occur late in the disease course. In severely affected infants or young children, growth and development tend to be impaired ([114]). Signs and symptoms of nutritional deficiency are absent. The neurologic and cutaneous manifestations of vitamin B_6 deficiency are not observed.

Histopathology of the iron overload in hereditary sideroblastic anemia. **A,B:** Liver section of a 26-year-old man with moderate hemochromatosis. **C,D:** Autopsy liver section of a 45-year-old man with micronodular cirrhosis and hemochromatosis. **E,F:** Section from the heart of the latter patient with marked hemosiderosis. (**A**, **C**, and **E**: hematoxylin stain; **B**, **D**, and **F**: Prussian blue stain.) See Color Plate.

The anemia is highly variable. In severe cases, hypochromia and microcytosis are pronounced [mean corpuscular volume (MCV), 50 to 60 fl], and striking anisocytosis, poikilocytosis, target cells, and occasional siderocytes are prominent findings on blood smear (Fig. 29.1); the red cell volume distribution is abnormally wide. Some females with the X-linked trait have a biphasic Coulter counter red cell histogram ([31], [116]) (Fig. 29.5), or only a very small microcytic erythrocyte peak may be evident. Leukocyte and platelet values usually are normal but may be reduced in the presence of splenomegaly (hypersplenism). Erythroid hyperplasia is found on marrow examination, and maturation is usually normoblastic but with poorly developed cytoplasm. Megaloblastic changes may be observed if complicating folate deficiency is present. Marrow reticuloendothelial iron is increased, and the ring sideroblast abnormality is prominent in late, nondividing erythroblasts ([226], [227]). Transferrin saturation is increased, as is the serum ferritin level, and transferrin levels tend to be decreased. Ferrokinetic studies reflect ineffective erythropoiesis.

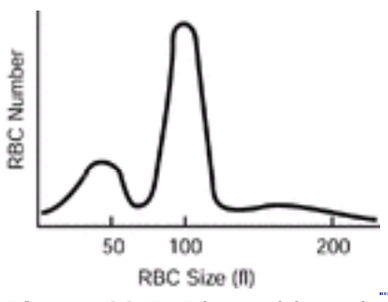

Figure 29.5. Dimorphic red cell distribution in a female patient with X-linked sideroblastic anemia. Redrawn from the output of a Coulter analyzer. RBC, red blood cell.

The FEP level usually is low or normal ([13], [25], [115]). In one female patient, the low FEP level was shown to be restricted to the microcytic red cells ([119]). Kindreds in which the FEP was increased ([25], [115], [173]) can be expected to represent disorders other than XLSA due to ALAS2 defects. In the recently reported mutant involving the *ALAS2* promoter region, the affected proband and her son had raised FEP levels, but an apparent abnormality of ferrochelatase was also observed ([415]).

In the XLSA/A variant among four kindreds so far encountered, the neurologic features are overriding and include delayed motor development, incoordination, and nonprogressive cerebellar atrophy with or without atrophy of pons and medulla ([161], [168], [169], [228]). The anemia is mild to moderate, and morphologic features are indistinguishable from the other hereditary forms, including variable abnormalities in female carriers as observed in XLSA. The FEP is increased. Iron overload has not been evident.

PEARSON SYNDROME The refractory sideroblastic anemia in Pearson syndrome is a component of a multisystem disorder that is also characterized by complications of exocrine pancreatic insufficiency, episodes of lactic acidosis, and eventual hepatic and renal failure ([207], [208] and [209]). The anemia is detected soon after birth or in early childhood. It is normocytic or slightly macrocytic, and the reticulocyte count is low. Variable degrees of neutropenia and thrombocytopenia occur concomitantly or shortly after the onset of anemia. Hemoglobin F levels are usually elevated, and FEP values have been increased when measured. The bone marrow is hypercellular or normocellular, and vacuolization of both erythroid and myeloid marrow precursors is striking. Marrow hemosiderin content is increased, and ring sideroblasts have been noted in most cases. Patients with variant forms of this mitochondrial disease appear to survive longer, and the anemia may remit ([214], [216], [217], [229]).

Treatment and Prognosis

Approximately 75% of patients with hereditary sideroblastic anemia due to identified ALAS2 defects can be expected to respond to pyridoxine administration (Table 29.3). Doses of 50 to 100 mg/day are large compared with the estimated adult daily requirement for vitamin B_6 of 1.5 to 2.0 mg and are sufficient for a maximal response. Higher doses may be toxic. No convincing evidence is available that the parenteral route or PLP, the active coenzyme form, is more effective than oral administration. However, the response to pyridoxine is quite variable. With an optimal response, reticulocytosis is observed, blood hemoglobin concentration returns to normal or near normal levels in 1 to 2 months, and low FEP levels increase to normal ([13], [230]). Morphologic abnormalities of the red cells, however, rarely completely disappear ([13]), even when ALA synthase activity and hemoglobin levels are restored with pyridoxine supplementation. Approximately two-thirds of responding patients experience a distinct but suboptimal improvement with pyridoxine administration (Table 29.3), and the hemoglobin concentration stabilizes at less than normal levels. When an effect of pyridoxine is achieved, continued maintenance treatment is necessary because relapses follow within several months after discontinuing the vitamin. In a few instances, subsequent remissions with resumed treatment were less complete ([13]). In the occasional case with accompanying megaloblastic changes, folic acid should be given, which usually leads to normoblastic maturation, suboptimal reticulocytosis, and some increase in hemoglobin levels. In severely anemic individuals who do not respond to pyridoxine, periodic red cell transfusions are necessary to relieve symptoms and, in children, to allow normal growth and development.

Based on the assessed extent of iron overload, including liver biopsy, an iron depletion program should be instituted to prevent or stabilize already established organ damage ([121], [231], [232]). Graded phlebotomies are well tolerated and preferred in patients with mild or moderate anemia in the absence of contraindications such as heart disease ([25], [121], [225], [233], [234] and [235]). After the initial removal of all storage iron, maintenance phlebotomies should be continued indefinitely. For patients with severe anemia, or for those who depend on regular transfusions and thus become massively iron loaded ([236], [237]), the iron-chelating agent deferoxamine is administered. As recommended for thalassemia ([237]), it is infused over 12 hours subcutaneously or intravenously, at 40 mg/kg/day, and for at least 5 days each week.

Although iron removal with deferoxamine is enhanced by ascorbate, large supplements can cause acute cardiac toxicity by facilitating excessive mobilization of ferritin iron, and any intake of the vitamin should be limited to 200 mg daily ([238]). The risks of deferoxamine treatment are minimal ([239]). Occasional local reactions can be controlled with inclusion of small amounts of hydrocortisone in the infusate. Rare hypersensitivity is amenable to desensitization ([240]). Reported visual and auditory neurotoxicity is unlikely without excessive doses of the drug. The increased risk of infection with *Yersinia* (and perhaps other organisms) in iron overload, although uncommon, increases further with deferoxamine treatment ([241]). Removal of the iron excess has also reduced severity of the anemia ([11], [31], [234], [235]) by improving erythroblast mitochondrial function, such as restoration of secondary ferrochelatase deficiency ([235]), and by diminishing the ineffective erythropoiesis ([24], [234]).

Splenectomy in hereditary sideroblastic anemia appears to be invariably complicated by thromboembolic complications and, often, a fatal outcome ([128], [129], [142], [242]). Factors other than persistent thrombocytosis seem to play a role. Control of the platelet count and anticoagulant therapy usually are not effective, so splenectomy is contraindicated.

Although gene therapy to correct these disorders may be possible in the future, the supportive measures available provide for a favorable prognosis and often for normal survival. Bone marrow transplantation has been carried out successfully in five cases ([181], [188], [243]). In contrast to acquired idiopathic sideroblastic anemia (AISA), predisposition to leukemic evolution has not been observed.

ACQUIRED IDIOPATHIC SIDEROBLASTIC ANEMIA

Since the initial description of AISA by Bjorkman ([43]), a considerable spectrum of its manifestations has been recognized. The anemia may be associated with hematologic findings characteristic of certain stem cell disorders, namely the myeloproliferative diseases ([244], [245] and [246]) and the myelodysplastic syndromes ([247], [248], [249], [250] and [251]). Uncommonly, the ring sideroblast abnormality is observed in acute leukemia and in erythroleukemia at the time of diagnosis ([252], [253]). The disorder is the result of clonal growth of an altered erythroid or hematopoietic progenitor cell with a proliferative advantage over the normal cell population and, thus, has been included among the myelodysplastic syndromes ([254]). Commonly, a variable iron overload state is also present ([11], [29], [45], [250], [255]).

Etiology and Pathogenesis

CLONALITY That AISA has clonal features was first suspected from the morphologic and kinetic findings of two populations of red cells, the hypochromic, short-lived cell population being the product of the abnormal clone that bears the characteristic ring sideroblasts ([255], [256] and [257]). The clonal derivation of the disorder was specifically indicated by the finding of a single glucose-6-phosphate dehydrogenase isoenzyme in hematopoietic cells, but not in fibroblasts, of an individual who was also heterozygous for glucose-6-phosphate dehydrogenase polymorphism ([258]). Further evidence has been provided with simultaneous clonality and cytochemical analysis of erythroid progenitors ([259]). Findings of cytogenetic studies corroborated the clonality of the abnormal hematopoiesis ([260], [261] and [262]). Chromosomal abnormalities have been observed at the level of the multipotential stem cell, the trilineage myeloid stem cell, or only an erythroid precursor cell ([262]); cytogenetically abnormal ringed sideroblasts have also been demonstrated ([263]). Chromosomal abnormalities are detectable in bone marrow cells in approximately 50% of patients, and deletions in chromosomes 5, 11, and 20 as well as trisomy 8 and loss of Y in males occur most frequently ([251], [264]). Although structurally abnormal X chromosomes are uncommon, Xq13 breakpoints were particularly associated with myelodysplasia and ring sideroblasts in one study ([265]). These abnormalities cannot involve the gene for erythroid ALA synthase, which is located on Xp11.21 ([62], [63]), or the gene for the erythroid transcription factor GATA-1, located on Xp21.11 ([266]). In a few patients, abnormalities of the long arm of chromosome 3 have been associated with thrombocytosis ([267], [268]) and may involve the gene for cholinesterase, which has been mapped to the 3q-21-ter region and implicated in megakaryocyte development ([269]). In common with the myelodysplastic syndromes, mutations in the ras and fms genes have been demonstrated in blood cells of some patients with acquired sideroblastic anemia as another marker of clonality ([270], [271]). The pathogenetic significance of these mutational events is not known, and they do not clearly relate to the stage of the disorder or to the progression to acute leukemia. The factors or agents that might be responsible for the various genetic changes remain to be identified ([272]). The natural history of acquired sideroblastic anemia is commonly characterized by a chronic, stable anemia and, less often, by a progressive marrow failure state or leukemic evolution ([250], [251]). An initial genetic change causing expansion of an abnormal hematopoietic clone manifested by defective erythroid cell development is thus insufficient to result in a malignancy, even when persisting for many years. A “second hit” or mutation appears to be necessary for leukemic evolution ([273], [274]) that can be reversible, whereas the fundamental defect expressed in the sideroblastic state persists ([275], [276]). The occasional occurrence of the ring sideroblast abnormality in association with lymphoproliferative disorders may or may not reflect a defect at the level of the multipotential stem cell ([8]). Observations of a therapeutic response to immunosuppressive agents ([277], [278]) suggest potential defects in immune surveillance and removal of transformed stem cells by such therapy in the pathogenesis.

ABNORMALITIES OF HEME SYNTHESIS The defective erythropoiesis is mainly characterized by impaired hemoglobin synthesis. Various studies have indicated that the biosynthesis of heme is impaired, and any accompanying aberrations of globin synthesis appear to be secondary as they are reversed *in vitro* by the addition of heme ([9], [10]). Reduced activity of ALA synthase in marrow cells was the most consistent abnormality in earlier series of patients ([124], [279], [280] and [281]) and was particularly demonstrable in the youngest erythroblast fraction ([282]). In some patients, the addition of PLP enhanced the low enzyme activity *in vitro*, but reported erythropoietic responses to pyridoxine ([2], [13]) or to PLP administration ([283]), as well as restoration of low ALA synthase activity to normal ([279], [284]), were unusual and likely reflected an inherited defect of ALAS2 ([122], [130]). In a later study, the activity of detergent-solubilized ALA synthase in bone marrow cells was actually somewhat increased ([125]), suggesting enhanced translation of the enzyme in response to raised cellular iron levels. A common feature is mild to moderate elevation of the FEP ([255]), rarely reaching values encountered in hereditary protoporphyria ([53], [250], [257], [285]) and implicating marked ferrochelatase deficiency (see Chapter 31). The FEP increases further after pyridoxine administration but without improvement of the anemia ([255], [286], [287]), suggesting a block at the ferrochelatase step. Impaired activity of this enzyme was found in approximately one-half of patients studied ([124], [281]), likely representing a secondary effect of the mitochondrial iron deposition. Studies of iron metabolism in erythroid cells revealed increased accumulation of nonheme iron into membrane or mitochondrial fractions and reduced incorporation of iron into heme ([11], [12]). Thus, impaired iron utilization for heme biosynthesis remained the common denominator in the pathogenesis. The current thesis is that a defect causing diminished heme production in the abnormal clone is intrinsic to mitochondria ([288]), which would also account for the decreased activity of several other mitochondrial enzymes in granulocytes as well as erythroblasts, namely cytochrome oxidase, oligomycin-sensitive adenosine triphosphatase, and mitochondrial serine protease ([289]). Recent findings indicate molecular defects in mitochondrial DNA of hematopoietic cells, involving subunits of enzyme complexes of the respiratory chain. Various heteroplasmic point mutations of conserved nucleotides in mitochondrial DNA, as well as in transfer RNAs and mitochondrial ribosomal RNAs, have been found in the colony-forming unit granulocyte-erythroid-macrophage-megakaryocyte cell lineages of patients with AISA ([290], [291]). A majority of these affect cytochrome *c* oxidase and can be implicated in impaired reduction of iron for its incorporation into protoporphyrin by ferrochelatase. Such defects are consistent with the heterogeneity of hemoglobin content found between individual erythroblasts by scanning microspectrophotometry ([292]), as well as with the variable size of hypochromic microcytic erythrocyte and ring sideroblast cell populations in the disorder. Heteroplasmic mutations of mitochondrial DNA with an increasing proportion of mutant mitochondrial DNA accumulating in some daughter cells through random partitioning during cytokinesis would generate normal and abnormal erythroid cells with respect to mitochondrial function ([293]). A gradual accumulation of affected erythroid precursors and the known higher mutation rate in mitochondrial DNA than in nuclear DNA would provide a basis for the slowly progressive nature of the anemia and its expression in later life, respectively ([294]). The mechanism(s) by which the mitochondrial defects and the attendant mitochondrial siderosis are related or lead to the clonal disorder remains to be defined.

NUCLEAR ABNORMALITIES The principal, often macrocytic, red cell population in the blood may represent the progeny of the normal residual erythroid precursors with a shortened marrow maturation time in response to raised erythropoietin levels. The commonly observed morphologic nuclear abnormalities of erythroid precursors and their defective DNA synthesis and mitosis ([295], [296]), however, suggest that more viable precursors of the dysplastic clone produce the macrocytic erythrocytes, whereas a greater proportion of developing cells expressing impaired heme synthesis is destroyed in the bone marrow. By analogy, various other aberrations of erythroid cell metabolism can occur in dysplastic hematopoietic clones ([297]), including altered genetic control of globin chain production ([298]). Thus, hemoglobin H disease was acquired in association with erythroleukemia, acute leukemia, and myelofibrosis ([298]), as well as in sideroblastic anemia with myeloproliferative features ([299]) and in patients with sideroblastic anemia before leukemia developed ([300]).

IRON OVERLOAD Excessive absorption of dietary iron occurs in many, if not all, patients with stable disease and can be inferred to be a consequence of the ineffective erythropoiesis, as in inherited sideroblastic anemias and other long-standing disorders with erythroid maturation defects ([301], [302]). The iron deposition closely resembles that of hereditary hemochromatosis. Although the presence of at least one allele for this disorder would likely contribute to the iron overload ([28]), the incidence of *HFE* mutations is no greater than in the normal population ([28], [32], [34], [35]). Inadvertent administration of iron for the anemia and red cell transfusions add predictably to the parenchymal iron deposition ([236], [250], [303]).

Clinical Features

AISA usually occurs in middle-aged and older individuals, but younger persons, including children, are not spared. The anemia develops insidiously and may be discovered during a routine examination or in association with an unrelated complaint. The older individual more often experiences symptoms of fatigue and angina if there is coexisting coronary artery disease. Physical examination often reveals no abnormality except for pallor. Hepatosplenomegaly is found in one-third to one-half of patients. With advanced iron overload, usually after repeated red cell transfusions, symptoms and signs of liver decompensation as well as heart failure and arrhythmia occur.

Laboratory Findings

The anemia is usually moderate and may be normocytic but more often is macrocytic (Fig. 29.6). The mean corpuscular hemoglobin concentration is normal or slightly reduced, but a variable population of hypochromic cells is found on blood smear. A particularly characteristic finding is the presence of occasional basophilic stippling in hypochromic cells that stains positive for iron. Typical Pappenheimer bodies are uncommon unless there is associated hyposplenism or the spleen is absent. Leukocyte and platelet values are usually within the normal range. Moderate leukopenia, thrombocytopenia, or both tend to be accompanied by other myelodysplastic features, such as morphologically abnormal leukocytes (e.g., the pseudo-Pelger anomaly) or occasional immature forms in the peripheral blood ([251], [304]). Leukocytosis, thrombocytosis, or both may be seen and suggest a myeloproliferative rather than a myelodysplastic clone ([244], [245] and [246]).

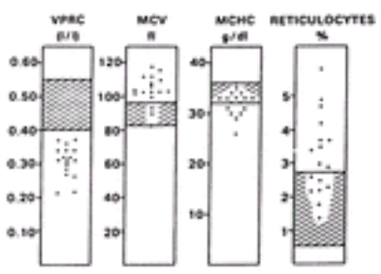

Figure 29.6. Characteristics of anemia in 17 patients with idiopathic acquired sideroblastic anemia. Shaded areas indicate normal range (mean ± two standard deviations). MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; VPRC, volume of packed red cells. (From Kushner JP, Lee GR, Wintrobe MM, Cartwright GE. Idiopathic refractory sideroblastic anemia. Clinical and laboratory investigation of 17 patients and review of the literature. Medicine 1971;50:139–159, with permission.)

Erythroid hyperplasia is found on bone marrow examination. A feature claimed to be helpful in distinguishing idiopathic sideroblastic anemia from erythroleukemia is the lack of periodic acid-Schiff–positive material in the erythroblasts. Mild megaloblastic changes are common and may or may not be related to accompanying folate deficiency. Marrow hemosiderin content is increased, and ring sideroblasts constitute from 15 to 100% of the erythroblasts unless masked by concomitant iron deficiency ([2], [305]). In contrast to hereditary sideroblastic anemia, ring sideroblasts are evident at all stages of erythroid maturation ([226]). Because the hematologic phenotype often may not be distinguishable from XLSA in female patients ([122]), their analysis of X-inactivation status and DNA for *ALAS2* defects should be considered.

Transferrin saturation is increased in most patients and exceeds 90% in approximately one-third of them ([255]). Substantially increased deposition of iron is found in the liver, but hepatic dysfunction is rare at presentation. Serum ferritin levels are elevated.

Characteristically, the FEP is moderately increased, up to 300 µg per dl (normal is 20 to 65 µg per dl). Values ranged from 1055 to 10,514 µg per dl in a few patients, and some had associated dermal photosensitivity (see Chapter 31) ([53], [250], [257], [285]).

Treatment and Prognosis

Treatment consists of supportive measures. Pyridoxine administration cannot be expected to be beneficial because ALAS2 defects are not involved in the pathogenesis. Occasional individuals reported to have shown a response ([14], [284]) almost always manifested a low MCV and likely represent XLSA ([122], [130]). Administration of large doses of androgen (e.g., 50 to 300 mg of oxymetholone per day) ([255]) is rarely useful and tends to produce or enhance fluid retention and hepatic dysfunction. The effectiveness of erythropoietin has been examined in patients with the myelodysplastic syndromes, including AISA. Most, if not all, patients with uncomplicated sideroblastic anemia have high levels of endogenous erythropoietin, and it would appear unlikely that additional administration of the hormone would be beneficial. However, recent studies indicate that prolonged administration of recombinant erythropoietin, with or without granulocyte colony-stimulating factor, can lead to gratifying improvement or even correction of the anemia ([306], [307]). A response is also more likely to occur if the endogenous serum erythropoietin level is not commensurate with the degree of the anemia.

In studies evaluating various drug regimens for the myelo-dysplasias, the refractory anemia with ring sideroblasts category was also included. Agents used have included amifostine and 5-azacytidine, as well as thalidomide ([288]). On the average, major responses with improved erythropoiesis or hematopoiesis have been low (<30%) and often transient.

Many patients with AISA are not significantly incapacitated by the anemia. Without abnormalities of the other hematopoietic cell lines and with minimal iron overload, usually no progression occurs for many years ([251]). Such patients frequently succumb to other concurrent diseases, but continued medical follow-up is indicated. Iron status should also be assessed with laboratory studies once per year. Transfusion of packed red cells is necessary for patients with symptomatic anemia, but it should be kept to a minimum because it accelerates the iron overload.

Iron overload, particularly when accentuated by repeated transfusions, can be a significant cause of morbidity and mortality (liver failure or heart failure) ([250]). When the serum ferritin level is approximately 500 µg per L or higher, along with the increased transferrin saturation, treatment for the iron overload should be considered. Histologic and chemical determination of iron in the liver biopsy provides the optimal assessment of the degree of iron overload. In mildly or moderately anemic individuals, iron removal can be accomplished with graded phlebotomies. Patients with more severe anemia ([308]) or who are transfusion-dependent require subcutaneous deferoxamine infusion as described for hereditary sideroblastic anemia. Because each unit of blood deposits 200 mg of iron, iron overload develops fairly rapidly with regular transfusions, and it is controlled more easily if treatment with deferoxamine is begun after approximately 20 units of blood have been given. In some cases, anemia was improved after iron removal ([11], [309], [310] and [311]); an independent effect of deferoxamine on erythropoiesis was also implicated ([310], [311]).

The survival of patients with isolated anemia who are stable and not transfusion-dependent may not differ from that of healthy individuals. Retrospective and prospective studies of 94 and 232 patients, respectively, with AISA have provided prognostic information to propose two subtypes of the disorder ([251], [304]). In one, termed *pure sideroblastic anemia*, the marrow failure is restricted to the erythroid cell lineage, overall survival was as in age-matched controls, and leukemic transformation was not observed. In the other, termed *refractory anemia with ring sideroblasts* or a “true” myelodysplastic syndrome, features of impaired granulopoiesis, megakaryopoiesis, or both also occur. Survival in this group was reduced to 56% at 3 years, and, in approximately 5% of cases, evolution to acute leukemia occurred. Other factors associated with the development of leukemia are the presence of few ring sideroblasts, more severe ineffective erythropoiesis, and impaired bone marrow colony formation ([250], [304], [312]). The probability of leukemic transformation is also increased in the presence of certain bone marrow karyotype abnormalities (e.g., monosomy 7, deletion 20q, or complex defects) ([250], [264], [313], [314] and [315]). When sideroblastic anemia follows therapy for various malignant disorders, leukemic evolution is the rule ([316], [317]).

REVERSIBLE SIDEROBLASTIC ANEMIAS

Alcoholism

Anemia associated with alcoholism usually has numerous causes ([318]). A ring sideroblast abnormality is never the sole cause but occurs in 25 to 30% of anemic

alcoholic patients ([318], [319]) and probably only in the presence of malnutrition and folate deficiency ([52], [320]).

The production of heme is impaired by ethanol, as indicated by the ability of heme to restore the concomitantly inhibited globin synthesis in reticulocytes ([321], [322]) and by the observation that the hemin-regulated inhibitor activity of globin translation increases ([323]). Inhibitory effects of alcohol have been observed at several steps of the heme biosynthetic pathway. Reduced activity of erythrocyte ALA dehydratase ([324], [325], [326], [327] and [328]) was believed to be related to zinc depletion ([327], [328]). Activity levels of erythrocyte uroporphyrinogen decarboxylase, leukocyte coproporphyrinogen oxidase and ferrochelatase are also decreased in alcoholic patients; those of ALA synthase and PBG deaminase are increased ([326], [329]). Certain abnormalities of vitamin B_6 metabolism have been observed. Serum levels of PLP are low in chronically ill alcoholic persons ([330], [331]) but do not correlate with the presence or absence of ring sideroblasts ([320]). Acetaldehyde enhanced the degradation of PLP ([330], [332]), and, in one study, alcohol-induced sideroblastic anemia responded to PLP but not to the combination of folic acid and pyridoxine ([333]). The colony formation of early (burst-forming unit erythroid) and late (colony-forming unit erythroid) human erythroid progenitor cells is preferentially suppressed by ethanol and acetaldehyde over that of myeloid cell progenitors at concentrations found *in vivo* and is partially reversed by folinic acid and pyridoxine ([334]). Thus, a direct role of vitamin B_6 deficiency in the sideroblastic change is uncertain. Important in the pathogenesis may be the direct effects of ethanol, acetaldehyde, or both on the heme biosynthetic steps or on mitochondrial metabolism because these agents also inhibit hepatic mitochondrial protein synthesis ([335]).

Blood hemoglobin values range from 6 to 10 g per dl, and the MCV is normal or increased. The transient sideroblastic change is commonly evident in dimorphic circulating erythrocytes. Siderocytes, present in approximately one-third of patients, are a specific finding ([318]) and provide the most persistent clue of the ethanol-associated ring sideroblast defect. Megaloblastic hematopoiesis resulting from folate deficiency is frequent but is not always present ([318]). Another common finding is vacuolization of pronormoblasts. The percentage of marrow ring sideroblasts ranges from 10 to 70%, and they typically represent later stage normoblasts. Marrow iron stores usually are increased, as are the serum transferrin saturation and the serum ferritin level.

Withdrawal of alcohol is followed by disappearance of ring sideroblasts within a few days to 2 weeks ([319]) (Fig. 29.7). Recovery from the anemia may occur over several weeks and also depends on the presence of other erythroid defects induced by alcohol ([319]) (see Chapter 43) as well as any associated medical illness that affects erythropoiesis. A prompt recovery phase may exhibit reticulocytosis and erythroid hyperplasia in the bone marrow resembling hemolytic anemia ([319]).

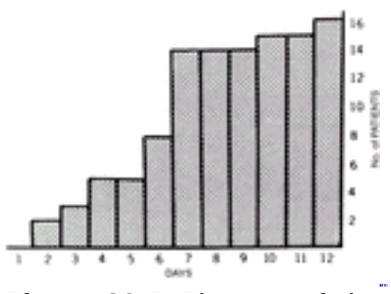

Figure 29.7. The rate of clearance in days of ring sideroblasts in 16 alcoholic patients after alcohol intake ceased. (From Eichner ER, Hillman RS. The evolution of anemia in alcoholic patients. Am J Med 1971;50:218–232, with permission.)

Drugs

ANTITUBERCULOUS AGENTS Reversible sideroblastic anemia occurs in association with the treatment of tuberculosis with INH; in a few patients, pyrazinamide and cycloserine also were implicated ([8]). These drugs interfere with vitamin B_6 metabolism, and deprivation of PLP reduces ALA synthesis and, thus, heme production ([8]). INH reacts with pyridoxal to form a hydrazone and inhibits pyridoxal phosphokinase. Bone marrow ALA synthase activity is also inhibited by INH in a dose-dependent manner *in vitro* and is restored by PLP ([124]). Cycloserine inhibits PLP-requiring enzyme reactions and directly inactivates pyridoxal ([8]). Pyrazin-amide appears to have anti–vitamin B_6 properties ([48]), but a specific mechanism has not been determined. The sideroblastic anemia that is inducible in guinea pigs with pharmacologic doses of INH and cycloserine ([49], [50]) is accompanied by reduced levels of blood PLP and PLP-dependent enzyme activities, including bone marrow ALA synthase ([50]). The relative incidence of severe anemia in relation to the extensive use of these drugs appears to be low, perhaps because of the regular concomitant administration of pyridoxine. Unknown contributory factors or another hematologic disorder may render certain individuals more susceptible to the antipyridoxine effects of the drugs ([8]). In one study, ring sideroblasts or increased erythroblast iron was found in 58% of all patients treated for tuberculosis ([336]). Anemia has occurred from 1 to 10 months after institution of INH treatment. It is moderately severe (volume of packed red cells, 0.20 to 0.26 L per L), the red cell indices are usually reduced, and the erythrocytes show dimorphic morphologic features with prominent hypochromia and microcytosis ([337]). Ring sideroblasts are invariably present in the bone marrow. Serum pyridoxal concentrations were subnormal in most patients studied ([338], [339]). Transferrin saturation tends to be increased. The anemia usually is promptly and fully reversed on withdrawal of the drug or by administering large doses of pyridoxine while continuing use of the drug.

CHLORAMPHENICOL The dose-dependent and reversible hematologic toxicity of chloramphenicol is characterized by suppression of erythropoiesis ([340]) and by the ring sideroblast abnormality ([5], [51], [341], [342]). A primary mitochondrial injury by the drug impairs heme synthesis as well as erythroid differentiation and proliferation. Therapeutic concentrations of chloramphenicol (10 µg/ml) inhibit the synthesis of mitochondrial membrane proteins, such as cytochrome $a + a_3$ and *b*, and, thus, mitochondrial respiration ([343], [344]). Impaired heme synthesis is evident in reduced activities of ferrochelatase ([345]) and ALA synthase ([346]), which appear to be secondary effects because these enzymes are synthesized in the cytosol. The greater sensitivity of the erythroid cell line to chloramphenicol has been demonstrated *in vitro* in that therapeutic concentrations of the drug inhibit erythroid colony growth but not granulocyte colony growth ([347]). Higher concentrations of serine and glycine in erythroid cell mitochondria were considered to play a role ([348]). Erythrokinetic parameters reflect a hypoproliferative state. Reticulocytopenia, increased serum iron values, and prolonged plasma iron clearance are characteristic ([340]). These abnormalities, as well as the ring sideroblasts and anemia, disappear when the drug is withdrawn.

Copper Deficiency

Copper deficiency generally does not occur in humans because daily requirements are low relative to its wide distribution in food ([349]). It has developed after gastrectomy ([350]) and in the settings of prolonged parenteral nutrition ([351], [352], [353], [354] and [355]) and forced enteral feeding ([356], [357] and [358]) if copper was not included in the formulations. Copper deficiency also occurs with the use of copper chelating agents ([359]) and after consumption of zinc supplements for prolonged periods ([360]). In two instances, the deficiency developed from ingestion of coins and was attributed to their zinc content ([361], [362]). A unique syndrome of severe sidero-blastic anemia, central nervous system demyelination, and profound copper deficiency with or without increased serum zinc levels for which no source could be identified has recently been described in four cases ([363], [364] and [365]). Except for the latter syndrome, the manifestations are limited to anemia regularly accompanied by neutropenia.

The pathogenesis is understood in part from extensive studies of the severe anemia that develops late in the course of dietary copper deficiency in swine ([366]). The microcytic hypochromic anemia is associated with several defects of iron metabolism. Intestinal absorption and mobilization of iron from reticuloendothelial cells and hepatocytes to transferrin are impaired because of the associated lack of ceruloplasmin (ferroxidase). In reticulocytes of deficient animals, protoporphyrin production from glycine and ALA and ferrochelatase activity are not reduced ([367]), but iron metabolism in erythroid mitochondria is impaired in that heme synthesis from ferric iron and protoporphyrin is decreased ([368]). It was postulated that the reduction of ferric iron to ferrous iron is defective, being somehow linked to the diminished levels of cytochrome oxidase also observed. Low levels of intracellular copper enzymes, such as cytochrome oxidase, may interfere with hematopoiesis in other ways and also account for the neutropenia. The cause of copper deficiency after ingestion of excess zinc is attributed to induction of the intestinal protein metallothionein by zinc ([369]). The metallothionein then preferentially binds copper ([370]), prevents its absorption, and enhances its excretion ([371]). In the syndrome with central nervous system demyelination, a derangement of copper uptake by the enterocyte, which may also be somehow linked to increased uptake of zinc, is hypothesized.

The anemia is progressive and may be profound if untreated; the hemoglobin reached a level of 3.5 g per dl in one patient ([360]). The MCV usually is normal or slightly

increased at presentation, but a hypochromic microcytic red cell population is detectable on the blood smear. The granulocytes are usually less than 1000 per mm ^{3}; the platelet count is normal. The bone marrow tends to be hypoplastic, and vacuolization of early erythroid and granulocytic precursors is another typical finding. In most instances, moderate numbers of ring sideroblasts are observed. Serum iron levels and transferrin saturation are normal. The serum copper and ceruloplasmin levels are uniformly low. In cases of zinc-induced copper deficiency, serum zinc levels are increased from two- to threefold above the mean normal value.

With correction of the copper deficit, recovery is prompt and complete. In some cases, recovery followed discontinuation of the excess zinc intake alone. Zinc as a therapeutic agent should thus be prescribed with caution ([372], [373]), and its use as a supplement promulgated by food faddists is discouraged.

Hypothermia

In 1982, O'Brien and co-workers described three patients who, during episodic hypothermia, exhibited erythroid hypoplasia and ring sideroblasts as well as thrombocytopenia in the presence of a normal number of megakaryocytes ([374]). As the body temperature returned to normal, these changes slowly reversed. The ring sideroblast abnormality might be explained by the well-known inhibition of the translocation of proteins into mitochondria by reduced temperature ([374], [375]). Heme synthesis ([376]) and iron incorporation into hemoglobin by reticulocytes ([377]) have also been shown to be diminished at lowered temperatures.

DISORDERS OF ERYTHROID HEME SYNTHESIS WITHOUT RING SIDEROBLASTS

Anemia of Lead Poisoning

Lead poisoning has occurred from a wide array of sources that includes lodged bullets, inhaled fumes in various industries or from lead particles in a firing range, ingested contaminated herbs and food supplements, and beverages containing lead solubilized from glazes of utensils and linings of stills ([378], [379]). In children, the primary source is ingestion of lead-based paint chips. Organic lead is acquired by absorption through the skin or by gasoline sniffing. Heterozygotes of hereditary ALA dehydratase deficiency are said to be more susceptible to lower levels of lead exposure ([380]), as are persons with one or both genes for the less common allele (*ALAD2*) of the enzyme ([381]). Although lead has been eliminated from various consumer products and occupational exposure is monitored, it remains the most common cause of occupational poisoning worldwide ([382]).

The anemia that accompanies lead poisoning (plumbism) is in part the result of various inhibitory effects of lead on heme biosynthesis ([383], [384]). Most steps in the heme biosynthetic pathway are inhibited by lead to varying degrees. Presumably, lead displaces an essential metal or reacts with active-site thiol groups of the enzymes, but the precise mechanism is not worked out in most cases. ALA dehydratase is most sensitive to lead *in vitro* and *in vivo*, followed by the ferrochelatase, coproporphyrinogen oxidase, and PBG deaminase steps, respectively. The effects of lead on the production of heme are also interrelated with iron metabolism. In erythroid cells, lead limits the intracellular delivery of iron to the site of ferrochelatase, and the surrogate metal zinc is inserted into protoporphyrin by ferrochelatase as in iron deficiency ([385], [386]) so that zinc protoporphyrin accumulates. The reduced iron supply to the site of heme synthesis probably accounts for the usual absence of the ring sideroblast abnormality in persons with lead intoxication. Ferrochelatase may be directly inhibited in acute and more severe lead intoxication, and, only then, nonchelated protoporphyrin accumulates in erythrocytes ([387], [388] and [389]). Lead also impairs globin synthesis ([390], [391]). With prolonged lead exposure, erythroid hypoplasia may occur ([392]).

Other effects of lead increase the rate of red cell destruction. Changes in the spatial arrangement of red cell membrane proteins caused by lead are believed to inhibit adenosine triphosphatase, leading to cellular loss of K^{+} ([393]). If the lead burden is sufficiently severe (i.e., with blood lead concentrations of 200 µg per dl or greater), impaired erythrocyte pyrimidine 5'-nucleotidase activity causes accumulation of nucleotides that inhibit the pentose phosphate shunt ([394]) and promote hemolysis as in the genetically determined deficiency of the enzyme ([395]) (see Chapter 33).

The typical clinical manifestations are autonomic neuropathy causing abdominal pain and ileus (lead colic) and motor neuropathy (lead palsy) ([396]). A lead line may be seen on the gums (Fig. 29.8) and tonsils. Occasionally, renal dysfunction (lead nephropathy) may prompt the diagnosis. These classic features denote advanced lead toxicity, and more recent experience indicates that insidious, nonspecific musculoskeletal and neuropsychiatric complaints are more prevalent ([378]).

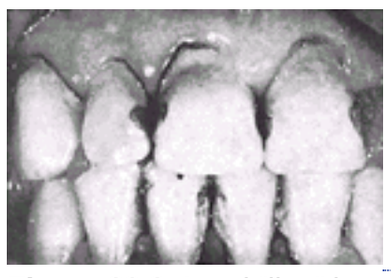

Figure 29.8. Lead “line” in a patient with plumbism. Under a hand lens, the lead line of blue-black sulfide, actually deposited in the gums immediately opposite to the teeth, appears as a clear row of dots or vertical streaks. (From Belknap EL. Differential diagnosis of lead poisoning. JAMA 1949;139:818–825, with permission.)

The hematologic changes in lead poisoning are variable, perhaps because of the diverse effects on the erythron. In a recent series of adult patients, anemia was present in only 25% of individuals ([378]). Anemia in children is also a late sign of lead poisoning by current standards ([397]) and frequently is compounded by iron deficiency ([398]). The severity of the anemia ranges from mild to moderate, and the red cells tend to be mildly hypochromic and microcytic (Table 29.4). The reticulocyte count may be raised in patients with overt hemolysis ([396]). Coarse basophilic stippling may be prominent (Fig. 29.9), representing aggregated ribosomes that presumably are retained because RNA degradation is impaired as a result of the pyrimidine 5'-nucleotidase deficiency, but it is not always found and does not correlate with the lead burden ([399]). Osmotic fragility of the erythrocytes is decreased; mechanical fragility is increased consequent to the membrane injury ([399]). An electrophoretically “fast” hemoglobin similar to hemoglobin A_3 may be found ([400]). In some patients, increased levels of hemoglobins A_2 and F were reported ([401]). The bone marrow usually reveals erythroid hyperplasia, but it may be hypoplastic. Authentic ring sideroblasts are uncommon, if they occur at all.

TABLE 29.4. Hematologic Changes in the Anemia of Lead Poisoning in Adults

		Normal (Range)	Lead Poisoning (Range)
Hemoglobin (g/dl)	♂	14.0–18.0	10.7
	♀	12–16	(8–13)
Volume packed red cells (L/L)	♂	0.40–0.54	0.35
	♀	0.37–0.47	(0.29–0.43)
Mean corpuscular volume (fl)		89 (83–96)	79 (70–92)
Mean corpuscular hemoglobin concentration (g/dl)		34 (32–36)	31 (27–36)
Reticulocytes (%)		1.6 (0.6–2.7)	4.4 (1.5–11.6)
Stippled cells (%)		Rare	1.8 (0.1–7.5)
Leukocytes (×10 ^{9}/L)		4–11	4–15

Adapted from Dagg JH, Goldberg A, Lochhead A, Smith JA. The relationship of lead poisoning to acute intermittent porphyria. QJM 1965;34:163–175; and Griggs RC. Lead poisoning: hematologic aspects. Prog Hematol 1964;4:117–137.

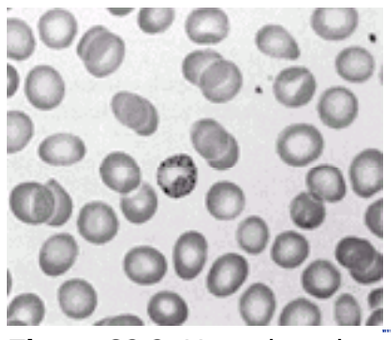

Figure 29.9. Hypochromia and red cell stippling in lead poisoning. See Color Plate.

The mean red cell lifespan is reduced with a random pattern of destruction despite problems with the accelerated ^{51}Cr elution from red cells due to lead effects on the red cell membrane ([402]). Serum iron levels tend to be normal or slightly increased unless the patient has associated iron deficiency. The findings of ferrokinetic studies are consistent with ineffective erythropoiesis accompanied by mild hemolysis ([402]).

Parameters of heme biosynthesis (porphyrin changes) reflect the inhibition of the various enzymatic steps and correlate with the lead burden ([383]). ALA dehydratase activity in erythrocytes is reduced in proportion to blood lead levels, and, in contrast to the hereditary deficiency of the enzyme, its *in vitro* activity is restored to normal by reducing agents such as glutathione or dithiothreitol ([383]). As a consequence of the reduced activity, urinary ALA is greatly increased, whereas levels of PBG are rarely increased, a combination that helps to distinguish plumbism from acute intermittent porphyria, in which PBG is excreted in greater excess than ALA. Urinary coproporphyrin, and to a lesser degree uroporphyrin, levels are also increased in lead poisoning. The zinc protoporphyrin level in erythrocytes is increased more than in iron deficiency.

The upper limit of the “normal” level of blood lead, which is mostly contained in erythrocytes ([403]), is 30 µg per dl of whole blood. Adults with concentrations of 30 to 75 µg per dl show decreased ALA dehydratase activity, increased urinary excretion of ALA, and an increase in erythrocyte protoporphyrin ([404]) and may have nonspecific mild symptoms of lead poisoning. Clear symptoms usually are associated with concentrations that exceed 75 µg per dl. Concentrations in urine greater than 0.1 mg per 24 hours also establish the diagnosis of lead intoxication. When urinary lead excretion is borderline, response to slow intravenous infusion of 25 mg/kg (not to exceed 2 g) of the chelator calcium disodium ethylenediaminetetraacetic acid can confirm the diagnosis; excretion of more than 0.2 mg of lead in 24 hours indicates an increased lead burden.

Treatment consists of removal of the lead source and administration of ethylenediaminetetraacetic acid, 50 mg/kg/day in two divided doses, by slow intravenous infusion with ample fluids for 5 days ([379] , [404]). This regimen may be repeated in 3 to 4 weeks, depending on the response of blood lead levels. Renal function should be monitored. Recovery usually is prompt. An oral chelating agent, 2,3-dimercaptosuccinic acid, is available for use in children ([405]).

Certain Porphyrias

Heme biosynthesis is strikingly perturbed in the various porphyrias that result from heterogeneous molecular defects at any specific step of the pathway beyond the ALA synthase step (see Chapter 31). Tissue-specific differences of expression and of regulation of most of the heme pathway enzymes likely account for the usual absence of anemia because, in the porphyrias, the defective enzymes do not become rate-limiting in the erythroid cell. In a few of them, erythroid heme production may be minimally compromised, as noted for protoporphyria previously, or accumulation of biosynthetic intermediates perturbs erythroid cell development, survival, or both.

CONGENITAL ERYTHROPOIETIC PORPHYRIA In this rare disorder, expressed as an autosomal-recessive trait, erythroid heme biosynthesis is not diminished ([406] , [407]). Because of the low residual uroporphyrinogen III synthase activity, uroporphyrin I is overproduced and occurs mainly in erythroid cells. Variable anemia is associated with dyserythropoiesis and varying degrees of peripheral hemolysis. The porphyrin accumulates in the nuclei of developing erythroblasts and is believed to affect their maturation. Anemia often is not the principal clinical problem. In some patients, the hemolytic process is improved by splenectomy.
HEPATOERYTHROPOIETIC PORPHYRIA Hepatoerythropoietic porphyria represents the homozygous deficiency of uroporphyrinogen decarboxylase and usually is expressed as a severe form of porphyria cutanea tarda from birth ([408]). More than 20 cases have been reported, and mild anemia was noted in one elderly sibling pair ([409]). The level of FEP as zinc protoporphyrin was elevated in all cases and is attributed to a relatively increased conversion of uroporphyrinogen III to protoporphyrin late in erythroid maturation when ferrochelatase becomes rate-limiting. The anemia, if it occurs in some homozygotes, has not been characterized.
HEREDITARY COPROPORPHYRIA (HARDEROPORPHYRIA) Anemia has been encountered only in the harderoporphyria variant of coproporphyria (see Chapter 31), in which large amounts of the tricarboxylic harderoporphyrin accumulate ([410] , [411]). Affected individuals carry homozygous or compound heterozygous mutations in the coproporphyrinogen III oxidase gene, and the expressed mutant enzyme has approximately 24% residual activity. Clinically, a hemolytic anemia is evident at birth, with hyperbilirubinemia, hepatosplenomegaly, and photosensitivity, but neurovisceral symptoms of acute porphyrias are absent. The anemia seems attributable to, at least, a photohemolysis component, in that erythrocyte porphyrin (reported as protoporphyrin) was increased approximately eightfold when compared to values in related asymptomatic heterozygotes, and it lessened with age. The mechanism has not been further characterized.

Miscellaneous

Several patients with congenital hypochromic microcytic anemia, hyperferremia, and iron overload of the liver but with reduced bone marrow iron content have been described ([412] , [413] and [414]). Findings of morphologic and ferrokinetic studies suggest a defect in the delivery of iron to erythroid cells. In two patients, bone marrow ferrochelatase activity was reduced by 80%, although its activity in the liver was normal ([414]). In a third patient, reticulocyte ferrochelatase activity was 6% of normal, and several mitochondrial enzymes were similarly affected in the liver ([413]). None of these patients exhibited ring sideroblasts, and the precise defects remain to be defined.

Hemochromatosis

IRON OVERLOAD

Iron overload can result from any process that causes iron accumulation in excess of iron loss. Examples of this include (a) red blood cell transfusions in individuals who do not experience blood loss (hemolytic anemia, aplastic anemia, sideroblastic anemia); (b) absorption of excessive amounts of normal daily dietary iron (hemochromatosis); and (c) absorption of increased amounts of excessive dietary iron (high-dose medicinal iron, African iron overload, wine with high iron content).

HEMOCHROMATOSIS

Definition

The proper definition of *hemochromatosis* is the presence of two copies of a mutation of the hemochromatosis gene (called *HFE gene*). An individual can have two copies of HFE gene mutations with or without iron overload and with or without illness or organ injury.

History

The first report of a person with hemochromatosis was included in a discussion of diabetes mellitus in 1865 ([1]). The patient was a 28-year-old Parisian man who sold newspapers and who died of a febrile illness complicating diabetes mellitus. His autopsy revealed hepatomegaly and hypertrophic cirrhosis.

The second case report of hemochromatosis was in 1871, involving a 51-year-old man who lived in Paris ([2]). He had skin bronzing of his face and hands. His autopsy revealed a chocolate-colored, enlarged liver. Microscopic examination of his liver showed pigment granules inside and outside of hepatocytes.

In 1886, the term *pigmentation cirrhosis* was used to describe the triad of skin bronzing, diabetes mellitus, and hepatic cirrhosis ([3]). The name *hämochromatose* was first used by von Recklinghausen in his 1889 description of 12 individuals who had pigmentation of multiple organs ([4]). He believed that the iron that accumulated in organs came from red blood cells.

Etiology

Before 1975, the cause of hemochromatosis was vigorously debated. Some investigators believed the disorder was heritable ([5]), whereas others insisted that its cause was alcohol abuse ([6]); additional considerations of cause included copper loading or ingestion of excessive dietary or medicinal iron.

In 1974, the results of segregation analysis in pedigree studies indicated that hemochromatosis was transmitted as an autoso-mal-recessive condition ([7]). One year

later, a high frequency of the HLA-A3 alloantigen was observed in five of seven subjects who had hemochromatosis ([8]). Linkage analysis in several centers provided strong evidence that the hemochromatosis allele was linked to the HLA locus on the short arm of chromosome 6 and that hemochromatosis was transmitted as an autosomal-recessive disorder ([9], [10], [11], [12], [13], [14] and [15]).

CLONING OF THE HEMOCHROMATOSIS GENE

In 1996, the hemochromatosis gene was isolated by positional cloning ([16]). The discoverers called the gene *HLA-H*, because its organization and structure were similar to genes in the HLA region that coded for HLA class I heavy chains. However, subsequent review determined that an HLA class I pseudogene located between the HLA-A and HLA-B loci had already been named and included in the Genome Databank as *HLA-H* ([17]). The Genome Databank also already included the designation *HFE* for the as yet unidentified hemochromatosis gene. To resolve this confusion, the name of the newly cloned and sequenced hemochromatosis gene was changed to *HFE* ([18], [19]).

FUNCTION OF THE HEMOCHROMATOSIS GENE

Before the isolation and cloning of the HFE gene, an animal model of iron loading was developed. The ß $_2$-microglobulin knock-out mouse expressed the hepatic iron-loading phenotype of human hemochromatosis ([20], [21] and [22]). These findings suggested that ß $_2$ microglobulin was involved in the regulation of iron absorption.

The normal HFE gene encodes for the production of normal HFE protein, which is expressed in crypt cells in the duodenum and in reticuloendothelial cells ([23]). In a normal individual with adequate body iron stores, the HFE protein binds to ß $_2$ microglobulin, which decreases the affinity of cell membrane transferrin receptors for transferrin, its ligand ([24], [25], [26] and [27]). This results in decreased iron absorption. In an iron-deficient individual, synthesis of HFE protein is decreased, there is less binding of HFE protein to ß $_2$ microglobulin, there is increased affinity of the transferrin receptor for transferrin, and more iron is absorbed by duodenal crypt cells.

EFFECTS OF THE HEMOCHROMATOSIS GENE MUTATION

The ß $_2$-microglobulin binding site on the HFE protein has two cysteine molecules that form a disulfide bridge in the binding site. In an iron-loaded individual with the Cys282Tyr mutation, tyrosine replaces a cysteine molecule. Because there are not two cysteine molecules, the disulfide bridge is absent. This prevents the abnormal HFE protein from binding to ß $_2$ microglobulin appropriately on the cell surface. Excessive iron is then absorbed through the crypt cells and passed into the circulation. The mechanism of HFE regulation of iron absorption remains unknown and is the subject of vigorous investigation ([28], [29], [30], [31], [32] and [33]).

PATHOPHYSIOLOGY

Normal humans absorb and lose approximately 1 mg of iron each day. Duodenal absorption of iron increases when iron deficiency occurs then drops to 1 mg/day after iron deficiency is corrected. Iron absorption decreases when iron stores are repleted.

In iron-loaded subjects with hemochromatosis, iron absorption usually is greater than 2 mg/day at a time when iron absorption should have decreased to nearly zero. After phlebotomy therapy induces iron deficiency in people with hemochromatosis, iron absorption may increase up to 10 mg/day and remains inappropriately elevated long after iron deficiency resolves ([34], [35] and [36]).

The basic cause of iron accumulation in hemochromatosis is the failure to down-regulate duodenal enterocyte absorption of iron. After iron absorption remains elevated for many years, liver iron storage sites become overloaded, and iron accumulates in the spleen, myocardium, pancreas, anterior pituitary, and other organs. Individuals with hemochromatosis may have a body iron burden that is more than ten times normal. Usually, such individuals do not develop symptoms or signs of illness until after they have been iron loaded for four to five decades. This suggests that heavy iron overload must be present for many years before sufficient organ injury occurs to cause recognizable symptoms or signs. Exceptions include the organ damage and death that occur in a few heavily iron-loaded children or teenagers in juvenile hemochromatosis.

Iron that is stored in modest amounts in ferritin is thought to be nontoxic. In the presence of excessive iron stores, reactive oxygen species are generated, especially the hydroxyl radical ([37], [38], [39] and [40]). It seems likely that the hydroxyl radical and the alkoxyl and peroxyl radicals are involved in lipid peroxidation, which damages microsomes, mitochondria, and lysosomes. Hydroxyl radicals are also thought to be involved in iron-related injury and damage of enzymes, DNA, and polysaccharides. Lipid peroxidation, lysosomal injury, and damage of mitochondria, endoplasmic reticulum, cell membranes, and DNA were discussed recently ([37], [38]).

HEMOCHROMATOSIS GENE

The HFE gene is located approximately 4 megabases telomeric to the HLA region. The HFE gene is structurally somewhat similar to other HLA class I–like genes. The HFE gene is composed of seven exons, of which the first six exons encode for the six domains of the HFE protein. The seven exons of HFE result in formation of a messenger RNA transcript that is approximately 4.2 kilobases in size. This in turn results in the synthesis of the HFE product, which consists of 343 amino acids. The most common iron-loading mutation of HFE (C282Y) is caused by a mutation of one nucleotide base (845G?A) in exon 4 of the HFE gene ([16]).

Hemochromatosis Gene Mutations

More than 30 mutations of the HFE gene have been reported (Table 30.1). The most common mutation that occurs in people who have hemochromatosis is a change in nucleotide 845 from the normal guanidine to adenine in exon 4 of the HFE gene (referred to as *845G? A*). This nucleotide change results in the substitution of tyrosine in place of the normal cysteine in position 282, referred to as *Cysteine282Tyrosine*, *Cys282Tyr*, or *C282Y*. This mutation causes the majority of iron accumulation in subjects who have hemochromatosis ([16]).

TABLE 30.1. Twenty-Three Mutations of the Hemochromatosis Gene (HFE) in Hemochromatosis Type 1: Nucleotide and Amino Acid Changes, Type of Mutation, Exon or Intron Involved, and Effect of the Mutation on Iron Loading

?, increased??, markedly increased;?, effect unknown; A, adenine; C, cytosine; G, guanine; IVS, intron sequence variant; T, thymine.

The second most common HFE gene mutation in hemochromatosis patients is a change in nucleotide 187 from the normal cytidine to guanidine (187C?G) in exon 2. This results in substitution of aspartate for the normal histidine at amino acid position 63. Both the C282Y and H63D mutations were identified in the initial report of the isolation and cloning of HFE (16). It is expected that additional mutations of the HFE gene will be identified in adults with hemochromatosis.

Of the known mutations of the HFE gene, 13 are missense mutations that result in substitution of the normal amino acid by another. There are seven known nonsense mutations of the HFE gene, six of which are splice errors that are associated with intron sequence variants. Two mutations involve a nucleotide change that does not result in an amino acid substitution. Some of the important known HFE gene mutations appear in Table 30.1. Mutations that occurred in noncoding regions of the HFE gene were discussed in detail in 2000 (54).

Hemochromatosis Gene Mutations in Hemochromatosis Patients

In the first report of the discovery of the HFE gene and its mutations, 83% of subjects with hemochromatosis were C282Y homozygotes (16). The prevalence of homozygosity for C282Y varies among populations from 33 to 100%. In the United States, 59 to 89% of hemochromatosis patients are C282Y/C282Y homozygotes. The percentage of hemochromatosis patients from 13 countries and Scandinavia with the C282Y and H63D genotypes appears in Table 30.2.

Prevalence of Hemochromatosis Gene Mutations in Different Populations

There are some populations that have a high prevalence of HFE mutations, such as Central, Western, and Northern Europe, and countries that were populated by people who originated in these areas, including the United States, Canada, and Australia (67 , 93). It is expected that the population prevalence of HFE mutations should be very low in parts of the world with little or no ancestry in Central and Western Europe, including sub-Saharan Africa, the Middle East, the Orient, and Native Americans in North, Central, and South America. The reported frequency of the C282Y and H63D mutations in several areas and populations of the United States appears in Table 30.3. The frequency of the C282Y mutation in the United States varies from 0 to 1.00% in whites; 0 to 0.22% in Mexican Americans; and 0 to 0.06% in blacks (Table 30.3). Comprehensive tabular data about genotype frequencies in many countries and in regions of different countries have been published (93 , 100).

Association of Iron Loading and Hemochromatosis Gene Mutations

Some mutations are associated with major iron loading, such as C282Y, R330M, IVS3 (+1) G?T, E168X, C282S, and R74X (Table 30.1). Some mutations are believed to have a modest or moderate effect on iron accumulation, such as H63D, S65C, G93R, I105T, and E168Q. Other mutations of HFE have been identified in individuals in whom iron loading was not present or in whom the effect of the mutation on iron accumulation could not be determined, such as V53M, V59M, Q127H, E277K, and in several intron sequence variants. The HFE mutations with major, mild, or unknown effects on iron accumulation are shown in Table 30.1.

FREQUENCY OF HEMOCHROMATOSIS IN MEN AND WOMEN

Because hemochromatosis is transmitted as an autosomal-recessive condition, there should be equal numbers of male and female homozygotes. Overt iron overload organ injury and illness occur more frequently in men than in women with this disorder. Comparing groups of homozygotes, men with hemochromatosis have approximately two and a half times as much mobilizable body storage iron as women. Of course, any woman with this disorder may be more heavily iron loaded than an affected man, but usually this is not the case. Women are protected somewhat by the loss of 15 to 25 mg of iron each month and by the transfer of approximately 750 mg of iron to the fetus during pregnancy.

Menstrual blood losses and pregnancy do not seem to explain all of the differences in body iron stores between male and female homozygotes. It is possible that an additional factor(s) prevents most women with hemochromatosis from absorbing and accumulating as much iron as affected men. Table 30.4 contains the frequency of symptoms and signs in groups of men and women with hemochromatosis from nine studies.

CLINICAL FEATURES OF HEMOCHROMATOSIS

Symptoms

The presence or absence of symptoms in subjects with hemochromatosis is related directly to the stage at which the diagnosis is established. Individuals who are found to have hemochromatosis during a routine office visit are expected to have no organ injury at the time, and they often are not heavily iron loaded. This is a common occurrence among women, young men, and children, and among the healthy siblings who undergo family screening after a proband is discovered.

Subjects in whom the diagnosis of hemochromatosis is established after seeking medical attention because of illness are expected to have symptoms of illness. These individuals usually are iron overloaded and have evidence of organ injury. The frequency of symptoms, physical signs, and laboratory abnormalities in subjects with hemochromatosis (sick probands) compared to probands who are identified during screening compared to their homozygous relatives who were identified during family evaluation (clinically unselected homozygotes) appear in Table 30.5, Table 30.7, and Table 30.8. Approximately 90% of people who are found to have hemochromatosis during screening are asymptomatic.

[a] If a subject had more than one of the four conditions listed, he or she was classified as having only the condition listed first.

[b] Arrhythmia was documented by electrocardiography.

From Bulaj ZJ, Ajioka RS, Phillips JD, et al. Disease-related conditions in relatives of patients with hemochromatosis. N Engl J Med 2000;343:1531, with permission.

The most common symptom in hemochromatosis patients is arthralgias, present in approximately 40% of homozygotes at the time of diagnosis (101 , 102). The joints most commonly involved are the metacarpal-phalangeal joints, especially the second and third (103). Knees, hips, shoulders, and other joints also can be symptomatic.

Other symptoms that are common in subjects with hemochromatosis include weakness, fatigue, and lethargy. These symptoms are nonspecific. Weight loss, abdominal pain, loss of libido in men, and palpitations also may occur in iron-loaded homozygotes. The frequency of arthralgias, abdominal pain, loss of libido or impotence, and palpitations from different study populations appears in Table 30.4 and Table 30.5.

Physical Examination Abnormalities

Gray or bronze pigmentation is the most common physical examination abnormality in hemochromatosis homozygotes, occurring in approximately 35 to 84%. Other common physical examination findings include arthropathy (13 to 68%), hepatomegaly (54 to 93%), splenomegaly (10 to 55%), irregular heart beat, congestive heart failure, telangiectases, and loss of midline body hair or testicular atrophy. The frequency of physical abnormalities in hemochromatosis from nine studies is shown in Table 30.4.

Laboratory Abnormalities

The most common laboratory abnormalities in subjects with hemochromatosis are elevation of serum iron concentration, percent saturation of transferrin average, and serum ferritin concentration. Transferrin saturation may be elevated in children or teenage homozygotes before serum ferritin elevation occurs, long before symptoms or physical examination abnormalities develop. The results of transferrin saturation and serum ferritin concentration in normal individuals, hemochromatosis heterozygotes, compound heterozygotes, and homozygotes according to HFE genotype from a very recent and large U.S. population study appear in Table 30.6. The typical values of transferrin saturation according to method of ascertainment in 505 Utah homozygotes appear in Table 30.7.

TABLE 30.6. Values of Transferrin Saturation and Serum Ferritin Concentration in Men and Women According to the Hemochromatosis Gene Genotype from a U.S. Population Study

	wt/wt	C282Y/wt	C282Y/H63D	C282Y/C282Y

Serum [a] ferritin (ng/ml)	52	56	70	159

wt, wild type.

[a] Geometric mean.

From Beutler E, Felitti VJ, Koziol JA, et al. Penetrance of 845G?A (C282Y) HFE hereditary haemochromatosis mutation in the USA. Lancet 2002;359:211–218, with permission.

Radiographs of hands are often abnormal in homozygotes who have arthralgias. Approximately 50% of homozygotes have radiographic changes. The plain films reveal narrowing of the metacarpal-phalangeal joint spaces, subperiosteal bone resorption, and periarticular demineralization (103). Plain films of knees may reveal chondrocalcinosis, calcium deposition in the cartilage that is visible across the joint space.

The next most common laboratory abnormality in patients with hemochromatosis is elevation of liver enzymes in serum alanine aminotransferase and aspartate aminotransferase, which occurs in 2 to 16% of subjects (Table 30.4, Table 30.5, Table 30.8, and Table 30.9). Usually, these enzymes are elevated to approximately two to five times the upper limit of normal. If hepatic failure is present, the enzymes may be very elevated, and jaundice may be present. Other common laboratory abnormalities include elevation of serum glucose concentration (8 to 36%); an arrhythmia on electrocardiography; cardiomegaly on chest radiography; a decreased ejection fraction on echocardiography; an elevated or very low thyroid-stimulating hormone in hypothyroidism or hyperthyroidism, respectively; and blood test evidence of hypogonadism, usually the hypogonadotrophic type with decreased serum concentrations of testosterone, dehydrotestosterone, leuteinizing hormone, and follicle-stimulating hormone (104). Table 30.4, Table 30.5, Table 30.8, and Table 30.9 show the frequency of lab abnormalities in individuals who have hemochromatosis.

TABLE 30.9. Age, Iron Phenotype, and Clinical Features of 194 Canadian Hemochromatosis Homozygotes [a]

	141 Men (M)		53 Women (W)		
	Discovered [a]	Probands	Discovered [a]	Probands	Normal Values
N	46	95	28	25	—
Age (yr)	48	53	54	63	—

Hepatocellular carcinoma (%)	1	5	0	5	—

[a] These data include observations on 120 probands and 74 other homozygotes discovered during evaluation of relatives or during screening, not due to illness. These data were adapted from Adams PC, Valberg LS. Evolving expression of hereditary hemochromatosis. Semin Liver Dis 1996;16:47–54. Frequency (%) was estimated from bar graphs. Numerical data not presented in original text.

From Barton JC, Edwards CQ, eds. Hemochromatosis: genetics, pathophysiology, diagnosis and treatment. Cambridge, UK: Cambridge University Press, 2000:315, with permission.

Liver Biopsy Findings

Liver biopsy usually is normal in young homozygotes whose serum ferritin is not elevated. When serum ferritin concentration is elevated, the hepatic parenchymal cell stainable iron is usually increased. The same comments apply to the measured hepatic iron concentration.

Many 40- to 50-year-old male homozygotes already have hepatic fibrosis at the time the diagnosis of hemochromatosis is established (2 to 32%) (Table 30.8). Approximately 20 to 92% of male homozygotes have cirrhosis at the time of diagnosis (Table 30.4). Most women with hemochromatosis do not have hepatic fibrosis or cirrhosis at the time of diagnosis. Hepatic cirrhosis is not expected to occur until the hepatic iron concentration is enormously elevated at approximately 22,000 µg (22 mg) of iron per gram of liver dry weight (normal, approximately 1000 µg iron per gram dry weight) ([105]).

Among homozygotes who are identified very late, 10 to 29% of those with cirrhosis develop hepatocellular carcinoma ([106], [107], [108] and [109]). Hepatocellular carcinoma in hemochromatosis may be multifocal rather than focal and may not cause the marked elevation of a-fetoprotein that is common in individuals who have a large nodular hepatoma. Multifocal hepatocellular carcinoma may not be visible by ultrasonography until nodules reach 1 cm in diameter. The frequency of hepatic fibrosis, cirrhosis, and hepatocellular carcinoma in hemochromatosis patients appears in Table 30.4, Table 30.5, Table 30.8, and Table 30.9.

HEMOCHROMATOSIS GENE MUTATIONS AND OTHER CONDITIONS

Hereditary Spherocytosis

Individuals who have hereditary spherocytosis may become heavily iron loaded and may develop hepatic cirrhosis when they are homozygous for HFE mutations. In a family that was studied in Utah, two brothers who were C282Y homozygotes were iron loaded ([110]). The propositus who had both hereditary spherocytosis and hemochromatosis had a much heavier body iron burden than his sibling who had hemochromatosis without spherocytosis. The son of the propositus was a C282Y/wild type (wt) heterozygote and had spherocytosis. His serum ferritin concentration and liver iron stores were only modestly elevated. The occurrence of homozygosity (or heterozygosity) for hemochromatosis and spherocytosis has been reported in several studies ([109], [111], [112], [113], [114], [115], [116] and [117]). In a 2002 report from Switzerland, a 37-year-old man who had hereditary spherocytosis was found to be homozygous for the C282Y mutation ([118]). After larger studies are performed and published, it will be possible to estimate the prevalence of one or more HFE mutations in subjects who have hereditary spherocytosis.

Arthritis

Hemochromatosis homozygotes with arthritis usually experience the onset of arthralgias in the second and third metacarpal-phalangeal joints ([119]). In some homozygotes, this may seem somewhat like rheumatoid arthritis, but the rheumatoid factor is usually negative. What looks like seronegative rheumatoid arthritis may in fact be the arthropathy of hemochromatosis. The knees are the next most frequently affected joints. Other joints also may be affected, including the proximal interphalangeal joints of the hands, wrists, hips, and shoulders ([101], [103], [106], [119], [120], [121], [122], [123], [124], [125], [126], [127], [128], [129], [130], [131], [132], [133], [134] and [135]). Initially, the metacarpal-phalangeal joints often are swollen, and there is decreased range of motion and limited ability to make a claw or fist. Hand radiographs reveal periarticular demineralization, loss of joint space, subperiosteal bone resorption, and the presence of spurs. Radiographs of the knees often reveal chondrocalcinosis ([103]).

There are reports of HFE gene mutation testing in patients who have arthritis. In a 1998 report, HFE mutations were sought in a group of 1000 patients who had inflammatory arthritis and in 1000 normal control subjects ([136]). Nearly all (94%) were whites who were born in England. Five patients in both the inflammatory arthritis group and the control group were found to be homozygous for the C282Y mutation of the HFE gene. This is the same as the frequency of homozygosity in the general European white population. These results are not surprising because the arthritis of hemochromatosis usually is of gradual onset rather than an acute inflammatory arthritis. Additional studies of HFE gene mutations in patients who have arthritis have been published. There are reports of rheumatoid factor–positive rheumatoid arthritis and homozygosity for the C282Y mutation ([130]).

In a study of the prevalence of the C282Y and the H63D mutations in a group of 92 patients who had rheumatoid arthritis and in 87 control subjects, 6.5% of the rheumatoid patients had the C282Y mutation, no different than in controls (6.9%) ([137]). The H63D mutation was present in 40% of the rheumatoid arthritis patients compared with 21% of control subjects. The increased frequency of the H63D mutation was present in the rheumatoid arthritis patients who were positive for a chromosome 6p HLA-DR epitope that is associated with increased susceptibility to, and severity of, rheumatoid arthritis (HLA-DRB1 QKRAA/QKRAA). The authors considered both H63D and the HLA-DRB1 QKRAA/QKRAA epitope to individually convey susceptibility to rheumatoid arthritis and that the combination of H63D and the epitope strengthened this susceptibility.

Diabetes Mellitus

Diabetes was present in the original case report of a patient with hemochromatosis. Although diabetes and hemochromatosis are known to segregate independently as genetic traits ([7]), diabetes is common in patients with far advanced hemochromatosis with cirrhosis (Table 30.4, Table 30.5, Table 30.8, and Table 30.9) ([107], [138], [139] and [140]). Uncontrolled studies have been performed to determine the prevalence of hemochromatosis in patients who have diabetes mellitus (ranging from 0.49 to 0.96%) ([141], [142] and [143]). In a study that was designed to identify hemochromatosis on the basis of blood tests and liver tests of iron stores, 894 diabetics (777 type II; 117 type I) and 467 control subjects were evaluated. Twelve type II diabetics (1.3%) and one control subject (0.2%) were found to have previously undiagnosed hemochromatosis. The diagnosis of hemochromatosis was not considered in these 12 individuals despite lengthy follow-up for diabetes type II. Transferrin saturation was 70 to 100%, and serum ferritin concentration was elevated at 620 to 3200 in the 12 patients found to have hemochromatosis ([144]).

In a study of HFE mutations in 220 male patients with diabetes type II, 0.45% were C282Y homozygotes, and 1.30% were C282Y/H63D compound heterozygotes. These results were similar to the prevalence of HFE mutations in the normal control group ([145]). In a study of the prevalence of late-onset type I diabetes, 1.30% of 716 diabetics were C282Y/C282Y homozygotes compared with 0.25% of 9174 control subjects. The prevalence of C282Y/H63D compound heterozygosity was similar in the diabetic and the control populations ([146]). A large study of the prevalence of HFE mutations and diabetes was published in 2002. Of 22,347 control subjects who did not have mutations of the HFE gene, 8.4% had diabetes compared with 5.6% of 124 C282Y homozygotes. Diabetes was present in 7.0% of C282Y/H63D

compound heterozygotes ([147]). A thorough review of diabetes and hemochromatosis was published in 2000 ([148]).

Other Endocrinopathy

Hypogonadism, thyroid disease, and adrenal insufficiency also occur in hemochromatosis patients, usually only in those who have been heavily iron loaded for decades. Of nondiabetic endocrinopathy in hemochromatosis, the second most common type is hypogonadism (Table 30.4, Table 30.5, Table 30.8, and Table 30.9). This is usually of the hypogonadotrophic type. Iron is deposited in the anterior pituitary secretory cells ([5] , [104] , [149] , [150] and [151]). In a study of mostly iron-depleted male hemochromatosis patients, 47% had hypogonadotrophic hypogonadism. The evidence for this was that these patients had low baseline serum concentrations of testosterone and low gonadotrophin concentrations, and these did not increase after administration of gonadotrophin-releasing hormone ([152]). Other smaller studies have demonstrated similar results ([104] , [152] , [153] , [154] , [155] , [156] , [157] and [158]).

Hypothalamic dysfunction may occur in hemochromatosis patients ([159] , [160] , [161] and [162]). A very good discussion of the pituitary-adrenal axis, the thyroid and parathyroid glands, testicles and ovaries, and their function in patients with hemochromatosis was published in 2000 ([104]).

Hepatocellular Carcinoma

Individuals with hemochromatosis who have cirrhosis have a 219-fold increased risk for the development of hepatocellular carcinoma ([107]) In those patients with end-stage hemochromatosis and cirrhosis, 10 to 29% develop hepatoma, although the great majority do not ([106] , [107] , [108] and [109]) (Table 30.8 and Table 30.9). There are also reports of hepatoma in hemochromatosis patients who did not have cirrhosis ([163] , [164] and [165]). The histologic classification of primary liver cancer in hemochromatosis reveals heterogeneity. Although the majority of primary liver cancers in hemochromatosis are of the hepatocellular type, biliary cancers also occur, including cholangiocarcinoma and combined hepatocellular cholangiocarcinoma ([109] , [165]).

In a study from Italy, 81 individuals with hepatocellular carcinoma and without known hemochromatosis were tested for the C282Y and H63D mutations. These results were compared to mutation testing in 128 normal individuals who did not have liver disease. Of the patients with hepatoma, 8.6% had a C282Y mutation, and 30.0% had an H63D mutation. Of the healthy controls, 1.6% had a C282Y mutation, and 24.0% had an H63D mutation. In the same study, the authors found an association between the C282Y mutation, serologic evidence of viral hepatitis, alcohol intake, and hepatocellular carcinoma ([166]). There are some reports that did not reveal an increased prevalence of HFE mutations in patients with hepatoma compared to control subjects ([167]). In a study of 61 cirrhotic patients without known hemochromatosis who underwent resection of the liver because of hepatoma, the prevalence of HFE mutations was significantly greater than in normal individuals ([168]).

Other Types of Cancer

There is evidence in the literature that iron can be carcinogenic. Possible mechanisms of carcinogenesis include redox cycling of iron, resulting in the production of reactive oxygen species and free radicals, which in turn causes lipid peroxidation and damage to proteins and DNA ([169]). Iron may facilitate tumor cell growth and may modify responses in the immune system. This very broad topic was discussed in detail recently ([170] , [171]).

Porphyria Cutanea Tarda

The single most common type of porphyria is porphyria cutanea tarda. An elevated amount of storage iron is characteristic of this disorder. The interaction of iron and porphyria cutanea tarda was reviewed recently ([172] , [173]). Also, the presence of one or two mutations of HFE is common in subjects who have this type of porphyria and increased storage iron. Patients with porphyria cutanea tarda (either sporadic or familial) and heavy iron loading may be homozygous for HFE mutations ([174] , [175]).

Evidence for an association of the uroporphyrinogen decarboxylase gene on chromosome 1q and hemochromatosis alleles on chromosome 6p was first presented in 1989 ([176]). This was substantiated after the HFE gene was cloned and sequenced, and HFE mutations were identified ([173] , [175] , [177]). In a study of 108 subjects in Utah who had porphyria cutanea tarda, 19% were C282Y homozygotes, and 7% were C282Y/H63D compound heterozygotes ([175]). The HFE mutation(s) causes increased iron absorption, which further depresses the already decreased activity of the enzyme uroporphyrinogen decarboxylase. This in turn results in the accumulation of uroporphyrin I in organs. Deposition of porphyrin in skin causes photosensitivity, blistering, and scarring.

Risk factors for the expression of porphyria cutanea tarda include mutations of HFE, hepatitis C, alcoholism, and oral estrogen (but possibly not transdermal estrogen) ([174]). Hepatitis C is a potent risk factor, present in up to 28 to 74% of individuals with this type of porphyria. A 2002 study from Galveston was performed to assess the factors involved in the expression of porphyria cutanea tarda ([178]). In 39 consecutive porphyric patients, 9% had HFE genotype C282Y/C282Y, 9% were C282Y/wt, 12% were C282Y/H63D, 9% were H63D/H63D, and 26% were H63D/wt; none had the S65C mutation. Of the porphyric patients, 79% drank alcohol, 73% of 11 women took estrogens, 86% were smokers, and 74% were positive for the hepatitis C virus antibody. The authors concluded that HFE mutations were common and that the expression of porphyria cutanea tarda was multifactorial. They found that 92% of their patients had three or more risk factors for the expression of porphyria.

A study was performed in France in 2002 to identify factors that contribute to the expression of the sporadic common type of porphyria cutanea tarda ([179]). The prevalence of the C282Y, H63D, and S65C mutations of HFE and antibody to the hepatitis C virus was compared in 65 patients with sporadic porphyria cutanea tarda and in 108 control subjects. Of the porphyria patients, 17% had the C282Y mutation (4% of controls); there was no significant difference in the prevalence of the H63D and S65C mutations or compound heterozygosity between groups; 28% of porphyrics had antibodies to the hepatitis C virus. The authors agreed with other reports that the expression of sporadic porphyria cutanea is multifactorial.

A large study was performed in Germany to compare the prevalence of mutations of the HFE gene in 190 patients who had sporadic porphyria cutanea tarda and 115 age-matched healthy blood donors ([180]). Among the porphyrics, 39% had the C282Y mutation (3% in control subjects); 12% were C282Y homozygotes (0% in controls). The H63D mutation was present in 45% of porphyrics (10% in controls); 9% of porphyrics were C282Y/H63D compound heterozygotes.

ß-Thalassemia Minor

There are published reports of the occurrence of both ß-thalassemia minor and hemochromatosis in the same person. In one family, an index case who had ß-thalassemia minor and hemochromatosis had a brother without ß-thalassemia minor who was homozygous for the C282Y mutation. The proband's wife was also a C282Y homozygote. One of their children had ß-thalassemia minor and hemochromatosis, whereas the other had hemochromatosis alone. The proband's brother married a woman who was a C282Y/wt heterozygote. Both of their children were C282Y homozygotes ([181]). This report was published long before the HFE gene was identified. The C282Y testing was performed in the family after DNA testing became available.

There are recent reports of the presence of mutations of the HFE gene in patients with ß-thalassemia minor who become iron loaded ([182] , [183] , [184] and [185]). In a study of 22 iron-loaded Italian patients with ß-thalassemia minor and 62 relatives, it was concluded that the ß-thalassemia trait worsens the iron-related complications of homozygosity for the C282Y mutation. It is believed that the mild ineffective erythropoiesis of ß-thalassemia trait results in exaggeration of the amount of iron absorbed by the duodenum. The authors presented evidence that C282Y heterozygotes and H63D heterozygotes with ß-thalassemia trait did not become iron loaded ([183]).

On the island of Sardinia, an area not reached by Celtic influence, the presence of the C282Y mutation is very rare. The H63D mutation prevalence is similar to other populations ([93]), and the prevalence of ß-thalassemia minor is 13% ([184]). A study of 15 Sardinian men with ß-thalassemia minor was conducted to estimate the prevalence of the H63D mutation in 152 Sardinian men who had ß-thalassemia minor. Approximately 2.6% were H63D homozygotes, 29.5% were H63D/wt heterozygotes, and 68% were wt/wt normal. Concurrent control subjects were not studied.

In a study from Turin, 71 subjects with transfusion-dependent ß-thalassemia major and 200 control subjects were tested for C282Y and H63D ([185]). None of the

patients (or controls) was homozygous for the C282Y mutation; one patient (1.4%) was a C282Y/H63D compound heterozygote (similar to 0% among controls); 21.0% of patients (20.0% of controls) were H63D heterozygotes; and one patient (1.4%) was homozygous for the H63D mutation (1.0% in controls). The patient who was homozygous for the H63D mutation was much more heavily iron loaded than expected. The authors concluded that two copies of the H63D mutation caused the heavy hepatic iron accumulation that was associated with advanced hepatic fibrosis. Individuals with either the H63D or the C282Y mutation were more heavily iron loaded than could be explained by transfusion-dependent homozygous ß-thalassemia.

Steatohepatitis

The prevalence of HFE gene mutations in subjects with nonalcoholic steatohepatitis has been studied. In a group of 36 men in Massachusetts who had nonalcoholic steatohepatitis, 2.8% were C282Y homozygotes, 17.0 % were C282Y heterozygotes, 5.6% were H63D homozygotes, and 44.0% were H63D heterozygotes. In 348 control subjects, none was a C282Y homozygote, 11.0% were C282Y heterozygotes, 2.9% were H63D homozygotes, and 26.0% were heterozygous for the H63D mutation. Individuals with nonalcoholic steatohepatitis who had an HFE mutation had higher values of transferrin saturation and serum ferritin concentration, and those with the C282Y mutation had significantly higher levels of alanine aminotransferase and hepatic fibrosis than those who did not have a C282Y mutation of HFE ([186]). There are data in the literature indicating that insulin resistance syndrome is associated with the metabolic abnormality that is present in subjects with nonalcoholic steatohepatitis, with or without mutations of HFE ([187], [188], [189] and [190]).

Acquired Refractory Sideroblastic Anemia

In the acquired, refractory, nonpyridoxine-responsive type of sideroblastic anemia, iron accumulation varies ([191]). In a study of 30 patients with this refractory myelodysplastic disorder, there was no difference in the prevalence of HFE mutations compared to the normal population in Oklahoma ([192]). In a study of 40 patients from Switzerland, Greece, and France who had primary acquired sideroblastic anemia with nontransfusional iron overload, 1.25% had the C282Y mutation, which was not different from the 200 normal controls (2.50%). The prevalence of the H63D mutation also was not significantly different in the patients with sideroblastic anemia (19%) and the controls (13%) ([193]). Ineffective erythropoiesis alone may adequately explain the increased intestinal absorption of iron, resulting in iron overload, in the acquired refractory type of sideroblastic anemia.

X-Linked Sideroblastic Anemia

There are reports of individuals who have both X-linked pyridoxine-responsive anemia with ring sideroblasts and heavy iron overload. The first known report of coinheritance of X-linked sideroblastic anemia and HFE gene mutations described a 59-year-old man in France. He had hepatic iron overload and was a C282Y/H63D compound heterozygote. He was much more iron loaded than his 61-year-old brother, who had the X-linked sideroblastic anemia but no HFE mutation ([194]).

In a study of 18 unrelated subjects with X-linked sideroblastic anemia, 17.0% of patients had the C282Y mutation (5.5% in white controls), and 23.0% had the H63D mutation (15.0% in controls) ([195]). The difference for the C282Y mutation was significant, but the difference was not significant for the H63D mutation. After iron depletion, the responsiveness to pyridoxine supplementation increased in some of the patients.

Infections

Individuals who have hemochromatosis are susceptible to infection by organisms that rarely cause illness in people with normal body iron stores, including *Vibrio vulnificus* and *Yersinia enterocolitica* ([196], [197], [198], [199], [200], [201], [202], [203], [204], [205], [206] and [207]). *Listeria* ([208]), *Escherichia coli* ([209]), and zygomycosis ([210]) also may occur in hemochromatosis patients ([208], [209]).

V. vulnificus is a motile free-living, gram-negative bacillus that grows as normal marine flora in warm coastal saline waters. It usually does not cause infection in humans except in iron-loaded individuals. When ingested with raw shellfish, it can cause gastroenteritis, septic arthritis, or fatal septicemia ([206], [207], [211]). Invasive organisms are encapsulated. The organism thrives in blood that has elevated iron content ([200], [212]).

Y. enterocolitica belongs to the family Enterobacterioceae. It can cause transfusion-induced sepsis, gastroenteritis, septic arthritis, hepatic abscesses, osteomyelitis, or bloody diarrhea. Usually, it is ingested in contaminated water, pork, milk, bean sprouts, or chocolate ([213], [214]). Whereas *Vibrio* is usually present in warm, salty, coastal waters, *Yersinia* is often present in colder climates or as a contaminant in any climate. In patients with hemochromatosis, *Yersinia* can cause severe infections ([212]), including multiple hepatic abscesses, as in recent reports ([213], [214], [215] and [216]). The literature concerning 46 known cases of hepatic abscesses caused by *Yersinia* was reviewed in 2001 ([213]).

Coronary Artery Disease

It is known that hemochromatosis can cause cardiac arrhythmias or congestive heart failure ([217], [218], [219], [220], [221], [222], [223], [224], [225] and [226]). Patients with hemochromatosis have a 300-fold increased risk of developing cardiomyopathy ([107]). There has been increasing interest in the possibility that hemochromatosis may be causally associated with the occurrence of coronary artery disease ([227], [228]), perhaps by lipid peroxidation. A 2002 report includes data about measurement of serum ferritin concentration, the C282Y mutation, C-reactive protein, and malondialdehyde in 849 individuals in Italy who underwent cardiac catheterization to establish or disprove the presence of coronary artery disease ([229]). Serum ferritin concentration values were higher in subjects whose C-reactive protein was elevated. There was no difference in the prevalence of elevated serum ferritin concentration between the group of 546 patients with coronary artery disease and the 303 individuals whose coronary arteries were normal. In the group with coronary artery disease, 4.8% were C282Y heterozygotes compared with 6.6% percent of the subjects with normal coronary arteries. The authors concluded that neither serum ferritin nor the C282Y mutation correlated with or allowed prediction of angiographically proved coronary artery disease.

In a comparison of 160 patients with severe coronary artery disease from Brazil and 160 age- and sex-matched control subjects, the prevalence of the C282Y mutation in the two groups was identical. The prevalence of H63D was similar in both groups. Compound heterozygosity for C282Y/H63D was minimally higher in the healthy control group (1.2%) than in those with coronary artery disease (0.6%) ([230]). In two additional studies of the prevalence of C282Y and H63D mutations in patients with coronary artery disease, the prevalence of C282Y and H63D mutations was similar in patients with or without coronary artery disease ([231], [232]). In an autopsy review of 41 iron-loaded subjects compared with 82 age-, sex-, and race-matched control subjects without iron overload from the Johns Hopkins Hospital, 33% of controls had three-vessel coronary artery disease compared with only 12% of the iron-loaded individuals ([233]). To date, the results of controlled studies do not provide evidence of increased prevalence of coronary artery disease in hemochromatosis or of an increased prevalence of hemochromatosis in patients with coronary artery disease.

DIAGNOSIS

History and Physical Examination Findings

The diagnosis of hemochromatosis may be suspected in an individual who has some combination of the following: arthralgias, right upper quadrant abdominal pain, impotence, palpitations, unexplained fatigue or weight loss, gray-bronze skin, hepatomegaly, stigmata of portal hypertension, diabetes, or hypogonadism. Of course, most hemochromatosis homozygotes do not have all of these findings. Individuals in whom the diagnosis is established during routine screening are nearly always asymptomatic and have no physical examination abnormalities. People in whom the diagnosis is established after seeking evaluation because of illness usually have several of the symptoms and physical examination abnormalities stated above. Only patients with far-advanced organ injury have all of the above symptoms and physical examination abnormalities. The frequency of symptoms and signs of hemochromatosis from nine reports appears in Table 30.4.

Laboratory Findings

Transferrin saturation is the first blood to become elevated in hemochromatosis homozygotes and usually is greater than 60% in symptomatic men and greater than

50% in symptomatic women ([219], [234], [235]). Unbound iron-binding capacity is usually decreased in homozygotes ([236], [237]). In iron-loaded patients, serum ferritin concentration is elevated. Liver-stainable iron and the hepatic iron index are also elevated in iron-loaded homozygotes ([237]). The sensitivity of elevated transferrin saturation to identify a patient with hemochromatosis is 94 to 98%, and its specificity is 70 to 98% ([234], [235], [237]). Typical results of transferrin saturation, serum ferritin concentration, hepatic iron concentration, and hepatic iron index in groups of hemochromatosis homozygotes appear in Table 30.7 and Table 30.9. The sensitivity of homozygosity for the C282Y mutation to identify patients with hemochromatosis in the Utah studies was 89% ([59]) whether or not iron overload was present.

EVALUATION OF RELATIVES

After the diagnosis of hemochromatosis is established in an individual, it is important to study the siblings of the proband. A choice of tests to perform are the same as for the index case: transferrin saturation, serum ferritin concentration, and DNA testing by polymerase chain reaction for mutations of the HFE gene.

Young homozygous siblings of a proband with hemochromatosis may have a normal serum ferritin concentration. Serum ferritin can be measured at 2- or 3-year intervals to determine when it becomes elevated. When serum ferritin becomes elevated, it is reasonable to begin intermittent phlebotomy therapy to prevent accumulation of excess iron in the liver and other organs.

Homozygous relatives who have a marked elevation of serum ferritin concentration (greater than 700 ng/ml in men; greater than 400 ng/ml in women) and elevated serum concentrations of liver enzymes may have hepatic injury. Liver biopsy in such individuals determines the presence or absence of hepatic fibrosis or cirrhosis and allows measurement of hepatic iron stores. Typical liver biopsy findings in probands and homozygous relatives appear in Table 30.5, Table 30.8, and Table 30.9. The great majority of homozygous relatives who are identified during family screening are less iron loaded and have fewer complications than the proband in the family (Table 30.5, Table 30.7, Table 30.8, and Table 30.9).

Because approximately 10% of whites of Central, Western, and Northern European ancestry are hemochromatosis heterozygotes, the occurrence of hemochromatosis in whites in consecutive generations is common. It seems reasonable to measure transferrin saturation or unbound iron–binding capacity in the interested parents and children of homozygotes in addition to all siblings of the proband. In a study of the relatives of 291 hemochromatosis probands, 214 homozygous relatives were identified ([59]). When these 214 clinically unselected individuals were stratified by age and sex, it became apparent that 90% of the homozygous male relatives were iron loaded by age 40 years, and 52% had iron-related organ injury. Clinically unselected female homozygous relatives became iron loaded on average approximately one decade later than men. After 50 years, 88% of clinically unselected female homozygous relatives became iron loaded, and 16% had iron-related organ injury ([59]).

The results of transferrin saturation and serum ferritin concentration tests in the 291 probands and their 214 clinically unselected homozygous relatives in the Utah studies appear in Table 30.7. The frequency of iron-related complications in the 291 Utah probands and their 214 homozygous relatives appears in Table 30.8.

DIFFERENTIAL DIAGNOSIS OF IRON OVERLOAD

Many disorders are known to be associated with increased body iron stores. Some of these heritable or acquired conditions appear in Table 30.10, including gene location, mode of heritability, and gene mutation responsible for the disorder. After the initial report of the isolation and cloning of the HFE gene, it became clear that a small percentage of hemochromatosis patients did not have a C282Y or H63D mutation ([16]). In fact, some people with hemochromatosis do not have an HFE mutation at all, such as people with hemochromatosis type 2 (juvenile hemochromatosis, chromosome 1q21) and hemochromatosis type 3 (mutation that inactivates transferrin receptor 2, chromosome 7q22) ([91], [238], [239], [240], [241], [242], [243], [244] and [245]). It is probable that additional mutations of non–chromosome 6 genes will be found to cause iron loading. Perhaps a mutation of any gene that normally down-regulates iron absorption will be found to result in accumulation of excess organ storage iron.

TABLE 30.10. Heritable and Acquired Disorders Associated with Iron Overload: Differential Diagnosis

Heritable Disorder	Chromosomal Assignment	Heritability	Cause of Iron Loading	References
Hemochromatosis type 1	6p21.3	Autosomal recessive	Mutations of HFE	16
Hemochromatosis type 2 [a]				
Type 2A	1q21	Autosomal recessive	Unknown	91, 238, 239, 240, 241 and 242
Type 2B	19q13	Autosomal recessive	Hepcidin antimicrobial peptide gene mutations	242a, 242b, 242c and 242d
Hemochromatosis type 3	7q22	Autosomal recessive	Inactivation of transferrin receptor 2	243, 244 and 245
Hemochromatosis type 4	2q32	Autosomal dominant	Ferroportin gene mutations	246, 247, 248, 249, 250, 251, and 252
Hemochromatosis type 5	11q 12-q13	Autosomal dominant	H-ferritin gene mutation	—
Porphyria cutanea tarda	1p34	Autosomal dominant or sporadic	Heterogeneous	171, 173, 174, 175 and 176, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268 and 269
African iron overload	Unknown	Autosomal dominant	Unknown	98, 270, 271, 272, 273, 274 and 275
Neonatal iron overload	Unknown	Heterogeneous	*In utero* iron transfer	276, 277, 278, 279, 280, 281 and 282
Atransferrinemia	3q21	Autosomal recessive	Transferrin gene mutations and red cell transfusions	283, 284
Aceruloplasminemia	3q23-q24	Autosomal recessive	Ceruloplasmin gene mutations	285, 286, 287, 288, 289, 290, 291 and 292
Hereditary hyperferritinemia and cataract syndrome	19q13.1-q13.3.3	Autosomal dominant	L-Ferritin gene mutations	293, 294, 295, 296, 297, 298, 299, 300, 301, 302 and 303
Friedreich ataxia	9p23-p11,9q13	Autosomal recessive	Frataxin gene mutations	304, 305, 306, 307, 308, 309, 310, 311 and 312
Panthothenase kinase–associated neurodegeneration	20p13-p12.3	Autosomal recessive	Pantothenase kinase gene mutations	330, 331 and 332
ß-Thalassemia major	11p15.5	Autosomal recessive	ß-Globin gene mutations, chronic hemolysis, red cell transfusions	—
Other chronic hemolytic anemias				
Hereditary X-linked sideroblastic anemia	Xp11.21	X-linked	d-Aminolevulinic acid synthase gene mutations	313, 314 and 315
Pyruvate kinase deficiency	1q21	Autosomal recessive	Pyruvate kinase gene mutations	316, 317 and 318
G6PD deficiency	Xq28	X-linked	G6PD gene mutations	319, 320
Congenital dyserythropoietic anemias	Type I 15q15.1-q15.3	Autosomal recessive	Ineffective erythropoiesis	323, 325, 329
	Type II 20q11.2	Autosomal recessive	Ineffective erythropoiesis	321, 322, 324
	Type III 15q21	Autosomal dominant	Ineffective erythropoiesis	326, 327 and 328

Acquired Disorder	Cause of Iron Loading
Transfusions	Red cell iron infusion

Medicinal iron	Excessive iron ingestion
Myelodysplasia with ring sideroblasts	Excessive iron absorption
Portocaval shunt	Excessive iron absorption

G6PD, glucose-6-phosphate dehydrogenase.

[a] Or juvenile hemochromatosis.

Often, it is simple for the physician to recognize the cause of excess iron stores, such as in patients with chronic hemolytic anemias or in the acquired disorders at the bottom of Table 30.10. In other patients, it may be more difficult to identify the cause of iron loading. An iron-loaded teenager with hypogonadism, decreased luteinizing hormone and follicle-stimulating hormone, cardiac arrhythmia, and congestive heart failure is more likely to have hemochromatosis type 2 (chromosome 1q21) than hemochromatosis type 1 (chromosome 6p21.3). Although the DNA tests for the C282Y and H63D mutations are widely available, commercial tests are not widely available to identify the mutations responsible for hemochromatosis types 2 and 3. Table 30.10 may provide ideas for the physician to consider and pursue for an individual whose iron overload does not have an obvious cause.

MANAGEMENT

Phlebotomy Therapy

INITIAL WEEKLY PHLEBOTOMY SCHEDULE The main treatment of hemochromatosis is phlebotomy therapy (234, 333). In a phlebotomy of 500 ml of whole blood with a hematocrit of 40%, 200 ml of packed red blood cells are removed. Because each 1 ml of packed red cells contains approximately 1 mg of iron, each 500-ml phlebotomy removes approximately 200 mg of iron. When the diagnosis of iron overload due to hemochromatosis is established, it is important to start the first phase of phlebotomy therapy. Most iron-loaded homozygotes tolerate removal of 500 ml of whole blood each week quite well. Some women, small individuals, or elderly patients may only tolerate removal of 250 ml of whole blood each week. Twice-weekly phlebotomy may be performed for very heavily iron-loaded patients who have cardiac arrhythmias or hepatic failure in an effort to improve cardiac and hepatic function quickly. Phlebotomy therapy should be continued until the hematocrit drops by approximately 1 to 2 g/dl below baseline, the red cell mean corpuscular volume drops by approximately 3 to 5 fl below baseline, and serum ferritin concentration drops to 20 to 50 ng/ml. These findings provide evidence of iron-limited erythropoiesis, which concludes the initial rapid sequence phase of phlebotomy therapy. The patient then enters the second, life-long maintenance phase of phlebotomy therapy (334, 335 and 336).

LIFE-LONG MAINTENANCE PHLEBOTOMY SCHEDULE After the initial iron depletion is accomplished, the patient enters the life-long maintenance phase of phlebotomy therapy. Removal of 500 ml of whole blood every 2 to 4 months (every 3 to 6 months in women) prevents reaccumulation of excessive organ storage iron. The goals of life-long maintenance phlebotomy therapy include maintenance of a normal hematocrit and maintenance of the serum ferritin concentration at approximately 50 ng/ml. If the ferritin is measured each year, a value greater than 100 ng/ml suggests that the frequency of phlebotomy needs to be increased to every 2 months. A very low serum ferritin and the presence of anemia indicate that the frequency of phlebotomy therapy can be decreased to 4- or 6-month intervals. Most patients and physicians want to know how to estimate how long it may take to cause iron depletion by weekly phlebotomy therapy. In hemochromatosis patients whose serum ferritin is not elevated due to hepatocellular injury and release of ferritin unrelated to body iron stores, a reasonable estimate of total body storage iron can be offered. Based on a study of the correlation of serum ferritin to the number of grams of iron removed by phlebotomy therapy, it was estimated that 1 ng/ml of pretreatment serum ferritin corresponded to nearly 8 mg of mobilizable iron (337). A person whose pretreatment serum ferritin concentration is 600 ng/ml is likely to have approximately 4800 mg of mobilizable storage iron. Because each 500-ml unit of blood with a hematocrit of 40% contains approximately 200 mg of iron, the patient is likely to undergo approximately 24 units of phlebotomy to achieve iron depletion. This simple estimate holds up reasonably well except in patients whose serum ferritin is markedly elevated and out of proportion to storage iron due to hepatic necrosis or another source of inflammation that causes ferritinemia. After the patient becomes iron depleted by rapid-sequence phlebotomy, the number of units of whole blood removed, multiplied by 200 mg iron per phlebotomy, provides a reliable measurement of the number of grams of iron that were removed.

CLINICAL CHANGES AFTER IRON DEPLETION If hepatic cirrhosis and arthropathy are not present before iron depletion therapy, these complications of hemochromatosis may be preventable by initial iron depletion followed by life-long maintenance phlebotomy therapy. Phlebotomy therapy for hemochromatosis patients has been discussed in considerable detail in recent publications (234, 332, 338). Overall, men require approximately twice as many units of phlebotomy to induce iron depletion as women (120, 339). Complications of hemochromatosis that respond to and complications that do not improve after phlebotomy therapy appear in Table 30.11. Treatment for specific problems usually should be managed as in patients who do not have hemochromatosis.

TABLE 30.11. Clinical Changes after Phlebotomy Therapy

Observed Complications of Iron Overload	Expected Treatment Outcome
None	Prevention of complications of iron overload; normal life expectancy.
Weakness, fatigue, lethargy	Resolution or marked improvement.
Elevated serum concentrations of hepatic enzymes	Resolution or marked improvement.
Hepatomegaly	Resolution often occurs.
Hepatic cirrhosis	No change.
Increased risk for primary liver cancer [a]	No change.
Right upper quadrant pain [b]	Resolution or marked improvement.
Arthropathy	Improvement in arthralgias sometimes occurs; change in joint deformity is rare; progression is sometimes seen.
Hypogonadotrophic hypogonadism	Resolution is rare.
Diabetes mellitus	Occasional improvement, often temporary.
Hyperthyroidism, hypothyroidism	Resolution is rare.
Cardiomyopathy	Resolution sometimes occurs.
Hyperpigmentation	Resolution usually occurs.
Hyperferritinemia [c]	Resolution.
Hyperferremia	Little or no change.
Excess absorption and storage of nonferrous metals [d]	Little or no change.
Infection with *Vibrio vulnificus* or other bacteria	Little or no change.

[a] Increased risk occurs only in persons with hepatic cirrhosis.

[b] Right upper quadrant pain in persons with hemochromatosis is often related to hepatic iron overload. In these cases, therapeutic phlebotomy usually results in marked improvement or resolution. However, right upper quadrant pain may also be caused by primary liver cancer portal vein thrombosis, gallbladder disease, lesions in the hepatic flexure or nephrolithiasis. Iron depletion alone does not alleviate right upper quadrant pain.

[c] Serum iron levels may be normal or subnormal in persons with hemochromatosis due to severe iron deficiency, chronic inflammatory or infectious disease, vitamin C deficiency, or prolonged fasting.

[d] Cobalt, manganese, zinc, and lead.

From Barton JC, McDonnell SM, Adams PC, et al. Management of hemochromatosis. Ann Intern Med 1998;129:935, with permission.

Dietary Changes

Subjects with hemochromatosis have increased risk to develop a life-threatening infection with *V. vulnificus* from raw shellfish (see the section Infections). Because of this risk, it is prudent to advise these individuals not to consume raw shellfish. Much more iron can be removed in each 500-ml whole blood phlebotomy each week than can be absorbed that week. For this reason, it is not necessary to impose severe dietary restrictions in an attempt to avoid all foods that contain iron. It is reasonable to advise the intake of less saturated fat and animal protein and more fresh vegetables and fruit, as for anyone else who desires to follow a prudent cardiovascular diet ([332]).

Alcohol Intake

Alcohol can be hepatotoxic. Individuals with hepatic damage from iron overload may benefit from avoiding drinks containing alcohol. It is estimated that 30 g of alcohol per day can worsen iron-related liver damage ([109] , [332] , [340]). The same amount of alcohol in a person with cirrhosis may also increase the individual's risk for the development of hepatocellular carcinoma ([109]).

Vitamins

It is reasonable for an individual who has hemochromatosis to avoid medicinal intake of vitamin C because it can increase the absorption of dietary iron ([332] , [341]). Vitamin C also may cause oxidative damage of the myocardium and cardiac conduction system, resulting in rare fatal arrhythmias in iron-loaded patients who have hemochromatosis or thalassemia major ([340] , [342] , [343] and [344]).

PROGNOSIS

The outlook for a patient with hemochromatosis is related to whether the patient undergoes iron depletion therapy before the development of cirrhosis or diabetes mellitus. In a study of 111 hemochromatosis patients in England, the average survival of 85 people who underwent phlebotomy therapy was 63 months, compared to 18 months in the 26 subjects who did not become iron depleted ([106]). In a study of survival among 251 hemochromatosis patients in Germany, those who became iron depleted experienced survival similar to the background population ([140]). Hemochromatosis patients with diabetes had a 10-year survival of 65% compared to 90% in the nondiabetics. The 10-year survival of hemochromatosis subjects with cirrhosis was 72% compared to 82% in the noncirrhotics. Very heavy iron overload that could not be depleted within 18 months from the onset of phlebotomy therapy was also associated with decreased survival. There are additional valuable reports of survival and prognosis in patients who have hemochromatosis ([138] , [139]).

IMAGING OF THE LIVER

Computed Tomographic Scanning of the Liver

Single-energy computed tomographic (CT) scanning is not adequately sensitive to distinguish hepatic iron overload from a fatty liver. CT scanning also has very limited value in the assessment of sources of hepatic inhomogeneity, including edema, regenerative nodules, perfusion abnormalities, iron and fibrosis, or cirrhosis ([345]). Dual-energy CT scanning is able to distinguish hepatic iron from fat ([346]). In a dual-energy CT scan, an iron-loaded liver appears brighter than paraspinous muscles.

Magnetic Resonance Imaging of the Liver

Magnetic resonance (MR) imaging has largely replaced CT scanning in the evaluation of livers that are presumed to be cirrhotic. Some of the advantages of MR scanning include superior contrast resolution, multiplanar capability, greater sensitivity and specificity in the detection and characterization of abnormalities, and no use of ionizing radiation ([345]). MR imaging can be used to identify hepatic cirrhosis, regenerating nodules, and hepatocellular carcinoma in subjects who have hemochromatosis.

Iron is a paramagnetic element that becomes magnetized in a magnetic field. The result is that the transverse (T2) relaxation time of iron becomes shortened compared to the longitudinal (T1) relaxation time. In an iron-loaded liver, the shortened T2 relaxation time causes a decrease in signal intensity. The result is that an iron-loaded liver appears darker than paraspinous muscles on T2-weighted MR images ([347]).

Gradient-echo MR scanning after gadolinium is considered to provide the most useful information about iron stores, using both T1- and T2-weighted images. An MR magnet strength of 1.5 Tesla provides better predictive ability than the 0.5-Tesla magnet. The intensity of the signal in liver commonly is compared to signal intensity in paraspinous muscles. Iron causes increased attenuation of the gradient-echo signal in hepatocytes ([345] , [348] , [349]), which means that iron-loaded liver tissue appears darker than paraspinous muscle. Whereas CT cannot quantitate iron stores that are less than five times normal, gradient-echo MR allows quantification of iron stores that are minimally increased ([347] , [350] , [351] , [352] and [353]).

Gradient-echo sequences allow quantitation of storage iron that correlates quite well with chemical quantitation on a liver biopsy sample. This means that MR scanning can provide credible estimation of the hepatic iron concentration in patients who, for any reason, do not undergo liver biopsy. After iron depletion, there is a decreased amount of attenuation of the gradient-echo signal, so the liver appears lighter than before ([347] , [350] , [351] , [352] and [353]).

Cost

The total charge for an MR scan of the liver is approximately $1000. The total charge for a needle biopsy of the liver is approximately $1800.

IRON CHELATION

Iron has little solubility in water. The amount of urinary iron excretion in normal and iron-loaded individuals is approximately 50 to 100 µg per 24 hours. Some compounds bind and make a water-soluble complex with iron, which results in urinary iron excretion that is much greater than normal. Two drugs are currently available for iron chelation therapy: deferoxamine and deferiprone. Deferoxamine is a biologic product of *Streptomyces pilosus*. Deferiprone is a synthetic hydroxypyridone. Good reviews about deferoxamine and deferiprone have been published recently ([354] , [355] , [356] and [357]).

Deferoxamine

PHARMACOKINETICS Deferoxamine is not absorbed from the gastrointestinal tract, so it must be administered parenterally by the subcutaneous, intramuscular, or intravenous route. This chemical enters cells and binds iron with great affinity. The deferoxamine–iron complex is water soluble, and nearly all deferoxamine is excreted by glomerular filtration and renal tubular secretion. Intravenous deferoxamine causes the greatest amount of urinary iron excretion, followed by the intramuscular and the subcutaneous routes. The intravenous route is associated with the greatest risk for infection. The intramuscular route usually requires injection of 2 ml into each buttock twice daily (for a daily dose of 2 g), and these large volumes are painful and not accepted well by patients. Overnight, 12-hour subcutaneous infusions usually are tolerated well and are reasonably effective. Details about pharmacokinetics have been published ([354] , [358]). High-dose deferoxamine may result in the excretion of 20 to 40 mg of iron per day. A patient with 8 g of excess storage iron whose deferoxamine-induced urinary iron excretion is 20 mg of iron per day has to receive deferoxamine therapy for 400 nights to become iron depleted. Deferoxamine therapy may have to be continued indefinitely in a patient who is heavily iron loaded.
EFFICACY There are no known reports of the therapeutic use of deferoxamine in a large group of individuals with hemochromatosis. The urinary iron excretion induced by deferoxamine was studied in five normal adults (three women, two men) and in six adult male hemochromatosis patients ([358]). The amount of iron excreted in urine during 6 hours was determined before and after the intramuscular administration of a small dose of deferoxamine (10 mg/kg body weight—15.24 µmol/kg). In normal subjects, the 6-hour urinary iron excretion averaged 6 µg (0.1 µmol) before and 464 µg (8.3 µmol) after deferoxamine. In the hemochromatosis

patients, the 6-hour urinary iron excretion averaged 71 µg (1.2 µmol) before and 6764 µg (121.0 µmol) after deferoxamine administration. In a 2000 study from Ferrara, deferoxamine-induced urinary iron excretion was measured in 27 consecutive iron-loaded subjects ([359]). Of these 27, 11 patients who were not transfusion-dependent included one person who had both hemochromatosis (a C282Y/C282Y homozygote) and hereditary spherocytosis. These 11 subjects received a 10-minute subcutaneous bolus of 1 g of deferoxamine every 12 hours. Their mean 48-hour urinary iron excretion was 5360 µg (range, 2240 to 13,885 µg). After an average of 18 months of deferoxamine therapy, the mean value of serum ferritin decreased by 72% (from 1625 to 456 ng/ml) but remained elevated in all three women and in three of the eight men. After 18 months of deferoxamine therapy, only 1 of the 11 individuals had a serum ferritin value that was less than 100 ng/ml. The patient who had both spherocytosis and homozygous hemochromatosis still had a moderately high serum ferritin concentration of 740 ng/ml after 28 months of deferoxamine therapy ([359]).

SIDE EFFECTS Most patients who are treated with deferoxamine experience painless swelling at the infusion site for approximately 15 minutes after subcutaneous infusion; pain and erythema at the site of administration occur in approximately 4% of patients ([359]). Individuals who have a large body iron burden are unlikely to experience complications from deferoxamine. The reason for this is that in iron-loaded subjects, most of the circulating deferoxamine binds iron, forming ferrioxamine. Ferrioxamine does not undergo oxidative deamination, so toxic metabolites (referred to as *B* and *C*) are not formed ([355]). The opposite of this occurs in subjects with a small iron burden who receive large doses of deferoxamine. Because not much iron is present, not much ferrioxamine is formed. The non–iron bound deferoxamine then undergoes deamination to the B and C metabolites, which can cause toxicity ([355]). Deferoxamine has been identified as a cause of retinal and auditory neurotoxicity ([355], [360], [361], [362] and [363]). There are reports of growth failure and metaphyseal bone deformities of the tibia, ulna, and radius in children with ß-thalassemia major who were treated with deferoxamine ([364], [365]). In children with ß-thalassemia who were treated with large doses of deferoxamine, renal and pulmonary complications were observed ([366], [367]). Recently, some very good discussions of deferoxamine have been published ([354], [355], [359], [368]).

COST The daily cost of 2 g of deferoxamine in Salt Lake City is approximately $60 or $22,000 per year. The tubing that connects the subcutaneous needle to the infusion pump costs approximately $1 per day. An additional cost is an infusion pump that can accept a 10-cc syringe (2 ml final volume per gram of deferoxamine; 4 to 8 ml per night), which costs approximately $1000.

Deferiprone

Deferoxamine is expensive, it requires a parenteral route of administration, it must be administered twice daily or for several hours each day, and it can cause side effects. Many oral iron chelators have been evaluated for efficiency and toxicity. The only currently acceptable oral iron chelator for use in iron-loaded subjects is the bidentate iron chelator 1,2-dimethyl-3-hydroxypyrid-4-one, which is called *deferiprone*, *CP20*, or *L1*.

PHARMACOKINETICS The mean absorption half-time of deferiprone is approximately 22 minutes, suggesting the stomach or duodenum as the site of absorption ([369]). Elimination is principally via kidneys, with approximately 75% recovery in urine as a glucuronide within 24 hours. Approximately 70% of the urinary excretion of deferiprone-iron occurs within 6 hours of ingestion. The 24-hour urinary iron excretion after a total dose of deferiprone, 75 mg/kg/day, is 5 to 30 mg, with a mean of 15 mg ([370]), or approximately 0.6 mg iron/body weight/day ([369]). Because of its rapid elimination, deferiprone is administered 2 to 4 times per day.

DOSAGE A typical dosage schedule for deferiprone is 50 to 100 mg/kg/day total, divided into two to four doses per day. In two recent studies, a total daily dose of 75 mg/kg was given, divided into three doses of 25 mg/kg each ([356], [357]).

EFFICACY In a study of 84 iron-loaded subjects who were treated with deferiprone, the mean serum concentration of ferritin decreased from an initial mean of 4207 ng/ml to 3139 ng/ml after 12 months (a 1-year decrease of 25%). After 48 months of treatment with deferiprone, the mean serum ferritin dropped to 1779 ng/ml (a 4-year decrease of 58%) ([370]). These mean values remained markedly elevated compared with upper normal values of approximately 325 ng/ml for men and 125 ng/ml for women. The results of a study that was designed to assess the efficacy and safety of deferiprone were published in 2002 ([371]). In this study, 532 Italian patients (age 6 to 54 years) with thalassemia major and iron overload were treated with oral deferiprone, 75 mg/kg body weight per day, divided into three daily doses. In the 151 patients who completed 3 years of deferiprone therapy, the mean serum ferritin decreased modestly from an initial value of 2579 to 2230 ng/ml (a 14% decline) ([371]).

LONG-TERM EFFECTS The long-term effects of deferiprone have been studied in 84 patients with transfusional iron overload for 167 patient years ([370]). Of these 84 patients, 77% had thalassemia major; none was known to be a hemochromatosis homozygote. After oral deferiprone, 70 to 80 mg/kg/day, the average 24-hour urinary iron excretion was approximately 0.5 mg/kg. This amount of urinary iron excretion was greater than the amount associated with deferoxamine ([358]). After 48 months of oral deferiprone therapy, the average serum ferritin value decreased from approximately 3100 ng/ml to approximately 1800 ng/ml but obviously did not drop into the normal range ([370]).

SIDE EFFECTS In a study of side effects in 151 patients with thalassemia who took oral deferiprone, 75 mg/kg body weight per day for 3 years, agranulocytosis (reversible) occurred in 0.4%, neutropenia in 3.9%, alanine aminotransferase rose in 2.8%, nausea with abdominal pain and vomiting affected 3.2%, and arthralgias occurred in 3.9% of the patients ([371]). In a study of the 84 iron-loaded patients cited above, the principal side effects were agranulocytosis (3.6%), severe nausea (4.7%), zinc deficiency (14.0%), arthropathy (20.0%), and elevation of aminotransferases in serum (45.0%). Treatment was discontinued in 20% of patients because of side effects or low compliance. The two patients who died did not have a cause of death related to deferiprone—neither patient took the drug in the 2 months before death ([370]). Hepatic injury and progressive hepatic fibrosis associated with deferiprone therapy have been reported ([370], [372]). Recently, a large study was performed to evaluate the possibility of progressive hepatic fibrosis in 56 patients with thalassemia major who underwent liver biopsy before and after deferiprone therapy ([357]). The authors concluded that after an average of 3 years of therapy between liver biopsies, deferiprone did not cause progressive hepatic fibrosis.

COST AND AVAILABILITY Deferiprone is not commercially available in the United States, so a cost in the United States has not been established.

Combination Chelation Therapy: Deferiprone Plus Deferoxamine

Interest is increasing in the use of combination chelation therapy for iron-loaded individuals who are transfusion dependent. In a study from London, five transfusion-dependent patients (age 17 to 58 years) were treated with oral deferiprone (75 to 110 mg/kg body weight per day) plus subcutaneous deferoxamine (various doses and rates of infusion) on 2 to 6 days per week ([373]). After 7 to 15 months of combination chelation therapy, the serum ferritin value decreased in all five patients ($p = .791$; not statistically significant).

Collaborators in Israel and Thailand studied different iron pools and clarified a rationale for the use of concurrent deferiprone and deferoxamine in iron-loaded, transfusion-dependent individuals ([368]). These investigators suggested that deferiprone enters cells, binds iron, and shuttles iron into plasma. Deferoxamine then binds the deferiprone iron in plasma, which makes iron-free deferiprone available to reenter cells to repeat this cycle of iron binding and shuttling. Other investigators made recent contributions to the understanding of the iron-shuttling property of deferiprone and also the interaction of deferiprone and deferoxamine ([374], [375] and [376]). The time seems right for the performance of randomized controlled trials to compare the use of deferiprone alone, deferoxamine alone, and combination chelation therapy, including deferiprone and deferoxamine, in transfusion-dependent, iron-loaded individuals ([377]).

It is important to note that phlebotomy therapy remains the treatment standard for hemochromatosis homozygotes.

Porphyria

The *porphyrias* are diverse disorders that result from various inherited enzyme defects in the heme biosynthetic pathway (Fig. 31.1). The first authentic cases of porphyria were described in 1874 ([1], [2]). Since that time, seven different kinds of porphyria have been distinguished (Fig. 31.1, Table 31.1), representing discrete, partial deficiencies of each of the seven enzymes beyond the first and rate-limiting (or 5-aminolevulinate synthase) step of the pathway (Table 31.2). The genes encoding these enzymes have been cloned, their chromosomal location is defined, and DNA analyses have revealed many heterogeneous molecular defects in all the porphyrias. The biosynthetic blocks resulting from the defective enzymes are largely expressed in the liver or bone marrow, the sites where the majority of heme is produced, but the clinical and pathologic phenotype of each porphyria is dictated by the associated enzyme defect and the mode of inheritance (Table 31.2) and is often influenced by certain metabolic and environmental factors. In some “late-onset porphy-rias,” acquired clonal hematopoietic disorders appear to contribute to the expression of an inherited but previously clinically silent enzyme defect.

Figure 31.1. The heme biosynthetic pathway, its enzymes, and the seven forms of human porphyria associated with deficiencies of these enzymes. The major compound excreted in excess in each of the human porphyrias is the substrate of the specific defective enzyme. In the acute or inducible porphyrias (*), increased hepatic 5-aminolevulinic acid (ALA) production results from release of the normal negative feedback on ALA synthase exerted by heme ([620]), indicated by the trail of arrows. CoA, coenzyme A; HMB, hydroxymethylbilane; PBG, porphobilinogen.

TABLE 31.1. Classification of the Porphyrias

Porphyrias with only cutaneous photosensitivity
Congenital erythropoietic porphyria
Porphyria cutanea tarda
Erythropoietic protoporphyria
Acute or inducible porphyrias
Porphyrias with only neurologic manifestations
Acute intermittent porphyria
5-aminolevulinic acid dehydratase porphyria
Porphyrias with both neurologic manifestations and cutaneous photosensitivity
Variegate porphyria
Hereditary coproporphyria
Dual porphyrias

TABLE 31.2. Genetic and Metabolic Features of the Porphyrias

Type of Porphyria	Autosomal Inheritance	Defective Enzyme	Gene (Symbol/Location [a])	Enzyme Activity (%) [b] Heterozygote	Enzyme Activity (%) [b] Homozygote [c]	Porphyrin/ Precursor Excreted [d]	Route of Excretion	Principal Tissue Source
ALA dehydratase	Recessive	ALA dehydratase	ALAD/9q	50	1	**ALA**, coproporphyrin	**Urine**	Liver
Acute intermittent	Dominant	PBG deaminase	HMBS/11q23.3	50	16	**PBG**, ALA	**Urine**	Liver
Congenital erythropoietic	Recessive	Uroporphyrinogen III synthase	UROS/10q	50	1–20	**Uroporphyrin I**	**Urine**	Bone marrow
Cutanea tarda	Dominant	Uroporphyrinogen decarboxylase	UROD/1p34	50	3–27	**Uroporphyrin I + III, 7-COOH porphyrin**	**Urine**	Liver
Hereditary coproporphyria	Dominant	Coproporphyrinogen oxidase	CPO/9	50	2–10	**Coproporphyrin**, PBG, ALA	**Feces**, urine	Liver
Variegate	Dominant	Protoporphyrinogen oxidase	PPOX/1q22	50	0–20	**Protoporphyrin**, PBG, ALA	**Feces**, urine	Liver
Protoporphyria	“Recessive” [e]	Ferrochelatase	FECH/18q	20–30	<10	**Protoporphyrin**	**Feces**	Bone marrow

ALA, 5-aminolevulinic acid; PBG, porphobilinogen.

[a] Gene symbol and chromosomal location as listed in the Human Gene Mutation Database, located at http://www.hgmd.org.

[b] Percentage of normal.

[c] Often a compound heterozygote.

[d] The major metabolite and route are shown in bold face. The route of porphyrin excretion is determined by the number of carboxyl groups on the porphyrin and hence by its water solubility.

[e] Usually one allele is mutant and the other, normal allele is underexpressed (see text).

Although the pathophysiologic mechanisms of the clinical manifestations of the porphyrias are only partly understood, two cardinal features prevail: cutaneous photosensitivity and neurologic symptoms of intermittent autonomic neuropathy, motor nerve palsies, and central nervous system disturbances. The cutaneous photosensitivity is a manifestation of the unique fluorescent properties of the porphyrins that accumulate in those porphyrias in which the enzyme defects lie beyond the porphobilinogen (PBG) deaminase (PBG-D) step in the heme pathway (Fig. 31.1). The neurologic manifestations are associated with increased production and excretion of the porphyrin precursors 5-aminolevulinic acid (ALA) and PBG, which characterize the acute or inducible porphyrias. Among these, however, photosensitivity also occurs when the enzyme defect leads to accumulation of porphyrins. The distinguishing clinical manifestations of the porphyrias form the basis for the classification in Table 31.1. The diagnosis of a specific porphyria is ascertained by its characteristic profile of accumulated and excreted metabolic intermediates of the heme synthetic pathway (Table 31.2).

PORPHYRIAS WITH CUTANEOUS PHOTOSENSITIVITY

Congenital Erythropoietic Porphyria

Congenital erythropoietic porphyria (CEP) (Gunther porphyria), the second least common of the porphyrias, is characterized by a marked accumulation in erythroid precursors of uroporphyrin and coproporphyrin, which are predominantly of the isomer I type because defects reside in the gene for the enzyme uroporphyrinogen III synthase (UROIII-S) (Fig. 31.1). Many marrow erythroblasts and immature circulating erythrocytes exhibit intense red fluorescence in ultraviolet light. The large amounts of porphyrins released from these cells cause the most intense photosensitivity of all the porphyrias.

Probably first recognized by Schultz ([1]) and Baumstark ([2]) in 1874, CEP was described comprehensively and distinguished from other porphyrias by Gunther in 1911 ([3]). It is a very rare disease, with approximately 150 cases reported ([4]). It occurs with equal frequency in males and females and in a wide variety of racial groups. Usually, the illness is first detected in infancy ([5]) but, in a number of instances, was not apparent until later in life ([6]). Most evidence is consistent with transmission of the disorder as an autosomal-recessive trait ([4], [5]).

MOLECULAR BASIS AND PATHOGENESIS The pattern of porphyrin accumulation in CEP reflects a defect in the conversion of PBG to uroporphyrinogen III. This conversion requires two enzymes: PBG-D and UROIII-S (Fig. 31.1). Affected people are homozygotes or compound heterozygotes for mutations in the *UROIII-S* gene that result in decreased activity of UROIII-S, leading to the overproduction of uroporphyrinogen I in erythroid precursors ([4], [5], [7], [8]). The activity of UROIII-S is severely impaired (1 to 20% of normal) in erythrocytes ([9]) and fibroblasts ([10], [11]). In heterozygotes (parents and some siblings of patients with the disease), the activity of the synthase is intermediate (approximately 50%) between that found in affected individuals and that in normal subjects ([12], [13]). Variation among patients in the amount of residual UROIII-S activity measured in cultured fibroblasts suggested heterogeneity of the genetic defect ([10]). This suggestion has been substantiated by the many varied mutations identified in the *UROIII-S* gene, which resides on chromosome 10 (10q25.3–q26.3) ([14]) and has alternative promoters that generate housekeeping and erythroid-specific transcripts ([4]). Molecular defects include point mutations, deletions, insertions, splicing defects, intron branch chain mutations, and erythroid-specific promoter mutations ([4], [5]). Among some 60 unrelated cases analyzed to date, close to 40 different mutant alleles have been reported ([4], [5]). Approximately one-third are homoallelic (for 11 different mutations), and approximately 20% of alleles remain undefined. The most common mutation (Cys73Arg) has occurred in one-third of alleles (and in one-half of homoallelic cases) and correlates with the most severe phenotype of nonimmune hydrops fetalis, transfusion-dependent anemia from birth, or both, particularly in homoallelic cases ([5], [7], [8]). In most instances, mild forms of the disease have been heteroallelic or only one mutant allele could be identified. Residual enzyme activity of the mutant proteins expressed in prokaryotic systems, or gene promoter-reporter activities in cases of promoter mutations, have provided more precise genotype/phenotype correlations ([4], [5]). Although defective UROIII-S operating in the erythron characterizes the primary inherited abnormality, no overall deficiency of heme production is evident, perhaps because normal UROIII-S activity appears to be the highest relative to all other heme biosynthetic enzymes in erythroid cells. It is more than 1000 times greater than ALA synthase ([15]), the rate-limiting enzyme, so that even very low residual enzyme activity seems to be sufficient to meet the cellular requirements for heme. Uroporphyrin I is the predominant urinary porphyrin, but increased excretion of uroporphyrin III also invariably occurs, implying up-regulation of the UROIII-S or of enzymes higher up in the pathway. These findings are consistent with the idea that the pathophysiology of CEP is a result of the accumulation of uroporphyrin I rather than of subnormal production of uroporphyrinogen III and heme ([16]). However, it is unclear why uroporphyrin I, not coproporphyrin I, is the main porphyrin excreted. Because uroporphyrinogen decarboxylase (URO-D) can use uroporphyrinogen I as a substrate (Chapter 7), one would expect coproporphyrin I to be the major porphyrin excreted when excessive amounts of uroporphyrinogen I are produced, although the relative URO-D activity in normal erythroid cells is on the order of one-tenth of that of UROIII-S ([15]). URO-D activity has been measured in two patients with typical CEP and was found to be normal ([17]). Laboratory parameters of hemolysis correlate with severity of anemia. Associated splenic sequestration leads to splenomegaly and variable leukopenia and thrombocytopenia. Whether photolysis of the porphyrin-laden erythrocytes occurs *in vivo* is not known. It has been suggested that, in some cases, two defects may be involved for the full clinical expression of the CEP ([6], [18]), one an inherited defect in UROIII-S and the other an inherited or an acquired dyserythropoietic disorder. Most patients with CEP appearing in adult life had no prior history of hematologic disease ([6]). Anemia with clinical and biochemical evidence of the disorder appeared at the same time, and a somatic mutation(s) in an acquired dyserythropoietic cell line may account for deficient UROIII-S activity. An equally plausible explanation is that an acquired erythropoietic disorder developed and contributed to an inherited but clinically silent enzymatic defect. Molecular studies of such cases have not been reported. Not all cases with a clinical phenotype of CEP seem to be associated with defects in UROIII-S. In a Norwegian boy with typical clinical findings, the pattern of porphyrins produced in the marrow and excreted in the urine strongly suggested that URO-D, not UROIII-S, was the defective enzyme ([19], [20]). A similar case was reported in the United States ([18]). Enzyme assays and pedigree studies demonstrated that the American patient was heterozygous for a dominantly transmitted defect in URO-D and probably was also homozygous for the trait responsible for dyserythropoietic anemia type I. Such observations suggest that apparent CEP in some cases may be a syndrome rather than a disease entity related only to a specific inherited defect. The anemia commonly resembles congenital dyserythropoietic anemia type I, and the inherited enzymatic defect in heme biosynthesis may not be the only cause of the anemia. The large amounts of porphyrins released from erythroid cells and deposited in multiple tissues ([21]) exert the principal damage in the skin and subcutaneous regions through oxygen-dependent phototoxic reactions on excitation by light (see section Porphyria Cutanea Tarda) ([22], [23]). This relentless process leads in varying degrees to the formation of subepidermal bullae, secondary infection, scarring, epidermal atrophy, and resorption of acral structures.

CLINICAL DESCRIPTION The first sign of the disease is often discoloration of the infant's diapers by the urine, which ranges in color from pink to deep burgundy. The most prominent manifestation is pronounced cutaneous photosensitivity. Exposure to sunlight is followed by the development of vesicular or bullous lesions containing a porphyrin-rich, fluorescent fluid. The lesions tend to heal slowly, leaving pigmented scars. Often, they become infected, ulcerated, and necrotic. Over a period of years, patients develop progressive mutilation and disfigurement with loss of portions of the fingers, nose, eyelids, or ears (Fig. 31.2). Corneal scarring can lead to blindness ([5]). Skin not exposed to light is unaffected. Hypertrichosis is prominent and fine hair growth may cover much of the face and extremities. The patients often adopt extreme precautions to avoid the sun. Deposition of porphyrin in the dentin of the teeth causes them to appear red (erythrodontia), brown, or yellowish. Even if discoloration is not apparent in ordinary light, the teeth exhibit red fluorescence in ultraviolet light. At necropsy, the entire skeleton has this red fluorescence ([21]). Osteopenia and osteolytic lesions can occur ([24]).

Anemia, the result of both hemolysis and ineffective erythropoiesis, is detected in most patients, and usually the spleen is enlarged.

LABORATORY FINDINGS The anemia is normocytic, normochromic, and of variable severity. Detailed morphologic descriptions of the blood and bone marrow have been reported in a few patients. Anisocytosis, poikilocytosis, polychromasia, basophilic stippling, and nucleated erythrocytes are fairly common features of the peripheral blood ([25]). Morphologic abnormalities of the bone marrow range from erythroid hyperplasia to striking dyserythropoiesis ([18], [25], [26]). Nuclear inclusions containing hemoglobin may be present ([18], [26], [27]). Results of studies of the marrow with light and fluorescence microscopy suggest the coexistence of normal and abnormal erythropoietic cells ([18], [26], [27]). Fluorescence is restricted to the morphologically abnormal cells and is most marked in cell nuclei ([18], [26], [27], [28] and [29]). Evidence of a dual nature of the erythroid precursors has been supported by ultrastructural studies in two cases ([18], [30]). Kinetic features of the anemia have been studied in several patients, and both a shortened red cell survival and ineffective erythropoiesis were observed ([31]). The ineffective erythropoiesis is manifested by a pronounced increase in early-labeled bile pigments (Chapter 9) ([32]). Kinetic studies also support the morphologic findings by demonstrating the production of both normal and abnormal erythrocytes in the same subject ([33], [34]). The morphologic and kinetic features of the anemia of CEP closely resemble those of congenital dyserythropoietic anemia type I (Chapter 46). The most characteristic metabolic abnormality is greatly increased urinary excretion of uroporphyrin I, a biologically useless isomer that cannot be converted to heme. Urinary excretion of uroporphyrin III and coproporphyrins I and III is also increased but to a lesser extent than uroporphyrin I ([5], [16]). High-pressure liquid chromatography analysis reveals a slight increase in urinary porphyrins with seven, six, and five carboxyl groups ([35]). Total urinary porphyrin excretion may exceed 100,000 µg daily (normal is <300 µg), and the urine usually fluoresces on exposure to ultraviolet light. Fecal excretion of porphyrins, especially coproporphyrin I, is greatly increased ([16], [36]). The concentration of uroporphyrin I is increased in erythrocytes and plasma, but the marrow porphyrin content exceeds that of the peripheral blood or other tissues ([16]).

TREATMENT Splenectomy may partially or completely relieve the hemolytic anemia and may also lead to reduced porphyrinuria and photosensitivity ([25], [26], [37], [38]). However, this operation is not always beneficial ([29], [39]) and is not always warranted by the degree of anemia. Suppression of erythropoiesis by transfusion decreases porphyrin excretion ([5], [40]). A young boy with CEP was successfully treated with chronic hypertransfusion ([41]); transfusion-induced iron overload was avoided by means of concomitant chelation therapy with a regimen similar to that developed for the treatment of thalassemia major (Chapter 42). After puberty, his relapse on this regimen was controlled with the addition of hydroxyurea ([42]). Another patient was treated successfully with long-term orally administered charcoal at a dose of 60 g three times daily ([43]). Oral charcoal appeared to act by binding porphyrins excreted in bile and serving as a sump that diverted circulating and skin porphyrins to a fecal route of elimination in two cases ([44], [45]) but had no effect in others ([5]). Brief courses of treatment with hematin brought about reductions in urinary and fecal porphyrins but no clinical improvement ([46], [47]). Longer courses of such therapy, perhaps by infusion pump, may deserve consideration in selected patients. In two patients, severe anemia improved with administration of the antioxidants a-tocopherol and ascorbic acid ([24]). Stem cell transplantation was successful in seven of nine patients ([4], [5]). In theory, the most definitive method to control the disease would be transfer of the normal gene into hematopoietic stem cells of the affected patient. To date, *in vitro* correction of the enzyme defect was achieved by retroviral transfer of the normal gene into deficient fibroblasts ([48], [49]) and lymphoblasts ([49], [50]) as well as into deficient hematopoietic progenitor cells ([51]). Techniques for efficient gene transfer into sufficient cells for infusion to permit long-term repopulation of the bone marrow continue to be under development. Prenatal diagnosis or exclusion of the disorder is possible with enzyme assay or DNA analysis of amniotic fluid cells ([52], [53]). Most patients must rely on avoidance of exposure to sunlight. They should be instructed to wear photoprotective clothing, including gloves and broad-brimmed hats. Conventional sunscreen agents are ineffective because they do not screen out the wavelengths in the Soret band of the nearly visible spectrum (around 400 nm) that are responsible for inducing porphyrin-mediated photosensitivity ([54]). To be effective, a local agent must be visible on the skin. Reflective materials, such as zinc oxide and titanium oxide, are useful, as is ordinary pigmented theatrical makeup ([55]). Preparations containing substituted quinones (such as Lawsone) and dihydroxyacetone turn the skin a cosmetically acceptable brownish-tan and may be effective ([56]). Therapy with ß-carotene beadlets may also offer some protection from the deleterious effects of light ([57]) (see section Erythropoietic Protoporphyria).

CONGENITAL ERYTHROPOIETIC PORPHYRIA IN ANIMALS CEP (pink tooth) in cattle appears to be milder than the human disorder. The disease is inherited as an autosomal-recessive trait, and heterozygous animals are clinically and biochemically normal ([58], [59]), although an increased ratio of coproporphyrin I to coproporphyrin III in the urine has been reported ([60]). Photosensitivity of the skin areas not covered by pigmented hair and hemolytic anemia have been observed ([61]). The teeth and bones are stained red ([59]). Furthermore, UROIII-S activity is severely impaired in erythrocyte lysates ([27], [62], [63]). A similar disorder has been observed in pigs and cats, but the inheritance pattern appears to be dominant ([64], [65], [66] and [67]). In the fox squirrel (*Sciurus niger*), as part of the apparently normal physiology of the species, large amounts of uroporphyrin I are deposited in the tissues and excreted in the urine ([68]). As in human CEP, the normoblasts and young erythrocytes show a red fluorescence; however, hemolytic anemia is lacking, and the fox squirrel seems to suffer no ill effects. Erythroid UROIII-S activity is lower than that found in the closely related but nonporphyric gray squirrel (*S. carolinensis*) ([68]).

Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is the most commonly encountered porphyric disorder. It is caused by defects of URO-D (Fig. 31.1) that are expressed in the liver, leading to accumulation of uroporphyrins, their release into plasma, and excretion in the urine ([16]). Clinical manifestations are limited to the skin in the form of a photosensitive bullous dermatosis as a consequence of the circulating uroporphyrins. Neurovisceral symptoms never occur. Symptoms usually arise in mid or later life (hence the name *tarda*) and are nearly always brought on by genetic and environmental factors, most often hepatic siderosis, alcohol abuse, hepatitis C virus, and estrogen therapy. Since the first comprehensive description of the disease in 1937 ([69]), three variant forms of the illness have been recognized: familial, sporadic, and acquired (toxic).

MOLECULAR BASIS AND PATHOGENESIS Among the variants of the disorder, a genetic basis has been established for one, designated *familial PCT* (type II), and it accounts for 20 to 30% of cases ([70], [71], [72], [73] and [74]). Studies of patients with subnormal URO-D activity in both hepatic and extrahepatic tissues, and their relatives, revealed that the enzyme defect is inherited as an autosomal-dominant trait ([75], [76], [77], [78] and [79]). Enzyme activity is one-half normal in all tissues, as is the amount of URO-D protein detected with antibodies ([80], [81] and [82]). In the rare homozygous form, also designated *hepatoerythropoietic porphyria (HEP)*, residual enzyme activity ranges from 3 to 27% of normal ([16], [82], [83], [84] and [85]), but immunoreactive enzyme is variable ([81], [82], [86]). Since the cloning of the human *URO-D* gene ([87]), located on chromosome 1 (1p34) ([88]), 57 different mutations in the gene have been identified at last count ([89]). Usually, a given mutation is found in one or in a few kindreds. The majority are various point mutations in the coding region of the gene or splice site mutations, resulting in changes of amino acids, frameshifts, or deletions of an exon. In some instances, large nucleotide deletions were detected. The defects usually result in the production of an unstable or inactive enzyme from the mutant allele. Structural consequences of many of the mutations were recently defined or predicted on the crystal structure of the enzyme ([90]). In the homozygous version, ten different mutations have been identified, with only one mutation occurring in several unrelated families ([89]). The mutations are homoallelic or heteroallelic, usually causing instability or impaired catalytic activity of the enzyme. In one instance, the clinical phenotype is unusually mild ([91]). When the URO-D defect is restricted to the liver and a genetic basis for the disorder is not evident, it is called *sporadic PCT* (type I) ([78], [80], [92]). Both the catalytic activity and the immunoreactivity of erythrocyte URO-D are normal in this variant ([81], [92]). In the liver, catalytic activity of URO-D is subnormal, but immunoreactive enzyme is present in normal or increased amounts ([93]). After prolonged remission is induced by phlebotomy therapy, both catalytic activity and immunoreactivity become normal ([93]). These findings, coupled with lack of a family history in most cases of sporadic PCT, suggest that this form of the disease is acquired and not inherited. At the molecular level, no mutations could be found in the *URO-D* gene or its promoter region ([94]). However, in a few families, clinically manifest PCT was associated with decreased URO-D activity in liver and normal activity in erythrocytes and other tissues ([89]). These cases have been called *type III PCT*; molecular studies have not identified *URO-D* mutations in them ([73]). The cutaneous damage produced by the increased concentration of uroporphyrins in plasma and skin of patients with PCT is based on the fundamental properties of the porphyrins. As they absorb light at 400 to 410 nm (Soret band), not only does their photoexcitation yield energy as fluorescence, but in the aerobic environment of tissues, reactive oxygen species (superoxide anion and other reactive metabolites) are produced ([95]) that are damaging to cells. *In vivo*, superoxide anions are generated by activation of xanthine oxidase ([96]). The complement system is light activated *in vitro* in sera containing porphyrins and *in vivo* in the skin of porphyric patients, promoting release of proteases from dermal mast cells ([23]). Chemotactic activity is also generated under these conditions, and the peroxides produced by photoexcitation of the porphyrin and those arising from polymorphonuclear leukocytes with activation of the complement system may act synergistically to contribute to the development of the cutaneous lesions. As a consequence of these events, the dermal–epidermal junction becomes disrupted and leads to skin fragility and the formation of vesicles and bullae that easily rupture. Sclerodermoid changes of the skin result from a light-independent effect (the “dark effect”) of the uroporphyrin on collagen synthesis by skin fibroblasts ([97]). The pathogenesis of the hyperpigmentation, hypopigmentation, and the hypertrichosis is not understood. Most family members carrying a defective gene of familial PCT do not have clinically apparent disease and have little or no uroporphyrin accumulation or excretion; in occasional pedigrees, overt manifestations of the disease have been noted in several generations ([76]). Clinical expression of both familial and sporadic PCT can nearly always be associated with prevalent confounding factors that cause hepatic injury, so the disorder remains silent without these. In large series of PCT, most patients had more than one of the four cardinal risk factors, namely iron excess, alcohol, viral infection (hepatitis C), and estrogen ([73], [74]).

Iron The central role of iron in the clinical expression of PCT has been recognized for over 40 years ([98], [99]). Numerous studies documented hepatocellular siderosis in most patients with significant uroporphyrinuria ([100], [101], [102], [103], [104], [105], [106] and [107]). The iron deposits generally are moderate in amount, 1.5 to 4 times normal, but

are usually greater with concomitant HLA-linked hemochromatosis (Chapter 30) ([102], [108], [109], [110], [111] and [112]). Except for the geographic variation in the frequency of the hemochromatosis *HFE* alleles ([89]), on the average, 35% of patients with sporadic PCT are heterozygous for the Cys282Tyr mutation, and 15% are homozygous or compound heterozygotes with the His63Asp mutation ([73], [74], [113], [114] and [115]). Transfusional iron overload is being recognized as another mechanism promoting clinical expression of PCT ([116], [117]). Removal of iron by repeated phlebotomy ([118], [119] and [120]) or by administration of deferoxamine ([121]) uniformly induces both clinical and biochemical remissions. Replenishment of iron stores is followed by prompt relapse in patients in whom a remission has been induced by phlebotomy ([102], [122]). Iron somehow plays an important part in impairing the residual activity of hepatic URO-D to levels that produce symptoms. It may inhibit the enzyme ([123], [124] and [125]), either through possible direct oxidant effects ([126]) or by participating in reactions that generate singlet oxygen ([127]), which then reacts with the enzyme. Iron may also promote oxidation of uroporphyrinogen to uroporphyrin. It has been proposed that an inhibitor is generated in liver cells that partially inactivates hepatic URO-D in an iron-dependent manner, as hepatic URO-D activity in the sporadic variant of PCT is diminished without reduction in enzyme protein, and iron depletion leads to normalization of enzyme activity ([73], [92], [93]).

Alcohol Ethanol exacerbates PCT. Heavy alcohol intake has been reported in 25 to 100% of patients in several studies ([73], [74], [105], [128], [129]), and hepatic cirrhosis is not uncommon ([105], [106]). Yet the porphyria is an uncommon complication of alcoholic liver disease, occurring in only approximately 2% of cases ([130]). The association of clinically expressed PCT with alcoholism may relate to its hepatotoxicity or its role in stimulating iron absorption ([131], [132]). In this regard, PCT is particularly common among the Bantu population of South Africa, where it is associated with excessive consumption of alcoholic beverages brewed in iron containers ([133], [134]), thus providing a double threat to susceptible people. Studies have suggested that an iron-loading gene other than the HLA-linked hemochromatosis gene plays a role in the iron overload of this population when iron intake is excessive (Chapter 30) ([135]).

Hepatitis C A striking association between symptomatic PCT, familial and sporadic, and hepatitis C is well recognized but is variable around the world. Although most patients with hepatitis C infection do not have the porphyria, as many as 80% of PCT patients are chronically infected with the virus in some locations ([73], [74], [89], [114], [136], [137], [138], [139] and [140]). This infection may explain, at least in part, the liver damage often found in PCT; how it may help unmask the disorder or affect URO-D is not known ([141]). Some association of PCT with human immunodeficiency virus (HIV) infection has also been described ([140], [142], [143]), and many such patients may be infected with both HIV and the hepatitis C virus ([140], [144]). Dual infection causes more severe hepatic disease; whether the HIV virus per se plays a role in the expression of PCT is not known. Because patients with at least the sporadic form often have underlying viral infection, they should be assessed for the presence of hepatitis C and HIV antibodies at the time of diagnosis ([140]).

Estrogen The association of estrogen ingestion and expression of PCT has been reported numerous times but only in a very small percentage of patients who ingest estrogens, consistent with an underlying predisposition to the disease. The cutaneous symptoms have occurred with the use of estrogen as postmenopausal supplement ([73], [145], [146] and [147]), for contraception ([145], [146], [147], [148], [149] and [150]), and for prostatic carcinoma ([145], [151], [152] and [153]). Uncommonly, patients present with the disorder during pregnancy ([154], [155] and [156]), but pregnancy has also been reported as not exacerbating PCT ([157], [158]). The mechanism of the estrogen effect is not known. It may be a minor factor, as phlebotomy alone has brought about full recovery. Most women needing estrogen supplements at the usual dose can probably use them, provided that storage iron is removed and maintained at a low level.

Renal Failure PCT occurs in patients with renal failure undergoing hemodialysis ([159], [160]). Symptoms may first arise in this setting for several reasons. Iron overload has been common in such patients ([160]), and intravenous iron now used in conjunction with erythropoietin may precipitate clinical PCT ([161]). Hemodialysis or peritoneal dialysis does not effectively clear circulating plasma uroporphyrins ([162], [163]), presumably because porphyrins are bound to proteins ([164]). The uremic state may also contribute to an inhibited URO-D and uroporphyrin accumulation independent of an underlying enzyme defect or inhibition ([165]). In two patients, erythrocyte URO-D assays indicated that familial PCT was present ([166], [167]). In most reported cases, the lack of family studies makes it difficult to classify the porphyria.

CLINICAL DESCRIPTION Cutaneous changes are the principal clinical manifestations of PCT ([16], [105], [168], [169]). Skin lesions are found predominantly on light-exposed areas such as the face and hands and, in women, on the legs and feet as well. There is little discomfort with sun exposure per se, and blue (visible) light triggers only an insidious cutaneous damage. The most common complaint is marked skin fragility in areas subjected to repeated minor trauma, such as the hands and forearms (Fig. 31.3). Vesicles and bullae form primarily on the dorsa of the hands and may erode, leaving atrophic scars that often display zones of both hyperpigmentation and hypopigmentation. Small, 1- to 2-mm, firm, whitish papules (milia) are commonly noted on the hands and, at times, on the face.

Figure 31.3. Porphyria cutanea tarda in a 60-year-old man. Note denuded skin areas over the fingers, an erosion, blisters, and milia. See Color Plate.

Facial hypertrichosis occurs in most patients, is generally more noticeable in women, and may be an isolated presenting feature ([170]). Hypertrichosis, sometimes striking, is occasionally observed on areas of the skin that are rarely exposed to the sun, such as the trunk and legs. Other findings include hyperpigmentation of facial skin, alopecia, and scleroderma-like changes on the skin of the face, neck, and hands. The histologic appearance of the scleroderma-like lesions is identical to that seen in patients with systemic scleroderma ([169]). Occasionally, patients have overt signs and symptoms of underlying liver disease, but no good correlation exists between the degree of liver disease and the occurrence or severity of the porphyria. In the homozygous form of familial PCT or HEP, the skin changes just described usually occur before the age of 5 years and may be severe ([82], [83], [89], [171]). Hepatosplenomegaly is occasionally noted, and dental fluorescence has been reported.

LABORATORY FINDINGS Patients with PCT excrete greatly increased amounts of porphyrins in the urine. Uroporphyrin and heptacarboxylic porphyrin predominate, with lesser amounts of coproporphyrin and small amounts of 5- and 6-carboxylate porphyrins ([105], [169], [172], [173]). Usually, the daily urinary excretion of uroporphyrin is approximately 3000 µg (normal, <50 µg) ([105], [173]), but considerably higher values may be found. Uroporphyrin in the urine is predominantly isomer I, whereas the heptacarboxylic porphyrin is predominantly isomer III ([16], [105], [174], [175]). Photosensitive cutaneous symptoms rarely occur when the daily urinary excretion of uroporphyrin is less than 1000 µg. Excretion of urinary coproporphyrin is slightly increased but rarely exceeds 600 µg daily ([105]). An unusual and distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces ([176]), and a slight increase may be noted in total fecal porphyrin excretion ([16], [173]). Homozygotes for the defect have mild anemia, and the erythrocyte protoporphyrin was found to be moderately increased when measured ([89], [177]). The serum iron concentration and, hence, transferrin saturation are often increased ([73], [105]). Values for liver function tests vary considerably from one patient to another. Some patients have mild degrees of jaundice and slight to moderate elevations in serum transaminase levels. Liver biopsy specimens display characteristic reddish-pink fluorescence ([105], [178], [179]). On microscopic examination, siderosis, periportal inflammation, focal necrosis, fatty infiltration, and some evidence of fibrosis are common findings ([105], [106], [175], [178], [179]). Often, fluorescent and birefringent needle inclusions are noted ([179], [180]). Electron microscopic studies reveal needlelike lucent areas, which appear to be in lysosomes ([179], [181]). Microscopic examinations of skin biopsy specimens show bullae formed by the separation of the epidermis from the dermis; periodic acid-Schiff–positive, diastase-resistant material around vessel walls in the upper dermis; and a sparse inflammatory cell infiltrate ([105], [169], [182], [183]). Immunofluorescence studies show deposition of immunoglobulin G (and less often immunoglobulin M) or complement around upper dermal vessels and at the dermal–epidermal junction ([183]).

TREATMENT Exposure to alcohol and excessive estrogen supplements in women should be avoided. Abstinence from alcohol can lead to remissions in some patients with the porphyria associated with alcoholic liver disease ([118], [119], [184]); however, removal of iron by phlebotomy can induce remissions even if alcohol intake continues. It is also of interest that a remission was achieved in patients with PCT and hepatitis C after treatment with a-interferon alone ([185], [186]). Transdermal administration of estrogen was found to be safe in a small number of patients ([187]) and avoids any possible first-pass effects of the hormone on the liver. The definitive treatment of both sporadic and familial PCT is the removal of iron stores by phlebotomy, which leads to clinical and biochemical remission in virtually every case and may improve concomitant hepatitis C virus infection. If there are no contraindications, 500 ml of blood can be removed every 2 weeks. Initial serum transferrin saturation and ferritin values are obtained to estimate the iron burden. Liver biopsy must also be considered to assess the disease status of associated viral hepatitis and hemochromatosis. Clinical remissions often occur after the removal of approximately 3 L of blood ([105], [118], [175]); patients who also have hemochromatosis usually require considerably more therapy and indefinite regular maintenance phlebotomies. The optimal approach is to achieve mild iron deficiency, defined by onset of iron-limited erythropoiesis in which the mean corpuscular volume is decreased to low normal, the serum transferrin saturation is normal, and the serum ferritin is near 20 µg/L or lower. Although further overproduction of uroporphyrins is halted thereafter, the chronically accumulated, relatively hydrophobic porphyrins are released slowly from the liver. Patients should be advised that formation of new skin lesions ceases gradually, and full recovery often extends over several months to a year or more ([105]). Remissions for years are the rule ([105], [118]) and are permanent when the known precipitating factors are avoided; any clinical and biochemical relapse responds to another course of phlebotomies. Chloroquine has also been used in the treatment of PCT ([188], [189], [190], [191]

and [192]). After the administration of 0.5 to 1.0 g/day for several days, a large amount of the porphyrins stored in the liver was mobilized and excreted in the urine ([188], [193]). This purging effect results from the formation of an easily excreted water-soluble complex between uroporphyrin and the drug ([194]). The chloroquine effect was often accompanied by malaise, anorexia, fever, and signs of hepatocellular damage. The subsequent use of lower doses made it possible to avoid the toxic response without impairing efficacy ([189], [195]), but this maneuver does not always preclude toxicity ([105]). Because of the potential danger of the hepatic reaction to chloroquine and because phlebotomy is usually safe and effective, administration of low doses of chloroquine should be reserved for patients for whom phlebotomy is unsuitable. The use of sunscreen agents effective in the Soret band of the spectrum and avoidance of sunlight through protective clothing can be useful until the beneficial effects of phlebotomy occur. These measures are the only means to help patients with the homozygous form of PCT because phlebotomy is not effective. Anemia and cutaneous symptoms responded to erythropoietin in one case ([196]). Efforts toward somatic gene therapy have been initiated by demonstrating correction of the enzyme defect with retroviral gene transfer *in vitro* in transformed B-cell lines ([197]). Prenatal exclusion of HEP has been possible ([198]). Treatment of patients with PCT complicating renal failure presents special challenges. The disorder may be particularly severe because such patients lack the renal excretory pathway for porphyrins, leading to higher porphyrin levels in plasma and tissues. Chloroquine–porphyrin complexes are not filtered out by standard hemodialysis. High-flux hemodialysis appears to remove porphyrins from plasma better and may be of some benefit ([199]). The treatment of choice is administration of recombinant erythropoietin to mobilize stored iron and relieve the anemia so that phlebotomies can be performed as necessary to induce remission ([200], [201]). This method is preferable to the alternative of depleting iron stores with the iron chelator deferoxamine ([201], [202]). In patients refractory to these treatment methods, the porphyria fully resolved after renal transplantation ([203], [204]).

TOXIC PORPHYRIA CUTANEA TARDA In Turkey between 1956 and 1961, an epidemic of acquired porphyria affecting more than 3000 people occurred as the result of exposure to flour contaminated with a seed wheat fungicide, hexachlorobenzene ([205], [206] and [207]). Members of both sexes were affected, and many of the subjects were children. Affected people developed hepatomegaly, hypertrichosis, hyperpigmentation, uroporphyrinuria, and a photosensitive dermatosis. Uroporphyrinuria and a variety of other signs and symptoms persisted in some individuals for more than 25 years ([208], [209]), and no effective therapy has been devised for this toxic porphyria. Subsequent studies in animals demonstrated that hexachlorobenzene, or one of its metabolites, is a potent inhibitor of hepatic URO-D ([210], [211], [212], [213] and [214]). Iron magnifies this inhibitory effect ([213]), and clear genetic susceptibility to this type of acquired porphyria has been shown in mice ([215]). Other polyhalogenated aromatic hydrocarbons also have produced a toxic porphyria in humans. 2,3,7,8-Tetrachlorodibenzo- *p*-dioxin, a by-product in the manufacture of the herbicides 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, and some polychlorinated biphenyls, has proved porphyrinogenic for humans ([216], [217] and [218]). Animal studies indicate that compounds of this class inhibit hepatic URO-D activity ([219], [220]). As in the case of hexachlorobenzene-induced porphyria, iron magnifies the inhibition of URO-D activity, and iron depletion minimizes the inhibitory effect of these agents ([221]). The parallel between the permissive effects of iron in acquired toxic porphyria and the role of iron in the pathogenesis of both familial and sporadic PCT is striking.

HEPATOCELLULAR CARCINOMA An increased frequency of hepatocellular carcinomas has been reported in patients with PCT ([222], [223], [224], [225] and [226]), and such tumors are associated with a long symptomatic period before the start of treatment as well as with the presence of cirrhosis or chronic active hepatitis ([225], [227]). The body iron status is not known in these cases, but iron overload could also play a role. In contrast, documented evidence supports a PCT-like illness as a manifestation of porphyrin-producing hepatoma in an otherwise normal liver in several cases ([228], [229], [230], [231], [232] and [233]). When the tumor could be surgically removed, the cutaneous symptoms and biochemical abnormalities remitted ([228], [233]).

ANIMAL MODELS OF PORPHYRIA CUTANEA TARDA The first genetically designed animal model of PCT and HEP was developed in zebrafish ([234]). Heterozygous and homozygous mutants have 67% and 36% of wild-type URO-D activity, respectively. The enzyme deficiency was linked to a missense mutation in the *URO-D* gene, predicting a Met38Arg substitution that involves a conserved amino acid across all species examined, including humans. The mutant phenotype could be rescued by transient and germline expression of the wild-type allele. Transgenic mice with one disrupted *URO-D* allele ($URO\text{-}D^{+/-}$) have half the wild-type hepatic URO-D protein and enzyme activity but no accumulation of porphyrins ([235]). However, in response to iron loading, hepatic porphyrins accumulate, and URO-D activity declines to 20%. When bred to $HFE^{-/-}$ mice, $URO\text{-}D^{+/-}/HFE^{-/-}$ animals developed a porphyric phenotype with further reduction of URO-D activity to 14%, resembling the human condition. $HFE^{-/-}$ mice that are fed ethanol also develop uroporphyria and reduced hepatic URO-D activity, seemingly mediated by effects of ethanol on hepatic iron metabolism ([236]).

Erythropoietic Protoporphyria

Erythropoietic protoporphyria (EPP), the third porphyric disorder with mainly cutaneous manifestations, is not uncommon, with an estimated prevalence of 1 per 75,000 to 200,000. Since the first clear description of the disease by Magnus et al. in 1961 ([237]), hundreds of cases have been reported throughout the world ([16], [238], [239], [240], [241] and [242]). Defects in the gene encoding ferrochelatase (FECH), the last enzyme in the heme biosynthetic pathway (Fig. 31.1), are responsible for the disorder and result in accumulation of protoporphyrin, mainly in erythroid tissue. The cutaneous manifestations are distinctive, but considerable individual variation is noted in clinical severity as well as in biochemical abnormalities. The inheritance pattern was considered heterogeneous ([239], [240] and [241]). Based on recent findings, transmission of EPP is favored as a recessive trait ([243]).

MOLECULAR BASIS AND PATHOGENESIS Subnormal FECH activity is found in all tissues examined from patients with EPP, which include bone marrow ([244]), reticulocytes ([245]), lymphocytes ([246], [247]), liver, and cultured skin fibroblasts ([248]). The protoporphyrin accumulates principally if not entirely in erythroid cells ([238]), whose contribution to heme production far exceeds that of all other tissues. Studies attempting to quantify the protoporphyrin tissue source in individual patients have been indirect, and different conclusions were reached ([249], [250] and [251]), likely reflecting the heterogeneity of the disorder. Although the normal relative activity of FECH in erythroid tissue, in contrast to liver, is the second lowest among the enzymes of the heme biosynthetic pathway and is only three times higher than 5-aminolevulinate synthase ([15]), defective FECH in EPP does not appear to be rate-limiting until late in erythroid development, so patients often exhibit a mild hypochromic-microcytic anemia ([244], [252], [253]). Protoporphyrin begins to accumulate in bone marrow erythroblasts just before the nucleus is lost ([254], [255]), and reticulocytes still within the marrow probably are the major source of protoporphyrin in plasma on its rapid release from these cells ([256], [257]). Because of its low water solubility, the protoporphyrin is not excreted in urine but is taken up by the liver and excreted exclusively through the biliary tract. Why some cases exhibit the ring sideroblast abnormality in erythroblasts (Chapter 29) ([258], [259]) but others do not ([244]) is not clear and may relate to the nature of the defect or to the presence of an independent abnormality involving heme biosynthesis. Based on clinical features and FECH activity in many pedigrees, inheritance of this porphyria was considered most often to follow an autosomal-dominant pattern ([241], [253], [260], [261] and [262]). In a few families, autosomal-recessive inheritance was suggested ([240], [241], [263]). Much individual variation is noted in the severity of clinical features and biochemical abnormalities ([16]). FECH activity in tissue lysates from patients with clinical EPP is only 20 to 30% of normal ([16], [238]), not the 50% value expected for an autosomal-dominant enzyme deficiency. Neither levels of FECH activity nor levels of erythrocyte and fecal protoporphyrin consistently correlate with severity of symptoms. Moreover, most obligate carriers of the disorder have no symptoms ([261]). Their erythrocyte and fecal protoporphyrin levels are usually normal ([16]), and tissue FECH activity is approximately 50% of normal ([16], [238]). To explain the great variability in the clinical phenotype, it was proposed that more than one allele is involved in the full expression of the disease ([239], [264]). This proposal was also supported by the finding that, within a family, FECH activity in mitogen-stimulated lymphocytes was lower in EPP patients than in those with a latent defect ([247]). The human *FECH* gene is located on chromosome 18 (18q21.3) and expresses two messenger RNAs (mRNAs), the housekeeping and the erythroid-specific form, differing in their 3' end ([265], [266] and [267]). Over 65 different mutations have been identified and are highly heterogeneous, including missense and nonsense mutations, nucleotide deletions and insertions, and intronic point mutations near intron/exon splice sites in one *FECH* allele ([242]). Most often, the defects lead to frameshifts or exon deletions, resulting in a truncated protein ("null allele") ([242], [268], [269]). The entire *FECH* gene was absent in one patient as a result of a chromosome 18q deletion ([270]). In a few instances, a mutation was found on each allele ([263], [271], [272]). Although these few compound heterozygotes clarified the phenotypic differences between symptomatic and asymptomatic members of the families, in all other cases, despite similar phenotypes, only one mutant allele was found ([242], [268], [269] and [270]). Then, it was established that co-inheritance of a "low-expression" normal allele of *FECH* along with the mutant allele determines clinical expression of the disorder ([273], [274]). The low-expression allele is highly associated with a specific ancestral haplotype that occurs in approximately 10% of whites at a single nucleotide polymorphism site in the *FECH* gene (IVS3-48T/C) that influences the use of a constitutive aberrant acceptor splice site in the gene ([275]). The aberrantly spliced RNA fraction is degraded, decreasing the steady-state level of FECH mRNA expressed by the allele. This discovery also correlates with the finding that only approximately 10% of individuals with a mutant *FECH* allele develop clinical symptoms. Alternatively, in some kindreds in which clinical disease is transmitted from generation to generation, a dominant-negative effect of *FECH* mutants may be operative ([276]). Because the enzyme activity is restricted to its homodimers ([277]), a mutant monomer could generate nonfunctional homodimers and heterodimers, and the average residual enzyme activity of approximately 25% would be accounted for by the wild-type homodimers. The ultimate effects of a specific mutation in the *FECH* gene should depend on how the mutation affects the integrity of the protein and whether the nonmutated allele is expressed at a lower level to reduce FECH activity to the 20 to 30% of normal as found in clinically overt EPP. The great variability in phenotype is also consistent with unique mutations encountered in most pedigrees of EPP ([242]), with only a few mutations so far recurring in unrelated families ([242], [278], [279]). The extent to which the enzyme deficiency affects heme biosynthesis in different tissues remains unsettled. Although erythroid cells accumulate the majority of protoporphyrin and release it into plasma, the liver may be a significant source in some patients ([238], [249]). Regardless of its origin, the protoporphyrin is extracted

from plasma by the liver and is secreted unchanged into the bile. The liver is capable of clearing large amounts of protoporphyrin, but its secretion across the canalicular membrane and into the bile appears to be rate-limiting ([280], [281] and [282]). Cholestasis results when large amounts of protoporphyrin are cleared and secreted, leading to obstruction of biliary radicles, protoporphyrin accumulation in hepatocytes, and liver damage. Yet despite microscopic evidence of hepatobiliary changes in many EPP patients, cirrhosis and hepatic failure occur in only a few (<5%) ([283], [284]). This complication tends to be an abrupt event, is unrelenting, and is not predictable from prior biochemical features or the clinical course of the patient. Likewise, genetic factors do not explain this fatal form of the disease. Whereas it occurred in two young siblings who were compound heterozygotes for two mutations ([272]), another compound heterozygote for different *FECH* mutations had no liver dysfunction at 27 years of age ([271]), and liver failure has occurred in heterozygotes ([285], [286]). Among eight unrelated EPP patients requiring liver transplantation, genetic heterogeneity was also observed; the mutations found shared only the property of causing a major structural alteration in the FECH protein ([287]). In a recent analysis of 112 EPP patients, all 18 who developed liver disease carried a null allele mutation, whereas none of 20 patients having missense mutations had liver disease as yet ([288]). Additional undetected molecular derangements or undefined hepatic factors, including a greater hepatic source of the excess protoporphyrin related to the defect, can be postulated. Excess alcohol intake ([289]) and viral hepatitis ([290]) have been reported to accentuate the genetic disorder. The deposition of protoporphyrin in endothelial cells of skin capillaries after release of the porphyrin into plasma is responsible for the light-induced skin damage in patients with EPP ([291], [292]). Porphyrin-sensitized, oxygen-dependent histochemical reactions and the activation of complement eliciting an inflammatory response are involved in the pathogenesis of the photodynamic skin damage ([22], [23]). The extensive double-bond structure of the protoporphyrin seems to render it particularly photoactive, resulting in the typical acute epidermal phototoxicity ([237]), in contrast to the porphyrins that accumulate in the other porphyrias with cutaneous photosensitivity. The activated porphyrin also stimulates fibroblast proliferation, accounting for a characteristic waxy thickening of the sun-exposed skin ([23]).

CLINICAL DESCRIPTION Usually, EPP first manifests in childhood or early adolescence ([16], [253], [261], [293]). It has occasionally developed as a similar phenotype in later years in the setting of acquired idiopathic sid-eroblastic anemia (Chapter 29) ([15]) or a myelodysplastic syndrome ([294], [295] and [296]), with a chromosome 18q deletion in bone marrow cells of some of the cases. The cutaneous features of photosensitivity are unlike those seen in patients with other porphyrias; bullae, scarring, sensitivity to trauma, hirsutism, and hyperpigmentation are extremely unusual ([291]). In some patients, the symptoms are subjective. Most patients, after exposure to the sun for periods of a few minutes up to several hours, have intensely unpleasant sensations of prickling, itching, or burning (photoparesthesias) followed by the development of erythema, urticaria, and edema ([253], [291]). Less commonly, solar urticaria, a confluent, hivelike rash, occurs within minutes of exposure and lasts approximately 30 minutes ([237], [291]). In general, the signs and symptoms involve only the uncovered areas of the body and subside in the course of hours or days without significant sequelae. Occasionally, these early reactions are followed within a day or two by vesicular, eczematous lesions (solar eczema) that become crusted ([297]), last for several weeks, and heal with scar formation ([253], [291]). Chronic skin changes may include shallow, pitted scars or pseudovesicles over the cheeks and nose and thickened, leathery skin (pachydermia) over the dorsa of the hands (Fig. 31.4A and Fig. 31.4B) ([253], [291], [297]). Many cutaneous manifestations of EPP do not differ greatly from those found in patients with photosensitivity of unknown cause (so-called polymorphic light eruptions), which is more common and is not associated with abnormal porphyrin metabolism. In one study of over 600 light-sensitive patients, only 8% were found to have laboratory evidence of EPP ([298]).

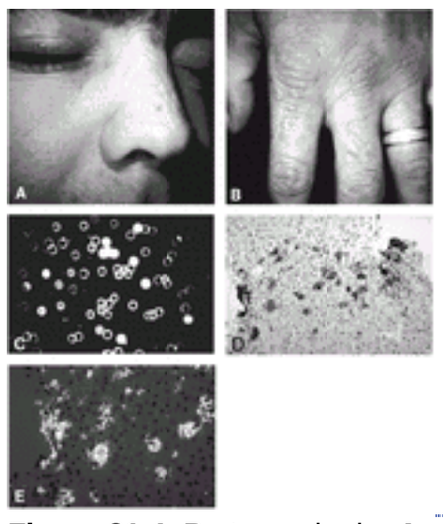

Figure 31.4. Protoporphyria. **A** and **B:** In a 29-year-old man. Note cobblestonelike, flesh-colored, lichenoid papules over the nose and dorsum of the hand joints. **C:** Dilute suspension of erythrocytes under the fluorescence microscope. Note a fraction of fluorescing cells. (Courtesy of Dr. Maureen Poh-Fitzpatrick, Columbia University, NY.) **D** and **E:** Needle biopsy section of liver. Note deposits of protoporphyrin pigment in the parenchyma and a portal triad **(D)**, and birefringence of the deposits, including a dark Maltese cross figure near the left center **(E)**. See Color Plate.

Cholelithiasis tends to develop early in life ([253], [299]) and ultimately occurs in approximately 10% of patients. The gallstones fluoresce and consist, in part, of precipitated protoporphyrin ([16], [300]). Although EPP is generally a benign disorder with clinical manifestations limited to the skin, a subset of patients develops progressive liver disease, leading to a fatal cirrhosis in the second to fourth decades of life ([283], [284]). At autopsy, massive hepatic deposits of protoporphyrin are found ([283], [301]). Associated with the fulminant liver failure are rising blood protoporphyrin levels with progressive cholestasis, hemolysis, increasing photosensitivity, and neurologic crises resembling those of the acute porphyrias ([302], [303]). The neurologic dysfunction was best correlated with a markedly increased level of plasma protoporphyrin and was believed to cause neurotoxicity ([302]).

LABORATORY FINDINGS The free erythrocyte protoporphyrin (FEP) concentration is greatly increased in symptomatic patients. Reported values range from 300 to 4500 µg/dl (normal, <50 µg/dl) ([16], [253], [261]). Increased levels of FEP are observed in certain other conditions, especially iron deficiency anemia, but only rarely do they exceed 300 µg/dl. The FEP may be as high in lead poisoning as in EPP ([304]); however, differentiation between the two is usually simple ([256]). In both lead poisoning and iron deficiency, the excess FEP is present as a zinc chelate ([305]) and can be distinguished spectrally from the nonchelated protoporphyrin found in EPP ([306]). Plasma protoporphyrin is usually increased as well, and a normal plasma porphyrin in a patient with increased FEP effectively excludes EPP. In asymptomatic carriers, the FEP ranges from normal values to 200 µg/dl ([261]). The life-threatening liver disease may be predicted by increasing FEP and plasma protoporphyrin levels along with altered liver function tests. In patients with severe protoporphyric liver disease, the FEP concentration generally exceeds 2000 µg/dl, and values greater than 8000 µg/dl have been reported ([283]). Fluorescence microscopy of a dilute suspension of freshly obtained blood reveals fluorescence in a variable proportion of erythrocytes (Fig. 31.4C) ([237]). Protoporphyrin is increased chiefly in young erythrocytes ([256], [307]) but is heterogeneous, and a population of reticulocytes without protoporphyrin is also present, reflecting a nonuniform expression of the genetic defect at the cellular level ([257]). In asymptomatic carriers, a small population of such fluorescytes may be detected even when the FEP concentration is normal ([239], [261], [308]). Many patients with EPP have mild, slightly hypochromic anemia ([252], [253], [298]). Studies of red cell survival and iron kinetics have failed to detect a characteristic abnormality ([16], [298]), but hemolysis is occasionally reported ([309], [310]). Severe hemolytic anemia may occur with advanced hepatic disease that is exacerbated by photooxidative stress occurring during the prolonged operative procedure of liver transplantation ([311]). Sideroblastic anemia was reported in a patient with EPP and severe protoporphyric liver disease ([258]) and was subsequently documented in nine additional patients with EPP ([259]). Fecal protoporphyrin excretion usually is increased in symptomatic patients ([253], [312]). Values may be as high as 1400 µg/g (dry weight) (normal, <100 µg/g) and vary widely from patient to patient, although variations in a given patient are not great ([313]). In some carriers, fecal protoporphyrin is increased even when the FEP is normal ([312]). An increasing ratio of FEP to fecal protoporphyrin and an increasing ratio of biliary protoporphyrin to biliary bile acids may also suggest impending hepatic decompensation ([284], [313], [314]). Urinary porphyrin and porphyrin precursor concentrations are normal. The majority of patients with EPP have no clinical evidence of liver disease, and liver function tests are generally normal. However, in most if not all cases, the liver contains dark brown pigment deposits (Fig. 31.4D) in hepatocytes, Kupffer cells, and portal macrophages as well as within the lumens of ductules and interlobular ducts that exhibit the characteristic red fluorescence of protoporphyrin when transilluminated with light of wavelength 380 to 500 nm ([315]). These deposits are crystalline in nature on electron microscopy. They also exhibit a distinctive type of birefringence, not shared by any other pigment known to occur in the liver, that is demonstrable in routinely fixed and stained paraffin-embedded sections and is as sensitive as the red fluorescence (Fig. 31.4E) ([315]). Not infrequently, the pigmentation is accompanied by bile stasis and varying degrees of portal inflammation, fibrosis, and ductular proliferation. In patients who have developed the protoporphyric liver disease, liver histology shows micronodular or macronodular cirrhosis and massive deposits of the pigment throughout ([283]).

TREATMENT Therapy is directed at reducing the consequences of sun exposure and minimizing the hepatotoxic effects of protoporphyrin. Topical sunscreens must be effective in the 400-nm portion of the spectrum to be useful. The only readily available effective topical preparations are opaque formulations containing oxidates of zinc or titanium. Most proprietary sunscreens contain compounds that reduce transmission only of the sun-burning portion of the spectrum between 290 and 320 nm. The induction of carotenemia (serum carotene levels above 400 µg/dl) is effective in reducing photosensitivity in many patients with EPP ([291]). Carotenemia is best induced by the administration of synthetic ß-carotene beadlets (Lumitene, Tishcon Corporation, Westbury, NY) in adults at a dose of 120 to 180 mg/day, but doses up to 300 mg/day may be needed ([316], [317]). The ability of carotene to quench photoexcited oxygen and to scavenge highly reactive free radicals probably explains its action ([318], [319] and [320]). Increased tolerance to sunlight occurs in many but not all patients after 3 to 4 weeks of treatment, and the protective effect may last 4 to 8

weeks after cessation of the drug ([291]). In northern climates, this therapy may be required only in spring and summer, but winter sports enthusiasts may benefit from more prolonged therapy. To date, no significant side effects have been reported in patients using ß-carotene. In patients unresponsive to ß-carotene, narrow band ultraviolet B (TL-01) phototherapy and psoralen and ultraviolet A light treatment have been effective ([321] , [322]). Two patients experienced marked reduction in photosensitivity with administration of pyridoxine ([323]). Oral cysteine also appears to be effective as a free radical quencher ([324]), and, in a preliminary report, a flavonoid mixture (hydroxyethylrutosides) was effective as an antioxidant ([325]). Attempts to minimize the hepatotoxic effects of protoporphyrin have been directed at both reducing the amount of protoporphyrin presented to the liver for excretion and depleting hepatic protoporphyrin stores. Suppression of erythropoiesis and the erythrocyte protoporphyrin accumulation can be achieved with transfusion therapy ([326] , [327]), but the hazards of transfusion-induced iron overload and the risk of transfusion-related infectious disorders make this form of therapy undesirable ([328]). In two patients, severe acute cholestasis and hepatitis were averted by blood exchange plus transfusions ([329]). Intravenous hematin, which diminishes the production of porphyrins and porphyrin precursors in other forms of porphyria (see Acute Intermittent Porphyria), has been administered to several patients with EPP ([330] , [331]). Modest decreases in protoporphyrin accumulation were observed, but no evidence establishes that hematin infusions have the potential to ameliorate or prevent protoporphyric liver disease. In one patient, administration of iron, either as carbonyl iron or ferrous sulfate, was followed by decreases in stool and erythrocyte porphyrins and improved liver function ([332]), but, in others, the disease was exacerbated by oral iron therapy ([333]). Whether protoporphyrin secreted in bile is reabsorbed by an enterohepatic circulation and secreted again by the liver ([334]) has been questioned ([335] , [336] and [337]). Administration of cholestyramine, which binds protoporphyrin ([335]), has produced a significant decline in erythrocyte and plasma protoporphyrin concentrations, a decrease in fecal excretion of protoporphyrin, and improvement of protoporphyric liver disease ([338] , [339]), but no controlled studies have been reported. More recently, the drug was found to promote urinary excretion of protoporphyrin through a presorption effect ([340]). Activated charcoal, a nonabsorbable porphyrin binder, has also been used successfully to interrupt the enterohepatic circulation of porphyrins ([341]). The potential for malabsorption of essential nutrients must be considered when therapy with cholestyramine or activated charcoal is considered. The excretion of protoporphyrin by the liver depends on bile salt excretion ([280]), and the administration of bile acids in both *in vitro* and *in vivo* experiments stimulates biliary secretion of protoporphyrin ([342]) and reduces hepatic protoporphyrin accumulation ([343] , [344]). Administration of chenodeoxycholic acid in patients with EPP also results in a sharp decrease of fecal protoporphyrin excretion ([345]), but the early ultrastructural changes in the liver are not improved ([346]). If biliary excretion of protoporphyrin is enhanced by the administration of bile salts, these agents, coupled with nonabsorbable porphyrin-binding compounds such as cholestyramine or charcoal, might provide a means of preventing or treating protoporphyric liver disease. Once severe liver damage has occurred, no form of medical therapy is effective. Thus, liver transplantation has been undertaken as a life-saving measure in approximately 30 cases ([287] , [303] , [347] , [348] and [349]). The results have been favorable in part, with some patients surviving for up to 10 years. However, the protoporphyrin burden from erythroid tissue remains, and protoporphyrin hepatopathy has recurred in the graft. It is possible that bone marrow transplantation should be performed early in the disease to optimally correct the metabolic defect, but better indicators for patients who are at risk of liver failure would be needed to justify this approach. In one patient with coincidental acute leukemia, a marrow transplant from a sibling with less severe EPP was beneficial for the patient's EPP ([350]). The most definitive treatment for the disease would be replacement of the defective gene in affected tissues. Targeting the hematopoietic stem cells with gene therapy will probably suffice once it is technically feasible. *In vitro* studies have demonstrated effective transfer of normal FECH complementary DNA into cultured fibroblasts from patients with EPP with correction of the biochemical defect ([351] , [352]). Genetic analysis of EPP patients' spouses for a low-output *FECH* allele now allows assessment for the probability of clinical disease in offspring.

ERYTHROPOIETIC PROTOPORPHYRIA IN ANIMALS Bovine EPP was described in 1977 ([353]) and is transmitted as an autosomal-recessive trait ([354]). Affected calves have acute photosensitization during the first few weeks of life, the erythrocyte and fecal protoporphyrin is greatly increased, and FECH is reduced to 10% in all tissues examined ([238]). The animals do not develop anemia or hepatobiliary disease. Carrier dams have approximately half the normal FECH activity. Immunochemical studies of the enzyme suggested a structural defect ([355]), and subsequent DNA analysis revealed a novel stop codon mutation (X417L) ([356]). A protoporphyric disorder occurs in mice that are fed a diet containing 2.5% by weight of griseofulvin ([357]) and exhibits a pronounced hepatic component ([358]). It is similar in many respects to the human disease, and the hepatic histopathologic abnormalities are indistinguishable by light or electron microscopy ([359] , [360] and [361]). Another murine EPP (*fch*) is produced by chemical mutagenesis with ethylnitrosourea ([362]). It is characterized by photosensitivity, mild hemolytic anemia, and severe hepatobiliary dysfunction in early life. FECH activity in various tissues is 2.7 to 6.3% of normal in homozygotes and approximately 50% in heterozygotes. A point mutation has been identified in the *FECH* gene (*Fechm1Pas*), and prokaryotic expression studies have substantiated it as the basis for the porphyria ([363]). Bone marrow transplantation is effective in this mouse model ([364]). Moreover, reversal of the phenotype and restoration of normal hematopoiesis have been achieved with preselective gene therapy ([365] , [366]) as well as with the use of a self-inactivating erythroid-specific lentiviral vector without preselection ([367]). A genetically designed model of EPP has been developed in zebrafish ([368]). Protoporphyrin IX accumulates in the mutant embryos, and the phenotype shows light-dependent hemolysis and liver disease. The mutation is a G?T transversion at a splice donor site in the *FECH* gene and creates a stop codon.

ACUTE OR INDUCIBLE PORPHYRIAS WITH NEUROLOGIC MANIFESTATIONS

Porphyrias manifesting neurologic and psychiatric illness are called *acute porphyrias* to reflect the often abrupt onset of symptoms. They are also referred to as *inducible porphyrias* because symptoms are commonly brought on by endogenous or exogenous factors that stimulate heme biosynthesis through certain biochemical mechanisms. These disorders are deficiencies of the remaining four enzymes of the heme synthetic pathway that restrict the capacity for the production of heme and lead to derepression of ALA synthase: PBG-D, ALA dehydratase (ALA-D), coproporphyrinogen oxidase (CP-O), and protoporphyrinogen oxidase (PP-O) (Fig. 31.1). During acute attacks, hepatic ALA synthase is markedly induced, and the porphyrin precursors (ALA and PBG) accumulate because PBG-D becomes rate-limiting, having the second lowest relative activity among the enzymes of the heme synthetic pathway ([15]). These events are best understood in the liver, and they may occur in neural tissue. Deficiencies of CP-O and PP-O also result in accumulation of their respective porphyrin substrates and therefore can be accompanied by photosensitivity, whereas only the precursors accumulate with deficient PBG-D and ALA-D, and photosensitivity does not occur.

Acute Intermittent Porphyria

Patients with *acute intermittent porphyria* (AIP) (pyrroloporphyria, Swedish porphyria) were probably reported by Gunther ([3]). The extensive family studies in Sweden by Waldenstrom provided the first comprehensive description of the disorder ([369]). It is transmitted in an autosomal-dominant manner with low penetrance and results from mutations in the gene encoding PBG-D (hydroxymethylbilane synthase, uroporphyrinogen I synthase) (Fig. 31.1) ([370]). The prevalence of the trait in most countries had been estimated at 1 to 2 per 100,000 ([16]). More recent population screening studies in northern Europe with enzyme assays and DNA analysis indicate a much higher prevalence of carriers, ranging from 1 to 2 per 10,000, and an even higher prevalence in Sweden and France ([16]). A similar frequency was reported in psychiatric patients in the United States ([371]).

MOLECULAR BASIS AND PATHOGENESIS A decreased conversion of PBG to porphyrins observed in liver tissue from patients with AIP provided the first evidence that the enzyme PBG-D is defective ([372]). Decreased catalytic activity of PBG-D to approximately half of normal was subsequently demonstrated in all tissues examined, including liver ([373]), erythrocytes ([374] , [375]), cultured skin fibroblasts ([376] , [377] and [378]), cultured amniotic cells ([378]), and mitogen-stimulated lymphocytes ([379]). Considerable heterogeneity of the defect became evident from biochemical and immunologic studies of the enzyme in erythrocytes from patients with AIP. Up to 10% of unrelated and clinically affected people had either normal or indeterminate levels of erythrocyte PBG-D activity ([380] , [381] and [382]). Overlapping enzyme activity levels could be resolved with internal family reference values ([383]), consistent with apparent genetic regulation of the enzyme activity ([384] , [385]). Patients with normal erythrocyte PBG-D activity responded to an ALA loading test with increased excretion of PBG and reduced excretion of fecal protoporphyrin, just like patients with low PBG-D activity in erythrocytes, suggesting that the defect is expressed in the liver but not in erythrocytes ([386]). Approximately 80% of patients with half-normal PBG-D catalytic activity were found to have half-normal PBG-D protein concentration, referred to as *cross-reacting immunologic material–negative*, and approximately 20% of pedigrees were *cross-reacting immunologic material–positive* (i.e., the PBG-D catalytic activity was half-normal, but the PBG-D protein was normal or even increased) ([370] , [387]). In addition, molecular heterogeneity was indicated by detection of differing restriction haplotypes for the *PBG-D* gene locus ([388] , [389] and [390]). After the cloning and sequencing of the *PBG-D* gene, the molecular basis for two isoforms of the enzyme was established ([391] , [392] , [393] and [394]), and genetic defects responsible for AIP could be identified. A single *PBG-D* gene, located in the chromosomal region 11q24 ([395]), under the control of two independently regulated promoters, produces two transcripts through alternative transcription and splicing. In the mRNA of the enzyme produced in all cells (ubiquitous mRNA), exon 1 is spliced to exon 3, whereas exon 1 is excluded in the transcript in erythroid cells, and translation begins in exon 3 (Fig. 31.5). Thus, the erythroid-specific protein lacks the 17 amino acids that are encoded by exon 1 for the ubiquitous enzyme.

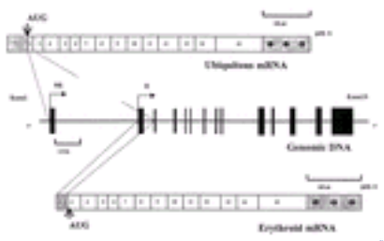

Figure 31.5. Structure of the human porphobilinogen deaminase gene and its two transcripts produced by alternative splicing. E, erythroid promoter; mRNA, messenger RNA; NE, nonerythroid promoter. (From Deybach J-C, Puy H. Acute intermittent porphyria: from clinical to molecular aspects. In: Kadish KM, et al., eds. The porphyrin handbook—medical aspects of porphyrins, vol. 14. Amsterdam: Academic Press, 2003:23–41, with permission.)

Approximately 200 different mutations have been identified in the *PBG-D* gene, most of which were found in single pedigrees ([269], [370], [390], [396]). High frequencies of a few mutations in restricted geographic areas (e.g., Sweden, Holland, Switzerland, Canada, Argentina) are believed to represent founder effects ([390]). On the other hand, approximately 3% of all index cases with AIP may have *de novo* mutations ([397]). Approximately 75% of mutations are single-base substitutions, and the remaining mutations consist of small insertions or deletions, resulting in a spectrum of splice defects of transcripts, frameshifts, stop codons, unstable proteins, or reduced catalytic activities of the enzyme ([390]). The least common mutations (i.e., involving the exon 1–intron 1 junction or exon 1) restrict the PBG-D defect to nonerythroid tissues and account for the normal activity of the enzyme in erythrocytes observed in such cases. In two families, compound heterozygotes (and in one family, a homozygote) for point mutations had severe PBG-D deficiency ([398], [399] and [400]). Although, in general, no correlation between the genotypes and phenotypes has been found, a few prevalent mutations exhibit higher penetrance ([401], [402]). Using the knowledge of the three-dimensional structure of PBG-D, structural and functional outcomes of the mutations can be predicted ([403], [404]). For instance, many mutations change amino acids in the vicinity of the active site of the enzyme, and a number of these are involved in binding the primer or substrate of the enzyme; others perturb conformation of the protein. The genetic lesion and its wide spectrum underlying AIP are now well defined, but the pathogenesis of the clinical manifestations remains poorly understood. Several mechanisms have been postulated for the neurovisceral symptoms and signs that characterize the disorder. One is that the porphyrin precursor ALA, which accumulates after the induction of ALA synthase ([405], [406], [407], [408] and [409]) in response to diminished cellular heme because of the PBG-D deficiency, is toxic to the nervous system. Studies in animals indicate that ALA can alter neural structure and function as an agonist for ?-aminobutyric acid receptors ([410], [411]), it inhibits release of neurotransmitters at neuromuscular junctions ([412], [413]) and spinal cord synapses ([414]), and it exerts lethal effects on neuronal and glial cells in culture ([415]). Additional support for ALA as the responsible neurotoxin includes the observation that patients with severe ALA-D deficiency and patients with hereditary tyrosinemia ([416], [417]), both of whom excrete ALA but not PBG, display neurologic features similar to those of patients with AIP. On the other hand, urine and serum levels of ALA, along with PBG, correlate only roughly with symptoms and signs ([409]). Furthermore, it has not been possible to produce an acute porphyric attack by administering ALA to animals ([418], [419]), normal human subjects ([420], [421]), or even patients with latent porphyria ([422]), although convulsion can be induced by intraventricular injection of ALA and PBG in rats ([422], [423]). A second postulated mechanism is that episodic depletion of cellular heme from marginal to critical levels deprives enzymatic oxidations and energy-producing reactions involving hemoproteins in neural tissues ([423]). Experimental inhibition of the heme biosynthetic pathway in dorsal root ganglia cultures causes severe segmental degeneration ([424]). The administration of heme to patients suffering an acute porphyric attack often reverses the neuropathic manifestations, but this effect may result from inhibition of hepatic ALA production by heme or its direct action on neural cells; it is not known whether intravenously administered heme enters the brain. Another mechanism was suggested by studies in animals that implicated accumulation of neurotoxic levels of tryptophan and serotonin. Heme depletion impairs catabolism of tryptophan by the heme-dependent enzyme hepatic tryptophan pyrrolase ([425], [426]). In one study, patients with attacks of AIP had serum levels of tryptophan, serotonin, and urinary 5-hydroxyindoleacetic acid that were above normal and that declined after hematin administration ([427]). Levels of melatonin, implicated in the regulation of the circadian rhythm, were found to be decreased ([427]). Results of studies in animals and in cultured pineal glands suggested that melatonin may also be involved in the regulation of heme synthesis in some manner ([428]). Most people (approximately 90%) heterozygous for the PBG-D defect are asymptomatic, but certain precipitating factors cause both biochemical and clinical evidence of the porphyric diathesis. Steroid compounds, both endogenous and synthetic, and drugs (Table 31.3) are the most commonly identified precipitating factors of symptoms ([16]). They stress the defective heme biosynthetic pathway. Gonadal hormones, especially the 5-ß steroids and ovarian hormones or their metabolites, are most significant and have been shown to induce hepatic ALA synthase ([16]). They probably account for the typical onset of symptoms at or shortly after puberty, as well as for the susceptibility of women to porphyric attacks during the luteal phase of the menstrual cycle, when progesterone is high. Hence, the benefit of a luteinizing hormone-releasing hormone analog peptide can be attributed to induction of pituitary refractoriness to luteinizing hormone-releasing hormone to suppress production of progesterone and its 5-ß metabolites ([429]). The barbiturates and sulfonamides head the list of countless drugs that can precipitate porphyric attacks and usually do so by inducing hepatic apocytochrome P-450 for their metabolism via microsomal hydroxylation, thereby increasing the need for hepatocellular heme ([16]), or by direct transcriptional activation of ALA synthase ([430]). However, the response of patients is highly variable ([16], [431]). Decreased caloric intake with intercurrent illness may precede acute attacks. Starvation is believed to contribute to the induction of hepatic ALA synthase by depleting cellular heme through mechanisms such as enhanced generation of cytochrome P-450 hemoproteins, induction of heme oxygenase, or both ([16]). With carbohydrate administration, urinary excretion of PBG often strikingly decreases, and symptoms tend to improve ([409], [432], [433]).

TABLE 31.3. Safe and Unsafe Drugs for Patients with Acute Porphyrias

Unsafe		
Aminoglutethimide	Ethanol excess [a]	Nifedipine
Barbiturates [a]	Ethchlorvynol	Novobiocin
Bupropion	Fentanyl	Phenylbutazone
Carbamazepine	Glutethimide	Primidone
Carbromal	Griseofulvin [a]	Progestins
Carisoprodol	Isopropyl meprobamate	Rifampin
Chloroquine	Ketoconazole	Succinimides
Chlorpropamide	Lamotrigine	Sulfonamides [a]
Danazol	Mephenytoin [a]	Sulfonylureas
Dapsone	Meprobamate [a]	Tramadol
Diclofenac	Methyprylon	Tranylcypromine
Diphenylhydantoin [a]	Metoclopramide	Trimethadione
Enalapril	Nefazodone	Valproic acid [a]
Ergot preparations		
Potentially unsafe		
Alfadolone	Estrogens (synthetic)	Nikethamide
Alphaxalone	Etomidate	Nitrazepam
Alkylating agents	5-Fluorouracil	Nitrofurantoin
2-Allyloxy-3-methylbenzamide	Fluroxene	Pentazocine
Benzodiazepines	Heavy metals	Phenoxybenzamine
Cephalosporins	Hydralazine	Procarbazine
Chloramphenicol	Iron chelators (DFO)	Propofol
Clonidine	Ketamine	Pyrazinamide
Colistin	Mefenamic acid	Spironolactone
Cyclosporin	Methyldopa	Theophylline
Diphenhydramine	Metyrapone	Tricyclic antidepressants
Erythromycin	Nalidixic acid	Troglitazone
Believed to be safe		
Acetaminophen	Digoxin	Nitrous oxide

Acetazolamide	Estrogens (natural/endogenous)	Penicillin and derivatives
Adrenaline	Fluoxetine	Phenothiazines
Allopurinol	Gabapentin	Procaine
Aminoglycosides	Gentamycin	Propanidid
Amitriptyline	Guanethidine	Propranolol
Aspirin	Ibuprofen	Neostigmine
Atropine	Indomethacin	Ranitidine
Azathioprine	Insulin	Rauwolfia alkaloids
Chloral hydrate	Labetalol	Streptomycin
Chlordiazepoxide	Lithium	Succinylcholine
Cimetidine	Losartan	Tetracyclines
Colchicine	Methenamine mandelate	6-Thioguanine
Corticosteroids	Methylphenidate	Thiouracil
Coumarins	Naproxen	Thyroxine
Cytarabine	Narcotic analgesics	Vigabatrin
Daunorubicin	Neostigmine	Vitamin C

NOTE: Statements about drugs in acute porphyrias are based on experience with patients, on tests in animals with experimental porphyria, and on studies in cell cultures. As most commonly used drugs have not been tested, they should be avoided if possible.

[a] Drugs that have most often been cited as agents precipitating acute attacks.

Adapted from Anderson KE, Sassa S, Bishop DF, Desnick RJ. Disorders of heme biosynthesis: X-linked sideroblastic anemia and the porphyrias. In: Scriver CS, Beaudet AI, Sly WS, Valle D, eds. The molecular and metabolic bases of inherited disease, 8th ed. New York: McGraw-Hill, 2001:2961–3062.

CLINICAL DESCRIPTION The clinical features of the defect are typically acute symptoms and signs reflecting neurovisceral and psychiatric deficits (Table 31.4). They are more common in women and are highly variable, even among affected siblings. Attacks usually last for several days to several months and are interspersed with long and variable asymptomatic periods. Patients may have as few as three attacks in a lifetime or as many as two or three per year (Fig. 31.6) ([409], [434], [435]). Most often, the acute attack is an autonomic neuropathy manifested by moderate to severe colicky abdominal pain that is variable in location and characteristically accompanied by constipation, which may be severe, and often vomiting (Table 31.4). In some cases, pain is predominant in the back and limbs. The abdomen is usually soft, with no rebound tenderness or other signs of peritoneal irritation, and dilated bowel loops may be palpable. The abdominal radiograph may show evidence of segmental intestinal dilation and spasm. Other common findings are tachycardia, labile hypertension or hypotension, and urinary retention ([409]). The pulse rate is often considered a good index for judging the activity of the disease and even the diagnosis ([436]).

TABLE 31.4. Signs and Symptoms of Acute Intermittent Porphyria

Signs and Symptoms	Incidence (%)
Abdominal pain	85–95
Vomiting	43–88
Constipation	48–84
Tachycardia	28–80
Muscle weakness	42–68
Mental changes	40–58
Hypertension	36–54
Extraabdominal pain	50–52
Sensory deficit	9–38
Fever	9–37
Convulsions	10–20
Respiratory paralysis	9–14

Data from three reports, 417 patients: Stein JA, Tschudy DP. Acute intermittent porphyria. A clinical and biochemical study of 46 patients. Medicine 1970;49:1–16; Waldenstrom J. The porphyrias as inborn errors of metabolism. Am J Med 1957;22:758–773; and Goldberg A. Acute intermittent porphyria: a study of 50 cases. QJM 1959;28:183–209.

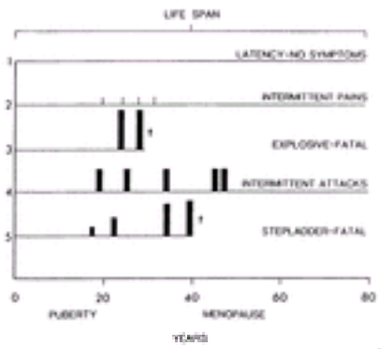

Figure 31.6. Typical courses of acute intermittent porphyria. (From Moore MR, et al. Disorders of porphyrin metabolism. New York: Plenum Publishing, 1987:79, with permission.)

Less often, and with prolonged or more severe attacks, peripheral motor neuropathy occurs. Symptoms include weakness in one or more extremities, especially the upper extremities and proximal musculature, that may progress to flaccid quadriparesis ([435], [437], [438] and [439]). Bulbar and respiratory muscle paralysis may be life-threatening. Blindness has resulted from both optic nerve and occipital lobe involvement ([409], [440], [441]). Sensory abnormalities occur less often. The extreme variability of neurologic abnormalities is further illustrated by manifestations of central nervous system disturbances. Acute anxiety and emotional lability can progress to confusion, frank psychosis, and coma ([438], [442], [443], [444] and [445]). Tonic-clonic seizures occurred in 17 to 32% in two series of patients ([409], [446]), but, from a recent assessment, lifetime prevalence of seizures among patients in Sweden was only 5% ([447]). Seizures may result from profound hyponatremia caused by inappropriate antidiuretic hormone secretion ([448]), reflecting hypothalamic dysfunction, or may be a cerebral manifestation of the metabolic defect ([16]). In older reports, the mortality rate from neurologic involvement was approximately 30% ([449]). Improvement in supportive care in the 1970s reduced the mortality rate to approximately 10% ([431], [433]), and the introduction of therapy with intravenous hematin reduced the mortality rate further ([446]). If peripheral nerve deficits develop, they may clear slowly, over months or even years. Depression, including suicidal tendencies, may follow an attack. Chronic hypertension and renal impairment are reported to develop in up to 50% of patients with AIP ([431], [449], [450] and [451]). The hypertension may predispose to renal insufficiency. The few reported children homozygous for the genetic defect ([399], [400], [452]) manifested central nervous system defects, including hypoplasia of brain structures, rather than the usual neurovisceral features. In one infant, the clinical phenotype appeared to be normal ([399]).

LABORATORY FINDINGS Results of routine hematologic measurements usually are within normal limits; however, leukocytosis occasionally is observed during acute attacks ([409]), a finding that may support an erroneous impression of an abdominal condition requiring an emergency operation. Anemia is an uncommon finding and, when present, may not be related to the porphyria ([409]). Some patients have an unexplained reduction in both the plasma volume and the red cell mass even though the volume of packed red cells is normal ([453]). Red cell survival is normal, suggesting that the decreased red cell mass results from reduced effective erythropoiesis ([453]). The biochemical hallmark is the excessive urinary excretion of the porphyrin precursors, PBG and, to a lesser extent, ALA. These compounds

are accurately quantified by ion exchange chromatography ([454]). Normally, less than 7 mg of ALA and less than 4 mg of PBG are excreted in 24 hours regardless of the analytic method used. During acute attacks, the urinary excretion of PBG ranges from 20 to 200 mg daily ([409], [455], [456]). In one study, 21 symptomatic patients excreted an average of 83 mg of PBG in 24 hours (range, 8 to 150 mg) ([409]). A rough correlation exists between the amount of PBG excreted and the severity of clinical symptoms. ALA and PBG excretion diminishes during remission but rarely returns to normal. In 12 asymptomatic patients, the average urinary PBG excretion was 32 mg in 24 hours (range, 12 to 60 mg), and ALA excretion was 10 mg in 24 hours (range, 6 to 18 mg) ([409]). Serum normally contains only trace amounts of ALA and PBG, but patients with AIP may have serum PBG concentrations as high as 300 µg/dl during acute attacks ([16]). Increases in the liver content of ALA and PBG have been noted at autopsy in patients who died during acute attacks. A rapid qualitative method of detecting excess PBG in urine is the Watson-Schwartz test ([457]). This test yields negative results in normal subjects and positive results when PBG excretion exceeds approximately 6 mg/L ([457]). Other urinary chromogens, particularly urobilinogen, as well as certain drugs and drug metabolites may also form a similar color when they react with Ehrlich reagent, but only the PBG–Ehrlich complex is water soluble and cannot be extracted with chloroform and butanol. When properly performed and interpreted, the Watson-Schwartz test is reliable. In inexperienced hands, false-positive results are common; in one referral center, 75% of patients with supposedly positive findings had normal values when quantified by chromatography ([409]). A variation of the Watson-Schwartz test, the Hoesch test, has been advocated for bedside screening ([458]). The sensitivity and specificity are less than those of the Watson-Schwartz test ([459]), but the simplicity of the Hoesch test may make it more reliable in inexperienced hands ([457]). A newer test, although more complicated, is more sensitive ([460]). A positive qualitative test should always be confirmed by ion exchange chromatography. Because PBG is a colorless compound, freshly excreted urine from patients with AIP appears normal in color. On exposure to light and air, two reactions are accelerated that cause PBG-containing urine to darken on storage. First, PBG is oxidized to porphobilin, a dark brown, amorphous product ([461]). Second, PBG may be nonenzymatically converted to a mixture of porphyrins, especially uroporphyrin, a reaction favored at acidic pH (approximately 4.0), and quantitation of uroporphyrin and coproporphyrin in urine can then detect mild to moderate elevations ([457]). Therefore, the so-called urine porphyrin screen commonly carried out is also positive. However, it merely detects an increased concentration of coproporphyrin, which can also be associated with a variety of illnesses, and is of little if any diagnostic value. Fecal porphyrin excretion is normal or only slightly increased ([16], [462], [463]). Another useful measurement for diagnosis and detection of relatives with the latent defect, in whom urinary PBG excretion is often normal ([375], [382]), is the erythrocyte PBG-D activity, provided that it is recognized that the erythrocyte value may be indeterminate or normal in up to 10% of cases because of heterogeneity of *PBG-D* mutations and, rarely, because the enzyme is not affected in red cells ([380], [381], [382] and [383]). DNA analysis constitutes the definitive means to identify a PBG-D defect, but the marked genetic heterogeneity encountered precludes the feasibility of a routine genetic test for diagnosis. However, molecular techniques have been refined for routine DNA analysis of new probands to localize the region of a mutation and simplify sequencing of the relevant DNA segment ([396], [464], [465]). Then, carriers within the family are easy to detect for preventive measures. Hyponatremia, reduced blood volume, and mild elevation of blood urea nitrogen often are observed during acute attacks ([409]). The findings may be attributed to vomiting. The syndrome of inappropriate antidiuretic hormone secretion has been documented ([409], [448], [466], [467]) and is presumably the result of a hypothalamic abnormality. When carefully sought, other evidence for hypothalamic involvement is found, such as disturbed regulation of growth hormone and adrenocorticotropic hormone secretion. However, the increased antidiuretic hormone secretion may be an appropriate response in patients with unexplained reduction in total blood volume ([468]), and fluid restriction would not be appropriate therapy for such patients. In one study of 45 patients hospitalized for acute porphyric attacks, hyponatremia was more often related to vomiting, poor intake, and excess renal sodium loss than to inappropriate secretion of antidiuretic hormone ([469]). Hypomagnesemia associated with tetany has also been reported ([433], [448]). Abnormal electroencephalographic patterns are a common laboratory sign of the neurologic dysfunction. Diffuse, nonspecific slowing of the wave pattern was found in 14 of 24 patients during an acute attack ([409]). Reversible abnormalities on both sides of the brain may be detected by magnetic resonance imaging ([470], [471]). The pattern suggests a vascular ischemia as the cause of cerebral dysfunction. In two cases with cortical blindness, similar lesions were limited to the occipital lobes ([472]). The cerebrospinal fluid usually is normal. The peripheral neuropathy is a “dying back” process in which neuron damage follows axonal demyelination ([16], [438]). Electrophysiologic studies and microscopic examination of nervous tissue ([473], [474], [475] and [476]) indicate that the acute attack affects primarily neuronal bodies, leading to an acute axonal degeneration of peripheral and autonomic nerves and to neuronal loss and gliosis in the central nervous system. In patients with latent porphyria, slower motor and sensory conduction velocities are detectable ([477]), as is parasympathetic dysfunction of peripheral nerves when assessed with bedside tests of cardiovascular reflexes ([478]). Parasympathetic dysfunction has also been demonstrated by spectral analysis of heart rate variability ([479]), which may predispose to arrhythmias in symptomatic and latent disease.

TREATMENT When an acute attack occurs, patients usually require hospitalization because the clinical course is difficult to predict, and causes for the symptoms other than porphyria must be excluded. Precipitating factors should be removed if possible, but often the specific factor in a particular attack cannot be identified. Pain should be treated with safe analgesics and narcotics such as morphine. Fluid, electrolyte, and caloric deficits should be restored. Carbohydrate is administered intravenously (as 10% dextrose) so that the equivalent of 300 to 500 g of glucose is given daily ([409], [433], [480]). Propranolol has been effective in reducing tachycardia and hypertension in some patients ([481]) but must be used very cautiously if at all in patients with hypovolemia ([482]). Maintenance of the patient's morale and alleviation of fear are also important and facilitate recovery. In very ill patients without improvement within 24 hours and in those who have progressive neurologic manifestations, therapy with intravenous hematin (soluble crystalline heme chloride) should be initiated. This compound has been used in therapeutic trials since the early 1970s ([483], [484], [485], [486], [487] and [488]), with the rationale being to correct the apparent heme deficiency and repress the overproduction of porphyrin precursors. Hematin became commercially available in 1983 (Panhematin, currently supplied by Ovation Pharmaceuticals, Inc., Deerfield, IL, 313 mg of hematin/vial), and its use in the treatment of the acute attack has been a significant advance. The benefits are most marked when the compound is given early in an attack, before potentially irreversible neuronal damage has occurred ([480], [485], [487], [489], [490]). Hematin, reconstituted with albumin, is administered in a dose of 3 to 5 mg/kg body weight once daily for 4 to 5 days. High doses (e.g., 1000 mg infused over 15 minutes) may produce acute renal failure ([491]), and local venous irritation at the site of injection may occur ([487], [488] and [489]). After infusion of hematin, a rapid decrease in ALA and PBG concentrations in serum and urine is observed, and clinical symptoms generally, but not always, improve within 48 hours. Because of instability of the hematin in solution, thrombocytopenia and a mild transient coagulopathy manifested by prolongation of both the partial thromboplastin time and the prothrombin time occur with some regularity during hematin infusion therapy ([492]) and are attributed to degradation products of hematin ([493], [494]). Clinical signs of bleeding are rarely observed and are usually associated with the simultaneous administration of heparin ([489], [495]). A Finnish preparation, heme arginate, is more stable ([496]) and does not produce coagulopathy ([497], [498]). Tin protoporphyrin, an inhibitor of heme oxygenase, in combination with heme arginate restored efficacy when tolerance to the heme developed ([499]), and it is being evaluated. The management of seizures is a considerable challenge. If they are related to metabolic disturbances of hyponatremia and hypomagnesemia, correction of these derangements may control them. However, if seizures are related to the porphyric diathesis or are a chronic associated problem, their management may be difficult because most effective anticonvulsants are contraindicated (Table 31.3) ([500], [501] and [502]). The use of bromides, a nineteenth-century mode of therapy, has been suggested as an alternative ([500]), but evidence is lacking for their effectiveness in this setting. An agent such as clonazepam appears to be safe ([438]), but its efficacy in the control of grand mal seizures is not documented. Magnesium sulfate has been advised ([503]) and was used effectively in one reported case ([504]). Two newer antiepileptic drugs, gabapentin and vigabatrin, are not metabolized by the liver and are probably the therapy of choice for epilepsy in acute hepatic porphyrias ([505]). Prevention of acute attacks is the cornerstone of treating the patient in whom the diagnosis has been established and includes identification of carriers among relatives. Avoidance of most drugs is important, and patients should receive a list of drugs to avoid (Table 31.3). The most extensive current list of safe and unsafe drugs is provided by Hift et al. ([506]). For anesthesia purposes, an adequate number of agents that are considered safe have been evaluated ([507]). Patients should be warned that fasting may induce attacks ([508]); they should take in sufficient calories to maintain a normal body weight and promptly consult a physician whenever adequate oral intake is interrupted by intercurrent illness. In women whose attacks are related to the menstrual cycle, prevention may be achieved by suppression of ovulation with oral contraceptives ([16], [409]). Paradoxically, oral contraceptive steroids can also worsen symptoms in some women ([16]). A long-acting agonist of luteinizing hormone-releasing hormone that permits suppression of ovulation without the administration of exogenous steroids is effective in women who have frequent cyclical attacks; it can be taken continuously ([429]) or intermittently with a progesterone ([509]). Association of AIP with pregnancy is rare, and reports consist of small series ([510]). Although earlier reports indicated a high rate of exacerbation and maternal mortality, meticulous prenatal and perinatal care can assure good maternal outcome. Low-dose estrogen replacement is probably safe in women with an acute porphyria who are naturally menopausal. A first step toward gene therapy has been taken with nonviral gene transfer in PBG-D–deficient fibroblasts from an AIP patient with restoration of PBG-D activity ([511]).

HEPATOCELLULAR CARCINOMA Several studies indicate an association between primary liver cancer and AIP. In Scandinavia, where the incidence of AIP is high, a retrospective population-based mortality study revealed that hepatocellular carcinoma was the cause of death in approximately one-fourth of patients with AIP ([512]). The relative risk for men was 70 and for women was 140. Liver cirrhosis was considerably more common in the patients (12.0%) than in controls (0.5%). Impaired detoxification capacity of mutagenic substances by the liver with impaired heme synthesis and cirrhosis are believed to enhance a genetic change over time. It was advised that all patients carrying an acute porphyria gene be screened for hepatocellular carcinoma after age 55. A cohort study in Denmark and Sweden found a standardized incidence ratio of 1.8 for 296 patients with AIP ([513]). In France, among 650 patients with acute hepatic porphyrias who were followed for 7 years, seven developed primary liver cancer ([514]). In two sisters elsewhere with AIP, hepatocellular carcinoma was associated with excessive intake of alcohol ([515]). In one patient with hepatoma but not porphyria, the tumor produced large amounts of PBG as an apparent paraneoplastic feature ([516]).

ANIMAL MODEL OF ACUTE INTERMITTENT PORPHYRIA That the neurologic syndrome representing the clinical features of AIP is related to the PBG-D defect has been verified in transgenic mouse experiments ([517]). The PBG-D–deficient mice exhibit the typical biochemical characteristics as well as the neuropathologic features of the human disease when treated with phenobarbital ([518]). The data suggest that heme deficiency and consequent dysfunction of heme proteins can cause

porphyric neuropathy. Moreover, the limited heme synthesis in the PBG-D–deficient mice impairs activation of cytochrome P-450 genes by phenobarbital ([519]), whereas zinc mesoporphyrin represses the induced hepatic ALA synthase and reduces heme oxygenase activity ([520]), making this compound a potential candidate for treatment of acute porphyrias.

5-Aminolevulinic Acid Dehydratase Deficiency Porphyria

ALA dehydratase deficiency porphyria (ADP) (plumboporphyria) is the most recently identified porphyria and has been described in seven unrelated cases. It is inherited as an autosomal-recessive trait, and mutations in both *ALA-D* alleles are responsible for the disorder. The clinical phenotype is strikingly similar to that of AIP.

MOLECULAR BASIS AND PATHOGENESIS ALA-D is the second enzyme in the heme biosynthetic pathway (Fig. 31.1) and is encoded by a single gene, located on chromosome 9 (9q34) ([521]). Analogous to the *PBG-D* gene, the *ALA-D* gene contains two promoter regions that generate housekeeping (ubiquitous) and erythroid-specific transcripts by alternative splicing of a separate exon 1 in each case to exon 2, but both transcripts encode identical ALA-D polypeptides ([522]). In seven reported patients (including two siblings), the erythrocyte enzyme activity was close to 1% of normal, and, in the asymptomatic parents and relatives carrying the trait, it was approximately 50% ([16] , [523] , [524] , [525] , [526] and [527]), in keeping with an earlier study of a family with heterozygous ALA-D deficiency and absence of clinical manifestations ([528]). Immunologic studies demonstrated considerably more enzyme protein (20 to 33%) than catalytic activity, implying that a structural defect affects the active site of the enzyme ([529] , [530] and [531]). In three of the cases, mutations have been identified in both alleles of the *ALA-D* gene ([532] , [533] and [534]), and they were compound heterozygotes. The mutations occurred near the catalytic site of the enzyme and would likely cause marked instability of the protein or may affect binding of the structural zincs of the enzyme. In an asymptomatic child heterozygous for a novel *ALA-D* mutation, enzyme activity was only 12%, whereas it was 30% in family members carrying the mutation ([535]). In the case with late onset ([526]), likewise, only a single mutation was identified, ALA-D activity was 1% of normal, and the late clinical expression of the disease was proposed to be related to the patient's coincidental acquisition of the clonal disorder polycythemia vera ([536]). Heterogeneity of the genetic defects probably accounts for the great phenotypic variation among the patients. The mechanisms for the dominating neurologic features present in all the cases appear to be similar to those discussed for AIP, and the large accumulation of ALA caused by the biosynthetic block supports its implicated importance as a neurotoxin in the pathogenesis. The neuropathies of hereditary tyrosinemia ([416] , [417]) and lead intoxication are likewise associated with ALA accumulation, and ALA-D is the enzyme in the heme synthetic pathway that is most susceptible to lead. The identification of two common alleles of human ALA-D (*ALAD1* and *ALAD2*), resulting in three polymorphic isozyme phenotypes ([537] , [538]), led to the demonstration that patients with ALAD1-2 and ALAD2-2 phenotypes had higher blood lead levels than those homozygous for the *ALAD-1* allele ([538] , [539]) and are thus at increased risk for lead poisoning effects. The molecular difference of one amino acid substitution accounts for the two alleles ([540]), but the mechanism for the increased binding of lead by the enzyme has not been established. Patients with a genetic ALA-D deficiency who also possess a susceptible isozyme phenotype may be at greater risk of developing signs of lead intoxication at a lower lead burden.

CLINICAL DESCRIPTION The clinical findings have varied widely among the small number of cases with ADP. A child had recurrent severe neurovisceral manifestations as well as severe respiratory muscle compromise since birth ([524]). Two unrelated male patients had onset of major symptoms of abdominal pain and motor neuropathies, with some respiratory muscle involvement in adolescence ([523]); they are reported as surviving more than 20 years later ([541]). Two brothers in their twenties manifested an acute episode of autonomic symptoms but no other neurologic deficits when the diagnosis was established ([527]). In these cases, precipitating factors were not clarified, but the symptomatology and course resemble the variable neural manifestations of acute porphyrias. In contrast, symptoms of motor neuropathy but no abdominal symptoms first developed in a man at age 63, persisted, and progressed in association with development of a hematopoietic clonal disorder ([526] , [536]). Heterozygotes for ALA-D deficiency are asymptomatic.

LABORATORY FINDINGS The distinguishing laboratory finding in ADP is a markedly increased urinary excretion of ALA that has ranged from 8 to 80 times the normal value and correlates with clinical severity; the PBG values are slightly increased, up to four times normal ([523] , [524] , [527] , [534]). Plasma ALA concentration is increased approximately tenfold ([526]). Urinary coproporphyrin (isomer III) is also typically raised 10- to 60-fold but remains unexplained. Fecal porphyrins are normal in most cases ([523] , [527] , [534]). The FEP is increased, from 3 to 30 times normal ([523] , [524] , [527] , [534]). This spectrum of biochemical abnormalities closely resembles those found in lead poisoning, although usually the abnormal values are considerably lower, and blood lead determinations would exclude this diagnosis. Despite the defects in both alleles, erythropoiesis does not appear to be compromised as hemoglobin values are normal. Heterozygotes for an ALA-D defect have no biochemical abnormalities except for the reduced levels of ALA-D activity ([528]).

TREATMENT Supportive measures as outlined for AIP are generally helpful for acute episodes of ADP as well. Hematin infusions appeared to be of benefit in one case ([525]). In the small child, the disease was reported to markedly impair nutrition and normal development. At age 6, liver transplantation was performed to attempt to reduce the metabolic abnormalities ([542]). The high basal urinary excretion of ALA and porphyrin was not influenced by this procedure, indicating that these products originate mainly in extrahepatic tissues. However, clinical challenges with drugs and intercurrent illnesses no longer increased the urinary ALA and PBG, so heme synthesis does not appear to be induced in nonhepatic tissues ([542]). It was hypothesized that a bone marrow transplant might more effectively remove the major source of the abnormal metabolites.

ACUTE OR INDUCIBLE PORPHYRIAS WITH BOTH NEUROLOGIC AND CUTANEOUS MANIFESTATIONS

Variegate Porphyria

Variegate porphyria (VP) (South African porphyria) is inherited as an autosomal-dominant trait with low penetrance and is caused by mutations in the gene encoding PP-O, the enzyme that catalyzes the penultimate step of heme biosynthesis (Fig. 31.1). Consequent accumulation of protoporphyrin (and coproporphyrin) leads to skin fragility and photosensitivity. Because the production of heme also is reduced and ALA synthesis is induced, acute neurovisceral attacks occur that closely mimic the picture of AIP.

Although Gunther ([3]) and Waldenstrom ([69]) recognized cases of porphyria in which neurologic and cutaneous manifestations occurred together, the extensive investigations of Dean and Barnes in South Africa provided the most complete information about this disease and clearly distinguished it from AIP. They identified 300 patients whose lineage was traced to a couple who migrated from Holland in 1688 ([134]). This common ancestor of almost all South African patients explained the prevalence of the disease of approximately 3 per 1000 among the white (Afrikaner) population ([543]). VP is less common outside South Africa, but hundreds of cases have been reported from other countries ([544]). The prevalence of VP in Finland has been estimated at 1.3 per 100,000 ([545]). In the United States and Europe, it has probably been underestimated or overlooked ([546] , [547]) because the cutaneous manifestations tend to be more mild in temperate and cold latitudes than in South Africa. Indirect evidence suggests that George III of England and other members of the royal houses of Stuart, Hanover, and Prussia suffered from this form of porphyria (often called *the royal malady*) ([548]). Attempts at retrospective diagnosis with DNA material from deceased relatives of George III were undertaken but have not proven conclusively that he had VP ([549]).

MOLECULAR BASIS AND PATHOGENESIS PP-O activity is half normal in cultured skin fibroblasts ([550]) and blood lymphocytes ([551]) and accounts for the observed pattern of porphyrin excretion (Table 31.2). The gene for the enzyme is the last of the heme synthesis enzymes to be cloned and characterized ([552] , [553] , [554] , [555] and [556]), and it has been mapped to chromosome 1 (1q23) ([553] , [555]). To date, at least 118 distinct mutations in the *PP-O* gene have been identified in patients with VP throughout the world ([16] , [544]) and include insertions, deletions, missense and nonsense mutations, and splice site mutations. Most of the mutations occur in single pedigrees, and only approximately 8% occur in four or more families. One mutation (C452T) in exon 3 of the gene, causing replacement of arginine by tryptophan in codon 59 (R59W), is found in 94% of VP patients in South Africa ([557] , [558]). It is also found in Holland, and it is fairly well established by linkage analysis that the families are related ([544]). When expressed in *Escherichia coli*, this mutant protein had an almost undetectable catalytic activity, presumably related to its location in the binding motif of flavin adenine dinucleotide, an essential cofactor for the enzyme ([559]). On average, mutations in heterozygotes are associated with a PP-O activity of 50%, with loss of all enzyme activity from the mutant allele, and thus are referred to as *severe* mutations. In compound heterozygotes and homozygotes, enzyme activities are less than 20% of normal, which would be contributed by residual activity of the mutant protein encoded by at least one of the alleles in heteroallelic cases or by residual activity from both alleles in homoallelic cases. Such mutations are referred to as *mild*. The photosensitivity symptoms are accounted for by the accumulating protoporphyrin and, to some extent, coproporphyrin, which are released into plasma and exert the photochemical reactions in the skin ([23]). Protoporphyrinogen is a competitive inhibitor of CP-O ([560]) and, as such, is believed to account for the accumulation of coproporphyrinogen and the increased excretion of coproporphyrin. The neurovisceral symptoms in VP can be attributed to a relative deficiency of PBG-D ([561]). This enzyme is inhibited by coproporphyrinogen and protoporphyrinogen in an allosteric manner, and their accumulation can account for the relative PBG-D deficiency ([562]). The inhibition may be insufficient to produce biochemical changes of increased PBG (and ALA) excretion during quiescent periods. With increased demands for heme and induction of

ALA synthase by endogenous or exogenous porphyrinogenic agents, the PBG-D step becomes rate-limiting so that the porphyrin precursors accumulate and may account for the neurologic manifestations, as in AIP.

CLINICAL DESCRIPTION VP is rarely expressed before puberty, and it is not uncommon for the disease to remain clinically and biochemically latent throughout life ([544]). Previously, in South Africa, 90% of patients were symptomatic, and cutaneous involvement was the initial symptom in one-half of patients ([543]). More recent experience reflects a changing pattern with less than 10% of VP patients experiencing a neurovisceral attack ([563]), and, with the advent of genetic testing, up to 60% are asymptomatic ([544]). The changes are attributed to more sensitive diagnostic testing, physician and patient education, and less use of drugs that precipitate symptoms. In the United States and Europe, skin manifestations are uncommon and, when present, tend to be mild and rarely are the initial manifestation of the disease ([544] , [545]). The characteristic cutaneous feature is severe mechanical fragility of the skin that is limited to sun-exposed areas, especially the face and hands (Fig. 31.7), and is often indistinguishable from PCT. Trivial mechanical trauma to these areas results in detachment of the epidermis from the dermis, with formations of bullae or erosions. The light microscopic and ultrastructural changes in the skin of patients with VP are also similar to those found in PCT. Vascular walls are particularly affected, and the pathologic changes are observed in asymptomatic patients with increased porphyrin excretion ([564]). In addition, facial hirsutism and hyperpigmentation are common.

Figure 31.7. Cutaneous manifestations of variegate porphyria. **A:** Bulla on index finger, pigmented scars, and collapsed blisters at fingertips of a 27-year-old woman. **B:** Hands of a 36-year-old man. Note erosions on back of hands, depigmented scars of past lesions, and subungual involvement. (Courtesy of Dr. Lennox Eales, University of Cape Town, South Africa.)

The neurovisceral attacks of VP do not differ in any important respect from those of AIP, although hyponatremia was quite common ([543]); psychiatric features are uncommon ([544]). Acute attacks are somewhat less common in VP than in AIP and usually have occurred after exposure to a porphyrinogenic drug (Table 31.3) ([543] , [565]). In early studies, the mortality rate during an acute attack approached 25% but was subsequently reduced dramatically ([566]). To date, 12 unrelated compound heterozygotes and two homozygotes for PP-O defects have been encountered ([544]). The major clinical features are severe photosensitivity and, commonly, mental retardation, seizures, sensory neuropathy, retarded growth, and skeletal abnormalities. With onset in adolescence, the permanent neurologic features are absent, but neurovisceral attacks may occur.

LABORATORY FINDINGS Patients with symptomatic VP with skin disease or with neurovisceral features uniformly have abnormal biochemical findings. The most characteristic and consistent laboratory abnormality is the excretion of large amounts of protoporphyrin and coproporphyrin in the feces ([16] , [543] , [566]). In South African patients, fecal protoporphyrin excretion reached 1500 µg/g dry weight, and fecal coproporphyrin excretion reached 1300 µg/g dry weight (normal total fecal porphyrin excretion is <200 µg/g) ([543]). A particularly significant feature is the presence of 5-COOH porphyrins ([567]). The diagnosis of VP can be established by fecal analysis during an acute attack, during periods when only cutaneous manifestations are present, or during a clinically latent stage of the disease with high-performance liquid chromatography techniques. However, up to 30% of asymptomatic patients have normal fecal porphyrin profiles ([544]). Measurement of porphyrins in bile sampled by duodenal aspiration has been shown in a series of patients to provide a clearer differentiation between patients or carriers and normal subjects, particularly in people in whom fecal porphyrin values are indeterminate ([568]). The mean biliary porphyrin value in patients with VP was 68.0 µmol/L, as compared with 0.7 µmol/L in normal controls, and the lowest patient value was more than nine times the highest control value. Because the plasma porphyrins are commonly increased, examination of plasma for the characteristic fluorescence emission spectrum observed in VP (emission maximum, 626 nm, at neutral pH) ([16]) is probably the fastest way to establish the diagnosis. For the detection of asymptomatic carriers, this method was found to be 100% specific and 86% sensitive in one study ([569]) but was not considered sufficiently sensitive in another ([570]). During acute attacks, ALA and PBG are excreted in large amounts in the urine, as in AIP. However, the demonstration of excessive urinary ALA or PBG justifies only the diagnosis of acute porphyric attack, and a more specific diagnosis is not possible without analysis of the feces or plasma. In contrast to AIP, urinary excretion of ALA and PBG generally returns to normal after an acute attack ([16] , [543] , [544]) and usually is normal or only slightly increased in patients in whom the only clinical manifestations are cutaneous. During latent periods, urinary porphyrin excretion is usually normal; during acute attacks, or in the presence of superimposed liver dysfunction, it may be greatly increased ([16] , [543] , [566]). When cutaneous symptoms alone are present, coproporphyrin is the major urinary porphyrin, but uroporphyrin excretion may also be increased ([543]). During acute attacks, nonenzymatic conversion of PBG to uroporphyrin may occur, giving rise to an artifactually dramatic elevation of urinary uroporphyrin excretion ([543]). Measurement of PP-O activity can establish the diagnosis. Because it is a mitochondrial enzyme, the assay requires nucleated cells, such as Epstein-Barr–transformed lymphocytes ([561] , [562]). Time and costs involved make it impractical as a routine diagnostic test. The FEP is somewhat increased in heterozygotes. In homozygotes or compound heterozygotes, it ranges from five to ten times above normal, but anemia is usually absent.

TREATMENT Acute attacks should be prevented and treated as outlined for AIP. Hematin or heme arginate is used for severe attacks and is most effective if administered early in the course of the attack ([485] , [490]). Glucose may be of benefit ([543]). Protection against sun exposure is the only practical way to deal with the photosensitivity. Identifying abnormal gene carriers, feasible only by fecal or plasma analysis, is important because, as in AIP, most acute attacks can be prevented by avoiding precipitating drugs or other factors. Because of the great heterogeneity of *PP-O* mutations recognized, DNA mutational analysis is less practical except in the rare areas where a single mutation is prevalent.

ANIMAL MODEL OF VARIEGATE PORPHYRIA A mouse model for South African VP with the R59W mutation has been established by targeted gene replacement ([571]). The biochemical features closely resemble the human disease.

Hereditary Coproporphyria

Hereditary coproporphyria (HCP) is transmitted as an autosomal-dominant trait with a low penetrance. Mutations in the gene encoding CP-O (Fig. 31.1) result in suboptimal activity of the enzyme and lead to accumulation and excessive excretion of coproporphyrin. Analogous to VP, the porphyrin produces photosensitivity, and neurovisceral attacks occur with induction of heme biosynthesis.

Excessive fecal excretion of coproporphyrin by a patient with porphyria was first noted in 1936 ([572]), clinical features were recorded in 1949 ([573]), and the first comprehensive description of the disorder was that of Berger and Goldberg ([574]). A review describing clinical and laboratory findings in 111 patients with HCP appeared in 1977 ([575]). The disorder is less common than AIP and VP.

MOLECULAR BASIS AND PATHOGENESIS CP-O activity is reduced to half normal in all tissues examined, including cultured skin fibroblasts ([576]), mixed leukocytes ([575]), lymphocytes ([577]), liver ([578] , [579]), and kidney ([579]). In homozygous cases, enzyme activity ranged from 2 to 10% of normal ([580] , [581] and [582]); in a compound heterozygous case, it was 22% ([583]). In the harderoporphyria variant of HCP, unique kinetic characteristics of the enzyme are associated with accumulation of a tricarboxylic coproporphyrin (harderoporphyrin) ([581] , [582] and [583]). The cloning and characterization of the *CP-O* gene ([584] , [585] and [586]), which is located on chromosome 3 (3q12) ([587]), led to the identification of numerous mutations in the gene. To date, at least 34 different mutations have been reported, and all but two have been restricted to single families ([588] , [589]). The mutations are predominantly missense mutations affecting enzyme function or stability or leading to production of incomplete proteins. Despite the marked allelic heterogeneity at the molecular level and a wide range of residual enzyme activities of mutant proteins, clinical features are similar. The proteins of two mutant alleles associated with harderoporphyria impair the second decarboxylation of coproporphyrinogen III from harderoporphyrinogen ([588]). The pathogenesis of the clinical features can be viewed as the same as in VP, with induction of ALA synthase during attacks ([590]). The photosensitivity occurs mainly during periods of a neurovisceral attack, probably because plasma levels of the photosensitizing coproporphyrin become sufficiently elevated. Coproporphyrin is transported efficiently from the hepatocyte into bile or plasma and does not accumulate in the liver ([591]). In harderoporphyria, the mechanism for the anemia has not been characterized. It seems attributable to at least a photohemolysis component in that erythrocyte porphyrin (reported as protoporphyrin) was increased approximately eightfold when compared to related asymptomatic heterozygotes, and it lessened with age ([583]).

CLINICAL DESCRIPTION The disease is generally latent before puberty, and two-thirds of patients have no symptoms ([575] , [592]). In one patient, the first attack occurred at age 84 ([592]). Acute attacks are usually precipitated by drugs ([593]), and acute peripheral neuropathy may be the only manifestation ([594] , [595]). The neuropathic findings are similar to those of AIP ([596] , [597]) but are generally less severe; occasionally, only psychiatric features are evident ([593]). Photosensitivity is less common than in VP, and unlike in the latter, it tends to occur mainly in the presence of neurovisceral episodes. Rarely, intermittent episodes of cutaneous symptoms may be the only clinical manifestation of the disease ([575]). The cutaneous symptoms are similar to those of VP and PCT. In the few homozygotes reported, the clinical picture does not appear to differ greatly from that in heterozygotes. In harderoporphyria, jaundice, hepatosplenomegaly, and anemia were present after birth and diminished with time ([581] , [582] and [583]).

LABORATORY FINDINGS The fecal coproporphyrin level is invariably increased after puberty and may approach or exceed 10,000 µg/g dry weight during an attack.

An increase in the fecal coproporphyrin isomer III to isomer I ratio is also a distinguishing feature, particularly in latent heterozygotes ([598]). During acute attacks, urinary coproporphyrin excretion may be profoundly increased but usually is normal during remissions. As in VP, urinary ALA and PBG are typically increased only during attacks. In harderoporphyria, the predominant fecal porphyrin is tricarboxylic coproporphyrin; in urine, it is detectable only in trace amounts. In some homozygotes, the hemoglobin is decreased, there is brisk reticulocytosis, and the accumulated erythrocyte porphyrin is protoporphyrin ([581] , [582]).

TREATMENT HCP should be managed as described under AIP and VP. Heme arginate is effective ([599] , [600]). Detection of affected relatives of patients is important because avoiding specific drugs will probably prevent overt symptoms. CP-O assays are not widely available, leaving stool porphyrin determinations as the only practical screening method.

HEPATOCELLULAR CARCINOMA One case of hepatocellular carcinoma associated with HCP has been reported ([601]). After surgical resection, no recurrence was observed at 5 years of follow-up.

DUAL PORPHYRIAS

During the last three decades, a number of families have been discovered to have defects of two distinct porphyrias. In two families, individuals had one or the other trait. Two cases of PCT were described in a family in which five other members had VP ([602]). In the second instance, a father had PCT and a daughter had typical EPP ([603]).

Nine different combinations have been described in which patients possessed two porphyria defects (Fig. 31.8). The first such type reported involved the occurrence of VP and PCT ([604]). In South Africa, 25 of 106 patients with VP excreted porphyrins typical of PCT as well. The clinical features and subsequent enzyme assays ([605]) were consistent with those of both porphyrias. Biochemical data in further cases were also consistent with concomitant defects of VP and PCT, but family studies were not reported ([606] , [607]). Additional dual porphyrias consisting of an acute form plus a cutaneous form that have been encountered include AIP with PCT, with clinical manifestations of both defects ([608]); HCP with PCT ([609]); HCP with CEP in a child manifesting hepatosplenomegaly, hemolytic anemia, severe photodermatosis, and impaired growth and mental development ([610]); and AIP with possible EPP and severe neurovisceral manifestations that were fatal ([611]). In the latter case, biochemical studies reflected a PBG-D defect as well as FECH deficiency. Analysis of the sciatic nerve revealed reduced PBG-D activity coupled with increased activity of ALA synthase, representing the first such data in human neural tissue.

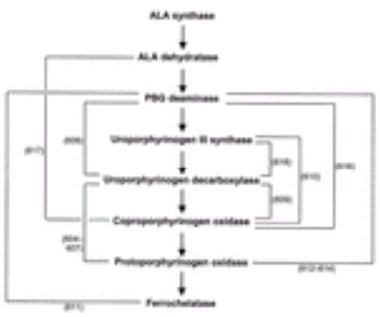

Figure 31.8. Enzyme defects in dual porphyrias. Pairs of the respective enzymes involved in the nine reported forms of dual porphyria are joined by brackets. Reference numbers are in parentheses. ALA, 5-aminolevulinic acid; PBG, porphobilinogen.

In 1985, a large kindred of 200 descendants stemming from a marriage in 1886 was encountered in Chester, Scotland, in which clinical presentations had been typical of AIP and, in some cases, were severe and fatal ([612] , [613] and [614]). Biochemical studies reflected values ranging from those observed in AIP to those found in VP. Clinically affected patients had both deficient PBG-D and PP-O activities in peripheral blood leukocytes, although there appeared to be some overlap with control values in some cases ([612]). A linkage analysis with polymorphic markers suggested that the locus for the disease is on chromosome 11 but is separate from the *PBG-D* gene ([615]). A second form of two coexisting acute porphyria defects involved PBG-D and CP-O ([616]). Among 17 family members examined, the dual enzyme deficiency was found in five, PBG-D deficiency alone in four, and CP-O deficiency alone in two ([616]). Only the proband with both defects suffered mild acute attacks of porphyria and had the most marked changes in porphyrin and porphyrin precursor excretions, probably involving a precipitating factor. In a third example, HCP with partial ALA-D deficiency was characterized by a severe neurologic attack ([617]). Dual deficiency of two nonacute porphyria defects, UROIII-S and URO-D, in a boy caused severe photosensitivity and hemolytic anemia ([618]), with subsequent development of severe osteoporosis, renal and liver siderosis, and nephrotic syndrome ([619]).

In all of the cases of dual porphyria reported, the diagnosis was based on quantitation of metabolic intermediates as well as enzyme analysis. Their occurrence, for the most part, probably represents coincidental inheritance of two defects. In some instances, consanguinity of parents was noted. Identification of specific molecular defects would further substantiate the various forms of dual porphyria. Atypical findings of porphyrins and their precursors encountered in the diagnostic evaluation may indicate the presence of a complex porphyric state.

Hereditary Spherocytosis and Other Anemias Due to Abnormalities of the Red Cell Membrane

This chapter focuses on hemolytic disorders resulting from primary abnormalities of the red cell membrane. The major emphasis is on hereditary spherocytosis (HS) and the hereditary elliptocytosis (HE) syndromes because these are the ones most commonly encountered by clinicians. The traditional classification of red cell membrane disorders has been based on red blood cell (RBC) shape changes, and this classification has been retained in this chapter because of its clinical applicability (Fig. 32.1). However, during the past several years, there has been an explosion of knowledge regarding the biology of the RBC membrane, and a basic understanding of this erythrocyte membrane structure and function is essential to appreciate the diverse pathophysiology of these disorders.

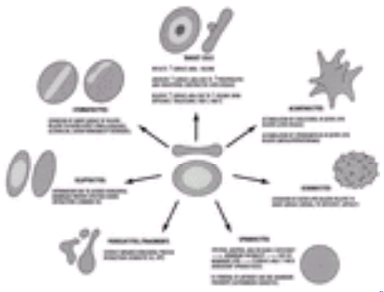

Figure 32.1. Diagrammatic representation of abnormal cells associated with red blood cell (RBC) membrane disorders. ?, increased; ?, decreased; ?, leads to; HE, hereditary elliptocytosis; HGB, hemoglobin; HPP, hereditary pyropoikilocytosis; MCV, mean corpuscular volume; PK, pyruvate kinase; R-E, reticulo-endothelial.

GENERAL CONSIDERATIONS OF THE RED CELL MEMBRANE

The RBC membrane structure is a bilayer of phospholipids intercalated with molecules of unesterified cholesterol and glycolipids. The phospholipids are asymmetrically organized, with the choline phospholipids (phosphatidylcholine and sphingomyelin) primarily on the outside of the bilayer and the amino phospholipids (phosphatidylethanolamine and phosphatidylserine) on the inside. The membrane also contains proteins that are asymmetrically organized. All glycoproteins are exposed on the outer membrane surface, and these are red cell antigens and receptors (e.g., glycophorins) or transport proteins (i.e., the anion transport channel). These integral membrane proteins penetrate or span the lipid bilayer, interact with the hydrophobic lipid core, and are tightly bound to the membrane. A separate protein network forms the membrane cytoskeleton, which interacts with both the integral membrane proteins and the lipid bilayer. This cytoskeleton is composed of spectrin, ankyrin, protein 4.1, pallidin (protein 4.2), and actin (Fig. 32.2). The biochemical and genetic characteristics of these RBC membrane proteins are depicted in Table 32.1. Spectrin is made up of aß-heterodimers that, at the head end, interact with other spectrin aß-dimers to form heterotetramers $(aß)_2$ in which the *N*-terminal end of a-spectrin and the C-terminus of ß-spectrin form the head region of the heterodimer. These spectrin tetramers are the major structural subunits of the membrane skeleton. The spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that favors spectrin tetramer formation. Near the dimer-dimer association site, spectrin tetramers interact with protein 3 (the anion exchange channel) via ankyrin, and this interaction is most important for the attachment of the cytoskeleton to the membrane. At the opposite end of the spectrin molecule, spectrin tetramers interact with actin via protein 4.1. In addition, there are other membrane protein interactions not directly involving spectrin. These interactions include glycophorin C to protein 4.1 and pallidin (protein 4.2) to band 3; the latter interaction is thought to stabilize ankyrin in the membrane. The horizontal protein interactions, mainly the interactions of spectrin dimers, are responsible for the lateral deformability of the cytoskeleton. Thus, these protein interactions are responsible for the overall stability of the membrane, thereby allowing the RBC to be deformable during its lifespan within the circulation ([1], [2], [3], [4] and [5]).

Hereditary RBC membrane disorders result from alterations in the quantity or quality (or both) of these individual proteins and their interactions with each other. HS is caused by an uncoupling of the cytoskeleton from the lipid bilayer, thereby leading to membrane instability with loss of lipids and some integral membrane proteins. HE disorders are the result of defects in spectrin dimer interactions, thereby leading to disruption of the skeletal lattice and RBC fragmentation. The development of methods using polyacrylamide gel electrophoresis of sodium dodecyl sulfate–solubilized red cell membrane proteins has allowed the separation and quantification of membrane proteins (Fig. 32.3) and the detection of membrane protein abnormalities in many hereditary red cell disorders. In some cases, the specific DNA mutations have been identified, and several excellent reviews of the molecular advances in these diseases are available ([2], [3] and [4]).

HEREDITARY SPHEROCYTOSIS

HS is a familial hemolytic disorder characterized by anemia, intermittent jaundice, splenomegaly, and responsiveness to splenectomy. However, there is marked heterogeneity of the clinical features, ranging from an asymptomatic condition to a fulminant hemolytic anemia. The morphologic hallmark of HS is the microspherocyte, which is caused by loss of membrane surface area and is characterized by an abnormal osmotic fragility *in vitro*. The interesting history of HS is recounted in detail by Dacie ([6]) and by Packman ([7]). The earliest clinical account of the disorder is probably the 1871 report of Vanlair and Masius ([8]), and the 1934 studies of Haden drew attention to a probable structural abnormality of the membrane as the basis for hemolysis ([9]). Subsequent investigation of HS afforded important insights into the structure and function of cell membranes and the role of the spleen in maintaining RBC integrity ([10]). It is now recognized that the intrinsic genetic defect causes qualitative and quantitative defects in membrane proteins; in turn, these are the result of a variety of molecular defects that are being defined.

Prevalence and Genetics

HS is the most common of the hereditary hemolytic anemias among people of Northern European descent. In the United States, the incidence of the disorder is approximately 1 in 5000 ([11]). However, this figure is probably an underestimate, not accounting for the patients with asymptomatic and mild forms, as suggested by the screening of blood donors for abnormal osmotic fragility ([12], [13]). The disease is encountered worldwide, but its incidence and prevalence in other ethnic groups are not clearly established.

In most affected families, HS is transmitted as an autosomal-dominant trait, and the identification of the disorder in multiple generations of affected families is the rule. Homozygosity for this dominantly transmitted HS gene has not been identified, thus suggesting that the homozygous state is incompatible with life. Nearly one-fourth of all newly diagnosed patients do not demonstrate a dominant inheritance pattern, and the parents of these patients are clinically and hematologically normal ([11], [14], [15]). New mutations have been implicated that may explain some of these sporadic cases; in support of this is the fact that approximately 50% of the offspring of individuals with sporadic HS also have the disease. An autosomal-recessive mode of inheritance also occurs, and this is supported by the descriptions of families in which apparently normal parents have had more than one affected child ([14], [16], [17], [18] and [19]). This recessive pattern may account for 20 to 25% of all HS cases ([12], [20]). It is manifested only in homozygous or compound heterozygous individuals and often is associated with severe hemolytic anemia ([12], [20]).

Pathogenesis

Hemolysis in HS results from the interplay of an intact spleen and an intrinsic membrane protein defect that leads to an abnormal RBC.

MEMBRANE PROTEIN DEFECTS Current concepts are that the primary lesion in HS erythrocytes is caused by membrane protein defects resulting in cytoskeleton instability. The first biochemical defect recognized in patients with HS was spectrin deficiency, and the degree of spectrin deficiency was reported to correlate with the extent of spherocytosis, the degree of abnormality of the osmotic fragility test, and severity of hemolysis (Fig. 32.4) ([12], [21]). In some cases, spectrin deficiency is the result of impaired synthesis, whereas in other instances, it is caused by quantitative or qualitative deficiencies of other proteins that integrate spectrin into the cell membrane. In the absence of these binding proteins, free spectrin is degraded, thereby leading to spectrin deficiency. Analysis of red cell membrane proteins in patients with HS has identified four abnormal patterns: spectrin deficiency alone, combined spectrin and ankyrin deficiency, band 3 deficiency, and protein 4.2 defects. Each of these subsets is associated with a variety of mutations that result in different protein abnormalities and varied clinical expression (Table 32.2). Most of these mutations have been tabulated recently ([22], [23]) and are available through web sites at Boston Children's Hospital (www.kidscancer.net/membrane/mutation.htm) or at the Human Gene Mutation Database in Cardiff (http://archive.uwcm.ac.uk/uwcm/mg/ns/7/1198974.html).

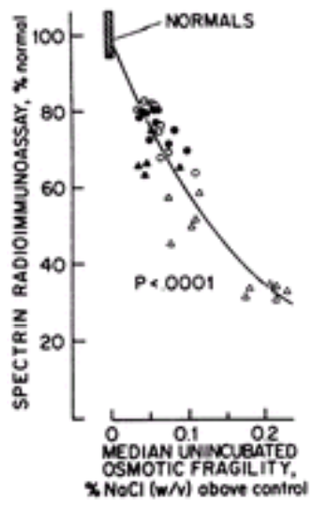

Figure 32.4. Relationship between spectrin deficiency and unincubated osmotic fragility in hereditary spherocytosis (HS) red cells. Spectrin content (measured by radioimmunoassay) is shown on the vertical axis, and osmotic fragility (measured by NaCl concentration producing 50% hemolysis of red blood cells) is shown on the horizontal axis. Circles represent patients with typical autosomal-dominant HS. Triangles represent patients with nondominant HS. Open symbols represent patients who have undergone splenectomy. (Reprinted from Agre P, Asimos A, Casella JF, et al. Inheritance pattern and clinical response to splenectomy as a reflection of erythrocyte spectrin deficiency in hereditary spherocytosis. N Engl J Med 1986;315:1579, with permission.)

TABLE 32.2. Clinical Classification of Hereditary Spherocytosis (HS)

	Silent Carrier HS	Mild HS	Moderate HS	Severe HS
Fraction of HS cases (%)	—	20–30	60–75	5–10
Hemoglobin (g/dl)	Normal	11–15	8–12	<6
Reticulocytes (%)	1–3	3–8	>8	>10
Peripheral blood smear	Normal	Few spherocytes	Moderate spherocytosis	Spherocytosis and poikilocytosis
Osmotic fragility				
Fresh	Normal	Normal/increased	Increased	Increased
Incubated	Slightly increased	Increased	Increased	Increased
Spectrin content (% normal) [a]	100	80–100	50–80	20–55

[a] Estimated from those cases associated with spectrin deficiency.

Modified from Lux SE, Palek J. Disorders of the red cell membrane. In: Handin RI, Lux SE, Stossel TO, eds. Blood: principles and practice of hematology. Philadelphia: JB Lippincott, 1995:1701.

Spectrin Deficiency Mutations of a-spectrin are associated with recessive forms of HS, whereas mutations of ß-spectrin occur in families with autosomal-dominant forms of HS ([23]). This difference reflects that the synthesis of a-spectrin is threefold greater than that of ß-spectrin, and the excess a-chains normally are degraded ([24], [25] and [26]). Heterozygotes for a-spectrin defects would still be expected to produce sufficient normal a-spectrin to approximately balance normal ß-spectrin production. Therefore, heterozygotes have a normal phenotype, and clinical abnormalities caused by a-spectrin deficiencies are found only in the homozygous or compound heterozygous states. In contrast, defects of ß-spectrin are more likely to be clinically apparent in the heterozygous state because synthesis of ß-spectrin is the rate-limiting factor for assembly of aß-spectrin heterodimers into the membrane. Red cell membranes isolated from individuals with autosomal-recessive HS have only 40 to 50% the normal amount of spectrin (relative to band protein 3), whereas red cell spectrin levels range from 60 to 80% of normal in the autosomal-dominant form of HS ([20]) (Table 32.2). A relatively common splice site mutation in the a-spectrin gene at codon 1729, a-spectrin LEPRA, is associated with a second mutation at codon 969 and low expression of a-spectrin. When inherited together with another low-expression a-spectrin mutation in *trans*, a-spectrin LEPRA is a common cause of severe, recessively inherited HS ([27], [28] and [29]). Mutations involving the ß-spectrin gene also lead to spectrin deficiency ([23]). Many of these mutations impair ß-spectrin synthesis ([30], [31] and [32]). Others produce truncated ß-spectrins that are unstable ([33]) or do not bind to ankyrin and, thus, are not assembled onto the membrane skeleton and undergo proteolytic degradation ([34]). ß-Spectrin Kissimmee contains a point mutation leading to defective binding of spectrin to protein 4.1 ([35], [36]).

Ankyrin Defects That a primary defect in the structure or function of ankyrin also might cause spectrin deficiency was first suggested by linkage studies that related dominant HS to the gene for ankyrin but not to the genes for a-spectrin, ß-spectrin, or protein 4.1 ([37]). In addition, HS was described in patients with translocation of chromosome 8 or deletion of the short arm of chromosome 8 where the ankyrin gene is located ([38], [39]); patients with HS and deletion of chromosome 8 were shown to have a decrease in red cell ankyrin content ([40]). Ankyrin is the principal binding site for spectrin on the red cell membrane, and studies of cytoskeletal protein assembly in reticulocytes indicate that ankyrin deficiency leads to decreased incorporation of spectrin on the membrane ([41]). Thus, in cases of HS caused by ankyrin deficiency, there is a proportional decrease in spectrin content although spectrin synthesis is normal. Of particular interest, the use of sensitive radioimmunoassay techniques to measure spectrin and ankyrin proteins has revealed that 75 to 80% of patients with autosomal-dominant HS have combined spectrin and ankyrin deficiency and that the two proteins are diminished equally (Fig. 32.5) ([42]). At least 35 different ankyrin mutations, primarily frameshift or nonsense in type, have been identified in HS ([5], [23], 42a, [43] and [44]). Most are associated with reduced or absent expression at the mutant allele. Ankyrin gene mutations are the most common cause of dominant HS ([23]). Ankyrin promotor mutations may be silent in the heterozygous state but cause recessive HS when both ankyrin alleles are affected ([45]).

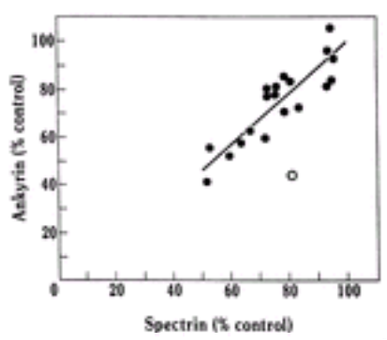

Figure 32.5. Relationship between spectrin and ankyrin content in red cells of patients with dominant hereditary spherocytosis. Each point, expressed as a percentage of control taken as 100%, represents the mean value for a kindred for both spectrin and ankyrin levels. The line represents a computer-generated fitting of the data for 19 of the 20 kindreds. The one discordant kindred (*open circle*) is relatively ankyrin deficient. (Reprinted from Savvides P, Shalev O, John KM, et al. Combined spectrin and ankyrin deficiency is common in autosomal dominant hereditary spherocytosis. Blood 1993;82:2953, with permission.)

Band 3 Deficiency Band 3 deficiency mutations are found in 10 to 20% of patients with mild to moderate autosomal-dominant HS ([46], [47], [48], [49] and [50]). These patients who are heterozygotes for a band 3 mutation have a 20 to 40% decrease of band 3 content (detected by an increased spectrin to band 3 ratio). In some HS subjects deficient in band 3, the deficiency is considerably greater in older RBCs, thus suggesting that band 3 protein is unstable because of a poor binding or a defective assembly of band 3 on the membrane ([51]). Protein 4.2 content in the membrane is decreased ([52]) or absent ([53]) in band 3–deficient HS patients. At least 45 band 3 mutations, the majority missense or small deletions in type, have been identified in HS patients ([22], [54]). Heterozygotes may be clinically silent ([52]) or exhibit mild to moderate HS ([54]). Homozygotes or compound heterozygotes for band 3 mutations usually exhibit more severe HS ([55], [56], [57] and [58]). Homozygosity for band 3 Coimbra was seen in a hydropic infant who had extremely severe HS and required regular red cell transfusions after birth ([56]). Her red cells entirely lacked band 3. She and members of another family who had less severe HS and were heterozygotes for another band 3 mutation ([59]) exhibited renal tubular acidosis, whereas renal handling of bicarbonate has been normal in most band 3–deficient HS patients, despite the fact that the anion exchanger mutation is expressed in both erythrocytes and the kidney ([60]).

Protein 4.2 (Pallidin) Deficiency Autosomal-recessive hereditary hemolytic anemia has been described in several patients with a complete or almost complete deficiency of protein 4.2. The phenotypes described in these reports have been quite heterogeneous, with RBC morphology characterized by spherocytes, elliptocytes, or spheroovalocytes. Deficiency of protein 4.2 in HS is relatively common in Japan ([61]). A few mutations have been described in these patients ([22]). One that appears to be common in the Japanese population (protein 4.2 ^{Nippon}) is associated in the homozygous state with a red cell morphology described as spherocytic, ovalocytic, and elliptocytic ([62]). Another mutant protein 4.2 (protein 4.2 ^{Lisboa}) is caused by a deletion that results in a complete absence of protein 4.2, and this is associated with a typical HS phenotype ([63]).

Red Blood Cell Membrane Protein Abnormalities in Animal Models of Hereditary Spherocytosis Early studies to identify a defect in the RBC protein skeleton were given impetus by the demonstration of marked spectrin deficiency associated with a spherocytic hemolytic anemia that occurs in house mice ([64] , [65] and [66]). The severity of hemolysis in these mice is a function of the degree of spectrin deficiency ([66]). Animals with the most severe anemia lacked both a- and ß-chains of spectrin and had massive hepatosplenomegaly, spherocytes approaching 100%, and reticulocyte counts exceeding 90%. Subsequently, other mutant HS mice have been identified, and, just as in human HS red cells, defects of a-spectrin, ß-spectrin, and ankyrin have been described. The ja/ja mouse has a ß-spectrin gene mutation with no detectable spectrin on the membrane ([67]). A very similar ß-spectrin mutation associated with spherocytic hemolytic anemia has been found in zebra fish ([68]). In contrast to the human ß-spectrin HS mutation, the heterozygous mouse appears normal with no evidence of hemolysis or spherocytosis, whereas the homozygous mouse is severely anemic. The sph/sph mouse mutants are characterized by a defect of a-spectrin, with only a small amount of ß-spectrin on the membrane ([24]). *sph/sph* and *ja/ja* mice that survive the neonatal period exhibit secondary hemochromatosis and often develop thrombi in major organs ([69] , [70]). The nb/nb mice have ankyrin deficiency ([24] , [71]). Both sph/sph and nb/nb spherocytes exhibit increased passive permeability to monovalent cations, as do their human counterparts ([72]). A naturally occurring total deficiency of red cell band 3 has been reported in cattle, which exhibit spherocytic anemia ([73]). Several transgenic mouse models with homozygous deficiency of band 3 have also been established; their RBCs are completely devoid of band 3 as well as protein 4.2 ([74] , [75]). Despite their lack of these two proteins, the membrane cytoskeleton is intact ([75]). Although these homozygous mice survive *in utero*, they are born severely anemic and require RBC transfusions to survive. Like sph/sph and ja/ja mice, band 3–deficient mice exhibit a hypercoagulable state, with thrombosis contributing to their high mortality ([76]). Finally, targeted disruption of the ß-adducin gene (*Add 2*) causes spherocytic anemia in mice ([77]). An equivalent disorder in humans has not been identified.

RED BLOOD CELL ABNORMALITIES Loss of membrane surface area is the major pathologic feature of HS RBCs (Fig. 32.6) and begins at the reticulocyte stage of red cell development ([78]). It has been known for years that HS red cells lose lipid and that the phospholipid and cholesterol content of HS membranes is decreased 15 to 20% ([79] , [80] , [81] and [82]). In most cases, it is thought that membrane loss occurs because the spectrin-deficient cytoskeleton is unable to provide adequate support for the lipid bilayer. Less often, band 3 defects are responsible for disruption of the lipid bilayer. The loss of membrane is characterized by release of small (0.2 to 0.5 µm) lipid vesicles that may contain band 3 but are devoid of spectrin ([21] , [83]). The loss of membrane surface area transforms red cells from biconcave discs to spherocytic forms. An important physiologic consequence of this is that cellular deformability of spherocytes is decreased compared with normal discoid red cells with a larger membrane surface. For HS red cells, this limits their ability to pass through the small fenestrations in the venous sinuses of the spleen (discussed in Splenic Entrapment) ([84] , [85]). Despite their membrane skeletal defects and lipid loss, HS red cells retain a normal transbilayer phospholipid distribution ([86]).

Figure 32.6. The pathophysiology of hereditary spherocytosis is a consequence of spectrin, ankyrin, or band 3 abnormalities that lead to membrane instability, loss of lipid microvesicles, decreased red cell surface area, reduced cellular deformability, and stagnation of red blood cells (RBCs) in the splenic cords (see text for details). ?, leads to.

The primary cytoskeleton defect in HS results in a variety of secondary metabolic changes. These metabolic effects include increased sodium and potassium flux across the HS membrane ([87] , [88] , [89] and [90]), which leads to increased membrane sodium-potassium adenosine triphosphatase activation; accelerated adenosine triphosphate (ATP) breakdown ([91]); increased rate of glycolysis ([89]); and a decreased concentration of 2,3-diphosphoglycerate (2,3-DPG). The latter is probably a consequence of a lower intracellular pH. However, because the decrease in red cell 2,3-DPG and intracellular acidosis both are corrected by splenectomy, they have been attributed to detention of spherocytes within the spleen ([92] , [93]). At one time, the above defects were considered part of the pathophysiology of HS, but it is now recognized that these are secondary events. Interestingly, HS red cells are slightly dehydrated, although the reason for decreased RBC water content is not known. One possibility is that it is related to K-Cl cotransport, a pathway that leads to dehydration and is activated by acid pH ([94]). This is an intriguing possibility because the pH is reduced in the splenic cords (discussed further in the section Splenic Conditioning). However, some investigators have found that K-Cl cotransport is decreased rather than increased in HS red cells ([95]). Another possibility is that red cell dehydration is caused by the increased Na^+/K^+ pump activity stimulated in response to the increased passive cation leaks. Because two K ions are transported in for every three Na ions extruded out of the cell, this can lead to a decrease in total cation content, water efflux from the red cell, and cellular dehydration ([96]). This dehydration of HS red cells is important because it can further impair their deformability ([84] , [97]).

ROLE OF THE SPLEEN IN PATHOPHYSIOLOGY The survival of infused HS red cells into normal recipients is reduced, whereas the survival of normal red cells in HS subjects is normal ([98]). This basic observation demonstrates an intrinsic defect in HS red cells. A second fundamental observation is that the survival of HS red cells in most splenectomized recipients is nearly normal ([10]). Moreover, despite the persistence of spherocytosis after splenectomy, red cell survival is normal or only slightly reduced ([99] , [100]). Taken together, these observations from several years ago demonstrated that an intrinsic red cell defect leads to RBC destruction, but only in the presence of an extrinsic factor—an intact spleen. The role of the spleen in ameliorating hemolysis appears to differ in band 3–deficient spherocytosis compared to spherocytosis due to spectrin-actin deficiency. In both types of spherocytosis, splenectomy prevents the premature loss of young red cells. In addition, as spectrin-actin–deficient cells age, they lose band 3–rich vesicles as a consequence of their lack of adequate cytoskeletal binding sites for band 3. Clustering of band 3 is thus minimized in these older spectrin-actin–deficient spherocytes, limiting the accumulation of naturally occurring autoantibodies that bind to sites on the band 3 molecule. Because band 3–deficient spherocytes have an excess of cytoskeletal binding sites, they do not lose additional band 3 as they age; consequently, they accumulate increasing amounts of surface-bound autoantibodies. Antibody coating contributes to shortened red cell survival, and its elimination may explain the greater improvement in postsplenectomy survival noted in spectrin-actin–deficient spherocytes as compared to band 3–deficient red cells ([101]).

Splenic Entrapment Radiolabeled spherocytes are sequestered selectively in the spleen ([102] , [103] and [104]); this occurs because of the unique anatomy of the splenic vasculature ([105] , [106] and [107]). Arterial blood enters directly into the splenic cords, a network of channels formed by reticulum cells and lined by macrophages. Most of the blood that enters the splenic cords passes rapidly through direct channels, which reenter the venous system after traversing fenestrations between the lining endothelial cells. A small fraction of blood in the splenic cords percolates more slowly through this maze before reaching the venous sinuses. The hematocrit of blood from the splenic cords is high, the environment is acidic, and the red cells are exposed to macrophages that line these channels. The size of fenestrations in the venous sinuses is small relative to the RBC size, and to pass through requires some degree of deformability of the red cell membrane. This, however, is a major problem for HS red cells, which have lost surface area and are dehydrated. Examination of spleens removed from patients with HS demonstrates congested cords and relatively empty venous sinuses ([108] , [109] and [110]). With electron microscopy, few spherocytes can be seen traversing sinus walls ([108] , [110]). The most severely damaged spherocytes, cells unable to negotiate the fenestrations in the venous sinus, are removed from the circulation by macrophages ([110]). However, impaired deformability of HS red cells is only significant for the passage of these cells through the spleen. After splenectomy, red cell survival is normal, even though spherocytes persist and sometimes are increased ([10]). Recent studies indicate that splenectomy has no effect on surface area loss by HS reticulocytes or mature red cells, because surface area loss is due to the intrinsic membrane lesion in these cells. Thus, although the role of the spleen in sequestering HS cells is unquestioned, the generation of spherocytes is an independent event that continues even after splenectomy ([78]).

Splenic Conditioning In addition to trapping HS red cells, the spleen also “conditions” these cells in a way that accelerates membrane loss and spherocyte formation. Some conditioned red cells reenter the systemic circulation, demonstrated most convincingly with Fe^{59} labeling of HS cells. Cohorts of cells so labeled gradually shift from osmotically normal to osmotically fragile cells during their circulation in patients with intact spleens ([102]). Osmotically fragile microspherocytes are concentrated in and emanate from the splenic pulp ([10] , [111]). The more conditioned or spheroidal cells are responsible for the most fragile portion of the fresh osmotic fragility curve. The mechanism of splenic conditioning is not clear. It may be the result of hemoconcentration and erythrostasis with macrophage-induced membrane injury ([112] , [113] and [114]). It may be related to the lower pH in the spleen ([115]) as well as in the sequestered red cells. As discussed in the section Red Blood Cell Abnormalities, this pH change may activate K-Cl cotransport, lead to cell dehydration, and further decrease deformability. Because the calculated transit time for spherocytes is short relative to the time required for severe metabolic compromise, it is unlikely that metabolic depletion is important, and the ATP content of HS cells

in the spleen is normal ([112]). The conditioning effect of the spleen is a cumulative injury, thought to result from several passages through this organ.

Clinical Features

Anemia, jaundice, and splenomegaly are the clinical features of HS most commonly encountered. However, signs and symptoms are highly variable, both with respect to age of onset and severity. For example, anemia or hyperbilirubinemia may be of such magnitude as to require exchange transfusion in the neonatal period ([116], [117] and [118]). On the other hand, the disorder may escape clinical recognition altogether, and in one reported case, the initial anemic problem was first recognized at 75 years of age ([119]). Anemia usually is mild to moderate, but sometimes, it is very severe, and, in some pedigrees, there may be no anemia. Jaundice is likely to be most prominent in the newborn. Approximately 30 to 50% of adults with HS have a history of jaundice during the first week of life ([117], [118]). The magnitude of hyperbilirubinemia may be such as to require exchange transfusion (119a). Virtually all HS infants who are homozygous for the mutation responsible for Gilbert syndrome are jaundiced enough to require phototherapy ([120]). In contrast to the frequency of jaundice, most newborns with HS are not anemic ([121]). However, anemia develops rapidly in the first month of life in many infants and often requires one or more RBC transfusions. Maturation of the splenic filtering function and development of the splenic circulation appear to increase the rate of hemolysis after birth; at the same time, the erythropoietic response to anemia is blunted. Within a few months, erythropoiesis increases, anemia improves, and the need for red cell transfusions disappears in all but the most severely affected infants ([121]). Beyond the neonatal period, jaundice is rarely intense. Characteristically, icterus is intermittent and is associated with fatigue, cold exposure, emotional distress, or pregnancy. An increase in scleral icterus and a darker urine color is commonly seen in children with nonspecific viral infections. Even when patients have no detectable jaundice, there usually is laboratory evidence of ongoing hemolysis ([17], [122], [123]). Splenomegaly is the rule, and in large family studies, palpable spleens have been detected in more than 75% of affected members ([17], [116]). No apparent correlation exists between spleen size and disease severity ([17]). The liver is normal in size and function.

From a clinical perspective, it has been useful to classify HS according to the severity of disease (Table 32.2). Moderate HS is the most common presentation, recognized as a chronic hemolytic disorder with characteristic red cell spherocytes on the peripheral blood smear. In most cases, the pattern of transmission is autosomal dominant, although recessive inheritance also is seen. Moderate HS accounts for 60 to 75% of all HS cases. It is associated with mild to moderate anemia, modest splenomegaly, and intermittent jaundice ([124]). Mild HS occurs in 20 to 30% of cases of autosomal-dominant HS. In these patients, anemia is not generally present because the bone marrow is able to fully compensate for the persistent destruction of red cells, and there is little or no splenomegaly ([124]). Because patients in this group usually are asymptomatic, they often are not diagnosed until later in life. Sometimes, they are identified as a result of hemolytic or aplastic episodes triggered by infection ([125]). Occasionally, the condition is identified only through family surveys performed to document the hereditary nature of hemolytic disease in a relative. Severe HS occurs in approximately 5% of all HS patients ([21], [126]). It is characterized by severe hemolytic anemia, the need for red cell transfusion, and usually an incomplete response to splenectomy ([126]). The pattern of inheritance is almost always recessive. The silent carrier of HS exists in families with autosomal-recessive HS. In most of these cases, the parents of an affected patient have no signs of HS or only a mild increase in the reticulocyte count, a few spherocytes on peripheral blood smear, a minimally abnormal incubated osmotic fragility, or an abnormal spectrin content detected when using sensitive techniques ([20]). Given that the incidence of HS in the United States is 1 in 5000 and that approximately 25% of all HS is autosomal recessive, it has been calculated that the HS silent carrier state might exist in 1.4% of the population ([2]).

The two major complications seen in HS are episodes of worsening anemia and the development of gallstones. Exacerbations of anemia occur in almost all HS patients, even in the large majority of HS patients who have mild or clinically silent disease. For example, previously mild anemia can become much more severe during pregnancy, usually because of the increased plasma volume but, occasionally, as a consequence of accelerated hemolysis ([127], [128] and [129]). As with other chronic hemolytic states, some anemic crises are preceded by a febrile illness and may be observed concurrently in more than one affected member of a single family ([130], [131]). In some cases, there may be increased hemolysis (decreased hemoglobin, increased reticulocytes, increased bilirubin concentration) associated with nonspecific viral infections. In other cases, just as with other individuals with chronic hemolysis, hypoplastic crises resulting from human parvovirus infection are seen ([132], [133]). These transient aplastic crises caused by an arrest of erythropoiesis are characterized by sudden decrease in hemoglobin concentration and reticulocytopenia. Recovery occurs within 7 to 10 days and is heralded by reticulocytosis and thrombocytosis ([132]). Less commonly, exaggeration of anemia is the result of exhaustion of folate reserves by the sustained increase in net DNA synthesis ([132]). Megaloblastic arrest of erythropoiesis has been observed most commonly during pregnancy or in association with liver disease ([17], [134], [135]). Cholelithiasis is common in HS just as in other chronic hemolytic disorders. Gallstones of the pigment type (caused by bilirubin) may be found in very young children ([136]), but the incidence of gallstones increases markedly with age, and they are present in 40 to 80% of adults ([137]). The history of family members with cholelithiasis in the second or third decade of life is a clue to the possibility of HS or other chronic hemolytic disorder. In patients with mild HS, cholelithiasis may be the first sign of an underlying red cell disorder. The development of gallstones is increased approximately fivefold in HS patients who are homozygotes for the uridine diphosphate–glucuronosyltransferase mutation responsible for Gilbert syndrome ([138]).

A few other unusual complications have been noted in HS patients. Heterotopia of the bone marrow has been noted rarely in the renal pelvis ([139]) or along the vertebral column ([140], [141], [142], [143] and [144]). These extramedullary masses of marrow may be mistaken for malignant tumors. After the spleen is removed, they undergo fatty metamorphosis ([144]). Hemosiderosis and multiple endocrine disorders resulting from transfusion-induced iron overload have been described ([145]). Interestingly, symptomatic iron overload also has been reported in some nontransfused HS patients who are heterozygous for the hemochromatosis gene ([146], [147] and [148]). Multiple myeloma has been reported in a few non-splenectomized HS patients ([149]), but the relationship with HS, if more than coincidental, remains to be determined. Chronic leg ulcers are an unusual complication in adults with HS ([150]).

Laboratory Features

The classic laboratory features of HS include minimal or no anemia, reticulocytosis, an increased mean corpuscular hemoglobin concentration (MCHC), spherocytes on the peripheral blood smear, hyperbilirubinemia, and an abnormal osmotic fragility test.

Although reticulocytosis with values of 5 to 20% is common, some mild HS patients first come to medical attention during a hypoplastic anemic crisis, and in these instances, the initial reticulocyte count can be extremely low. Usually, however, these patients have hyperbilirubinemia as evidence of accelerated RBC destruction. The reason for the marked reticulocytosis seen in mild to moderate HS in the face of minimal anemia is not clearly understood. At one time, it was thought to be caused by reduced 2,3-DPG levels; however, the partial pressure at which hemoglobin is half saturated with oxygen (p50) is normal ([112]). The reason for this compensated hemolysis in HS remains an enigma, but recent data indicate that serum erythropoietin levels are elevated in such patients, even when anemia is absent ([151]).

An increased MCHC obtained from an electronic cell counter is a characteristic feature of HS red cells ([152]). MCHC values greater than the upper limit of normal (35 to 36%) are common. This increased MCHC is a result of mild cellular dehydration ([122]). Examination of the indices obtained by automated cell counters is an excellent screening test for HS. An MCHC greater than 35.4 g per dl combined with a red cell distribution width greater than 14 has a sensitivity of 63% and a specificity of 100% ([153]). The mean corpuscular volume (MCV) usually is normal. However, considering the degree of reticulocytosis, the MCV in HS patients actually is low. This relatively low MCV may reflect membrane loss and cell dehydration. Fluctuations of mean corpuscular hemoglobin parallel those of the MCV.

RBC morphology is distinctive yet not diagnostic. Varying degrees of polychromatophilia and anisocytosis are noted. Anisocytosis is prominent, and the smaller cells are spherocytes, recognized by the intensity of staining, lack of central pallor, and size. Because the degree of spherocytosis or “conditioning” is a function of cell age, reticulocytes and young red cells are morphologically normal ([154]). The number of microspherocytes varies considerably from patient to patient; as few as 1 to 3 in mild HS to as many as 20 to 30 per high-power field in moderate HS (Fig. 32.7). In severe HS patients, many odd-shaped poikilocytes also are present in addition to the spherocytosis. Unlike the spherocytes associated with immune hemolytic disease and thermal injury, most HS spherocytes are fairly uniform in size and density. Acanthocytes are a feature of ß-spectrin deficiency HS cells ([35]), and pincered spherocytes may be noted in band 3–deficient HS cells ([22]).

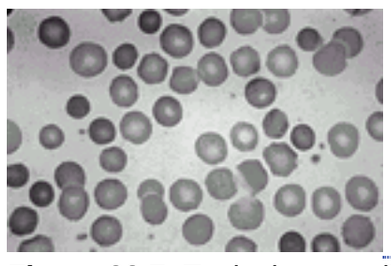

Figure 32.7. Typical smear (Wright stain) from patient with autosomal-dominant hereditary spherocytosis.

The bone marrow is characterized by erythroid hyperplasia. Normoblasts may constitute 25 to 60% of all nucleated cells. When complicated by folate deficiency, megaloblastic features of both myeloid and erythroid precursors are prominent ([134], [135], [155]). Examination of the bone marrow is not needed to diagnose HS.

OSMOTIC FRAGILITY TEST Red cells behave as osmometers when suspended in varying concentrations of salt solutions, and osmotic fragility of red cells is a measure of their spheroidicity. With a decreased membrane surface area relative to volume, spherocytes are unable to withstand the introduction of small amounts of free water that occurs when they are placed in progressively more hypotonic solutions. As a consequence, spherocytes "hemolyze" more than discoid RBCs at any salt concentration (Fig. 32.8). Hemolysis is determined by measuring the fraction of total hemoglobin released from red cells into the extracellular fluid at progressively more dilute salt concentrations. The fresh osmotic fragility test detects circulating spherocytes, those red cells that have been conditioned by the spleen. This appears as a "tail" produced by a small population of abnormal cells that undergo hemolysis at salt concentrations that do not affect normal red cells ([109]). The most sensitive test to detect HS is the incubated osmotic fragility test performed after incubating RBCs 18 to 24 hours under sterile conditions at 37°C. This procedure takes advantage of the observation that all erythrocytes lose membrane under these incubation conditions; however, the process is markedly accelerated in HS red cells. Hemolysis of HS cells may be complete at solute concentrations that cause little or no lysis of normal cells. HS individuals may have a normal fresh osmotic fragility if reduced surface area is balanced by a reduction in volume (due to cell dehydration) ([152]), but the osmotic fragility after prolonged incubation at 37°C is usually abnormal ([10], [15], [109], [156]). Although osmotic fragility correlates well with the magnitude of spherocytosis, no correlation is observed between osmotic fragility and hemoglobin concentration ([111]). Osmotic gradient ektacytometry is more sensitive and specific than the osmotic fragility test for the diagnosis of HS but is not widely available ([152]). Other laboratory tests used to diagnose HS include the autohemolysis test ([157]) and the glycerol lysis test ([158]), but these rarely are used nowadays, and they offer no advantage over the osmotic fragility test. A new flow cytometric test uses a fluorescent dye, is rapid and simple, and has high sensitivity and specificity ([159]) but has not yet been widely used.

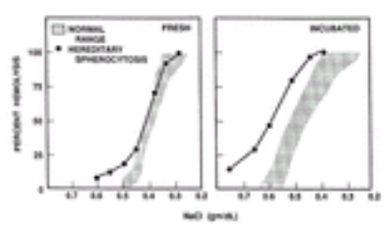

Figure 32.8. Osmotic fragility (as manifested by percent hemolysis) of normal and hereditary spherocytosis (HS) erythrocytes after incubation in salt solutions of varying tonicity. In fresh HS erythrocytes, note the "tail" of cells with increased sensitivity as a result of splenic conditioning (*left*). In the incubated red blood cells (RBCs), note that the entire HS population of RBCs is more osmotically sensitive (*right*). (Reprinted from Glader BE, Naumovski L. Hereditary red blood cell disorders. In: Rimoin DL, Connor JM, Pyeritz RE, et al., eds. Principles and practice of medical genetics. New York: Churchill Livingstone, 1996, with permission.)

In the past, doubt existed whether HS could be diagnosed in the newborn period because many HS infants have few circulating spherocytes. Moreover, fresh red cells from normal neonates are relatively resistant to osmotic lysis, whereas incubated infant erythrocytes are osmotically more fragile ([160]). However, it now has been shown that osmotic gradient ektacytometry reliably detects HS in newborns ([121]). The osmotic fragility test also detects HS in many but not all infants if appropriate normal neonatal RBC controls are used ([152], [160]).

MEMBRANE PROTEIN STUDIES Once the diagnosis of HS is made, it is possible to further characterize the specific membrane lesion. Studies using polyacrylamide gel electrophoresis separation of membrane proteins and specific radioimmunoassays allow quantification of membrane proteins, looking for abnormalities in spectrin, ankyrin, pallidin, or band 3. These studies, however, are not routine and are available only in select research laboratories. These membrane protein data are extremely important for enhancing our understanding of the biology of HS. However, there are no data yet to suggest that these analyses will identify clinically significant HS disorders not presently detected with the incubated osmotic fragility ([2]).

Diagnosis

The diagnosis of HS generally is straightforward. Often, there is a family history of HS or a history of a family member having had a splenectomy or cholecystectomy before the fourth decade of life. The signs and symptoms of HS are those associated with all chronic hemolytic states (mild pallor, intermittent jaundice, splenomegaly). Typical laboratory features include minimal or no anemia, reticulocytosis, increased MCHC and red cell distribution width, normal MCV despite reticulocytosis, spherocytes on the peripheral blood smear, hyperbilirubinemia, and an abnormal incubated osmotic fragility test. Other disorders, such as immune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, certain syndromes of red cell fragmentation, and thermal and chemical injury of red cells, also are associated with spherocytosis. In most of these conditions, however, spherocytes are but one of several types of abnormal RBCs present, whereas in HS, there are few abnormal forms other than spherocytes. In addition, HS spherocytes tend to be more uniform than those noted in other hemolytic anemias. The differentiation between HS and immune hemolytic disease is distinguished by a positive antiglobulin reaction.

Treatment

For practical purposes, the treatment of HS revolves around presplenectomy supportive care, the role of splenectomy, and postsplenectomy complications.

Neonates with severe hyperbilirubinemia caused by HS are at risk for kernicterus, and such infants should be treated with phototherapy or exchange transfusion, or both, as clinically indicated. During the first few months of life, erythropoietin therapy may diminish the need for red cell transfusions until erythropoiesis reaches its full postnatal expression ([161]). Aplastic crises occasionally can cause the hemoglobin to fall precipitously because the ongoing accelerated destruction of spherocytes is not balanced by new RBC production. Under these conditions, red cell transfusions often are necessary and may be life-saving. Folic acid is required to sustain erythropoiesis, and normal dietary folate may be inadequate for children with chronic hemolytic anemia. For this reason, HS patients are instructed to take supplementary folic acid (1 mg/day) to prevent the rare megaloblastic crises, although in mild cases, this is probably unnecessary ([162]).

HS is unique among the congenital hemolytic anemias in that splenectomy is permanently curative except in the unusual autosomal-recessive variant ([126]). Within days of removal of the spleen, jaundice fades, and the hemoglobin concentration rises ([163]). Nevertheless, red cell survival, although much improved, is not absolutely normal ([99], [100]). High normal values for reticulocytes and serum bilirubin reflect an ongoing but modest increase in red cell turnover ([163]). The numbers of peripheral blood microspherocytes are unchanged or may increase ([15]). The MCV usually falls, but the MCHC does not change significantly. Both leukocytosis and thrombocytosis are expected corollaries of splenectomy ([139]). Several reports indicate an increased rate of thrombotic events years after splenectomy for HS ([164], [165]). The degree of risk, although not clearly defined, should influence decisions as to whether to perform or avoid splenectomy. Anticoagulation with aspirin or other agents has not been evaluated in this setting.

In the past, splenectomy was recommended for all patients with HS, irrespective of the severity of anemia. The rationale for this opinion was that splenectomy eliminated the need for transfusion therapy, ensured freedom from aplastic crises, and minimized the risk of symptomatic cholelithiasis and its complications ([166]). This position has been tempered in recent years because it is now known that the spleen has a critical immunologic role in protecting against certain types of infections, and fatal sepsis caused by *Streptococcus pneumoniae* is a recognized complication in splenectomized children ([116], [167], [168]). The risk of postsplenectomy sepsis is greatest in children younger than 5 years of age, but even older children and adults also are at a somewhat increased risk compared with nonsplenectomized individuals. Death from sepsis may occur decades after splenectomy ([169], [170]). In one comprehensive review, postsplenectomy infection was assessed in 850 HS patients, 786 of whom were children ([171]). Most patients had undergone surgery during the first 5 years of life. Thirty cases of septicemia and 19 septic deaths were identified. The estimated rate of mortality from sepsis was approximately 200 times greater than that expected in the general population. Although

most septic episodes were observed in children whose spleens were removed in the first years of life, older children and adults were also susceptible.

The rationale that splenectomy prevents development of gallstones and symptomatic biliary tract disease, as well as obviates the need for major gallbladder surgery, probably is not as valid today as it was in the past. The availability of laparoscopic cholecystectomy to remove gallstones has had a significant impact on the management of nonanemic patients with mild HS who have gallstones. In these patients, if they have no signs or symptoms related to their hemolytic anemia or splenomegaly, it is reasonable to follow them without splenectomy. If surveillance ultrasound examinations reveal gallstones, it seems reasonable to perform a prophylactic laparoscopic cholecystectomy, particularly if symptoms of biliary colic occur. This procedure prevents significant biliary tract disease and, in some mild HS patients, avoids the need for splenectomy. Prophylactic cholecystectomy in patients without gallstones is unnecessary ([172]).

Children who are candidates for splenectomy include those with severe HS requiring red cell transfusions and those with moderate HS who manifest growth failure or other signs and symptoms of anemia. Whenever possible, splenectomy for children with HS should be done after 5 years of age. In a majority of cases, it is possible to perform the surgery using laparoscopic techniques ([173]). The one disadvantage of this procedure is that it takes longer and thereby requires approximately twice the anesthesia time. However, distinct advantages of laparoscopic splenectomy are the shorter hospitalization and the smaller surgical scar. Another interesting approach has been the use of partial splenectomy to retain splenic immunologic function while, at the same time, reducing the rate of hemolysis ([174] , [175]). In 37 of 40 children who underwent subtotal splenectomy, the procedure was successful. Three children required a secondary total splenectomy for recurrent jaundice and anemia 5 months to 6 years after their initial surgery ([175]). This approach might be particularly useful in children younger than 5 years of age who need frequent transfusions ([174]).

Any child who is to undergo splenectomy should receive pneumococcal vaccine before the spleen is removed. However, because not all pneumococcal subtypes are included in the current vaccine, one must be aware that overwhelming sepsis can occur in vaccinated children. The most important aspect of this awareness is to have parents alert their physician at the first sign of fever in a splenectomized child. The role of prophylactic antibiotics for immunized asplenic children is a matter of current controversy, and few good data exist to provide unequivocal recommendations. Our present policy is extremely conservative, in that all splenectomized children previously vaccinated with pneumococcal vaccine also are prescribed penicillin prophylactically (125 to 250 mg twice a day). How long to continue penicillin prophylaxis also is a matter of considerable controversy. In the absence of data from clinical studies, our current approach is to continue prophylaxis to at least 10 years of life. In addition, at the onset of fever (>38.5°C) patients/parents are advised to see their physician. Management usually includes obtaining a blood culture and administering a parenteral cephalosporin antibiotic. The problem of postsplenectomy sepsis today is compounded by the emergence of penicillin-resistant *S. pneumoniae* ([176] , [177]). To date, no vancomycin-resistant pneumococci have emerged, and this can be given as a second antibiotic for a very sick patient.

HEREDITARY ELLIPTOCYTOSIS SYNDROMES

The *HE syndromes* are a family of genetically determined RBC disorders characterized by elliptical red cells on the peripheral blood smear (Fig. 32.9). Some HE syndromes are associated with symptomatic hemolytic disease, although most are clinically silent and often discovered accidentally when a blood smear is reviewed. The varied clinical and hematologic manifestations of HE are an expression of the numerous molecular defects that give rise to the elliptocyte. Several disorders now are classified under HE. *Common HE* is a dominantly inherited condition characterized by many elliptocytes in the peripheral blood smear. However, the clinical severity of common HE is extremely variable, ranging from an incidental asymptomatic condition to a moderate hemolytic anemia. The clinical expression of coinheritance of two common HE genes, homozygous HE, ranges from moderate anemia to fatal hydrops fetalis. *Hereditary pyropoikilocytosis* (HPP) is a severe recessively inherited hemolytic anemia, with red cell fragments, microspherocytes, and poikilocytes seen on the peripheral smear. From a clinical perspective, it is difficult to distinguish HPP from homozygous or doubly heterozygous common HE. Once regarded as a separate condition, HPP is biochemically related to common HE, occurs in families in which other members have common HE, and now is considered to be a variant of this disorder. Spherocytic HE is a rare condition in which both ovalocytes and spherocytes are present on the blood smear. *Southeast Asian ovalocytosis* (SAO), also known as *stomatocytic elliptocytosis*, is an HE variant prevalent in the malaria-infested belt of Southeast Asia and the South Pacific, and it is characterized by rigid spoon-shaped cells that have either a longitudinal slit or a transverse ridge. The following sections discuss the membrane biology, pathophysiology, clinical characteristics, and laboratory features of these HE disorders.

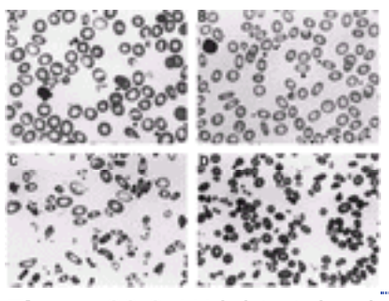

Figure 32.9. Wright-stained peripheral blood smears (original magnification ×500) of different hereditary elliptocytosis syndromes. **A:** Micropoikilocytes and elliptocytes in a neonate with transient poikilocytosis and a Sp a $^{I/65}$ mutation. **B:** Same child at 7 months of age now exhibiting common hereditary elliptocytosis. **C:** Compound heterozygous hereditary elliptocytosis due to two a-spectrin mutations (Sp a $^{I/65}$ and Sp a $^{I/50a}$). Note distorted red cell shapes, elliptocytes, fragments, and budding forms. **D:** Hereditary pyropoikilocytosis. Red cell abnormalities are similar to those in **(C)** but with the addition of numerous spherocytes. (Reprinted from Iarocci TA, Wagner GM, Mohandas N, et al. Hereditary poikilocytic anemia associated with the co-inheritance of two alpha spectrin abnormalities. Blood 1988;71:1390–1396, with permission.)

Prevalence of All Hereditary Elliptocytosis Variants

When considered together, the HE variants occur with an estimated frequency of 1 in 1000 to 1 in 5000 ([178] , [179]). The distribution of HE is worldwide, and no racial or ethnic group appears to be spared. In the U.S. population, the prevalence of HE is approximately 3 to 5 per 10,000 ([178]), and it appears to be much more common among blacks. In areas where malaria is endemic, HE occurs considerably more frequently, with common HE having a prevalence of 0.6% ([180]) in equatorial Africa. Resistance of hereditary elliptocytes to invasion by malaria parasites may explain the high frequency of HE (30%) in Malayan aborigines ([181]). Like HS, HE is transmitted as an autosomal-dominant trait ([182] , [183]) and, in most cases, is associated with no or minimal clinical abnormalities. Both homozygous HE and compound heterozygosity for different HE mutations occur, and these cases account for the cases of clinically severe hemolytic anemia.

Pathogenesis of Common Hereditary Elliptocytosis Disorders

The HE disorders are caused by intrinsic membrane protein abnormalities, which lead to an alteration in RBC membrane function, changes in RBC shape, and, in some cases, hemolysis.

MEMBRANE PROTEIN DEFECTS That the primary defect in HE resides in the membrane cytoskeleton is suggested by the retention of an elliptical shape by ghosts and membrane skeletons prepared from hereditary elliptocytes, uniform instability of HE membrane skeletons and ghosts to mechanical stress, and abnormal heat sensitivity of spectrin prepared from the red cells of some patients with HE ([184]). In addition, a similar biochemical lesion is seen in red cells of patients with HPP, an autosomal-recessive congenital hemolytic disorder characterized by severe anemia and extreme micropoikilocytosis ([185] , [186]). The similarity of red cell morphology in HPP to that associated with heat injury of RBCs prompted an assessment of the thermal stability of patient cells. Whereas normal red cells fragment at temperatures exceeding 49°C, cells in this disorder exhibited striking membrane instability at 45° to 46°C ([187]). Subsequent studies demonstrated that the susceptibility of HPP red cells to heat injury is the result of thermal instability of HPP spectrin ([187]). Spectrin extracted from most HE red cells is quantitatively normal but is structurally abnormal. Whereas more than 90% of spectrin extracted from normal red cells is in the form of tetramers ([188] , [189]), a major portion of the spectrin extracted from hereditary elliptocytic RBCs, including erythrocytes from patients with HPP, is present as dimers ([190] , [191]). Moreover, spectrin dimers prepared from HE red cells do not form tetramers in solution, in ghosts, or on inside-out vesicles ([191] , [192]). The spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that normally favors spectrin tetramer formation. The impaired self-association of spectrin aß-dimers into tetramers is thought to be responsible for RBC membrane instability in the HE syndromes ([193] , [194]). A large number of reports now have documented that HE is associated with dysfunction or deficiencies of spectrin, protein 4.1, and glycophorin ([2] , [3] , [195] , [196]).

Spectrin Abnormalities In more than 60% of all patients with HE, mutations of spectrin are found ([197], [198]). A recent compilation listed 25 a-spectrin mutations and 15 ß-spectrin mutations associated with a clinical phenotype of HE/HPP ([199]). The majority of these mutations were missense with smaller numbers of splicing, deletion, or insertion abnormalities also reported. Individuals inheriting a single copy of an a-spectrin mutation generally have asymptomatic elliptocytosis, whereas those with two copies often have severe hemolytic disease. The clinical phenotype produced by a-spectrin mutants is determined by two factors: the relative amount of spectrin present as dimer ([200]) and the total spectrin content of the membrane ([197]). In HE cells, the percentage of spectrin present as dimer is high, and spectrin content is normal; in HPP red cells, the percentage of spectrin dimers also is high, but the spectrin content is decreased ([197], [201]). Tryptic digestion of spectrin followed by electrophoretic separation allows identification of specific tryptic peptide patterns and may be a useful step in identifying the location of a spectrin mutation ([196], [202], [203]). The 80-kd aI domain peptide is the largest tryptic peptide, contains the *N*-terminal end of the spectrin molecule, and, importantly, contains the self-association site of normal spectrin heterodimers ([204], [205]). Almost all a-spectrin mutations seen in HE syndromes are found within the 80-kd aI domain. Molecular modeling reveals that the clinical severity of these mutations is a function of the extent to which they disrupt the self-association of a- and ß-spectrin subunits ([206]). Mutations contained within the 80-kd aI domain yield tryptic peptides of abnormal size, different from the normal 80-kd aI domain peptide. Mutations are designated by a superscript identifying the abnormal domain and the most prevalent tryptic peptide that is generated. Sp a $^{I/74}$, an abnormal spectrin in which tryptic digestion of domain I of the a-spectrin chains generates a peptide of 74 kd instead of the normal 80-kd peptide, is the most common of these molecular variants ([207], [208], [209], [210] and [211]). It is the result of one of four amino acid substitutions at codon 28 of the a-spectrin chain ([211], [212]). Sp a $^{I/74}$ is the most severe of the a-spectrin mutations. Sp a $^{I/65}$ is a variant that results in a similar but milder clinical phenotype than that associated with the Sp a $^{I/74}$ variant ([213], [214], [215], [216] and [217]), and this mutation is very common. Sp a $^{I/46}$ (also identified as Sp a $^{I/50}$) occurs primarily in black individuals, but occasionally, it is reported as a cause of HE in whites ([218]). Mutations distant from the aI domain also have been detected ([219], [220]). It is postulated that they exert a long-range effect on spectrin self-association by disrupting the transfer of information between spectrin repeats, by the loss of cross-reactions with ß-spectrin near the ankyrin binding site, or, in the case of exon deletions, by register shifts between a and ß subunits ([221]). One particularly interesting variant is Sp a $^{V/41}$, also referred to as Sp a ^{Lely} (Lely: low-expression allele from Lyon) ([222], [223]). Sp a $^{V/41}$ has a reduced propensity to form dimers with a-spectrin ([222], [223]). When Sp a $^{V/41}$ is present as a sole mutation, it is clinically silent because normal a-spectrin is synthesized in large excess of ß-spectrin ([224]). However, when Sp a $^{V/41}$ is present in *trans* to an a-spectrin mutant that causes HE, incorporation of the latter into aß-heterodimers is favored, thereby leading to an increased proportion of the elliptocytogenic spectrin in the red cells and increased clinical severity. Conversely, when coinherited in *cis* to an HE a-spectrin mutation, it reduces the amount of the mutation incorporated into dimers and ameliorates clinical severity. In this way, Sp a $^{V/41}$ plays an important role in modifying the clinical expression of HE. This particular polymorphism is common, affecting approximately 30% of the a-spectrin alleles of Europeans and 20% of Japanese and West Africans (224a). Mutations in ß-spectrin may also lead to common HE. Inheritance of two ß-spectrin mutations can be associated with an unusually severe clinical phenotype. Homozygosity for ß-spectrin Providence was associated with recurrent hydrops fetalis ([225]), and homozygosity for ß-spectrin Buffalo was associated with fatal and near-fatal neonatal hemolytic anemia ([226]).

Protein 4.1 Defects Protein 4.1 abnormalities associated with HE are much less common than spectrin mutations. One site on protein 4.1 binds to the distal end of the spectrin aß-heterodimer, thereby increasing the binding of spectrin to actin. Protein 4.1 interacts with glycophorin C at a second site, thereby enhancing attachment of spectrin to the membrane ([188], [227], [228], [229], [230], [231], [232] and [233]). Deficiency of protein 4.1 has been described in several kindreds from southern France and northern Africa ([234], [235], [236], [237] and [238]). A partial deficiency of protein 4.1 is associated with mild dominantly inherited HE. Heterozygotes have approximately 50% of the normal amount of protein 4.1 and have mild hemolytic anemia. Homozygotes have no detectable protein 4.1 and a severe transfusion-dependent hemolytic anemia with prominent elliptocytosis and spherocytosis ([236], [238]). Structural abnormalities of protein 4.1 have also been found that interfere with the normal function of the molecule and lead to elliptocytosis ([239], [240]).

Glycophorin C Deficiency Mutations associated with glycophorin C deficiency occasionally are associated with HE. These cases usually also include partial deficiency of protein 4.1. Glycophorin C is decreased in patients with protein 4.1 deficiency, presumably because the two proteins stabilize each other on the membrane ([241], [242]). In contrast to other forms of HE, heterozygous carriers of glycophorin C deficiency are asymptomatic with normal RBC morphology. Homozygous-deficient individuals have mild elliptocytosis but no anemia ([243]).

MEMBRANE ABNORMALITIES LEADING TO ELLIPTOCYTE FORMATION Most abnormalities in HE are caused by spectrin mutations that affect the spectrin heterodimer contact site, thereby leading to decreased spectrin tetramer formation and, consequently, disrupting the horizontal integrity of the membrane skeleton. As a result, membrane skeletons and whole cells are mechanically unstable ([193], [194]). The red cell lesion in protein 4.1 deficiency is thought to affect the spectrin–actin interaction, which also is a horizontal interaction ([194]). Abnormalities in cellular deformability and membrane fragility are proportional to reduced levels of protein 4.1 ([238]), reflecting the role of this protein in enhancing the interaction of spectrin and actin ([188]). The mechanical stability of protein 4.1–deficient membranes can be restored *in vitro* by adding back purified protein 4.1 to the membrane skeleton ([244]). The basis for elliptocytosis and mechanical instability of glyco-phorin C–deficient red cells is not known. It appears to be related to a concomitant partial deficiency of protein 4.1, as evidenced by a full correction of membrane instability by introduction of protein 4.1 into the cells. The mechanism by which these protein defects result in elliptocyte formation is not clear. It is of particular interest that HE red cells acquire their shape after release from the bone marrow and as they age *in vivo* ([179], [245], [246]). It also is significant that normal red cells assume an elliptical shape in capillaries ([247]) and *in vitro* when exposed to shear stress ([248]), and, with passage through the microcirculation or with removal of shear stress, they resume a normal biconcave shape. However, if mechanical distortion is maintained for long periods, even normal red cells remain misshapen ([249]), thus suggesting that the membrane skeleton is altered as a consequence of sustained shape changes. In the case of HE, it is possible that weakened spectrin heterodimer contacts may lead to skeletal reorganization after less extensive deformation or shear stress. With repeated distortions imposed by passage through small capillaries, cells with unstable membrane skeletons thus may gradually elongate to form irreversible elliptocytes. Red cells with even more severe skeletal defects presumably are unable to withstand the shear stresses experienced in the normal circulation and thus may undergo fragmentation. This process may explain the poikilocytosis seen in homozygous HE and HPP and in mild HE associated with neonatal poikilocytosis. In all of the hemolytic HE syndromes, the more severely distorted cells are retained in splenic cords ([104], [250], [251]). As a result, splenectomy markedly ameliorates the anemia associated with these clinically symptomatic variants.

ANIMAL MODELS OF HEREDITARY ELLIPTOCYTOSIS A spontaneously occurring mouse model of severe HE is associated with neonatal thrombosis, premature death, and accumulation of renal hemosiderin. Aberrant splicing leads to the absence of exon 11 of a-spectrin and a truncated protein that is not capable of supporting normal dimer/tetramer stability. These mice are also severely deficient in membrane spectrin and ankyrin ([252]). Absence of erythrocyte ß-adducin, a protein that enhances spectrin-actin binding, was induced by gene targeting in mice and led to a mild sphero-elliptocytic hemolytic anemia reminiscent of human spherocytic elliptocytosis ([253]).

Clinical and Laboratory Features of Hereditary Elliptocytosis Syndromes

Although all HE variants are marked by the presence of at least 15% elliptical red cells, they are clinically and hematologically quite heterogeneous (Table 32.3). This heterogeneity, in part, reflects the diverse causes of HE, and there is much overlap when these disorders are classified on a clinical, biochemical, or molecular basis.

TABLE 32.3. Clinical Classification of Hereditary Elliptocytosis (HE) Syndrome

	Common HE	Homozygous HE	Hereditary Pyropoikilocytosis	Spherocytic Elliptocytes	Southeast Asian Ovalocytosis
Anemia	None	Moderate–severe	Severe	Mild–moderate	None
Hemolysis	None–mild	Moderate–severe	Severe	Mild–moderate	None
Splenomegaly	None	Present	Present	Present	None
Peripheral blood smear	15–90% elliptocytes	Poikilocytes; elliptocytes; fragments	Poikilocytosis; RBC budding with fragments; microspherocytes	Elliptocytes; spherocytes	Rounded elliptocytes, some having a transverse bar that divides the cell
Osmotic fragility	Normal	Increased	Increased	Increased	Normal–decreased
Inheritance	Dominant	Recessive	Recessive	Dominant	Dominant
Other	Poikilocytosis with severe hemolysis, seen transiently in some infants	Low MCV	Low MCV		Rigid RBC resistant to penetration by malaria parasites

MCV, mean corpuscular volume; RBC, red blood cell.

Common Hereditary Elliptocytosis In most cases, individuals with common HE are discovered accidentally when elliptocytes are identified during routine evaluation

of the peripheral blood film. These individuals usually are not anemic, their red cell survival is normal, and there is no splenomegaly ([179], [198], [245], [254]). In contrast to the clinical picture, the peripheral blood smear is striking, containing 15 to 100% elliptocytes ([179], [245]) (Fig. 32.8). Other common HE cases involve mild compensated hemolysis without anemia. However, in 5 to 20% of cases, the hemolytic process is incompletely compensated, and patients have a moderate to severe hemolytic anemia (hemoglobin concentration, 9 to 12 g per dl; reticulocyte count, =20 to 25%) ([182], [255], [256]). Of particular interest, the peripheral blood smear in these hemolytic cases reveals many poikilocytes, as well as numerous elliptocytes. The spleen may be enlarged ([256]), and gallstones ([254]) occur with increased frequency. As in other hemolytic states, abrupt episodes of more severe anemia may occur ([183]). In some families, hemolytic HE has been transmitted through several generations. In other families, however, not all individuals with HE manifest chronic hemolysis, and this presumably reflects other genetic factors that modify disease expression. The reason for the variable clinical expression of common HE, even within families, has been a puzzle. A partial answer to this variability has been provided by the recognition of the Sp $a^{V/41}$ allele, which modifies the clinical phenotype by allowing greater expression of the variant a-spectrin ([222]). For example, in one family, heterozygosity for both Sp $a^{I/65}$ and the Sp $a^{V/41}$ mutation resulted in markedly increased elliptocytosis compared with siblings with only the Sp $a^{I/65}$ mutation (Sp $a/Sp\ a^{I/65}$) ([222]). Also, individuals heterozygous for Sp $a^{I/74}$ and Sp $a^{V/41}$ have marked elliptocytosis, poikilocytosis, and hemolysis compared with their siblings who have only the Sp $a^{I/74}$ mutation (Sp $a/Sp\ a^{I/74}$) ([222]). Coinheritance of other erythrocyte disorders, such as thalassemia, may also accentuate the clinical abnormalities that accompany common HE ([257]). HE with infantile poikilocytosis is a clinical manifestation of HE that occurs almost exclusively in black families. Affected young infants have moderately severe hemolytic anemia and hyperbilirubinemia in the newborn period, the latter often necessitating exchange transfusion ([258], [259]). The blood smear is characterized by marked red cell fragmentation and poikilocytosis in addition to elliptocytosis (Fig. 32.9B) ([258], [259] and [260]). These morphologic changes are indistinguishable from those noted in patients with HPP. In contrast to HPP, however, hemolysis gradually lessens, and the clinical and hematologic features convert to those of mild HE by 6 to 12 months of age (Fig. 32.9C). The basis for this curious phenomenon in the neonatal period is not known. In part, it is thought to be the result of an increased concentration of free 2,3-DPG, the latter having a destabilizing influence on protein 4.1–actin interactions and thus causing membrane skeleton instability ([261], [262]). The increase in free 2,3-DPG reflects the well-known lack of interaction of this intermediate with fetal hemoglobin.

HOMOZYGOUS (DOUBLY HETEROZYGOUS) HEREDITARY ELLIPTOCYTOSIS Homozygous and doubly heterozygous HE are characterized by chronic hemolytic anemia of variable severity. Morphologic characteristics include marked poikilocytosis, microelliptocytosis, and red cell fragmentation ([179], [215], [263], [264]). In many cases, both parents have nonhemolytic HE, or, because many individuals with a single a-spectrin mutation are clinically silent, parental anemia or RBC abnormalities may not be present. These disorders and HPP often have a very similar clinical presentation. The homozygous state for the Sp $a^{I/65}$ variant ([214]) and the Sp $a^{I/74}$ variant ([207]) have been described. Those individuals homozygous for Sp $a^{I/65}$ have moderate hemolysis, whereas those patients homozygous for the Sp $a^{I/74}$ mutation have much more severe hemolytic anemia, often requiring splenectomy ([207]). The latter homozygous group of HE subjects may have numerous small microspherocytes in their peripheral blood, and their clinical presentation is indistinguishable from HPP ([265]). Several cases presumed to result from homozygosity now are known to be a consequence of double heterozygosity for different spectrin mutations. The doubly heterozygous states for the Sp $a^{I/65}$ and Sp $a^{I/46}$ variants and the Sp $a^{I/74}$ and Sp $a^{I/61}$ variants ([266]) have been described. These double heterozygote variants are associated with the homozygous HE or HPP clinical phenotypes.

HEREDITARY PYROPOIKILOCYTOSIS This severe congenital hemolytic anemia, which clinically is very similar to homozygous HE, is characterized by extreme micropoikilocytosis and an autosomal mode of inheritance. HPP is the result of a double heterozygous state for an a-spectrin mutant and a defect involving spectrin synthesis. In many pedigrees, one parent or a sibling has an a-spectrin variant with or without nonhemolytic HE, whereas the other parent is normal ([267], [268]). The abnormality is silent when present in isolation because a-spectrin normally is produced in excess ([224]). Although HPP once was regarded as a distinct entity, it now is considered a subtype of common HE. Both HE and HPP often exist in the same family, and the same molecular spectrin defects are seen in HPP and severe HE (discussed in Spectrin Abnormalities). The one fundamental difference between these two entities is that red cells of the HPP subjects also are partially deficient in spectrin as detected by a decreased spectrin to band 3 ratio ([197], [201]). In part, this may reflect that some elliptocytogenic a-spectrin mutants are unstable, and this might lead to spectrin deficiency ([201], [269]). Whatever the mechanism, decreased red cell spectrin is a constant feature of HPP and probably explains the abundance of microspherocytes noted in association with this disorder. In infancy or early childhood, affected individuals manifest moderately severe hemolytic anemia (hemoglobin concentration, 5 to 9 g per dl; reticulocyte count, 13 to 35%). Splenectomy is followed by an increase in hemoglobin concentration (to 9 to 11 g per dl) and a decrease in reticulocytes (to 3 to 7%) ([267], [268]). Most ([186], [270], [271]), but not all, cases involve blacks. Growth retardation related to anemia, frontal bossing, and premature gallbladder disease are reported complications. Most impressive are changes in red cell morphology, which include extreme poikilocytosis, microspherocytosis, microelliptocytosis, membrane budding, and cell fragments. The MCV may be extremely low, 30 to 50 fl ([271]); MCHC is normal; and osmotic fragility is increased ([186], [271]).

SPHEROCYTIC ELLIPTOCYTOSIS This syndrome is characterized morphologically by two populations of cells: red cells that are more rounded than typical hereditary elliptocytes and a variable number of microspherocytes. In contrast to other HE syndromes with hemolysis, no poikilocytes or fragments are seen. The disorder has been seen primarily in families of European descent ([182], [255], [272], [273], [274], [275] and [276]) and may account for as many as 15 to 25% of cases of HE in whites. Affected individuals have an incompletely compensated hemolytic process with mild anemia and predisposition to aplastic crises. The relative numbers of spherocytes and elliptocytes vary considerably, even within families ([182], [274]). As in HS, the osmotic fragility ([182], [275]) and mechanical fragility ([182], [272], [275]) may be increased. Splenectomy is curative ([182], [251], [255], [256], [273]).

SOUTHEAST ASIAN OVALOCYTOSIS This interesting variant, also known as *stomatocytic elliptocytosis*, is characterized morphologically by round elliptocytes (ovalocytes), many of which have one or two transverse ridges. These red cells are found in people from Malaysia, New Guinea, Indonesia, and the Philippines ([277], [278], [279] and [280]). Their presence is not associated with any significant anemia or hemolysis. The RBCs in SAO manifest increased red cell rigidity ([181], [281]), increased thermal stability ([282], [283]), and decreased osmotic fragility ([284]). Also, these red cells are resistant *in vitro* to invasion by several strains of malaria ([282], [283], [285], [286]). In populations in which SAO is prevalent, its frequency is increased in older individuals, suggesting a favorable effect on longevity ([287]). The molecular defect in SAO results from an abnormal band 3 protein. This is a consequence of two mutations on the same gene: a deletion of 9 codons encoding for amino acids 400 to 408 ([288], [289]) and a missense mutation resulting in a substitution of lysine for glutamate at amino acid 56 ([290]). All carriers of the SAO phenotype are heterozygotes, with one normal band 3 allele and one mutant band 3. Tight binding of band 3 protein to ankyrin ([291]) is present in SAO red cells ([292]), restricting lateral mobility of this protein. Because band 3 protein is a receptor for malarial parasites ([293]), its reduced mobility may limit invagination and penetration by the parasite ([181], [281]). Studies in children in Papua New Guinea indicate that SAO does not actually reduce the incidence of infection with *Plasmodium falciparum*, but it does provide remarkable protection against cerebral malaria. This effect is likely due to reduced cytoadherence of SAO red cells to the cerebral vasculature, but the exact mechanism is not yet known ([294]). Resistance of SAO red cells to malaria most likely is related to the altered band 3 protein because this protein is a receptor for the parasite ([293]). The reduced lateral mobility of band 3 protein in SAO red cells may limit invagination and penetration by the parasite ([181], [281]).

Laboratory Evaluation

Initial laboratory studies in a patient with a suspected HE syndrome should assess whether the patient is anemic (hemoglobin concentration/hematocrit), whether the anemia is well compensated (reticulocyte count), and whether the anemia is caused by accelerated RBC destruction (increased serum lactate dehydrogenase and bilirubin concentration). The mean cell volume (MCV) also is important because hemolytic variants with RBC fragmentation often manifest severe microcytosis as a result of RBC fragmentation. A careful evaluation of the blood smear is essential both for the diagnosis of HE and the classification of the disorder into major subtypes. At least 15% and often as many as 50 to 90% of red cells are oval, whereas smears from normal subjects contain fewer than 15% elliptocytes ([179], [245]). In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is usually minimal or absent with the exception of spherocytic elliptocytosis, in which the presence of “fat” ovalocytes is associated with accelerated red cell destruction. In other patients with hemolytic forms of HE, poikilocytosis almost always is seen on the blood film, and in homozygous HE and HPP, many red cells circulate as cell fragments, producing a marked decrease in mean cell volume. The finding of red cell fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP. Osmotic fragility is normal in nonhemolytic HE ([157], [295]) but is increased in spherocytic elliptocytosis and HPP and in those hemolytic HE variants with poikilocytosis on their peripheral blood film ([2], [255]). The osmotic fragility is decreased (i.e., resistant to hemolysis) in SAO red cells ([284]).

The finding of more than 30% oval red cells on the peripheral blood film, some containing a central slit or a transverse ridge, together with an absence of clinical and laboratory evidence of hemolysis in an individual from Southeast Asia or the South Pacific is highly suggestive of SAO. A screening test for SAO is the failure of ovalocytes to undergo membrane changes (form spicules) after metabolic depletion or when suspended in hypertonic salt solutions ([281], [282]). The mechanism of this resistance to change in shape presumably is because of the extreme rigidity of the red cell membrane. Also, as noted previously, the osmotic fragility is decreased.

Once the diagnosis of an HE syndrome is established, additional laboratory studies can further define the cellular and molecular defect ([3]). Sodium dodecyl sulfate-polyacrylamide gel electrophoresis of solubilized membrane proteins may reveal proteins of abnormal mobility. A partial deficiency of spectrin may be detected by a decreased spectrin to band 3 ratio, and this is helpful to diagnose HPP ([197], [201]). Nondenaturing gel electrophoresis can be used to analyze the ratio of tetrameric and dimeric spectrin and, thereby, detect the most common functional abnormality in HE (an increase in the fraction of dimeric spectrin) ([196], [202]). Tryptic

peptide digestion of spectrin followed by electrophoretic separation can detect tryptic peptides of abnormal size that reflect underlying a-spectrin mutations responsible for elliptocytosis syndromes.

Treatment

In view of the benign nature of autosomal-dominant HE, therapeutic intervention is not indicated in most individuals. Also, in those individuals with SAO, no therapy is needed. However, patients with variants that are associated with chronic hemolytic anemia (homozygous HE, HPP, spherocytic HE) may benefit from splenectomy. In HE cases associated with hemolysis, the cords of the spleen are congested with red cells ([104], [296]). Removal of the spleen is followed by improvement or normalization of the hemoglobin concentration and decrease in the reticulocyte count, despite persistence of elliptocytes ([254]).

STOMATOCYTIC DISORDERS

Stomatocytes are erythrocytes with a central slit or stoma instead of a circular area of pallor when examined on dried smears. In wet preparations, they are uniconcave rather than biconcave, giving them a bowllike appearance. *In vitro*, stomatocytes are produced by drugs that intercalate into the inner half of the lipid bilayer, thereby expanding the inner lipid surface area relative to that of the outer half of the bilayer ([297]). In contrast, echinocytes (RBCs with numerous fine spicules) are thought to be the result of preferential expansion of the outer lipid bilayer relative to the inner layer. A few stomatocytes may be observed in blood smears prepared from normal individuals, as well as from patients with acute alcoholism and hepatobiliary disease ([298]). In addition, acquired stomatocytosis occurs in individuals receiving vinca alkaloids [vinblastine (Velban), vincristine] ([299]). Large numbers of stomatocytes are associated with rare hereditary disorders of red cell cation permeability ([300]) leading to increased red cell water content (hereditary stomatocytosis) ([301], [302]) or cellular dehydration (hereditary xerocytosis or dehydrated stomatocytosis) ([303]). Stomatocytosis also is associated with an absence of Rh blood group antigens on the red cell membrane (Rh-null phenotype). Each of these stomatocytic disorders is associated with mild to moderate hemolysis.

To appreciate the pathophysiology of hereditary stomatocytosis and hereditary xerocytosis, an understanding of normal red cell cation and water transport is essential. The RBC membrane, which is freely permeable to water, controls its volume primarily through regulation of the monovalent cation content. Small passive cation leaks (sodium in, potassium out) are normally balanced by the active outward transport of sodium (3 mEq per l of red cells per hour) and inward transport of potassium (2 mEq per l per hour). These cation pumps are linked, require ATP, and are dependent on the membrane enzyme Na-K adenosine triphosphatase. If the membrane permeability leak to monovalent cations increases, cation pumps have limited compensatory ability, and, if this capacity is exceeded, red cell volume changes in parallel with the total cation change. Red cells swell when the inward sodium leak exceeds the potassium leak out; red cells shrink when the potassium leak out exceeds the inward sodium leak. These membrane permeability abnormalities are recognized by observing altered RBC hydration (decreased or increased MCHC) and altered red cell sodium, potassium, and total monovalent cation content.

Hereditary Stomatocytosis

Hereditary stomatocytosis (also known as *hereditary hydrocytosis*) refers to a heterogeneous group of autosomal-dominant hemolytic anemias caused by altered sodium permeability of the red cell membrane ([302], [304], [305] and [306]). The major pathophysiologic abnormality is the result of a marked increase in sodium permeability (15 to 40 times normal), and this leads to an increase in RBC sodium, a lesser decrease in intracellular potassium, an increase in total monovalent cation content, and, thereby, an increase in cell water ([301], [305], [307]). Despite a marked compensatory increase of active sodium and potassium transport, increased pump activity is unable to compensate for the markedly increased inward sodium leak ([301], [305], [308]). Treatment of these cells with dimethyl adipimidate (a bifunctional imidoester that cross-links proteins) normalizes membrane permeability, corrects cell cation and water content, improves membrane deformability, and corrects the abnormal RBC morphology ([309]). Moreover, these treated RBCs have an improved survival *in vivo* ([309]). In most patients, excess cation permeability is associated with an absence of red cell membrane protein band 7 on sodium dodecyl sulfate gels ([310], [311] and [312]). This protein is referred to as *band 7.2* or *stomatin* ([313], [314], [315], [316] and [317]), and its function is currently unknown. No abnormalities in the stomatin gene, which has been isolated and cloned ([318], [319]), have been identified in stomatin-deficient individuals with hereditary stomatocytosis ([300]). Homozygous knock-out mice that completely lack the murine analog of erythrocyte band 7.2 exhibit no features of the hereditary stomatocytosis syndrome seen in humans, suggesting that 7.2 deficiency is not the proximate cause of the disease in humans, although it may be a marker for another membrane defect that is responsible ([320]).

The severity of hemolytic disease is diverse, both between different families and among affected members of the same family ([307]). In most patients, symptoms related to intermittent anemia and jaundice are so mild that no therapy is required ([305], [306] and [307]). Rarely, the anemia is of sufficient severity to require transfusion therapy ([301], [307]). Exchange transfusion for severe neonatal hyperbilirubinemia was required in one case ([301]). Splenomegaly is an expected corollary of severe anemia ([301], [305]). Anemia characteristically is mild. Reticulocytosis is moderate (10 to 20%) in most patients, but wide variation is noted. The MCV is elevated, often strikingly, whereas the MCHC is normal or low (as a result of increased cell water content). Approximately 10 to 50% of circulating red cells are stomatocytes (Fig. 32.10A). Osmotic fragility is increased ([305], [306], [321]). Measurement of red cell sodium (increased content) and potassium (decreased content) identifies these abnormalities. In most patients, hemolytic anemia is improved after splenectomy ([301], [308], [322]), but there is a high risk of postsplenectomy thromboembolic disease so that splenectomy is usually considered contraindicated ([323]).

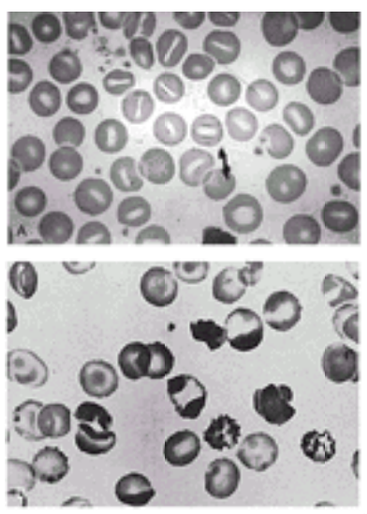

Figure 32.10. A: Peripheral blood smear (Wright stain) from a patient with hereditary hydrocytosis. Note the characteristic red blood cells (RBCs) have a mouthlike appearance—hence the term *stomatocytosis*. **B:** Peripheral blood smear (Wright stain) from a patient with hereditary xerocytosis showing dense, abnormal RBC forms where hemoglobin appears puddled at the periphery.

Hereditary Xerocytosis

Hereditary xerocytosis (also known as *dehydrated stomatocytosis*) is a rare autosomal-dominant hemolytic anemia characterized by red cell dehydration and decreased osmotic fragility ([303], [324], [325]). The mechanism of cellular dehydration involves net potassium loss from cells that is not accompanied by a proportional gain of sodium. Measurement of RBC cations reveals a slight increase in cell sodium content, a greater decrease in potassium concentration, and, thus, a decrease in the net intracellular cation content and cell dehydration ([303]). In some cases, reduced red cell 2,3-DPG has been noted ([321], [326]). Also, in several families, an increase in erythrocyte phosphatidylcholine content has been observed ([327], [328]). The specific relationship between elevated membrane lecithin and the increased leakiness of the membrane to potassium is not known. Although the total red cell membrane protein content may be elevated ([329]), specific abnormalities of stomatin or other membrane proteins are not seen ([300], [325]). The red cells in hereditary xerocytosis are sensitive to shear stress and readily undergo membrane fragmentation ([324], [325]). The locus for both hereditary xerocytosis and pseudohyperkalemia (see Intermediate Stomatocytic Syndromes) maps to the same region of chromosome 16, but the affected gene has not yet been identified ([330], [331]). A subset of patients with hereditary xerocytosis also exhibits transient perinatal edema, which is unrelated to the

degree of anemia and uninfluenced by red cell transfusion. The basis for ascites is unknown ([332]).

These patients characteristically have moderate to severe hemolysis. The MCHC is increased, reflecting cellular dehydration, whereas the MCV is slightly increased, reflecting the increase in reticulocyte count ([303]). Peripheral blood film reveals stomatocytes, target cells, spiculated cells, and some cells in which hemoglobin is concentrated ("puddled") in discrete areas on the cell periphery (Fig. 32.10B). The osmotic fragility is characteristically decreased. Splenectomy has minimal effect on the hemolytic anemia ([303]), increases the risk of thrombosis ([323]), and is, therefore, to be avoided.

Intermediate Stomatocytic Syndromes

Some cases of hereditary RBC cation permeability abnormalities share features of both hereditary stomatocytosis and xerocytosis (Table 32.4). Affected individuals have stomatocytes and target cells on the peripheral blood smear. The osmotic fragility of red cells is either normal or slightly increased. The sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the red cell volume usually are normal or slightly reduced. In the variant known as *cryohydrocytosis*, RBCs *in vitro* at 5°C gain sodium and manifest greater autohemolysis than at 37°C ([333], [334]). In another variant, potassium loss is accelerated in the cold, and blood samples left at room temperature for a few hours may manifest pseudohyperkalemia as a result of potassium efflux from red cells into the plasma ([335], [336]). In contrast to cryohydrocytosis, these RBCs in the cold manifest greater potassium loss than sodium gain and thereby lose water (cryoxerocytes) ([335], [336]). Despite the mildly dehydrated red cells, no anemia or hemolysis is associated with this defect. Careful analysis of potassium loss at low temperatures is an excellent way to distinguish between cryohydrocytosis, pseudohyperkalemia, and intermediate forms; at least five different phenotypes can be distinguished ([337], [338], [339], [340] and [341]).

TABLE 32.4. Features of Hereditary Stomatocytic Syndromes

	Stomatocytosis	Cryohydrocytosis	Pseudohyperkalemia	Xerocytosis
Anemia	Severe	Mild–moderate	None	Mild–moderate
Hemolysis	Severe	Moderate	Mild	Moderate
Peripheral blood smear	Stomatocytes	Stomatocytes	Target cells; stomatocytes	RBCs with puddled hemoglobin; target cells; stomatocytes
Mean corpuscular volume (80–100 fl)	110–150	90–105	83–91	84–122
Mean corpuscular hemoglobin concentration (32, 33, 34, 35 and 36)	24–30	34–40	34–36	34–38
Fresh osmotic fragility	Increased	Normal	Normal/decreased	Decreased
RBC Na^+ (5–12 mEq/l)	60–100	40–50	Sl increased	10–30
RBC K^+ (90–103 mEq/l)	20–55	55–65	Sl increased	60–90
RBC $Na^+ + K^+$ (95–110 mEq/l)	110–140	100–105	Low normal	75–99
Other features	Absence of protein band 7 (stomatin)	Cold Na leak in > cold K leak out = cold autohemolysis	Cold K leak out ? RBC dehydration	Increased phosphatidylcholine content

Rh-Null Disease

Most hematologists are familiar with the Rh antigen because of the immune sensitization that occurs in Rh-negative individuals exposed to Rh-positive red cells. However, the importance of the Rh antigen for normal functional integrity of red cell membranes was recognized through the discovery of red cells lacking all Rh antigens (Rh_{null}) ([342]). Rh-null hemolytic disease occurs in those rare individuals who have no Rh antigen expression, and this is different from the Rh-negative phenotype (cde) in which Rh proteins are present. The Rh-null phenotype is estimated to occur with a frequency of 1 in 6 million ([343]), and there is a high incidence of consanguinity among parents of affected individuals. Studies of the Rh locus have revealed two closely linked genes, one encoding the D polypeptide and the other encoding the Cc, Ee protein ([344], [345], [346] and [347]). These Rh proteins are linked to the red cell membrane skeleton ([348], [349]), but their function is unknown. The Rh-null phenotype is the result of mutations in the Rh antigen locus (called the *amorph type*) or in a regulator protein (Rh 50) located on a different chromosome that modulates Rh expression ([350], [351] and [352]).

Rh-null disease is characterized by mild to moderate normocytic, normochromic hemolytic anemia ([342], [343], [353]). The hemoglobin concentration is decreased (8 to 13 g per dl), and reticulocytes are increased (6 to 20%). Numerous stomatocytes and some spherocytes are seen on peripheral blood smears. The red cell total monovalent cation and water content is decreased, and these cells are dehydrated. However, the osmotic fragility of incubated cells is increased, thus reflecting a marked reduction of membrane surface area ([354], [355]). The half-survival time of ^{51}Cr-labeled red cells is 10 to 12 days, but the reason for shortened red cell survival is not known ([343], [353]). Hemolytic anemia is improved by splenectomy ([356]).

ACANTHOCYTIC DISORDERS

Acanthocytes are dense, contracted red cells with several irregularly spaced "thorny" projections on the surface. Acanthocytes differ from echinocytes in that there are fewer projections, and the width and length of these projections vary considerably ([357]). No central pallor is evident. By contrast, echinocytic spicules are similar in dimension and evenly distributed around the cell periphery. Acquired acanthocytosis is encountered in malnourished states such as anorexia nervosa ([358]), in hypothyroidism, after splenectomy ([359]), and in severe hepatocellular disease. Acanthocytosis also is seen in hereditary disorders such as abetalipoproteinemia and in patients with the Macleod phenotype.

Acanthocytosis in liver disease (hepatocellular injury) is attributable to a marked increase in the cholesterol content and the cholesterol to phospholipid ratio of red cell membranes ([360]). This red cell lipid profile is in contrast to the equal increase in both cholesterol and phospholipid seen in obstructive liver disease ([361]). In cirrhotic liver disease, abnormal lipoproteins produced by the liver are loaded with cholesterol; this excess cholesterol is readily transferred to RBCs, resulting in the formation of flat, scalloped cells ([361], [362]). These cells, however, are further conditioned by the spleen, resulting in membrane fragmentation, and the evolution of acanthocytes that look like "spurs."

These spur RBCs are cholesterol loaded, with a decreased surface area to volume ratio, and their cellular deformability is decreased. Once formed in the spleen, spur cells over time are destroyed by the spleen, thereby accounting for the hemolytic anemia associated with severe liver disease. Affected patients usually have moderate-to-severe hemolysis, hyperbilirubinemia, splenomegaly, and clinical and laboratory evidence of laboratory liver dysfunction. The peripheral blood contains numerous acanthocytes, very similar in appearance to those seen in abetalipoproteinemia. This spur cell anemia can occur in any condition associated with severe hepatocyte injury.

Abetalipoproteinemia

Abetalipoproteinemia (also known as *Bassen-Kornzweig syndrome*) is a rare, genetic disorder characterized by acanthocytosis, malabsorption of fat, hypolipidemia, retinitis pigmentosa, and progressive ataxia ([363], [364] and [365]). The primary biochemical lesion is defective synthesis of apoprotein B (365a) and, consequently, an absence of several lipoprotein fractions: low-density lipoproteins, very-low-density lipoproteins, and chylomicrons ([366], [367] and [368]). Also, the metabolic activities of

these lipoproteins (mobilization of triglycerides from the liver, transport of preformed triglycerides from the intestinal mucosa, and transport of phospholipid and cholesterol between phospholipid membranes) are impaired. Plasma cholesterol, phospholipid, and triglyceride levels are very low ([364], [365], [369], [370]); the serum appears transparent.

The relationship between the disturbance in plasma lipid content and acanthocyte formation is not clear. Total red cell lipid and phospholipid content is normal ([369]), but there is a net increase in sphingomyelin concentration, thereby reversing the usual phosphatidylcholine to sphingomyelin ratio ([370], [371], [372] and [373]). This phospholipid distribution is similar to that seen in the plasma in which a similar increase in sphingomyelin exists relative to phosphatidylcholine ([370], [372], [374]). Red cell precursors and young erythrocytes are of normal shape in this disorder. Acanthocyte formation increases as RBCs age in the circulation ([361]). Moreover, normal red cells become acanthocytic when infused into individuals with abetalipoproteinemia.

Unlike acanthocytes produced in liver disease, those from subjects with abetalipoproteinemia do not revert to a discoid shape when incubated in normal serum. However, this acanthocytosis is reversed *in vitro* after lipids are extracted with detergents ([375]). Acanthocyte formation is thought to reflect an increase in the surface area of the outer lipid bilayer relative to the inner bilayer, presumably because of increased sphingomyelin in the outer bilayer leaflet ([376]). Acanthocytes do resume a discocyte morphology after incubation with chlorpromazine, an agent known to expand the inner lipid bilayer, thereby normalizing the bilayer asymmetry ([377]).

Although affected infants ostensibly are normal at birth, steatorrhea, abdominal distention, and growth failure develop in the first months of life. Retinitis pigmentosa and progressive ataxia are first noted in children between 5 and 10 years of age. Treatment with vitamin E prevents or reverses the neurologic abnormalities ([378]). Without treatment, neurologic disability is progressive, with death usually occurring during the second or third decade ([379], [380] and [381]). In some cases, cardiac arrhythmias ([382]) and heart failure ([381]) precede death. Because several instances of consanguinity among parents of affected children have been noted ([363], [380], [382]), an autosomal-recessive mode of transmission is assumed.

For unknown reasons, the membrane lesion in abetalipoproteinemia (increased sphingomyelin) is less damaging than that which occurs in the spur cells of liver disease (increased cholesterol). The latter is associated with a moderate-to-severe hemolysis, whereas anemia in abetalipoproteinemia usually is mild or nonexistent ([363], [364], [382], [383] and [384]). Occasionally, in children with abetalipoproteinemia, the anemia is severe ([380], [384]); this most likely is a result of broad nutritional deficiencies related to malabsorption in children. Folate deficiency as a cause of anemia in some patients is well documented ([364], [384]). The lifespan of labeled acanthocytes in abetalipoproteinemia is shortened only slightly ([370], [380], [385]). Reticulocyte counts are normal or slightly increased ([365], [380], [382], [385]). The most striking hematologic feature is the presence of large numbers of acanthocytes (50 to 70%) on the blood smear (Fig. 32.11) ([364]). Osmotic fragility is normal or slightly decreased.

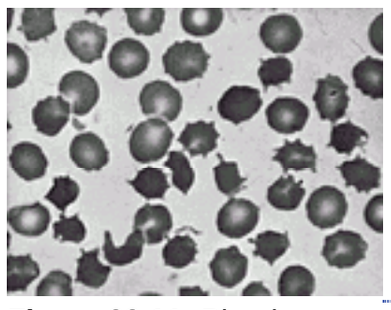

Figure 32.11. Blood smear of acanthocytes from a patient with abetalipoproteinemia.

The diagnosis of abetalipoproteinemia is suggested by the demonstration of acanthocytes in an individual with severe malabsorption, retinitis pigmentosa, or a disorder resembling Friedreich ataxia. The most helpful screening test is the determination of serum cholesterol, phospholipid, and triglyceride levels, which are very low. The diagnosis is confirmed by demonstrating the absence of beta lipoproteins in plasma.

Neuroacanthocytosis

Acanthocytes are a feature of the peripheral blood smear in a group of patients with a degenerative neurologic disorder characterized by movement abnormalities, psychiatric symptoms, areflexia, and an elevated plasma creatine kinase ([378]). Serum lipoprotein electrophoresis is normal. Anemia, if present, is mild ([382], [386]).

Macleod Phenotype

The Macleod phenotype, named after the first patient described, is characterized by a decreased expression of the Kell antigen on the red cell surface and decreased reactivity to Kell antiserum ([387]). Associated findings include acanthocytosis, polychromasia, a mild well-compensated hemolytic anemia ([388], [389], [390] and [391]), and susceptibility to alloimmunization by Kell antigens. Elevated serum creatine phosphokinase levels are seen, often accompanied by myopathy and peripheral neuropathy. Central nervous system abnormalities may appear, particularly after the fourth decade of life ([392]). The number of acanthocytes in blood smears ranges from 25 to 85%. Just as in other cases of acanthocytoses, the surface projections of these acanthocytes are thought to be related to asymmetry of the lipid bilayer because agents that expand the inner lipid layer correct the acanthocytosis ([393]). Studies of membrane lipid and protein composition, membrane fluidity, and intercellular enzyme at ATP levels are normal ([394], [395]).

The Macleod phenotype is the result of an absence of the XK antigen, a protein precursor necessary for Kell antigen expression. The gene controlling XK synthesis is not part of the Kell autosomal gene complex, but rather is located on the X chromosome. A second, larger protein also exists, which carries the Kell blood group antigen ([396], [397]); RBCs with the Macleod phenotype lack this protein, as well as the XK antigen. In contrast, Kell-null RBCs lack the larger protein, but have more than normal amounts of the XK antigen; Kell-null RBCs are normal in shape ([398]). At least 19 different mutations affecting the XK gene locus lead to the Macleod phenotype ([399]). Eight of these are deletions, some of which extend to adjacent genes on the X chromosome, giving rise to varying phenotypes that may include chronic granulomatous disease, Duchenne's muscular dystrophy, and retinitis pigmentosa along with the Macleod phenotype ([374], [380], [400], [401] and [402]). Only a small subset of boys who inherit X-linked chronic granulomatous disease have large deletions such as those mentioned above and express the Macleod phenotype. They lack erythrocyte XK, have an increased number of reticulocytes and shortened red cell survival, and may occasionally require red cell transfusions. Their carrier mothers have a dual population of XK-positive and XK-negative erythrocytes and variable numbers of acanthocytes. Most X-linked chronic granulomatous disease patients do not exhibit the Macleod phenotype. Their red cells are morphologically and serologically normal.

ECHINOCYTIC DISORDERS

Echinocytes are RBCs with numerous fine uniform spicules equally throughout the cell surface. These cells differ morphologically from acanthocytes, which have fewer projections, and the spicules vary in size. It is thought that echinocytes are the result of preferential expansion of the outer lipid bilayer relative to the inner layer ([297]). As mentioned previously, stomatocytes, in contrast, are produced by agents that expand the inner lipid surface area relative to the outer half of the bilayer. The presence of echinocytes on the peripheral blood film often is an artifact caused by interactions of red cells with glass ([359]). However, echinocytes also are seen in association with hemolytic anemias in patients with hypophosphatemia ([403]), in patients with pyruvate kinase deficiency ([359]), in patients with uremia ([404]), and in some long-distance runners ([405]). The mechanism of echinocytosis in these diverse disorders is not entirely clear. However, *in vitro*, it is known that a variety of factors, such as exposure of red cells to certain drugs ([406]), loading by calcium ([407]), or ATP depletion ([408], [409]), can induce echinocyte formation. In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution may be a consequence of decreased aminophospholipid translocase activity, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer half of the bilayer to the inner half ([410]).

TARGET CELL DISORDERS

Target cells are discoid RBCs with a centralized hemoglobinized area in the clear center, thereby resembling a target. Target cells are the morphologic expression of an increase in the ratio of the cell-surface area to cell volume. This ratio is influenced by increases in the surface area, as well as decreases in cell volume. Causes of target cell formation may be both acquired and hereditary. In microcytic red cells of patients with iron deficiency, thalassemia disorders, and certain hemoglobinopathies, a decreased cell volume caused by less hemoglobinization results in a relative excess of cell-surface area. Thus, the surface area to volume ratio is increased and, hence, the expression of target cells. In obstructive liver disease and disorders of intrahepatic cholestasis, target cell formation is the result of an absolute increase of the cell-surface area because of a net membrane accumulation of both phospholipids and cholesterol ([361]). The accumulation is caused by abnormal low-density lipoproteins that occur in obstructive jaundice; these low-density lipoproteins are laden with cholesterol and lecithin, which is readily transferable to red cell membrane, thereby leading to an expansion of the cell membrane surface ([361]). Target cells have a decreased osmotic fragility, as the excess of membrane surface area leads to an increase of the critical hemolytic volume. These target cells have a normal survival in circulation.

Familial Lecithin-Cholesterol Acyltransferase Deficiency

Lecithin-cholesterol acyltransferase (LCAT) catalyzes the transfer of fatty acids from phosphatidylcholine to cholesterol. This enzyme is in the circulation complexed with high-density lipoproteins. Familial LCAT deficiency is a rare disorder characterized by mild anemia, corneal opacities, renal disease, and premature atherosclerosis ([411] , [412] , [413] and [414]). Most descriptions of the condition have come from Norway, although it has been detected throughout Europe, Canada, and Japan. Results of family studies support an autosomal-recessive mode of transmission ([415]). Several mutations in LCAT leading to deficient enzyme activity have been described ([413] , [414]). Deficient plasma LCAT activity is responsible for a marked decrease in plasma levels of unesterified cholesterol and an increase in the amount of free cholesterol. The red cell membrane may contain twice the normal amounts of unesterified cholesterol, but phosphatidylcholine also is increased, whereas sphingomyelin and phosphatidylethanolamine are reduced ([416]). These RBC lipid changes are reversible when the target cells are incubated with normal plasma. The anemia is mild, and target cells are prominent on the peripheral blood smear. Both hemolysis and decreased erythropoiesis have been implicated in the pathogenesis of the anemia; the latter may relate to coexistent renal disease.

Foam cells and “sea-blue histiocytes” have been noted in both the bone marrow and the spleen of all patients studied ([411] , [417]). The material accumulated within histiocytes is possibly unesterified cholesterol and phosphatidylcholine.

Hereditary Hemolytic Anemias Due to Enzyme Disorders

OVERVIEW OF RED BLOOD CELL METABOLISM

Mature red blood cells (RBCs) are anucleate (thereby incapable of cell division), devoid of ribosomes (thereby incapable of protein synthesis), and lack mitochondria (thereby incapable of oxidative phosphorylation) (see Chapter 8). Despite these limitations, RBCs survive 100 to 120 days in the circulation and effectively deliver oxygen to peripheral tissues. Glucose is the main metabolic substrate of RBCs, and it is metabolized by two major pathways: the glycolytic or “energy-producing” pathway and the hexose monophosphate (HMP) shunt or “protective” pathway. Under normal conditions, approximately 90% of glucose flows through glycolysis, with a much smaller fraction being channeled through the HMP pathway. However, the fraction of glucose entering the pentose phosphate pathway can increase significantly under conditions of increased oxidative stress. The major products of glycolysis are adenosine triphosphate (ATP; a source of energy for numerous RBC membrane and metabolic reactions), reduced nicotinamide adenine dinucleotide (a necessary cofactor for methemoglobin reduction by cytochrome b_5 reductase), and 2,3-diphosphoglycerate (2,3-DPG; an important intermediate that modulates hemoglobin-oxygen affinity) (Fig. 33.1). Mature RBCs are incapable of *de novo* purine or pyrimidine synthesis, although many enzymes of nucleotide metabolism are present in erythrocytes. The latter are now known to be important for RBC preservation *in vitro*, and it also is recognized that abnormalities in purine and pyrimidine metabolism are associated with inherited hemolytic disease.

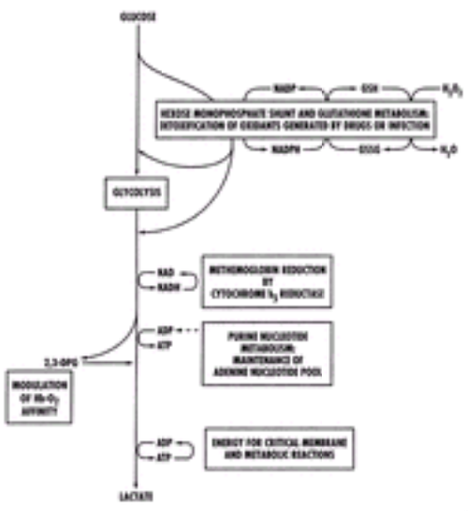

Figure 33.1. Summary of overall glycolysis, hexose monophosphate shunt, glutathione metabolism, and red blood cell nucleotide metabolism. ADP, adenosine diphosphate; ATP, adenosine triphosphate; 2,3-DPG, 2,3-diphosphoglycerate; GSH, reduced glutathione; GSSG, oxidized glutathione; Hb, hemoglobin; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

The consequences of red cell enzymopathies are diverse. Some enzyme variants cause hemolytic disease with anemia being the sole expression of the enzymopathy. In other enzyme disorders, hemolysis is one feature of a multisystem disease affecting many tissues. Also, in some cases, erythrocyte enzyme abnormalities have no adverse effects on RBC function, and, if they occur in patients with hemolytic anemia, it is not always clear that the enzyme deficiency and hemolysis are causally related. This chapter focuses on the varied enzyme defects associated with hemolysis. These RBC enzyme disorders are due to abnormalities in the HMP shunt and glutathione metabolism, glycolytic enzyme deficiencies, and abnormalities in purine and pyrimidine metabolism.

DISORDERS OF HEXOSE MONOPHOSPHATE SHUNT AND GLUTATHIONE METABOLISM

The HMP shunt pathway metabolizes 5 to 10% of glucose used by RBCs, and this is critical for protecting red cells against oxidant injury (Fig. 33.2). The HMP pathway is the only RBC source of reduced nicotinamide adenine dinucleotide phosphate (NADPH), a cofactor important in glutathione metabolism. RBCs contain relatively high concentrations of reduced glutathione (GSH), a sulfhydryl-containing tripeptide (glutamylcysteinylglycine) that functions as an intracellular reducing agent that protects cells against oxidant injury. Oxidants, such as superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), are produced by exogenous factors (i.e., drugs, infection) and also are formed within red cells as a consequence of reactions of hemoglobin with oxygen. However, when these oxidants accumulate within red cells, hemoglobin and other proteins are oxidized, leading to loss of function and RBC death. Under normal circumstances, this does not occur because GSH, in conjunction with the enzyme glutathione peroxidase (GSH-Px), rapidly inactivates these compounds. During the oxidant detoxification process, however, GSH itself is converted to oxidized glutathione (GSSG), and GSH levels fall. To sustain protection against persistent oxidant injury, GSH levels must be maintained, and this is accomplished by glutathione reductase (GSSG-Red), which catalyzes reduction of GSSG to GSH. This reaction requires the NADPH generated by glucose-6-phosphate dehydrogenase (G6PD), the first enzymatic reaction of the HMP shunt. Thus, it is the tight coupling of the HMP shunt and glutathione metabolism that is responsible for protecting intracellular proteins from oxidative assault. Almost all hemolytic episodes related to altered HMP shunt and glutathione metabolism are due to G6PD deficiency, and this enzyme deficiency is known to affect millions of people throughout the world (1, 2 and 3). Rare cases of hemolysis associated with decreased GSSG-Red activity, GSH-Px deficiency, and deficiencies of GSH synthetic enzymes also have been described.

Figure 33.2. Hexose monophosphate shunt, enzymes of glutathione metabolism, protection from oxidant assault, and relationship to glycolytic metabolism. Enzymes are shown in boxes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; G-3-P, glyceraldehyde-3-phosphate; G-6-PD, glucose-6-phosphate dehydrogenase; ?-Glu-Cys-Synth, ?-glutamyl-cysteine synthetase; GSH, reduced glutathione; GSH-Px, glutathione peroxidase; GSH-Synth, glutathione synthetase; GSSG, oxidized glutathione; GSSG-Red, glutathione reductase; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate;

6-P-G, 6-phosphogluconate; 6-PGD, 6-phosphogluconate dehydrogenase; Ribose-5-P, ribose-5-phosphate.

Glucose-6-Phosphate Dehydrogenase Deficiency

The importance of this enzyme for red cell integrity was first recognized after the observation that some African-American soldiers taking the antimalarial drug primaquine would develop acute hemolytic anemia with hemoglobinuria. Initially, it was observed that GSH was decreased in the RBCs of susceptible individuals during acute hemolytic episodes. Subsequently, the activity of G6PD, one of the enzymes needed to keep adequate GSH levels, was found to be deficient in affected red cells ([4], [5]). Soon thereafter, the worldwide distribution of G6PD deficiency became apparent, and the variation of clinical expression of enzyme deficiency was discovered. In most individuals with G6PD deficiency, there is no anemia in the steady state and reticulocyte counts are normal, but RBC survival may be slightly decreased. However, episodic exacerbations of hemolysis accompanied by anemia occur in association with the administration of certain drugs and with some infections. In a minority of cases, G6PD deficiency is associated with a chronic hemolytic process. To date, over 400 G6PD biochemical variants have been recognized ([1], [6], [7] and [8]).

GENETICS The gene for G6PD is located on the X chromosome (band X q28) ([9], [10] and [11]). The fact that normal males and females have the same enzyme activity in their red cells is explained by the Lyon hypothesis ([12]). This hypothesis maintains that one of two X chromosomes in each cell of the female embryo is inactivated and remains inactive throughout subsequent cell divisions for the duration of life. In fact, studies by Beutler on females with G6PD deficiency were used in proof of the Lyon hypothesis ([13]). Enzyme deficiency is expressed in males carrying a variant gene, whereas heterozygous females usually are clinically normal. However, depending on the degree of lyonization and the degree to which the abnormal G6PD variant is expressed, the mean RBC enzyme activity in females may be normal, moderately reduced, or grossly deficient. A female with 50% normal G6PD activity has 50% normal red cells and 50% G6PD-deficient red cells. The G6PD-deficient cells in females, however, are as vulnerable to hemolysis as enzyme-deficient RBCs in males. The concept of X chromosome inactivation and the study of G6PD has been informative in other areas. In particular, it has facilitated our understanding of monoclonal and multiclonal disorders of cell proliferation. Most tumors, both benign and malignant, can be demonstrated to have a clonal origin, being derived from one cell ([14], [15] and [16]). For example, analysis of the G6PD enzyme in uterine myomata of women heterozygous for G6PD A and G6PD B revealed that any given tumor had either G6PD A or enzyme B but not both ([17]). The same principle has been used to demonstrate the clonal origin of the malignant transformation of acute leukemia ([18], [19]) and chronic myelocytic leukemia ([20]), and also the clonal nature of polycythemia vera ([21]), primary thrombocythemia ([22]), and paroxysmal nocturnal hemoglobinuria ([23]).

PREVALENCE AND GEOGRAPHIC DISTRIBUTION Deficiency of G6PD is the most common metabolic disorder of RBCs and has been estimated to affect over 400 million people worldwide ([24]). Although global in its distribution, G6PD deficiency is encountered with greatest frequency in the tropical and subtropical zones of the Eastern Hemisphere. The incidence of the deficiency state is approximately 20% among African Bantu males ([25], [26]), 12% in African-American men ([27], [28]), and 8% in Brazilian blacks. As many as 20% of female African Americans may be heterozygous for G6PD mutants ([29]), and as many as 1% are homozygous. In Sardinia, the incidence varies from 35% at low altitudes to 3% in areas above 600 meters ([30]). The deficiency state has been reported from most areas of Greece, again with greatest frequency (20 to 32%) in the lowlands ([31]). The condition is also prevalent among Sephardic Jews, and as many as 60 to 70% of Kurdish Jews may be affected ([1], [6], [32]). In the male Asian population, the incidence of G6PD deficiency is estimated to be 14.0% in Cambodia ([33]), 5.5% in South China ([34], [35]), 2.6% in India ([33]), and less than 0.1% in Japan ([36]). It is rare among native Americans ([37]). Because of its high incidence among populations in which malaria was once endemic, G6PD deficiency is believed to have conferred a selective advantage against infection by *Plasmodium falciparum* malaria ([38], [39] and [40]). Partial indirect support for this is that G6PD deficiency in Sardinia is more common at sea level compared to higher elevations, and this also parallels the endemicity of malaria. In addition, it has been observed that parasitized female heterozygotes for G6PD deficiency (who therefore have normal and G6PD-deficient RBCs) have more malaria parasites in their normal erythrocytes compared to their G6PD-deficient cells ([41]). Moreover, it has been demonstrated that the *in vitro* growth of malarial parasites is inhibited in G6PD-deficient red cells ([42]). The precise reasons for the observed inhibition of parasite growth in G6PD-deficient red cells are not known. One possibility is that the oxidant stress that causes GSH instability and destroys the host RBC also kills the parasite ([43], [44] and [45]). An alternative explanation is provided by the observation that infected, G6PD-deficient red cells are unable to generate the ribose derivatives needed by the parasite for nucleic acid synthesis ([46]). Thus, inhibition of parasite growth rather than oxidative destruction of the parasite, host cell, or both may be an important mechanism for the balanced polymorphism of the G6PD gene.

THE ENZYME AND ITS VARIANTS The monomeric form of G6PD contains 515 amino acids and has a molecular weight of 59 kd ([47], [48]). The active form of G6PD *in vivo* is a dimer, which requires nicotinamide adenine dinucleotide phosphate (NADP) for its stability ([24]). The G6PD gene has been cloned and sequenced. It is known to contain 13 exons and is over 18 kb in length ([48], [49] and [50]). The normal or wild-type enzyme is G6PD B, although hundreds of variant enzymes now have been identified. By international agreement, standardized methods have been used to characterize these enzyme variants, which differ on the basis of biochemical properties such as kinetic activity, electrophoretic mobility, the Michaelis constant for its substrate glucose-6-phosphate and cofactor NADP, the ability to use different substrate analogs, heat stability, and pH optima. Throughout the years, the published list of recognized G6PD biochemical variants has been periodically updated ([51], [52]), and over 400 biochemical variant forms of G6PD are recognized ([1]). However, differences between some variants are subtle and most likely reflect minor technical differences between laboratories rather than true enzyme differences. Moreover, the advances in molecular biology have revealed that many so-called G6PD variants, in fact, have the same DNA defect (see below). The World Health Organization has classified G6PD variants on the magnitude of the enzyme deficiency and also on the severity of hemolysis ([53]). *Class I variants* have very severe enzyme deficiency (less than 10 to 20% of normal) and have chronic hemolytic anemia. *Class II variants* also have severe enzyme deficiency (less than 10% of normal), but there is usually only intermittent hemolysis. *Class III variants* have moderate enzyme deficiency (10 to 60% of normal) with intermittent hemolysis usually associated with infection or drugs. *Class IV variants* have no enzyme deficiency or hemolysis. *Class V variants* are those in which enzyme activity is increased. Variants in the last two groups, although of much interest to biologists, geneticists, and anthropologists, are of no major clinical significance. The normal wild-type enzyme, G6PD B, is found in most whites and Asians and in a majority of blacks. It has normal catalytic activity and is not associated with hemolysis (class IV). A commonly encountered variant is G6PD A+, which is found in 20 to 30% of blacks from Africa ([54]). It has normal catalytic properties and does not cause hemolysis (class IV). It differs from G6PD B in that it has a much faster electrophoretic mobility (the letters A and B refer to relative electrophoretic mobilities). The structure of G6PD A+ differs from that of G6PD B by the substitution of a single amino acid, an asparagine for aspartate at the 126th position of the protein ([55]). Another common variant, G6PD A–, is the enzyme responsible for primaquine sensitivity in blacks, and it is the most common variant associated with mild to moderate hemolysis (class III). This G6PD variant is found in 10 to 15% of African Americans, with similar frequencies in western and central Africa ([56]). It has an electrophoretic mobility identical to that of G6PD A+. However, this is an unstable enzyme, and its catalytic activity, although nearly normal in bone marrow cells and reticulocytes ([57]), decreases markedly in older RBCs ([58]). Hence, this variant is designated G6PD A- compared with G6PD A+ (the + and - denote enzyme activity). G6PD Mediterranean is the most common abnormal variant found in whites, particularly those whose origins are in the Mediterranean area. The electrophoretic mobility of G6PD Mediterranean is identical to that of G6PD B, but it is synthesized at a reduced rate ([57]), its catalytic activity is markedly reduced, and hemolysis can be severe (class II). G6PD Canton is a common variant enzyme seen in Asians ([59]). Its biochemical properties are very similar to those of G6PD Mediterranean. Recent advances in molecular biology have further enhanced our understanding of G6PD deficiency, and now over 140 different gene mutations or mutation combinations have been identified ([2], [8], [60]). These DNA changes are almost all missense mutations leading to single amino acid substitutions in the enzyme. Large deletions have not been identified, suggesting that complete absence of G6PD might be lethal ([1]). The mutations are located throughout the entire coding region of the gene ([3]). However, in class I variants associated with chronic hemolysis, mutations are clustered around exon 10, an area that governs the formation of the active G6PD dimer ([3], [61]). The correlation between the different biochemical variants, the site of genetic mutation, and the extent of hemolysis is a matter of current investigation ([1], [3], [61], [62] and [63]). An interesting example of how molecular biology has enhanced our understanding relates to G6PD A–, once believed to be a single unstable variant found in blacks throughout the world. However, molecular analysis now has demonstrated that G6PD A- may have more than one genotype. In all cases, there is a mutation at nucleotide 376 (A?G), which is also the nucleotide substitution characteristic of G6PD A+. In addition, the G6PD A- variants have a second mutation; in the majority of cases, it is at nucleotide 202 (G?A) ([1], [64]). A smaller fraction of G6PD A- subjects have the second substitution at nucleotide 680 (G?T) or at nucleotide 968 (T?C) ([65]). Thus, the G6PD A- variant, once believed to be a single homogeneous mutation in Africans, now turns out to represent at least three different genotypes ([1]). Also, a number of G6PD variants originally described in non-Africans are now found to have one of the known G6PD A- mutations (Table 33.1). For example, G6PD Betica ([66]), a Spanish variant, and G6PD Matera ([67]), an Italian variant, have demonstrated base substitutions at nucleotides 202 and 376, identical to the common G6PD A- variant. They are examples, therefore, of G6PD A–. One subject with G6PD Betica had base substitutions at nucleotides 376 and 968, identical to the less common G6PD A- variant ([66]).

Modified from Beutler E. G6PD deficiency. Blood 1994;84:3613–3636; Beutler E. Glucose-6-phosphate dehydrogenase deficiency. N Engl J Med 1991;324:169–174; and Miwa S, Fujii H. Molecular basis of erythroenzymopathies associated with hereditary hemolytic anemia: tabulation of mutant enzymes. Am J Hematol 1996;51:122–132.

There are several other variants that appear clinically heterogeneous but have been found to be genetically more uniform. For example, G6PD Mediterranean involves many different ethnic groups, although most subjects have the same genetic defect, a single base substitution (C?T) at nucleotide 563 ([66], [67] and [68]). Moreover, just as in the case of G6PD A–, many of the different biochemical variants have turned out to have the same molecular defect as G6PD Mediterranean (Table 33.1). Because leukocyte and platelet G6PD is regulated by the same gene as that of red cells, documentation of decreased activity in the white blood cells ([69], [70] and [71]) and platelets ([70]) of deficient individuals is not surprising. Because of the normally short survival of leukocytes and platelets, however, most individuals with G6PD deficiency do not manifest impairment of phagocytosis or bactericidal activity of granulocytes ([70], [71]). The exception to this occurs with class I G6PD deficiency, in which some affected individuals have neutrophil dysfunction and increased susceptibility to infection ([72], [73]).

PATHOPHYSIOLOGY As red cells age, the activity of G6PD declines exponentially. The normal enzyme (G6PD B) has an *in vivo* half-life of 62 days ([57]). Despite this loss of enzyme activity, normal old RBCs contain sufficient G6PD activity to generate NADPH and thereby sustain GSH levels in the face of oxidant stress. In contrast, the G6PD variants associated with hemolysis are unstable and have much shorter half-lives. The activity of G6PD A- in reticulocytes is normal, but it declines rapidly thereafter with a half-life of only 13 days ([57], [74]). The instability of G6PD Mediterranean is even more pronounced, with a half-life measured in hours ([57]). The clinical correlate of this age-related enzyme instability is that hemolysis in patients with G6PD A- generally is mild and limited to older deficient erythrocytes. In contrast, the enzymatic defect in G6PD Mediterranean is due to much greater enzyme instability, and RBCs of all ages are grossly deficient. Consequently, the entire RBC population of individuals with G6PD Mediterranean is susceptible to oxidant-induced injury, and this can lead to severe hemolytic anemia. G6PD-deficient erythrocytes exposed to oxidants (infection, drugs, fava beans) become depleted of GSH. This reaction is central to the cell injury in this disorder because once GSH is depleted, there is further oxidation of other RBC sulfhydryl-containing proteins. Oxidation of the sulfhydryl groups on hemoglobin leads to the formation of denatured globin or sulfhemoglobin. The latter form insoluble masses that attach to the red cell membrane by disulfide bridges; these are known as *Heinz bodies* ([75]). Also, with some class I variants, the oxidation of membrane sulfhydryl groups leads to the accumulation of membrane polypeptide aggregates, presumably due to disulfide bond formation between spectrin dimers and between spectrin and other membrane proteins ([76], [77], [78] and [79]). The end result of these changes is the production of rigid, nondeformable erythrocytes that are susceptible to stagnation and destruction by reticuloendothelial macrophages in the spleen and liver ([80], [81]). Both extravascular and intravascular hemolysis occurs in G6PD-deficient individuals, the latter giving rise to hemoglobinemia and hemoglobinuria. It should also be noted that some patients with unstable hemoglobinopathies also may manifest oxidant injury because these abnormal hemoglobins are inordinately susceptible to mild oxidant stress. In almost all cases, however, acute hemolysis with oxidant injury is due to G6PD deficiency.

CLINICAL AND HEMATOLOGIC FEATURES The clinical expression of G6PD variants encompasses a continuous spectrum of hemolytic syndromes. In most affected individuals, the deficiency state goes unrecognized, whereas in some it causes episodic or chronic anemia. The common clinical entities encountered are acute hemolytic anemia, favism, congenital nonspherocytic hemolytic anemia, and neonatal hyperbilirubinemia.

Acute Hemolytic Anemia With the most prevalent G6PD variants (G6PD A- and G6PD Mediterranean), severe hemolysis occurs only after exposure to certain offending agents. In the steady state, there is no anemia or alteration in blood morphology. Sudden destruction of enzyme-deficient erythrocytes is triggered by drugs having a high redox potential and by selected infectious or metabolic perturbations. The clinical and laboratory features of an acute hemolytic episode are best illustrated in a figure from a classic study with primaquine-induced hemolysis in subjects with G6PD A- (Fig. 33.3) ([4], [5]). After 2 to 4 days of primaquine ingestion, all the signs, symptoms, and laboratory results characteristic of an acute hemolytic episode are observed. Jaundice, pallor, and dark urine, with or without abdominal and back pain, are sudden in onset. An abrupt decrement of 3 to 4 g per dl in hemoglobin concentration occurs. Cell fragments, microspherocytes, and eccentrocytes, also referred to as “blister” or “bite” cells, are observed on blood smears. In response to anemia, red cell production increases; an increase in reticulocytes is apparent within 5 days and is maximal by 7 to 10 days after onset of hemolysis. Despite continued drug exposure, the acute hemolytic process ends spontaneously after approximately 1 week, and the hemoglobin concentration thereafter returns to normal levels. The anemia is self-limited because the old susceptible population of erythrocytes is replaced by younger RBCs with sufficient G6PD activity to withstand an oxidative assault. Although red cell survival remains shortened as long as use of the drug continues, compensation by the erythroid marrow effectively abolishes the anemia in subjects with G6PD A–. In contrast, hemolysis occurring with the G6PD Mediterranean variant is more severe because this variant has a very short intraerythrocytic half-life, and thus a larger population of circulating erythrocytes is vulnerable to injury ([82]). Hemolytic crises occur in heterozygous female subjects, as well as in hemizygous male patients. In virtually all cases, acute hemolytic episodes are due to administration of drugs or are associated with infection or fava bean exposure.

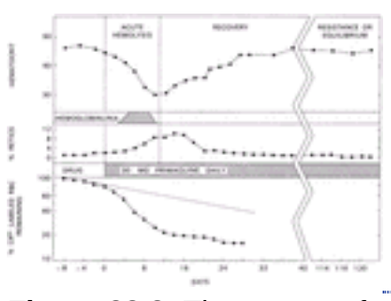

Figure 33.3. The course of primaquine-induced hemolysis in the glucose-6-phosphate dehydrogenase A- variant. RBC, red blood cell. (From Alving A, et al. Mitigation of the haemolytic effect of primaquine and enhancement of its action against exoerythrocytic forms of the Chesson strain of *Plasmodium vivax* by intermittent regimens of drug administration. Bull World Health Organ 1960;22:621–631, with permission.)

Drug-Induced Hemolysis Primaquine is but one of several drugs that can precipitate hemolysis. The common denominator of these drugs is their interaction with hemoglobin and oxygen, thus accelerating the intracellular formation of H_2O_2 and other oxidizing radicals. The published lists of suspect drugs are lengthy; however, many of the putative hemolytic agents were incriminated before it was recognized that infections often mimic the adverse effects of drugs. Consequently, many hemolytic events previously ascribed to drugs may, in fact, have resulted from infections for which drugs were given. Aspirin is such a drug, and it now is recognized that it can safely be given to individuals with class II and III G6PD variants. Some drugs and chemicals, however, are predictably injurious for all G6PD-deficient subjects ([1], [6]), and these agents are listed in Table 33.2. Other drugs, although producing a modest shortening of survival of G6PD-deficient red cells, can be given safely in usual therapeutic doses to individuals with class II and III G6PD variants (Table 33.2). Ascorbic acid is safe in usual therapeutic doses, although large amounts may pose problems ([83]). Similarly, acetaminophen (Tylenol), aminoptyrine, sulfisoxazole (Gantrisin), sulfamethoxazole, and vitamin K can be given safely in usual therapeutic doses ([6]).

TABLE 33.2. Drugs and Chemicals Associated with Hemolysis in Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

Unsafe (class I, II, and III G6PD variants)
Acetanilid
Furazolidone (Furoxone)
Methylene blue

Nalidixic acid (NegGram)
Naphthalene (Mothballs)
Nitrofurantoin (Furadantin)
Phenazopyridine (Pyridium)
Phenylhydrazine
Primaquine
Sulfacetamide
Sulfamethoxazole (Gantanol)
Sulfanilamide
Sulfapyridine
Thiazolsulfone
Toluidine blue
Trinitrotoluene (TNT)

Safe in usual therapeutic doses (class II and III G6PD variants) [a]

Acetaminophen
Ascorbic acid
Aspirin
Chloramphenicol
Chloroquine
Colchicine
Diphenhydramine
Isoniazid
Phenacetin
Phenylbutazone
Phenytoin
Probenecid
Procainamide
Pyrimethamine
Quinidine
Quinine
Streptomycin
Sulfamethoxypyridazine
Sulfisoxazole
Trimethoprim
Tripelennamine
Vitamin K

[a] Safety for class I G6PD variants is not known.

Modified from Beutler E. G6PD deficiency. Blood 1994;84:3613–3636; and Beutler E. Glucose-6-phosphate dehydrogenase deficiency. N Engl J Med 1991;324:169–174.

Infection-Induced Hemolysis Infection is probably the most common factor inciting hemolysis ([84], [85]). Approximately 20% of G6PD-deficient subjects with pneumonia experience an abrupt drop in hemoglobin concentration ([84]). In a study of the role of G6PD deficiency in the anemia associated with acute infection, 12 of 17 black patients with infection and anemia were found to have G6PD deficiency ([26]). A variety of infectious agents have been implicated: salmonella ([86], [87] and [88]), *Escherichia coli* ([84]), ß-hemolytic streptococci ([89]), and rickettsiae ([90]). Hemolysis is particularly prominent in G6PD-deficient subjects with viral hepatitis ([88], [91], [92]). The accelerated destruction of red cells imposes a bilirubin load on an already damaged liver, resulting in an exaggerated increase in serum bilirubin level. Despite the magnitude of bilirubin retention, however, convalescence is generally complete and uneventful. Although hemolysis triggered by infection characteristically is mild, on rare occasions, acute renal failure secondary to massive intravascular hemolysis has been observed ([90], [91]). The mechanism for destruction of G6PD-deficient red cells during infection is not known. One possible explanation for this relationship is that oxidants generated by phagocytosing macrophages may diffuse into the extracellular medium, where they pose an oxidative threat to G6PD-deficient erythrocytes ([93]).

Hemolysis Associated with Diabetic Acidosis Diabetic ketoacidosis rarely is associated with triggering destruction of G6PD-deficient red cells ([94]). Correction of acidosis and restoration of glucose homeostasis reverse the hemolytic process. Changes in blood pH, glucose ([95]), and pyruvate ([96]) have been proposed as possible mechanisms for hemolysis. Also, occult infection may be a common trigger for inducing both acute hemolysis and diabetic acidosis.

Favism That exposure to the fava bean (*Vicia fava*, broad bean) is toxic and potentially fatal for some individuals has been known, allegedly, since the time of Pythagoras. Subsequent investigation revealed that individuals made ill by the fava bean invariably are deficient in G6PD ([97]). Unlike other agents capable of inducing hemolysis, the fava bean is toxic for only a few G6PD-deficient individuals. The variant most frequently implicated is G6PD Mediterranean and, as a result, favism is encountered most commonly in Italy, Greece, and the Middle East ([1], [98]). It also is found in Asia ([33]) and other areas to which this gene mutation has traveled. It is of particular interest that Africans and African Americans with G6PD deficiency are much less susceptible, although hemolytic episodes have been reported ([99]). Most cases of favism result from ingestion of fresh beans. Consequently, the peak seasonal incidence of this disorder (April and May) coincides with harvesting of the bean ([100]). Hemolysis of comparable severity can follow consumption of dried beans. The syndrome has been observed in nursing infants of mothers who have eaten the beans ([100]), as well as in a newborn infant whose mother had eaten fava beans 5 days before delivery ([101]). Enzyme deficiency was held responsible for fatal hydrops fetalis in the male infant of a hematologically normal Chinese woman who ingested fava beans during the final month of pregnancy ([102]). Moreover, inhalation of pollen from the fava plant has been incriminated ([103]). Favism occurs most commonly in children between the ages of 1 and 5 years. As with other clinical manifestations of G6PD deficiency syndromes, it is seen primarily in males, although it also can occur in females with severe enzyme deficiency. Symptoms of acute intravascular hemolysis occur within 5 to 24 hours of ingestion of the bean. Headache, nausea, back pain, chills, and fever are followed by hemoglobinuria, anemia, and jaundice. The drop in hemoglobin concentration is precipitous, often severe, and may require a red cell transfusion. Favism does not occur in all susceptible G6PD-deficient individuals ([104]), and it is believed that additional genetic factors are involved, presumably related to how fava bean oxidants are metabolized. Furthermore, the reaction to the fava bean by the same individual at different times may not be consistent ([100]). Clearly, a factor other than enzyme deficiency is operative. Two pyrimidine aglycones, divicine and isouramil, have been implicated as the toxic components of fava beans ([105], [106]). Both compounds rapidly overwhelm the GSH-generating capacity of G6PD-deficient cells and reproduce many of the metabolic derangements noted during hemolytic episodes ([107]). To date, however, there are no convincing data to explain the erratic hemolytic episodes seen in favism.

Chronic Nonspherocytic Hemolytic Anemia A small fraction of G6PD-deficient individuals have chronic life-long hemolysis in the absence of infection or drug exposure. These class I G6PD variants are extremely heterogeneous with respect to biochemical kinetics but have in common very low *in vitro* activity, marked instability, or both ([61]). Over 90 different G6PD variants have been identified on the basis of their biochemical properties ([51]), whereas 61 have been characterized at a molecular level ([61]). As noted previously, most of these variants have DNA mutations at exon 10, an area that affects monomer–dimer interactions and thereby enzyme activity ([61]). The hemolytic anemia associated with class I variants is indistinguishable from the congenital nonspherocytic hemolytic syndromes related to glycolytic enzyme deficiencies. Anemia and jaundice often are noted first in the newborn period. Hyperbilirubinemia often necessitates exchange transfusion. Typically, hemolysis occurs in the absence of a recognized triggering factor, although exposure to drugs or chemicals with oxidant potential exaggerates an already established hemolytic process. Beyond infancy, signs and symptoms of the hemolytic disorder are subtle and inconstant. Pallor is observed infrequently, scleral icterus is noted intermittently, and rarely the spleen is enlarged. As with other chronic hemolytic anemias, the course may be complicated by parvovirus-induced aplastic crises. A temporary arrest of erythropoiesis, usually associated with a febrile illness, is attended by an abrupt drop in hemoglobin concentration. Often such a “crisis” is the event that first leads to examination of the blood. Exaggeration of anemia occurs after exposure to drugs with oxidant properties, even those that are safe for individuals with class II and III G6PD variants. Hemolysis also can be accelerated with exposure to fava beans ([108]). No hematologic alterations of the class I variants are distinctive. The hemolytic process may be fully compensated, although mild to moderate anemia is the rule (hemoglobin, 8 to 10 g per dl). Under basal

conditions, the usual reticulocyte count is 10 to 15%. Splenectomy generally is of little benefit ([109]). In a few instances, leukocyte dysfunction due to G6PD deficiency has been described in severely deficient patients ([72], [73], [110]). The abnormality is characterized functionally by defective bactericidal activity (but normal chemotaxis and phagocytosis) and clinically by recurrent infections with catalase-positive organisms. Overall, however, clinical infections are not a major problem in G6PD deficiency.

Neonatal Hyperbilirubinemia Hemolysis, hyperbilirubinemia, or both resulting from G6PD deficiency are well documented in the newborn period ([111]) and may occur *in utero* ([112]). At particular risk are those neonates with the rare class I G6PD variants. Close monitoring of serum bilirubin levels in infants known to be G6PD deficient is warranted ([112], [113] and [114]). From a practical perspective, however, neonatal hyperbilirubinemia is seen with the more common G6PD Mediterranean (class II) and also has been reported in enzyme-deficient infants from both Greece ([115], [116]) and Italy ([117]). An increase in the incidence of neonatal hyperbilirubinemia also is seen in Southeast Asia ([33], [118]) and China ([119]); a significant fraction in China is associated with G6PD Canton ([120]). African-American infants with G6PD A- (class III) appear to be at minimal risk, whereas African and Jamaican black infants have an increased incidence of neonatal hyperbilirubinemia ([121], [122] and [123]). Moreover, in the latter group, untreated hyperbilirubinemia often leads to kernicterus with severe neurologic injury or death ([123], [124]). Because black Africans and African Americans have the same G6PD A- genotypes, the adverse outcomes in Africa are believed to relate to local customs and differences in oxidant exposure. Another example suggesting that local environmental variables are probably important is the observation that the incidence of hyperbilirubinemia in G6PD-deficient infants born in Australia to Greek immigrants is lower than that noted in deficient infants in Greece ([125]). Herbs used in traditional Chinese medicine and clothing impregnated with naphthalene also are examples of covert oxidants to which susceptible infants may be exposed. Moreover, drugs (e.g., sulfonamides), chemicals (e.g., ascorbate), and fava bean ingestion by mothers in late gestation have been implicated as the inciting stimulus of hemolysis in newborns ([102], [126]). Although the cause of hyperbilirubinemia in G6PD-deficient infants sometimes reflects accelerated red cell breakdown ([111], [123], [127]), often there is no obvious RBC destruction or oxidant exposure, and it has been suggested that hyperbilirubinemia may have another etiology, possibly related to impaired liver clearance of bilirubin. In support of this hypothesis are the observations that carboxyhemoglobin production, a marker of hemolysis or RBC breakdown, is the same in G6PD Mediterranean–deficient neonates with or without hyperbilirubinemia ([128]). It is now believed that the variable degree of hyperbilirubinemia in G6PD-deficient neonates reflects the presence or absence of the variant form of uridine-diphosphoglucoronylsyl-transferase responsible for Gilbert syndrome ([112]). The relative importance of the latter is underscored by the observation that most jaundiced G6PD-deficient neonates are not anemic and that evidence for increased bilirubin production secondary to hemolysis often is lacking ([129]).

DIAGNOSIS Because of its prevalence and worldwide distribution, G6PD deficiency should be given serious consideration in the differential diagnosis of any nonimmune hemolytic anemia. Most commonly, anemia is first recognized during or after an infectious illness or after exposure to one of several suspect drugs or chemicals. Clinical and hematologic features reflect the severity of hemolysis but are not themselves specifically from G6PD deficiency. Irregularly contracted erythrocytes (eccentrocytes with hemoglobin puddled to one side of the RBC) and “bite” cells are seen in the Wright-stained peripheral blood smear. Previously, these bite cells were considered a consequence of splenic removal of Heinz bodies. Now, however, it is recognized that these RBCs contain a coagulum of hemoglobin that has separated from the membrane, often leaving an unstained non–hemoglobin-containing cell membrane (i.e., having the appearance of a bite removed from the cell) ([79]). These morphologic alterations are a consequence of the oxidative assault on hemoglobin. Brilliant cresyl blue supravital stains of the peripheral blood may reveal Heinz bodies during hemolytic episodes. The specific diagnosis of G6PD deficiency is made by adding a measured amount of hemolysate to an assay mixture containing substrate (glucose-6-phosphate) and cofactor (NADP) and then spectrophotometrically measuring the rate of NADPH generation ([130]). Alternatively, a variety of screening tests that use hemolysate as a source of enzyme also can be used. The fluorescent spot test is the simplest, most reliable, and most sensitive of the screening methods ([131]). This test is based on the fluorescence of NADPH after glucose-6-phosphate and NADP are added to a hemolysate of test cells. Other screening methods detect NADPH generation indirectly by measuring the transfer of hydrogen ions from NADPH to an acceptor. In the methemoglobin reduction test ([132]), methylene blue is the acceptor used for the transfer of hydrogen from NADPH to methemoglobin, thereby facilitating its reduction. It is important to mention this test because, when combined with a technique for the elution of methemoglobin from intact cells, it can be used to detect relative G6PD sufficiency of individual RBCs ([133]), thereby detecting the carrier state with approximately 75% reliability. Regardless of the specific test used to detect G6PD deficiency, however, false-negative reactions occur if the most severe enzyme-deficient RBCs have been removed by hemolysis. This generally is not critical in testing male whites, but it certainly is a problem in diagnosing some white females and blacks of both sexes, especially during the reticulocytosis after acute hemolysis. In these cases, family members can be studied. An alternative approach to diagnosis is to wait until the hemolytic crisis is over and reevaluate the patient after the RBC mass is repopulated with cells of all ages (approximately 2 to 3 months).

TREATMENT Management of the patient with G6PD deficiency is determined by the clinical syndrome with which it is associated. Individuals having variants associated with acute hemolysis on rare occasions may have a significant fall in hemoglobin concentration requiring a RBC transfusion. This is more commonly the case in G6PD Mediterranean (class II) than in G6PD A- (class III). All affected individuals should avoid exposure to drugs known to trigger hemolysis. Pregnant and nursing women known to be heterozygous for the deficiency also should avoid ingestion of drugs with oxidant potential because some drugs gain access to the fetal circulation and to breast milk. If the indication for its use is sound, however, an offending drug justifiably may be given despite modest shortening of red cell survival. For example, primaquine can be safely given to individuals with the G6PD A- variant, provided it is started cautiously (15 mg/day or 45 mg once or twice weekly) and the blood count is monitored closely ([134]). The mild anemia caused by its administration is rapidly corrected by a compensatory erythropoietic effort and does not recur unless the dose of drug is escalated. Chronic nonspherocytic hemolytic anemia due to class I G6PD variants may require more active intervention. Exchange transfusion during the first week of life often is required to prevent bilirubin encephalopathy. Beyond the newborn period, anemia persists, but it rarely is of such severity as to require regular blood transfusions. During aplastic crises, however, transfusions may be life-saving. As with other syndromes resulting from G6PD deficiency, drugs capable of exaggerating hemolysis should be avoided. Splenectomy, although occasionally bringing about a modest improvement in hemoglobin concentration ([135]), is generally without benefit ([109]). Because of its antioxidant properties, vitamin E has been proposed as a therapeutic agent ([136], [137] and [138]), but subsequent evaluation of large doses of the vitamin failed to demonstrate an ameliorative effect on anemia ([139]). Therapy for neonatal hemolysis and hyperbilirubinemia resulting from G6PD deficiency includes the following: phototherapy or exchange transfusion to prevent kernicterus, RBC transfusion for symptomatic anemia, removal of potential oxidants that may be contributing to hemolysis, and treatment of associated infections. In infants known to be G6PD deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of Sn-mesoporphyrin, an inhibitor of heme oxygenase, is highly effective and safe ([140]). A study from Nigeria has reported a much poorer outcome for G6PD-deficient infants born at home, presumably a reflection of delayed identification and treatment of hyperbilirubinemia in these neonates ([123]). In the United States, there is concern that changes in health care delivery that include early discharge of newborn infants may have similar consequences. In support of this is the report of four newborn infants with G6PD deficiency (three African-American and one mixed Peruvian/Chinese) who developed kernicterus after early hospital discharge ([141]). This report is disturbing because kernicterus in the United States has been rare in recent years and because the adverse outcomes in these four cases occurred despite adherence to the early neonatal discharge guidelines of the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists.

SCREENING Generalized screening for G6PD deficiency does not exist because most common variants responsible for acquired hemolytic anemia pose little serious health hazard. It could be argued that certain Mediterranean populations, especially Kurdish Jews with a 60 to 70% incidence of G6PD deficiency, might benefit from knowing their G6PD status and thereby avoid obvious oxidant exposures. Also, neonatal screening for G6PD deficiency has been very effective in reducing the incidence of favism later in life in Sardinia ([142]) and other regions where this potentially fatal complication is common ([111]). In the United States, where the most common G6PD mutation is the A- variant found in African Americans (who are much less susceptible to favism and in whom life-threatening hemolytic episodes are rare), neonatal screening is not considered to be cost-effective. The class I G6PD variants associated with chronic hemolysis are so rare as to render screening impractical. Similarly, prenatal diagnosis using molecular techniques is potentially available, but the benign course of most G6PD variants has precluded its development ([143]). Routine blood bank screening likewise appears to be unwarranted, and G6PD deficiency is not considered a problem in transfusion medicine. Even in areas where G6PD deficiency is endemic, screening of blood donors is not required. One careful evaluation of the recipients of G6PD-deficient blood uncovered no deleterious consequences ([144]). However, patients receiving G6PD Mediterranean blood may have an increased serum bilirubin and lactate dehydrogenase (LDH) concentration after transfusion, and this can be confused with a transfusion reaction ([145]). In premature infants, simple transfusions with G6PD-deficient red cells have been associated with hemolysis and severe hyperbilirubinemia requiring exchange transfusion ([146]). Also, massive intravascular hemolysis has occurred in an Indian neonate after an exchange transfusion with G6PD-deficient blood ([147]). In view of these occurrences, it has been recommended that, in areas where G6PD deficiency (presumably class II variants) is common, donor blood should be screened for the enzyme before transfusing premature infants ([146]) or using the blood for a neonatal exchange transfusion ([147]). This recommendation currently is not standard blood-banking practice.

Related Disorders of Hexose Monophosphate Shunt and Glutathione Metabolism

In addition to G6PD, other enzymes of the HMP shunt pathway [6-phosphogluconate dehydrogenase (6PGD)], the closely linked reactions of glutathione metabolism (GSSG-Red, GSH-Px), and the glutathione synthetic pathway are important in protecting RBCs against oxidant injury. Rare abnormalities in several of these enzymes have been reported, and, in some cases, they are associated with hemolysis.

6-Phosphogluconate Dehydrogenase Deficiency The enzyme 6PGD catalyzes the conversion of 6-phosphogluconate to pentose-5-phosphate (Fig. 33.2), and, in the process, NADPH is generated from NADP. Although deficiency of 6PGD is well documented, it appears to have little or no significance for red cell viability. Presumably, this reflects the fact that NADPH is generated by the proximal enzyme, G6PD, suggesting that the second dehydrogenase may not be necessary for cell

integrity. A mutant 6PGD (the “Whitechapel” variant) is transmitted as an autosomal-recessive trait. Heterozygotes have one-half normal activity and are asymptomatic ([148] , [149]). Homozygotes have only 2 to 5% normal enzyme activity, but there rarely are hematologic or other clinical expressions of the enzyme deficiency ([150] , [151]).

GLUTATHIONE REDUCTASE DEFICIENCY GSSG is reduced in the presence of NADPH by glutathione reductase (GSSG-Red) (Fig. 33.2). The amino acid sequence of the purified enzyme has been determined ([152]). It contains flavin adenine dinucleotide as a prosthetic component, and, as a result, normal enzyme activity is dependent on the dietary availability of riboflavin. Not surprisingly, partial GSSG-Red deficiency is a relatively common feature of disorders that are compounded by suboptimal nutrition ([153]). GSSG-Red levels are restored within days by the administration of physiologic quantities of riboflavin ([154]). The association between riboflavin-induced GSSG-Red deficiency and various disease states is of no hematologic consequence ([154] , [155]). Genetically determined GSSG-Red deficiency has been documented in three siblings who were offspring of a consanguineous marriage ([156]). Enzyme activity was not enhanced by incubation of hemolysates with flavin adenine dinucleotide. Despite near absence of erythrocyte GSSG-Red activity, the siblings were hematologically normal, except for episodes of hemolysis after the ingestion of fava beans. Very low activity of GSSG-Red was found also in leukocytes, but no increased susceptibility to infection was noted ([157]). Two of the siblings acquired cataracts at an early age. During the past 20 years, there have been no new reports of hereditary GSSG-Red deficiency associated with hemolysis.

GLUTATHIONE PEROXIDASE DEFICIENCY GSH-Px catalyzes the oxidation of GSH by peroxides, including hydrogen peroxide and organic hydroperoxides (Fig. 33.2). Rare cases of hemolysis in association with moderate deficiency of erythrocyte GSH-Px activity have been described in adults and children ([158] , [159] and [160]). Of all the reported cases suggesting a relationship between hemolysis and GSH-Px deficiency, one of the most persuasive was that of a 9-month-old Japanese girl with chronic nonspherocytic hemolytic anemia ([161]). This patient's erythrocyte GSH-Px activity was 17% of control activity, whereas her hematologically normal parents had 51 to 66% of control enzyme activity. However, it is not known whether this specific enzyme defect was responsible for the patient's chronic hemolytic anemia. The general consensus today is that GSH-Px deficiency is probably not a cause of hemolysis or other hematologic problems. The reason for this opinion is that many healthy normal individuals, particularly those of Jewish or Mediterranean ancestry, have reduced GSH-Px activity without evidence of hemolysis ([162]). Moreover, low GSH-Px activity in the absence of hemolysis also is observed in normal people from New Zealand with selenium deficiency (selenium being an integral part of GSH-Px) ([163] , [164]). In view of these observations, the putative role of GSH-Px deficiency as a cause of hemolysis is being questioned. Some argue that GSH-Px is only one of the cellular mechanisms available to detoxify peroxides. Under physiologic conditions, catalase and nonenzymatic reduction of oxidants by GSH also may be important factors regulating the rate of H_2O_2 detoxification. From a clinical perspective, however, because of the controversial role of GSH-Px as a cause of hemolysis, any patient with hemolytic anemia and reduced GSH-Px activity should also be evaluated for another enzymopathy. Levels of GSH-Px in the erythrocytes of healthy newborn infants are approximately one-half those seen in older children and adults ([165]). Adult levels generally are achieved by 6 to 10 months of age. GSH-Px deficiency has been incriminated as a cause for neonatal jaundice ([166]), although a relationship between GSH-Px levels and magnitude of bilirubinemia has not been identified in prospective studies. When cord RBCs are stressed with peroxide under conditions preventing regeneration of GSH, the amount of GSH oxidized is similar for cord and adult erythrocytes ([167]). Low GSH-Px activity in cord RBCs thus appears to be without functional significance.

DEFECTS IN GLUTATHIONE SYNTHESIS Glutathione is actively synthesized in RBCs and has an intracel-lular half-life of only 4 days, in part due to cellular efflux of GSSG. RBCs are capable of *de novo* GSH synthesis, and this is accomplished by two critical enzymes (Fig. 33.2). ?-Glutamyl-cysteine synthetase (?-GCSynth) catalyzes the first step in GSH synthesis, the formation of ?-glutamyl-cysteine from glutamic acid and cysteine. Glutathione synthetase (GSHSynth) catalyzes the formation of GSH from glutamyl-cysteine and glycine. In many tissues, but not in RBCs, these two enzymes are part of the ?-glutamyl cycle, which is involved with the synthesis and degradation of GSH and is also believed to have a role in amino acid transport across cell membranes. Hereditary hemolytic anemia, characterized by reduced GSH content, has been reported in patients with deficiencies of both ?-GCSynth and GSHSynth activity. The clinical effects of these disorders depend on the severity of enzyme deficiency and whether the ?-glutamyl cycle also is affected in nonerythroid tissues.

?-Glutamyl-Cysteine Synthetase Deficiency ?-GCSynth is a rare hemolytic anemia that was first described in two adults who were brother and sister ([168]). Both of these patients had a life-long history of mild hemolytic anemia, intermittent jaundice, cholelithiasis, and splenomegaly. They also manifested severe neurologic dysfunction and generalized aminoaciduria ([169]). This disorder appeared to be an autosomal-recessive condition, and, in the family studied, presumed carriers had reduced ?-GCSynth activity, although erythrocyte GSH levels were normal. Hemolytic anemia was seen only in the homozygous state in which erythrocyte GSH levels were approximately 5% of normal, and there was markedly reduced ?-GCSynth activity. A second patient with ?-GCSynth deficiency, unrelated to the first cases, was a 22-year-old woman with markedly reduced RBC GCSynth activity, severely reduced erythrocyte GSH concentration, and chronic hemolytic anemia ([170]). Family members of this patient had 50% reduced enzyme activity but no decrease in RBC glutathione content or evidence of hemolysis. Of particular interest, in contrast to the first patients described with GCSynth deficiency, this patient had no neurologic disease. Subsequently, there have been reports of a few other affected families with ?-GCSynth deficiency manifested by hemolytic disease without neurologic involvement; the molecular defect in these cases was associated with different missense mutations ([171] , [172]). There is no specific therapy for GCSynth deficiency, although it would seem prudent to obtain periodic gallbladder ultrasound examinations because affected patients have had cholecystectomies.

Glutathione Synthetase Deficiency GSHSynth deficiency has been incriminated as the cause of chronic hemolytic anemia alone (due to isolated RBC enzyme deficiency) and as the cause of a generalized syndrome (due to enzyme deficiency in many tissues) characterized by mild hemolytic disease, severe metabolic acidosis, and mental deterioration. The first syndrome, mild hemolytic anemia and intermittent jaundice, has been described in several families ([173] , [174] , [175] , [176] , [177] , [178] , [179] and [180]). Exposure to oxidant drugs and to fava beans has occasioned temporary acceleration of hemolysis. Splenomegaly has been noted in approximately one-half of the reported cases. A concurrent deficiency of glutathione S-transferase (GSH-ST) is believed to be caused by the instability of this enzyme in the absence of adequate intracellular GSH ([173]). The second, more generalized syndrome is characterized by mild hemolytic anemia, persistent metabolic acidosis presenting in the newborn period, and progressive cerebral and cerebellar degeneration ([179] , [181] , [182]). The latter is characterized pathologically by atrophy of the granular cell layer of the cerebellum and focal lesions in the cortex and thalamus ([183]). Acidosis is caused by the accumulation of 5-oxoproline, a metabolic product of ?-glutamyl-cysteine. Abnormally large quantities of the dipeptide are produced because of the loss of feedback inhibition of ?-GCSynth by GSH. This disorder is suspected in patients with hemolytic anemia and markedly reduced RBC GSH content. Virtually no GSHSynth activity is detected in homozygous deficient individuals ([168] , [174] , [184]). Rarely, therapy is required for the hematologic consequences of GSH deficiency. Exposure to drugs and chemicals with oxidant potential should be avoided by those individuals with chronic hemolytic anemia. In some cases, splenectomy has been efficacious in modifying the anemia, although hemolysis may continue as manifested by persistent reticulocytosis ([177] , [180]). In those individuals with GSHSynth deficiency and oxoprolinemia, oral sodium citrate administration is necessary to control acidosis ([182]).

Glutathione S-Transferase Deficiency GSH-ST conjugates GSH with electrophilic xenobiotics to detoxify them. The enzyme may play a role in the active transport of GSH-xenobiotic conjugates from the red cell. Isolated deficiency of GSH-ST was detected in an adult man with mild hemolytic anemia and splenomegaly ([185]). Because family members were not available for study, a causal relationship between the GSH-ST deficiency and hemolysis could not be established. The significance of this enzyme deficiency remains to be defined.

DISORDERS OF GLYCOLYSIS: GENERAL CONSIDERATIONS

Hemolytic anemias due to glycolytic enzymopathies are relatively rare, affecting only a few thousand individuals ([8] , [186] , [187]) in contrast to G6PD deficiency, which affects millions throughout the world. Abnormalities in virtually every glycolytic enzyme have been described, although over 90% of cases associated with hemolysis are due to pyruvate kinase (PK) deficiency (Fig. 33.4). Most glycolytic enzymopathies manifest an autosomal-recessive pattern of inheritance. Heterozygotes are almost always hematologically normal, although their RBCs contain less than normal levels of enzyme activity. It once was believed that hemolysis occurred only in those individuals who were homozygous for the enzyme deficiency. However, true homozygosity for a given mutant enzyme now is known to be less common and is usually restricted to consanguineous kindred. The vast majority of cases of hemolytic anemia due to glycolytic enzyme deficiencies are a consequence of double heterozygosity for two different enzyme variants, and this accounts for the diverse biochemical and clinical heterogeneity of the red cell glycolytic enzymopathies. The one exception to this autosomal mode of inheritance for glycolytic enzymopathies is phosphoglycerate kinase (PGK) deficiency, which is an X-linked disorder.

Figure 33.4. Overall metabolic pathway of glycolysis in the erythrocyte. Enzymes are shown in boxes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; DHAP, dihydroxyacetone phosphate; DPG, diphosphoglycerate; DPGM, diphosphoglycerate mutase; DPGP, diphosphoglycerate phosphatase; G-3-P, glyceraldehyde-3-phosphate; G-3-PD, glyceraldehyde-3-phosphate dehydrogenase; GPI, glucosephosphate isomerase; HK, hexokinase; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; PEP, phosphoenolpyruvate; PFK, phosphofructokinase; PG, phosphoglycerate; PGK, phosphoglycerate kinase; PGM, phosphoglycerate mutase; PK, pyruvate kinase; LDH, lactate dehydrogenase; TPI, triose phosphate isomerase.

Clinical manifestations of hemolysis due to glycolytic enzymopathies include chronic anemia, reticulocytosis, and some degree of hyperbilirubinemia. In the vast majority of cases, the hemolytic process is recognized and diagnosed in childhood. Frequently, there is a history of neonatal jaundice, often requiring an exchange transfusion and rarely causing kernicterus. The magnitude of chronic anemia varies; there may be accelerated hemolysis with some nonspecific infections or transient aplastic crises associated with parvovirus infection. In some enzymopathies, such as PK deficiency, the adverse consequences are restricted to the erythrocyte. In other cases, such as in phosphofructokinase (PFK), aldolase, triose phosphate isomerase (TPI), and PGK deficiencies, hemolytic anemia is but one feature of multisystem disease (Table 33.3).

TABLE 33.3. Features of Glycolytic and Nucleotide Enzymopathies

Enzymopathy	Approximate Fraction of Enzymopathies [a] (%)	Mode of Inheritance	Molecular Abnormalities Identified to Date (Reference)	Effects of Enzymopathy
Hexokinase	<1	AR	2 (262, 263)	Mild/severe CNSHA
Glucosephosphate isomerase	3–5	AR	29 (272, 278)	Moderate/severe CNSHA ± neurologic deficits
Phosphofructokinase	<1	AR	15 (303)	Mild CNSHA ± myopathy
Aldolase	<1	AR	4 (316, 317, 318 and 319)	Mild/moderate CNSHA ± myopathy
Triose phosphate isomerase	<1	AR	14 (325)	Moderate/severe CNSHA, neurologic deficits
Phosphoglycerate kinase	<1	X-linked	14 (302)	Mild/severe CNSHA ± neurologic deficits ± myopathy
Pyruvate kinase	80–90	AR	133 (208)	Moderate/severe CNSHA
Pyrimidine 5' nucleotidase	2–3	AR	—	Moderate CNSHA
Adenosine deaminase excess	<1	Autosomal dominant	—	Mild CNSHA
Adenylate kinase	<1	AR	6 (413)	CNSHA

AR, autosomal recessive; CNSHA, chronic nonspherocytic hemolytic anemia.

[a] Approximate estimates derived from references 186, 187, 266, and Mentzer W. Pyruvate kinase deficiency and disorders of glycolysis. In: Nathan DG, et al., eds. Hematology of infancy and childhood. Philadelphia: WB Saunders, 2003.

The possibility of a glycolytic defect usually is considered when chronic hemolytic anemia cannot be explained by the more common causes (i.e., hereditary spherocytosis or hemoglobinopathies). There are no specific morphologic abnormalities, although anisocytosis and poikilocytosis are common. In virtually all cases, a specific assay of RBC enzyme activity is necessary to make the diagnosis. Screening tests are readily available, but these have limited value when there is a partial deficiency or a mixed population of RBCs. A particular problem in identifying glycolytic enzymopathies relates to the fact that the most severely deficient cells are removed (i.e., hemolyzed), and the remaining cells may be biochemically less abnormal. Consequently, “false-negative” assays can obscure the correct diagnosis. For this reason, it is sometimes helpful to study parents and other family members for the presumed heterozygous state of the enzyme deficiency. In some cases, DNA-based molecular diagnostic tests may be available.

Therapy for RBC glycolytic defects is similar to that for other chronic hemolytic anemias. RBC transfusions often are indicated. Splenectomy usually is beneficial in severely anemic patients because the spleen (along with the liver) participates in the destruction of enzymatically abnormal cells. In most cases, however, the response to splenectomy is only partial, and hemolysis usually continues, although RBC transfusion requirements may decrease. Cholelithiasis is a common problem, and all patients with glycolytic enzymopathies should have periodic gallbladder ultrasound examinations, even after splenectomy. The biologic and clinical features of specific glycolytic disorders are summarized in the following paragraphs.

Pyruvate Kinase Deficiency

Of the enzymatic deficiencies involving glycolysis, PK deficiency is the most common, the most extensively studied, and the first to be recognized. Over 400 cases have been reported (188, 189, 190, 191 and 192). Undoubtedly, there many more cases, because newly diagnosed patients currently are not reported unless there are unusual associated findings.

GEOGRAPHIC DISTRIBUTION Most cases of PK deficiency have been reported from Northern Europe, the United States, and Japan; however, the disorder occurs worldwide (186, 189, 190). The frequency of the heterozygote state has been estimated on the basis of studies that screened various populations for low enzyme activity. In Germany and in the United States, the prevalence of apparent heterozygosity for PK deficiency has been estimated to be approximately 1% (189). In one report from Hong Kong, 3% of newborn infants were noted to be heterozygous for a PK variant (193). A particularly high frequency exists among the Pennsylvania Amish, in whom the disorder can be traced to a single immigrant couple (194, 195 and 196). In studies of the most common PK mutations found in a white population, a prevalence of PK deficiency has been estimated to be 51 per million population (197).

BIOCHEMICAL GENETICS PK catalyzes the conversion of phosphoenolpyruvate to pyruvate; this is one of the two glycolytic reactions resulting in net ATP production (Fig. 33.4). The enzyme is allosterically activated by fructose-1,6-diphosphate (FDP) and is inhibited by its product, ATP. PK is a tetrameric protein with a molecular weight of 230 kd. There are two different PK genes (PKM2 and PKLR), which encode for four distinct PK isozymes. The PKM2 gene has been cloned and assigned to chromosome 15 (15q22) (198); it encodes for two isozymes (PK-M2 and PK-M1). PK-M2 is the isozyme present in all tissues during fetal life. As fetal maturation proceeds, other tissue-specific PK isozymes begin to appear. PK-M2 persists as the predominant isozyme in mature leukocytes and certain other tissues (platelets, lung, kidney, spleen, adipose tissue). In addition, PK-M2 is the major isozyme in erythroid precursors (8). PK-M1, which differs from PK-M2 as a result of alternative splicing, is the PK isozyme present in mature muscle and brain tissue (199). The PKLR gene has been cloned and assigned to chromosome 1(1q21) (200);

it also encodes for two isozymes (PK-L and PK-R). PK-L is the predominant isozyme in hepatocytes ([201]). PK-R is the isozyme present in mature erythrocytes ([202] , [203]). The chemical differences between PK-L and PK-R are due to tissue-specific promoters. The hemolytic anemia associated with PK deficiency is due to mutations of the PKLR gene. In some patients with hemolytic anemia, a decrease in the liver PK-L isozyme has also been observed, but this is of no clinical significance because the liver also has residual PK-M2 activity ([204] , [205] and [206]). During normal erythroid differentiation, the PK isozyme switches from the M2- to the R-type ([8]). It is of interest that in one severe form of PK deficiency (PK Beppu), PK-M2–type persists in mature erythrocytes, and it has been proposed that this compensatory PK-M2 production allows affected red cells to survive, analogous to the beneficial effect of persistent fetal hemoglobin production in homozygous ß-thalassemia ([8]). At last report, 133 different mutations of the PKLR gene have been identified as causes of chronic hemolytic anemia ([190] , [207] , [208] and [209]). Most of these are missense mutations (approximately 70%), although a few are either nonsense or insertional mutations, deletions, or splicing abnormalities ([8] , [208]). Most of the known PK mutations are very rare, occurring only once; however, three mutations are seen with some frequency ([190]). A significant fraction of affected whites (30 to 40%) have at least one 1529G?A mutation resulting in an amino acid change (510Arg?Gln) ([209] , [210]). This particular mutation is found in the United States and in northern Europe. A second common mutation, 1456C?T (484Arg?Trp), is observed in Spain, Portugal, and Italy where it accounts for approximately 30% of all cases. However, in this area of southern Europe, the 1529G?A mutation is rare. A third common mutation, 1468C?T (Arg490?Trp), is found predominantly in the Eastern Hemisphere. The PK deficiency seen in the Amish population is associated with one mutation 1436G?A (479Arg?His) ([196]). The variable phenotypic expression of PK deficiency undoubtedly reflects the heterogeneity of these different PK mutants. At one time, PK deficiency was believed to be a consequence of decreased production of a structurally normal enzyme, but it is now recognized that most PK variants are abnormal proteins that differ with respect to their biochemical kinetics and physical properties ([211] , [212] and [213]). The heterozygous state for a PK variant is clinically silent. In a few cases, mild hemolytic disease has been attributed to heterozygosity for a single mutant PK enzyme ([193] , [213] , [214]); however, the diagnostic methods used do not exclude the possibility of a second PK mutant. There is little or no relationship between severity of hemolysis and the assessment of PK activity *in vitro* ([8] , [189]). In part, this reflects the fact that *in vitro* assay conditions are very different from what exists *in vivo*. In addition, the presence of young RBCs with elevated enzyme activity can mask the presence of a very unstable PK variant, or there can be persistence of PK-M2 in mature RBCs ([8] , [215] , [216]). Moreover, because most individuals with PK deficiency are doubly heterozygous for two different PKLR mutants ([8]), the study of RBCs from affected subjects characterizes the mixture of PK variants without providing specific information about the individual enzymes. In the minority of individuals with homozygous disease, a relationship between defective PK enzymes and severity of hemolysis occasionally is apparent ([192] , [211] , [212]). The characteristics of PK variants associated with severe hemolysis in these presumed homozygotes include decreased affinity for phosphoenolpyruvate, increased inhibition by ATP, thermal instability, and impaired response to the allosteric activator FDP ([211] , [212] , [217] , [218]). Clearly, the current molecular biology studies to identify PKLR mutations associated with PK deficiency should further clarify the relationship of gene structure and hemolysis ([190]).

PATHOPHYSIOLOGY PK deficiency results in impaired glucose utilization and, thereby, decreased pyruvate and lactate production. In addition, glycolytic intermediates proximal to the block accumulate in red cells, and the levels of 2,3-DPG may increase up to threefold ([219] , [220]). The major impairment due to PK deficiency is a diminished capacity to generate ATP ([221]). Paradoxically, however, PK-deficient patients with high reticulocyte counts may have normal or even elevated levels of ATP ([221]). This occurs because PK-deficient reticulocytes generate ATP through mitochondrial oxidative phosphorylation, and this is associated with a six- to sevenfold increase in oxygen consumption compared to normal reticulocytes ([221] , [222]). The advantage of oxidative phosphorylation for PK-deficient reticulocytes is that ATP can be generated, requiring minimal flow of pyruvate from glycolysis. When reticulocytes mature, however, mitochondria disappear, oxidative phosphorylation ceases, and ATP levels fall. The effects of this vary because there are marked cellular differences in the enzyme content of PK-deficient red cells. In severely PK-deficient RBCs, the fall in ATP leads to cell injury, although the precise ATP-dependent reactions leading to irreversible membrane injury are not known. In some cases, this injury is characterized by an increase in membrane calcium, accelerated potassium loss, decreased total monovalent cation content, and cellular dehydration ([222]). The end result of these changes is a loss of membrane plasticity and the formation of rigid RBCs marked for premature destruction in the spleen ([223] , [224]). Those reticulocytes most deficient in PK are doomed to almost immediate extinction once they lose their mitochondria. Less severely deficient cells survive to a nearly normal age, their ATP needs satisfied despite marginal metabolic resources ([222]). This vulnerability of enzyme-deficient reticulocytes is seen in erythrokinetic studies, which demonstrate that reticulocyte-rich fractions of blood from PK-deficient subjects have a shorter survival than do reticulocyte-poor fractions ([222] , [224]). Given the unique metabolic abnormalities of the PK-deficient reticulocyte, it is understandable why the spleen poses a problem for them. Because of their greater adhesive tendencies, reticulocytes endure a longer sojourn in the spleen ([223] , [224]), where limited oxygen and glucose restrict effective oxidative phosphorylation ([222]). Impaired ATP production then leads to RBC destruction in the spleen or in the liver after escape from the spleen ([223] , [224]). Because severely deficient reticulocytes are metabolically more stable in the absence of the spleen, an exaggerated and sustained reticulocytosis follows splenectomy ([189]). As noted previously, the concentration of 2,3-DPG may be up to three times normal ([219]). This increase is responsible for a rightward shift in the oxygen dissociation curve of hemoglobin. As a result, PK-deficient subjects have a greater exercise tolerance than would be expected from the degree of anemia ([220]).

CLINICAL FEATURES The clinical expression of PK deficiency is quite variable, ranging from hydrops fetalis ([225] , [226]) to pronounced neonatal jaundice requiring multiple exchange transfusions ([193] , [227] , [228]) and occasionally complicated by kernicterus ([194] , [229]) to a fully compensated hemolytic process detected as an incidental finding in adults ([188]). Unlike hemolysis associated with G6PD deficiency, the jaundice noted in PK-deficient infants invariably is associated with anemia and often with splenomegaly. The PK deficiency observed among the Pennsylvania Amish is particularly severe ([194]). Beyond the neonatal period, anemia of varying degree, jaundice, and splenomegaly characterize erythrocyte PK deficiency. There are no specific or distinguishing clinical characteristics of this disorder, and no tissues are affected besides the red cells. Anemia may be surprisingly well tolerated because of the increased red cell 2,3-DPG content, which is responsible for a rightward shift in the oxygen dissociation curve of hemoglobin. The clinical course may be complicated by aplastic crises, characterized by an abrupt but temporary arrest of erythropoiesis and a precipitous drop in hemoglobin concentration and reticulocyte count. These crises usually are related to infection with a parvovirus-like agent that is cytotoxic for erythroid progenitors ([230] , [231]). After the first decade of life, gallstones are detected with increased frequency ([189]). Bone changes associated with hyperplastic bone marrow, such as those seen in thalassemia, occasionally may result in frontal bossing ([232]). Chronic leg ulcers occur rarely ([233] , [234]). Pregnancy has been tolerated without unusual complications ([221]). Iron overload is a predictable complication of chronic transfusion therapy ([234]), but it may also occur in patients with limited or no history of transfusions ([235] , [236] and [237]). Because hemosiderosis occurring in minimally transfused PK-deficient individuals is rare, it has been suggested that this may be due to coexistent inheritance of the more common hereditary hemochromatosis gene ([235] , [236]).

DIAGNOSIS Anemia due to PK deficiency is moderate to severe in degree. The hemoglobin concentration characteristically is 6 to 12 g per dl ([189]). The peripheral blood reveals all the morphologic hallmarks of accelerated erythropoiesis: polychromatophilia, anisocytosis, poikilocytosis, and variable numbers of nucleated red cells. Irregularly contracted erythrocytes with surface spicules ([238]), tailed poikilocytes ([221]), and acanthocytes ([229]) have been observed in the smears of some affected individuals. Before splenectomy, the reticulocyte count may be increased (5 to 15%), but after splenectomy, reticulocyte counts as high as 70% occasionally are noted ([189] , [212]). This is due to the longer survival of PK-deficient reticulocytes after splenectomy. The hematologic features of PK deficiency are not distinctive. The specific diagnosis rests on laboratory documentation. The once used autohemolysis test has no current use in the diagnosis of PK deficiency ([239]). Simple specific enzyme screening tests are available, but false-negative results are common because of the many different variant enzyme kinetics. In cases in which PK deficiency is suspected, a direct quantitative assay of the enzyme is essential. Leukocytes must be excluded from the system because the leukocyte PKM2 gene is not affected in hemolytic variants of PK deficiency, and the PK activity of white blood cells is 300 times that of normal red cells ([240]). Most deficient individuals have 5 to 25% of the normal mean activity. Heterozygous carriers of a PK variant have approximately one-half normal activity, although there is considerable overlap with normal. The biochemical heterozygote sometimes is difficult to detect. Recommended methods for the characterization of PK variants have been established by the International Committee for Standardization in Hematology ([211]). In patients, usually infants, who are transfused before the enzyme disorder is recognized, the dilution of enzyme-deficient RBCs with transfused cells often makes it difficult to make the diagnosis based on chemical enzyme analysis. In these cases, molecular diagnostic techniques that require small amounts of DNA may become very useful ([209]). In families with a child with PK deficiency, the issue of prenatal diagnosis in subsequent pregnancies is a matter of concern. There is one report in which biochemical techniques were used successfully to assay for red cell PK deficiency at 30 weeks of gestation ([241]). However, because of the large volume of blood necessary to characterize the enzyme and distinguish PKLR and PKM gene products, biochemical enzyme assays most likely will have limited utility in the prenatal diagnosis of PK deficiency. For this reason, direct DNA analysis is preferred whenever possible ([242]). In one family in which both parents were heterozygotes for PK deficiency and the DNA defect was known, analysis of amniocytes indicated that the fetus was not involved ([242]). In another family with a known mutation, PK-deficiency was diagnosed on the basis of cord blood DNA studies ([242]). In the latter case, the family did not want prenatal testing, but the results indicate that a positive diagnosis of this disorder could have been made prenatally. Most assuredly, molecular diagnostic techniques for the prenatal diagnosis of PK deficiency will prove to be useful. In particular, this should be helpful in diagnosing those fetuses with the more common mutation described above, believed to account for 45% of cases of PK deficiency in non-Gypsy whites. The large number of cases of PK deficiency in Gypsies is associated with a unique deletional mutation that also could be used for molecular diagnosis ([242]). Acquired erythrocyte PK deficiency has been observed in patients with acute leukemia, preleukemia, and refractory sideroblastic anemia and after exposure to chemotherapy ([243] , [244]). The causes of acquired enzyme deficiency are multifactorial. In some cases, injury of bone marrow stem cells with disturbance of protein synthesis is likely, whereas in other cases a posttranslational modification of the enzyme may be responsible ([243]). In cases of acquired PK deficiency, the degree of enzyme deficiency is not severe enough to cause hemolytic anemia.

TREATMENT During the first years of life, severe anemia is managed with red cell transfusions. Maintenance of the hemoglobin concentration above 8 g per dl permits normal growth and development while minimizing the risk of life-threatening aplastic crises. The decision for transfusion therapy must relate to patient

tolerance of anemia rather than an arbitrary level of hemoglobin. Because of increased red cell 2,3-DPG content, patients may tolerate moderately severe anemia with little problem ([220]). Splenectomy is useful for long-term control of anemia. However, because of the well-known risk of postsplenectomy sepsis due to *Streptococcus pneumoniae* in young children, surgery should be delayed until 5 years of age whenever possible. Preoperative assessment of red cell survival and splenic sequestration is of no value in selecting patients for splenectomy, and this in part reflects the importance of the liver as a site of red cell destruction. Splenectomy is followed by improvement, but not correction, of the hemolytic disorder ([189] , [221] , [224]). Transfusion requirements, if present before splenectomy, decrease or are eliminated. In almost all patients, an incompletely compensated hemolytic process with reticulocytosis, some degree of hyperbilirubinemia, and an ongoing risk for gallstone formation usually persist. A severe hemolytic anemia associated with PK deficiency in basenji dogs has been corrected by bone marrow transplantation ([245]). Similarly, marrow transplantation has been shown to be effective in mutant mice with splenomegaly and chronic hemolytic anemia due to PK deficiency ([246]). These successes with bone marrow transplantation in animals clearly indicate a possible role for this therapy in humans. There is one report of a 5-year-old boy with transfusion-dependent hemolytic anemia due to PK deficiency who received an HLA-identical bone marrow transplant from his sister; he is alive and well at 8 years of age without evidence of hemolysis ([247]). Despite the success in this one patient, in almost all cases of hemolytic anemia due to PK deficiency, the risk-benefit ratio currently remains weighted in favor of splenectomy over bone marrow transplantation. In the future, this may change. Moreover, PK deficiency (as a single-gene defect, of recessive inheritance, affecting primarily one cell line, and being amenable to hematopoietic stem cell modification) is considered a candidate disease for gene therapy, and preliminary studies are in progress in this area ([248]). A variant associated with increased PK activity has been described. RBCs from affected family members displayed high levels of ATP and low levels of 2,3-DPG with an associated erythrocytosis ([249]).

Other Glycolytic Enzymopathies

Hexokinase Deficiency Hexokinase (HK) catalyzes the conversion of glucose to glucose-6-phosphate (Fig. 33.4). As the first enzyme in the glycolytic pathway, HK has a strategic role in the regulation of glucose consumption. The activity of HK declines rapidly as red cells age, and, in older cells, HK activity is lower than that of any other glycolytic enzyme. Deficiency of HK is responsible for subnormal glucose consumption and lactate production ([250]). The concentrations of glycolytic intermediates and ATP are decreased ([250] , [251]). The concentration of 2,3-DPG also may be low, and this has consequences on hemoglobin-oxygen affinity and work performance (see below). There are four HK isozymes, and each one is coded for by a different gene (HK1, HK2, HK3, HK4). The HK1 gene codes for the HK found in erythrocytes, and this gene maps to chromosome 10 ([252] , [253] and [254]). Type I HK isozyme also is present in lymphocytes and platelets. However, deficiency of type I HK isozyme in lymphocytes is offset by an increase in the amount of type III isozyme ([255]). As with PK deficiency, deficient HK activity may result from quantitative deficiency of an apparently normal enzyme ([251] , [256]) or from abnormalities that affect substrate affinity ([250] , [257] , [258]) or heat stability ([259] , [260] and [261]). The molecular defect in HK deficiency has been identified in one individual with HK deficiency (HK Melzo) associated with chronic hemolytic anemia ([262]). In this mutation, one allele has a 96 bp deletion, whereas the other allele has a single base pair substitution causing a single amino acid substitution. In a Dutch family with HK deficiency (HK Utrecht) and hemolytic anemia, a missense mutation (2039C?G) also has been identified ([263]). Seventeen different kindred with HK deficiency have been described in families of European, Mediterranean, Scandinavian, and Asian background ([251] , [254] , [256] , [257] and [258]). The inheritance pattern is consistent with an autosomal-recessive mode of transmission. In approximately 25% of reported cases, neonatal hyperbilirubinemia can occur and may require exchange transfusion ([250] , [256] , [264]). In many affected individuals, mild anemia or recurrent episodes of jaundice are not noted until after the first decade of life. Splenomegaly is common. Regular RBC transfusions may be required in severely affected patients ([256]). Splenectomy ameliorates but does not cure the hemolytic process ([250] , [256] , [257]). Symptoms may be out of proportion to the degree of anemia because low levels of erythrocyte 2,3-DPG reduce oxygen release to tissues at any given oxygen tension ([220] , [265]). There are no unique RBC features associated with HK deficiency. The diagnosis rests on the assay of red cell HK activity. Because HK is among the most age dependent of red cell enzymes, its activity must be considered in relation to the reticulocyte count or the activity of other age-dependent enzymes ([256]).
GLUCOSEPHOSPHATE ISOMERASE DEFICIENCY Glucosephosphate isomerase (GPI) catalyzes the interconversion of fructose-6-phosphate and glucose-6-phosphate (Fig. 33.4). Although a very rare cause of hemolysis, GPI deficiency is the third most common enzymatic defect associated with hemolytic disease, exceeded only by deficiencies of G6PD and PK ([266]). Since the first description of the disorder in 1968 ([267]), approximately 50 cases have been reported ([8] , [268] , [269] , [270] , [271] and [272]). Just as in the case of PK deficiency, many more cases probably exist but are not published or listed in any rare disease registry. It is estimated that 0.2% of North Americans are heterozygous for a GPI mutant ([273]). The gene for GPI is located on chromosome 19, and it has been isolated and sequenced ([274] , [275]). Twenty-nine different gene mutations of GPI associated with hemolysis have been identified ([8] , [272] , [276] , [277] and [278]). A single form of GPI is synthesized by all cells of the body; consequently, structural mutations of the enzyme are expressed in all tissues ([270] , [279]). Because most mutations result in enzyme instability ([280]), the defect imposes functional compromise only in older mature erythrocytes. Both missense mutations and gene deletion have been described ([272] , [276] , [281] , [282]). It is inherited in an autosomal-recessive manner. Obligate heterozygotes for mutant alleles are hematologically normal but have reduced red cell GPI activity. Symptomatic GPI deficiency results equally from homozygosity for a single mutant gene and compound heterozygosity for two different abnormal alleles ([8] , [276] , [281] , [283]). Compared with normal red cells of similar age, GPI-deficient cells accumulate glucose-6-phosphate and are deficient in ATP and 2,3-DPG ([279]). Also, GPI-deficient RBCs are less able to support increased metabolic flow through the HMP shunt because fructose-6-phosphate must pass through the GPI reaction in reverse direction. An animal model of GPI deficiency in the mouse may help clarify the pathophysiology ([284]). The severity of hemolytic disease varies considerably. Hydrops fetalis with death in neonates has been reported ([283] , [285] , [286]), and anemia and hyperbilirubinemia complicate the postnatal course in many patients ([270] , [279]). Chronic transfusion therapy may be required. As with other chronic hemolytic anemias, the clinical course may be complicated by aplastic and hyperhemolytic crises. Mental retardation and excessive stores of hepatic glycogen were noted in a single patient ([283]). Neuromuscular impairment (hypotonia, ataxia, dysarthria, mental retardation) occasionally has been seen, but only in five of the known variants ([272]). Splenectomy has eliminated or dramatically reduced the transfusion requirement in most patients ([267] , [269] , [270] , [273]). Postsplenectomy hemoglobin concentrations are 8 to 10 g per dl. After splenectomy, reticulocyte counts may increase dramatically (50 to 75%) ([273]). Red cell morphology is characterized by anisocytosis, poikilocytosis, polychromatophilia, and often the presence of nucleated forms. Definitive diagnosis requires specific enzyme assay of a RBC hemolysate. Prenatal diagnosis of GPI by enzymatic assay of amniotic fluid cells was demonstrated in a kindred with unusually severe hemolytic disease ([285]). Antenatal diagnosis also is possible by direct enzyme assay of trophoblastic cells ([287]). Although several abnormal GPI mutations have been identified, to date there is no reported experience using molecular techniques for prenatal diagnosis.
PHOSPHOFRUCTOKINASE DEFICIENCY PFK catalyzes the phosphorylation of fructose-6-phosphate to FDP, and this is one of the rate-limiting reactions of glycolysis (Fig. 33.4). The PFK enzyme in RBCs is a tetrameric protein made up of varying combinations of muscle or M-type subunits, liver or L-type subunits, and platelet or P-type subunits ([288] , [289] and [290]). Three different structural loci encode for these M, L, and P subunits of PFK. The M-type subunit is encoded for a gene on chromosome 1 ([291]), and this gene has been characterized ([292]) and cloned ([293] , [294]). The L-type PFK subunit is encoded by a gene located on chromosome 21 ([295]), and the structural organization of this gene also has been characterized ([296]) and cloned ([297]). The gene encoding for the P subunits of PFK is located on chromosome 10 ([298]). The subunits are variably expressed in different tissues. Muscle and liver PFKs are composed exclusively of M4 and L4 tetramers, respectively. The RBC contains equal amounts of M and L subtypes, and all possible tetrameric variations are present (L_4, L_3M_1, L_2M_2, L_1M_3, M_4) ([290]). Neutrophil PFK is composed primarily of L4 homotetramers, and platelet PFK consists of both P and L subunits. The variable structure of PFK in different tissues provides an explanation for the diversity of syndromes associated with deficiency states. These syndromes include chronic hemolytic disease with myopathy, hemolytic disease alone, and myopathy alone ([299]). The first PFK deficiency syndrome described was characterized by congenital nonspherocytic hemolytic disease and myopathy (Tarui disease, glycogenosis type VII) ([300] , [301]). More than 39 unrelated families have been identified ([302]). It is inherited as an autosomal-recessive disorder. The myopathy is characterized by muscle fatigue and cramping with exercise and pathologically by increased muscle glycogen ([300]). There is a mild compensated hemolytic anemia. The hemoglobin concentration is normal or even increased. Both myopathy and hemolytic disease result from the total lack of M subunit expression. Biopsies of muscle reveal that PFK activity is completely lacking, whereas erythrocyte PFK activity is approximately 50% of normal ([300] , [301] , [303]). The red cell PFK in these patients is composed exclusively of L4 subunits ([290] , [300]). Glycolytic intermediates proximal to PFK are increased in concentration, and those distal to the block are decreased ([303] , [304]). Of particular interest, 2,3-DPG is decreased ([305]), and this presumably leads to an unfavorable shift of the hemoglobin-oxygen affinity, thereby accounting for the mild erythrocytosis in some patients and absence of anemia despite shortened red cell survival in others. PFK deficiency also has been implicated as the cause of hemolytic disease in the absence of myopathy ([290] , [304] , [306] , [307]). Some individuals manifest mild myopathic symptoms during ischemic exercise tolerance tests ([304]). This syndrome is attributed to the synthesis of an unstable but catalytically active M subunit. Muscle cells are protected because of continued synthesis of the enzyme, whereas anucleate erythrocytes, incapable of protein synthesis, sustain early loss of enzyme activity ([306]). Although myopathy without hemolysis has also been attributed to PFK deficiency, hemolytic disease may have been dismissed because of the absence of anemia ([304]). Heterozygosity for L subunit deficiency is associated with approximately one-half normal red cell PFK activity, but with no myopathic or hemolytic features ([304] , [308] , [309]).
ALDOLASE DEFICIENCY Aldolase catalyzes the conversion of fructose-1,6-diphosphate to dihydroxyacetone and glyceraldehyde-3-phosphate (Fig. 33.4). Aldolase is a tetrameric protein, and three tissue isozymes (A, B, C) have been identified ([310]). Type A aldolase, the main isozyme in RBCs and muscle, has been characterized and cloned ([311] , [312]). The gene that encodes aldolase A is located on chromosome 16 ([313]). Aldolase deficiency as a cause of hemolytic anemia is very rare and has been identified in only four kindred. The first case was documented in a child whose parents were first cousins. In addition to mild hemolytic anemia,

the child had hepatomegaly associated with increased glycogen deposition and psychomotor retardation ([314]). A second report of aldolase deficiency, in a Japanese family, described more severe hemolytic anemia (hemoglobin, 6 g per dl; 7 to 8% reticulocytes) without attendant hepatomegaly or developmental delay ([315]). In a third case, a 4-1/2-year-old boy in Germany was identified with aldolase deficiency ([316]). He had a history of neonatal jaundice, recurrent episodes of jaundice beyond the newborn period, and anemia requiring red cell transfusions in the first year of life. In addition, however, he had a myopathy characterized by severe muscle weakness, exercise intolerance, and laboratory evidence of rhabdomyolysis in association with fever and an upper respiratory infection. In a fourth reported case, a young girl of Sicilian extraction had a transfusion-dependent hemolytic anemia requiring splenectomy at 40 months of age ([317]). She also had a myopathy with recurrent and progressive episodes of rhabdomyolysis. She died due to hyperkalemia and rhabdomyolysis during a febrile illness associated with gastrointestinal hemorrhage at 54 months of age. Molecular analysis in each of the above cases has identified several different missense or nonsense mutations, each resulting in a thermolabile unstable enzyme ([316] , [317] , [318] and [319]). The mechanism of hemolysis in these cases is uncertain. Deficient red cells accumulate proximal glycolytic intermediates, especially FDP.

TRIOSE PHOSPHATE ISOMERASE DEFICIENCY TPI catalyzes the reversible isomerization of glyceraldehyde-3-phosphate and dihydroxyacetone phosphate (DHAP) (Fig. 33.4). TPI is a dimeric enzyme composed of identical subunits. Several electrophoretically distinct bands result from posttranslational modification of a single protein ([320]) that is encoded by a single structural gene located on the short arm of chromosome 12 ([321]). Only one isozyme of TPI is produced, and, thus, enzyme deficiency involves all body tissues. Enzyme activity is greatly reduced in red cells as well as in leukocytes, muscle, and skin fibroblasts ([271]). Thirty-five cases of TPI deficiency with hemolytic anemia have been identified. The enzyme abnormality in almost all cases is due to a single amino acid substitution that results in an unstable enzyme ([322]). Fourteen different point mutations in the TPI gene have been identified and reviewed ([323] , [324] and [325]). Eleven are missense mutations resulting in a single amino acid substitution and one is due to a deletion. The majority of the mutants result in heat-labile enzymes with residual catalytic activity. All clinically affected patients have been homozygotes or, less commonly, compound heterozygotes. Of the 14 known mutations, one accounts for the molecular defect in most studied families with TPI deficiency; this variant is due to a 315G?C mutation that results in an amino acid substitution (104Glu?Asp) ([323] , [325]). Hemolysis due to TPI deficiency is one aspect of a multiple system disease. A most unique feature of this enzymopathy is an associated severe neurologic disorder characterized by spasticity, motor retardation, and hypotonia ([325] , [326]). It is inherited as an autosomal-recessive disorder. Heterozygotes, with one-half normal erythrocyte TPI activity, are clinically normal. It is of interest that the frequency of the heterozygous state for TPI deficiency is relatively high (0.1 to 0.5% in whites, 5.5% in blacks) ([327]). Despite this estimate, only 35 individuals with symptomatic disease have been identified ([8] , [299] , [325]). The rare incidence of clinically significant homozygous TPI deficiency suggests incompatibility with fetal life. TPI deficiency is a progressive, ultimately fatal disease. In most cases, anemia and hyperbilirubinemia have been noted at birth or during the first weeks of life ([325] , [326] , [328]). The degree of anemia is variable, but most affected infants and children require periodic blood transfusions. Death from hemolytic anemia in the first week of life occurred in a sibling and in a cousin of the patient described in the first reported case ([326]). Splenectomy appears to have no discernible benefit ([326]). Late in the first year of life, spasticity and a delay in the acquisition of motor skills are noted. Neurologic involvement generally is progressive, giving rise to paraparesis, weakness, and hypotonia. Recurrent systemic infections are a problem in most affected children, but it is not known whether these are related to impaired TPI activity in phagocytes. Death, probably from cardiac arrhythmias, usually occurs before the fifth birthday. In the only adult thus far identified as having TPI deficiency ([329]), neurologic dysfunction, although profound, was stable. An interesting report of TPI deficiency with chronic hemolytic anemia has been described in a 13-year-old boy and his 23-year-old brother. Noteworthy was the observation that the 13-year-old boy had hyperkinetic torsion dyskinesia, but his 23-year-old brother had no neurologic abnormalities ([330] , [331]). The diagnosis of TPI deficiency is suspected in young children with chronic hemolytic disease that is not due to the more common causes of hemolysis. Associated motor neurologic symptoms raise the index of suspicion for TPI deficiency. There are no specific RBC abnormalities. In suspected cases, it is necessary to assay for TPI activity in an RBC hemolysate. Prenatal diagnosis of TPI deficiency initially relied on biochemical analyses of cultured fetal amniocytes, and in one published report, this was successful ([332]). Later, prenatal diagnosis of TPI was attempted by assaying fetal RBCs obtained by ultrasound-guided cordocentesis. The wide variability of normal activity levels and the lack of sufficient control data, however, limited the interpretation of these assays ([333]). Another inherent problem with tests that require fetal blood from cordocentesis is that the procedures cannot be done before 20 weeks of gestation. More recently, the large number of cases associated with the codon 104 mutation has allowed the use of chorionic villous biopsy samples and molecular techniques for prenatal diagnosis ([334] , [335]). The pathophysiologic basis for hemolytic disease is not known. DHAP accumulates 20- to 60-fold ([326]), but the significance of this is unknown because a similar accumulation of DHAP occurs in diphosphoglyceromutase (DPGM) deficiency without any apparent effect.

PHOSPHOGLYCERATE KINASE DEFICIENCY PGK catalyzes the conversion of 1,3-DPG to 3-phosphoglycerate, and this is one of two glycolytic reactions resulting in net ATP generation from adenosine diphosphate (Fig. 33.1). An alternative fate of 1,3-DPG is the formation of 2,3-DPG, a reaction catalyzed by 2,3-DPGM. The product of the latter reaction is 2,3-DPG, an important intermediate that is known to enhance oxygen release from hemoglobin. Hereditary deficiency of PGK activity has been recognized as a rare cause of chronic hemolytic anemia for over 30 years ([336]). Red cells severely deficient in PGK predictably accumulate DHAP ([337]), have higher than normal concentrations of 2,3-DPG ([337]), and have decreased concentrations of ATP ([336]). The altered intermediate profile in PGK-deficient RBCs thus reflects an increased flow of triose phosphates through the DPG pathway at the expense of ATP generation. The genetics of this disorder are unique amongst glycolytic enzymopathies in that it is X-linked ([336]). PGK is known to be encoded by a single structural gene on the X-chromosome q13 ([338]). The complete amino acid sequence ([339] , [340]) and genomic organization of PGK ([341]) have been defined. Biochemical variants of PGK with abnormal kinetics, enzyme instability, or both have been observed in 23 separate families, and the single amino acid substitutions and genomic structure have been identified for 14 variants ([8] , [302]), including PGK Amiens ([342]), PGK Munchen ([343]), PGK Uppsala ([344]), PGK Tokyo ([345]), PGK Matsue ([346]), PGK Shizuoka ([347]), PGK Michigan ([348]), and others. Almost all of these are due to missense mutations leading to amino acid substitutions ([8] , [302]). Similar to G6PD deficiency, male hemizygotes with little or no enzyme activity are symptomatic with chronic hemolysis that can be severe, often requiring RBC transfusions ([336] , [349] , [350]). In contrast, females who are mosaics have normal and PGK-deficient red cells, and there may be variable degrees of hemolysis ([336] , [351]). Clinical exacerbations of hemolysis, most of which appear to be triggered by intercurrent infections, are responsible for recurrent episodes of jaundice. Splenectomy obviates transfusion in most patients but does not fully correct the hemolytic process. In deficient male subjects, PGK activity is decreased in leukocytes ([336]), platelets, muscle, liver, and brain, as well as in red cells ([352]). Although leukocyte PGK activity also is low, there is no evidence that affected individuals have leukocyte dysfunction or increased infections. Of far greater consequence is progressive neurologic deterioration. Deficient male infants experience apparent normal development until 3 to 4 years of age, when motor regression, expressive aphasia, and emotional lability become apparent. Seizures and progressive extrapyramidal disease follow late in the first decade ([336] , [337] , [349] , [353]). Most PGK variants manifest both hemolysis and neurologic disease (PGK Uppsala, PGK Tokyo, PGK Matsue, PGK Michigan); however, there are exceptions. PGK Shizuoka is characterized by hemolysis and muscle disease ([347]), whereas PGK San Francisco has only hemolysis without other symptoms ([354]). At the other extreme, recurrent exertional rhabdomyolysis producing renal failure but without associated hematologic or neurologic disease has been observed in PGK Creteil ([355]). Also, clinically silent variants producing PGK deficiency have been described, and these variants differ from the normal enzyme with respect to electrophoretic mobility and isoelectric focusing ([338]). The reasons for these phenotypic differences in PGK deficiency remain to be defined.

Glycolytic Enzymopathies of Doubtful Clinical Significance

Hemolysis has been associated with deficiencies of other glycolytic enzymes, but the causal relationship between enzymopathy and reported hematologic disturbances is far from clear ([266]).

Glyceraldehyde-3-Phosphate Dehydrogenase Deficiency The enzyme glyceraldehyde-3-phosphate dehydrogenase catalyzes the reversible conversion of glyceraldehyde-3-phosphate to 1,3-DPG (Fig. 33.4). This reaction is coupled to the reversible reduction of nicotinamide adenine dinucleotide to reduced nicotinamide adenine dinucleotide. The latter is the major cofactor for methemoglobin reduction by cytochrome b_5 reductase. Mild hemolytic anemia attributed to glyceraldehyde-3-phosphate dehydrogenase deficiency was described in two brief reports over 30 years ago ([356] , [357]). The limited content of these reports precludes conclusions regarding the relationship between glyceraldehyde-3-phosphate dehydrogenase deficiency and hemolysis.

2,3-DIPHOSPHOGLYCEROMUTASE DEFICIENCY The enzyme 2,3-DPGM has more than one metabolic role. Its main function relates to its catalytic role in the conversion of 1,3-DPG to 2,3-DPG (Fig. 33.4). This reaction is of special interest because 2,3-DPG reduces the affinity of hemoglobin for oxygen, thereby shifting the oxygen-hemoglobin dissociation curve to the right (see Chapter 8). A second function of the enzyme relates to its phosphatase activity, which catalyzes the degradation of 2,3-DPG to 3-phosphoglyceric acid (3-PGA). These two different actions of 2,3-DPGM reflect two different active sites on the same molecule ([358]). Deficiency of red cell 2,3-DPGM is associated with deficiency of 2,3-DPG phosphatase of comparable magnitude ([358] , [359]). The third metabolic role of this enzyme is to facilitate the conversion of 3-PGA to 2-PGA. The reports of 2,3-DPGM deficiency are too few and too disparate to permit a unified clinical description. Total deficiency of the mutase and phosphatase activity of DPGM and 2,3-DPG phosphatase activity was described in a 42-year-old man who was well except for ruddy cyanosis and a hemoglobin of 19 g per dl ([359]). Erythrocyte 2,3-DPG content was low, as was the p50 determination. Two of his children had approximately 55% normal 2,3-DPGM activity, suggesting that they were heterozygous and their father was homozygous, with fully compensated hemolytic process ([360] , [361]). Deficiency of 2,3-DPGM imparts no known metabolic lesion having implications for cell survival. Deficient cells consume glucose normally and contain normal or increased amounts of ATP and reduced levels of glutathione and triose phosphates ([359] , [361]). It seems doubtful that 2,3-DPGM deficiency is a cause of significant clinical disease.

ENOLASE DEFICIENCY Enolase catalyzes the conversion of 2-PGA to phospho-enolpyruvate (Fig. 33.4). Chronic hemolytic anemia associated with erythrocyte enolase deficiency was identified in two sisters ([362]). Ingestion of nitrofurantoin exacerbated the condition, an occurrence not explained by the enzyme deficiency.
LACTATE DEHYDROGENASE DEFICIENCY LDH catalyzes the terminal reaction in glycolysis, the conversion of pyruvate to lactate (Fig. 33.4). The enzyme is a tetrameric protein composed of H and M subunits. Severe deficiency of LDH in erythrocytes, leukocytes, platelets, and serum of a 65-year-old Japanese man has been reported ([363]). This individual was homozygous for an autosomal-recessively transmitted deficiency of the H subunit of LDH. Although no anemia or evidence of hemolysis was noted, red cells contained a marked increase of glyceraldehyde-3-phosphate, DHAP, and FDP. This severe LDH deficiency was without effect on red cell integrity.

DISORDERS OF ERYTHROCYTE NUCLEOTIDE METABOLISM

Mature RBCs are incapable of *de novo* purine or pyrimidine synthesis, although many enzymes of nucleotide metabolism are present in erythrocytes (Fig. 33.5). The latter are now known to be important for RBC preservation *in vitro*; it also is recognized that abnormalities in purine and pyrimidine metabolism are associated with inherited hemolytic disease.

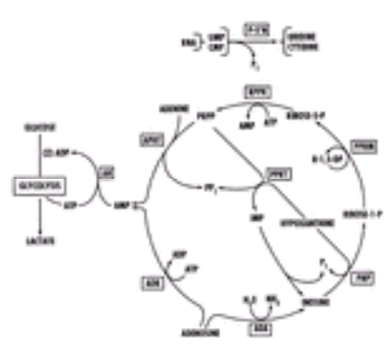

Figure 33.5. Schema of purine and pyrimidine metabolism in mature erythrocytes. Enzymes are shown in boxes. ADA, adenosine deaminase; ADK, adenosine kinase; ADP, adenosine diphosphate; AK, adenylate kinase; AMP, adenosine monophosphate; APRT, adenine phosphoribosyltransferase; ATP, adenosine triphosphate; CMP, cytidine monophosphate; IMP, inosine monophosphate; PPRM, pyrophosphoribosyl mutase; PPRT, pyrophosphoribosyl transferase; PNP, purine nucleoside phosphorylase; P5'N, pyrimidine 5' nucleotidase; PRPP, phosphoribosyl pyrophosphate; RPPK, ribopyrophosphoryl kinase; UMP, uridine monophosphate.

Initial interest in RBC nucleotide metabolism was stimulated by blood bank concerns related to ATP and 2,3-DPG loss during storage of RBCs. Several studies demonstrated that inosine, adenosine, and adenine each could minimize loss of organic phosphates and thereby improve viability of stored blood. These studies defined an important role for purine nucleoside metabolism in maintaining energy pools of stored RBCs, and this has had a major impact on the science of transfusion medicine ([364]).

In certain immune and metabolic disorders due to inborn errors of purine metabolism, erythrocytes share the same enzymatic deficiency, without any adverse effect on RBC function or viability. The RBC enzyme abnormalities in these cases can serve as a marker of disease in other tissues, and, in some cases, assay of red cell enzyme activity is used for diagnostic purposes ([365]). Such disorders include adenosine deaminase (ADA) deficiency associated with severe combined immune deficiency ([366]); nucleoside phosphorylase deficiency associated with impaired T-cell immunity ([367]); complete hypoxanthine-guanine phosphoribosyl transferase deficiency associated with Lesch-Nyhan syndrome ([368]); partial hypoxanthine-guanine phosphoribosyl transferase deficiency (30% normal activity) associated with increased uric acid production and gouty arthritis ([369]); elevated ribosephosphate pyrophosphokinase (PRPP synthetase) activity associated with increased urate production and gout ([370]); and adenine phosphoribosyl transferase defiance associated with renal stone formation ([371]).

Red cell purine and pyrimidine enzyme disorders also have been associated with inherited hemolytic syndromes, and these cases have further identified the important role of nucleotide metabolism in mature erythrocytes. The remainder of this section focuses on the purine and pyrimidine enzyme disorders that cause hemolysis: pyrimidine 5' nucleotidase (P5'N) deficiency, ADA excess, and adenylate kinase (AK) deficiency.

Pyrimidine 5' Nucleotidase Deficiency

Ribosomal RNA in normal reticulocytes is degraded to 5' nucleotides. The enzyme P5'N then further catalyzes the degradation of cytidine and uridine mononucleotides to inorganic phosphate and the corresponding nucleoside. The mononucleotides are impermeable to the RBC membrane, but after P5'N exposure, the nucleosides can passively diffuse from the cell. P5'N thus rids maturing reticulocytes of pyrimidine degradation products of RNA without compromising the adenine nucleotide pool necessary for energy-dependent reactions. Another enzyme, thymidylate nucleotidase, is believed to catalyze the degradation of thymidine monophosphate in a similar manner. This is supported by the observation that P5'N-deficient cells exhibit brisk nucleotidase activity when thymidine and deoxyuridine monophosphates are used as substrates ([372] , [373] , [374] and [375]).

Reticulocytes deficient in P5'N accumulate large quantities of cytidine and uridine compounds, increasing the total nucleotide pool to more than five times that present in normal red cells ([373] , [376] , [377]). Cases of P5'N deficiency formerly were classified as “high ATP syndromes” owing to the erroneous assumption that the large amount of nucleotide within deficient cells was adenine phosphate rather than pyrimidine phosphate ([378] , [379]). In addition to the increased nucleotide pool content, elevated levels of GSH ([380]) and decreased activity of PRPP synthetase are consistent but unexplained findings of P5'N deficiency ([378] , [379]). As a consequence of impaired ribosomal degradation, intracellular aggregates form in P5'N-deficient cells, and these appear as basophilic stippling on Wright-stained peripheral blood smears. The molecular biology of P5'N is not clearly defined at this time, and the P5'N gene has not been identified.

P5'N deficiency is a rare RBC defect, yet it is the most common enzyme abnormality affecting nucleotide metabolism and is overall the fourth most common enzyme abnormality associated with hereditary hemolytic anemia ([266] , [375]). Approximately 35 unrelated kindred representing wide geographic distribution have been reported with a predisposition for people of Mediterranean, Jewish, and African ancestry ([375] , [381]). In all families studied, the disorder follows an autosomal-recessive mode of transmission ([378] , [379] , [382] , [383] and [384]). Family members who are biochemical heterozygotes are hematologically normal, whereas homozygotes with less than 5 to 10% normal P5'N activity have life-long hemolytic anemia associated with splenomegaly and intermittent jaundice. The disorder is characterized by mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. Transfusions usually are not required. Splenectomy is followed by a modest increase in hemoglobin concentration but affords no significant benefit ([379] , [381] , [384]). There are no P5'N abnormalities in platelets or leukocytes of affected patients. Developmental retardation has been noted ([382]).

The possibility of P5'N deficiency as the cause of hemolysis is suggested by the presence of marked basophilic stippling, a unique RBC morphologic feature characteristic of this hemolytic disorder. Definitive diagnosis requires demonstration of decreased RBC nucleotidase activity ([381]) or increased pyrimidine nucleotides in erythrocytes. Normally, RBC nucleotides are almost entirely adenine nucleotides. However, in P5'N deficiency, up to 80% of the nucleotide pool may be pyrimidine nucleotides. This is the basis for a simple screening test that uses ultraviolet spectroscopy to demonstrate a shift in the absorption spectrum of red cell lysates ([384]).

The reason why P5'N deficiency leads to hemolytic anemia is not known, although there have been a variety of proposed mechanisms ([385] , [386]). One curious explanation relates to a concomitant decrease in the G6PD activity of P5'N-deficient cells ([387]), which is associated with decreased pentose phosphate shunt activity and increased incubated Heinz body formation. The mechanism whereby P5'N deficiency affects pentose phosphate shunt activity involves both competitive inhibition of glucose-6-phosphate and noncompetitive inhibition of NADP for G6PD by pyrimidine nucleotides ([387]). It is interesting that both P5'N and G6PD deficiencies are characterized by hemolytic crises complicating intercurrent infections. Also of interest was the report of a Bangladeshi family that had the genes for both hemoglobin E and P5'N deficiency ([388]). One individual homozygous for both conditions had a severe hemolytic anemia, whereas family members homozygous for hemoglobin E were asymptomatic and those homozygous for P5'N had a mild hemolytic anemia. Globin-chain synthetic studies indicated that the interaction between these two genotypes was due to decreased hemoglobin E stability in P5'N-deficient erythrocytes. Because, as described above, the HMP shunt is impaired in P5'N deficiency, it was postulated that the marked hemoglobin instability in enzyme-deficient cells was due to oxidant stresses exerting their effects on hemoglobin E that normally is

mildly unstable ([388]).

The P5'N enzyme is readily inactivated by heavy metals such as lead, and it has been proposed that the basophilic stippling in lead poisoning is secondary to acquired P5'N deficiency ([389] , [390]). As blood lead levels approach 200 µg per dl packed red cells, P5'N activity decreases to levels comparable to those associated with the homozygous deficiency state, intracellular pyrimidine nucleotides accumulate, and basophilic stippling can be demonstrated ([373] , [390]). As in congenital P5'N deficiency, pyrimidine nucleotide accumulation inhibits pentose phosphate shunt activity, further compounding a direct inhibitory action of lead on G6PD ([391]).

Adenosine Deaminase Excess

Adenosine is a common substrate for two different enzymes, adenosine kinase (ADK) and ADA. The Km (adenosine) is much lower for ADK than for ADA, and, thus, normal metabolism is believed to proceed through ADK with phosphorylation of adenosine to form adenosine monophosphate (AMP) (Fig. 33.5). In the presence of plasma adenosine, ADK thereby helps maintain the red cell adenine nucleotide pool ([392] , [393]). ADA leads to the deamination of adenosine with the formation of inosine, and this enzyme is critical for normal immune function. Hereditary deficiency of ADA is associated with severe combined immunodeficiency ([366]), and because the enzyme deficiency also exists in erythrocytes, assay of red cell ADA can be used to diagnose this immune disorder. Red cell adenine nucleotide content is increased in severe ADA deficiency, but this has no adverse effects on RBCs, and there is no anemia ([394] , [395]). Surprisingly, however, hereditary hemolytic anemia occurs in association with a 60- to 100-fold excess of normal ADA activity ([396]), and this has been described in a few families including a large kindred of English-Irish ancestry and in a Japanese family ([397]). In these patients with hemolysis and increased RBC-ADA activity, erythrocyte ATP content is reduced ([396] , [397]). The decrease in adenine nucleotides presumably occurs because elevated ADA activity effectively competes with ADK, producing a “relative” deficiency of the latter enzyme ([381] , [393]).

In patients with hemolytic anemia and marked ADA excess, the purified enzyme exhibits normal biochemical properties, and the defect appears to be due to excess production of a structurally normal enzyme ([398] , [399] and [400]). The synthesis of this enzyme is directed by a gene on chromosome 20, and posttranslational modifications result in different tissue isozymes. No specific DNA mutation has been identified to account for increased ADA production in patients with hemolytic anemia.

This rare hemolytic enzymopathy is unique because it is associated with an enzyme excess and also because it is inherited in an autosomal-dominant pattern ([396] , [401]). Clinical features include mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. No other tissues share in enzyme excess, and there are no other systemic effects. There are no distinguishing clinical, hematologic, or morphologic features to aid in the diagnosis of this condition. The specific diagnosis can be suspected if red cell ATP levels are low and confirmed by demonstrating increased ADA activity in a hemolysate. Usually, no specific therapy is indicated because most patients have very mild anemia. In contrast to the rare patients with a marked excess of enzyme activity and hemolytic anemia, a much smaller increase in enzyme activity (two- to fourfold) has been observed in most patients with congenital hypoplastic anemia (Diamond-Blackfan syndrome) ([402] , [403]) (see Chapter 45). The pathophysiologic significance of this modest increase is unknown.

Adenylate Kinase Deficiency

AK catalyzes the interconversion of adenine nucleotides (AMP + ATP ? 2ADP) (Fig. 33.5). This is believed to be the only enzyme reaction in mature RBCs that can lead to adenosine diphosphate synthesis from AMP, and, thus, AK would appear to have a critical role in salvaging AMP and protecting the erythrocyte adenine nucleotide pool ([404]). In erythrocytes, AMP is formed in two reactions: the ADK-mediated phosphorylation of adenosine and the adenine phosphoribosyl transferase–mediated phosphorylation of PRPP. There are three isozymes: AK1, AK2, and AK3 ([405]). AK1 is the isozyme in red cells, muscle, and brain.

Hereditary nonspherocytic hemolytic anemia in association with AK deficiency has been described in nine different kindred distributed worldwide ([404] , [406] , [407] , [408] , [409] , [410] , [411] , [412] and [413]). This is an autosomal-recessive disorder, and heterozygote-deficient individuals are not affected. A moderate to severe chronic nonspherocytic hemolytic anemia has been reported in almost all homozygous or compound heterozygous enzyme-deficient individuals. Splenectomy sometimes is beneficial ([410]). Mental retardation has been reported in some cases with severe erythrocyte AK deficiency ([407] , [410] , [411] and [412]), and this may reflect that AK1 is the isozyme in both RBCs and brain.

The causal relationship of this enzyme abnormality to hemolysis is not entirely clear because some individuals with profound AK deficiency have no evidence of hemolysis ([404]). In one sibship, there was congenital hemolytic anemia and less than 1% normal erythrocyte AK activity in an 8-year-old girl, whereas her brother also had no detectable AK activity but was hematologically normal ([404]). In another family with AK deficiency, a 4-year-old girl had chronic hemolysis with occasional exacerbations during infections and occasionally required RBC transfusions ([409]). Her RBCs had no detectable AK activity, whereas her parents had half-normal activity. In this patient, decreased activity of other phosphotransferases was noted; in particular, PRPP synthetase activity was reduced, just as in P5'N deficiency. The authors proposed that defects in multiple phosphotransferases may be responsible for the shortened lifespan of AK-deficient RBCs ([409]). The significance of these observations is unknown.

Molecular analysis has revealed the gene defect in six of the known kindred with chronic hemolysis and AK deficiency. In the first case, a single nucleotide substitution resulting in an amino acid change (Arg121?Trp) was detected ([8] , [405]). Analysis of subsequent probands has revealed other missense mutations ([411] , [413]), nonsense mutations ([412]), and deletion mutations ([413]).

Mechanisms of Immune Destruction of Erythrocytes

Immune destruction of erythrocytes is initiated by the binding of immunoglobulin (Ig) G or IgM antibodies to protein or carbohydrate antigens on the red cell surface. Erythrocytes come under attack by the immune system as a consequence of autoimmune, alloimmune, or isoimmune processes. IgG-sensitized erythrocytes can be destroyed directly (i.e., without complement activation) because cells of the reticuloendothelial system (tissue macrophages) express receptors that bind the Fc portion of the IgG molecule. In contrast, immune destruction of IgM-sensitized red cells is an indirect process that appears to depend entirely on complement activation because humans apparently lack specific receptors for the Fc portion of IgM. Complement mediates destruction of erythrocytes in two ways. First, cells can undergo direct complement-induced cytolysis. However, such immune-mediated intravascular hemolysis is rarely observed clinically because erythrocytes express membrane proteins that have evolved specifically to restrict complement-induced injury (Fig. 34.1). Only when there is massive complement activation are the protective effects of the membrane regulatory proteins overwhelmed.

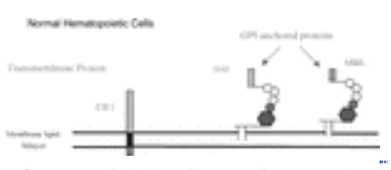

Figure 34.1. Complement regulatory proteins on normal erythrocytes. Although the primary function of red cell complement receptor (CR) 1 (CD35) is immune adherence mediated through binding of activation and degradation products of complement C3 and C4, it also has complement inhibitory activity. CR1 has decay-accelerating activity for both the classic and alternative pathways of complement, and it serves as a cofactor for enzymatic degradation of complement C3b and C4b by factor I. CR1 is an example of a transmembrane protein that has three domains: an ectoplasmic domain (rectangle with horizontal lines), a transmembrane domain (dark rectangle), and a cytoplasmic domain (rectangle below lipid bilayer). Decay-accelerating factor (DAF; CD55) is a glycosyl phosphatidylinositol (GPI)–anchored protein that inhibits the formation and stability of the C3 convertases of both the classic and the alternative pathways. Membrane inhibitor of reactive lysis (MIRL; CD59) is also GPI-anchored. It inhibits complement-mediated lysis by blocking the formation of the membrane attack complex of complement. In contrast to transmembrane proteins like CR1, GPI-anchored proteins such as DAF (CD55) and MIRL (CD59) lack the cytoplasmic and transmembrane domains. This class of proteins is anchored to the cell by a GPI moiety consisting of phosphatidylinositol (dark hexagon), glucosamine (dark circle), and three mannose (light circles) molecules. The GPI moiety is linked to the COOH-terminus of the protein portion of the molecule by ethanol-amine. The GPI-anchored proteins are deficient in paroxysmal nocturnal hemoglobinuria (PNH), accounting for the abnormal sensitivity of erythrocytes of PNH to complement-mediated lysis.

The pathologic circumstances associated with major transfusion reactions and paroxysmal cold hemoglobinuria illustrate the stringent conditions required to induce direct complement-mediated intravascular hemolysis. Infusion of ABO-mismatched blood is invariably associated with intravascular hemolysis, with complement activation sufficient to mediate this process occurring because the following four conditions are present concomitantly: (a) the naturally occurring antibodies are present in high titer; (b) the antibodies are of the IgM type; (c) the carbohydrate antigens that are recognized by the antibodies are present in high density on the red cell membrane; (d) the antibodies are active at 37°C. Direct complement-mediated intravascular hemolysis is also observed in paroxysmal cold hemoglobinuria, but again, a set of exceptional circumstances is required to produce the intravascular hemolysis mediated in this case by an IgG antibody (the Donath-Landsteiner antibody). First, the antigens (most commonly, the carbohydrate moiety of the glycolipids that comprise the P blood group system) that are recognized by the Donath-Landsteiner antibody are present in high density on the red cell surface. Second, the unusual thermal properties of the Donath-Landsteiner antibody that result in fixation of both complement components C1 and C4 at cold temperatures greatly enhance the efficiency with which the remainder of the complement cascade is activated on subsequent warming to 37°C ([1]).

In contrast to paroxysmal cold hemoglobinuria, chronic cold agglutinin disease is less commonly associated with clinically significant intravascular hemolysis. Inasmuch as the antibodies of cold agglutinin disease are often present in very high titer, are of the IgM type, and recognize carbohydrate antigens that are present in high density on the erythrocyte membrane, this observation seems discrepant. However, the apparent discrepancy is explained by the thermal properties of the cold agglutinin antibody and its interactions with complement. Unlike the IgG Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria that fixes both complement C1 and C4 at cold temperatures, the IgM antibodies of cold agglutinin disease fix only C1 ([1]). This difference reduces the efficiency with which the remainder of the complement cascade is activated when the blood is warmed to 37°C. Additionally, the thermal amplitude of most cold agglutinins is relatively low. Consequently, the antibody dissociates from the red cell surface at temperatures sufficiently high for efficient complement activation. Thus, the capacity of the IgM antibodies of cold agglutinin disease to activate complement is inadequate to overcome the protective effects of the membrane regulatory proteins (Fig. 34.1).

An uncommon disease further underscores the physiologic importance of erythrocyte membrane proteins that regulate complement. Paroxysmal nocturnal hemoglobinuria (PNH) is characterized by chronic complement-mediated intravascular hemolysis that occurs independent of antibody (see Chapter 37). In this case, the erythrocytes undergo spontaneous hemolysis mediated by the alternative pathway of complement because they lack two of the membrane regulatory proteins [decay-accelerating factor (DAF; CD55) and membrane inhibitor of reactive lysis (MIRL; CD59)] that normally restrict the functional activity of the complement system (Fig. 34.1).

The second mechanism by which complement mediates destruction of erythrocytes is an indirect process that depends on complement activation and then on subsequent recognition of both activation and degradation products of the third component of complement (C3) by specific receptors on reticuloendothelial cells. All IgM antibodies mediate extravascular, cell-dependent hemolysis via this mechanism; under some conditions, warm antibodies of the IgG type may also activate complement. In such cases, clearance of the IgG and C3 opsonized cells is greatly enhanced because the simultaneous engagement of both complement and Fc receptors augments the phagocytic process synergistically ([2]).

Under most clinical circumstances, immune destruction is an extravascular process that depends on recognition by specific receptors on reticuloendothelial cells of erythrocytes opsonized with IgG, complement, or both. To understand more completely the pathophysiology that underlies immune hemolysis, familiarity with the function of the complement system and the receptors for both the Fc portion of IgG and for the activation and degradation products of C3 is needed.

COMPLEMENT SYSTEM

There are three distinct pathways that lead to C3 deposition and subsequent formation of the membrane attack complex of complement (Fig. 34.2). The classic pathway is activated by antibody, whereas activation of the alternative pathway occurs independent of antibody. With the exception of PNH, complement-mediated destruction of erythrocytes is mediated by the classic pathway. The lectin pathway is activated by binding of a protein complex to specific carbohydrates expressed primarily by microbial organisms. The activation complex of the lectin pathway consists of both a recognition unit (mannose-binding lectin or L- or H-ficolin) and an

activation unit [mannose-binding lectin–associated serine proteases 1, 2, and 3 (MASP-1, MASP-2, and MASP-3)]. Although the lectin pathway is not discussed in detail in this chapter because it has no apparent role in immune destruction of erythrocytes, it has been the subject of recent reviews by others ([3], [4], [5], [6] and [7]).

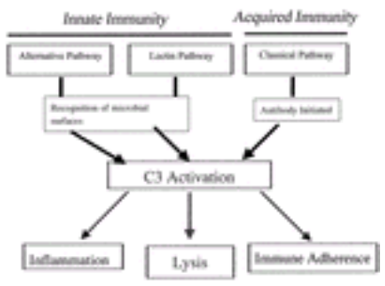

Figure 34.2. The complement system. Although there are three distinct pathways for complement activation, immune destruction of human erythrocytes is mediated by the classic pathway (with one exception). Direct lysis of human red blood cells by complement is unusual because of protection by the complement regulatory proteins (Fig. 34.1). The reticuloendothelial system, through recognition of surface-bound IgG or activation and degradation products of complement C3 and C4, mediates destruction of erythrocytes in most cases of immune hemolytic anemia. Rarely (e.g., major transfusion reactions), complement activation is brisk enough so that clinical signs and symptoms of inflammation may be observed (mediated by C3a and C5a). The alternative pathway mediates immune lysis of paroxysmal nocturnal hemoglobinuria erythrocytes.

Classic Pathway of Complement

The classic pathway is activated when the first component of complement (C1) binds to the Fc portion of an IgG or an IgM antibody that is affixed to an antigen on the red cell membrane surface. Antibodies of the IgA, IgD, and IgE classes lack the binding site for C1 and thus are unable to activate complement. Of the IgG subclasses, IgG3 binds C1 most efficiently, followed in order of efficiency by IgG1 and IgG2. IgG4 interacts poorly with C1 and appears to lack the capacity to activate the classic pathway ([8]).

C1 is actually composed of three subunits (C1q, C1r, and C1s). The stoichiometry is as follows: one unit of C1q, two units of C1r, and two units of C1s. The C1q component binds weakly to the C1r $_2$C1s $_2$ tetramer, and the structural and functional integrity of the C1 complex is calcium dependent ([9]). The binding constant for this reaction (5×10^7 M-1) is such that approximately 80% of the C1q and C1r $_2$C1s $_2$ subunits are combined as C1 molecules in the plasma ([10], [11]). C1q is the subunit of the complex that binds to the Fc portion of IgG or IgM. The ultrastructure of C1q is complex and distinctive ([8], [12], [13]). The molecule is composed of six globular heads extending from a collagenlike stem with the six stems joined together in a bunch (under electron microscopy, the side view of the molecule looks remarkably similar to a bouquet of tulips).

Each of the six globular heads of C1q has a binding site that is specific for a region in the Fc portion of the Ig molecule ([8]). Binding of a single head, however, is weak and lasts only a fraction of a second. Firm binding lasting several minutes requires the interaction of at least two of the heads (Fig. 34.3, part 1). Whereas each IgG molecule has two C1q binding sites (one in each of its two Fc domains), a single C1q molecule cannot bind firmly to a single IgG molecule because the binding sites in IgG are located on opposite sides of the Fc moiety. Inasmuch as the C1q molecule is relatively inflexible, two of its globular heads cannot engage both of the Fc binding sites of a single IgG molecule simultaneously.

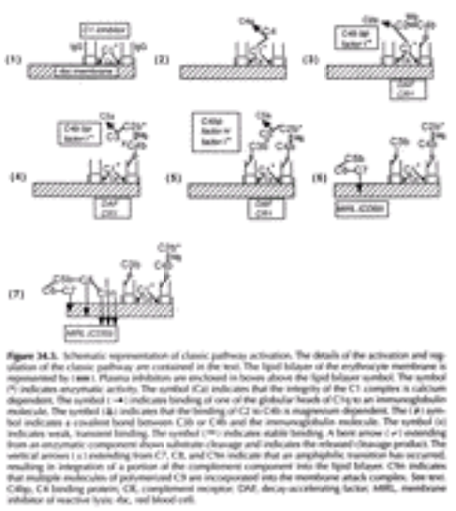

Figure 34.3. Schematic representation of classic pathway activation. The details of the activation and regulation of the classic pathway are contained in the text. The lipid bilayer of the erythrocyte membrane is represented by ( ). Plasma inhibitors are enclosed in boxes above the lipid bilayer symbol. The symbol (*) indicates enzymatic activity. The symbol (Ca) indicates that the integrity of the C1 complex is calcium dependent. The symbol ( ) indicates binding of one of the globular heads of C1q to an immunoglobulin molecule. The symbol ( ) indicates that the binding of C2 to C4b is magnesium dependent. The ( ) symbol indicates a covalent bond between C3b or C4b and the immunoglobulin molecule. The symbol (×) indicates weak, transient binding. The symbol ( ) indicates stable binding. A bent arrow ( ) extending from an enzymatic component shows substrate cleavage and indicates the released cleavage product. The vertical arrows (?) extending from C7, C8, and C9n indicate that an amphiphilic transition has occurred, resulting in integration of a portion of the complement component into the lipid bilayer. C9n indicates that multiple molecules of polymerized C9 are incorporated into the membrane attack complex. See text. C4bp, C4 binding protein; CR, complement receptor; DAF, decay-accelerating factor; MIRL, membrane inhibitor of reactive lysis; rbc, red blood cell.

For IgG to activate the classic pathway, at least two molecules must be bound to the erythrocyte in close proximity to each other (within 30 to 40 nm) (Fig. 34.3, part 1) ([12], [13] and [14]). This requirement means that the number of copies of antigen/cell is an important determinant of complement activation. In some cases, however, antigens that are present in relatively low numbers may be able to support complement activation if they are free to move within the plane of the membrane so that patches or clusters can form. The relatively low density of the Rh antigen, its even distribution over the entire membrane surface, and its inability to patch due to constraints imposed by its structure and interactions with other membrane constituents probably account for the lack of complement activation induced by anti-Rh antibodies ([15], [16]).

The efficiency with which IgG is able to activate the classic pathway is also enhanced when an immune reaction generates polyclonal antibodies that recognize different epitopes on the same antigen. Under these conditions, the stringent spacial requirements for C1q binding to Fc may be met when two or more molecules of IgG bind to a single antigenic structure.

In contrast to IgG, IgM is a highly efficient activator of the classic pathway. The pentameric structure of IgM means that five Fc moieties are present in the same molecule with at least three (and probably five) C1q binding sites available ([17]). Thus, a single molecule of IgM has the capacity to activate the classic pathway. However, the C1q binding sites are not exposed unless the IgM molecule assumes the “staple” form. To assume this configuration, at least two of the subunits of the IgM molecule must engage the cellular antigen ([18]). Thus, antigen density also has an impact on the capacity of IgM to activate complement. When free in plasma, IgM does not activate complement because it exists in a star-shaped, planar form. Under these conditions, the C1q binding sites are not exposed. Interaction with antigen causes the F(ab')2 arms to bend so that they are at right angles to the central Fc core of the molecule (the staple configuration). This conformational change exposes the C1q binding sites, allowing complement activation to proceed.

Both C1r and C1s are serine proteases that exist in their native state as zymogens (inactive proenzymes). As noted above, the integrity of the C1r $_2$C1s $_2$ complex is dependent on calcium ([9]), and the C1s molecules are located at either end of the linear tetramer with the two C1r molecules in the middle ([9]). The primary structure

of C1r and C1s is very similar, suggesting that they arose by gene duplication. Enzymatic activity is expressed after proteolytic cleavage of the zymogens. Apparently, binding of C1q to Ig induces a conformational change in C1 that causes autoactivation of the two C1r molecules ([19]). The precise mechanism by which autoactivation occurs remains obscure; however, available evidence suggests that as each C1r molecule undergoes autoactivation, it cleaves its partner within the tetramer. By enzymatic cleavage, the two proteolytically activated C1r molecules subsequently activate their contiguous C1s partners ([8]). Binding of C1 is rapid, but activation is a relatively slow process ([19]). This discrepancy appears to be due to the fact that not all C1 binding sites have the capacity to support activation of C1.

Binding of C1 to Ig is a crucial amplification step in the generation of the classic pathway cascade because activated C1s has the capacity to proteolytically cleave many molecules of C4 and C2. Because of its enormous destructive capacity elaborate safeguards for restricting the activity of complement have evolved. These checkpoints usually involve inhibition of the formation or activity of an enzymatic step in the pathway so that amplification is dampened. The first such complement regulatory factor is C1 inhibitor (Fig. 34.3, part 1). This heavily glycosylated plasma protein (40% carbohydrate by weight) binds in a 1:1 stoichiometric relationship with activated C1r and C1s, forming an extremely stable (probably covalent) complex. Binding of C1 inhibitor causes activated C1r and C1s to dissociate from the C1 complex, leaving C1q bound to Ig ([8]). Because the rate of reaction of C1 inhibitor with activated C1r and C1s is so rapid, the half-life of activated C1 in the plasma is only 10 to 20 seconds ([20]). C1 inhibitor is a member of the superfamily of serine protease inhibitors (serpins), and it also has the capacity to block the activity of plasmin, kallikrein, factor XIa, and factor XIIa ([15]). Deficiency of C1 inhibitor underlies the clinical disorder angioedema, a disease that exists in both inherited and acquired forms ([21]).

The natural substrates for activated C1 are C4 and C2. Activated C1s cleaves C4 near the amino terminus of the a-chain of this disulfide-linked heterotrimer (Fig. 34.3, part 2) ([22]). The smaller cleavage fragment, designated C4a, is a weak anaphylatoxin ([23]). The larger fragment, C4b, contains an internal thioester bond that is exposed when C4 is cleaved by C1s ([24]). By acyl transfer, this thioester group located in the a-chain can form either an ester or an imidoester bond with the Ig molecule or with an erythrocyte membrane glycoprotein (in particular, glycophorin A) ([25], [26]). The half-life of the activated C4 is extremely short (approximately 60 µsec by analogy with nascent C3b, see below). During this period, the activated protein can diffuse approximately 40 nm. Thus, C4b is found in clusters around the Ig-C1 complex.

There are two C4 genes: C4A and C4B ([27]). The protein product of the two genes differs by only four amino acids, with the sequence variation being centered around the thioester reactive site ([28]). This difference appears to influence the type of bond that is formed between nascent C4b and its target surface and, in so doing, to account for the two- to fourfold greater hemolytic activity of C4B compared to C4A ([29], [30]). Studies have shown that C4B reacts more effectively with hydroxyl groups, forming ester bonds, whereas C4A displays a preference for amide bond formation because of preferential interaction with primary amino groups. Due to the relative abundance and accessibility of the carbohydrate moiety of erythrocytes, the opportunity for ester bond formation is greater than for amide bond formation. Consequently, C4B binds to erythrocytes approximately four times more efficiently than C4A. This quantitative difference in binding appears to account entirely for the greater hemolytic activity of C4B compared to C4A ([29]). Of additional interest is the observation that the Rodgers (Rg) and Chido (Ch) blood group phenotypes are determined by C4 genotype ([31]). With rare exception, individuals expressing only C4A (5% of the Caucasian population) are $Rh^{+}Ch^{-}$, whereas those expressing only C4B (2% of the population) are $Rh^{-}Ch^{+}$. Most of the Caucasian population (93%) expresses both C4A and C4B and is, therefore, $Rh^{+}Ch^{+}$. That the antigenic determinant is on the C4d portion of the molecule (the fragment containing the thioester reactive site) implies that some low-level activation of the classic pathway occurs on erythrocytes under normal physiologic conditions.

The covalent attachment of C4b serves as the nidus for the formation of the C3 convertase of the classic pathway by providing a magnesium-dependent binding site for C2, a zymogen belonging to the family of serine proteases (Fig. 34.3, part 3) ([32]). C2 that is bound to C4b at a distance no greater than 60 nm from an Ig-activated C1 complex is cleaved by C1s into fragments of C2a and C2b. The C2b fragment remains bound and functions as the enzymatic subunit of the classic pathway C3 convertase. (Note that there is not universal agreement on the nomenclature of the C2 fragments. Many investigators continue to use the original nomenclature in which the enzymatic subunit of C2 was designated C2a.) No definite biologic function has been attributed to the nonenzymatic C2a peptide.

The activity of the C3 convertase of the classic pathway is regulated by its intrinsic instability and by both plasma and membrane proteins (Fig. 34.3, part 3). The plasma constituent, C4b-binding protein, restricts convertase activity by binding to C4b and inhibiting the subsequent binding of C2 or by accelerating the decay of formed C4b2b complexes, or both ([33], [34] and [35]). C4b-binding protein also serves as a cofactor for the enzymatic degradation of C4b by the plasma serine protease, factor I ([33], [36], [37]). C4b-binding protein has an interesting structure in that it is composed of seven identical chains that are linked by disulfide bonds ([38]). Electron micrographs show a spiderlike structure consisting of seven elongated subunits (resembling tentacles) linked to a small central body ([38]). Approximately 50% of C4b-binding protein in plasma is complexed with protein S, the vitamin K–dependent protein C cofactor that plays a critical role in hemostasis ([39]).

The activity of the classic pathway C3 convertase (C4b2b) is also regulated by two erythrocyte membrane proteins: complement receptor type 1 (CR1; CD35) and DAF (CD55) (Fig. 34.3, part 3). CR1 regulates the convertase activity in much the same way as C4b-binding protein (i.e., it binds to C4b preventing formation of the complex, accelerates the decay of the C4b2b complex, and serves as a factor I cofactor) ([40], [41] and [42]). In contrast, DAF lacks factor I cofactor activity, and it does not appear to block convertase formation. Rather, DAF (as its name suggests) restricts convertase activity by accelerating the decay of the C4b2b complex ([43], [44]). Membrane cofactor protein (MCP; CD46) is another cellular protein that inhibits complement activation. As does CR1, MCP serves as a cofactor for the factor I–mediated cleavage of C4b (and C3b) ([45]). MCP, however, is not expressed by erythrocytes and, therefore, does not participate in regulation of immune hemolysis.

CR1 and DAF share a common structural motif consisting of cysteine-rich units of approximately 60 amino acids called *short consensus repeats* (SCRs). DAF contains four SCRs, whereas CR1 contains 30 SCR units. This structural feature is also shared by other complement proteins [factor H, C4b-binding protein, MCP (CD46), and complement receptor type 2 (CR2; CD21)]. All of these proteins interact with C3b, C4b, or both. The genes for these proteins have been localized to the long arm of chromosome 1 (band q32); together, this gene family is referred to as the *regulators of complement activation* ([46]). CR1 is a type I integral membrane protein, whereas DAF is anchored to the cell through a glycosyl phosphatidylinositol (GPI) moiety (Fig. 34.1). Like all GPI-anchored proteins, DAF is deficient on the erythrocytes from patients with PNH, and this deficiency accounts in part for the complement-mediated lysis that is the clinical hallmark of the disease (see Chapter 37).

The classical pathway C5 convertase is formed when C3 in the fluid phase is cleaved into C3a and C3b fragments by the C2b component of the C4b2b complex (Fig. 34.3, part 4). The 77–amino acid C3a molecule that is liberated from the amino-terminal end of the a-chain of C3 as a consequence of cleavage by C2b is an anaphylatoxin that is approximately tenfold more potent than C4a, but approximately 200-fold less potent than C5a ([23], [47]). Recently, the molecular cloning of the receptor for C3a was reported ([48], [49]). Although the C3a receptor is structurally and functionally similar to the C5a receptor, the tissue distribution of the two anaphylatoxin receptors appears to be different. Whether the C3a receptor is also the receptor for C4a is under investigation. Like C4b, C3b contains an internal thioester bond that mediates the covalent attachment of the molecule to Ig or cell-surface constituents (Fig. 34.3, part 5) ([50], [51] and [52]). Thus, the C3b that becomes membrane bound is found in clusters around the C4b2b complex because the extremely short half-life of the binding site (approximately 60 µsec) limits the distance that nascent C3b can diffuse before it becomes inactive ([53]). Although only 10 to 15% of the C3b that is generated by C4b2b becomes cell bound, this step is nonetheless an important part of the amplification process because each convertase mediates the deposition of approximately 200 molecules of C3b ([54]).

The same plasma and cellular proteins that control the activity of the C3 convertase (Fig. 34.3, part 5) regulate the C5 convertase. In the case of the C5 convertase, CR1 also binds to C3b and serves as a cofactor for factor I–mediated degradation of C3b to iC3b and, subsequently, to C3dg ([55], [56]). This latter C3 degradation fragment is the predominant form of C3 found on circulating erythrocytes in patients with immune hemolytic anemias involving complement activation (e.g., chronic cold agglutinin disease) ([57]). In addition to CR1, the plasma protein factor H serves as a cofactor for factor I–mediated degradation of C3b to iC3b. Under physiologic conditions, however, factor H does not support the factor I–mediated cleavage of iC3b to C3c and C3dg ([55]). Factor H, a single-chain glycoprotein consisting of 20 SCR units ([58]), is an important regulator of the C3 and C5 convertases of the alternative pathway (see Alternative Pathway of Complement).

C2b is also the catalytic subunit of the classic pathway C5 convertase (C4b2b3b) ([59]). In this case, cell-bound C3b serves as the attachment site for C5, thereby positioning it for enzymatic activation by C2b (Fig. 34.3, part 5). Nascent C5b is generated when C2b cleaves a 74–amino acid peptide (C5a) from the amino-terminal portion of the a-chain of C5 ([60], [61]). In addition to being a potent anaphylatoxin, C5a is an important component of the immune process that mediates a variety of proinflammatory events through binding with a specific G protein–coupled receptor expressed on a variety of tissues ([62]). Unlike C4b and C3b, C5b does not contain an internal thioester bond; thus, it does not bind covalently to the cell membrane ([24]). Rather, C5b serves as the nidus for the formation of the membrane attack complex (MAC). The number of C5b molecules that are activated by the classic pathway C3 convertase is greatly constrained because only C5 that is bound to a C3b

molecule that is in close proximity to a C4b2b complex can be cleaved. Thus, each C4b2b complex generates only two or three molecules of C5b. The functional half-life of C5b is approximately 2 minutes, and it appears to undergo irreversible inactivation while still bound to C3b ([59]).

After the generation of C5b, no further enzymatic activity is involved in either the formation or the cytolytic activity of the MAC that consists of C5b, C6, C7, C8, and C9 (C5b-9). Components C6, C7, and C9 are single-chain polypeptides ([63], [64], [65], [66] and [67]). As discussed above, C5b is a disulfide-linked heterodimer that is the product of a single gene. C8 consists of three nonidentical peptide chains ([68]). The a- and ?-chains comprise a disulfide-linked unit that is noncovalently associated with the ß-chain. Apparently, the three polypeptide chains that comprise C8 are the products of separate genes ([69]). There are structural and antigenic similarities among four of the components (C6, C7, C8, and C9), and at the nucleotide level, modest homology is observed for C7, C8a, C8ß, and C9 ([53]).

Formation of the MAC is initiated when nascent C5b (i.e., still complexed with C3b) binds specifically to C6, forming a stable, hydrophilic complex ([70], [71]). Binding to the C5b6 complex induces a conformational change in C7 that exposes a labile membrane-binding site and causes the molecule to undergo a hydrophilic-amphiphilic transition ([72], [73]). This process allows the trimolecular C5b67 complex to integrate into the lipid bilayer of the erythrocyte (Fig. 34.3, part 6). Once inserted into the cell, the complex is stable. Binding of C8 to the C5b67 complex is mediated through the ß-chain that has a specific recognition site for C5b ([74]). Binding to C5b67 induces a conformational rearrangement that allows the a-chain of C8 to insert into the hydrophobic core of the lipid bilayer and exposes a single binding site for C9. Binding to C8a within the C5b-8 complex ([75]) causes C9 to unfold. This conformational change exposes hydrophobic regions that allow the molecule to insert into the membrane (Fig. 34.3, part 7), exposing a binding site for an additional C9 molecule. Binding to C5b-9 $_1$ causes the second C9 molecule to undergo the same conformational change as the first C9 molecule; in this way, multiple molecules of C9 become incorporated into the MAC (C5b-9 $_n$) ([49]). The C9 molecules undergo polymerization, and this process forms the ringlike structure that appears as the classic doughnut lesion visualized by electron microscopy ([76], [77]). Individual MACs are heterogeneous in size due to differences in C9 composition ([78], [79] and [80]). Thus, the stoichiometry of the MAC is C5b $_1$, C6 $_1$, C7 $_1$, C81, and C9 $_n$, where n ranges from 2 to 18 depending on the experimental conditions ([53], [79], [80]). On normal human erythrocytes that have undergone hemolysis, the average C8 to C9 ratio is 1:3, whereas on PNH erythrocytes that have undergone lysis, the average C8 to C9 ratio is 1:6 ([81]). These results indicate that MIRL (CD59), a GPI-anchored protein that is deficient in PNH, restricts the incorporation of C9 into the MAC.

Disruption of the integrity of the lipid bilayer of the erythrocyte by the MAC creates an osmotic gradient because small ions can traverse the damaged membrane, but large cytoplasmic components such as hemoglobin cannot. The consequent inflow of water causes the cell to expand rapidly. If membrane damage is sufficient, the cell ruptures, releasing hemoglobin into the plasma (a process called *colloid osmotic lysis*). The mechanism by which the MAC produces cell lysis is debated. According to the “leaky patch” hypothesis, insertion of the hydrophobic elements of the MAC causes local disruption of the integrity of the phospholipid bilayer ([82]). The proponents of the competing “pore” hypothesis argue that the polar surfaces of the MAC components aggregate, forming a hydrophilic channel through the membrane ([83]). Data in support of both hypotheses have been presented ([82], [83]), suggesting that both processes may be operative depending on the experimental conditions.

A number of plasma proteins, including S protein (vitronectin) ([84]), and apolipoproteins (particularly clusterin) have been shown to inhibit the activity of the MAC *in vitro* ([70], [85], [86], [87] and [88]). The importance of these plasma constituents in regulating the lytic actions of complement *in vivo*, however, has not been established unequivocally. Erythrocytes are protected from lytic action of the MAC by MIRL (CD59) (Fig. 34.3, part 7) ([89], [90]). This GPI-anchored protein (Fig. 34.1) inhibits MAC formation primarily by binding to C8, thereby restricting the subsequent binding and polymerization of C9 ([91], [92] and [93]). The importance of MIRL *in vivo* was made clear by a patient with an isolated deficiency of this complement regulatory protein ([94]). That patient had a syndrome characterized by recurrent episodes of intravascular hemolysis that was clinically indistinguishable from PNH.

Alternative Pathway of Complement

Activation of the classic pathway is highly specific in that antibody is required to initiate the process. Thus, the system is quiescent unless erythrocyte antigens become targets for immune attack as a consequence of some pathologic process, be it autoimmune, alloimmune, or isoimmune. Therefore, under normal physiologic conditions, host erythrocytes do not require protection against the classic pathway. In contrast, there is no specific initiating factor for the alternative pathway. Consequently, the alternative pathway does not discriminate between host and foreign cells. Rather, the burden of avoiding attack by the alternative pathway is borne directly by host cells that rely on membrane factors to restrict the activity of the system. Because they are continuously exposed to complement activation by the alternative pathway, erythrocytes have evolved specific cell-surface constituents (DAF, MIRL, and CR1) (Fig. 34.1) that protect them against complement-mediated destruction. That normal erythrocytes never undergo immune destruction mediated by the alternative pathway is a testament to the effectiveness of these two proteins. On the other hand, the chronic complement-mediated intravascular hemolysis that is characteristic of PNH is mediated by the alternative pathway. That PNH is a consequence of the deficiency of DAF and MIRL underscores the essential role that these proteins play in protecting normal erythrocytes from injury by the alternative pathway.

Inasmuch as antibody is not required for its activation, the alternative pathway functions as the first line of defense against bacterial infections in the nonimmune host ([95]). Thus, the alternative pathway, like the lectin pathway, is a component of the innate immune system ([96], [97]). The alternative pathway is activated by certain microorganisms because the biochemical properties (e.g., the sialic acid content) of these potential pathogens favor the formation and stability of the C3 convertase. On alternative pathway activators, the binding of the catalytic subunit (factor B) of the C3 convertase is favored over the binding of the convertase inhibitory protein (factor H). Erythrocytes are exposed to the same plasma factors as invading organisms, and yet normal red cells are completely resistant to injury mediated by the alternative pathway. Thus, erythrocytes serve as the paradigm for understanding the elaborate mechanisms that have evolved to protect host cells against the untoward consequences of alternative pathway activation.

In plasma, the alternative pathway is in a state of continuous, low-grade activation. Thus, the system is primed for attack at all times. Activation of the alternative pathway is initiated by direct formation of the C3 convertase, consisting of hydrolyzed C3 and activated factor B ([98]). The activity of the system is kept at a low level because, in the plasma, the formation and stability of the amplification C3 convertase are tightly controlled by the endogenous regulatory protein, factor H. Nonetheless, some low-grade activation does occur because the internal thioester in native C3 is subject to spontaneous hydrolysis. Nascent (C3•H $_2$O) undergoes a conformational change that transiently exposes a magnesium-dependent binding site for factor B ([98]). The catalytic subunit of the alternative pathway C3 convertase (Bb) is generated when factor B that is bound to (C3•H $_2$O) is cleaved by factor D into Ba and Bb fragments ([99]). Factor D, a trace plasma protein, is a serine protease without a zymogen form (i.e., it is always functionally active) ([53]). Factor B is both structurally and functionally homologous to C2 of the classic pathway ([27]). Like C2, factor B is a serine protease that exists in its native state as a zymogen with enzymatic cleavage being required for activation ([100]). Further, activated C2 (C2b) and factor B (Bb) have the same natural substrates (i.e., C3 and C5). Although factor B and C2 share only modest (37%) amino acid sequence homology, the genes that encode these two proteins are structurally similar and closely associated in the major histocompatibility complex region of chromosome 6. Together, these observations suggest that the C2 and factor B arose by gene duplication.

Activation of the alternative pathway on erythrocytes is initiated when native C3 binds to C3•H $_2$O:Bb. The subsequent enzymatic cleavage of C3a from native C3 induces a conformational change in the resulting C3b molecule such that the internal thioester becomes exposed. By acyl transfer, nascent C3b binds covalently to glycophorin A, the major erythrocyte sialoglycoprotein ([101]). Although both ester and imidoester bonds can form, the majority of C3b on erythrocytes is bound via an ester bond to the carbohydrate moiety of glycophorin A ([101]). The cell-surface C3 convertase is formed when factor B binds to C3b in a magnesium-dependent reaction. Factor B is activated by factor D ([99]), and the amplification C3 convertase (C3bBb) is stabilized by factor P (properdin) ([102]) (Fig. 34.4, part 1, Fig. 34.4, part 2, and Fig. 34.4, part 3).

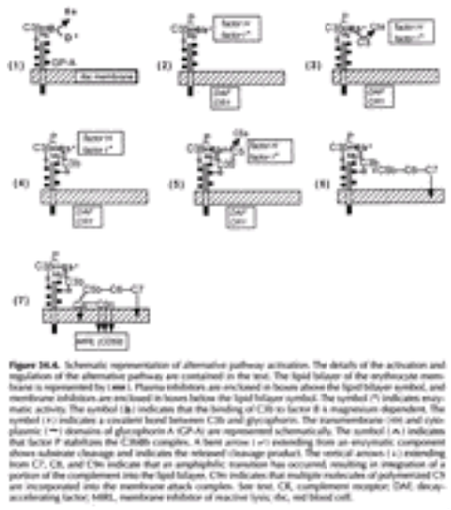

Figure 34.4. Schematic representation of alternative pathway activation. The details of the activation and regulation of the alternative pathway are contained in the text. The lipid bilayer of the erythrocyte membrane is represented by ( ). Plasma inhibitors are enclosed in boxes above the lipid bilayer symbol, and membrane inhibitors are enclosed in boxes below the lipid bilayer symbol. The symbol (*) indicates enzymatic activity. The symbol ( ) indicates that the binding of C3b to factor B is magnesium dependent. The symbol ( ) indicates a covalent bond between C3b and glycophorin. The transmembrane (□) and cytoplasmic ( ) domains of glycophorin A (GP-A) are represented schematically. The symbol ( ) indicates that factor P stabilizes the C3bBb complex. A bent arrow ( ) extending from an enzymatic component shows substrate cleavage and indicates the released cleavage product. The vertical arrows (?) extending from C7, C8, and C9n indicate that an amphiphilic transition has occurred, resulting in integration of a portion of the complement into the lipid bilayer. C9n indicates that multiple molecules of polymerized C9 are incorporated into the membrane attack complex. See text. CR, complement receptor; DAF, decay-accelerating factor; MIRL, membrane inhibitor of reactive lysis; rbc, red blood cell.

Both plasma factors and membrane proteins control the formation and stability of the alternative pathway C3 convertase (Fig. 34.4, part 2 and Fig. 34.4, part 2). Factor H ([103]) regulates the formation and stability of the convertase in the following three ways: First, by binding to C3b, it inhibits factor B binding; second, by binding to C3bBb, it displaces Bb from the complex; third, by binding to C3b, it acts as a cofactor for the enzymatic degradation of C3b to iC3b by factor I ([55] , [104] , [105]). DAF (CD55) is the erythrocyte membrane constituent that is primarily responsible for regulating the activity of the alternative pathway C3 convertase. It binds to the C3bBb complex causing the enzymatic subunit to dissociate ([43]). CR1 also controls C3 convertase activity. Using isolated complement components, purified CR1 has been shown to accelerate the decay of the alternative pathway C3 convertase *in vitro* ([106]). *In vivo*, however, it appears likely that erythrocyte CR1 functions primarily as a factor I cofactor rather than as a regulator of the C3 convertase because blocking CR1 function does not enhance alternative pathway C3 convertase activity when serum is used as the complement source ([107]). Further, available evidence suggests that CR1 exerts its activity intercellularly (binding to C3b on neighboring cells), whereas DAF functions as an intracellular regulator of the convertase (binding to C3bBb on the same cell) ([108]).

The C5 convertase of the alternative pathway consists of C3bBbC3b, with one of the C3b molecules acting as the binding site for Bb and the other molecule serving to position C5 for cleavage by Bb ([109]) (Fig. 34.4, part 4 and Fig. 34.4, part 4). As is the case for the C3 convertase, the C5 convertase is stabilized by factor P, and the same plasma and membrane constituents that regulate the C3 convertase control the activity of the C5 convertase (Fig. 34.4, part 4 and Fig. 34.4, part 4). Generation of C5b as a result of enzymatic cleavage of C5 by Bb releases C5a and initiates formation of the MAC (Fig. 34.4, part 6 and Fig. 34.4, part 6) in a manner analogous to that described above for the classic pathway. The cytolytic activity of the MAC formed on erythrocytes by the alternative pathway is inhibited by MIRL (CD59) (Fig. 34.3, part 7).

RECEPTORS FOR COMPLEMENT AND IMMUNOGLOBULIN G

That immune destruction of erythrocytes is rarely a consequence of complement-mediated intravascular hemolysis is a testament to the effectiveness of the membrane regulatory proteins DAF (CD55) and MIRL (CD59). In most cases of immune hemolytic anemia, erythrocyte destruction is an extravascular process that is mediated by cells of the reticuloendothelial system. Professional phagocytes that are found in the spleen and liver express receptors for the Fc portion of IgG and for activation (C3b) and degradation (iC3b) products of complement. Binding to these specific receptors (Fc?R, CR1, and CR3) stimulates phagocytosis of erythrocytes opsonized with IgG or complement, or both.

Complement Receptors

Four classes of CRs have been recognized (Table 34.1). Two of these (CR1 and CR2) share a similar structural motif and belong to the regulators of complement activation superfamily ([53]). CR1 ([42] , [110] , [111]) and CR2 ([112]) recognize different ligands and have different patterns of tissue expression (Table 34.1). Because it is not expressed by tissue macrophages, CR2 does not participate in immune destruction of erythrocytes. The other two CRs (CR3 and CR4) belong to the integrin superfamily ([113]). They are heterodimers that have a unique a-chain but share a common ß-chain. Although their ligand binding specificity and tissue distribution show considerable overlap (Table 34.1), only CR3 has been shown unequivocally to participate in immune destruction of erythrocytes. The C3 activation and degradation products that are found on erythrocytes and the mechanisms involved in their generation are illustrated in Figure. 34.5.

TABLE 34.1. Characteristics of Complement Receptors (CRs)

Receptor	Relative Molecular Mass (kd)	Complement Ligand	Cellular Distribution	Functions
CR1 (CD35)	210–330 (four allotypes); single-chain gp with ~30 SCRs	C3b (high affinity); C4b, iC3b (weak affinity)	RBCs; PMNs; Mo; Mf; B and some T lymphocytes; follicular dendritic cells; Langerhans cells; Kupffer cells	Regulates C3, C4, and C5 convertase of classic and alternative pathways of complement; factor I cofactor; RBC CR1, [a] phagocyte CR1 [b]
CR2 (CD21)	145; integral membrane gp with 15 SCRs	C3dg, C3d	B lymphocytes; follicular dendritic cells	Immune modulation; cellular receptor for the Epstein-Barr virus
CR3 (CD11b/CD18)	165 (CD11b), 95 (CD18); heterodimer	iC3b	PMNs; Mo; Mf; NK cells; cytotoxic T cells	Adherence and phagocytosis of opsonized RBCs
CR4 (CD11c/CD18)	150 (CD11c), 95 (CD18); heterodimer	iC3b	PMNs; Mo; Mf; NK cells; cytotoxic T cells	Undefined

gp, glycoprotein; Mo, monocyte; Mf, macrophage; NK, natural killer; PMN, polymorphonuclear neutrophil; RBC, red blood cell; SCR, short consensus repeat.

[a] RBC CR1 transports immune complexes to macrophages for clearance.

[b] Phagocyte CR1 promotes the adherence and phagocytosis of sensitized cells and immune complexes.

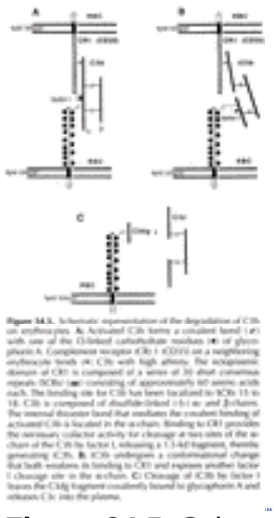

Figure 34.5. Schematic representation of the degradation of C3b on erythrocytes. **A:** Activated C3b forms a covalent bond ( ) with one of the O-linked carbohydrate residues (•) of glyco-phorin A. Complement receptor (CR) 1 (CD35) on a neighboring erythrocyte binds (*) C3b with high affinity. The ectoplasmic domain of CR1 is composed of a series of 30 short consensus repeats (SCRs) ( ) consisting of approximately 60 amino acids each. The binding site for C3b has been localized to SCRs 15 to 18. C3b is composed of disulfide-linked (-S-) a- and ß-chains. The internal thioester bond that mediates the covalent binding of activated C3b is located in the a-chain. Binding to CR1 provides the necessary cofactor activity for cleavage at two sites of the a-chain of the C3b by factor I, releasing a 1.5-kd fragment, thereby generating iC3b. **B:** iC3b undergoes a conformational change that both weakens its binding to CR1 and exposes another factor I cleavage site in the a-chain. **C:** Cleavage of iC3b by factor I leaves the C3dg fragment covalently bound to glycophorin A and releases C3c into the plasma.

COMPLEMENT RECEPTOR 1 As discussed above, erythrocyte CR1 functions as a regulator of the C3 and C5 amplification convertases of both the classic and the alternative pathways. Along with factor H, it serves as a cofactor for factor I–mediated degradation of C3b to iC3b, and it is an essential cofactor for the subsequent conversion of iC3b to C3c and C3dg by factor I (Fig. 34.4). Erythrocyte CR1 also appears to be critically important in the processing of immune complexes. Complement opsonized immune complexes bind with high affinity to erythrocyte CR1. The cell-bound complexes are transported to the liver, where they are removed as the erythrocytes traverse the hepatic circulation. In delivering the immune complexes, the red cells are neither trapped nor detained in the liver, although it appears that some erythrocyte CR1 is consumed during the process ([114]). In addition to erythrocytes, a variety of tissues including professional phagocytes of the spleen and liver express CR1 ([110] , [115] , [116] and [117]). Four different CR1 allotypes have been identified that vary in size from 250 to 160 kd ([118] , [119] and [120]). The gene frequency for the most common allotype (called *A* or *F*) is 0.82. The second most common allotype (called *B* or *S*) has a frequency of 0.18. The other two allotypes (called *C* and *D*) are rare. CR1 is comprised of 30 SCR units, and discrete binding sites for C3b and C4b have been identified. The binding site for C3b has been localized to SCRs 15 to 18, whereas the C4b binding is located within SCRs 1 to 4 ([121] , [122] and [123]). Erythrocytes bearing C3b bind specifically to CR1 on macrophages, but this interaction does not induce phagocytosis *in vitro* unless the macrophages have been stimulated ([117]). In contrast, erythrocytes bearing C3b and even small amounts of IgG are avidly ingested by unstimulated monocytes ([2]). Together, these observations suggest that an important role of CRs in immune clearance of opsonized erythrocytes is to mediate attachment to receptor-bearing cells of the reticuloendothelial system so that the phagocytic process that is induced through low-affinity ligation of Fc receptors by cell-bound IgG can be initiated. However, it is clear from *in vivc* studies that opsonization with complement alone is sufficient to produce rapid clearance of sensitized erythrocytes (see Destruction by Immunoglobulin M Antibodies). Reticuloendothelial cell CR1 may play a limited role in this process, as cell-bound C3b is very rapidly degraded to iC3b and then to C3dg (Fig. 34.5). Whereas *in vitro* studies have shown that CR1 does bind iC3b, the affinity is much lower than for C3b ([117]). Binding of erythrocyte C3dg to CR1 has not been observed. CR1 binds C4b, although the affinity is relatively low, and a high density of C4b is required ([117]). However, based on the observation that C4b in combination with C3b (as would be found during classic pathway activation) enhances the interaction of complement-opsonized erythrocytes with cells expressing CR1, it is conceivable that C4b plays a minor role in immune destruction of erythrocytes. In support of this suggestion, C4b has been shown to function as an opsonin in C3-deficient patients ([117]).

COMPLEMENT RECEPTOR 2 The primary structure of CR2 (CD21) is similar to that of CR1 in that both proteins are single-chain polypeptides composed in large part of a series of SCRs (CR2 has 15 SCR units, whereas CR1 has 30 SCR units). The natural ligand for CR2 is C3dg; however, this receptor does not appear to participate in immune destruction of erythrocytes because studies have shown that erythrocytes from patients with chronic cold agglutinin disease bearing C3dg have a normal lifespan ([57]). That CR2 is not expressed on phagocytic cells accounts for its lack of participation in the immune destruction of erythrocytes. CR2 is expressed on B lymphocytes, where it plays a pivotal role in immune response ([124]). CR2 is also the B-cell receptor for Epstein-Barr virus ([112]).

COMPLEMENT RECEPTOR 3 Unlike CR1 and CR2, CR3 does not belong to the regulators of complement activation family; rather, it is a member of the integrin superfamily of proteins ([113] , [125]). CR3 is a heterodimer consisting of noncovalently linked a- (CD11b) and ß- (CD18) chains that are the products of different genes ([125]). Phagocytic cells express CR3, and they bind erythrocytes bearing iC3b with high affinity. In the absence of stimulation, however, they do not ingest iC3b opsonized cells *in vitro* ([126]). Nonetheless, it seems likely that CR3 plays a central role in immune destruction of opsonized erythrocytes. Not only is CR3 required for binding and ingestion of iC3b opsonized cells, but also both IgG- and C3b-dependent phagocytosis require the participation of CR3 ([127] , [128] , [129] and [130]). There is no evidence that CR3 binds either C3b or C3dg. Thus, the conversion of iC3b to C3dg by the concert actions of factor I and CR1 may provide some protection of complement-opsonized erythrocytes because the ligand for CR3 is destroyed in the process ([131]).

COMPLEMENT RECEPTOR 4 Like CR3, CR4 (p150,95) is a member of the integrin superfamily ([132]). It belongs to the ß $_2$ subgroup of integrins along with leukocyte function antigen-1 and CR3. These molecules share a common ß-chain (CD18), but each has a unique a-chain (CD11a for leukocyte function antigen-1, CD11b for CR3, and CD11c for CR4). An abnormality of the ß-chain resulting in a deficiency of all three members of the CD11/CD18 family underlies the leukocyte adhesion deficiency syndrome. Patients with this rare inherited disease are usually identified within the first 2 years of life because of recurrent, often fatal bacterial infections ([133]). *In vitro* studies have shown that CR4 on culture-derived macrophages binds both iC3b- and C3dg-bearing erythrocytes. Little is known about the function of CR4. Whereas tissue macrophages express a high number of CR4 molecules/cell, binding to CR4 on activated macrophages does not cause ingestion of complement-opsonized erythrocytes ([117]). Thus, until more definitive data become available, the role of CR4 in the immune destruction of erythrocytes must be considered speculative.

Fc? Receptors

Three distinct classes of Fc? receptors have been recognized (Table 34.2); within each class, additional heterogeneity is observed ([134] , [135] , [136] and [137]). In some cases, the heterogeneity is due simply to allelic polymorphisms, whereas in other cases, the different isoforms are the products of either alternative splicing or separate, highly homologous genes. The loci for the Fc? receptors are clustered on chromosome 1q23, supporting the hypothesis that these closely related proteins arose by gene duplication. Available evidence suggests that Fc?RI and Fc?RIIIa require an additional subunit (called ?) for assembly and signaling ([135]). Based on similarities in structural motifs, the Fc? receptors have been placed in the Ig superfamily. As their names suggest, these receptors bind to a region in the Fc portion of IgG. Their affinity for IgG1 and IgG3 is greater than for IgG2 and IgG4, and there is considerable overlap in the tissue distribution of the Fc? receptors. In particular, tissue macrophages express all three types, and each of the three receptors can mediate adherence and phagocytosis of IgG-opsonized particles. Thus, it appears likely that all three classes of Fc? receptors participate in immune destruction of erythrocytes. In addition to phagocytosis, Fc? receptors participate in a myriad of other inflammatory and immunomodulatory functions including antibody-dependent cell-mediated cytotoxicity (ADCC), mast cell degranulation, superoxide production, release of cytokines, and regulation of lymphocyte secretion and antibody production.

TABLE 34.2. Characteristics of Fc? Receptors

Receptor	Relative Molecular Mass (kd)	Affinity for IgG	Cellular Distribution	Functions
Fc?RI (CD64)	72; integral membrane gp IgG; mediates	High (1–3 × 10^{-8} L/M)	Mo; tissue Mf	Binds monomeric; interferon-? stimulated
			PMNs	ADCC and rosetting of IgG-coated RBCs; not essential for phagocytosis
Fc?RII (CDw32)	40; integral membrane gp	Low (2 × 10^{-5} L/M)	Mo; tissue Mf; platelets; PMNs; B lymphocytes	Binds aggregated IgG; mediates ADCC; weak mediator of rosetting; important for phagocytosis

Fc?RIII (CD16)	50–80; both integral membrane (Fc?RIIIa) and glycosyl phosphatidylinositol–anchored (Fc?RIIIb) forms	Low (5×10^{-5} L/M)	PMNs (Fc?RIIIb); tissue Mf; natural killer cells (Fc?RIIIa)	Binds aggregated IgG; important for clearance of IgG-sensitized RBCs

ADCC, antibody-dependent cellular cytotoxicity; gp, glycoprotein; Ig, immunoglobulin; Mo, monocyte; Mf, macrophage; PMN, polymorphonuclear neutrophil; RBC, red blood cell.

Fc? Receptor I Fc?RI is distinctive because it is the only Fc? receptor for which the binding of monomeric IgG can be measured directly. Accordingly, Fc?RI is called the *high-affinity receptor* (Table 34.2). The isotype specificity of Fc?RI is as follows: IgG3 > IgG1 > IgG4 >>> IgG2 ([136], [137]). Fc?RI is expressed constitutively by monocytes and tissue macrophages but not by natural killer (NK) cells or by B or T lymphocytes. Neutrophil expression of Fc?RI requires stimulation with interferon-?, whereas monocyte expression can be enhanced eight- to tenfold by treatment with this cytokine. In addition to its capacity to mediate phagocytosis, Fc?RI also directs ADCC ([136], [138]). Congenital deficiency of Fc?RI has been reported in four members of a family ([139]). These individuals were healthy with no circulating immune complexes, no evidence of autoimmune pathology, and no increased susceptibility to infections. *In vitro* studies showed that monocytes from the affected subjects bound aggregated IgG and phagocytosed IgG-coated erythrocytes via Fc?RII. These observations provide clear evidence of redundancy of function, underscoring the critically important role that Fc? receptors play in host defense.

Fc? RECEPTOR II Three different genes encode at least six different Fc?RII transcripts ([135], [137]). This receptor has a low affinity for monomeric IgG; however, binding of immune complexes to Fc?RII can be readily demonstrated. Based on these observations, it appears likely that *in vivo* Fc?RII binds IgG that is clustered on opsonized particles. Fc?RII has the widest tissue distribution among the Fc? receptors, being constitutively expressed on all peripheral blood elements except NK cells and T lymphocytes ([135]). There is no evidence of enhancement of Fc?RII expression by cytokines, although neutrophil-directed ADCC is augmented by treatment with interferon-? ([136]). The isotype specificity of Fc?RII is as follows: IgG1 = IgG3 >>> IgG2, IgG4 ([135]). Like Fc?RI, Fc?RII has the capacity both to mediate phagocytosis and to direct ADCC ([137]). Humans with inherited deficiencies of Fc?RII have not been reported. Mice lacking Fc?RII have been generated using homologous recombination ([134]). Studies using the mutant animals suggested that Fc?RII acts as a general negative regulator of the immune response.

Fc? RECEPTOR III Two forms of this receptor have been identified. In one case (Fc?RIIIa), the receptor is an integral protein (i.e., it has ectoplasmic, transmembrane, and cytoplasmic domains). In this case, the protein is anchored to the plasma membrane via the transmembrane domain that consists of a short stretch of hydrophobic amino acid residues (Fig. 34.1). In contrast to Fc?RIIIa, Fc?RIIIb is GPI-anchored. In this case, the protein has the same ectoplasmic domain as Fc?RIIIa, but the transmembrane and cytoplasmic domains are replaced by the GPI moiety that serves as the membrane anchor (Fig. 34.1). The two Fc?RIII are the products of separate, but highly homologous, genes. A single amino acid substitution at position 203 determines the nature of the anchor. Phe-203 is found in the transmembrane form (Fc?RIIIa), and Ser-203 is found in the GPI-anchored form (Fc?RIIIb) ([135]). Expression appears to be tissue specific with neutrophils expressing Fc?RIIIb exclusively and natural killer cells and macrophages expressing only Fc?RIIIa. Important functional differences have been reported between the two forms of Fc?RIII. Fc?RIIIa can mediate phagocytosis and direct ADCC, whereas Fc?RIIIb can direct ADCC of red cells, but it appears incapable of mediating phagocytosis ([137], [138]). Although there are conflicting data, some *in vitro* studies suggest that engagement of neutrophil Fc?RIIIb can trigger a respiratory burst ([137]). The physiologic role of Fc?RIIIb *in vivo* has not been clearly defined. Subjects with isolated deficiencies of Fc?RIIIb have been reported. One of the subjects had systemic lupus erythematosus ([140]), whereas two others were healthy without evidence of either immune complex disease or increased susceptibility to infection ([141]). Additionally, patients with PNH (who are deficient in neutrophil Fc?RIIIb) are not afflicted with immune complex disease. Polymorphisms affecting Fc?RIIIb are the basis of the biallelic NA antigen system of neutrophils ([135]). Like Fc?RII, Fc?RIII has an affinity for monomeric IgG that is too low to be measured directly. Indirect studies, however, have defined the isotype specificity as follows: IgG1 = IgG3 >>> IgG2, IgG4 ([136], [137]). *In vivo* studies suggest a critically important role for Fc?RIIIa in immune destruction of erythrocytes. Using the Fab fragment of a monoclonal antibody that blocks the function of Fc?RIIIa on the mononuclear phagocytic system of chimpanzees, Clarkson and colleagues ([142]) reported a dramatic inhibition of clearance of autologous erythrocytes bearing IgG. Those same investigators also presented *in vivo* evidence that monoclonal anti-Fc?RIII ameliorates destruction of platelets in patients with immune thrombocytopenic purpura ([143]). These findings complement other observations that have shown that antibody-coated erythrocytes and platelets are cleared primarily by macrophages in the red pulp of the spleen and that these cells express Fc?RIIIa in high density ([136]). Surprisingly, studies using targeted gene disruption showed that opsonization by murine peritoneal macrophages of sheep erythrocytes coated with murine IgG1 is mediated specifically by Fc?RIII ([144]). Whether this degree of specificity exists in humans remains to be determined. Additional studies showed that the Fc?RIII knock-out mice lacked IgG-mediated mast cell degranulation, were resistant to IgG-dependent passive cutaneous anaphylaxis, and exhibited an impaired Arthus reaction ([144]).

MECHANISMS OF IMMUNE DESTRUCTION OF ERYTHROCYTES

Destruction by Immunoglobulin M Antibodies

Inasmuch as receptors that are specific for the Fc portion of IgM do not exist, destruction of erythrocytes sensitized with IgM antibodies is mediated indirectly by the complement system. As discussed in detail above, complement mediates destruction in the following two ways: (a) directly by cytolysis, and (b) indirectly through interaction of cell-bound activation and degradation fragments of C3 with specific receptors on reticuloendothelial cells, principally liver macrophages (Kupffer cells).

Because of its pentameric structure, IgM activates complement efficiently. High-titer IgM antibodies such as anti-A and anti-B can cause direct intravascular hemolysis by generating the cytolytic MAC of complement on the erythrocyte surface. If the antibody density is great enough, complement activation may be sufficiently robust to overwhelm the inhibitory activity of the complement regulatory proteins DAF (CD55) and MIRL (CD59). When ^{51}Cr-labeled red cells are infused into ABO-incompatible subjects with relatively high concentrations of IgM antibodies, hemoglobinemia appears abruptly and is pronounced, reflecting the virtually instantaneous destruction of incompatible cells by complement-mediated lysis ([145], [146]). At least 80% of the hemoglobin contained in the injected cells appears in plasma, with peak levels being reached in less than 60 seconds.

However, in most clinical situations, IgM antierythrocyte antibodies are present in sublytic quantities. Under these conditions, DAF (CD55) and MIRL (CD59) are able to prevent direct cell lysis. Nonetheless, some C3b is deposited on the cell surface as a consequence of the IgM-induced complement activation, and interactions of C3b and iC3b with their specific receptors on liver macrophages (Kupffer cells) are ultimately responsible for the immune destruction of erythrocytes under sublytic conditions. Although ligation of erythrocyte-bound C3b to CR1 on Kupffer cells may mediate some of the clearance, interaction between erythrocyte-bound iC3b and macrophage CR3 is probably the principal mediator of extravascular destruction of complement-sensitized erythrocytes. Erythrocyte-bound C3b is rapidly degraded to iC3b because both plasma factor H and CR1 on neighboring erythrocytes can serve as a cofactor for the enzymatic conversion of C3b to iC3b (Fig. 34.5). The half-life of erythrocyte-bound iC3b is probably longer than that of C3b because, under physiologic conditions, only CR1 can provide the obligatory cofactor activity for conversion of iC3b to C3dg by factor I. Further, the affinity of CR1 for iC3b is much weaker than the affinity of CR1 for C3b (Fig. 34.5). It seems likely that clearance of the complement-sensitized erythrocytes is mediated by phagocytosis because the liver lacks the unique anatomy of the spleen and is thus unable to sequester cells (discussed more in Destruction by Immunoglobulin G Antibodies). *In vivo* studies have shown that when small quantities of ABO-incompatible ^{51}Cr-labeled red cells are infused into subjects with normal levels of anti-A and anti-B isoagglutinins, one-half of the labeled erythrocytes are removed in just under 2 minutes, and surface counting shows rapid accumulation of radioactivity over the liver ([145]). That clearance of complement-opsonized cells is mediated by the liver explains why patients with cold agglutinin disease do not benefit from splenectomy. Once erythrocyte-bound iC3b has been converted to C3dg, the cells are no longer subject to immune destruction because the specific receptor for C3dg (CR2) is not expressed by phagocytic cells (Table 34.1). Thus, erythrocytes bearing C3dg only have a normal lifespan ([23], [57]).

Destruction by Immunoglobulin G Antibodies

As discussed in detail above, IgG is a relatively ineffective initiator of activation of the classic pathway of complement because two antibody molecules bound in close proximity are required to support binding of C1q. Consequently, direct complement-mediated cytolysis of erythrocytes induced by IgG antibodies is unusual (an exception is the Donath-Landsteiner antibody of paroxysmal cold hemoglobinuria). In the absence of complement activation, IgG-sensitized erythrocytes are cleared primarily by the spleen. Two processes appear to be involved. First, binding to Fc receptors expressed by tissue macrophages in the red pulp of the spleen can mediate direct phagocytosis. Second, partial phagocytosis, in which a portion of the membrane is removed by the phagocytes, results in a decrease in the surface area to volume ratio. This process appears to be responsible for the production of spherocytes, the morphologic hallmark of immune hemolytic anemia. The loss of deformability that is a consequence of spherocyte formation results in sequestration of the abnormal cells in the red pulp because they are too rigid to traverse the splenic cords into the sinuses. The trapped spherocytes are vulnerable to phagocytosis by professional phagocytes that are found in abundance in the splenic cords. Additionally, the lifespan of the sequestered cells is shortened by the unfavorable metabolic environment found in the splenic cords (a process called *splenic conditioning*). Once trapped, cell destruction appears to be complete within minutes.

When small volumes of ^{51}Cr-tagged Rh0(D) red cells are injected into individuals with relatively high titers of IgG anti-Rh0 antibodies, the labeled erythrocytes are removed quickly from the circulation, and a concomitant increase of radioactivity is noted over the spleen and, to a smaller degree, over the liver ([145], [147], [148]). The half-life of these cells in the circulation is only a few minutes, and minimal amounts of hemoglobin appear in plasma, attesting to the predominantly extravascular destruction of erythrocytes sensitized with IgG antibodies. Even when larger volumes of Rh-incompatible red cells are given, the concentration of plasma free hemoglobin does not reach levels higher than those that would be derived from 12% of the total number of cells infused. Further, the amount of extracellular hemoglobin reaches a peak 1 hour after transfusion, suggesting that intravascular spillage occurs only when the mechanisms for removal of extravascularly released heme proteins have been saturated ([145]). The mechanism of hemoglobin release under these circumstances is obscure.

Extravascular splenic destruction of anti-Rh antibody-coated red cells occurs over a wide range of antibody concentrations ([149]). The speed of removal from the circulation appears to depend on the amount of antibody coating the red cells ([149], [150]). Antibody concentrations of 25 µg/ml of red cells (corresponding to a titer of 1:64 or more) are required to bring about their clearance with a single passage through the spleen, the clearance half-time being approximately 20 minutes. Antibody concentrations of less than 5 µg/ml of red cells and corresponding to titers of 1:8 or less may bring about the removal of red cells in a half-time of 60 to 100 minutes ([149], [151]). The liver clears red cells coated with IgG antibodies less efficiently than does the spleen. Even when erythrocytes are sensitized with as much as 40 µg of antibody/ml of red cells, only approximately one-third are cleared by a single passage through the liver ([149]). Nevertheless, the liver plays a clinically significant role in the destruction of red cells. A rough correlation exists between the amount of antibody fixed to the red cell surface and the site of destruction (smaller amounts of antibody leading mainly to splenic sequestration and larger amounts of antibody leading to increased sequestration within the liver) ([147], [150], [152]).

The more rapid clearance of erythrocytes sensitized with a higher density of IgG antibodies and the shift in the clearance from the spleen to the liver are due to complement activation ([149], [152]). The presence of C3b, iC3b, or both acts synergistically with IgG to generate a potent phagocytic signal ([2]). *In vivo* studies involving complement-deficient subjects showed a reduced rate of clearance of IgG-sensitized red cells, although the sensitized cells were still cleared more rapidly than normal ([152], [153] and [154]). Together, these studies demonstrate that IgG alone can mediate red cell clearance, but the concomitant presence of cell-bound C3 fragments greatly enhances the rate of immune-mediated destruction.

That Fc receptors play a critical role in immune destruction *in vivo* is further demonstrated by the therapeutic approach to management of autoimmune hemolytic anemia (and immune thrombocytopenic purpura). Treatment with corticosteroids, intravenous IgG, anti-D, and splenectomy is aimed at reducing the capacity of reticuloendothelial cells to mediate immune clearance of IgG-sensitized cells ([155]). After splenectomy, the rate of clearance of IgG-sensitized red cells is significantly decreased, whereas the rate of clearance of complement-sensitized cells is unchanged ([156]). IgG sensitization must be increased by approximately fourfold to produce an equal rate of clearance in splenectomized subjects compared to clearance in the same subjects before splenectomy. Under conditions of higher IgG sensitization, complement is activated, resulting in destruction of the opsonized cells by the liver in the postsplenectomy subjects. The most important features of red cell destruction by IgM and IgG antibodies are summarized in Table 34.3.

TABLE 34.3. Red Cell Destruction by Immunoglobulin (Ig) M and IgG Antibodies

	Predominant Site of Red Blood Cell Destruction						
		Extravascular					
Antibody	**Intravascular**	**Liver**	**Spleen**	**Complement Dependency**	**Hemoglobinuria**	**Bilirubinemia**	**Specificity of Antiglobulin Test**
Low-titer IgM [a]	+	+	–	+	±	+	Anti-C
High-titer IgM	+	–	–	+	+	+	Anti-C
Low-titer IgG [b]	–	–	+	–	–	+	Anti-IgG
High-titer IgG	–	±	+	–	±	+	Anti-IgG

Anti-C, anti-complement.

[a] Anti-A or anti-B blood group antibodies are examples of IgM antibodies that can be present at low or high concentrations.

[b] Anti-Rho(D) is an example of an IgG antibody that can be present at low or high concentrations.

Role of Cytotoxic Cells in Immune Red Cell Destruction

Although the primary mechanisms of extravascular red cell destruction are splenic sequestration and macrophage-mediated phagocytosis, direct cytotoxicity mediated by neutrophils, eosinophils, monocytes, and lymphocytes independent of phagocytosis has been demonstrated ([157]). This process (called *ADCC*) is dependent on engagement of Fc receptors on the effector cells by erythrocytes opsonized with IgG. All three classes of Fc? receptors can direct ADCC ([138]). Although the process is not dependent on complement, the presence of activation and degradation products of C3 on the target cell enhances ADCC mediated by lymphocytes ([158]). This situation is analogous to that observed for phagocytosis by monocytes, in which the concomitant engagement of Fc and CRs has a synergistic effect ([2]). Further, the susceptibility of individual erythrocytes to ADCC appears to be proportional to the total IgG available for interaction with effector cells ([159]).

ADCC of nucleated cells by cytotoxic lymphocytes is a complex process that appears to involve effector systems that can kill cells by more than one mechanism ([160]). In the case of red cells, however, hemolysis induced by cytotoxic T lymphocytes and NK cells appears to be mediated by perforin ([161]). This 70-kd protein is found in the granules of cytolytic T cells and NK cells. When incubated with target cells, perforin binds to the membrane and undergoes a Ca^{2+}-dependent polymerization that forms a transmembrane channel. Consequently, the cells undergo colloid osmotic lysis in a manner analogous to that induced by complement. When viewed by electron microscopy, the membrane lesion induced by perforin is indistinguishable from the ringed “donut” lesion characteristic of complement-mediated lysis ([161]). In addition to functional similarities, perforin shows limited structural homology with MAC components. In contrast to the MAC-induced hemolysis, however, hemolysis mediated by perforin is not regulated by MIRL ([162]).

ADCC appears to function primarily as a mechanism for destroying tumor cells and cells infected with virus. The contribution ADCC makes to immune destruction of red cells has not been clearly defined. That an *in vitro* assay based on ADCC can be used to predict the severity of hemolytic disease of the newborn due to anti-D, however, suggests that the process may be pathophysiologically relevant ([163], [164]).

Autoimmune Hemolytic Anemias

CLASSIFICATION

Autoimmune hemolytic anemia (AIHA) occurs when a patient produces pathologic antibodies that attach to and lead to the destruction of red blood cells (RBCs), causing anemia. For AIHA to be present, both pathogenic antibodies and associated erythrocyte consumption must occur. These syndromes can be most easily classified according to the characteristic temperature activity of the antibodies (Table 35.1). Cold active antibodies typically have little, if any, activity at body temperature but display increasing affinity for the RBC as the temperature approaches 0°C. Conversely, warm active antibodies have their greatest affinity at 37°C. Although notable exceptions occur, as a general rule, cold active antibodies are generally of the immunoglobulin (Ig) M type, fix complement, and may lead to immediate intravascular destruction of erythrocytes or their removal from the circulation by the liver. Warm antibodies are typically of the IgG variety, may or may not fix complement, and primarily lead to RBC loss by splenic removal of the sensitized cells. These mechanisms are detailed later in this chapter. Occasionally, a patient may have mixed cold and warm antibodies, which are particularly troublesome clinically as they usually cause severe RBC destruction and frequently respond poorly to therapy ([1]).

TABLE 35.1. Classification of Immune Hemolytic Anemias

Cold active antibodies
Cold agglutinin disease
Primary or idiopathic
Secondary
Lymphoproliferative diseases
Autoimmune disorders
Infections
Mycoplasma pneumoniae
Infectious mononucleosis
Other viruses
Paroxysmal cold hemoglobinuria
Syphilis
Measles, mumps, other viruses
Mixed cold and warm active antibodies
Warm active antibodies
Idiopathic autoimmune hemolytic anemia
Secondary autoimmune hemolytic anemia
Lymphoproliferative disorders
Autoimmune disorders
Other malignancies
Viral infections
Immune deficiency states
Drug-induced hemolytic anemia
Drug adsorption type (penicillin)
Neoantigen type (quinidine/stibophen)
Autoimmune type (a-methyldopa)

Drug-induced hemolytic anemia is caused by warm active antibodies that may be clinically and serologically indistinguishable from the idiopathic warm autoimmune type (a-methyldopa type) or dependent on the presence of the drug in serologic studies to demonstrate attachment of the antibody to the RBC. The clinical spectrum of drug-induced antibody attachment to erythrocytes ranges from asymptomatic positive serologic studies to life-threatening massive hemolysis ([2]).

ETIOLOGY OF AUTOIMMUNE RESPONSE

Mechanisms of Immune Self-Tolerance

The immune system faces the unenviable task of protecting the body against foreign invaders while not mounting any significant response to self-antigens. To attain these goals, the system has evolved into a multistep process of producing an immune response with attendant control points at each step (Fig. 35.1). Autoimmune syndromes may result if these processes are not properly regulated and subjected to the appropriate balance. However, the exact mechanism(s) by which autoimmune disease occurs is still not known.

Figure 35.1. Stages at which self-tolerance can block B-cell development. Arrows indicate the normal pathway of development. X indicates where these differentiation steps can be interrupted for self-reactive B cells as a consequence of encountering self-antigen. sIgM, surface immunoglobulin M. (Adapted from Schlomchik MJ. Mechanisms of immune self-tolerance and how they fail in autoimmune disease. In: Silberstein L, ed. Autoimmune disorders of blood. Bethesda, MD: American Association of Blood Banks, 1996:1–34.)

CENTRAL TOLERANCE: FIRST CHANCE AT CONTROL *Central tolerance* refers to control steps in place in the bone marrow or the thymus that prohibit the development and peripheral release of clones of B and T cells reactive to self-antigens ([3]). To prepare for the potential diversity of a world full of antigens, B cells rearrange Ig genes recombining segments $V_{H,\ J,\ and\ D}$ and V_L, and T cells rearrange receptors (T-cell receptors) to recognize intruders and ensure their demise. As one might expect given the vast potential of recombinations possible, reactions with self-antigens can and do occur. If these cells are found to react strongly with antigens in early fetal life, the stimulation leads to apoptosis, thus removing the cell from the population, never to be seen again, in a negative selection process termed *clonal deletion* ([4], [5]). This was predicted by Owen in 1945 ([6]), who observed that dizygotic cattle twins that had exchanged blood and stem cells *in utero* were tolerant of the other's blood after birth. This concept has been proven with transgenic mice experiments that implanted Ig genes for specific antigens present in one strain of mouse and absent in another. Entire clones of B cells producing the transgene product are absent in the strain exhibiting the target antigen. Full production of antibody occurs in the strain not producing the antigen ([7], [8]). Exactly what happens to these B cells is not clear ([4], [9]). Strong interactions between antigen and immune cells in the bone marrow or thymus lead to the cells' early demise. However, weak interactions with a low-avidity antigen pose less of a threat to self and are kept in the repertoire in a positive-selection process to enhance the immune response against invaders ([10]). T cells express unique and specific receptors by recombining Va and Vß or V? and Vd gene segments ([11]). Macrophages and dendritic cells in the fetal thymus engulf and process outside material, such as RBCs, for presentation to thymocytes. T cells recognize antigens when randomly recombined receptors match a peptide sequence from an antigen presented in conjunction with major histocompatibility complex (MHC) class I/II molecules ([12]). MHC molecules are membrane glycoproteins on macrophages and dendritic cells required for T-cell recognition and processing of antigen peptides. T cells with the $CD4^+$ helper phenotype require MHC class II, and T cells that are $CD8^+$ suppressor cells recognize MHC class I ([13], [14]). T cells undergo a fate similar to deleted B-cell clones if their T-cell receptors bind with high affinity to peptide-presenting cells in the fetal thymus. More than 95% of thymocytes and lymphocytes are banished from the fetal population through cell death by apoptosis so that self-tolerance may be maintained throughout adult life ([15]). Another central control mechanism to prevent autoimmune disease is the inactivation, but not elimination, of cells designed to respond to self-antigens. This process, termed *clonal anergy*, produces B cells that have less surface Ig, have shorter half-lives in the peripheral circulation, and respond poorly to encountered antigen ([7], [16]). An equivalent process occurs in T-cell development, whereby T cells are incapable of responding appropriately to peptides presented ([17]). Central tolerance has significant limitations. Removal of any and all potential self-reactive cells is not only impossible but may also be undesirable. All of these control points must be balanced with the body's need to have a ready army to defend it against outside foes. A workable compromise is established with the elimination of the high-affinity responding cells only, leaving the weakly self-responding clones available for deployment against intruders. The sheer numbers of potential proteins to be encountered in the body make it unlikely that all potential self-reacting clones are effectively destroyed *in utero* ([18]). Also, many proteins, such as thyroglobulin, are tissue specific and never circulate, thus they are not available for presentation to immune cells in the thymus or bone marrow. Still other immunogens, such as the I antigen on RBCs, are not expressed significantly until after birth, making fetal presentation an impossibility ([19]). Autoimmune diseases are frequently associated with a relative increase in $CD5^+$ B lymphocytes ([20]). This particular type of lymphocyte, also called a *B-1 cell*, is a population of B cells that arises from progenitors in the fetal peritoneal cavity. They develop in this relative sanctuary without exposure to antigens; therefore, no tolerance develops ([21]). They do not participate in the typical B-cell immune response but normally produce the low-affinity, “natural” IgM antibodies with broad reactivity to bacterial and blood group antigens ([22]). Perhaps partly because they may be less likely to encounter antigens during fetal life, $CD5^+$ B cells are overrepresented in autoimmune and malignant processes such as chronic lymphocytic leukemia (CLL) ([23]). They are also believed to play a role in regulating the immune system network. In CLL, the $CD5^+$ malignant clone is not typically the cell responsible for producing the pathologic RBC autoantibody but may participate in its induction ([24], [25]).

PERIPHERAL TOLERANCE: BACKUP CONTROL MECHANISMS There are many ways in which autoimmune populations may arise. That some cells escape the control mechanisms just described is well known. Realizing that many self-reactive immune cells evade early destruction, other mechanisms of restraining the immune response exist to provide further protection. For an immune response to occur as planned, the appropriate B cell must first encounter the antigen and process it for presentation to a T cell. Absence of circulating antigens in fetal life may continue after birth, and the cell is never stimulated to produce antibodies. This *clonal ignorance* may continue for as long as the antigen remains secluded in tissue or circulates in very small quantities. If an infectious or inflammatory process releases antigen into the circulation, a postinfectious autoimmune syndrome may result due to the exposure to this self-antigen. An example of this is the release of thyroglobulin after thyroiditis. Antithyroglobulin antibodies may result ([26]). Another important control in muting an antigen response is the need for the correctly matched B and T cells to be in the same place at the same time for optimal responses to occur ([27]). Chance may not favor the meeting of two different cell types of low concentration. Also, incomplete deletion of B cells in the bone marrow can be compensated somewhat by deletion of the corresponding clone of T cells needed to maximize the response. The appropriate stimulatory T cell for surviving clones of B cells simply may not exist or vice versa. Once the matched pair of T cell and B cell or other antigen-presenting cell encounters each other in the presence of the target antigen, activation still does not automatically take place. Co-stimulatory molecules (receptor/ligand pairs) must bind at the same time as the MHC/peptides bind to activate the respective cells (Fig. 35.2) ([28]). If the co-stimulatory molecules are not present, *anergy*, an unstable state of metabolic arrest that may lead to apoptosis, may result. This is yet another mechanism to retard or prevent antibody responses to self-antigens ([10]).

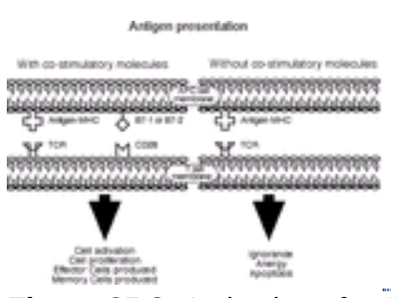

Figure 35.2. Activation of naïve T cells in the presence or absence of a co-stimulatory signal. Physiologic activation of naïve T cells requires two signals. The first signal is initiated by the binding of a peptide–major histocompatibility complex (MHC) complex to the T-cell–antigen receptor (TCR); the second is initiated by the binding of a co-stimulatory ligand (B7-1 or B7-2) to its receptor (CD28). Both the peptide-MHC complex and the co-stimulatory ligand are presented to the T cell by an antigen-presenting cell (APC). Stimulation of naïve T cells through the TCR in the presence of a co-stimulatory signal leads to cell proliferation and the generation of effector cells and memory cells. In the absence of a co-stimulatory signal, activation of naïve T cells is nonproductive. In some cases, the T cell remains oblivious to stimulation of the TCR (ignorance). In other situations, activation of the TCR renders the lymphocyte refractory to further stimulation (anergy) or leads to its death (apoptosis). The precise outcome of T-cell stimulation in the absence of a co-stimulatory signal appears to depend on its state of activation and differentiation. (From Reiser H, Stadecker MJ. Costimulatory B7 molecules in the pathogenesis of infectious and autoimmune diseases. N Engl J Med 1996;335:1369–1377, with permission.)

When the offending agent is eradicated, B cells are still mutating their variable region genes randomly to produce high-affinity antibodies. Once again, the opportunity for the development of a self-reactive clone exists ([29]). There being no further need for legions of cells to fight the intruder, some cells are programmed for apoptosis after a certain amount of proliferation ([30], [31]). Those that survive may become memory B cells ([32]). Cells may die after receiving apoptotic death signals after binding of a receptor–ligand pair of genes called *Fas* (CD95) and *Fas ligand* (*FasL*). Activated B cells express Fas, and activated T cells express both Fas and FasL on their cell surfaces ([33], [34]). T cells may serve as assassins for unwanted stimulated cells, causing death by apoptosis. Evidence that this is true is supplied by the identification of mutations in the *Fas* gene that impair signal transduction and therefore impede subsequent apoptosis in patients with the rare Canale-Smith syndrome, an autoimmune lymphoproliferation of lymphoid hyperplasia, hemolytic anemia, and immune thrombocytopenia ([35]). Interleukin (IL)-2 also induces apoptosis. In fact, the absence of IL-2 or its high-affinity receptor is associated with AIHA. Overexpression of antiapoptotic molecules such as Bcl-2 can have a similar effect ([36]). These molecules not only control the proliferation of the immune response but also decrease the chance of autoimmune antibodies being produced by random mutation. Another receptor–ligand pair limiting the immune response is made up of CTLA4 (*c*ytotoxic *T l*ymphocyte *a*ntigen 4 or CD152) and B7-1 (CD80) or

B7-2 (CD86). Only activated T cells display the CTLA4 receptor, which, once bound to CD80/86 on an activated B cell, transmits a suicide signal, eventually destroying the T cell ([37]). Recall from Figure 35.2 that these same B7 molecules activate the uninformed T cell through CD28. B7 molecules have a 100-fold greater affinity for CTLA4 than CD28, thus favoring control of the immune response, once activated ([28]). Therefore, B7s provide both positive and negative feedback for the immune response, depending on the receptor bound.

Induction of Autoimmune Destruction

There are two types of T-helper cell responses, Th1 and Th2 ([38]). Figure 35.3 depicts some of the conditions favoring the production of each and the consequences of each path. Th1 helper cells tend to favor autoimmune and allergic inflammatory tissue destruction. Th2 cells, in general, tend to protect against autoimmune disease. If Th1 cells predominate over Th2, autoimmune disease is more likely to result ([36]).

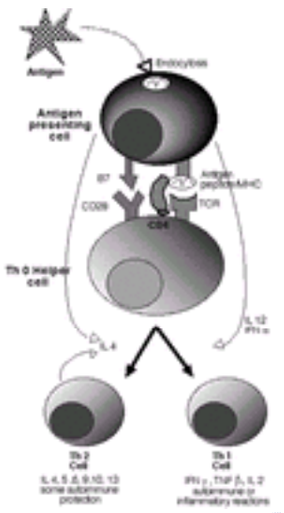

Figure 35.3. Immune response pathways. Antigen or autoantigen is engulfed by an antigen-presenting cell (dendritic cell, monocyte, macrophage, or B cell) and digested into peptides. These peptides are presented with major histocompatibility complex (MHC) type II molecules to an appropriate CD4 T cell (Th 0). This reaction is enhanced by CD4 interactions. Activation of the T cell proceeds if co-stimulatory molecules B7 bind to CD28 to produce the necessary signals. Depending on the prevailing cytokine influence, the cell develops into a Th 1 [interferon (IFN)-a, interleukin (IL)-12] or Th 2 (IL-4) cell. Th 1 cells and Th 2 cells release the cytokines listed, influencing the general reaction toward inflammation/autoimmunity (Th 1) or relative autoimmune protection (Th 2). TCR, T-cell receptor; TNF, tumor necrosis factor. (Redrawn from Mackay IR. Tolerance and autoimmunity. BMJ 2000;321:93–96; Reiser H, Stadecker MJ. Costimulatory B7 molecules in the pathogenesis of infectious and autoimmune diseases. N Engl J Med 1996;335:1369–1377; and Ring GH, Lakkis FG. Breakdown of self-tolerance and the pathogenesis of autoimmunity. Semin Nephrol 1999;19:25–33.)

Despite the controls previously discussed, the immune response may still proceed via other pathways of activation. Bacteria may activate lymphocytes even without co-stimulatory molecules by superantigens such as lipopolysaccharides. A very strong first activation signal may induce a cell to express its co-stimulatory molecules ([39] , [40]). Infection and inflammation can lead to a nonspecific activation of lymphocytes ([41]). Antigen-presenting cells, such as macrophages and dendritic cells, may display these molecules and activate cells to start the response ([42]). Therefore, during infection or inflammation, self-reactive antibodies may be nonspecifically induced despite other control mechanisms.

Genetic and Environmental Risk Factors Despite all of the intense study of the immune system, the exact inciting event or trigger that produces an autoimmune syndrome remains illusive. Genetic factors clearly play a role, particularly the HLA genes. MHC genes determine which antigens are presented, thus potentially coding for a general susceptibility to autoimmune processes. The phenotype confers a predisposition, not a predestination, as most people do not develop disease ([3]). Studies with identical twins rarely display significant concordance ([43]). It is unknown where, in the many steps required to generate the immune response, these genes may exercise their influence, be it in the central tolerance stage or in curtailing a response already in progress. Clearly, more work needs to be done in this area. Environmental factors also have a very significant influence on the outcome. Infections can disrupt tolerance by exposing self-antigens through tissue necrosis. Their destructive inflammatory effects may break down vascular or cellular barriers that previously prevented access of those antigens to the immune system. *Epitope spreading* is the subsequent autoimmune response to these formerly cryptic antigens. Infectious agents produce responses to many different peptide sequences in their antigen composition. *Molecular mimicry* results when organism epitopes cross-react with host antigens via shared sequences, producing tissue destruction ([44]). Our extensive pharmacopoeia can produce life-threatening hemolytic complications from induction of antibody to new immunogens consisting of drugs bound to tissues. Medications may produce generalized autoimmune syndromes such as procainamide-induced lupus ([45]). Once again, it is not known exactly how these agents incite pathologic antibodies.

SEROLOGIC INVESTIGATION OF ERYTHROCYTE AUTOANTIBODIES

The demonstration of Igs or evidence of complement fixation and attachment to the surface of the cell supports the diagnosis of immune-mediated destruction of RBCs. *Ex vivo* and, occasionally, *in vivo* cells coated with IgM may spontaneously agglutinate as a result of the pentameric antibody's ability to cross-link cells. These have been called “complete” antibodies. In contrast are the IgG-coated cells, which do not typically agglutinate saline-suspended RBCs and are thus called “incomplete” antibodies.

The explanation for this serologic difference lies in the physical properties of the RBCs and the involved antibody molecules. Erythrocytes have a strong net negative charge called the *zeta potential* produced by the sialoglycoprotein coat, such that approximately 18 nm is the shortest span between two cells. Factors other than negative charge may also play a role in the distance they keep. Water that is tightly bound to the surface of the cells may keep cells apart. IgM molecules with their large pentameric structure allow approximately 30-nm maximum distance between two binding sites and can therefore connect two cells. The smaller IgG can muster a span of only 12 nm between antigen recognition sites and thus usually cannot lead to agglutination alone ([46]). Some IgG antibodies can, indeed, agglutinate RBCs, such as in the anti-A, anti-B, and anti-M reactions. This reveals the influence on agglutination of the number of antigen sites per cell ([47]) and even how far the antigenic determinants project from the surface of the RBC. A and B oligosaccharides extend well beyond the lipid bilayer membrane ([48]). With their relative abundance, they are also close together on the cell surface, enhancing agglutination. Still, whereas the number of IgG molecules required to agglutinate RBCs has been measured at approximately 7000 to 20,000 per cell, the number of IgM necessary is only 25 to 50 per cell ([49] , [50]). Other serologic tricks to enhance agglutination by IgG antibodies include treating the cells with enzymes to reduce the surface charge; centrifuging the mixtures; adding water-soluble polymers such as albumin, polyvinylpyrrolidone (PVP), or dextran; and adding plasma, the most significant constituent of which is fibrinogen ([51]). However, the most common way to enhance these reactions and determine the presence of immune system components on cells is through the direct antiglobulin test (DAT).

Direct Antiglobulin Test

In 1908, Moreschi described antiglobulin reactions as an aid to RBC agglutination ([52]). This work went largely unnoticed until 1945 when the investigation of anti–RBC antibodies was revolutionized with the development of the antiglobulin test by Coombs, Mourant, and Race ([53]) and its application to diagnosing IgG coating of cells in hemolytic disease of the newborn in 1946 ([54]). Until this time, it was known that complete antibodies would produce spontaneous aggregation of RBCs without extra manipulation and that incomplete antibodies could not spontaneously agglutinate cells. The principle of the DAT or direct Coombs test is quite simple. To ascertain if the patient's cells are coated with Ig, complement, or both, add antisera with reactivity to human Ig and/or complement molecules to the patient's RBC suspension, thus providing the necessary cross-link to elicit agglutination. Figure 35.4 illustrates the principle of the test. An ethylenediaminetetraacetic acid–collected sample from the patient is used to prevent subsequent complement adherence to the RBC membrane *in vitro*. The test is performed by first washing the patient's cells to remove any nonspecifically attached proteins. Antiserum is added, and the mixture is centrifuged to enhance agglutination. Results are read by resuspending the cells gently and observing carefully for clumps. Magnifying mirrors or low-power microscopy aids in discerning weak reactions. Negative reactions are incubated at room temperature for 5 more minutes, spun, and read again, as this further promotes positive reactions in the presence of complement ([55]). Initial testing is done with polyspecific antisera, which contain anti-IgG, anti-C3d, and, occasionally, some anti–light chain activity. Monospecific reagents differentiate

between IgG and C3d to further define the reaction pattern. Other monospecific antisera are available for C3b, C4b, C4d, and IgG heavy chain ([56]). Specific antiserum for IgM or IgA is rarely used as IgM is not usually found still attached to the cell surface and IgA, if found at all, is very rarely a cause of Ig coating by itself ([57] , [58]). Monoclonal reagents have been licensed by the U.S. Food and Drug Administration, the most common of which is anti-C3d. It does not cross-react with any other complement components ([56]).

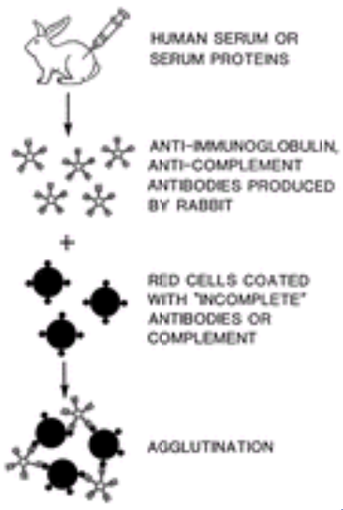

Figure 35.4. Direct antiglobulin test. Rabbits or goats are immunized with human serum or serum components. The resulting sera containing anti–?-globulin or anticomplement antibodies are then added to test samples of RBCs. If human ?-globulins, complement components, or both are bound to the cell surface, agglutination occurs. (From Foerster J. In: Lee G, et al., eds. Wintrobe's clinical hematology, 9th ed. Philadelphia: Lea & Febiger, 1993: Chapter 40, with permission.)

A significant shortcoming of the original DAT methodology is its relative insensitivity. New technology has allowed much greater sensitivity in detecting Igs and complement on cells. The previously described tube method can detect approximately 150 to 200 molecules IgG per cell ([59]). Using PVP enhancement and an autoanalyzer, as few as 8 IgG molecules per cell would produce 5% agglutination. If bromelin was added with the PVP, 1 molecule per cell would produce 5% agglutination and 3 molecules could give 50% ([60]). Flow cytometry, enzyme-linked antiglobulin tests, radioimmunoassays using ^{125}I-labeled anti-IgG or ^{125}I-staphylococcal protein A, solid phase techniques using microtiter plates, and gel testing have all produced acceptable results ([51]). However, only the tube test, solid phase test, and gel tests are in routine use in most laboratories. Gel tests have an advantage of producing stable results that can be read by another observer at a later time in case of questionable interpretations.

If the DAT is positive for antibody attached to the cell surface, this antibody is eluted from the cell with chemicals such as acid or xylene, and any binding specificities are further investigated with a reagent cell panel. Elutions are not typically performed on DAT specimens positive only for complement as these molecules would not be expected to have antigen-binding specificity. Occasionally, however, when antibody presence is suspected but perhaps in too low a concentration to be detected on the cells, eluates may show reactivity. Elution tends to produce a more concentrated antibody solution so that reactions are stronger. Once the antibody is in solution, indirect antiglobulin methodology may shed some light on the special characteristics of the antibody.

Indirect Antiglobulin Test

Approximately 80% of patients with AIHA have autoantibodies in their serum as well as on their cells ([61]). They, as well as alloantibodies, are detected by the indirect antiglobulin test (IAT) or indirect Coombs test. This is more commonly referred to as the *antibody screen*. Unlike the DAT, which uses patient's *cells* with reagent serum, the IAT tests the patient's *serum* against reagent cells. Ig from the serum attaches to the reagent cells and is detected with antiglobulin sera, which cross-link the cells together and produce agglutination as in the DAT.

The precise antigen(s) to which the majority of warm autoantibodies attach is still a well-kept secret. Warm autoantibodies are typically panagglutinins, reacting with every cell in the diagnostic RBC panel. Many panagglutinins were believed to react with a basic determinant of the Rh antigen system, as they did not react with the very rare Rh $_{null}$ cells that have no Rh antigens on them ([62]). However, as more eluates are studied with a broader population of rare null phenotypes, it has been shown that, in addition to Rh, autoantibodies react to LW antigens, glycophorins A, B, C, and D, and very rarely, Kidd or Kell blood group system antigens ([63]). A small number of case reports exist describing AIHAs associated with ABO antigens ([64] , [65]).

Serologic Difficulties Secondary to the Autoantibodies

ABO typing discrepancies are not common with warm autoantibodies but can be quite problematic with the spontaneous agglutination frequently seen with cold autoantibodies. Rh typing may pose a similar set of problems. Vigorous washing of the patient's cells and using prewarming techniques may permit accurate typing. Invalid results due to agglutination of all back-typing reactions with the patient's serum are not uncommon with cold autoantibodies ([55]). However, the cold autoantibody is rarely as strong as the naturally occurring isoagglutinins. For example, the patient's washed, prewarmed cells may type as A, but the warmed serum may give a weakly positive reaction with A $_1$ cells as well as the expected strong reaction to B cells. Cold autoadsorption of the serum, a technique similar to the autoadsorptions described below, may resolve the discrepancy. Using IgG antiglobulin serum or reducing and inactivating the IgM with dithiothreitol may eliminate the unwanted reactions but also may destroy the desired ones, especially if the IgG component of anti-A and anti-B is very weak, as might be seen in non–group O individuals. Interpretations must be made with caution ([55]).

The IAT is not critical to the diagnosis of AIHA, warm or cold, but an autoantibody in the serum can become very problematic for the transfusion service if blood products will be required. Panagglutinins or spontaneous agglutination from cold antibodies masks the presence of any potential alloantibodies that may cause hemolytic transfusion reactions. These autoantibodies must be removed from the serum in ways that permit the alloantibodies to remain. If the patient has not recently been transfused, this may be accomplished by a procedure known as *autoadsorption* ([55]). The patient's own cells are treated with acid or enzymes to remove the autoantibody from the cells, and then the patient's serum is repeatedly mixed with these treated autologous cells until all autoantibody is removed. By definition, alloantibodies do not attach to autologous cells and should remain behind in the serum for identification in the usual manner with a diagnostic panel of reagent cells ([56]). The situation is more difficult if the patient has been recently transfused and has allogeneic cells circulating that may possess antigens that could potentially remove the very antibody to be identified. Alloadsorption of the patient's serum with three different types of RBC stroma, each carefully selected for absence of specific antigens, is performed. Antibodies to these specific, high-risk antigens are available for identification after removal of the panagglutinin, and the appropriate antigen-negative RBC unit can be selected for transfusion ([55]).

Cross-matching RBCs for a patient with circulating autoantibody is difficult. Once it has been determined that no unexpected alloantibodies are present, the laboratory chooses the ABO-compatible units available and releases them as “cross-match incompatible.” As it is not possible to determine whether this incompatibility is due solely to the autoantibody, one should transfuse with caution. The physician is required by transfusion regulations to sign a form indicating awareness of the incompatibility and the urgent need for transfusion. It is not expected that these transfused cells will fare any more or less poorly than the patient's own. Rarely has a transfusion incited greater autoimmune activity and increased destruction of all circulating cells.

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY COLD ACTIVE ANTIBODIES

Cold active antibodies exhibit increased titer and RBC binding activity as the temperature approaches 0°C. Two different clinical syndromes are manifested from cold autoimmune antibodies. Cold agglutinin disease (CAD) is associated with IgM antibodies usually directed at the RBC I antigen. It typically occurs in adult patients and may be primary or secondary to another disease process, usually infectious. Paroxysmal cold hemoglobinuria (PCH) is caused by the so-called Donath-Landsteiner ([66]) antibody, an IgG hemolysin. With the decline in syphilis, PCH is uncommon and seen rarely outside the pediatric population. Both syndromes are much less

common than warm AIHA and make up approximately 20% or less of AIHAs. Table 35.2 summarizes the various types of cold autoantibodies.

TABLE 35.2. Cold Autoantibodies

	Primary Cold Agglutinin Disease	Secondary Cold Autoantibodies	Paroxysmal Cold Hemoglobinuria
Ig	IgM	IgM	IgG
Clonality	Monoclonal	Monoclonal/polyclonal	Polyclonal
Direct antiglobulin test	C3	C3	C3
Hemolysis	Chronic, mild	Self-limited, mild to severe	Episodic, self-limited; mild to severe
Target red blood cell antigen	I	I, i	P

C3, complement third component; Ig, immunoglobulin.

Cold Agglutinin Disease

Although Landsteiner first described cold agglutinins in 1903 ([67]), it was not until the late 1940s and early 1950s that the connection between cold autoantibodies and RBC destruction was made firmly. In the 1950s, Schubothe coined the term *CAD*, and the disorder became recognized as a separate entity from other acquired hemolytic processes ([68]). The pathologic IgM antibodies responsible are distinguished from naturally occurring cold autoantibodies by their titer and *thermal amplitude*, a term describing the range of temperatures over which the antibody is reactive. Natural cold autoantibodies occur in titers less than 1:64 measured at 4°C and have no activity at temperatures much higher than that. However, pathologic cold agglutinins typically have titers well over 1:1000 and may react at 28 to 31°C or even up to 37°C ([57]).

PRIMARY VERSUS SECONDARY COLD AGGLUTININ DISEASE*Primary* or *idiopathic CAD* is typically an affliction of older adults with a peak incidence around age 70 ([68]). Both sexes are affected, but women predominate ([69]). A monoclonal IgM ? ([70]) antibody is the usual culprit, and, as with other monoclonal gammopathies of unknown significance, B-cell neoplasms may eventually be diagnosed, but patients usually tolerate a relatively benign, waxing and waning hemolytic anemia. Patients with Waldenström macroglobulinemia or other B-cell neoplasms may produce monoclonal anti–RBC antibodies with cold reactivity. As in primary CAD, they are nearly always IgM ?. Another interesting characteristic of these B-cell clones is a distinctive karyotype of trisomy 3q11-q29 ([71]), trisomy 12 or 48,XX,+3,+12 found in 40% of patients. These chromosomal abnormalities have also been identified in patients with the chronic idiopathic variety. Further studies on the Ig and clonal cell populations revealed that the monoclonal cold agglutinins are produced by the (pre-) neoplastic B-cell clones ([72], [73]). This type of secondary cold agglutinin may be effectively treated with successful chemotherapeutic maneuvers directed at the neoplasm. Relapse of the tumor may be heralded by return of hemolysis. Other non–B-cell tumors reported in association with cold antibody formation include squamous carcinoma of the lung, metastatic adrenal adenocarcinoma, metastatic adenocarcinoma of the colon, basal cell carcinoma, and a mixed parotid tumor ([74]). Another scenario of secondary cold autoantibody hemolysis occurs in young adults after *Mycoplasma pneumoniae* infection or infectious mononucleosis. This is a transient process lasting a few weeks and seldom requires more than supportive care. These polyclonal IgM ? or ? Igs are self-limited but, in rare cases, may cause massive intravascular hemolysis and acute renal failure. See Table 35.3 for other disease processes that have been associated with cold agglutinins.

Autoimmune diseases
Tropical eosinophilia

CHARACTERISTICS OF THE ANTIBODY

Immunochemistry and Origin As stated earlier, nearly all cold agglutinins are IgM. A few reports of IgG or IgA agglutinins are recorded, and a mixed IgM-IgG has been seen in infectious mononucleosis and angioimmunoblastic lymphadenopathy ([75]). Those patients with non-IgM antibodies are more likely to have cold autoantibody hemolysis secondary to another disease and are less likely to display specificity for the I antigen ([69], [76]). Structural studies of cold agglutinins have focused on the variable regions or idiotypic determinants of the molecules. These are the regions that determine what antigen is bound by the antibody. Antiidiotypic antibodies and direct nucleotide sequencing of the rearranged Ig variable region genes have revealed significant cross-reactivity and homologies among cold autoantibodies with similar specificity ([77], [78]). For instance, the monoclonal antiidiotypic antibody 9G4 recognizes an idiotypic determinant present on the heavy chains of both anti-I and anti-i cold agglutinins and also on the neoplastic B cells secreting them ([79]). Further studies to ascertain the structural basis for this similarity revealed that essentially all pathologic anti-I and anti-i cold agglutinins are derived from a distinct subset of heavy-chain variable region genes called *V_H4 family genes*, specifically V_H4-21 ([80]). It is interesting that harmless, naturally occurring anti-I/i antibodies may use V_H4-21 but do not require this variable region heavy-chain gene. They may use V_H3 gene segments as well ([81]). In an *in vitro* system, IgM autoantibodies with the V_H4-21 heavy-chain variable region gene were produced and harvested from cell lines derived from a patient with Wiskott-Aldrich syndrome. They were found to react not only with the i antigen on RBCs but also

with most pre-B cells in adult bone marrow and with a subpopulation of early B cells residing in the mantle zone of secondary follicles that constitutively coexpress the CD5 surface antigen. The investigators postulated that these gene products may play a role in B-cell development, differentiation, or both ([82]). Therefore, chronic CAD may represent a dysregulation of an early B-cell clone. The initiating event for this exuberant expansion, however, is unknown. Unlike the heavy-chain genes, light-chain variable region genes are not quite so restricted. Anti-I autoantibodies appear to derive from the V?III gene family. The anti-i antibodies are not limited to V?III but use other V? genes as well ([78]). ?–Light chains also appear in anti-i antibodies ([83]). Thus, it seems that the fine antigen specificities are determined by the V_L genes, and the more constant V_H4-21 gene aids with the larger interaction with the I/i complex. The V_H4-21 gene is also found in other antibodies, including rheumatoid factor autoantibodies and alloantibodies to other blood group antigens ([84]). The Ig gene regulation for anti-i/I antibodies may not differ greatly from that of normal antibody production. Common idiotypic determinants on these antibodies and the potential to create antiidiotypic antibodies may be an avenue of therapeutic application in the future as we learn more about their production ([79]).

I/i Blood Group System Specificity More than 90% of cold active antibodies have the I antigen as their target on the RBC, and the i antigen is the binding site for a significant portion of the remaining 10% ([57]). The I/i blood group system was defined when Wiener and colleagues tested the serum from a patient with CAD against more than 22,000 random blood samples ([85]). Five samples from that group, as well as the patient's own cells, were not agglutinated and thus labeled as “i” or “I-negative.” A few years earlier, it was reported that high-titer cold agglutinins poorly agglutinate fetal cord blood cells ([86], [87]). Testing sera against adult RBCs and cord blood cells provides the basis for assessing specificity and the conclusion that nearly all are I-specific. This conclusion may not be entirely valid, as is discussed below. The I/i RBC antigen system is composed of repeating *N*-acetyllactosamine units linked to ceramide or to other membrane glycoproteins, band 3 and band 4.5 ([48], [88]). Evidence suggests that the major difference between the two is the presence of branching oligosaccharide chains in the I antigen. The i antigen is linear (Fig. 35.5). Antigen switching proceeds with development of the newborn. Only the i antigen is expressed in fetal life with gradual conversion to I from just before birth to approximately 18 months, when minimal amounts of i remain ([89]). This is due to the work of a branching enzyme, [ß1?6]- *N*-acetylglucaminyl transferase ([90]). Rare adults express only the unbranched i_{adult} antigen ([91]). The I/i determinants also serve as the nucleus for ABO. H substance, a precursor to ABO, is formed by substitution of the terminal Gal of the I structure with Fuca([1] and [2]) ([92]). Understanding these structural similarities helps explain the combinations of specificity sometimes seen (e.g., IA, iH, IB, and so forth).

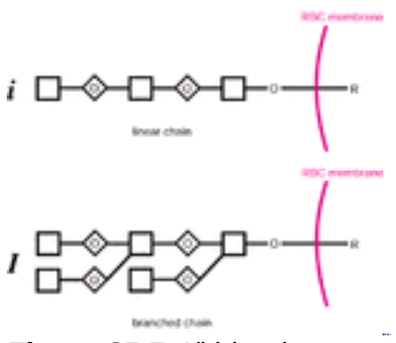

Figure 35.5. I/i blood group antigens. Structure of the I/i blood group system. R denotes ceramide or protein in the red blood cell (RBC) membrane. Open squares represent galactose. Circles in squares depict *N*-acetylglucosamine. The linear i antigen is converted to the branched chain I antigen by a “branching enzyme,” [ß1?6]- *N*-acetylglucaminyl transferase. (Adapted from Siegel DL, Silberstein LE. Red blood cell autoantibodies. In: Anderson KC, Ness PM, eds. Scientific basis of transfusion medicine. Philadelphia: WB Saunders, 1994:517–526.)

I and i antigens are expressed on other cells, including granulocytes, lymphocytes, macrophages, and platelets ([93]). On B lymphocytes, the antigens are carried on high-molecular-weight glycoproteins known as the *leukocyte common antigen* or *CD45*. T cells express I/i antigens on lower-molecular-weight sialoglycoproteins ([94]). The presence of these RBC antigens on lymphocytes, particularly on CD45, a protein tyrosine phosphatase involved in regulating lymphocyte activation and proliferation, raises questions about the role these antibodies may play in immune regulation. CD45 antigens may be abnormally expressed on cells in autoimmune disease, and antibodies to I/i antigens can be lymphocytotoxic ([75], [95]). Other uncommon but reported antigen targets include Pr, so labeled due to protease sensitivity of the antigen. The Pr determinants are O-glycosidically linked oligosaccharides of glycophorins A or B ([96]). Anti-Pr cold agglutinins tend to be high titer, have a wide thermal range, and usually cause symptomatic anemia ([92], [97]). Other infrequent targets are Gd, Fl, Vo, Li, Sa, Lud, M, N, Me, Om, D, Sd^X, and P in one case report ([63], [69], [98]). The fact that *M. pneumoniae* induces anti-I antibodies in the majority of patients is potentially related to the finding that sialylated I/i antigens serve as specific *Mycoplasma* receptors ([99]). This minor modification of antigen may incite autoantibodies. Another theory suggests that an I-like antigen appears on the organism itself, and cross-reacting antibodies form that lead to RBC lysis ([100]). Despite the high rate of antibody production, clinically significant hemolysis occurs in very few patients ([101]). The antibodies are usually IgM ? but can be ? ([102]). However, unlike chronic CAD, they are polyclonal ([103]). Infectious mononucleosis is also associated with CAD but to a much lesser degree than *Mycoplasma*. Estimates of 0.1 to 3.0% of patients with clinical hemolysis have been published ([104], [105]). However, anti-i is present in 8 to 69% of sera postinfection ([106], [107] and [108]). Therefore, the majority of patients' antibodies are asymptomatic. Anti-I activity is usually noted as well but not to the same degree. Also, anti-Pr and anti-N have been reported ([109], [110]). Both IgM and IgG antibodies as well as IgM rheumatoid-like factors reacting with IgG may act as cold agglutinins after infectious mononucleosis ([111], [112]). See Table 35.3 for a list of other infectious diseases associated with cold agglutinins, most of which are anti-I, although anti-i has been seen in cytomegalovirus infections and in lymphomas ([113]).

Functional Characteristics Cold agglutinins attach to the RBC in the cooler peripheral circulation. As the blood proceeds back to the warmer central circulation, the antibody dissociates from the cell. Antibodies that attach, fix complement, and then dissociate are free to attack another unsuspecting erythrocyte and begin the process again ([114]). Complement fixation and activation, which are responsible for the destruction of the cells, prefer the warmer central temperatures. If the titer of the antibody is high enough and the thermal range of activity wide enough, there is adequate temperature overlap to produce maximum hemolysis at 22 ± 10°C ([68]) (Fig. 35.6). Because of this diversity of temperature requirements for optimal activity of the antibody and complement, RBC destruction is usually not particularly severe with cold autoantibodies. Quite impressive exceptions occur, and these are typically the ones with high titers (<1:1000) or with activity up to 37°C even in the face of modest titers, as thermal amplitude is a better predictor of hemolysis than titer ([75], [115]). Cold agglutinins of high titer but narrower thermal amplitude may produce a clinical picture of bursts of hemolysis associated with exposure to cold. This can manifest as intermittent hemoglobinuria between quiescent periods ([114]).

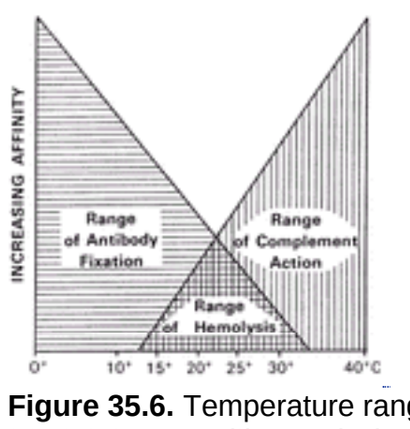

Figure 35.6. Temperature ranges for cold agglutinin fixation and lytic complement action. (From Schubothe H. The cold hemagglutinin disease. Semin Hematol 1966;3:27–47, with permission.)

A frequent misconception about cold agglutinins is the assumption that they are cryoglobulins. These are two separate disease processes. Cold agglutinins are cryoprecipitable in up to one-third of those with anti-i specificity, but only rarely do anti-I antibodies precipitate in the cold ([75]). This confusion may result from the fact that both can cause agglutination in peripheral blood vessels perfusing cooler parts of the body, such as the fingertips and nose. Both may lead to cyanosis and Raynaud phenomenon. However, the cryoglobulins do not fix complement on the RBCs or cause hemolysis.

CLINICAL MANIFESTATIONS Mild, chronic hemolytic anemia with exacerbations in the winter is the general rule for CAD. Rarely does the hemoglobin drop below 70 g/L ([116]). Pallor and jaundice may occur if the rate of hemolysis is greater than the liver's ability to metabolize the bilirubin ([69]). Some patients have intermittent bursts of hemolysis associated with hemoglobinemia and hemoglobinuria on exposure to cold and may be forced to move to warmer climates to prevent attacks. Acrocyanosis can occur from agglutination of cells in the cooler vessels of the hands, ears, nose, and feet ([57], [69]). Digits become cold and stiff, painful, or numb and may turn purplish or limbs may manifest livedo reticularis, a mottled appearance. This is readily reversible on warming the affected area. Only rarely does actual gangrene of digits develop, and nearly all of these cases had an associated cryoglob-ulin ([117]). A minority of chronic CAD patients have mild splenomegaly or a slightly enlarged liver. Spleens may be larger or more frequently palpable in secondary cold agglutinins due to lymphoma or infectious mononucleosis ([69]). If hemolysis does occur after *Mycoplasma* infections, it begins when the patient is recovering from the pneumonia and titers for cold autoantibodies are at their peak. The process, even if severe, resolves spontaneously within 1 to 3 weeks ([57]). Hemolytic anemia after infectious mononucleosis may begin with the onset of illness or

within the next 3 weeks ([69]). The self-limited, postinfectious CAD tends to affect younger patients, whereas the chronic idiopathic form is a disease of the elderly with peak incidence at approximately age 70 ([68]).

LABORATORY FEATURES Mild chronic anemia is the rule, but the hemoglobin may fall to 50 or 60 g/L, especially in the winter months in cold climates. The peripheral smear, if not from a prewarmed specimen spread on a warm slide, may show significant agglutination and clumping of cells under magnification. Agglutinates are frequently visible in the specimen tube and can be so pronounced as to give the appearance of a large clot. Dissolution with warming proves the clumped and clotted appearance to be due to a cold agglutinin instead of rouleaux or fibrin strands. Often, the first suspicion of a cold agglutinin comes from the hematology laboratory's failed attempt to obtain a meaningful RBC count and indices. The RBC count is artificially lowered and the mean corpuscular volume falsely elevated, producing an unbelievably high mean corpuscular hemoglobin concentration. The reticulocyte count is modestly elevated except in rare cases of concomitant marrow failure such as those due to parvovirus B19 infection ([118]). Spherocytosis is not pronounced as in warm AIHA. Leukocyte and platelet counts are usually normal, but low levels of both have been reported as has leukocytosis ([69]). Bilirubin is mildly elevated and rarely more than 3 mg/dl. Lactate dehydrogenase may be increased, reflecting RBC destruction, and complement and haptoglobin can be low or absent. In brisk hemolysis, hemoglobinuria and hemoglobinemia are manifest. The DAT is positive with polyspecific and anticomplement antisera. As previously discussed, the IgM has dissociated and is not detectable. In extremely rare cases, the antibody involved is IgG or IgA either alone or in addition to IgM ([57] , [69]). Mixed warm and cold autoantibodies are not rare and are discussed later. Titers measured at 4°C may range from 1:1000 to 1:1,000,000, although typical values are between 1:1000 and 1:500,000. Much lower levels can be clinically significant if activity is measurable at 37°C. Postinfectious CAD titers are lower (<1:4000) than the chronic idiopathic or lymphoma-associated varieties. In patients with monoclonal IgM, evaluation of serum proteins frequently reveals an M spike, which serial observations show to be stable in the chronic idiopathic disease ([119]).

MANAGEMENT

Primary Cold Agglutinin Disease Due to the mild, chronic nature of the anemia, the majority of patients need no specific therapy other than the general principle of avoiding temperatures below that at which their antibody shows activity. In some climates, this may necessitate a move closer to the equator. Somewhat extreme measures using an environmental suit to maintain temperature have been successful ([120]). For patients with more severe anemia and cardiovascular compromise, aggressive therapy is indicated.

Immunosuppressive Therapy Ideally, one would prefer a method that would suppress production of only the pathologic antibody. In the absence of that therapeutic advance, a common approach in treating symptomatic CAD is to use cyclophosphamide or chlorambucil. A minority of patients respond, but symptoms and transfusions can be avoided in those responders. Chlorambucil, beginning with 2 or 4 mg/day and increasing by 2 mg every 2 months until either a response is obtained or unacceptable myelotoxicity results, is one alternative. Twice-weekly blood counts plus reticulocyte count should be monitored for toxicity ([57] , [121]). Pulse therapy with cyclophosphamide at 250 mg/day and prednisone 100 mg/day for 4 days every 2 to 3 weeks, blood counts permitting, or a large-dose regimen of cyclophosphamide, 1000 mg, and methylprednisolone, 500 mg intravenously, may adequately control hemolysis ([122]). a-Interferon has reportedly produced significant remissions ([123]). Rituximab, a chimeric human/murine monoclonal CD20 antibody, has been used with success in CAD in several case reports and series ([124] , [125] , [126] , [127] and [128]). These patients were refractory to other treatment regimens. Its proposed mechanism of action involves complement-dependent cytotoxicity, antibody-dependent cellular cytotoxicity, direct apoptotic effects, and inhibition of B-cell proliferation. *In vitro* evidence suggests that steroids may provide synergistic effects with rituximab ([129]). Doses used mimic the lymphoma treatment regimens of 375 mg/m^2 each week for 4 weeks. Some pediatric patients were successful with just two infusions ([130]). In a notoriously difficult to treat disease, it provides another option.

Plasmapheresis Given the fact that IgM has an intravascular distribution, it would seem logical that plasmapheresis or plasma exchange would provide rapid relief from hemolysis due to cold autoantibodies. Unfortunately, the results have been somewhat disappointing, in general ([131] , [132]). Removing the circulating antibody does not have any demonstrable effect on production of new antibodies by the clone of cells responsible. Therefore, improvements are very temporary. In patients with chronic CAD, plasmapheresis should probably be combined with immunosuppressive therapy in an attempt to decrease production ([133]). Successful use of plasmapheresis to temporarily decrease cold agglutinin titers, allowing safe coronary artery bypass surgery, has been reported ([134]). Other reports of successful cardiac surgery involving warm cardioplegia have circumvented the need for cold exposure and thus the risk of hemolysis ([135] , [136]).

Blood Transfusion Fortunately, most patients with CAD have such mild anemia that transfusion is not needed. It is best to avoid blood transfusion, if possible, in patients with CAD. Patients with high-titer or wide thermal amplitude antibodies can pose extremely difficult serologic problems for the blood bank laboratory. Testing needs to be performed carefully at 37°C to minimize the effects of the cold agglutinin so that a search for alloantibodies may be properly performed ([57]). This still does not eliminate interference from some particularly pesky autoantibodies. Time-consuming and technically challenging cold autoadsorptions may be necessary to rule out the presence of underlying alloantibodies. Often, incompatible units are released due to residual agglutination from the cold autoantibody. Most cold agglutinins are directed at the I antigen, which is present on nearly all adult donor cells. Locating i $_{adult}$ cells is not practical due to their rarity. Reports have documented i $_{adult}$ cells effectiveness and lack thereof ([137] , [138]). If transfusion is necessary to treat significant cardiovascular compromise, infusing the cells through an inline blood warmer at 37°C is the best method ([139]). Uncontrolled heating of RBC products is quite dangerous due to the damaging effects of excessive heat and should be avoided. If blood warmers are not available, transfusion may still be accomplished by the slow infusion of room temperature RBCs into a large vein while keeping the patient warm ([57] , [69]).

Steroids Unlike their effectiveness in treating warm AIHA, steroids have little or no place as monotherapy in the treatment of CAD. They have been part of multidrug regimens. The few reports of a response have been suspect in their serologic evaluations ([140]) or have required such high maintenance doses of prednisone that side effects of therapy were intolerable ([141]).

Splenectomy Given the fact that most RBC destruction occurs in the liver in CAD, it is no surprise that splenectomy has been essentially ineffective in treating CAD and is not advised. In a few, rare patients that have the unusual serologic characteristic of hemolysins reactive at 37°C as well as agglutinating activity at cooler temperatures, splenectomy may have some benefit ([57] , [142]).

Secondary Cold Agglutinin Disease Hemolysis from cold agglutinins associated with infection is of 2 to 3 weeks' duration, and therapy is typically not required. Given the transient nature of the antibody, even in the rare patient with significant hemolysis, supportive measures such as transfusion and plasmapheresis should suffice. Attempts to alter antibody production with immunosuppressives are generally not indicated. Patients with cold agglutinins and malignancies should have their treatment regimens directed at their underlying disease with the addition of supportive measures as the clinical situation dictates.

Paroxysmal Cold Hemoglobinuria

PCH was the first hemolytic anemia to be described due to its dramatic presentation of intermittent attacks of pain, fever, and hemoglobinuria after exposure to the cold. The differentiation between hematuria and hemoglobinuria was made by Dressler in 1854 ([143]) in a patient who was probably a congenital syphilitic child. Further reports published in the 1860s ([144] , [145]) more fully described the attacks in relation to exposure to cold. In their classic 1904 paper, Donath and Landsteiner ([66]) described the antibody that now bears their names (D-L antibody), which produces the syndrome and the pathogenic mechanism behind it. It is a hemolysin that binds to the RBC at low temperatures and fixes complement. When the cells are warmed, they are destroyed by complement lysis. There are three clinical syndromes in which the D-L antibody occurs: (a) chronic PCH associated with late-stage or congenital syphilis, (b) acute transient PCH occurring after an infectious illness, and (c) chronic idiopathic PCH. Due to effective treatments for syphilis, the first type, which used to be the most common, is now extremely rare. Chronic idiopathic PCH has always been uncommon. The acute transient variety is believed to be one of the most common causes of acute hemolytic anemia of children ([146] , [147]).

CHARACTERISTICS OF THE ANTIBODY

Immunochemistry and Origin Unlike cold agglutinins, antibodies that cause PCH are IgG and also, most likely, polyclonal ([148]). Originally described in patients with advanced or congenital syphilis, the antibody is not cross-reactive in syphilis serologic tests in patients with syphilis or in those who manifest the acute, transient variety of PCH ([149] , [150]). PCH has been reported in more than one family member, suggesting a genetic predisposition ([69]). The origin or stimulus for antibody production is likely microorganism antigen(s) that induce antibodies that cross-react with the P blood group system ([151]).

P Antigen Specificity Until 1963, the D-L antibody was believed to be “nonspecific” for RBCs in that it reacted with all erythrocytes. Specificity for the P antigen was shown by Levine, Celano, and Falkowski's experiments with rare pp cells. They also showed failure of the antibody to react with P ^{k} cells. P $_1$ and P $_2$ cells were lysed by the D-L antibody ([152] , [153]). Chemical studies of the P antigen have shown that it is a glycosphingolipid globoside ([154] , [155]) quite similar to Forssman glycolipids present in many microorganisms. Indeed, the antibody can be inhibited by globoside and, to a lesser degree, by Forssman glycolipids ([151]).

Functional Characteristics The D-L IgG antibody is a potent hemolysin, causing significant RBC destruction even in low titers. The D-L antibody is classically described as a “biphasic” hemolysin. This is based on the test for the antibody originally described by Donath and Landsteiner whereby the patient's serum is incubated with RBCs at 0 to 4°C and then warmed to 37°C to produce lysis. The antibody requires the cooler temperatures to bind to the RBC, but complement lysis does not proceed until the temperature is raised. For optimal lysis, complement C1 should be available when the antibody initially binds ([149] , [150]). On warming, C4, C2, and the remainder of the complement cascade bind and disrupt the membrane producing lysis. Some D-L antibodies have a wider thermal amplitude and bind to the RBC at temperatures compatible with complement activity. These seem to be “monophasic” hemolysins in that cooling is not necessary to produce binding activity. At least one author believes that the distinction between biphasic and monophasic activity is unwarranted, representing only differences in thermal amplitude ([69]). Also, other cold active antibodies that vigorously fix complement may produce *in vitro* hemolysis biphasically but yet not have the distinguishing characteristics (IgG,

anti-P specificity) that qualify them as true D-L antibodies.

CLINICAL MANIFESTATIONS The sudden onset of fever, back or leg pain, and hemoglobinuria after exposure to the cold are the hallmarks of PCH. Cold exposure may be only a few minutes, and symptoms may follow shortly or several hours later. Fever to 40°C is not unusual. Other symptoms may include pain or aching in the back, legs, or abdomen, cramps, headache, nausea, vomiting, and diarrhea. The first urine voided after the onset is dark red or even black and typically clears in a few hours. Rarely, it persists for a few days. The spleen may be palpable during an attack and shortly thereafter, and mild jaundice may appear ([69]). Vasomotor phenomena manifest as cold urticaria, tingling of hands and feet, cyanosis, and Raynaud phenomenon, and even gangrene has been reported ([156] , [157]). Systemic symptoms may appear without the hemoglobinuria and vice versa. There does not appear to be any racial or gender predilection in PCH. Almost exclusively, children are affected by the acute transient syndrome ([57] , [69]). An antecedent upper respiratory infection in children is usually identified, although the exact organism may not be discovered. Attacks have been associated with measles ([158]), measles vaccinations ([159]), mumps ([160]), *Mycoplasma* pneumonia ([161]), influenza A, adenovirus, varicella ([162]), cytomegalovirus, *Haemophilus influenzae* ([163]), and infectious mononucleosis ([164]). These episodes are self-limited and not expected to recur in the future. They can, however, be quite severe and even life-threatening without supportive care. Although PCH is uncommon, it may not be as rare as initial reports suggested. In series of all hemolytic anemias, the incidence has ranged from 1.7 to 10.0% ([57] , [105] , [165]). PCH may account for more than 40% of immune hemolytic anemias in children under 5 years of age ([166]). The original chronic PCH associated with syphilis has all but disappeared. It was characterized by relapsing episodes of hemoglobinuria with cold exposure. Treating the syphilis usually treated the PCH, although some patients' hemolysis did not respond to antiluetic therapy ([69]). The diagnosis of chronic PCH now should prompt an investigation for occult syphilis infection and, in its absence, should be considered the idiopathic variety. These cases are quite rare.

LABORATORY FEATURES Hematologic findings in PCH are typical for acute, severe intravascular hemolysis. Hemoglobins less than 50 g/L can be seen ([158] , [159] , [163] , [166]). Spherocytes, nucleated RBCs, polychromatophilia, anisocytosis, poikilocytosis ([57]), and erythrophagocytosis by neutrophils ([158] , [166] , [167]) have been reported. The white blood cell count may be depressed very early in the attack but is usually normal or high. Platelet counts are usually normal. Reticulocytopenia is quite common early in the episode, but reticulocytosis appears in the recovery phase ([69]). Once haptoglobin is exhausted, hemoglobinuria results. The plasma is frequently red, reflecting the free hemoglobin. As in other instances of hemolysis, the lactate dehydrogenase and bilirubin (mostly unconjugated) are elevated. Complement levels are depressed. Urine tests are positive for hemoglobin and methemoglobin, giving it its dark red to almost black appearance. Occasionally, RBCs are found in the sediment, but the discoloration is primarily pigment. Rarely does the patient have renal insufficiency with elevated blood urea nitrogen and creatinine ([168]). Proteinuria may be detected, and hemosiderinuria is found in patients with the chronic variety. The Donath-Landsteiner test is a simple procedure involving incubating the patient's serum in melting ice with washed group O, P-positive RBCs and fresh normal serum as a source of complement. After 30 to 60 minutes, the tube is moved to 37°C for another incubation of similar duration. Lysis visible to the naked eye after the warm incubation is a positive test ([55]). Appropriate controls should be run simultaneously. Other serologic testing in the blood bank should reveal a positive DAT with anticomplement antisera. The anti-IgG DAT is rarely positive due to dissociation of the antibody from the cell at warmer temperatures. If the blood specimen is processed at cold temperatures, one can occasionally demonstrate IgG on the surface of the cells ([57]). The D-L antibody may be demonstrated using the IAT. The method of using an ice-cold saline wash to avoid elution of the antibody and then testing with monospecific antisera for IgG has been shown to be a very sensitive indicator for antibody presence ([57]). Differentiation between cold agglutinins and the D-L antibody can be made by careful characterization of the antibody involved, including specificity and Ig class. The classic age discrepancy and the rare occurrence of cold agglutinins in children may lend clinical support to the diagnosis.

MANAGEMENT Treatment of acute attacks is essentially supportive. Given the transient nature of the syndrome, little else is indicated. In severely anemic children, steroids are usually given, although their benefit has not been documented ([160] , [166]). Blood transfusion may be safely accomplished with bank blood even though essentially all units are P antigen positive. Delaying a needed transfusion to locate the 1 unit of pp blood in 200,000 units ([55]) may put the patient in far more danger than transfusing readily available P units. Warming the patient and the blood is advisable. The hemoglobin rises the expected amount in most situations. In the rare patient in whom the hemoglobin does not rise, rare-donor files can locate pp or Tj(a–) units. When this pp antigen blood is available, transfusion results have been excellent ([169]). As with other immune hemolytic anemias, critical situations may be ameliorated by plasmapheresis ([170]). Chronic PCH is best treated by the avoidance of cold and rarely requires any other therapy. Patients that have documented syphilis should be treated for that, and most show resolution of the hemolytic attacks ([171] , [172]).

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY MIXED WARM AND COLD ACTIVE ANTIBODIES

A significant number of patients with warm AIHA also have cold agglutinins in their serum. In fact, in one series, nearly 35% of these patients had low-titer cold agglutinins that caused agglutination of normal RBCs at 20°C ([57]). There was, however, no activity from the cold antibody at 30°C. Although the cold active antibody is abnormal in its thermal amplitude, it is not believed to play a role in RBC destruction. This is contrasted with the rare patient who, in addition to a warm antibody, has a cold active IgM antibody in high titer at 4°C and wide thermal amplitude with activity at 30°C or even 37°C. These cases satisfy the criteria for both warm autoimmune hemolysis and cold agglutinin syndrome. The clinical presentation of these patients with mixed warm and cold active antibodies is typically quite severe hemolysis without the characteristics of CAD, such as exacerbation with cold exposure or acral cyanosis ([173]). Many of these reported cases are idiopathic or have lymphoproliferative disorders. Other associations with systemic lupus erythematosus or viral infection have been reported ([173] , [174]). Concomitant immune thrombocytopenia has also been reported ([173]).

Laboratory investigations show a DAT positive for both IgG and complement in the vast majority. Eluates show the warm IgG panagglutinin without specificity. The cold agglutinin specificity is typically I, but i and Om have also been found ([173] , [174]). Hemoglobin values may be quite low (<50 g/L) ([173]). Transfusion is complicated by both autoantibodies and the increased difficulty of ruling out alloantibodies in their presence ([55]). Units are released cross-match incompatible as with any autoantibody present in the serum. However, their survival should not be expected to differ markedly from the patient's own cells.

Steroids are the mainstay of therapy as well as treatment of any underlying disease ([173] , [175]). Other immunosuppressives and splenectomy have also been used ([176]).

IMMUNE HEMOLYTIC ANEMIAS CAUSED BY WARM ACTIVE ANTIBODIES

Autoantibodies with greatest activity at 37°C are responsible for the majority of patients with AIHA. Excluding drug-induced autoantibodies, approximately 70% of all AIHA patients have the warm antibody type ([57] , [105]). In general, these antibodies are IgG, may or may not fix complement, and destroy RBCs by extravascular hemolysis in the spleen. Exceptions occur as is discussed later. They may be secondary to an underlying disease, such as systemic lupus, lymphoproliferative or other neoplastic diseases, infections, or immune deficiency syndromes. In some cases, no underlying process is ever identified, and they are labeled *idiopathic*. Drugs may induce the production of warm active antibodies reacting with combinations of the medication and the RBC membrane, or, in the case of a-methyldopa, a true autoantibody that is not dependent on the presence of the drug.

Primary versus Secondary Autoimmune Hemolytic Anemia

Primary or *idiopathic warm AIHA* accounts for less than half of the cases. It can occur in any age group, and females predominate in ratios of approximately 2:1 in most series ([105] , [141] , [177]). There is no racial predilection, but a genetic predisposition is suggested by the occurrence of more than one case of AIHA in one family ([69]). No blood group has been consistently shown to be selectively affected. HLA-A1, -B7, and -B8 recur in the literature as being overrepresented in this population. However, not all series have reached this conclusion ([178] , [179] , [180] and [181]). The incidence of AIHA has been reported to be in the range of 1 per 75,000 to 2 per 100,000 ([141] , [182]). This incidence rises some with age, but most of the increase is a reflection of the secondary hemolytic anemias as opposed to idiopathic. The immune system abnormality that leads to the production of the pathologic antibody in either primary or secondary hemolytic anemia is still not completely understood, as discussed earlier.

With an aggressive search and long follow-up, most patients with warm autoantibodies are found to have an underlying associated condition. Percentages of secondary disease have risen over the years from 22% to more than 80% ([105] , [141] , [177] , [183]), probably reflecting more intensive investigation rather than a real change in the spectrum of disease. In Conley's review of warm autoimmune antibody cases, 19 of 33 that would have previously been labeled as idiopathic could be linked to an underlying immune-mediated disorder with careful history and follow-up ([184]). Table 35.4 lists many diseases and other events that have been reported to occur with warm autoantibodies.

TABLE 35.4. Diseases or Conditions That Have Been Associated with Warm Autoimmune Antibodies

Autoimmune disorders
Systemic lupus erythematosus
Rheumatoid arthritis
Scleroderma
Ulcerative colitis
Antiphospholipid antibodies
Chronic lymphocytic leukemia
Acute myelocytic leukemia
Hodgkin disease
Non-Hodgkin lymphoma
Other lymphoproliferative disorders
Multiple myeloma
Thymoma
Waldenström macroglobulinemia
Epstein-Barr virus infection
Hepatitis C virus infection
Diphtheria-pertussis-tetanus vaccinations
Ovarian dermoid cyst
Teratoma
Kaposi sarcoma
Carcinoma
Pregnancy
Bone marrow transplantation
Congenital immune deficiency states
Hypogammaglobulinemia
Dysglobulinemia
Acquired immunodeficiency syndrome

Malignancy-associated AIHA has been an accepted phenomenon for quite some time. Lymphoproliferative disorders are the most commonly documented coexisting tumors, but others, such as ovarian dermoid cysts, teratomas, Kaposi sarcoma, and carcinomas, have been reported ([185]). The origin of these pathologic antibodies is uncertain. Mere coincidence is statistically unlikely but might account for a very few. A case report by Sthoeger et al. ([186]) supports the concept of the malignant cell as the source of the antierythrocyte antibody in that the monotypic heavy and light chains eluted from the RBCs were identical to those expressed on the surface of B-CLL clones. However, the vast majority of warm autoimmune antibodies associated with tumors are not monoclonal, but polyclonal. Another theory believed to explain the occurrence of both autoimmune disease and malignancy is a disruption of normal immune function surveillance that allows autoantibodies to form and neoplasia to proliferate ([185]). The aberrant immune system function secondary to effects of the tumor itself in B-CLL has been discussed earlier.

The association of AIHA with other nonmalignant diseases, frequently of immunologic origin, lends more support to theories of general immune system disturbance as an etiology. Human immunodeficiency virus infection ([187] , [188]), thymic disorders ([189] , [190]), and other immune deficiency states ([191]) can be associated with autoimmune hemolysis. In patients with ulcerative colitis and warm AIHA, colectomy has also successfully treated the hemolytic anemia ([192]). Systemic lupus erythematosus is frequently complicated by warm autoantibodies. Childhood viral illnesses are commonly associated with warm antibody RBC destruction. Other diseases may have less clear significance in their relation to the hemolysis.

CHARACTERISTICS OF THE ANTIBODY

Immunochemistry and Origin Compared to cold active antibodies, little is known or understood about the immunochemistry and origin of warm active antibodies. No cell line is available to provide a source of antibody for antigen-binding and structural studies. The target antigen(s) is unknown. It appears that most antibodies are IgG with a preponderance of IgG1 and, to a lesser extent, IgG3—the two subclasses most adept at fixing complement ([193]). The subtypes vary in their efficiency at causing hemolysis due to higher affinities of the macrophage Fc receptors for the IgG3 and IgG1 subclasses ([194] , [195]). Various combinations of IgG subclasses may occur together. It is uncommon for IgA or IgM to occur in concert with IgG, and it is even more rare for them to occur singly ([57] , [58]). Table 35.5 compares the serologic findings of the different types of immune hemolytic anemias.

TABLE 35.5. Serologic Overview of Hemolytic Anemias

	Warm Autoimmune Hemolytic Anemia	Cold Agglutinin Disease	Mixed Warm and Cold Autoimmune Hemolytic Anemia	Paroxysmal Cold Hemoglobinuria	x Drug-Induced Hemolytic Anemia
Percentage of cases	40–70%	16–32%	7–8%	32% in children; rare in adults	12–18%
Direct antiglobulin test	IgG ± C3; rarely C3 alone	C3	IgG ± C3	C3	IgG or C3; occasionally IgG ± C3
Ig	IgG, occasionally with IgA or IgM	IgM	IgG, IgM	IgG	IgG
Eluate	IgG	Nonreactive	IgG	Nonreactive	IgG or nonreactive
Antibody specificity	Panagglutinin; rarely Rh or other	I, i; rare Pr	Unclear; rare I, i	P	Rh-related; drug-dependent

C3, complement third component; Ig, immunoglobulin.

Blood Group Specificity Warm autoantibodies are described as *panagglutinins* in that they react with all the RBCs in the diagnostic panel. Many investigations of the specificity of antibodies to date have been serologic and thus rely on the existence of very rare antigen-negative cells to do the proper studies or on monoclonal antibodies to block particular epitopes. Expression of complementary DNA of Rh-related antigens and anion transporter band 3 in cell lines allowed investigation of antibody binding by flow cytometry ([196]). Of the reported specificities, Rh is by far the most common, appearing in 70%, due to reaction with all but the Rh_{null} cell. Occasionally, the IAT identifies an antibody with relative Rh specificity for a particular Rh antigen such as e. It is extremely rare for antibodies of true specificity to occur in the absence of those of broader specificity. Thus, little is to be gained by transfusing antigen-negative blood to these patients. Indeed, intentionally giving RBCs possessing antigens foreign to the host may stimulate alloantibodies and further complicate the problem ([197]). Other blood group specificities that have been reported include Wright (Wr^b), En^a, Duffy (Fy^b), Gerbich (Ge), Kidd (Jk^a), Kell (K), Lutheran (Lu), LW, M, N, S, Pr, A, B, I^T, Sc3, U, Vel, and Xg^a ([63] , [69]).

CLINICAL MANIFESTATIONS AIHA may present in all manners of severity from a clinically insignificant increase in RBC turnover to fatal fulminant hemolysis. Most patients present with an insidious onset of weakness, fatigue, dyspnea on exertion, and other symptoms of anemia ([198]). These gradual symptoms tend to accompany the idiopathic variety or those varieties that are secondary to malignancies or other autoimmune diseases. If the RBCs can survive in the circulation for approximately 2.5 days, a steady state may be reached with increased marrow production. Hemolysis rates greater than 20% per day may cause hypovolemic shock and death if not aggressively treated ([199]). The more aggressive, life-threatening end of the hemolytic spectrum tends to occur after viral infections, especially in children, and may produce prostration, shock, and death. Other signs and symptoms may include unexplained fever, abdominal pain, headache, anorexia, and confusion ([198]). In older patients with less cardiac reserve, angina may be an ominous symptom. Thrombophlebitis may also occur. Persons with concomitant antiphospholipid antibodies may

be at higher risk for thromboembolic events ([200]). In those patients with hemolysis associated with other conditions, symptoms attributable to their underlying disease may predominate (Table 35.6). A careful history of any recent drug ingestion—prescription, over-the-counter, or illicit—should be obtained.

TABLE 35.6. Most Common Presenting Signs and Symptoms in Patients with Autoimmune Hemolytic Anemia of the Warm Reactive Type

Symptom	Frequency (%)
Weakness	88
Dizziness	50
Fever	37
Bleeding	10
Dyspnea	9
Cough	6
Weight loss	5
Gastrointestinal disturbance	5
Anorexia	4
Dark urine	3
Angina	2
Confusion	2

Sign	Frequency (%)
Splenomegaly	82
Hepatomegaly	45
Lymphadenopathy	34
Jaundice	21
Thyromegaly	10
Edema	6
Cardiac failure	5
Pallor	4

Modified from Pirofsky B. Clinical aspects of autoimmune hemolytic anemia. Semin Hematol 1976;13:251–265.

If hemolysis is brisk, jaundice may be noticeable as well as mild splenomegaly, hepatomegaly, pallor, and edema. Rarely, hemoglobinemia and subsequent hemoglobinuria with dark or red urine may bring the patient to medical attention. Even among the idiopathic AIHAs, lymphadenopathy may occur in up to 25% ([198]). However, very large nodes or spleen should alert the clinician to the possibility of an underlying lymphoproliferative process requiring specific therapy. In only a very few patients with rampant hemolysis or, rarely, agglutination induced by the autoantibody will peripheral cyanosis occur. This is much more characteristic of CAD. The acute onset of hemolysis after an infectious episode may be severe but also tends to be short-lived ([69]). In contrast, the more insidious onset of the idiopathic or other secondary types may have a waxing and waning course for several years or follow the progression of the underlying disease.

Pregnancy Pregnancy may pose a special situation in AIHA. The rate of autoantibody formation in pregnant women has been reported at 1.0 per 50,000 as opposed to 0.2 per 50,000 in an age-comparable control population ([201]). Hemolysis tends to increase during the pregnancy and may remit after delivery of the infant. Hemoglobins below 50 g/L have been reported ([202]). Cases of recurring DAT-negative hemolytic anemia with pregnancy have been documented ([203] , [204]). Infants born to mothers with hemolytic anemia may not suffer any hemolysis or may have a positive DAT and consequent RBC destruction from the passively acquired antibody. Even if difficulties are encountered initially, the infant should be expected to become normal in a few weeks to months as there is no ongoing production of antibodies ([204] , [205]).

Infancy and Childhood AIHA in infancy and childhood can be quite different from that in adults. The disease onset is more likely to be sudden and severe. Cases in very young infants have been reported ([206]). It usually is preceded by a viral infection. There is a slight male predominance, and the prognosis is relatively good for a complete and lasting remission within several weeks of the onset. Most children respond well to steroids and rarely is splenectomy considered ([69]). A particular association of childhood vaccines and hemolytic anemia has been documented ([207] , [208]). Children can have very severe Evans syndrome ([209]).

Evans Syndrome The concomitant presence of purpura or petechiae may herald a low platelet count and indicate Evans syndrome, which was originally described in 1949 as immune thrombocytopenia and AIHA ([210] , [211]). The thrombocytopenia may precede, occur concurrently with, or follow the AIHA ([177]). This is more common in children and is less likely to respond well to therapy ([212] , [213]). Multiagent protocols have shown some success ([214] , [215]). Severe cases have required stem cell transplantation ([216]), although standard treatment regimens recommended for AIHA alone are typically used first. These are discussed in more detail below.

Immune Deficiency Syndromes Since the 1960s, it has been noted that AIHA occurs in patients with congenital or acquired immune deficiency syndromes. These cases are characterized by variable hypogammaglobulinemia, recurrent infections, lymphopenia, and an assortment of other signs and symptoms, such as splenomegaly, thrombocytopenia, eczema, and more recently, acquired immunodeficiency syndrome ([69] , [188]).

Stem Cell Transplantation Hemolytic anemia after stem cell transplantation has various etiologies. Mismatched ABO types produce hemolysis, which is sometimes quite significant until the transplanted marrow assumes primary residence and the host antibodies or cells are exhausted. Mixed chimerism can give rise to syndromes in which the host immune cells make antibodies to minor RBC antigens on RBCs produced by the transplanted stem cells. Autoimmune hemolysis complete with panagglutinin months after transplant is also possible. Serologic studies should provide the appropriate diagnosis ([217]). In addition, nonimmune, microangiopathic hemolysis associated with cyclosporine and other graft-versus-host preventatives is also well described ([218]).

LABORATORY FEATURES Hemoglobin and hematocrit values at presentation can vary from essentially normal in the compensated hemolyzing patient to extremely low in the rare patient with fulminant RBC destruction. The mean corpuscular volume is usually elevated, reflecting the young population of cells and perhaps a relative folate deficiency in those patients with chronic hemolysis and no replacement. Reticulocyte counts are usually elevated, sometimes remarkably so, but may be depressed early in the course ([219]). Reticulocytopenia may have myriad causes, including marrow shutdown from intervening infection, malignancy invasion, parvovirus B19 infection, or the possibility of the autoimmune antibody being directed at antigens in great concentration on the reticulocytes themselves ([69] , [220] , [221] and [222]). The bone marrow is usually hyperplastic even in the face of reticulocytopenia ([219]). The peripheral smear typically reflects the reticulocytosis with polychromatophilia and macrocytosis, as well as nucleated RBCs. Spontaneous agglutination is uncommon with warm autoantibodies but may occur if the cells are strongly sensitized with Ig. Variable amounts of microspherocytes are produced when the splenic sinusoidal macrophages bind and extract their pound of flesh from the RBC membrane. As the surface to volume ratio decreases with membrane loss, the cell assumes an increasingly spheric shape and becomes less malleable and less able to traverse the small capillaries ([223]). The presence of erythro-phagocytosis by monocytes, or rarely neutrophils, on the peripheral smear is an indication of AIHA ([224]). White blood cell counts are usually slightly elevated but may be depressed. Platelet counts typically are normal but may be low ([141] , [219]). Leukopenia and thrombocytopenia may also be immune-mediated, as shown in some cases by the presence of antileukocyte and antiplatelet antibodies ([225]). Platelet dysfunction may occur as well ([226]). The serum bilirubin is elevated but is rarely above 5 mg/dl in the absence of concomitant liver disease, and the major fraction is unconjugated ([227]). Hemoglobinemia and depressed or absent haptoglobin can be seen in rapid hemolysis, even if it is extravascular. Urobilinogens are increased, and hemoglobinuria and hemosiderinuria may follow severe hemolysis. However, only very rarely has renal failure been reported ([228]). Stercobilinogens may turn the stool dark. Biologic false-positive syphilis tests are common, and other abnormal antibodies have been reported, including antithyroid antibodies, rheumatoid factors, and anticardiolipin antibodies. Serum Ig abnormalities have been reported with both elevations or depressed levels. No constant pattern has been elucidated ([229] , [230]). The hallmark of immune-mediated hemolytic anemia is the presence of Ig, complement, or both on the surface of the RBC. In over 95% of warm AIHA cases, the DAT is positive. Series vary in their DAT results. Between 20 and 66% have only IgG on the surface, 24 to 63% have IgG and C3, 7 to 14% have only C3, and 1 to 4% are DAT negative ([57] , [182] , [231]). Patients with systemic lupus erythematosus are particularly prone to positive tests for complement on the cells. IgG1 predominates, either alone or in combination with other subclasses, and IgG4 is uncommon. In rare cases of warm hemolysins, IgM antibodies that fix complement and are associated with severe, life-threatening hemolysis have been reported ([232]). It is even more uncommon for IgG antibodies to act as hemolysins ([233]). The severity of hemolysis is loosely correlated with the number of antibodies bound to the cell and the strength of the DAT ([234] , [235]). However, others factors play a large role in the significance of the clinical picture, such as the subclass of Ig. There remain still other characteristics yet to be defined that explain why hemolysis occurs in DAT-negative patients, whereas other patients have globulins demonstrable on their cells without any significant increase in RBC turnover. If standard techniques do not produce a positive DAT, other, more sensitive techniques discussed earlier may be successful. Some patients with negative DATs may have hemolysis from low-affinity IgG antibodies that are inadvertently removed in the wash phase of the Coombs test ([59]). IgA-mediated hemolysis is an often cited and rarely found cause

of a negative DAT. A large series found 124 patients who had IgA on their RBCs out of 5235 patients evaluated at an immunohematology referral center. Of the 124, only 6 had IgA as the sole Ig attached to the cell. All six also had complement detectable ([58]). The antibody screen reveals the presence of the panagglutinin in the serum in 80% of cases. Specificity for other antigens can be sought as described earlier but is difficult to accurately obtain without a large selection of rare, antigen-negative cells and is of marginal clinical benefit.

MANAGEMENT General principles of treatment are guided by the severity of hemolysis. Those patients with a positive DAT, mildly elevated reticulocyte count, and normal hematocrit should not be subjected to the possible side effects of steroid therapy. Folate deficiency can be avoided with daily supplements, which probably should be given to any patient with hemolysis. When the RBC lifespan shortens past the point of marrow compensation and anemia appears, intervention is indicated. Given the high proportion of secondary hemolytic anemias, a search for an underlying disorder (Table 35.4) that requires specific therapy, such as a lymphoproliferative disorder, is indicated. Treatment of the secondary disorder may also bring the AIHA under control. However, in some situations, each disorder must be addressed separately. Many treatment options exist for these patients, who can have vast differences in the severity of their disease ([236] , [237] and [238]).

Steroids Glucocorticoids are the initial therapy of choice for warm AIHA. Doses that are likely to achieve the desired clinical result are 1.0 to 1.5 mg/kg or 40 mg/m ^{2} of body surface area/day of prednisone or its equivalent. Higher daily doses or high-dose pulsed therapy may be efficacious ([237] , [239]). Response may not be evident for 3 or 4 days but should be noticeable by 7 days. Reticulocyte counts may increase, and the hemoglobin should rise 20 or 30 g/L/week. Once the hemoglobin reaches 100 g/L, weaning of the steroid can begin. The rate of decrease should parallel the response. Those who respond rapidly may have their dose reduced over 4 to 6 weeks to 20 mg prednisone/m ^{2}/day. Beyond this point, tapering should proceed more slowly over 3 to 4 months. Some even continue a low dose (e.g., 5 to 10 mg every other day) for prolonged periods thereafter to prevent relapse, although no data exist to fully support this practice. This schedule should be adjusted for the individual patient's response to the treatment and to any of the significant side effects that can result. The side effects, which include increased susceptibility to infection, hypertension, fluid retention, diabetes, myopathy, peptic ulceration, osteoporosis, and even reversible facial cosmetic changes, may be intolerable to some patients. Alternate-day steroid therapy decreases some of the side effects and may still be effective. Strong consideration should be given to concomitant prophylactic gastric acid control. Initial responses to steroids are generally excellent with more than 80% of patients having a prompt reduction in hemolysis. Only 7% in one series responded after 2 weeks, and even fewer responded after 3 weeks. Therefore, if there has been no improvement after 3 weeks of therapy, the patient can be considered a steroid treatment failure ([141]). Approximately 15 to 20% of patients have no response to steroids and need splenectomy or cytotoxic drugs. Recurrence of hemolysis after remission is usually gradual, especially if the steroids were weaned over a prolonged period. However, relapse will indeed occur in the vast majority of patients. Approximately 40 to 50% of patients require maintenance doses of prednisone, 5 to 20 mg/day ([240]). If the maintenance prednisone dose is greater than 15 mg/day, other measures should be considered. The DAT usually remains positive, although the strength of the reactions may decrease with clinical remission. Free autoantibody in the serum (positive IAT or antibody screen) may disappear, but the DAT remains positive in most patients ([69]). Complete and lasting remission rates from steroids alone are reported as 16 to 35% of patients ([241] , [242]). Even some of the long-term remission patients still have a positive DAT ([241]). How steroids control the hemolysis in these patients has been the subject of extensive investigation. There is good experimental evidence in animal models to support the claim of decreased antibody formation. Titers of autoantibody decrease, and gammaglobulin levels also fall ([243] , [244]). Another hypothesis for the rapid decrease in hemolysis after drug administration is alteration of the affinity of the antibody for the antigen ([245] , [246]). An understanding of the mechanism of this avidity change remains illusive. Probably the most immediate effect of steroids is to decrease the clearance of erythrocytes by the monocyte-macrophage system. Guinea pig studies have shown us that steroids are most effective in this when the cells are coated with IgG alone. Less effect is seen when complement appears with the IgG, and the least benefit is noted when complement and IgM are involved ([247]). This is in keeping with the clinical observations of little, if any, efficacy of steroids in CAD. The decreased clearance may be due to a drop in the number of Fc and C3 receptors on the surface of the macrophages ([247] , [248]).

Transfusion Despite the high rates of response to steroid therapy and the relative speed of their benefit, some patients present with critically low hemoglobins and associated symptoms that require immediate intervention. Transfusions should be avoided if at all possible due to the serologic difficulties encountered but never withheld from the patient in extremis. Keep in mind that the chief function of the transfusion is to temporize the patient until the steroids or other specific therapy has had time to work. Destruction of the transfused cells occurs at the same rate as that of autologous cells ([249]). Hematocrits may rise with transfusion or may continue to fall rapidly until the hemolytic process is under control ([57] , [141]). Only rarely does the autoantibody have true specificity for an identifiable antigen, justifying the transfusion of specific antigen-negative RBCs ([250]). ABO typing the patient's blood is usually not a problem with warm autoantibodies like it can be with cold agglutinins. However, some patients may have invalid ABO results with spontaneous agglutination or similar difficulties with Rh testing in albumin ([139]). If there is doubt about the accuracy of results, the antibody can be eluted from the cell and testing repeated ([55]). More problems arise during the antibody screen and cross-matching of donor units in those patients with free autoantibody in their serum that acts as a panagglutinin. In these patients, all cross-matches are incompatible, and units must be transfused with caution. In patients with panagglutinins in their serum, auto- and alloadsorption techniques can uncover alloantibodies induced from previous exposures to blood or pregnancy. An accurate transfusion history is vital for the complete evaluation of these blood samples. The incidence of alloantibodies has been variably reported from 14 ([100]) to 40% ([251]). Alloadsorption techniques may more accurately reflect the true incidence, as it is more likely to remove autoantibodies of mimicking specificities ([252]). Some advocate transfusing completely phenotypically matched cells if possible, but few laboratories have the capability or the blood inventory to do this ([253]). In the end, incompatible units are released and should be transfused slowly and under vigilant watch for untoward reactions. *In vivo* compatibility testing with ^{51}Cr-labeled RBCs is of little or no value in this situation ([57]). Given the fact that the patient who requires transfusion is nearly always profoundly anemic and in high-output heart failure, the most likely serious complication is dangerous fluid overload. These patients typically do not have the volume depletion of hemorrhagic shock and almost always require judicious diuretic use to maintain euvolemia. Bovine hemoglobin solution given to a young patient with profound hemolysis and increasing reactions to standard RBC infusions was a successful temporizing measure until aggressive immunosuppressive therapies controlled the underlying hemolytic process ([254]).

Splenectomy Splenectomy is indicated in those surgical candidates who have not responded to prednisone, require prednisone doses greater than 10 to 20 mg/day to maintain remission, or have suffered intolerable side effects from prednisone therapy. The rationale for its effect is twofold. The spleen is the major site of RBC sequestration and destruction in warm AIHA due to IgG antibodies. Splenectomy has little effect on the clearance of IgM-coated cells and therefore would not be indicated in the unusual patient with a warm active IgM antibody. Recall that it is not an effective treatment for cold agglutinins either. The spleen is also believed to be a major producer of IgG antibodies. Removal of a source of autoantibody can decrease the titer and subsequent clearance. Some investigators report utility in determining the amount of cells removed by the spleen using ^{51}Cr-tagged RBCs ([255] , [256]). However, others have not found it so useful ([242] , [257]), and still others argue that, in patients refractory to steroids and other therapies, splenectomy is the next option regardless of predictors of its success ([57]). Response rates to splenectomy vary. Indeed, published accounts range from virtually ineffective to near 100% success ([57] , [258]). Overall responses are probably around 60 to 75%, but many of these patients relapse or remain on steroids, albeit at lower, more tolerable doses ([57] , [257] , [258]). Likelihood of response to splenectomy may be higher in idiopathic hemolytic anemia than in secondary ([259]). The complications of splenectomy are those inherent in major abdominal surgery and also include subdiaphragmatic abscess, pulmonary embolism, and increased susceptibility to infections, especially in children ([69] , [260]). Appropriate vaccinations should be given preoperatively. Subsequent to splenectomy, patients should be given antibiotics promptly with any febrile illness. Morbidity and mortality rates of 5 to 10% are involved with splenectomy, but many believe that the complications of long-term steroid use rival these risks ([258]). Splenic irradiation may be a useful alternative in nonoperative candidates ([261]).

Other Immunosuppressive Drugs Antimitotic and antimetabolite drugs became available in the 1950s. These potent immunosuppressive drugs were used in AIHA and other autoimmune diseases in the hope that their immunosuppressive effect would be greater than their known bone marrow suppression. Early anecdotal success with nitrogen mustard ([262]) led to other therapeutic attempts with azathioprine and, later, cyclophosphamide. Azathioprine and other antimetabolites could effectively block the primary response to a purified protein antigen but had minimal effect on the secondary response ([263] , [264]). Despite this, many case reports document remissions in patients in whom other treatments had failed, including steroids and splenectomy ([257] , [265] , [266]). Cyclophosphamide is a very effective immunosuppressive agent that has the capacity to suppress the immune response when administered before, during, or after antigen presentation ([267]). This is particularly desirable for administration after the onset of immune hemolysis. Beneficial effects of cyclophosphamide therapy are reported in reviews ([240] , [242] , [257]). Great caution is advised with prescribing any myelotoxic drug. Blood counts should be followed closely. Other significant side effects from the antimetabolites and cyclophosphamide include hemorrhagic cystitis/bladder fibrosis, development of secondary malignancies, sterility, and alopecia ([57] , [240] , [268] , [269]). No properly controlled trial exists from which to draw conclusions, but the reviews and case reports suggest a response rate of approximately 40 to 60% in those patients who did not respond to steroids and splenectomy ([242] , [257] , [258]). Patients who are not operative candidates and have not responded to steroids may be given a trial of immunosuppressive drugs. A reasonable regimen might include azathioprine, 80 mg/m ^{2}/day, or cyclophosphamide, 60 mg/m ^{2}/day, concomitantly with prednisone, 40 mg/m ^{2}/day. Taper the prednisone over approximately 3 months and continue the cytotoxic agent for 6 months before reducing the dose gradually ([240]). Bone marrow suppression may dictate minor dose adjustments. Rapid withdrawal has led to rebound immune response ([270]). Alternatively, high-dose cyclophosphamide (50 mg/kg/day for 4 days) produced a complete remission in 66% of patients refractory to other therapies. Severe myelotoxicity and its attendant potential for complications are expected ([271]). Rituximab is a chimeric human/murine monoclonal anti-CD20 antibody approved for use in lymphoma. Successful rituximab use in refractory warm AIHA has been documented in several case reports, although not as many as with CAD ([272] , [273] , [274] and [275]). Regimens identical to the lymphoma treatment doses of 375 mg/m ^{2}/week for 4 weeks have produced remissions in some patients refractory to other therapeutic regimens. One series in refractory pediatric patients reported a response rate of 87%. Twenty-three percent of the responders relapsed, but subsequent courses of rituximab induced additional remissions ([276]). Thus far, few side effects have been experienced by the patients reported, but be aware that severe reactions to the infusion, including fatalities,

have been reported ([277]). B-cell counts remain low for months after treatment, raising the risk of infections due to poor immune response ([278]). To date, rituximab has been used in refractory patients. If remissions remain durable and potential side effects are believed to be less harmful than other treatments for warm AIHA, such as prolonged steroid use or splenectomy, its use may become more common. Mycophenolate mofetil, an inhibitor of inosine 5'-monophosphate dehydrogenase, is an immune suppressant first used in allograft rejection. It has been shown to induce complete or partial remission of hemolysis in case reports. Doses begin at 1 g/day and are then increased to 2 g/day. In cases of partial remission, reduction in doses of other immunosuppressives was possible without sacrificing efficacy. Long-term side effects of this relatively new medication are not fully established. Short-term side effects consist primarily of gastrointestinal intolerance and mild myelosuppression ([279] , [280]). Alemtuzumab (Campath-1H) is a humanized IgG monoclonal antibody targeted against the CD52 antigen found on lymphocytes and monocytes. The primary therapeutic result is through the profound depletion of T cells, particularly the CD4 population. In a pilot study of various types of autoimmune cytopenias, some response was demonstrated, including in AIHA and Evans syndrome patients. After a test dose of 1 mg, patients were given 10 mg/day for 10 days. Some patients were also given cyclosporine in follow-up, making the effect of the alemtuzumab alone difficult to interpret ([281]). Cyclosporine A has been used successfully and unsuccessfully in refractory hemolytic anemia patients, like many of the other immunosuppressive medications previously described. Doses of 3 mg/kg/day with target serum levels of 200 to 400 ng/ml produced remissions ([282]). It has also been used in combination with other remedies with some success, including danazol and prednisone ([215] , [283] , [284]).

Other Therapies Intravenous Ig has not enjoyed the success in AIHA that it has in immune thrombocytopenia. Case reports of success ([285] , [286] and [287]) and failure ([288] , [289]) have appeared. Escalating the dose from the standard 0.4 g/kg/day for 5 days to 1.0 g/kg/day was helpful. In one refractory patient, weekly maintenance infusions of 800 mg/kg/week helped to control transfusion requirements ([290]). The mechanism of action of intravenous Ig is not completely clear. Recent evidence suggests that intravenous Ig exerts inhibitory effects on dendritic cells by down-regulating co-stimulatory molecules, blocking maturation, and modifying their interactions with lipopolysaccharide and cytokines ([291]). Other mechanisms include modulating expression and function of Fc receptors, interfering with the activation of complement, modulating immune response through antiidiotype antibodies, and effects on B and T cells ([292]). Plasmapheresis has been used with limited success in attempts to remove the antibody ([57] , [293] , [294]). Given the large volume of distribution of IgG, it is not surprising that removal is difficult. However, in some patients in whom fulminant hemolysis proceeds unchecked, it may serve as a temporizing measure until other immunosuppressive therapies have time to take effect. Selective removal of IgG with staphylococcal protein A columns has also been reported with some benefit ([295]). Danazol, an androgen with minimal masculinizing effects, has had anecdotal success. It may inhibit binding of the antibody to the cell ([296]). Doses of 600 to 800 mg/day in conjunction with prednisone produced variable responses in 13 of 15 patients ([297]). Stem cell transplantation has now been described for many severe, life-threatening autoimmune syndromes, including hemolytic anemia and Evans syndrome. Sources of the stem cells have been autologous, HLA-matched sibling and cord blood ([216] , [298] , [299]). Relapses and the expected range of complications, including death, have occurred. As more refractory patients arise, stem cell reconstitution after high-dose immune suppressive regimens will no doubt expand. Anecdotal success has been reported with vinca-loaded platelets ([300] , [301]). Heparin, a drug well known to be anticomplementary, has offered temporary alleviation but only in those patients with a clearly complement-dependent mechanism ([302] , [303]). Thymectomy in infants has been followed by improvement in isolated cases of severe AIHA ([105] , [304]).

Drug-Induced Immune Hemolytic Anemia

The first documented case of an immune-mediated, drug-induced cytopenia, reported in 1949, was thrombocytopenia secondary to allylisopropyl-acetylcarbamide (Sedormid) ingestion ([305]). In 1953, Snapper described a patient who suffered hemolysis after treatment with mephenytoin (Mesantoin) and recovered fully after discontinuation of the drug ([306]). In 1956, Harris' report of acute intravascular hemolysis in a patient treated for the second time with stibophen for schistosomiasis appeared ([307]). Agglutination of the patient's RBCs *in vitro* occurred only in the presence of the drug. After discontinuation of the drug, hemolysis resolved in a few weeks, and the DAT reverted to negative approximately 2 months later. Immune hemolysis produced by the interaction of drug, antibody, and RBC membrane is uncommon now that our pharmaceutical armamentarium has expanded to include other therapeutic options not prone to this complication. a-Methyldopa used to be responsible for the majority of drug-associated positive DATs and hemolytic anemia. High-dose penicillin (<10 million units/day) was also responsible for many cases of drug-induced hemolysis. With other effective antihypertensives and antibiotics now available, they are prescribed less frequently. Table 35.7 lists some medications associated with immune hemolysis, a positive DAT, or both.

TABLE 35.7. Drugs Associated with Immune Hemolysis/Autoantibodies

Acetaminophen	Doxepin	Oxaliplatin
Aminopyrine	“Ecstasy”	*p*-Aminosalicylic acid
Amphotericin B	Elliptinium acetate	Penicillin G
Ampicillin	Erythromycin	Phenacetin [a]
Antazoline	Etodolac	Phenytoin
Apazone (azapropazone) [a]	Fenfluramine [a]	Podophyllotoxin
Buthiazide (butazide)	Fenoprofen	Probenecid
Carbenicillin	Fludarabine [a]	Procainamide [a]
Carbimazole [a]	Fluorescein	Propyphenazone
Carboplatin	5-Fluorouracil	Pyramidon
Catergen [a]	Glafenine [a]	Quinidine
Cefotaxime	Hydralazine	Quinine
Cefotetan [a]	Hydrochlorothiazide	Ranitidine
Cefoxitin [a]	Ibuprofen [a]	Rifampin (rifampicin)
Ceftazidime	Insulin	Sodium pentothal
Ceftriaxone	Interferon-a	Stibophen
Cephaloridine	Intravenous contrast media	Streptomycin [a]
Cephalothin	Isoniazid	Sulfonamides
Chaparral [a]	Latamoxef [a]	Sulfonylurea derivative
Chlorambucil	Levodopa [a]	Sulindac
Chlorinated hydrocarbons (insecticides) [a]	Mefenamic acid [a]	Suprofen
2-Chlorodeoxyadenosine	Mefloquine	Suramin
Chlorpromazine [a]	Melphalan	Teniposide [a]
Chlorpropamide	6-Mercaptopurine	Tetracycline
Cianidanol [a]	Mephenytoin	Thiazides
Ciprofloxacin	Methadone	Thiopental
Cisplatin	Methicillin	Thioridazine
Cladribine	Methotrexate	Tolbutamide
Cyclofenil [a]	Methyldopa	Tolmetin [a]
Diclofenac [a]	Nafcillin	Triamterene
Diethylstilbestrol	Nalidixic acid	Trimellitic anhydride
Diglycoaldehyde	Nomifensine [a]	Zomepirac
Dipyrone	Omeprazole	

[a] Medications associated with the autoantibody mechanism as well as a drug-dependent (drug adsorption or neoantigen) type.

MECHANISMS OF DRUG–ANTIBODY ATTACHMENT Drugs may lead to *in vivo* hemolysis by a number of different mechanisms. Despite the fact that some of these require the presence of the drug, combining as a hapten with a protein or membrane component to form a neoantigen, they are still grouped most conveniently under the autoimmune heading. One subset of drugs, of which a-methyldopa is the most prominent member, somehow produces an antibody indistinguishable from the previously described true autoimmune Igs. These drug-induced antibodies are not drug-dependent in the effector phase of RBC destruction but, curiously, do eventually resolve after discontinuation of the offending agent. The major mechanisms are (a) drug adsorption type, in which the antibody reacts with a drug tightly bound to the RBC membrane; (b) neoantigen type (also known as the *immune complex type*), in which the drug combines loosely with the RBC membrane, and the antibody reacts with a new antigenic site(s) created by the combination of drug and membrane; and (c) autoimmune type, which is indistinguishable from true AIHA without drug exposure (Fig. 35.7). Some medications may produce hemolysis by more than one mechanism, and differentiating between them is not always possible. The nonimmunologic adsorption of proteins to the RBC membrane is also discussed. This produces a positive DAT but is not associated with increased RBC destruction.

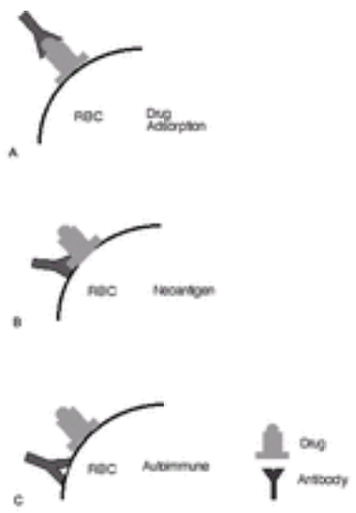

Figure 35.7. Based on a proposed theory of drug-induced antibody reactions. **A:** The antibody attaches only to the drug, which is tightly bound to the red blood cell (RBC) membrane (penicillin type). **B:** The antibody attaches to a neoantigen created by components of both the drug and the RBC membrane (quinidine/stibophen type). **C:** The antibody attaches mainly to the membrane, not requiring the presence of the drug (a-methyldopa type). (Adapted from Habbibi B. Drug induced red blood cell autoantibodies co-developed with drug specific antibodies causing haemolytic anaemias. Br J Haematol 1985;61:139–143.)

Drug Adsorption Mechanism (Penicillin Type) In this mechanism, the drug binds tightly to the RBC membrane and the antibody attaches to the drug without direct interaction with the erythrocyte. Antipenicillin antibody interacting with RBCs was first reported in a prospective transfusion recipient whose serum reacted with an entire panel of RBCs stored in penicillin as an antibacterial ([308]). Subsequently, reports appeared of patients receiving high-dose penicillin therapy who developed hemolytic anemia ([309], [310] and [311]). Penicillin binds to the RBC membrane covalently and can be demonstrated on the cell in most patients receiving high doses of the drug even in the absence of antibody ([312]). Attachment of only the drug does not harm the erythrocyte. However, when given in large doses (<10 million units/day), it can induce production of IgG antibody, which attaches to the membrane-bound drug, thus producing a positive DAT with anti-IgG sera ([312]). Eluates from these cells do not react with RBC panels, in stark contrast to the previously discussed true autoimmune antibodies, which display panagglutinin activity. The explanation lies in the fact that penicillin-induced antibodies are attached to the drug alone and not to membrane components of the erythrocyte. If reagent cell suspensions are first coated with penicillin, agglutination occurs with all cells, thus providing a diagnostic testing strategy when drug-induced hemolysis is suspected ([57]). Although penicillin may react with different proteins to form several haptenic groups, it is the benzylpenicilloyl determinant to which the majority of antibodies bind. Most sera contain IgM antibodies to benzylpenicilloyl, but these do not cause hemolysis. High-titered IgG anti-benzylpenicilloyl antibodies are responsible for the positive DAT and appear in approximately 3% of patients receiving high doses of the drug ([313]). The presence of a positive DAT is not cause for cessation of the drug. Only some of these patients develop hemolysis ([57]). Rare exceptions of complement fixation to the RBCs exist in patients on penicillin. These have been associated with IgG attachment, and the DAT is positive with both anti-IgG and anti-C3 sera ([314], [315]). RBC destruction in the drug adsorption mechanism of hemolysis is through sequestration by splenic macrophages of the IgG-coated cells ([311], [316]). Rarely, when associated with complement fixation, the cells may be lysed ([317]). Anemia develops gradually over approximately 7 to 10 days but can be life-threatening if not recognized and the drug discontinued. Once the medication is stopped, the hemolysis resolves over the ensuing couple of weeks. However, the DAT may remain positive for several weeks. Of clinical importance is the observation that other signs of penicillin hypersensitivity, such as urticaria and airway reactivity, are usually absent ([57]). Other drugs can cause hemolysis by this mechanism. Cephalosporins have antigenic cross-reactivity with penicillin; hemolysis has been reported ([318], [319], [320], [321] and [322]). Tetracycline ([323], [324]), tolbutamide ([325]), and semisynthetic penicillins ([326], [327]) are also in this category. Carbromal has been associated with a positive DAT but not hemolysis ([328]).

Neoantigen Mechanism (Quinidine/Stibophen Type) The neo-antigen mechanism is also known as the *immune complex* or *innocent bystander mechanism*, but these descriptors are now not adequate to explain the pathophysiology as currently understood. Old theory suggested that the drug formed an immune complex with the anti-drug antibody in the circulation, then attached nonspecifically to the RBC (the “innocent bystander”), and subsequently led to its destruction by activation of the complement cascade. This was supported by demonstration of low avidity of the drug for the RBC membrane and the presence of complement alone by the DAT ([329]). However, in studies in which the complex displayed a rare specificity for a particular alloantigen on the RBC, such as I or Rh, the antibody would not bind to cells lacking that particular antigen, even in the presence of the drug ([330], [331]). This suggests that the interaction was, indeed, not nonspecific for an “innocent bystander” RBC but required a component of the erythrocyte membrane to bind to the antigen recognition site on the antibody. This concept is supported by careful studies of quinidine/quinine-induced thrombocytopenia that have shown that the culprit IgG binds to the platelet membrane via its Fab domain and not its Fc end to the platelet's Fc receptor ([332], [333]). This suggests that the antibody is specific for a combination antigen, or *neoantigen*, created by both the drug and the RBC. Investigations with rare antigen-negative cells revealed that these antibodies have specific sites on the RBC membrane to which they attach along with the drug ([334], [335]). Other studies support this concept ([336], [337], [338], [339] and [340]). It should be emphasized that this unique trimolecular complex applies to the effector phase of the process. It is presumed that the antibody is formed to the bound drug on the RBC membrane, although, in the face of the low avidity of this association, the mechanism is not understood. Both the drug adsorption mechanism and the neoantigen mechanism are truly drug-dependent in that the drug or its metabolite is required for RBC binding and destruction. The neoantigen mechanism differs from the drug adsorption mechanism in a few key areas. Unlike the penicillin model, these drugs bind very loosely to the RBC membrane. Only a small dose of the medication is required for hemolysis to occur as opposed to the very large doses of penicillin required. Hemolysis is usually sudden, severe, and accompanied by hemoglobi-nuria ([2]) instead of the subacute anemia typically seen with the drug adsorption type. Renal failure is a frequent occurrence in the neoantigen mechanism ([341], [342]). The effector phase is mediated predominantly by complement fixation and subsequent intravascular cell lysis. Some sequestration of erythrocytes occurs in the splenic macrophages or the liver via complement receptors. The DAT is positive only for the presence of complement, and Ig, which may be IgM or IgG, is rarely still attached to the cell ([57]). Therefore, eluates are nonreactive primarily because there is no Ig to elute. *In vitro*, the patient's serum reacts with RBCs only in the presence of the drug or a reactive metabolite ([57]). These drugs may also induce thrombocytopenia by similar mechanisms ([332], [333]).

Autoimmune Mechanism (a-Methyldopa Type) Unlike the previous two mechanisms, which require the presence of the offending drug for antibody reaction with the RBC membrane, hemolysis induced by a-methyldopa is truly autoimmune in nature. Antibodies bind to erythrocyte membrane antigens in a manner indistinguishable from the sporadic AIHA discussed earlier. a-Methyldopa is responsible for the most cases and is the most extensively studied ([2], [223], [343], [344]). Other medications, such as levodopa ([345]) and procainamide ([346]), have also been documented to incite such a reaction. The DAT becomes positive in 8 to 36% of patients taking a-methyldopa; the larger the daily dose, the more likely the positive Coombs test ([344], [347]). The positive DAT is detected approximately 3 to 6 months into treatment, although some may require over 3 years of therapy ([348]). This delay is not shortened when patients with a history of a positive DAT on a-methyldopa are rechallenged with the drug ([2]). Those patients without evidence of hemolysis may have variably reactive direct Coombs tests. However, those with overt RBC destruction typically have 2 to 4 or more reactions with anti-IgG sera ([57]). Anticomplement tests are usually negative. Some weakly positive anti-C3 DATs have been reported ([57]). Despite a high incidence of Ig coating of RBCs, only 0.8% of patients actually develop clinical hemolysis ([2]). Explanations of this phenomenon have been unsatisfactory. The amount of antibody on the RBC correlates poorly with *in vivo* hemolysis, and no threshold has ever been well established ([105], [349]). In one series, only those patients who had IgM and C1q on their cells in addition to IgG developed hemolysis ([350]). Others contend that reticuloendothelial function is impaired in patients taking a-methyldopa and that this may explain the low incidence of significant hemolysis ([351]). The characteristics of the IgG antibody eluted from the RBCs are strikingly similar to those in idiopathic warm AIHA. They are polyclonal ([352]) and bind as a panagglutinin to reagent cells even in the absence of the drug. As in warm AIHA, these antibodies have a predilection for Rh antigens at a very basic level, with some specific anti-c and anti-e documented ([352], [353]). They react with the same ~34-kd, Rh-related polypeptide that idiopathic warm autoantibodies have been shown to bind ([354]). Other, much less common targets include Wr^b ([61]), Jk^a (

[355]), and U ([356]). Because of their similar reactions and absence of requirement for the drug to be present, these antibodies would be indistinguishable from the spontaneously arising variety without the drug history. Indeed, it begs the question of whether other, as yet unidentified exposures incite the production of autoimmune RBC antibodies. a-Methyldopa induces autoimmune RBC antibodies by an unknown mechanism. Early studies focused on the possibility of RBC binding, or alteration of RBC membrane proteins to enhance immunogenicity, or both. Several observations do not support these concepts. The kinetics of the antibody are inconsistent with those induced by immunogens. The DAT is positive months after initial exposure ([2]), and rechallenge does not produce an anamnestic response but the same delay in antibody production ([357]). The drug binds poorly, if at all, to the erythrocyte membrane ([353], [358]). Alteration of the RBC membrane producing a positive DAT should persist for the life of the RBC and does not explain the rapid reversal to negative frequently seen when the drug is discontinued. Patients with the simultaneous development of drug-dependent and drug-induced autoantibodies with the same specificity suggest that there is interaction between the drug and the membrane ([335], [359]). In immunologic theory of haptens binding to carrier proteins, the immune sera may contain antibodies to the hapten, to the carrier molecule, or to combined antigen sites on both. In the case of RBCs, the result could be antidrug antibodies (e.g., penicillin), RBC autoantibodies (e.g., a-methyldopa), or drug-dependent neoantigen antibodies (e.g., quinidine). Some investigators have proposed theories that a-methyldopa alters the immune system directly by inhibiting suppressor T-cell function ([360]). However, other investigators could not reproduce these results ([361]). Work on procainamide, another drug known to induce autoantibodies to RBCs and other antigens, has produced additional hypotheses. It may combine with proteins to form neoantigens ([362], [363]), induce T-cell autoreactivity ([364]), or act as an adjuvant for polyclonal activation of autoantibody clones ([365]). Many observations of immune system effects still have not elucidated the basic mechanism of autoantibody induction by these medications.

Nonimmunologic Protein Adsorption Mechanism Proteins other than Igs may nonspecifically attach to the RBC membrane and cause positive antiglobulin reactions. These do not cause increased RBC destruction and are of importance only because of the need to differentiate them from those of clinical significance. This is most commonly seen in patients on cephalosporins, which actually produce a positive DAT in approximately 3% of patients ([366], [367]). Many different types of proteins have been detected on the erythrocyte within a few days of instituting the medication, including fibrinogen, albumin, complement, Igs, a $_2$-macroglobulin, and others ([367]). Clinical distinction between this benign finding and other, potentially significant ones involves the demonstration of a nonreactive eluate with cephalosporin-treated cells and the absence or low titer of antidrug antibodies in the patient's serum ([57]). Adding to the confusion is the fact that cephalosporins may cause hemolysis by either the drug adsorption or the neoantigen mechanism. In the absence of hemolysis, a positive DAT is not a cause for discontinuing the medication. Table 35.8 summarizes the different proposed mechanisms of drug-RBC-antibody interactions.

TABLE 35.8. Mechanisms of Drug-Induced Hemolysis or Positive Direct Antiglobulin Test

	Drug Adsorption	Neoantigen	Autoimmune	Nonimmune Adsorption
Prototype drug	Penicillin	Quinidine/stibophen	a-Methyldopa	First generation cephalosporins
Role of drug	Cell-bound hapten	Antibody binds drug + RBC	Induces drug-independent RBC antibody	Modifies RBC membrane; adsorbs proteins nonspecifically
Typical direct antiglobulin test	IgG	Complement third component	IgG	Non-Ig
Antibody reactions	Reacts only with drug-coated cells	Reacts only with drug present	Drug-independent panagglutinin	No antibody present
Typical clinical presentation	Subacute onset; mild to severe hemolysis	Acute onset; severe hemolysis	Insidious onset; chronic mild hemolysis	No hemolysis

Ig, immunoglobulin; RBC, red blood cell.

Multiple Mechanisms Many medications have been implicated in producing hemolysis by more than one mechanism, sometimes simultaneously in the same patient. Those documented to have caused autoantibodies and drug-dependent antibodies are phenacetin ([368]), streptomycin ([369]), tolmetin ([370]), fenoprofen ([371]), suprofen ([372]), sulindac ([373]), and zomepirac ([374]). Nomifensine ([375]), diclofenac ([376]), teniposide ([377]), cianidanol ([378]), cefotetan ([322]), hydrochlorothia-zide ([379]), cefoxitin, ceftriaxone ([359]), and cefotaxime ([380]) are also on this list. Penicillins may rarely react via the neoantigen mechanism ([317]), and quinidine ([381]) occasionally acts as a hapten. Triamterene ([382]) has been reported to use both mechanisms as well. Discontinuation of the medications leads to prompt resolution of the hemolysis in most cases.

CLINICAL MANIFESTATIONS The clinical features are similar to those found in idiopathic AIHA, including pallor, jaundice, and easy fatigability. Splenomegaly is not uncommon, but lymphadenopathy and hepatomegaly should not be attributed to drug-related hemolysis ([343]). The severity of these symptoms depends on the rate of hemolysis, which is, in part, dependent on the mechanism involved. Those patients with the neoantigen mechanism are at the greatest risk for plummeting hemoglobins, hemoglobinuria, and renal failure ([2], [341], [383]). Cefotetan has been implicated in many severe hemolytic reactions ([384], [385] and [386]). Fatal reactions are rare but may occur ([322], [387]). The drug adsorption and autoimmune varieties are typically characterized by insidious onset of hemolysis over days to weeks. A careful medication history is necessary to evaluate the possibility of a culprit drug in all patients with AIHA.

LABORATORY FEATURES Just as with idiopathic AIHA, anemia with reticulocytosis and a positive DAT are the hallmarks of the condition. Elevated indirect bilirubin and lactate dehydrogenase are common findings. In rampant RBC destruction, hemoglobinemia and hemoglobinuria with elevated creatinine are manifest. Distinguishing between the mechanisms involved can be accomplished by the serologic results. One can differentiate the neoantigen mechanism from cold autoantibodies by the absence of high-titer cold agglutinins or D-L antibodies in the drug-induced cases. Drug-induced antibodies also do not react in the absence of the drug or a metabolite in IATs. Only a careful history and resolution of the hemolysis after discontinuation of the drug can separate the a-methyldopa variety from true autoimmune antibodies. The positive DAT may persist for a few weeks to months after stopping the medication responsible, especially with the autoimmune mechanism ([57]).

MANAGEMENT Take a careful drug history, including over-the-counter medications as well as illicit drugs. Discontinuing the implicated medication is usually all that is necessary in management of drug-induced hemolytic anemia. Problems may arise when a positive DAT occurs and uncertainty exists as to whether significant RBC destruction is occurring. As previously described, many medications may be associated with a positive Coombs test and yet not cause hemolysis. The drug need not be stopped in these patients. In the case of penicillin, in which very high doses are associated with significant reactions, merely decreasing the dose or adding another antibiotic may suffice to keep the patient out of danger. Substituting another penicillin in the face of hemolytic anemia is not advisable due to the cross-reactivity of the antibodies ([57]). In cases of brisk hemolysis associated with the neoantigen mechanism, stopping the offending agent can be life-saving. Prednisone therapy is rarely indicated, and its helpfulness is questionable ([388]). Transfusion can be accomplished, usually without difficulty in cross-matching as the antibodies in the drug adsorption and neoantigen mechanisms are drug-dependent. However, patients with the autoimmune mechanism may encounter the same difficulties as previously discussed in the warm AIHA section. It is important to keep in mind that the transfused cells may be destroyed at the same rate as the patient's cells if drug or active metabolites are still circulating. Prognosis is typically excellent for these patients after discontinuation of the drug. With the variety of choices of pharmaceuticals available, alternative therapies are nearly always available to treat the patient's original condition adequately.

Alloimmune Hemolytic Disease of the Fetus and Newborn

Alloimmune hemolytic disease of the fetus and newborn (HDF/N) results from the destruction of red cells by maternal immunoglobulin (Ig) G antibodies that gain access to the fetal circulation during gestation. The antibodies may be directed against Rhesus or other blood group antigens on fetal red cells, inherited from the father, that are not present on the mother's red cells. The outcome of immunized pregnancies varies drastically, ranging from asymptomatic infants demonstrating only laboratory evidence of maternal antibodies to fetal or perinatal death ([1]). Clinical manifestations of severe hemolytic disease before birth include profound fetal anemia, hepatosplenomegaly, generalized edema, massive ascites, and congestive heart failure. The accelerated destruction of fetal red cells elicits extramedullary hematopoiesis and release of nucleated and other immature red cells into the peripheral circulation (erythroblastosis fetalis). Ongoing hemolysis of red cells after birth results in neonatal hyperbilirubinemia and may lead to kernicterus and permanent brain damage or death.

HISTORICAL BACKGROUND

The twentieth century witnessed the identification of HDF/N as a clinical entity, the delineation of its underlying pathogenesis, and the introduction of an effective strategy for preventing its most common, severe form. Numerous case reports in the 1900s and earlier described stillborn, edematous infants with hydrops fetalis and anemic infants with prominent jaundice dying within days of birth. Not until 1932 were these phenomena unified on Occam's razor as manifestations of the same hematologic disease process when Diamond et al. described the interrelationship of neonatal anemia, jaundice, and edema as symptoms that occur in varying degrees and combinations in erythroblastosis fetalis ([2]).

The precise etiology of the disease remained obscure until seminal observations on blood group antigens and incompatibility in pregnancy were made in the 1940s. Landsteiner and Weiner first used immune sera raised in rabbits against red blood cells from Rhesus monkeys to agglutinate human red blood cells, thus discovering the Rhesus factor ([3]). This antigen, now known as the D antigen of the Rhesus blood group in humans, is present exclusively on red cells of Rh-positive individuals. In the year before this discovery, Levine and Stetson recognized that a woman could become immunized against paternally inherited red blood cell determinants during pregnancy ([4]). Using Landsteiner's anti-Rh antisera to investigate cases of erythroblastosis fetalis, Levine and colleagues subsequently demonstrated that 90% of the mothers were Rh-negative, and all the fathers and infants were Rh-positive ([5]). This statistical association as well as the presence of Rh agglutinins in the blood of mothers with affected infants supported their theory that alloimmunization and transplacental passage of these antibodies caused destruction of fetal red cells ([5]). The inciting stimulus for red cell alloimmunization in pregnancy, the passage of fetal red cells into the maternal circulation or fetal-maternal hemorrhage (FMH), was directly demonstrated by Chown in 1954 ([6]).

Methods to monitor alloimmunized pregnancies and to treat affected fetuses and infants were first introduced in the late 1940s. Neonatal exchange transfusion enabled simultaneous correction of the anemia and reduction of bilirubin concentration in affected infants ([1], [7]). In 1961, Liley described the relationship between the concentration of bilirubin in amniotic fluid and the degree of destruction of fetal red cells, providing a tool to assess the severity of intrauterine hemolytic disease ([8]). Two years later, Liley introduced the technique of intraperitoneal transfusion of anemic fetuses, which was used for more than 20 years before it was largely supplanted with intravascular transfusion techniques ([9]).

Primary prevention of D alloimmunization became possible with the advent of anti-D immune prophylaxis. The ability of passively transferred antibodies to effectively block active immunization to foreign antigens was first demonstrated by Von Dungern in 1900 ([1]). Experimental studies in the 1960s applied this approach to D alloimmunization, revealing that Rh-negative men could be protected if administered anti-D immune globulin (RhIG) before transfusion with Rh-positive red cells ([10], [11]). Between 1963 and 1968, clinical trials involving Rh-negative pregnant women demonstrated that administration of RhIG within 72 hours of delivery was successful in reducing the incidence of D alloimmunization from 7 to 15% to 1 to 2% ([12], [13], [14], [15], [16] and [17]). Metaanalysis of clinical trials of postpartum RhIG administration confirms a greater than 90% reduction in the alloimmunization rate among treated women compared to untreated women (Table 36.1) ([17]). The recognition that FMH occurring primarily in the third trimester contributed to residual risk of alloimmunization during pregnancy led to the clinical observation that additional, antenatal RhIG prophylaxis could further reduce the risk of D alloimmunization to below 1% ([18], [19]). Metaanalysis of two randomized controlled trials involving more than 4500 women confirms the effectiveness of antenatal administration of RhIG at 28 weeks and 32 weeks of pregnancy (Table 36.1) ([20], [21] and [22]).

TABLE 36.1. Metaanalysis of Anti-D Immune Globulin (RhIG) Clinical Trials

	Treatment	Control	Odds Ratio, 95% Confidence Interval
Postpartum RhIG (treatment) vs. no treatment (control)			

Immunization after 6 mo (5 RCTs)	10/4756 (0.2%)	204/2824 (7%)	0.08 (0.06, 0.11)
Immunization in a subsequent pregnancy (4 RCTs)	11/682 (1.6%)	57/389 (14.6%)	0.12 (0.70, 0.19)
Postpartum and antenatal RhIG (treatment) vs. postpartum RhIG (control)			
Immunization in pregnancy after birth of Rh-positive infant (2 RCTs)	5/1112 (0.4%)	13/1185 (1.1%)	0.44 (0.18, 1.12)
Immunization at 2–12 mo, primigravidae (1 RCT)	0/362 (0)	4/360 (0.7%)	0.13 (0.02, 0.96)

RCT, randomized controlled trial.

From Lee D, Rawlinson VI. Multicentre trial of antepartum low dose anti-D immunoglobulin. Transfus Med 1995;5:15–19; and Hensleigh PA. Preventing rhesus isoimmunization: antepartum Rh immune globulin prophylaxis versus a sensitive test for risk identification. Am J Obstet Gynecol 1983;146:749–755.

By 1971, the administration of RhIG to D-negative women after delivery of a D-positive infant and after abortion was recommended by the World Health Organization and rapidly came into widespread practice ([23]). Recommendations for antenatal administration of RhIG were more controversial because of supply concerns and economic cost-benefit arguments but were introduced in Canada and the United States in 1979 to 1980 and in the United Kingdom in 1998 ([24], [25], [26] and [27]). In the United States, the incidence of HDF/N due to anti-D decreased from 40.5 to 10.6 cases/10,000 total births between 1970 and 1986 ([28], [29]). RhIG accounted for most of this improvement, but the trend toward smaller families and improved quality of perinatal care also contributed to the decline in the incidence of anti-D in pregnant women and related perinatal mortality, respectively ([30]).

Despite all preventive efforts, HDF/N due to anti-D continues to occur at a low rate ([29]). Failure to prevent maternal D alloimmunization is usually due to a failure to administer RhIG appropriately or, less commonly, to production of anti-D antibodies early in pregnancy before an antenatal dose of RhIG. No prophylactic measures are available to prevent sensitization to other blood group antigens in pregnancy, most notably Rhesus (c), Kell (K1), and Duffy (Fy^a), and the corresponding maternal alloantibodies can cause severe HDF/N ([31], [32] and [33]). Consequently, the ability to clinically manage such alloimmunized pregnancies and treat affected infants is still of paramount importance.

PATHOPHYSIOLOGY

The risk of maternal alloimmunization to blood group antigens is influenced by the frequency of blood group alleles in the population and the volume of incompatible red cell exposure, as well as the immunogenicity of the offending red cell antigen and maternal immune responsiveness. The propensity of maternal red cell antibodies to cause HDF/N and the severity of the resultant condition are affected by the inherent characteristics of the red cell antibodies and the compensatory physiologic reaction to the anemia in the infant.

Fetal-Maternal Hemorrhage

Although the fetal circulation is separated from the maternal circulation by placental membranes and fetal capillaries, blood cells pass between the fetal and maternal bloodstreams throughout gestation. FMH occurs in 3% of pregnancies in the first trimester, 12% in the second trimester, 45% in the third trimester, and 64 to 100% after delivery ([34], [35]). The total volume of fetal cells in the maternal circulation is usually small and does not exceed 0.1 to 0.25 ml in most cases ([36]). Large-volume FMH occurs less often, with more than 15 ml of fetal red cells (approximately 30 ml whole blood) detected at a rate of 1.6% after cesarean section or complicated vaginal delivery and 0.7% after spontaneous vaginal delivery ([37]). Invasive procedures, clinical maneuvers, or other traumatic events during pregnancy may also elicit sufficient FMH to induce or augment red cell alloantibody production in susceptible pregnant women (Table 36.2) ([38], [39] and [40]).

TABLE 36.2. Fetal-Maternal Hemorrhage and RhD Alloimmunization: Rates among Rh-Negative Women with D-Positive Infants, Who Do Not Receive Anti-D Immune Globulin

	Fetal-Maternal Hemorrhage (%)	Primary RhD Alloimmunization (%)
Pregnancy and delivery		
Before 29 wk of gestation	3–12	0.3–1.9
35 wk to delivery	65–100	7–15
Abortion		
Induced abortion	4–30	4–5
Spontaneous abortion	3–12	1.5–2.0
Threatened abortion	10	ND
Ectopic pregnancy	24	Case reports
Amniocentesis	7–15	2–5
Cordocentesis	57	ND
Chorionic villous sampling	14	1–2
External cephalic version	2–28	ND
Abdominal trauma	28	Case reports

ND, not determined.

Maternal Alloimmunization to Blood Group Antigens

The likelihood of a relevant blood group incompatibility occurring in pregnancy depends on the frequency of blood group alleles in the population ([41]). American Indians and Asians are almost all D-positive; consequently, D alloimmunization is extremely rare among these populations ([41]). In white and African-American populations in the United States, approximately 15% and 8%, respectively, are D-negative and lack a functional D gene on both chromosomes ([41]). Overall, incompatibility with respect to the D antigen occurs in approximately 10% of all pregnancies; among D-negative women, approximately 60 to 70% of pregnancies yield D-positive infants. Although virtually all pregnant women are exposed to fetal red cells with childbirth, alloimmunization to blood group antigens occurs in only a fraction of incompatible pregnancies. Approximately 1 in 6 multiparous D-negative women developed anti-D antibodies without RhIG prophylaxis in incompatible pregnancies. The risk of alloimmunization to the D antigen has been estimated for other obstetric interventions (Table 36.2) ([38], [39] and [40]).

A primary determinant of the risk of red cell alloimmunization is the volume of incompatible red cell exposure. Less than 1 ml of D-positive, fetal red cells is sufficient to induce anti-D antibody formation in 0.3 to 1.9% of D-negative women before delivery, whereas transfusion of a unit of D-positive red cells (300 ml) immunizes approximately 70% of D-negative individuals ([16], [41]). Host factors also influence the risk of red cell alloimmunization. Concomitant ABO and D incompatibility between the mother and fetus (e.g., a type O, D-negative mother with a type A, B, or AB, D-positive fetus) results in an almost ninefold reduction in the risk of

alloimmunization to the D antigen in a first pregnancy ([18], [42]). ABO incompatibility does not prevent a secondary immune response in a sensitized individual in subsequent pregnancies. The D antigen is one of the most potent immunogens among red cell antigens, but even after incompatible blood transfusion or multiple D-positive pregnancies, approximately 30% of D-negative individuals do not produce anti-D antibodies and are called *nonresponders* ([41]). Complex genetic factors regulate immune responses, and the basis of this variability to red cell immunization among individuals is not well understood.

The overall frequency of alloimmunization to clinically significant blood group antigens among women ranges from 0.04% to 0.3% ([43], [44], [45], [46] and [47]). The variability in these rates may be due to geographic differences in blood group antigen expression, national blood transfusion practice, and higher order birth and abortion rates in the population, as well as the sensitivity of laboratory methods used in prenatal antibody screening ([43], [44], [45], [46] and [47]). Anti-D is still among the most frequently detected antibodies in sensitized pregnancies despite a precipitous decline in incidence after the introduction of RhIG prophylaxis (Table 36.3) ([43], [44]). In recent decades, other red cell alloantibodies have accounted for proportionately more cases of maternal alloimmunization and HDF/N. The K1 antigen surpassed the D antigen as the leading cause of alloimmunization among women in a recent series, occurring at a rate of 3.2 in 1000 compared to 2.7 in 1000 for anti-D ([44]). Women who develop anti-K1 antibodies in pregnancy often have a history of blood transfusion as the immunizing stimulus ([48]).

TABLE 36.3. Red Cell Alloantibodies: Occurrence in Women and Association with Hemolytic Disease of the Fetus and Newborn (HDF/N)

Blood Group System	Antibody Incidence (Number per 1000 Samples) 1967 [a]	1996 [b]	Association with HDF/N
Rhesus (Rh)			
D	43.3	2.7	Mild to severe HDF/N, hydrops fetalis
C	0.1	0.7	Mild to severe HDF/N, hydrops fetalis
c	1.2	0.9	Mild to severe HDF/N, hydrops fetalis
E	1.3	2.0	Mild to severe HDF/N, hydrops fetalis
e	0.05	0	Mild to severe HDF/N, hydrops fetalis (rare)
Other			Other Rh specificities in rare cases of moderate to severe fetal anemia: C ^{w}, C ^{x}, Go ^{a}, RH36 (Berrens, Be ^{a}), RH37 (Evans), RH32
Kell			
K1	2.1	3.0	Mild to severe HDF/N, hydrops fetalis
K2	0	0.03	Other Kell specificities in rare cases of moderate to severe fetal anemia: k [(Cellano; K2) (rare)], Js ^{a}, Js ^{b}, Ku
Lewis (Le ^{a}, Le ^{b})	2.2	3.0	Not a cause of HDF/N
Duffy			
Fy ^{a}	0.4	0.8	Mild to severe HDF/N, hydrops fetalis
Fy ^{b}	0.02	0.03	Not a cause of HDF; no or mild HDN
MNS			
M	0.7	0.5	Rare cases of moderate to severe HDF
N	0.1	0.03	Not a cause of HDF; no or mild HDN
S	0.2	0.1	Rare cases of moderate to severe HDF
Other			Other MNS specificities in rare cases of moderate to severe fetal anemia: s, U, Mt ^{a}
Lutheran (Lu ^{a},Lu ^{b})	0.02	0.1	No or mild HDF/N
Ii	0.3	0.1	Not a cause of HDF/N
Kidd			
Jk ^{a}	0.2	0.2	Mild to severe HDF/N
Jk ^{b}	0	0	Mild to severe HDF/N (rare)
P (P1)	0.6	0.03	Not a cause of HDF/NOther P group specificities in rare cases of moderate to severe fetal anemia: PP $_{1}$P ^{k}
Other	0.3	0.03	HLA (Bg ^{a}, Bg ^{b}, Bg ^{c}): Not a cause of HDF/N
			Other blood group specificities in rare cases of moderate to severe fetal anemia: Diego (Di ^{a}), Cartwright (Yt ^{a}), Biles (Bi), Radin (Rd), Wright (Wr ^{a})

ABO Blood Group Isoagglutinins

ABO incompatibility occurs statistically in one of every five pregnancies. ABO isoagglutinins are present in the sera of all individuals whose red cells lack the corresponding antigen and are usually of the IgM class. High titers of IgG antibodies are more likely to occur in group O individuals than in group A or B individuals, and increased antibody production after antigenic stimulation can occur ([32]). Consequently, group O mothers with potent IgG anti-A, -B, or -A,B are at greatest risk of having affected infants. Among group A or B infants born to group O mothers, 30 to 50% have detectable maternal IgG antibody bound to their red cells compared to 5% among all infants ([49]). Because ABO IgG antibodies can occur without prior red cell exposure, they can result in HDN in a first pregnancy. However, ABO antigens are not fully developed on red cells at birth, and similar carbohydrate antigens occur on other tissues that effectively neutralize anti-A, anti-B, and anti-A,B antibodies to a large extent, thereby mitigating their effect. At birth, neonatal anemia due to ABO HDN is usually mild. Antibodies directed against other carbohydrate blood group antigens (Lewis, I, P) are naturally occurring IgM that are inconsequential in pregnancy because IgM is not transported across the placenta.

Fetal and Neonatal Immune-Mediated Anemia

In contrast to antibodies against carbohydrate blood group antigens, antibodies against Rhesus, Kell, or other protein blood group antigens only rarely occur without exposure to incompatible red cells ([41]). IgM predominates in the primary immune response after the initial stimulus, and 4 weeks to 6 months may elapse before IgG is detected. Because FMH usually occurs late in the third trimester or at delivery, IgG antibodies against red cell alloantigens usually do not reach appreciable concentration to cause significant disease in a first pregnancy. In subsequent incompatible pregnancies, however, an anamnestic immune response after only minimal exposure to incompatible red cells rapidly produces IgG with enhanced avidity for target fetal red cells, translating to earlier onset and greater severity of hemolytic disease.

Maternal IgG red cell antibodies bind to their target red cells and cause Fc receptor–mediated extravascular destruction by splenic macrophages and other cytotoxic effector cells in the reticuloendothelial system. Progressive removal of portions of the red cell membrane by macrophages and other phagocytic cells in the spleen

results in the appearance of spherocytes in the peripheral circulation. The immunoglobulin subclasses IgG1 and IgG3 have greater affinity for Fc receptors on phagocytic cells than IgG2 and IgG4, which may account for their association with more severe hemolytic disease ([41], [50]). The concomitant presence of maternal anti-HLA and anti-D is associated with a mild course of HDF/N, possibly due to the competitive binding of the HLA antibodies to Fc receptors on cytotoxic effector cells ([51]).

Extravascular destruction of red cells often cannot account completely for the degree of fetal anemia due to anti-K1, unlike most cases of HDF due to anti-D and other red cell alloantibodies. Severe fetal anemia may occur with anti-K1 despite low maternal antibody titers and falsely reassuring concentrations of bilirubin in amniotic fluid ([48], [52]). In Kell-sensitized pregnancies, affected fetuses often have fewer reticulocytes and normoblasts in their peripheral circulation than infants with comparable anemia caused by anti-D, suggesting impaired production of red cells ([53], [54]). Anti-K1 was shown to specifically inhibit the growth of K1-positive erythroid progenitor cells *in vitro*, whereas anti-D exhibited no effect with D-positive precursors in the same assay ([55]). These observations support the dual action of maternal anti-Kell in eliciting both peripheral red cell destruction and erythropoietic suppression to produce fetal anemia.

Most cases of severe fetal anemia are caused by anti-D, anti-c, anti-K1, or rarely, anti-Fy ^{a} or other IgG red cell alloantibodies (Table 36.3). Compensatory hematopoiesis in the bone marrow and extramedullary hematopoiesis primarily in the liver and spleen result in the release of nucleated red cells, reticulocytes, normoblasts, and other immature erythrocytes in the fetal circulation. Severely affected fetuses have marked hepatosplenomegaly due to the extramedullary hematopoiesis, which can lead to portal and umbilical venous obstruction, portal hypertension, and hepatocellular damage ([1]). Production of albumin and other plasma proteins by the liver is markedly impaired, and hypoproteinemia results. Severe anemia and hepatic dysfunction with hypoproteinemia and portal hypertension may also lead to the development of congestive heart failure. Hydrops fetalis describes the ultimate outcome of these physiologic insults, with the development of generalized edema (anasarca), massive ascites, and pleural and pericardial effusions. Although the pathogenesis of hydrops fetalis is not clearly defined, the extent of hepatic damage rather than the degree of anemia more consistently correlates with the severity of the condition ([1]).

Neonatal Immune-Mediated Hyperbilirubinemia

Immune-mediated destruction of fetal red cells results in increased serum concentration of free heme, which is further metabolized to unconjugated (indirect) bilirubin. During gestation, unconjugated bilirubin and other metabolites are transported across the placenta and eliminated by the mother. When this connection is severed at birth, unconjugated bilirubin accumulates because infants have immature liver function and are not capable of efficiently metabolizing bilirubin.

Unconjugated bilirubin is transported in the plasma bound to albumin, but when its concentration exceeds the plasma-binding capacity or when it is displaced from carrier proteins, the lipophilic, free molecule can cross cell membranes and impair mitochondrial function to cause cell death. Preterm infants are at greater risk for developing bilirubin encephalopathy than are term infants because of the immaturity of their blood–brain barrier as well as their more pronounced hepatic deficiency. Bilirubin toxicity is potentiated by factors that displace bound bilirubin or otherwise increase circulating levels of unbound bilirubin, such as decreased albumin concentration, free heme molecules, acidosis, increased levels of free fatty acids, or drugs such as sulfonamides and sodium benzoate ([1]). Infants with severe unconjugated hyperbilirubinemia may develop nerve deafness or the spectrum of kernicterus, leading to severe brain damage, mental retardation, spastic choreoathetosis, or, in many cases, death.

CLINICAL FEATURES

The clinical spectrum of HDF/N ranges from the ominous, intrauterine development of hydrops fetalis to varying degrees of neonatal hyperbilirubinemia and anemia. Approximately one-half of infants with detectable maternal anti-D are unaffected or only mildly affected, whereas 30% have moderate disease in the neonatal period, and approximately 20% are severely affected *in utero* (Table 36.4) ([1], [56]). The onset of intrauterine disease occurs before 34 weeks' gestation in approximately one-half of the cohort of severely affected fetuses, or approximately 9% of affected pregnancies, overall ([56]). Similar trends are observed when anti-c, anti-Kell, and anti-Fy ^{a} are detected in pregnancy, in that many fetuses are unaffected, and most of the rest have only mild or moderate disease, but a small number manifests hydrops or severe anemia necessitating intrauterine transfusion (Table 36.4) ([31], [32] and [33], [48], [56], [57]). Maternal IgG antibodies with other specificities have been implicated in cases of severe fetal anemia or life-threatening HDN in rare cases ([31], [32] and [33], [58], [59]).

TABLE 36.4. Clinical Series of Rhesus, Kell, and Duffy Alloantibodies in Pregnancy

			Severity (% Affected Pregnancies Resulting in Mild, Moderate, or Severe Disease) [b]			
	Antibodies (Number)	Affected Pregnancies [a] (Number)	None or Mild (%)	Mild-Moderate (e.g., Phototherapy and/or Neonatal Exchange Transfusion) (%)	Severe (e.g., Intrauterine Transfusion, Hydrops, or Perinatal Death) (%)	Reference
Rhesus						
D	566	257	51	30	19	1, 56
c, cE	302	164	70	23	7	1
E	633	162	89	11	—	1
C, Ce, C^{w}, e	193	50	86	14	—	1
Kell	478	16	50	37	13	1
K1	127	13	30	30	38	48
Duffy	35	6	67	16	16	1
Fy^{a}	68	47	94	2	4	57

[a] An affected pregnancy is one with maternal antibody and an antigen-positive, antigen-indeterminate, or direct antiglobulin test–positive fetus or infant.

[b] Definitions of disease severity and treatment thresholds may vary over time within a study period and among studies, but for purposes of comparison, severity of disease is classified in this table based on highest level of treatment performed.

Severely affected newborn infants demonstrate cord hemoglobin concentrations less than 12 g/dl and cord bilirubin concentrations greater than 5 mg/dl. If treatment is received before delivery, the course of hemolytic disease in the neonatal period may be relatively mild. These infants are at risk for developing late anemia several weeks after birth because intrauterine transfusion may suppress erythropoiesis and persistent circulating maternal alloantibody may cause ongoing hemolysis for 4 to 8 weeks. Infants with moderate disease have 12 to 14 g/dl hemoglobin in cord blood and 7 to 12 mg/dl hemoglobin in the first days of life. The bilirubin level in cord blood rarely exceeds 5 mg/dl, reflecting the prior clearance by the maternal liver *in utero*. After birth, however, jaundice may occur within the first 24 to 36 hours of life, earlier than the “physiologic jaundice” otherwise associated with immature liver function, and the bilirubin concentration peaks between 3 and 5 days of life. Mild HDN is characterized by cord hemoglobin of 14 g/dl or greater and only slightly increased bilirubin (<4 g/dl).

The most common cause of HDN currently is maternal ABO antibodies, although only a minority of infants with detectable maternal ABO antibodies have clinical signs of hemolysis. Exceedingly rare cases of fetal anemia due to ABO antibodies have been reported, but nonimmune hydrops superimposed on ABO incompatibility could not be excluded ([1]). Nonimmune hydrops fetalis may be caused by intrauterine infection, cardiac disease, or chromosomal disorders (Table 36.5). Because the neonatal anemia is usually mild, the compensatory hematopoietic activity in ABO HDN is not as pronounced as in HDN due to anti-D or anti-K1. Consequently, nucleated red cells and erythropoietic progenitors may be evident, but spherocytes predominate in the peripheral blood smear of infants with ABO HDN (Fig. 36.1). The failure to recognize hemolysis due to ABO blood group incompatibility or other risk factors for hyperbilirubinemia resulted in 90 cases of kernicterus in a 17-year

period ([60]). This modern day tragedy underscores the importance of monitoring progressive jaundice in all infants.

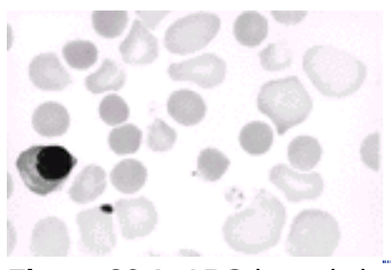

Figure 36.1. ABO hemolytic disease of the newborn (HDN). Peripheral blood from an infant with ABO HDN, with numerous spherocytes, occasional nucleated red cells, anisocytosis, and polychromasia (Wright-Giemsa stain). See Color Plate. TABLE 36.5. Differential Diagnosis

Hydrops fetalis (fetal edema, anemia)
Hemolytic disease of the fetus due to maternal anti-D, -c, -K1, -Fy [a], or other blood group antibodies
Homozygous a-thalassemia
Twin-to-twin or fetomaternal transfusion
High-output cardiac failure
Congenital infection (e.g., parvovirus, cytomegalovirus, toxoplasmosis, syphilis)
Genetic disorders (e.g., Turner syndrome, 45 XO)
Idiopathic
Neonatal hyperbilirubinemia (nonphysiologic)
Unconjugated (indirect) hyperbilirubinemia
Hemolysis
Hemolytic disease of the newborn due to maternal ABO isohemagglutinins, anti-D, or other blood group antibodies
Hereditary spherocytosis
Glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency
a-Thalassemia
Extravascular blood loss/accumulation (e.g., cephalohematoma)
Genetic disorders (e.g., Crigler-Najjar syndrome; Gilbert syndrome)
Endocrine disease (e.g., hypothyroidism)
Conjugated (direct) hyperbilirubinemia
Infection, sepsis
Metabolic disorders (e.g., Dubin-Johnson syndrome, cystic fibrosis)
Anatomic abnormalities (e.g., biliary atresia)
Cholestasis from total parenteral nutrition or antibiotics (e.g., ceftriaxone)

LABORATORY EVALUATION
