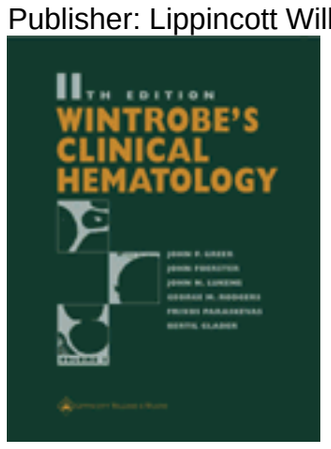
Wintrobe's Clinical Hematology, 11th Ed
by John P. Greer (Editor), John Foerster (Editor), John N. Lukens (Editor)
Publisher: Lippincott Williams & Wilkins Publishers; 11th edition (December 2003)



Wintrobe's Clinical Hematology

CONTENTS

PART V DISORDERS OF HEMOSTASIS AND COAGULATION

Section 1. Introduction

Section 2. Thrombocytopenia

Section 3. Other Disorders of Primary Hemostasis

Section 4. Coagulation Disorders

Section 5. Thrombosis

PART VI NONMALIGNANT DISORDERS OF LEUKOCYTES, THE SPLEEN, AND/OR IMMUNOGLOBINS

PART VII HEMATOLOGIC MALIGNANCIES

Section 1. General Aspects

Section 2. Acute Leukemias

Section 3. Myeloproliferative Disorders

Section 4. Lymphoproliferative Disorders

Section 5. Plasma Cell Dyscrasias

APPENDIX B: Comparative Hematology

Color Plate

Contributing Authors

Nancy C. Andrews, MD, PhD
Associate Professor, Department of Pediatrics, Harvard Medical School, Associate Investigator, Department of Medicine, Howard Hughes Medical Institute and Children's Hospital, Boston, Massachusetts

Richard Aplenc, MD, MSCE
Assistant Professor of Pediatrics, Department of Pediatrics, University of Pennsylvania School of Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Robert J. Arceci, MD, PhD
Director and King Fahd Professor of Pediatric Oncology, Department of Pediatric Oncology, Sidney Kimmel Comprehensive Cancer Center at John Hopkins, Baltimore, Maryland

Edward R. Arrowsmith, MD, MPH
Chattanooga Oncology and Hematology Associates, Chattanooga, Tennessee

Maria R. Baer, MD
Professor, Department of Medicine, Leukemia Section, University at Buffalo State University of New York School of Medicine and Biomedical Sciences, Roswell Park Cancer Institute, Buffalo, New York

Allan B. Becker, MD, FRCPC
Professor, Department of Pediatrics and Child Health, Section of Allergy and Clinical Immunology, University of Manitoba Faculty of Medicine, Health Sciences Centre, Winnipeg, Manitoba, Canada

A. Dean Befus, PhD
Professor and AstraZeneca Canada Inc.; Chair in Asthma Research, Department of Medicine, University of Alberta Faculty of Medicine and Dentistry, Edmonton, Alberta, Canada

Frederick G. Behm
Department of Pathology, St. Jude Children's Research Hospital, Memphis, Tennessee

Maurice C. Bondurant, PhD
Associate Professor, Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee

Caterina Borgna-Pignatti, MD
Professor of Pediatrics, Department of Clinical and Experimental Medicine/Pediatrics, University of Ferrara, Ferrara, Italy

Sylvia S. Bottomley, MD
Professor of Medicine, Department of Medicine, Hematology/Oncology Section, University of Oklahoma College of Medicine and Department of Veterans Affairs Medical Center, Oklahoma City, Oklahoma

Stephen J. Brandt, MD
Associate Professor, Departments of Medicine, Cell and Developmental Biology, and Cancer Biology, Division of Hematology/Oncology, Vanderbilt University School of Medicine, Nashville, Tennessee

Kathleen Brummel-Ziedins, PhD
Research Assistant Professor of Biochemistry, Department of Biochemistry, University of Vermont College of Medicine, Burlington, Vermont

David C. Calverley, MD
Assistant Professor of Medicine, Division of Hematology and Medical Oncology, University of Colorado Health Sciences Center School of Medicine, Denver, Colorado

Thai M. Cao, MD
Clinical Instructor of Medicine, Department of Medicine, Division of Bone Marrow Transplantation, Stanford University Medical Center, Stanford, California

Ralph Carmel, MD
Director of Research, Department of Medicine, New York Methodist Hospital, Brooklyn, New York, Professor of Medicine, Department of Medicine, Weill Medical College of Cornell University, New York, New York

Howard H. W. Chan, MBChB, FRCPC
Research Fellow, Transfusion Medicine, Departments of Hematology and Internal Medicine, McMaster University Faculty of Health Sciences, Hamilton, Ontario, Canada

William C. Chapman, MD
Professor of Surgery; Chief, Section of Transplantation, Washington University School of Medicine, St. Louis, Missouri

Robert D. Christensen, MD
Professor and Chairman, Department of Pediatrics, University of South Florida College of Medicine, All Children's Hospital, St. Petersburg, Florida

Douglas A. Clark, MD
New Mexico Cancer Center, Albuquerque, New Mexico

John B. Cousar, MD
Professor of Pathology, Department of Pathology, University of Virginia Health System, Charlottesville, Virginia

Steven E. Coutre, MD
Assistant Professor of Medicine (Hematology), Department of Medicine, Stanford University School of Medicine, Stanford, California

Steven R. Deitcher, MD
Head, Section of Hematology and Coagulation Medicine, Department of Hematology and Medical Oncology, The Cleveland Clinic Foundation, Cleveland, Ohio

Judah A. Denburg, MD
Professor, Department of Medicine, McMaster University School of Medicine, Hamilton, Ontario, Canada

Robert J. Desnick, PhD, MD
Professor of Human Genetics and Pediatrics; Chairman, Department of Human Genetics, Mount Sinai School of Medicine of the City University of New York, New

York, New York

Emmanuel N. Dessypris, MD, FACP
Professor of Medicine, Medical College of Virginia, Virginia Commonwealth University School of Medicine, Chief of Medicine, H.H. McGuire Veterans Affairs Medical Center, Richmond, Virginia

Angela Dispenzieri, MD
Assistant Professor, Department of Medicine, Division of Hematology, Mayo Clinic, Rochester, Minnesota

Donald C. Doll, MD
Professor of Medicine, Departments of Hematology and Medical Oncology, Ellis Fischel Cancer Center, University of Missouri'Columbia School of Medicine, Columbia, Missouri

Cynthia E. Dunbar, MD
Section Chief, Molecular Hematopoiesis Section, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Justus Georg Duyster, MD
Internal Medicine III, Technical University of Munich, Munich, Germany

Anne F. Eder, MD, PhD
Assistant Professor, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Corwin Q. Edwards, MD
Professor, Department of Medicine, Associate Director, Internal Medicine Training Program, University of Utah School of Medicine, Director of Graduate Medical Education, LDS Hospital, Salt Lake City, Utah

Stephen J. Everse, PhD
Assistant Professor, Department of Biochemistry, University of Vermont College of Medicine, Burlington, Vermont

John Foerster, MD, FRCPC
Professor of Medicine, Division of Hematology/Oncology, University of Manitoba Faculty of Medicine, Director of Research, St. Boniface General Hospital, Winnipeg, Manitoba, Canada

Rafael Fonseca, MD
Associate Professor of Medicine, Department of Hematology, Mayo Medical School, Mayo Clinic, Rochester, Minnesota

Kenneth D. Friedman, MD
Medical Director, The Blood Center of Southeastern Wisconsin, Inc., Milwaukee, Wisconsin

Renzo Galanello, MD
Professor of Pediatrics, Dip. di Scienze Biomediche e Biotecnologie, University of Cagliari-Ospedale Microcitemie, Cagliari, Italy

Susan A. Galel, MD
Associate Professor, Department of Pathology, Stanford University School of Medicine, Stanford, California

Paul S. Gaynon, MD
Professor of Pediatrics, Children's Hospital of Los Angeles, Keck School of Medicine, University of Southern California, Los Angeles, Californina

Morie A. Gertz, MD
Professor of Medicine, Division of Hematology, Mayo Medical School, Chair, Division of Hematology, Mayo Clinic, Rochester, Minnesota

Bertil Glader, MD, PhD
Professor of Pediatrics, Division of Hematology/Oncology, Stanford University School of Medicine, Stanford, California

Jeremy Goodman, MD
Surgery Resident, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri

Stacey A. Goodman, MD
Associate Professor of Medicine, Department of Medicine, Division of Hematology/Oncology, Vanderbilt University School of Medicine, Nashville, Tennessee

Preface

Blut ist ein ganz besondrer Saft.
Goethe, 1808

Maxwell M. Wintrobe often cited Goethe, “Blood is a very special kind of fluid,” and the Eleventh Edition of *Wintrobe's Clinical Hematology* is a testimony to Dr. Wintrobe's legacy and commitment to the field of hematology. This edition extends the chronicle of progress to 60 years since the first edition of the book. The first six editions were the sole work of Dr. Wintrobe. When he retired from the editorship, Dr. Wintrobe recruited five former fellows to take over the task: Jack Athens, Tom Bithell, Dane Boggs, John Foerster, and Richard Lee. John Foerster remains an editor from the original group, and John Lukens joined the editorship in the eighth edition. John Greer, Frixos Paraskevas, and George Rodgers contributed to the ninth edition and became editors of the tenth edition. Bert Glader is a welcome addition to the present edition. Of the present group of editors, three (Foerster, Lukens, and Rodgers) worked directly with Dr. Wintrobe, whereas the other three (Glader, Greer, and Paraskevas) have been associated with Wintrobe-trained individuals.

Dr. Wintrobe recognized the work of predecessors and the foundation of clinical hematology in basic research. In *Blood, Pure and Eloquent. A Story of Discovery, of People and of Ideas* (1980), Dr. Wintrobe edited historical milestones in hematology and emphasized three lessons of history:

1. Research starts with an idea, which may take many directions before becoming a valid concept: “The path of progress is anything but straight. It is rough and rocky and often seems to wander endlessly and in all directions; it has many blind alleys and is strewn with the debris of false hopes, of failures, and discouragement. The course of research has been likened to the flow of a stream that ultimately becomes a rushing torrent.”
2. A sense of skepticism is warranted in the practice of medicine: “What was held to be the truth yesterday may not be so regarded today, and tomorrow the story may again be somewhat different.”
3. Perseverance is required to make progress: “… many look, but few see. It is the exceptional person who recognizes the unusual event or manifestation. Still fewer pursue it to a new understanding. Many may ask questions but few have the imagination, the energy, and the overpowering drive to persist in the search for an answer, especially when this must be done in the face of difficulties and failures and even in spite of scorn from their peers” (1).

Although his statements may seem pessimistic, Dr. Wintrobe optimistically recognized the importance of building on prior contributions and the relationship between clinical hematology and basic research. Hematology has many stories characterized initially by clinical observations that are now understood at a molecular genetic level (2,3). Sickle cell anemia, pernicious anemia, hemophilia, Burkitt lymphoma, acute promyelocytic leukemia, and chronic myeloid leukemia are among the most interesting topics in medicine. The speed of basic research to the clinical bedside was remarkable in the twentieth century, and it promises to be even faster and more widely applied in the future.

The Eleventh Edition of *Wintrobe's Clinical Hematology* ushers in the twenty-first century with the same principles found in the prior editions and with the additional availability of the knowledge base through the Internet. The value of books has been questioned in this new era. This edition retains the historical perspective of *Wintrobe's Clinical Hematology*, with extensive references; brings together the body of information on hematology in a single source; and bridges topics to the Internet with Web links cited by many of the authors in their chapters. As with other multiauthored textbooks, there are occasional redundancies, which are important observations that allow a chapter to stand alone, and there are cross references to other chapters that indicate the interdependence of the topics.

We appreciate each author's contribution to the book. We have brought together clinician educators, pathologists, and physician scientists to review their topics of expertise. All of the chapters except Dr. Wintrobe's introduction to the approach to hematologic problems either have been revised or are new with an emphasis on molecular aspects of hematology. This edition recognizes the transition from a morphologic classification of hematopoietic neoplasms to the World Health Organization's classification that incorporates molecular genetics.

We appreciate the efforts of Jonathan Pine, Senior Executive Editor at Lippincott Williams & Wilkins; Alyson Forbes, Developmental Editor, and Tanya Lazar, Managing Editor at Lippincott; Mary Ann McLaughlin, Supervising Editor at Lippincott; and Lucinda Ewing and Jane McQueen, Production Editors at Silverchair Science + Communications. Their unique combination of persistence and kindness and their commitment to the principles of prior editions brought the project to completion. We hope the readers find the information they seek in the Eleventh Edition of *Wintrobe's Clinical Hematology*.

Below, each of us acknowledges people who have assisted him in this endeavor.

Debbie Saurette, my faithful secretary and colleague, has provided invaluable services in the completion of this edition. My wife, Gisela, and our children David, Steven, and Susan, physicians all, have been a constant source of support and inspiration. Special thanks go to my mentors, Dr. L. G. Israels, whose enthusiasm for hematology and his ability to combine effectively clinical service, teaching, and research, drew me to this specialty as a medical student; Dr. M. M. Wintrobe, who taught me in his own unique way and gave me the opportunity to contribute to several editions of this great textbook; Dr. B. Benacerraf, who nurtured my interests in immunology; and my colleagues at the Mayo Clinic and elsewhere who have contributed valuable chapters to this text.

John Foerster

I wish to thank Jennifer Lu, Kari Costa, Theresa McCann, and Annamarie Coelho for administrative help. I also wish to acknowledge the many outstanding authors I have had the privilege to work with in the preparation of this edition. Last, but most of all, I want to acknowledge the understanding and support of my wife, Lou Ann; my children, Laurie, Anders, and Eric; their families; and our friends.

Bert Glader

I wish to thank Billi Bean, my assistant and colleague; Patti Lee at the Eskind Library of the Vanderbilt University School of Medicine; my wife, Gay; and our children, Lesley, Adam, and Scott; my mentors, including Robert Collins, John Flexner, Stanley Graber, Sanford Krantz, and John Lukens; Ellen Benneyworth and other nurses; and our patients.

John P. Greer

My contribution to this edition could not have been made without the understanding and unselfish support of my wife, Cauley Lukens. She and our children have weathered long hours and aborted vacations with encouragement and grace.

John N. Lukens

I want to express my deeply felt gratitude and appreciation to my wife Maria for her support and unwavering encouragement throughout the period of writing and especially when deadline worries became unmanageable. Maria, as a pathologist, has also been the testing ground for fine-tuning of complex concepts, helping me to lift them from the unfathomable depths of technicality and into the light of understanding. I want to thank Ms. Lynne Savage for her expert secretarial assistance and perseverance when “last copy” was proved to be just another in a never-ending line of typing. Our librarian, Donna Pacholok, helped me navigate the complex connections with the Internet. My sincere thanks to several colleagues for providing literature assistance or photography from their own data: A. A. Anderson, G. G. Gao, J. E. Gretz, L.A. Herzenberg, H. Kogelberg, J. Lambris, D. Y. Mason, C. Morales, K. H. Roux, P. Nickerson, H. Seguchi, S. Shaw, and H. Zimmerman.

Frixos Paraskevas

I acknowledge Robyn LeMon and Sherry Hartline for typing assistance, my numerous contributors for their hard work and timely submissions, and my family and friends for their support.

George M. Rodgers

Examination of the Blood and Bone Marrow

Careful assessment of the blood elements is often the first step in assessment of hematologic function and diagnosis. Many hematologic disorders are defined by specific findings gleaned from blood tests. Examination of blood smears and hematologic parameters often yields important diagnostic information and allows broad differential diagnostic impressions to be formed, directing further, more specific testing. Careful examination of cellular morphology, in concert with quantification of the blood elements and evaluation of a variety of parameters relating to cellular size and shape, is required. This chapter introduces the fundamental concepts that underlie laboratory evaluation of the blood and outlines additional testing that may aid in evaluating a hematologic disorder, including special stains and bone marrow examination. Limitations of such tests are also addressed.

Blood elements include erythrocytes, or red cells; leukocytes, or white cells; and platelets. Although detailed morphologic descriptions and functional characteristics of each of the cell types are included in subsequent chapters, basic features necessary for blood smear analyses are covered in this chapter. *Red cells* are the most numerous cells in the blood and are required for tissue respiration. Erythrocytes lack nuclei and contain hemoglobin, an iron-containing protein that acts in the transport of oxygen and carbon dioxide. *White blood cells* serve in immune function and include a variety of cell types that have specific functions and characteristic morphologic appearances. In contrast to red cells, white cells are nucleated. The five types of white blood cells seen normally in blood smears are neutrophils, lymphocytes, monocytes, eosinophils, and basophils. *Platelets* are cytoplasmic fragments derived from megakaryocytes in the bone marrow that function in coagulation and hemostasis.

Evaluation of the blood requires quantification of each of the cellular elements by either manual or automated methods. Automated methods, using properly calibrated equipment ([1]), are usually more precise than manual procedures. In addition, automated methods may provide additional data describing characteristics such as cell volume. However, the automated measurements describe *average* cell characteristics but do not adequately describe the scatter of individual values around the average. Hence, a bimodal population of small (microcytic) and large (macrocytic) red cells might register as a normal cell size. Therefore, a thorough examination of blood also requires microscopic evaluation of a stained blood film to complement the hematology analyzer data.

SPECIMEN COLLECTION

Proper specimen collection is required for reliable and accurate laboratory data to be obtained on any hematologic specimen. Before a specimen is obtained, careful thought as to what studies are needed will aid in proper handling of the material and prevent collection of inadequate or unusable specimens. Communication with laboratory personnel who will analyze the specimen is often helpful in ensuring that specimens will be handled properly and that the requested testing can be performed.

A number of factors may affect hematologic measurements, and each specimen should be collected in a standardized manner to reduce variability. Factors such as patient activity, level of patient hydration, medications, sex, age, race, smoking, and anxiety may affect hematologic parameters significantly ([2], [3] and [4]). Similarly, the age of the specimen may affect the quality of the data collected ([5]). Thus, data such as patient age, sex, and time of specimen collection should be noted. Correlative clinical information is also extremely important in evaluating hematologic specimens. For example, a patient who has had severe diarrhea or vomiting before admission may be sufficiently dehydrated to have an erroneous increase in red blood cell concentration.

Most often, blood is collected by venipuncture into tubes containing anticoagulant. The three most commonly used anticoagulants are tripotassium or disodium salts of ethylenediaminetetraacetic acid (EDTA), trisodium citrate, and heparin. EDTA and disodium citrate act to remove calcium, which is essential for the initiation of coagulation, from the blood. Heparin acts by forming a complex with antithrombin III in the plasma to prevent the formation of thrombin. EDTA is the preferred anticoagulant for blood cell counts because it produces complete anticoagulation with minimal morphologic and physical effects on all types of blood cells ([6]). Heparin causes a bluish coloration of the background when a blood smear is stained with one of the Romanowsky dyes but does not affect cell size or shape. Heparin is most often used for prevention of red blood cell hemolysis, for osmotic fragility testing, and for functional and immunologic analysis of leukocytes. Heparin does not completely inhibit white blood cell or platelet clumping. Trisodium citrate is the preferred anticoagulant for platelet and coagulation studies. Other anticoagulants have been identified that give results similar to EDTA, such as argatroban ([7]), although none has achieved widespread use in normal clinical settings

The concentration of the anticoagulant used may affect cell concentration measures if it is inappropriate for the volume of blood collected and may also distort cellular

morphology. Most often, blood is collected directly into commercially prepared negative-pressure vacuum tubes (Vacutainer tubes; Becton Dickinson, Franklin Lakes, NJ), which contain the correct concentration of anticoagulant when filled appropriately, thereby minimizing error ([8]). Anticoagulated blood may be stored at 4°C for a 24-hour period without significantly altering cell counts or cellular morphology ([5]). However, it is preferable to perform hematologic analysis as soon as possible after the blood is obtained.

RELIABILITY OF TESTS

In addition to proper acquisition of specimens, data reliability requires precise and reproducible testing methods. Both manual and automated testing of hematologic specimens must be interpreted in light of test precision. This becomes especially important when evaluating the significance of small changes. All laboratory tests are evaluated with respect to both accuracy and reproducibility. *Accuracy* is the difference between the measured value and the true value, which implies that a true value is known. Clearly, this may present difficulties when dealing with biologic specimens. The National Committee for Clinical Laboratory Standards and the International Committee for Standards in Haematology have attempted to develop standards to assess the accuracy of hematologic examination ([9]) and automated blood cell analyzers ([10]). Automated instrumentation requires regular quality assurance evaluations and careful calibration to reach expected performance goals and ability to collect reproducible data ([1], [11]).

CELL COUNTS

Cell counts are important parameters in evaluating the blood. Cell counts may be determined either manually or by automated hematology analyzers. Whether performed by manual or automated methodologies, the accuracy and precision of the counts depend on proper dilution of the blood sample and precise sample measurement. Blood must be precisely aliquoted and diluted, so that cells are evenly distributed within the sample to be analyzed. Because blood contains large numbers of cells, sample dilution is usually required for accurate analysis. The type of diluent is dependent on the cell type to be enumerated. Thus, red cell counts require dilution with an isotonic medium, whereas in white cell or platelet counts, a diluent that lyses the more numerous red cells is often used to simplify counting. The extent of dilution also depends on the cell type. In general, red cell counts need more dilution than is required for the less abundant white blood cells. Errors in cell counts are caused primarily by errors in sample measurement, dilution, or enumeration of cells. The highest degree of precision occurs when a very large number of cells can be evaluated. Clearly, automated methods are superior to manual methods for counting large numbers of cells and minimizing statistical error. Table 1.1 lists the comparable values of reproducibility for automated and manual (hemocytometer) counting methods.

TABLE 1.1. Reproducibility of Blood Counting Procedures

Cell Type Counted	Two Coefficients of Variation	
	Hemocytometer [a] (%)	Automated Hematology Analyzer (%)
Red cells	±11.0	±1.0
White cells	±16.0	±1.5
Platelets [b]	±22.0	±2.0
Reticulocytes	±33.9	±5.0

[a] Minimum error. Usual error.

[b] Error may be greater with low (<35 × 10^9/L) or very high (>450 × 10^9/L) platelet counts.

Data derived from Bentley S, Johnson A, Bishop C. A parallel evaluation of four automated hematology analyzers. Am J Clin Pathol 1993;100:626–632; and Wintrobe M. A simple and accurate hematocrit. J Lab Clin Med 1929;15:287–289.

Manual counts are carried out after appropriate dilution of the sample in a *hemocytometer*, a specially constructed counting chamber that contains a specific volume. Cells may then be counted with a microscope. Red blood cells, leukocytes, and platelets may be counted by this method ([13]). Due to the inherent imprecision of manual counts and the amount of technical time required, most cell counting is now performed by automated or semiautomated instruments. These machines increase the accuracy and speed of analysis by the clinical laboratory, particularly as test entry, sampling, sample dilution, and analysis are incorporated into single systems with minimal human manipulation ([12], [13]). With increasing levels of automation, some hematology analyzers have now moved to complete automation, which can be coupled with other laboratory tests using the same tube of blood. There are a variety of different automated hematology analyzers available, dependent on the volume of samples to be tested and the needs of the physician group ordering testing. The analyzers range in price and workload capacity from those that would be appropriate for an individual physician's office or point-of-care facility to those needed in a busy reference laboratory with capacity for over 100 samples to be analyzed per hour ([14]).

Most automated hematology analyzers perform a variety of hematologic measurements, such as hemoglobin concentration (Hb), red cell size, and leukocyte differentials. Newer instruments may also perform more specialized testing, such as reticulocyte counts ([15]). The ability of the new analyzers to perform accurate white cell differential counts, particularly those that can perform a five-part differential (enumerating neutrophils, lymphocytes, monocytes, eosinophils, and basophils), has been a significant technologic advance over the past 10 years. Automated methods for white cell counts and differentials use several distinct technical approaches ([16]), including those that measure changes in electrical impedance and those that use differences in light scatter or optical properties, either alone or in combination ([17]). Another recent advance in hematology analyzers is incorporation of argon laser technology, allowing integration of some flow cytometric data using specific fluorochrome stains, such as T-cell subsets (CD4:CD8) or CD34 positive cells, with routine hematologic analyses ([18]).

Aperture-Impedance Counters

This type of analyzer, which includes the Coulter (Beckman Coulter, Hialeah, FL), the Sysmex (Baxter Diagnostics, Waukegan, IL), and some Cell-Dyn (Abbott Diagnostics, Santa Clara, CA) instruments, enumerates cells in a small aperture by measuring changes in electrical resistance as the cell passes through the orifice (Fig. 1.1). A constant current passes between two platinum electrodes on either side of the orifice. The diluent that suspends the cells is more electrically conductive than are the cells. Hence, as each cell passes through the orifice, there is a momentary decrease in electrical conductance so that an electrical impulse is generated and recorded electronically. The drop in voltage is proportional to cell size, allowing average cell size to be determined simultaneously ([19], [20]).

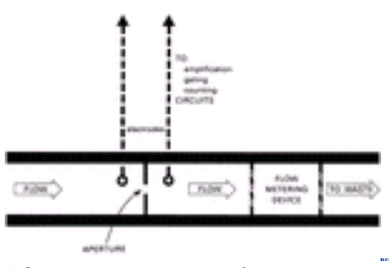

Figure 1.1. Impedance type of automated hematology analyzer. As the cells pass through the aperture, they alter the current flow between the electrodes, generating an electronic pulse. Each pulse is recorded electronically. The magnitude of the pulse is proportional to the cell's volume.

Instruments using aperture-impedance technology require even cell suspensions so that cells pass individually through the electrical current. Distortion of the electrical pulses may occur when the cells do not pass through the center of the aperture or when more than one cell enters the aperture at a time. The data may be electronically adjusted to exclude distorted peaks, and both upper and lower limits of particle size can be set to exclude cellular clumps or debris. Using size limitation

parameters, the instrument can be used to count particles of different sizes, thereby allowing different blood elements to be enumerated ([21]). Most of the modern analyzers can also be set to flag abnormal or suspect results, allowing for identification of those samples that need further, manual evaluation ([22]).

The Coulter-type counters are probably the most widely used example of hematology analyzers that use electrical impedance methods. Most models print data in numerical form as well as providing histograms of blood cell size (Fig. 1.2). Newer models often combine impedance and optical methodologies (described below). Data generated include a three- or five-part white cell differential in addition to red cell counts, white cell counts, platelet counts, reticulocyte counts, hemoglobin, hematocrit (Hct), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), red cell distribution width (RDW), and mean platelet volume (MPV). This type of instrumentation fully analyzes up to 109 samples per hour, depending on the model used, and flags abnormal red and white cell populations, including blasts and atypical cells [23].

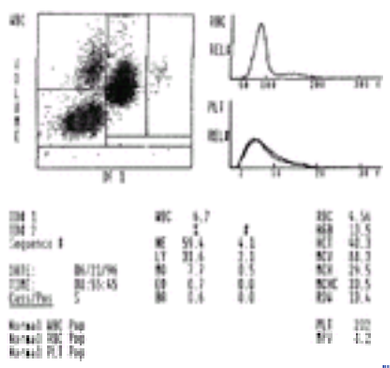

Figure 1.2. Histograms and printout generated by the Coulter STKR automated hematology analyzer. BA, basophil; EO, eosinophil; HCT, hematocrit; HGB, hemoglobin; LY, lymphocyte; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MO, monocyte; MPV, mean platelet volume; NE, neutrophil; PLT, platelet; RBC, red blood cell; RDW, red cell distribution width; WBC, white blood cell.

Optical Method Counters

The other method commonly used in hematology analyzers depends on the light scatter properties of blood cells ([24], [25]). Some instruments that use this technology include the Technicon series (H6000, H*1, H*2, H*3) (Bayer Diagnostic Division, Tarrytown, NY) and the Cell-Dyn instruments. In these systems, diluted blood passes through a flow cell detector placed in the path of a narrowly focused beam of light (usually a laser) (Fig. 1.3). When the blood cells pass through the counting chamber, they interrupt or alter the beam of light, thereby generating an electrical impulse that may be recorded. The pattern of light scattering using different angles of detection may also be used to determine cell size, volume, shape, and cell cytoplasmic complexity ([17], [19]). Optical systems count red cells, white cells, and platelets with precision equivalent to that observed in electrical impedance methods ([26], [27]). Similar to the impedance analyzers, many of the optical analyzers can process over 100 specimens per hour and have the capacity to flag abnormal parameters ([26]).

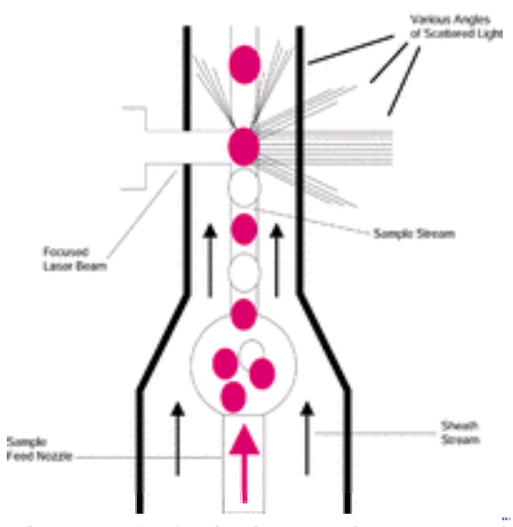

Figure 1.3. Optical type of automated hematology analyzer. A suspension of cells is passed through a flow chamber and focused into a single cell sample stream. The cells pass through a chamber and interact with a laser light beam. The scatter of the laser light beam at different angles is recorded, generating signals that are converted to electronic signals giving information about cell size, structure, internal structure, and granularity. (Adapted from Cell-Dyn 3500 Operator's Manual. Santa Clara, CA: Abbott Diagnostics, 1993.)

Combined Impedance and Optical Counters

Some of the newer hematology analyzers have combined impedance and optical methods together within one instrument, thereby allowing for optimal use and integration of the data generated by each method. Often, these are high-volume instruments, appropriate for larger hospitals and reference laboratories, and may be more expensive than some of the single-approach models. Examples of combined impedance and optical method analyzers include the Beckman Coulter Gen-S (Hialeah, FL) and Cell-Dyn 4000. Many of these newer instruments also provide an automated reticulocyte count and have improved precision of automated differential counts so as to lower the need for manual reviews by a technician ([28]).

RED BLOOD CELL ANALYTIC PARAMETERS

Red blood cells are defined by three quantitative values: the volume of packed red cells or Hct, the Hb, and the red cell concentration per unit volume. Three additional indices describing average qualitative characteristics of the red cell population are also collected. These include mean MCV, MCH, and MCHC. All of these values are collected and calculated by automated counters, largely replacing many of the previously used manual or semiautomated methods of red blood cell characterization with certain exceptions as noted below.

Volume of Packed Red Cells (Hematocrit)

The volume of packed red cells, or Hct, is the proportion of the volume of a blood sample that is occupied by red blood cells. The Hct may be determined manually by centrifugation of blood at a given speed and time in a standardized glass tube with a uniform bore, as was originally described by Wintrobe ([29]). The height of the column of red cells compared with that of the total blood sample after centrifugation yields the Hct. Macro (using 3-mm test tubes) methods with low-speed centrifugation or micro methods using capillary tubes and high-speed centrifugation may be used.

The manual method of measuring Hct has proved to be a simple and accurate method of assessing red cell status. It is easily performed with little specialized equipment, allowing it to be adapted for situations in which automated cell analysis is not readily available or for office use. However, several sources of error are inherent in the technique. The spun Hct measures the red cell concentration, not red cell mass. Therefore, patients in shock or with volume depletion may have normal or high Hct measurements due to hemoconcentration despite a decreased red cell mass. Technical sources of error in manual Hct determinations usually arise from inappropriate concentrations of anticoagulants ([30]), poor mixing of samples, or insufficient centrifugation ([29]). Another inherent error in manual Hct determinations arises from trapping of plasma in the red cell column. This may account for 1 to 3% of the volume in microcapillary tube methods, with macrotube methods trapping more plasma ([31], [32]). In addition, it should be noted that abnormal red cells (e.g., sickle cells, microcytic cells, macrocytic cells, or spherocytes) often trap higher volumes of plasma due to increased cellular rigidity, possibly accounting for up to 6% of the red cell volume ([31]). Very high Hcts, as in polycythemia,

may also have excess plasma trapping. Manual Hct methods typically have a precision [coefficient of variation (CV)] of approximately 2% ([31]).

Automated analyzers do not depend on centrifugation techniques to determine Hct, but instead calculate Hct by direct measurements of red cell number and red cell volume (Hct = red cell number/red cell volume). The automated Hct closely parallels manually obtained values, so that manual Hct methodology is used as the reference method for automated methods (with correction for the error induced by plasma trapping). Errors of automated Hct calculation are more common in patients with polycythemia ([33]) or abnormal plasma osmotic pressures ([34]). Manual methods of Hct determination may be preferable in these cases. The precision of most automated Hcts is less than 1% (CV) ([28]).

Hemoglobin Concentration

Hemoglobin is an intensely colored protein, which allows its measurement by a variety of colorimetric and spectrophotometric techniques. Hemoglobin is found in the blood in a variety of forms, including oxyhemoglobin, carboxyhemoglobin, methemoglobin, and other minor components. These may be converted to a single stable compound, cyanmethemoglobin, by mixing blood with Drabkin solution, which contains potassium ferricyanide and potassium cyanide ([35] , [36]). Sulfhemoglobin is not converted but is rarely present in significant amounts. The absorbance of the cyanhemoglobin is measured in a spectrophotometer at 540 nm to determine hemoglobin. Similar methods are used in both manual methods and automated cell analyzers. Hb is expressed in grams per deciliter (g/dl) of whole blood. The main errors in measurement arise from dilution errors or increased sample turbidity due to improperly lysed red cells, leukocytosis, or increased levels of lipid or protein in the plasma ([37] , [38] , [39] and [40]). Using automated methods, the precision for hemoglobin determinations is less than 1% (CV) ([25]).

Red Cell Count

Manual methods for counting red cells have proven to be very inaccurate, and automated counters provide a much more accurate reflection of red cell numbers ([26] , [41]). Both erythrocytes and leukocytes are counted in whole blood that has been diluted in an isotonic medium. As the number of red cells greatly exceeds the number of white cells (by a factor of 500 or more), the error introduced by counting both cell types is negligible. However, when marked leukocytosis is present, red cell counts and volume determinations may be erroneous unless corrected for white cell effects. The observed precision for red cell counts using automated hematology analyzers is less than 1% (CV) ([28]) compared with a minimal estimated value of 11% using manual methods ([29]).

Mean Corpuscular Volume

The average volume of the red blood cells is a useful red cell index that is used in classification of anemias and may provide insights into pathophysiology of red cell disorders ([42]). The MCV is usually measured directly with automated instruments but may also be calculated from the erythrocyte count and the Hct by means of the following formula ([29]).

$$\text{MCV} = \text{Hct (L/L)} \times 1000/\text{red cell count } (10^{12}/\text{L})$$

The MCV is measured in femtoliters (fl, or 10^{-15} L). Using automated methods, this value is derived by dividing the summation of the red cell volumes by the erythrocyte count. The CV in most automated systems is approximately 1% ([28]).

Agglutination of red blood cells, as in cold agglutinin disease, may result in a falsely elevated MCV ([43]). Most automated systems gate out MCVs above 360 fl, thereby excluding most red cell clumps, although this may falsely lower Hct determinations. In addition, severe hyperglycemia (glucose >600 mg/dl) may cause osmotic swelling of the red cells, leading to a falsely elevated MCV ([34] , [44]). The CV for automated MCV measurements is less than 1%, compared with approximately 10% for manual methods ([32]).

Mean Corpuscular Hemoglobin

MCH is a measure of the average hemoglobin content per red cell. It may be calculated manually or by automated methods using the following formula [29] .

$$\text{MCH} = \text{hemoglobin (g/L)}/\text{red cell count } (10^{12}/\text{L})$$

MCH is expressed in picograms (pg, or 10^{-12} g). Thus, the MCH is a reflection of hemoglobin mass. In anemias in which hemoglobin synthesis is impaired, such as iron deficiency anemia, hemoglobin mass per red cell decreases with a resultant decrease in MCH. MCH measurements may be falsely elevated by hyperlipidemia ([38]), as increased plasma turbidity may erroneously elevate the hemoglobin measurement. Leukocytosis may also spuriously elevate MCV values ([37]). Centrifugation of the blood sample to eliminate the turbidity followed by manual hemoglobin determination allows correction of the MCH value. The CV for automated analysis of MCH is less than 1% in most modern analyzers, compared with approximately 10% for manual methods ([28] , [32]).

Mean Corpuscular Hemoglobin Concentration

The average concentration of hemoglobin in a given red cell volume or MCHC may be calculated by the following formula ([29]).

$$\text{MCHC} = \text{hemoglobin (g/dl)}/\text{Hct (L/L)}$$

The MCHC is expressed in grams of hemoglobin per deciliter of packed red blood cells. This represents measurement of Hb or the ratio of hemoglobin mass to the volume of red cells. With the exception of hereditary spherocytosis and some cases of homozygous sickle cell or hemoglobin C disease, MCHC values will not exceed 37 g/dl. This level is close to the solubility value for hemoglobin, and further increases in Hb may lead to crystallization. The accuracy of the MCHC determination is affected by factors that affect measurement of either Hct (plasma trapping or presence of abnormal red cells) or hemoglobin (hyperlipidemia, leukocytosis) ([37]). The CV for MCHC for automated methods ranges between 1.0 and 1.5% ([28]).

As noted above, the MCV, MCH, and MCHC reflect average values and may not adequately describe blood samples when mixed populations of cells are present. For example, in sideroblastic anemias, a dimorphic red cell population of both hypochromic and normochromic cells may be present, yet the indices may be normochromic and normocytic. It is important to examine the blood smear as well as red cell histograms to detect such dimorphic populations. The MCV is an extremely useful value in classification of anemias ([42]), but the MCH and MCHC often do not add significant, clinically relevant information. However, the MCH and MCHC play an important role in laboratory quality control because these values will remain stable for a given specimen over time ([19]).

Red Cell Distribution Width

The *RDW* is a red cell measurement that quantitates red cell volume heterogeneity that is provided by the more modern automated hematology analyzers and reflects the range of red cell sizes measured within a sample ([45]). RDW has been proposed to be useful in early classification of anemias because it becomes abnormal earlier in nutritional deficiency anemias than any of the other red cell parameters, especially in cases of iron deficiency anemia ([42] , [46] , [47]). RDW is particularly useful when characterizing microcytic anemias, particularly distinguishing between iron deficiency anemia (high RDW, normal to low MCV) and uncomplicated heterozygous thalassemia (normal RDW, low MCV) ([42] , [47] , [48] , [49] and [50]). RDW is useful as a method for initial characterization of anemia, particularly microcytic anemias, although other tests are usually required to confirm the diagnosis ([51]). RDW is also useful in identifying red cell fragmentation, agglutination, or dimorphic cell populations (including patients who have had transfusions or have been recently treated for a nutritional deficiency) ([47] , [52]).

Automated Reticulocyte Counts

Determination of the numbers of reticulocytes or immature, nonnucleated red blood cells that contain RNA provides useful information about the bone marrow's

capacity to synthesize and release red cells in response to a physiologic challenge, such as anemia. In the past, reticulocyte counts were performed manually using supravital staining with methylene blue. Reticulocytes will stain precipitated RNA that appears as a dark blue meshwork or granules (at least two per cell) allowing reticulocytes to be identified and enumerated by manual counting methods ([53]). Normal values for reticulocytes in adults are 0.5 to 1.5%, although they may be 2.5 to 6.5% in newborns (falling to adult levels by the second week of life). Because there are relatively low numbers of reticulocytes, the CV for reticulocyte counting is relatively large (10 to 20%). To increase accuracy of reticulocyte counting, alternative methods using flow cytometry and staining with acridine orange or thioflavin allow for many more cells to be analyzed, thereby increasing accuracy and precision of counts ([15] , [54] , [55]).

Stand-alone reticulocyte analyzers, such as the Sysmex R-2000 or ABX PENTRA 120 Retic (ABX Diagnostics, Montpellier, France), allow for determination of reticulocyte counts without requiring a full flow cytometer, affording increased accuracy over manual counts. Many of the newest automated hematology analyzers, such as the Coulter STKS, Coulter GenS or the Cell-Dyn 4000, have automated reticulocyte counting as part of the testing capabilities and allow reticulocyte counts to be included with routine complete blood count parameters. Comparisons of stand-alone instruments, integrated hematology analyzers, and flow cytometric methods show that these automated methods provide similar data with superior accuracy when compared to manual counting methods, with similar CVs of 5 to 8% ([56] , [57] and [58]).

LEUKOCYTE ANALYSIS

White Blood Cell Counts

Leukocytes may be enumerated by either manual methods or automated hematology analyzers. Leukocytes are counted after dilution of blood in a diluent that lyses the red blood cells (usually acid or detergent). The much lower numbers of leukocytes present require less dilution of the blood than is needed for red blood cell counts (usually a 1:20 dilution, although it may be less in cases of leukocytopenia or more with leukocytosis). Manual counts are done using a hemocytometer or counting chamber. As with red cell counts, manual leukocyte counts have more inherent error, with CVs ranging from 6.5% in cases with normal or increased white cell counts to 15% in cases with decreased white cell counts. Automated methods characteristically yield CVs in the 1 to 3% range ([26] , [28]). Automated leukocyte counts may be falsely elevated in the presence of cryoglobulins or cryofibrinogen ([59]), aggregated platelets ([60]), and nucleated red blood cells or when there is incomplete lysis of red cells, requiring manual counting. Falsely low neutrophil counts have also been reported due to granulocyte agglutination secondary to surface immunoglobulin interactions ([61]).

Leukocyte Differentials

White cells are analyzed to find the percentage of each white blood cell type by doing a differential leukocyte count, providing important information in evaluation of the patient. Uniform standards for performing manual differential leukocyte counts on blood smears have been proposed by the National Committee for Clinical Laboratory Standards ([62]) to ensure reproducibility of results between laboratories. It is important to scan the smear at low power to ensure that all atypical cells and cellular distribution patterns are recognized. In wedge-pushed smears, leukocytes tend to aggregate in the feathered edge and side of the blood smear rather than in the center of the slide. Larger cells (blasts, monocytes) also tend to aggregate at the edges of the blood smear ([63]). Use of coverslip preparations and spinner systems tends to minimize this artifact of cell distribution. For wedge-push smears, it is recommended that a battlement pattern of smear scanning be used in which one counts fields in one direction, then changes direction and counts an equal number of fields before changing direction again to minimize distributional errors ([41]).

In manual leukocyte counts, three main sources of error are encountered: distribution of cells on the slide, cell recognition errors, and statistical sampling errors ([57] , [58]). Poor blood smear preparation and staining are major contributors to cell recognition and cell distribution errors ([63]). Statistical errors are the main source of error inherent in manual counts, due to the small sample size in counts of 100 or 200 cells. The CV in manual counts is between 5 and 10% and is also highly dependent on the skill of the technician performing the differential. Accuracy may be improved by increasing the numbers of cells counted, but for practical purposes, most laboratories will do a differential on 100 white cells ([64]). Automated methods of differential counting tend to be more accurate because of the much larger numbers of cells evaluated, with CV of 3 to 5% ([64] , [65] , [66] and [67]).

Automated methods of obtaining a leukocyte differential have been developed that markedly decrease the time and cost of performing routine examinations as well as increasing accuracy. However, automated analysis is incapable of accurately identifying and classifying all types of cells and is particularly insensitive to abnormal or immature cells. Therefore, most analyzers will identify possible abnormal white cell populations by flagging, indicating the need for examination by a skilled morphologist for confirmation ([68]). The automated instruments used for performing automated leukocyte differentials are of two general types: those that perform cell identification on the basis of pattern recognition using stained blood smear slides and automated microscopy, and flow-through systems that identify cells on the basis of size, cell complexity, or staining characteristics.

Pattern recognition systems were first available in the early 1970s and included such instruments as the Hematrack, Coulter diff 3 and diff 4, Abbott\R ADC 500, and the Leukocyte Automatic Recognition Counter ([69] , [70]). This technology uses a blood film on a glass slide that was stained and loaded onto the instrument. A computer drives a microscopic mechanical stage until a dark staining area, corresponding to a leukocyte nucleus, is detected. Using data collected for each cell on cell size, nuclear and cytoplasmic coloration, and density, the computer matches the data patterns with specifications for each white cell type and identifies the cell. Most pattern recognition technology is hampered by many of the same limitations of accuracy—limited numbers of cells counted, difficulties in classifying abnormal cell types, and cell distribution characteristics—as manual counts ([71]). Although the automated pattern recognition systems do decrease technician time, they are significantly slower than the flow-through methods. Hence, pattern recognition systems are now rarely used, and the instruments are no longer manufactured.

Because of the ability to link the automated differential to the rest of the automated hematologic analysis, most recent methods use a flow-through system that generates a leukocyte differential as a part of the complete blood count ([67] , [72]). Flow-through systems collect and analyze data from large numbers of white blood cells to provide a differential count that has a high degree of precision when compared to manual methods. White blood cell determination depends on both cell size and cytochemical staining characteristics (Technicon H6000, H*1, H*2, H*3 series) ([73]) or on the basis of cell volume and internal complexity as measured by electrical impedance and light scatter characteristics [Coulter STKR and Gen-S series ([58] , [74]), Cell-Dyn 4000 ([28]), Sysmex NE-8000 ([75]), Bayer Advia 120 (Bayer Diagnostic Division, Tarrytown, NY) ([28]), and Cobas-Helios (Roche Diagnostic Systems, Inc., Branchburg, NJ) ([27]) systems].

Systems that use myeloperoxidase staining characteristics of cells perform cell counts on specimens via continuous-flow cytometric analysis of blood samples in which the red cells have been lysed and white cells fixed. The cells are suspended in diluent and passed through a flow cell in a continuous stream so that single cells are analyzed for cell size (dark field light scatter) and cytochemical characteristics of myeloperoxidase staining (bright field detector). The data are plotted as a scattergram reflecting cell size (light scatter) on the *y*-axis and myeloperoxidase staining intensity or activity on the *x*-axis (Fig. 1.4), which gives rise to a six-part differential (neutrophils, lymphocytes, monocytes, eosinophils, basophils, and large unstained cells).

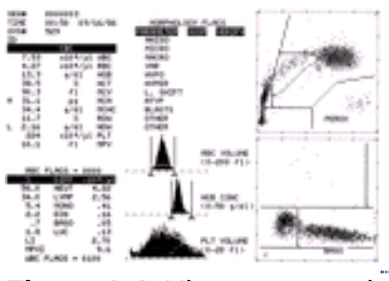

Figure 1.4. Histograms and printout generated by the H*1 automated hematology analyzer. ANISO, anisocytosis; ATYP, atypical; BASO, basophils; CBC, complete blood count; CONC, concentration; DIFF, differential; EOS, eosinophils; HCT, hematocrit; HDW, reticulocyte hemoglobin distribution width; HGB, hemoglobin; L. SHIFT, left shift; LUC, large unstained cell; LYMP, lymphocyte; MACRO, macrocyte; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MICRO, microcyte; MONO, monocyte; MPV, mean platelet volume; NEUT, neutrophil; PEROX, peroxidase; PLT, platelet; RBC, red blood cell; RDW, red cell distribution width; VAR, variant; WBC, white blood cell.

The total white blood cell count as well as the neutrophil, lymphocyte, monocyte, and eosinophil counts are enumerated in the myeloperoxidase channel. Lymphocytes are characterized as small (low-scatter) unstained cells. Larger atypical lymphocytes, blasts, or circulating plasma cells fall into the large unstained cells channel. Neutrophils have stronger peroxidase staining and appear as larger cells. Eosinophils have very strong peroxidase activity but appear smaller than neutrophils because they tend to absorb some of their own light scatter. Monocytes have lower levels of peroxidase activity and are usually found between neutrophils and the large unstained cell areas. The system uses floating myeloperoxidase staining thresholds to bracket the neutrophil area, which helps adjust for individual sample differences in myeloperoxidase staining. To enumerate basophils, which are difficult to enumerate with automated flow-through techniques, the later models (Technicon H*1, H*2, and H*3) use a basophil-nuclear lobularity channel. For this determination, red blood cells and white blood cells are differentially lysed, leaving bare leukocyte nuclei, with the exception of basophils, which are resistant to lysis and can then be counted based on cell size. Light scatter data obtained from the leukocyte nuclei may also help identify blasts, which have a lower light scatter than do mature lymphocyte nuclei. The nuclear lobularity index is a measurement of the number of mononuclear and polynuclear cells that may help identify immature neutrophils or nucleated red blood cells when correlated with mean peroxidase activity and cell count data. These abnormal cell populations generate a flag, indicating a need for morphologic review of the peripheral smear. Studies using these systems have shown good ability to identify acute leukemias ([76], [77] and [78]), myelodysplastic syndromes ([79]), and acute infection or inflammation ([80]). Analysis using this technique examines thousands of cells per sample, increasing statistical accuracy ([64], [66]). The H*3 analyzers may perform 60 or more leukocyte differentials per hour.

The remaining instruments use leukocyte volume determinations based on electrical impedance or coupled with light scatter data to generate a leukocyte differential. Initially, this type of methodology gave rise to a three-part differential that enumerated only neutrophils, monocytes, and lymphocytes, exemplified by the Coulter S-Plus series of analyzers. This count was based on white cells that had been lysed, with subsequent collapse of the cellular cytoplasm around the nucleus and cytoplasmic granules ([81]). The cells were divided into three distinct size populations: large cells (neutrophils), intermediate cells (monocytes), and small cells (lymphocytes). When clear-cut size populations were not discernible, the machine generated a flag to indicate that the peripheral smear needed to be reviewed. This type of technology is best at enumerating neutrophils and lymphocytes, with high levels of correlation between manual and instrument determinations, but was less effective on monocytic counts because of lower cell numbers. In addition, other cell populations, including eosinophils, basophils, atypical lymphocytes, blasts, immature granulocytes, and plasma cells, tended to fall into the monocytic region or granulocyte region and confounded the data. Depending on the patient population studied (i.e., the percentage of normal vs. abnormal samples), the proportion of false negatives (samples in which a true abnormal population was not detected by the analyzer) varied from 4 to 16% ([82], [83]). This value is similar to those of the manual methods, in which the false negative rate is estimated to be 9% ([71]). The three-part differential is most useful as a screening tool.

The need for more detailed white cell analysis has led to development of the improved white cell differential analysis by combination of impedance methods with conductivity or light scatter measurements. This modification has greatly improved the ability of later model analyzers to provide full, five-part, differential white blood cell counts. The most commonly used hematology analyzers of this later generation include the Coulter STKS or Gen-S, the Sysmex NE-8000 or NE-9000, and the Cell-Dyn 3500 or 4000, although new upgrades and models appear with great rapidity ([28], [84]).

The Coulter STKS and Gen-S use electronic impedance to measure volume, high-frequency electromagnetic fields to measure conductivity, and light scatter with a monochromatic laser to determine cell cytoplasmic complexity or granule content, analyzing up to 144 specimens per hour. These generate a three-dimensional scatter plot (Fig. 1.2) that can separate the leukocytes into neutrophils, lymphocytes, monocytes, eosinophils, and basophils with flags for abnormal populations ([58], [84]). The Sysmex NE-8000 uses electrical impedance and electromagnetic data to identify the monocytes, neutrophils, and lymphocytes, then identifies eosinophils and basophils based on a proprietary lysing agent ([85], [86]). It may analyze up to 120 samples per hour. The Cell-Dyn 3000 identifies all of the leukocyte classes based on light scatter properties [small-angle forward light scatter, wide-angle light scatter, orthogonal light scatter, and depolarized light scatter ([87])]. The Cell-Dyn 3500 uses both impedance and laser light scatter at 0-, 10-, and 90-degree angles ([90], [91]). When compared among themselves and with the Technicon H*1 or H*2, all of the automated hematology analyzers mentioned above had excellent accuracy and precision for typical clinical laboratory usage with slight differences between the different technologies but a marked improvement over manual methods. Most studies find a poor correlation value for basophil counts ([88]), probably reflecting the very low levels of these cells available for manual counts. The Cobas analyzer uses a flow cytometric and light scatter technology that allows somewhat improved detection of band neutrophils over other systems with similar accuracy and precision with regard to other white and red blood cell parameters ([27], [89]). All of the above approaches appear to offer sensitive and efficient evaluation of leukocyte differentials, although instrument flags may require technician review for some cases ([28]).

In addition to their use in providing a differential count of white blood cells, the flow-through techniques of automated cell counting also can provide reproducible and accurate absolute numbers of each cell type because they analyze large cell populations ([28]). Use of percentages (as in the leukocyte differential) may mask some cytopenias or excessive numbers of cells. Absolute counts are used to define some disease states, such as chronic lymphocytic leukemia and chronic myelomonocytic leukemia. Absolute neutrophil counts are often useful when monitoring bone marrow recovery after chemotherapy or bone marrow transplant ([90]).

PLATELET ANALYSIS

Platelets are anucleate cytoplasmic fragments that are 2 to 4 microns in diameter. As with the other blood components, they may be counted by either manual or automated methods. Manual methods involve dilution of blood samples and counting in a counting chamber or hemocytometer using phase contrast microscopy. Sources of error are similar to other manual counts and include dilution errors and low sample numbers. The CV, especially in patients with thrombocytopenia, may be greater than 15% ([91], [92]). Platelets are counted in automated hematology analyzers after removal of red cells by sedimentation or centrifugation or using whole blood. Platelets are identified by light scatter, impedance characteristics, or both ([91], [93]). These give highly reliable platelet counts with a CV of less than 2%. Falsely low platelet counts may be caused by the presence of platelet clumps or platelet agglutinins ([60]) or adsorption of platelets to leukocytes ([94], [95]). Fragments of red or white blood cells may falsely elevate the automated platelet count, but this usually gives rise to an abnormal histogram that identifies the spurious result ([96], [97]).

Automated hematology analyzers also determine MPV, which has been correlated with several disease states ([98], [99]). In general, MPV has an inverse relationship with platelet number, with larger platelet volumes seen in thrombocytopenic patients in whom platelets are decreased due to peripheral destruction (as in idiopathic thrombocytopenia purpura) ([100], [101]). MPV is characteristically increased in hyperthyroidism ([102]) and myeloproliferative disorders ([103]). However, it should be noted that platelets tend to swell during the first 2 hours in EDTA anticoagulant, shrinking again with longer storage ([104], [105]). Decreased MPV has been associated with megakaryocytic hypoplasia and cytotoxic drug therapy ([101], [106]).

Reticulated platelets are newly released platelets that retain residual RNA, analogous to red cell reticulocytes. Reticulated platelet counts give an estimate of thrombopoiesis and may be useful in distinguishing platelet destruction syndromes from hypoplastic platelet production ([107], [108]). Reticulated platelets are usually detected by flow cytometric methods using thiazole orange dyes that bind to RNA ([109], [110]). Normal values vary between 3 and 20% ([109]), and 2.5- to 4.5-fold increases in reticulated platelet counts are seen in the clinical setting of idiopathic thrombocytopenia purpura ([111], [112]). Increased reticulated platelets may herald the return of platelet production after chemotherapy ([113]). Although automated hematology analyzers offering reticulated platelet counts are not yet available, it is anticipated that this test may be incorporated in newer models, similar to the reticulocyte count.

ADVANTAGES AND SOURCES OF ERROR WITH AUTOMATED HEMATOLOGY ANALYZERS

Clearly, the use of automated hematology analyzers has reduced laboratory costs and turnaround time coincident with improving the accuracy and reproducibility of blood counts. The CV for most of the parameters measured is in the range of 1 to 2%. This level of reproducibility is not achievable with the use of most manual techniques (Table 1.1 and Table 1.2).

TABLE 1.2. Reproducibility of Red Cell Indices

Index	Method Used	% Error (±2 Coefficients of Variation)

Hemoglobin concentration	Spectrophotometric	1.0–2.0
	Automated	<1.0
Mean corpuscular volume	Hemocytometer	9.5
	Automated	<1.0
Mean corpuscular hemoglobin	Hemocytometer	10.0
	Automated	0.6–1.2
Mean corpuscular hemoglobin concentration	Automated	1.0–1.5

From Bentley S, Johnson A, Bishop C. A parallel evaluation of four automated hematology analyzers. Am J Clin Pathol 1993;100:626–632; NCCLS. Reference and standard procedure for quantitative determination of haemoglobin in blood, 2nd ed. Document H15-A2. NCCLS, 1994; and International Committee for Standardization in Haematology. Recommendations for reference method for haemoglobinometry in human blood (ICSH Standard 1986) and specifications for international haemoglobincyanide reference preparation, 3rd ed. Clin Lab Haematol 1987;9:73–79, with permission.

Despite this high degree of accuracy, several potential errors may invalidate automated collection of data. Proper calibration of instrumentation is essential for collection of accurate data. Faulty current settings, which determine threshold counting values as well as variation in either the counting volumes or flow characteristics of a sample, negatively affect data accuracy. Electrical or mechanical failures or even minor voltage fluctuations may induce marked errors in data collection. Careful calibration of the instrumentation initially, followed by frequent evaluation of reproducibility by analysis of samples with known cell concentrations, is an essential quality control measure ([114]). Reference methods for instrument calibration have been developed by both the National Committee for Clinical Laboratory Standards and the International Committee for Standards in Haematology and are widely used by hospital and clinical laboratories to ensure regulatory compliance ([6], [11], [21], [62]).

Certain disease states are also associated with spuriously high or low results, although some of these are specific to a particular type of instrumentation (summarized in Table 1.3). Therefore, the individual values obtained from the automated hematology analyzer must be interpreted in context with the clinical findings. In addition, careful examination of the stained blood film often imparts additional information that may not be reflected in the average values that constitute the automated data. For example, decreased red blood cell counts, macrocytosis, and extremely high MCHC have been observed in patients with cold agglutinin disease with a higher thermal amplitude and in some patients with elevated serum viscosity ([115]). High levels of paraprotein may lead to falsely elevated hemoglobin levels, therefore affecting MCH and MCHC calculations ([39]). Many analyzers report spurious increases in hemoglobin levels when white cell counts exceed 30 × 10^9/L due to increased turbidity. This has been addressed in the Sysmex systems by use of two lysing agents and redesign of the flow system so that hemoglobin levels remain extremely accurate in the face of white blood cell counts as high as 100 × 10^9/L ([116]). Extremely high white cell counts may also falsely raise the red cell count and Hct as the white cell count is incorporated into the red cell count. High glucose levels (>400 to 600 mg/dl) and the associated hyperosmolarity cause red cell swelling and generate a high MCV and Hct with a falsely low MCHC ([34], [117]). The increased turbidity associated with hyperlipidemia may also cause falsely elevated hemoglobin determinations, MCH, and MCHC ([37]).

TABLE 1.3. Disorders and Conditions That May Reduce the Accuracy of Blood Cell Counting [a]

Component	Disorder/Condition	Effect on Cell Count	Rationale
Red cells	Microcytosis or schistocytes	May underestimate RBC	Lower threshold of RBC counting window is greater than microcyte size.
	Howell-Jolly bodies	May spuriously elevate platelet count (in whole blood platelet counters only)	Howell-Jolly bodies are similar in size to platelets.
	Polycythemia	May underestimate RBC	Increased coincidence counting.
White cells	Leukocytosis	Overestimate RBC	Increased coincidence counting.
	Acute leukemia and chronic lymphocytic leukemia, viral infections	May spuriously lower WBC	Increased fragility of leukocytes, including immature forms.
	Chemotherapy of acute leukemia	May artifactually increase platelet count	Leukemic cell nuclear or cytoplasmic fragments identified as platelets.
Platelets	Platelet agglutinins	May underestimate platelet count, sometimes with spurious increase in WBC	Platelet clumping. Aggregates may be identified as leukocytes.
Plasma	Cold agglutinins	May underestimate RBC with spurious macrocytosis	Red cell doublets, triplets, and so forth have increased volume.
	Cryoglobulins, cryofibrinogens	Variation in platelet count	Protein precipitates may be identified as platelets.

RBC, red blood cell count; WBC, white blood cell count.

[a] Some of these examples affect counts only when certain instruments are used. The effects depend on dilution, solutions used, and specimen temperatures. Adapted from Koepke JA. Laboratory hematology. New York: Churchill Livingstone, 1984.

Despite the high level of accuracy and precision, the automated hematology analyzers usually have false-positive rates (flagging) of 10 to 25% of patients, requiring manual examination of the blood smear ([28]). Blood smear examination still plays an important role in characterizing samples that raise flags or show findings outside the parameters set in a particular laboratory. In addition, some cells require morphologic examination to identify, such as Sézary cells ([118]), and red cell morphology is best analyzed by direct smear examination ([72]).

MORPHOLOGIC ANALYSIS OF BLOOD CELLS

Careful evaluation of a well-prepared blood smear is an important part of the evaluation of hematologic disease. Although a specific diagnosis may be suggested by the data obtained from an automated hematology analyzer, many diseases may have normal blood counts but abnormal cellular morphology. Examples of abnormal red cells that may be seen in the peripheral blood smear examination and are associated with specific disease states are found in Table 1.4. However, morphologic analysis may be greatly hampered by poorly prepared or stained blood smears. Preparation of satisfactory blood smears requires careful attention to preparation of the blood smear and staining techniques and familiarity with the morphologic appearances of normal and pathologic cell types.

TABLE 1.4. Pathologic Red Cells in Blood Smears

Red Cell Type	Description	Underlying Change	Disease State Associations
Acanthocyte (spur cell)	Irregularly spiculated red cells with projections of varying length and dense center	Altered cell membrane lipids	Abetalipoproteinemia, parenchymal liver disease, postsplenectomy.
Basophilic stippling	Punctuate basophilic inclusions	Precipitated ribosomes (RNA)	Coarse stippling: lead intoxication, thalassemia. Fine stippling: a variety of anemias.
Bite cell (degmactyte)	Smooth semicircle taken from one edge	Heinz body pitting by spleen	Glucose-6-phosphate dehydrogenase deficiency, drug-induced oxidant hemolysis.

Burr cell (echinocyte) or crenated red cell	Red cells with short, evenly spaced spicules and preserved central pallor	May be associated with altered membrane lipids	Usually artifactual. Seen in uremia, bleeding ulcers, gastric carcinoma.
Cabot's rings	Circular, blue, threadlike inclusion with dots	Nuclear remnant	Postsplenectomy, hemolytic anemia, megaloblastic anemia.
Ovalocyte (elliptocyte)	Elliptically shaped cell	Abnormal cytoskeletal proteins	Hereditary elliptocytosis.
Howell-Jolly bodies	Small, discrete, basophilic, dense inclusions; usually single	Nuclear remnant (DNA)	Postsplenectomy, hemolytic anemia, megaloblastic anemia.
Hypochromic red cell	Prominent central pallor	Diminished hemoglobin synthesis	Iron deficiency anemia, thalassemia, sideroblastic anemia.
Leptocyte	Flat, waferlike, thin, hypochromic cell	—	Obstructive liver disease, thalassemia.
Macrocyte	Red cells larger than normal (>8.5 µm), well-filled with hemoglobin	Young red cells, abnormal red cell maturation	Increased erythropoiesis. Oval macrocytes in megaloblastic anemia. Round macrocytes in liver disease.
Microcyte	Red cells smaller than normal (<7.0 µm)	—	Hypochromic red cell (see Chapter 27)
Pappenheimer bodies	Small, dense, basophilic granules	Iron-containing siderosome or mitochondrial remnant	Sideroblastic anemia, postsplenectomy.
Polychromatophilia	Grayish or blue hue often seen in macrocytes	Ribosomal material	Reticulocytosis, premature marrow release of red cells.
Rouleaux	Red cell aggregates resembling stack of coins	Red cell clumping by circulating paraprotein	Paraproteinemia.
Schistocyte (helmet cell)	Distorted, fragmented cell; two or three pointed ends	Mechanical distortion in microvasculature by fibrin strands, disruption by prosthetic heart valve	Microangiopathic hemolytic anemia (disseminated intravascular coagulation, thrombotic thrombocytopenic purpura), prosthetic heart valves, severe burns).
Sickle cell (drepanocyte)	Bipolar, spiculated forms, sickle-shaped, pointed at both ends	Molecular aggregation of HbS	Sickle cell disorders, not including S trait.
Spherocyte	Spherical cell with dense appearance and absent central pallor, usually decreased diameter	Decreased membrane redundancy	Hereditary spherocytosis, immunohemolytic anemia.
Stomatocyte	Mouth or cuplike deformity	Membrane defect with abnormal cation permeability	Hereditary stomatocytosis, immunohemolytic anemia.
Target cell (codocyte)	Targetlike appearance, often hypochromic	Increased redundancy of cell membrane	Liver disease, postsplenectomy, thalassemia, hemoglobin disease.
Teardrop cell (dacryocyte)	Distorted, drop-shaped cell	—	Myelofibrosis, myelophthisic anemia.

Preparation of Blood Smears

Blood films may be prepared on either glass slides or coverslips. Each method has specific advantages and disadvantages. Blood smears are often prepared from samples of anticoagulated blood remaining from automated hematologic analysis. However, artifacts in cell appearance and staining may be induced by the anticoagulant. Optimal morphology and staining are obtained from noncoagulated blood, most often from a fingerstick procedure. Mechanical dragging of the cells across the glass of the slide or coverslip also distorts the cells; however, this artifact may be minimized with proper technique.

Coverslip smears (Fig. 1.5A) are prepared using a good grade of flat, no. 1, 1/2-inch square (or 22 × 22 mm) coverslips that are free of lint, dust, and grease. Such coverslips allow optimal spreading of the blood over the surface and minimal artifact. Usually, high-quality coverslips do not require additional cleaning, although there may be some deterioration with age. Plastic “nonwettable” coverslips are not satisfactory for these preparations. The smear is prepared by holding the coverslip by two adjacent corners between the thumb and index finger. A small drop of either fresh or anticoagulated blood is placed in the center of the coverslip. The size of the drop of blood is critical. If the drop is too large, a thick smear results. If the drop of blood is too small, a very thin smear is obtained. A second coverslip is then grasped in a similar fashion with the other hand, placed across the first coverslip, and rotated 45 degrees with a steady, rapid, and gentle motion. The two coverslips are then immediately pulled apart and allowed to air dry. If done properly, this procedure produces two coverslips with even dispersion of blood without holes or thick areas.

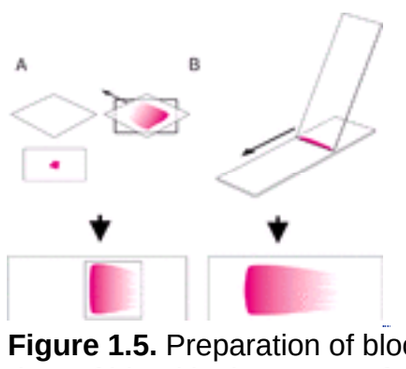

Figure 1.5. Preparation of blood smears. Blood smears may be prepared by the coverslip **(A)** or slide wedge method **(B)**. Coverslip smears are prepared by placing a drop of blood in the center of a coverslip and spreading the blood by rotating a second coverslip over it. Wedge smears are prepared by placing a drop of blood on a slide and using a second slide to push the blood out along the length of the slide. (Adapted from Bauer JD. Clinical laboratory methods, 9th ed. St. Louis: C.V. Mosby, 1982:270.)

Blood smears may also be prepared on clean glass slides by the wedge method (Fig. 1.5B). This often leads to irregular distribution of cells on the slide, a distinct disadvantage over the coverslip procedure. However, glass slides are less fragile and easier to handle and may be labeled more easily than coverslips. To prepare a slide blood smear, a drop of blood is placed in the middle of the slide approximately 1 to 2 cm from one end. A second spreader slide is placed at a 30- to 45-degree angle and moved backward to make contact with the blood drop. The blood drop will spread along the slide edge, then the spreader slide is moved rapidly forward. This technique creates a film of blood that is 3 to 4 cm long. Artifact may be introduced by irregular edges in the spreader and by the speed at which the spreader is moved. Glass slide preparations have increased incidence of accumulation of the larger white cells at the edges of the film, increasing cellular distribution errors. Fast movement of the spreader results in a more uniformly distributed population of cells.

Automated techniques for blood smear preparation have also been developed that produce very uniform blood smears. Two major types of instruments are used: those that use centrifugation and those that mechanically spread the blood. Centrifugation techniques are often most useful when a small number of cells must be concentrated in a small area, as in preparing smears of cells in fluids such as cerebrospinal fluid. Mechanical spreaders mimic the manual technique and are useful when large numbers of blood smears are prepared. In general, smears made by automated techniques are usually inferior to those made by an experienced technician.

Routine Staining of Blood Smears

Blood smears are usually stained with either Wright or May-Grunwald-Giemsa stains. Both stains are modifications of the Romanowsky procedure ([119]). The stain may be purchased commercially or may be made in the laboratory. The basic stain is formulated from methylene blue and eosin. The Wright stain formulation uses sodium bicarbonate to convert methylene blue to methylene azure, which stains the cell. Giemsa stains use known quantities of acid bichromate to form the converted

azure compounds. All types of Romanowsky stains are water insoluble but can be dissolved in methyl alcohol. The stain must be free of water, which induces red blood cell artifacts. Water artifacts may be avoided by fixation of slides or coverslips in anhydrous methanol before staining.

Optimal staining conditions must be established for each new batch of stain. The methylene blue conversion to azure compounds continues to occur while the stain is in the bottle, so staining conditions may change over time. Methyl azures are basic dyes that impart a violet-blue coloration when binding to the acidic components of the cell, such as nucleic acids and proteins. The eosin reacts with the basic cellular elements, imparting a reddish hue to cytoplasmic components and hemoglobin. A properly stained slide has a pink tint. The red cells will have an orange to pink coloration, and leukocytes have purplish-blue nuclei. The Romanowsky stains differentially stain leukocyte granules, which aids in morphologic analysis of the cells. Thus, neutrophil granules are slightly basic and stain weakly with the azurophilic component. The eosinophils contain a strongly basic spermine derivative and stain strongly with eosin. In contrast, basophil granules contain predominately acidic proteins and stain a deep blue-violet. No precipitate should overlie the cells because this indicates use of slides or coverslips that were not cleaned properly. Dust on slides may also induce artifacts. Staining solutions should be filtered or replaced weekly if used heavily.

Occasionally, an excessive blue coloration of the cells is seen. This may be caused by excessive staining times, improperly prepared or aged buffer that is too alkaline, old blood smears, or blood smears that are too thick. The quality of the staining may be improved by quick and vigorous rinsing with distilled water. If the areas of the slide between cells are staining, it usually indicates inadequate washing of the slide, heparin anticoagulation, or possible paraproteinemia. When the staining appears too pink or red, the usual problem is buffer that is too acidic. This results in pale-stained leukocyte nuclei, excessively orange-red blood cells, and bright red eosinophil granules. Other causes of excessive red coloration include inadequate staining times and excessive washing of the slide. Most often, problems with staining are caused by problems with the pH of the solutions, and new buffers often correct the problem.

Examination of the Blood Smear

The blood smear should be initially examined under an intermediate power (10 to 20× objective) to assess the adequacy of cellular distribution and staining. An estimate of the white blood cell count may also be made at this power, and scanning for abnormal cellular elements, such as blasts or nucleated red blood cells, can be performed. It is important to scan over the entire blood smear to ensure that abnormal populations, which may be concentrated at the edges of the smear, are not missed. Use of an oil immersion lens (50 or 63×) is usually sufficient for performing leukocyte differential counts, although a 100× oil lens may be necessary for study of cellular inclusions or cytoplasmic granules. Systematic evaluation of the blood smear is essential so that all cell types are examined and characterized. Each cell type should be evaluated for both quantitative and qualitative abnormalities.

It is difficult to evaluate quantitative abnormalities of red cells on a blood smear; however, the red blood cells should be evaluated for variations in size, shape, and hemoglobin distribution and the presence of cellular inclusions. The red cells are usually unevenly distributed throughout the blood film. Optimal red cell morphology is seen in an area of the smear where the red cells are close together but do not overlap. Areas where the red cells are spread too thinly or thickly have increased artifacts. In some blood smears, the red cells appear to stick together, forming what appear to be stacks of red blood cells, termed *rouleaux*. This finding may be mimicked in normal patients in areas of the smear where the red cells are too close together. However, if rouleaux persists in thinner areas of the blood film, it suggests the presence of a paraprotein coating the red cells and causing agglutination due to loss of normal electrostatic repulsion between red cells.

Red cells should be uniform in size and shape with an average diameter of 7.2 to 7.9 µm. This may be evaluated by use of a micrometer or by comparison with the diameter of a small lymphocyte nucleus, which is approximately the same size or slightly smaller. Variation in red cell size is called *anisocytosis*. Cells that are larger than 9 µm and well hemoglobinated are considered *macrocytes*. Less mature erythrocytes are macrocytic and have a bluish tint to the hemoglobin (polychromatophilia) or have fine basophilic stippling of the cell due to remnant RNA and ribosomes. *Microcytes* are cells with a diameter of less than 6 µm.

Normal erythroid cells are round. Variations in red cell shape are called *poikilocytosis*. The red cell should have a pale central area with a rim of red to orange hemoglobin. Hypochromia reflects poor hemoglobinization and results in a very thin rim of hemoglobin or an increased area of central pallor. Abnormal distribution of hemoglobin may result in formation of a cell with a central spot of hemoglobin surrounded by an area of pallor, called a *target cell*. Abnormal hemoglobins may also form crystals. Spherocytes and macrocytes lack an area of central pallor because of increased thickness of the cell. Red cells may also contain inclusions, such as remnants of nuclear material (Howell-Jolly bodies), remnants of mitochondria or siderosomes (Pappenheimer bodies), or infectious agents (malarial parasites).

Platelet numbers and morphology are then evaluated. Platelets appear as small blue cytoplasmic fragments with red to purple granules. Platelets are usually 1 to 2 µm in diameter with wide variation in shape. Platelet numbers may be estimated from the blood film. Normal platelet counts should have several (5 to 15) platelets per oil immersion field or approximately 1 platelet for 10 to 20 red blood cells. It should be noted that platelets may aggregate if uncoagulated blood or a fingerstick preparation is used, and this may cause the spurious impression of a low platelet count.

Leukocyte morphology and distribution are analyzed last. The number of leukocytes may be estimated by scanning the blood film at an intermediate power. Abnormal distribution of larger cells should be excluded by examination of the edges of the blood film in particular ([62], [63]). White cells at the edges of the blood smear may appear artifactually smaller (because of cellular shrinkage and poor spreading of the cell) or larger (because of cellular disruption). Care must be taken when making the smear because cells, particularly neoplastic cells, may be disrupted by too much mechanical pressure. Optimal morphology of the leukocytes requires that blood smears be made promptly. Significant artifact begins to be observed in blood that has been held for several hours and includes cytoplasmic vacuolation, nuclear karyorrhexis, and cytoplasmic disruption.

The white blood cells normally seen in the blood smear include neutrophils, eosinophils, basophils, lymphocytes, and monocytes. The presence of immature myeloid cells (myelocytes, metamyelocytes, promyelocytes, and blasts) is distinctly abnormal. At least 100 cells should be identified and counted to yield a manual white blood cell differential ([62], [63]). In addition to identifying relative populations of white cells by performing a differential count, the cells should be closely examined for morphologic abnormalities of the cytoplasm and nucleus. For example, infection or growth factor therapy often leads to increased prominence of the primary (azurophilic) granules in neutrophils, which is called *toxic granulation* ([120]). In contrast, many myelodysplastic disorders are characterized by hypogranularity of neutrophils in addition to abnormal nuclear segmentation. Cytoplasmic inclusions may be seen in some storage disorders or lysosomal disorders ([63]).

Other Means of Examining Blood

Occasionally, it is necessary to examine fresh blood as a wet mount. Wet preparations are made by placing a drop of blood on a slide, covering the drop with a coverslip, and surrounding the coverslip with petroleum jelly or paraffin wax to seal the edges. If needed, the blood may be diluted with isotonic saline, or in some cases, it may be fixed with buffered glutaraldehyde for later examination. The blood may then be viewed with light or phase contrast microscopy. Wet mounts are used to detect sickling of red cells, spherocytes, and parasites within erythrocytes. Some organisms, such as spirochetes and trypanosomes, may be detected by movements. Dark field illumination enhances the refractile qualities of leukocyte granules or malarial pigment ([121]). Phase contrast microscopy accentuates the fine cellular details of cells, especially cytoplasmic granules and intracellular inclusions ([122]). Platelets are well visualized with phase contrast, and this aids in performance of manual platelet counts ([21]).

Supravital staining is performed on living, motile cells and helps avoid artifacts induced by smear preparation, fixation, and staining ([123], [124]). However, such preparations are not permanent, a distinct disadvantage. Supravital stains are often used to detect red cell inclusions. These include crystal violet staining that detects Heinz bodies, which are denatured hemoglobin inclusions that appear as irregularly shaped purple bodies within the red cell. Brilliant cresyl blue may be used to precipitate and stain unstable hemoglobins, such as hemoglobin Zurich and hemoglobin H ([125]).

The most commonly used supravital stain is new methylene blue or brilliant cresyl blue, used for reticulocyte determinations. These stains allow visualization of the reticulin network of erythrocyte ribosomes in newly formed red blood cells ([56]). Reticulocyte counts are used in evaluation of new red cell production and are helpful in determining the hematopoietic activity of the bone marrow and marrow response to anemia ([54]). Reticulocytes are not identified positively on Wright-stained blood smears, although their presence is suggested by polychromatophilia of red blood cells. Recently, many automated hematology analyzers have incorporated staining to detect reticulocytes. These automated procedures appear to perform reticulocyte counting with a higher degree of precision than can be achieved manually ([28], [56], [57]). The degree of ribosomal staining may also be quantitated to allow assessment of reticulocyte age ([55]). Automated reticulocyte counts may have increased errors in the presence of Heinz bodies ([126]) or Howell-Jolly bodies ([127]) in the red cells. Normal reference values for reticulocytes are influenced by patient age and sex ([128]).

BONE MARROW EXAMINATION

Diagnosis and management of many hematologic diseases depend on examination of the bone marrow. Bone marrow examination usually involves two separate, but interrelated, specimens ([129]). The first is a cytologic preparation of bone marrow cells obtained by aspiration of the marrow and a smear of the cells, allowing excellent visualization of cell morphology and enumeration of the marrow cellular elements. The second specimen is a needle biopsy of the bone and associated marrow, which allows optimal evaluation of bone marrow cellularity, fibrosis, infections, or infiltrative diseases.

There are several indications for performing a bone marrow examination. These include further workup of hematologic abnormalities observed in the peripheral blood smear, evaluation of primary bone marrow tumors, staging for bone marrow involvement by metastatic tumors, assessment of infectious disease processes including fever of unknown origin, and evaluation of metabolic storage diseases. Before a bone marrow examination is carried out, clear diagnostic goals about the information to be obtained from the procedure should be defined. Before the procedure, one should decide whether any special studies are needed so that all the necessary specimens may be collected and handled correctly. Clearly, the decision to perform a bone marrow examination as well as the choice of tests to be performed using the material should be made on an individualized basis.

Several sites may be used for bone marrow aspiration and biopsy ([134]). In part, the site chosen reflects the normal distribution of bone marrow with the age of the patient. At birth, hematopoietic marrow is found in all of the bones of the body. However, by early childhood, fat cells begin to replace the bone marrow hematopoietic cells in the extremities. In adults, hematopoiesis is limited to the axial skeleton and proximal portions of the extremities ([135]). Thus, younger children may have marrow examinations from the anterior medial tibial area, whereas adult marrow is best sampled from the sternum at the second intercostal space or from either the anterior or posterior iliac crest area. Sternal marrows do not allow a biopsy to be performed, and several possible complications, including hemorrhage and pericardial tamponade, may occur if the inner table of the sternum is penetrated by the needle at areas other than the second intercostal space. The sternal marrow space in an adult is only approximately 1 cm thick at the second intercostal space, so care must be taken to avoid penetrating the chest cavity. In contrast, little morbidity is associated with iliac crest aspiration and biopsy, and the posterior iliac crest is the most common site for bone marrow sampling. The anterior iliac crest may be used if previous radiation, surgery, or patient discomfort do not allow a posterior approach.

Bone Marrow Aspiration and Biopsy

Bone marrow is semifluid and easily aspirated through a needle. Many types of needles have been used for performing marrow aspiration. Most are 14- to 18-gauge, and many have a removable obturator, which prevents plugging of the needle before aspiration, and a stylet that may be used to express the bone marrow biopsy sample (Fig. 1.6). Some models, primarily used for sternal bone marrow aspiration procedures, have adjustable guards that limit the extent of needle penetration.

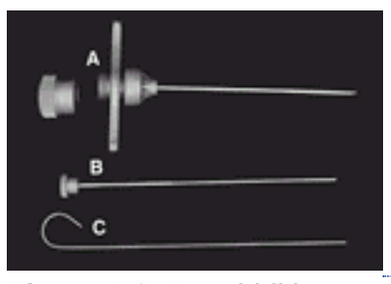

Figure 1.6. Jamshidi bone marrow aspiration and biopsy needle. This type of hollow needle with a beveled tip **(A)** is satisfactory for percutaneous biopsy of the bone marrow. The needle is inserted with the obturator **(B)** in place. The biopsy is expressed from the needle using the stylet **(C)**.

In most cases, marrow aspiration and biopsy may be carried out with little risk of patient discomfort, provided adequate local anesthesia is used. Apprehensive patients may be sedated before the procedure, but this is usually not necessary. The procedure is performed under sterile conditions. The skin at the site of the biopsy is shaved, if necessary, and cleaned with a disinfectant solution. The skin, subcutaneous tissue, and periosteum in the area of the biopsy are anesthetized with a local anesthetic, such as 1% lidocaine, using a 25-gauge needle. Care must be taken to fully anesthetize the periosteum, where most of the bone pain fibers are located. After the anesthetic has taken effect, a small cut is made in the skin overlying the biopsy site, and the marrow aspiration needle is inserted through the skin, subcutaneous tissues, and bone cortex with a slight rotating motion. Entrance of the needle into the bone marrow cavity should be sensed as a slight give or increase in the speed of needle advancement. The needle obturator is removed, and the needle is attached to a 10- or 20-ml syringe. Aspiration of the marrow is achieved by rapid suctioning with the syringe so that 0.2 to 2.0 ml of bloody fluid is obtained ([130]). Aspiration may cause a very brief, sharp pain. If no pain is noted and no marrow is obtained, the needle may be rotated and suction applied again. If no marrow is obtained, another sampling site may be required.

The aspirated material is given to a technical assistant, who makes smears of the material and assesses the quality of the material by noting the presence of marrow spicules. The smears must be made quickly to avoid clotting in a manner similar to that described for blood smears. After several smears are made, the aspirate is allowed to clot for later fixation and processing by the histology laboratory. If additional material is needed for flow cytometry, cytogenetics, culture, or other special studies, additional aspirations may be performed by withdrawing the needle and repositioning it in a new site ([130]). Occasionally, a portion of an anticoagulated marrow aspirate is spun down to obtain a buffy coat, thereby concentrating the cellular elements in a very hypocellular specimen. EDTA is the best anticoagulant to use because it introduces the least amount of morphologic artifact to the specimen ([131] , [132]). In some instances, no marrow can be aspirated (dry tap). In these cases, it is essential to make smears from material at the tip of the needle and also to make touch preparations from the biopsy, as outlined below, to allow cytologic examination of the bone marrow elements ([133] , [134]).

The bone marrow biopsy may be performed using the same skin incision if the aspirate has been performed in the iliac crest area. A separate biopsy needle that is slightly larger than the needle used for aspiration may be used, or the same needle that was used for the bone marrow aspiration may be reused. Care must be taken to reposition the needle biopsy site away from the area where the aspiration was performed to avoid collection of a specimen with extensive artifact induced by the aspiration procedure. The biopsy needle may require more pressure to enter the bone because of the larger bore size. Once the needle is in place in the bone, the stylet may be inserted to give an approximation of the size of the bone core within the needle. The biopsy needle is rotated and gently rocked to free the biopsy from the surrounding bone and then advanced slightly farther. The biopsy is then removed from the bone by withdrawing the needle. The biopsy is expressed from the needle by the stylet. Touch preparations of the bone biopsy should be made, particularly if no aspirate was obtained, to allow cytologic examination of the bone marrow elements. The bony core is then fixed and processed for histologic examination.

Once the biopsy is completed, manual pressure is applied to the site for several minutes to achieve hemostasis. The site is then bandaged and the patient instructed to remain recumbent so as to apply further pressure for approximately 60 minutes. If a patient is thrombocytopenic, pressure bandages should be applied and the site checked frequently for prolonged bleeding.

Staining and Evaluation of Bone Marrow Aspirates and Touch Preparations

The bone marrow aspirate or touch preparation slides are stained with either Wright or May-Grunwald-Giemsa stains, similar to the procedure for blood smears. These stains allow excellent morphologic detail and allow differential counts to be performed ([135]). Unstained smears should be retained for possible special stains if indicated ([129]).

Evaluation of bone marrow aspirates gives little information about the total cellularity of the bone marrow because of fluctuations in cell counts induced by peripheral blood contamination of the bone marrow specimen ([129] , [136]). An overall impression of the cellularity may be given (i.e., cellular or paucicellular). More accurate evaluation of bone marrow cellularity requires examination of a bone marrow biopsy section, although the biopsy represents a tiny fraction of the total marrow and may also be subject to sampling error ([137]). The stained aspirate smear will have a central zone of dark marrow particles surrounded by a thinner area of dispersed bone marrow cells and red cells. Low-power examination allows evaluation of the adequacy of cellularity and of the presence of megakaryocytes. Tumor cells or granulomas may also be seen by scanning the aspirate smear at low power.

The aspirate smear allows cytologic examination of the bone marrow cells. A minimum of 500 nucleated cells should be evaluated under oil immersion magnification. Only intact cells are evaluated; all bare nuclei are excluded. Counting is performed in an area where few bare nuclei are present and the cells are not overlapping, found in clusters, or artifactually distorted. This is usually in the dispersed cell zone adjacent to the spicule. It should be noted that spicules may be absent in pediatric marrows, and marrow will appear as a uniform dispersion of cells. Reference ranges for the percentage of bone marrow cell types vary widely between laboratories and are used only as guides for what is to be expected in normal bone marrow samples ([129], [136]). Results of differential counts from sternal bone marrow aspirate smears obtained from 12 healthy men at the University of Utah are presented in Table 1.5 as an example of bone marrow differential count reference ranges. The proportions of each cell type and maturational sequence are determined from the differential counts. In addition, the myeloid to erythroid ratio may be calculated.

TABLE 1.5. Differential Counts of Bone Marrow Aspirates from 12 Healthy Men

	Mean (%)	Observed Range (%)	95% Confidence (%)
Neutrophilic series (total)	53.6	49.2–65.0	33.6–73.6
Myeloblast	0.9	0.2–1.5	0.1–1.7
Promyelocyte	3.3	2.1–4.1	1.9–4.7
Myelocyte	12.7	8.2–15.7	8.5–16.9
Metamyelocyte	15.9	9.6–24.6	7.1–24.7
Band	12.4	9.5–15.3	9.4–15.4
Segmented	7.4	6.0–12.0	3.8–11.0
Eosinophilic series (total)	3.1	1.2–5.3	1.1–5.2
Myelocyte	0.8	0.2–1.3	0.2–1.4
Metamyelocyte	1.2	0.4–2.2	0.2–2.2
Band	0.9	0.2–2.4	0–2.7
Segmented	0.5	0–1.3	0–1.1
Basophilic and mast cells	<0.1	0–0.2	—
Erythrocytic series (total)	25.6	18.4–33.8	15.0–36.2
Pronormoblasts	0.6	0.2–1.3	0.1–1.1
Basophilic	1.4	0.5–2.4	0.4–2.4
Polychromatophilic	21.6	17.9–29.2	13.1–30.1
Orthochromatic	2.0	0.4–4.6	0.3–3.7
Lymphocytes	16.2	11.1–23.2	8.6–23.8
Plasma cells	1.3	0.4–3.9	0–3.5
Monocytes	0.3	0–0.8	0–0.6
Megakaryocytes	<0.1	0–0.4	—
Reticulum cells	0.3	0–0.9	0–0.8
Myeloid to erythroid ratio	2.3	1.5–3.3	1.1–3.5

Differences in cell differential results among infants, children, and adults exist (Table 1.6) ([129], [138]). In general, lymphocytes are more commonly seen in the marrow of children, especially those younger than 4 years of age, where they may compose up to 40% of the marrow cellularity ([139], [140] and [141]). Plasma cells are rare in the marrow of infants and children. Lymphocytes are much less numerous in adult bone marrows, usually making up less than 20% of adult marrow cellularity. Lymphocyte and plasma cell counts in adults tend to be quite variable, perhaps reflecting the tendency of these cells to be unevenly distributed in the bone marrow of adults. Often, lymphoid cells are found in nodular aggregates in older adults, and plasma cells tend to be associated with blood vessels ([142], [143]).

TABLE 1.6. Changes in Differential Counts of Bone Marrow with Age

		Birth	1 Mo–1 Yr	1–4 Yr	4–12 Yr	Adult
Neutrophilic series	Mean (%)	60	33	50	52	57
	95% limits	42–78	17–47	32–68	35–69	39–79
Eosinophilic series	Mean (%)	3	3	6	3	3
	95% limits	1–5	1–5	2–10	1–5	1–5
Lymphocytes	Mean (%)	14	47	22	18	17
	95% limits	3–25	34–63	8–36	12–28	10–24
Erythrocytic	Mean (%)	14	8	19	21	0
	95% limits	2–28	2–16	11–27	11–31	10–30
Myeloid to erythroid ratio	Mean	4.3	4.0	2.6	2.5	2.6

The means and 95% confidence limits in this table were calculated by combining data published in Osgood, Seaman. The cellular composition of bone marrow as obtained by sternal puncture. Physiol Rev 1939;24:105–114; with the data in Table 1.5.

During the first month of life, erythroid cells are prominent because of high levels of erythropoietin ([129], [144]); thereafter, the erythroid cells make up 10 to 40% of the marrow cells. Relatively few early erythroid precursors (normoblasts) are usually seen, and more mature forms predominate. Erythroid cells should be examined for abnormalities in morphology as well as iron content because these parameters are often deranged in pathologic states. The myeloid cells are usually the predominant element within the bone marrow, and more mature cells are most numerous. Increased numbers of immature myeloid cells usually indicate a disease process. Children tend to have higher numbers of eosinophils and eosinophilic precursor cells than do adults, although many medications may increase the bone marrow eosinophil count. Megakaryocytes constitute the least abundant cell type seen in the bone marrow, usually making up less than 1% of the cells.

In addition to the hematopoietic cells mentioned above, a variety of other cells may be seen in bone marrow aspirates in varying proportions. These include macrophages, mast cells, stromal cells, osteoblasts, osteoclasts, and fat cells. Normally, these cells make up less than 1% of the total marrow cellularity; however, they may be increased in a variety of reactive and pathologic processes. Aspirate smears are excellent for evaluation of macrophage hemophagocytosis ([145]) or storage disorders ([129]). Osteoclasts and osteoblasts are most often seen in aspirates obtained from children in whom active bony remodeling is taking place and are distinctly abnormal when seen in adult aspirates ([129]).

Examination of Bone Marrow Histologic Sections

Bone marrow core biopsies and the clot obtained from the aspiration procedure are usually fixed in formalin or in a coagulative fixative, such as B5. The bony core will require decalcification before histologic processing. The fixed materials are processed and embedded in paraffin or plastic, and sections are made for examination. Plastic embedding allows preparation of very thin (2-µm) sections that allow optimal morphologic assessment but requires additional technical expertise and longer

processing times (48 hours), making them impractical for most laboratories ([146]). Well-prepared, thin (3- to 4-µm) sections from paraffin-embedded materials are usually sufficient for morphologic assessment and may be prepared using routine histologic methods. The bone marrow biopsy and clot sections are stained with either hematoxylin and eosin or Giemsa stains for morphologic examination.

Bone marrow biopsies are useful in evaluation of the cellularity of the bone marrow sampled. Several caveats must be kept in mind when assessing cellularity. Studies show variations in cellularity even within the same biopsy site ([137]) as well as between different anatomic sites. However, comparisons of the relative proportions of myeloid, erythroid, and megakaryocytic cells appear to be constant even in widely separated biopsy sites ([147] , [148]). In older patients, the subcortical area is often hypocellular, and care must be taken to obtain a large enough biopsy to allow evaluation of the marrow away from this area ([137]). The bone marrow biopsy section provides the best representation of the bone marrow and its anatomic relationships. The clot section, which is prepared from the bone marrow aspirate material, has a degree of inherent artifact because the bone marrow is removed from its normal relationship with bone, blood vessels, and other stromal elements. In particular, cellularity estimations may be falsely elevated by collapse of the normal stromal network ([129]).

In addition to providing information about the anatomic distribution and relationships of hematopoietic cells, the bone marrow biopsy is useful for evaluation of focal infiltrative processes such as carcinoma, lymphoma, other tumors, granulomatous inflammation, and fibrosis ([149] , [150] and [151]). Occasionally, the marrow is so involved with an infiltrative process that no aspiration can be obtained (dry tap), and the biopsy provides the only diagnostic material ([133]). In addition, evaluation of other bone elements, such as bony trabeculae, blood vessels, and stroma, requires a biopsy specimen.

SPECIAL STAINS

Several special stains may be performed on peripheral blood smears, bone marrow aspirate smears, bone marrow touch preparations, and bone marrow biopsy materials, providing additional information about the cell lineage beyond what is obtained by standard staining with Romanowsky or hematoxylin and eosin stains. Special stains generally fall into two categories: cytochemical stains that use enzymatic reactions by the cell to impart staining and immunocytochemical stains that stain cell-specific antigen epitopes. These stains are particularly useful in characterization of primary hematologic or metastatic malignancies.

Cytochemical Stains

Cytochemical stains are extremely useful in the diagnosis and classification of acute leukemias. They allow correct identification of myeloid and lymphoid acute leukemias ([152]), as well as providing the basis for subclassification of the acute myeloid leukemias by the French-American-British criteria and the World Health Organization classification ([153] , [154] and [155]). Cytochemical stains are usually performed on peripheral blood films, bone marrow aspirates, or touch preparations made from bone marrow, lymph node, or other tissue biopsies. Best results are obtained by using freshly obtained materials; however, some reactions may be carried out on materials that are several years old.

MYELOPEROXIDASE Primary granules of neutrophils and secondary granules of eosinophils contain myeloperoxidase ([156]). Monocytic lysosomal granules are faintly positive ([157]). Lymphocytes and nucleated red blood cells lack the enzyme. Originally, the stain depended on oxidation of benzidine by hydrogen peroxide ([158]); however, because benzidine is a potential carcinogen, alternative substrates have been identified. Suitable alternatives are 3-amino-9-ethylcarbazole ([159]) or 4-chloro-1-naphthol ([160]), which are oxidized by the myeloperoxidase to form a brown-colored precipitate in myeloperoxidase-containing cells. The myeloperoxidase enzyme is sensitive to light, and smears should be stained immediately or sheltered from light. Enzymatic activity in cells may diminish over time, so the stain should not be performed in blood smears older than 3 weeks. Permount coverslip mounting medium (Fisher Scientific, Pittsburgh, PA) may cause fading of the stain, and its use should be avoided. Myeloperoxidase is also sensitive to heat and methanol treatment. Erythroid cells may stain for peroxidase after methanol treatment due to a nonenzymatic interaction between the staining reagents and hemoglobin. This is called the *pseudoperoxidase* or *Lepehne reaction*.
SUDAN BLACK B Sudan black B stains intracellular phospholipids and other lipids. The pattern of staining closely parallels the myeloperoxidase reaction, with positive staining of granulocytic cells and eosinophils, weak monocytic staining, and no staining of lymphocytes, although some positivity may be seen in azurophilic granules of lymphoblasts ([161]). Sudan black B has an advantage over myeloperoxidase in that it may be used to stain older blood or bone marrow smears, and there is little fading of the stain over time ([162]).
SPECIFIC (NAPHTHOL AS-D CHLOROACETATE) ESTERASE The specific (naphthol AS-D chloroacetate) esterase stain, also called the *Leder stain*, is used to identify cells of the granulocytic series ([163] , [164]). It fails to stain lymphocytes, and monocytes usually do not stain. Because of enzymatic stability in formalin-fixed, paraffin-embedded tissues, this stain is extremely useful for identifying granulocytes and mast cells in tissue sections ([163]). Thus, it is particularly helpful in diagnosis of extramedullary myeloid tumors (granulocytic sarcoma, chloroma) composed of myeloid blasts found in tissues ([165]). The esterase enzyme within the cell hydrolyzes the naphthol AS-D chloroacetate substrate ([166]). This reaction product is then coupled to a diazo salt to form a bright red-pink reaction product at the site of enzymatic activity. The enzyme activity is inhibited by the presence of mercury, acid solutions, heat, and iodine. These may give rise to false-negative staining results.
NONSPECIFIC (ALPHA-NAPHTHYL BUTYRATE OR ALPHA-NAPHTHYL ACETATE) ESTERASES Nonspecific (alpha-naphthyl butyrate or alpha-naphthyl acetate) esterase stains are used to identify monocytic cells but do not stain granulocytes or eosinophils ([166] , [167]). Mature T lymphocytes stain with a characteristic focal, dotlike pattern. In addition to monocytes, the stain reacts with macrophages, histiocytes, megakaryocytes, and some carcinomas. The alpha-naphthyl butyrate stain is considered to be more specific, although slightly less sensitive, than the alpha-naphthyl acetate stain ([167]). Differential staining with the different esterases is seen in megakaryoblasts, which do not stain with the alpha-naphthyl butyrate but stain with the alpha-naphthyl acetate substrate ([168]).
TERMINAL DEOXYNUCLEOTIDYL TRANSFERASE Terminal deoxynucleotidyl transferase (TdT) is an intranuclear enzyme that catalyzes the addition of deoxynucleotide triphosphates to the 3'-hydroxyl ends of oligonucleotides or polydeoxynucleotides without need for a template strand ([169]). TdT is found normally in the nucleus of thymocytes and immature lymphoid cells within the bone marrow but is not found in mature lymphocytes. Hence, it is a useful marker in identifying acute lymphoblastic leukemias and lymphoblastic lymphomas ([169] , [170]). TdT activity is found in approximately 90% of acute lymphoblastic leukemias as well as in a small subset of acute myelogenous leukemias ([171] , [172] and [173]). TdT levels may be measured biochemically ([174]) and by cytochemical staining with an immunofluorescent technique ([175]), by flow cytometry after permeabilization of cells ([176] , [177]), or by immunohistochemical methods ([178]). Indirect immunofluorescent staining is very sensitive and may be applied to air-dried samples several weeks after collection ([179]). Immunohistochemical methods of TdT detection may be used on frozen ([180]) and paraffin-embedded tissue sections ([181]). A panel of myeloperoxidase (or Sudan black B), alpha-naphthyl butyrate esterase (or double esterase stain), and TdT staining is often used to characterize acute leukemias. More precise lineage assignment may be provided by flow cytometric analysis if fresh bone marrow or peripheral blood is available ([182]). However, because the French-American-British subclassification of acute myelogenous leukemias and the World Health Organization classification of the acute myelogenous leukemias–not otherwise specified are based on the cytochemical staining pattern of the blasts ([153] , [154] and [155]), these stains are usually performed even when flow cytometric analysis is performed. In addition, cytochemical stains may be retrospectively performed on bone marrow or peripheral blood smears collected at the time of bone marrow examination when a diagnosis of acute leukemia was not suspected and fresh material was not collected for flow cytometric analysis.
LEUKOCYTE ALKALINE PHOSPHATASE Alkaline phosphatase activity is found in the cytoplasm of neutrophils, osteoblasts, vascular endothelial cells, and some lymphocytes. The alkaline phosphatase level of peripheral blood neutrophils is quantitated by the leukocyte alkaline phosphatase (LAP) score and is useful as a screening test to differentiate chronic myelogenous leukemia from leukemoid reactions and other myeloproliferative disorders ([183]). The LAP score is usually performed using the Kaplow procedure ([184]). This method uses a naphthol AS-BI phosphate as the substrate, which is coupled to fast violet B salt by the enzyme to produce a bright red reaction product that is visualized over neutrophils. The LAP score is determined by evaluation of the staining intensity (ranging from 0 to 4+) of 100 counted neutrophils or bands. Normal LAP scores range from 15 to 130, but there may be variation in these ranges between laboratories. Many different disease states may cause elevation or depression of the LAP score (Table 1.7). Patients with chronic myelogenous leukemia have low LAP scores (usually between 0 and 13). Paroxysmal nocturnal hemoglobinuria and some myelodysplastic syndromes may also be characterized by low LAP scores. Leukemoid reactions in response to infection and other myeloproliferative disorders (myelofibrosis with myeloid metaplasia and polycythemia vera) often have an elevated LAP score ([183]). There is rapid loss of alkaline phosphatase activity in samples drawn in EDTA anti-coagulant ([185]). The test is optimally performed on fresh capillary blood fingerstick smears or on blood anticoagulated with heparin and should be performed within 48 hours after collection of the sample. The blood smears may be held in the freezer for 2 to 3 weeks with little loss of activity.

TABLE 1.7. Conditions Associated with Abnormal Leukocyte Alkaline Phosphatase (LAP) Scores

Low LAP Score (<15)
CML
Paroxysmal nocturnal hemoglobinuria

	Hematologic neoplasms (rare)
	Myelodysplastic syndromes
	Rare infections or toxic exposures
High LAP score (>130)	
	Infections
	Growth factor therapy
	Myeloproliferative disorders other than CML
	Inflammatory disorders
	Pregnancy, oral contraceptives
	Stress
	Drugs (lithium, corticosteroids, estrogen)

CML, chronic myelogenous leukemia.

ACID PHOSPHATASE Acid phosphatase is found in all hematopoietic cells, but the highest levels are found in macrophages and osteoclasts ([186]). A localized dotlike pattern is seen in many T lymphoblasts, but this staining pattern is not reliable. The tartrate-resistant acid phosphatase (TRAP) is an isoenzyme of acid phosphatase that is found in high levels in the cells of hairy cell leukemia ([187]) and osteoclasts. Several methods of measuring TRAP activity have been described, but one using naphthol AS-BI phosphoric acid coupled to fast garnet GBC is reliable and reproducible ([188]). Not all cases of hairy cell leukemia stain for TRAP, and staining intensity may be variable. Positive TRAP staining may also be seen in some activated T lymphocytes, macrophages, and some histiocytes (such as Gaucher cells) ([189]).

PERIODIC ACID-SCHIFF The periodic acid-Schiff (PAS) stain detects intracellular glycogen and neutral mucopolysaccharides, which are found in variable quantities in most hematopoietic cells ([190]). PAS staining is seen in blasts of both acute lymphoblastic and acute myelogenous leukemias, although there is great variability between cases ([152] , [160] , [198]). Erythroleukemias demonstrate an intense diffuse cytoplasmic positivity with PAS, which may be helpful in diagnosis ([191]). In addition, PAS staining is very useful in demonstrating the abnormal glucocerebrosidase accumulation in Gaucher disease.

IRON Cellular iron is found as either ferritin or hemosiderin. It is identified in cells by the Perls' or Prussian blue reaction, in which ionic iron reacts with acid ferrocyanide to impart a blue color ([192]). The stain is used to identify iron in nucleated red blood cells (sideroblastic iron) and histiocytes (reticuloendothelial iron) or to identify Pappenheimer bodies in erythrocytes. Normally, red cell precursors contain one or more small (<1 μm in diameter) blue granules in 20 to 50% of the cells. When increased numbers of these granules surround at least two-thirds of the nucleus of the red cell precursor, the cell is called a *ringed sideroblast* ([155]). The stain is best used on bone marrow aspirate smears but can also be used on blood films and aspirate clot tissue sections. Decalcification of the bone marrow core biopsy may lead to loss of iron from the cells, leading to a false impression of low iron.

TOLUIDINE BLUE Toluidine blue specifically marks basophils and mast cells by reacting with the acid mucopolysaccharides in the cell granules to form metachromatic complexes ([166]). Malignant mast cells or basophils may have low levels of acid mucopolysaccharides and may not react with this stain ([193]).

Immunocytochemical Stains

Immunocytochemical staining is based on the use of an antibody that recognizes a specific antigenic epitope on a cell. There is a high level of specificity with immunologically based methods, allowing for more accurate diagnoses. In general, these types of stains may be applied to blood smears, bone marrow aspirates, cellular suspensions, or tissue sections. Not all antibody preparations are equally effective on all types of specimens, and staining procedures may vary dependent on the specimen type. A wide variety of antibodies specific to hematopoietic cellular antigens is available commercially. Some of the newer antibodies have replaced classical cytochemical stains and may be useful on older or fixed specimens.

Immunocytochemical staining of fresh blood or bone marrow cell suspensions and analysis by flow cytometry are becoming increasingly common in clinical laboratories ([194] , [195]). The flow cytometer detects both light scatter data and the presence of specific fluorochrome-labeled antibodies that have bound to the cell surface. Use of different fluorochromes can allow more than one antibody to be studied simultaneously on the same cell by means of different excitation wavelengths. The study of these cell surface markers allows rapid and accurate analysis of lymphomas and leukemias, enumeration of T-cell subsets, and identification of tumor cells. In addition, recent advances have allowed detection of intracytoplasmic or nuclear antigens, such as myeloperoxidase and TdT, by flow cytometric analysis ([195] , [196]). In many cases, particularly in the acute leukemias, the flow cytometric analysis of an acute leukemia provides important prognostic information that is not available through cytochemical staining ([195] , [197] , [198]). Clinical and technical aspects of flow cytometric analysis of hematologic tumors are covered in detail in Chapter 3.

Immunohistochemical staining is the use of specific antibody probes on tissue sections or smears of blood and bone marrow. This allows the localization of a specific antigenic epitope to the cell surface, cytoplasm, or nucleus. The antigen binding may then be detected by immunofluorescence, which requires a special fluorescence microscope, or by enzymatic formation of a colored reaction product linked to the antigen–antibody complex. Immunoenzymatic staining techniques include immunoperoxidase, immunoalkaline phosphatase, and avidin-biotin techniques ([199]). These procedures allow study of the specimen with standard light microscopy and provide a permanent record of staining that may be reexamined. In the past, the repertoire of antibodies available for use on paraffin-embedded tissues was limited, and many antibodies required frozen sections of fresh tissues to be used. Over time, however, there has been a large increase in the number of antibodies that can be used on fixed and processed tissues, so frozen section analysis has limited usefulness in light of the severe drawbacks of frozen section morphology ([200]). Recently, several automated immunostaining instruments have become available that allow highly reproducible results and require less technician time and expertise ([201] , [202]).

Antibodies are routinely available that allow immunophenotyping of malignant lymphomas and leukemias in paraffin-embedded tissues and aid in recognition of malignant lymphoid infiltrates that may be confused with reactive processes ([202] , [203]). Many commonly used cytochemical stains, including myeloperoxidase ([204]), TdT ([196]), and TRAP ([205]), are available as immunohistochemical stains that may then be applied to tissue sections as needed.

OTHER LABORATORY STUDIES

Cytogenetic Analysis

Many hematologic malignancies and premalignant conditions are associated with specific cytogenetic changes ([206] , [207] , [208] , [209] and [210]). These include distinctive changes in chromosome number, translocations, and inversions of genetic material. These chromosomal changes are often associated with activation or increased transcription of oncogenes and may contribute to acquisition of a malignant phenotype ([209] , [211]). Cytogenetic analysis has become important in diagnosing hematologic disorders, identifying specific prognostic subgroups, and monitoring for progression of disease or residual disease after therapy and is integral to the most current classification of hematologic malignancies, such as the World Health Organization classification ([155] , [212] , [213]). Both standard chromosomal preparations and fluorescent-labeled *in situ* hybridization techniques may be used for cytogenetic analysis of chromosomal changes ([210] , [214] , [215]). Further details about cytogenetic techniques and analysis are provided in Chapter 4.

Molecular Genetics

In addition to standard morphologic analysis and cytogenetics, technology has been developed that allows analysis of molecular changes in hematologic malignancies ([212] , [216] , [217]). By use of Southern blot and polymerase chain reaction (PCR) techniques, hematopoietic proliferations may be studied for genetic alterations associated with development of malignancy ([217] , [218]). Molecular genetic analysis was initially used to identify monoclonality in lymphoid neoplasms by identifying either immunoglobulin (B-cell) or T-cell receptor gene rearrangements ([219] , [220]). This finding is extremely useful in classification of lymphoproliferative disorders that may be difficult to diagnose on morphologic grounds alone or that lack specific phenotypic markers ([221]). In the past few years, there has been an explosion in the use of molecular techniques to detect translocations that previously had been detected only by conventional cytogenetics. Common tests include the *bcr-abl* translocations seen in chronic myelogenous leukemia and acute leukemia ([222] , [223] , [224] and [225]), *bcl*-2 translocations characteristic of follicular lymphomas ([226] , [227] and [228]), and the t(15;17) translocation associated with promyelocytic leukemia ([229] , [230]). As molecular characterization and genetic profiling of specific

hematologic disorders expand, such as through microarray analysis ([231]), it may be anticipated that more PCR and molecular tests will be developed. Molecular studies have an advantage over conventional morphologic and cytogenetic analyses in that they may detect very small populations of malignant cells (as few as 1 to 5% of the cells in a sample) and can lead to more rapid test completion (especially with PCR-based testing) ([230] , [234] , [235]). Molecular tests are most useful when a specific entity is being tested for or in monitoring residual disease as they do not provide effective screening capability for genetic alterations, as do conventional cytogenetics ([217] , [232] , [233]).

This degree of sensitivity makes molecular testing, particularly by PCR or *in situ* hybridization, very attractive for the purpose of monitoring for tumor persistence or recurrence after therapy. Previously, molecular genetic studies required collection of fresh or frozen diagnostic material; however, many of the newer assays can make use of formalin-fixed materials with sensitivity similar to that of fresh or frozen materials ([234] , [235]). This allows analysis to be performed on a wider range of cases, including archival materials. The topic of molecular genetics is covered in further detail in Chapter 5.

Electron Microscopy

The electron microscope allows examination of ultrastructural details of a cell. In the past, electron microscopy was used as a research tool and, occasionally, as a diagnostic tool for difficult hematologic diagnoses. However, with the advent of increasing numbers of specific immunocytochemical stains, the use of the electron microscope as a diagnostic tool for hematopathologic processes has been largely discontinued.

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate (ESR) is a common but nonspecific test that is often used as an indicator of active disease. It reflects the tendency of red blood cells to settle more rapidly in the face of some disease states, usually because of increases in plasma fibrinogen, immunoglobulins, and other acute-phase reaction proteins. In addition, changes in red cell shape or numbers may affect the ESR. Sickle cells and polycythemia tend to decrease the ESR, whereas anemia may increase it. ESR also increases with age in otherwise healthy people (although it tends to fall in adults older than the age of 75) ([236] , [237]) and tends to be higher in women ([237]). People with liver diseases, carcinomas, or other serious diseases may have a normal to low ESR because of an inability to produce the acute-phase proteins.

A common cause of ESR elevation is infection, but monoclonal gammopathy must be ruled out in patients who have a persistent, unexplained elevation in ESR. Elevated ESRs are also seen with pregnancy, malignancies, collagen vascular diseases, rheumatic heart disease, and other chronic disease states, including human immunodeficiency virus infection ([238]). The ESR is a poor screening test in asymptomatic individuals, detecting elevations in 4 to 8% of adults and, hence, should not be used to screen asymptomatic people for disease ([239]). The test is probably best used in the clinical scenario of a patient with vague complaints to aid in the clinical decision to undergo further testing ([240]) or as a tool to follow the course of a disease state. ESR is most commonly used for monitoring the clinical course of temporal arteritis, rheumatoid arthritis, or polymyalgia rheumatica ([241] , [242]). It may also be useful for monitoring for relapse of Hodgkin's disease or non-Hodgkin's lymphomas ([243]).

The ESR is measured by the Westergren or Wintrobe method or by a modification of these tests ([244]). Both are measured in millimeters per hour, but the normal values for each method vary because of differences in tube length and shape. Both methods require correction for patient anemia. Several technical variations to the method of ESR determination have been introduced, including micromethods, sedimentation at a 45-degree angle, and the zeta sedimentation rate. The zeta sedimentation rate measures erythrocyte packing in four 45-second cycles of dispersion and compaction in capillary tubes. This requires a special instrument, the Zetafuge (Coulter Electronics, Hisleah, FL), but gives reproducible results on very small amounts of blood that are not affected by anemia ([245]).

Plasma and Blood Viscosity

Plasma viscosity measurements are advocated by some authors as being superior to ESR measurements for monitoring disease states, particularly in autoimmune diseases and diseases characterized by the secretion of large amounts of immunoglobulin into the plasma (such as plasma cell dyscrasias) ([246] , [247]). Plasma viscosity measurements have the advantage of no red cell influences on the value obtained and yield a narrower reference range of normal values than observed with ESR ([248]). However, plasma viscosity is used more rarely than ESR, probably reflecting clinical familiarity with the latter test. Like ESR, plasma viscosity may increase with age ([236]). Direct measurement of acute-phase proteins, such as C-reactive protein, may also be used to monitor the course of inflammatory diseases ([249]). However, these tests are usually more expensive than ESR determinations and may not provide sufficient additional clinical information to justify the added expense ([250]).

Whole blood viscosity measurements are of limited clinical use because the measured blood viscosity may have little bearing on the viscosity of the blood in the circulation. Increased blood viscosity may contribute to the morbidity and mortality of patients with sickle cell disease, polycythemia, and ischemic vascular disease.

Total Quantity of Blood

In most cases, the total number of erythrocytes is closely related to the red cell concentration of the blood or Hct. However, blood volume may not reflect erythrocyte concentration, including immediately after severe hemorrhage, severe dehydration, or over-hydration. To accurately assess the blood volume in these patients, plasma volume or red cell volume must be determined ([251]). The plasma volume is measured by dilution methods. A substance that is confined to the intravascular plasma compartment, such as Evans blue dye ([252]), ^{131}I-labeled albumin, or radioactive indium-labeled transferrin, is injected and the volume of distribution calculated from the degree of dilution of the injected substance over 15 to 30 minutes. Radiolabeled albumin is the most commonly used plasma label, but corrections must be made because the label is gradually removed from the circulation into the extravascular space, leading to errors of 10% or more in plasma volume determinations ([253]).

Total red cell volume is calculated by the Ashby technique, which uses radiolabeled red blood cells. A number of radioisotopes may be used, but ^{51}Cr and ^{99m}Tc are the most common ([173] , [254]). The red cell volume is then calculated by the dilution of the labeled cells over time using the following formula.

$$\text{Red cell volume} = \text{cpm of isotope injected} / \text{cpm/ml red cell concentration per unit volume in sample}$$

Usually, the measurements are made after a 15-minute interval, although longer periods may be needed with high blood viscosity due to high Hcts to ensure complete labeled cell mixing. Total red cell volume measurements must be corrected with splenic enlargement secondary to sequestration of the labeled cells within this organ. Red cell volume may also be calculated from the total plasma volume and measured Hct by means of the following equation.

$$\text{Red cell volume} = \text{Hct} \times \text{plasma volume} / 100 - \text{Hct}$$

Total plasma volume may be useful in monitoring fluid and blood replacement. Red cell volume measurements are used to document true polycythemia ([255] , [256]), although some authors advocate the use of erythropoietin levels and red cell colony growth as less invasive surrogate tests for red cell volume or red cell mass measurements ([257]). Total blood volume may be calculated from the sum of total red cell volume and plasma volume measurements.

CELL MEMBRANE AND PROTEINS

The basic structure of the eukaryotic cell membrane is a phospholipid bilayer. Phospholipids are amphipathic (i.e., they consist of hydrophobic and polar (hydrophilic) groups). In the bilayer, the hydrophobic fatty chains interact facing each other, whereas the polar head groups face the outside of the cell (for the outer layer) or the inside of the cell (for the inner layer).

The cell membrane contains two groups of proteins: *integral* o *r intrinsic*, which interact directly with the hydrophobic side chains of the phospholipids (they can be removed only by detergents) and *peripheral* or *extrinsic*, which are attached indirectly by interactions with the integral proteins or the polar groups of the phospholipids (they can be removed by high-salt solutions). Integral proteins are embedded within the cell membrane in a variety of ways listed below.

Type I Proteins

These proteins are oriented with the -NH_2 terminal outside the cell and the COOH terminal intracellularly and pass only once through the phospholipid bilayer. The transmembrane region of the protein contains 20 to 25 hydrophobic amino acids that interact with the hydrophobic tails of the membrane lipids.

Type II Proteins

These proteins have the opposite orientation to type I (i.e., their -NH_2 terminal is inside the cell, whereas the -COOH terminal faces the outside).

Glycosylphosphatidylinositol Anchor

Some integral proteins interact with the membrane via a glycosylphosphatidylinositol (GPI) anchor that is attached by an amide bond of the protein (see Chapter 18).

Type III Proteins (Multispan Proteins)

These proteins cross the phospholipid bilayer several times. Those having four transmembrane regions are of two different families: (a) the tetraspan (TM4) superfamily (SF) (i.e., CD9, CD37, CD53, CD63, CD81, and CD82) and (b) the “membrane-spanning” four domain (MS4A) family (i.e., CD20). Other proteins cross the membrane seven times [i.e., CD97, CD128 [interleukin (IL)-8R], the Duffy antigen (CD234), G protein–coupled receptors, chemokine receptors, and so forth]. The multidrug resistance protein (CD243) crosses the membrane 12 times.

PROTEIN FAMILIES

In most of the leukocyte antigens, there are amino-acid sequences that are similar to those of other proteins. In 1983, Dayhof introduced the term *superfamily* (*SF*) for proteins with 50% or less sequence similarity and the term *family* for more than 50% identity. Amino acid homologies among various proteins sometimes are clustered in short sequences that form discrete structural units known as *domains*. Usually, a domain is defined by evidence of secondary and tertiary structure and in most cases it is encoded by a single exon. The best-known domains are those of the immunoglobulin (Ig) molecule, the complement control protein (CCP), epidermal growth factor (EGF), fibronectin (FN) type III, cytokine receptor, and C-type lectin. Extracellular regions of proteins may have a single domain, as in the case of Thy-1 (CD90) antigen, the smallest member of the IgSF, or several domains, as with the C3 receptor (CD35), which contains 30 CCP domains. In some cases, all domains are of the same type, but in others, there is a mixture of domains [i.e., the L-selectin (CD62L) contains C-type, EGF, and CCP domains]. If the segment of a protein is not a domain, then the term *repeat* is used. Smaller structures, which are still expected to form a folded unit, are called *motifs*.

Immunoglobulin Superfamily

The IgSF was the first to be identified and is the largest group, with more than 100 members. The identities are clustered in sequences corresponding to the Ig fold. The *Ig fold* is the Ig domain that comprises two ß-pleated sheets held together by a disulfide bond. The Ig molecule has the *C domain* (found in the constant regions of the Ig heavy and light chains), which has two ß-pleated sheets, and the *V domain* (found in the variable regions). There are two IgSF C-domains, C-1 and C-2. The C-1 is similar to the C-domains of the Ig molecule both for its length between the cysteines of the disulfide bond and the organization of the ß sheets. The C-2 has the same length as the C-domains of the Ig molecule but has a V-like pattern in the ß strands. The strands of Ig domains are defined by the letters A, B, C, D, E, F, G, and A', C', and C?. The C-1 lacks A' strand and C-2 lacks A' and D. Analysis of the ß sheet and loop topology of Ig domains with less than 25% residue identity separates several new types (i.e., c-, h-, s-, and v-).

C-Type Lectin Superfamily (CL Domain)

Members of this family are called *C-type* because of their Ca $^{2+}$-dependent carbohydrate binding (hence "C"). A substantial number of members in this family are type II proteins. All three selectins (E, P, and L) and CD23 belong to this SF. In addition to the C-binding domain, the selectins contain CCP repeats. The C-domain contains a network of anti-parallel ß strands and 2-amphipathic a helices, which flank the ß secondary structure.

Important members of this family are the selectins (see CD62), some natural killer (NK) cell receptors (NKG2), the eosinophilic major basic protein (member of the "C-type" SF but lacks the Ca $^{2+}$-binding residues).

Cytokine Receptor Superfamily (Cytokine-Binding Domain)

Type I: This SF includes the receptors for IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-10, granulocyte-macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor, and erythropoietin. The cytokine receptors contain four kinds of domains: IgSF, FN type III, cytokine receptor, and CCP. FN type III is composed of two ß sheets packed face to face, folded like the IgSF domains. The cytokine receptor domain has four cysteines and the W–S–X–W–S motif. The CCP structure has two antiparallel ß sheets and a short section of triple-stranded ß sheets.

Type II: Includes the receptors for interferon (IFN)-a, -ß, and -?.

Tumor Necrosis Factor/Nerve Growth Factor Superfamily (TN Domain)

The TN domain comprises two sheets of eight antiparallel strands forming a "ß-jellyroll." Members of the family are CD70 (CD27L), CD153 (CD30L), CD154 (CD40L), CD178 [CD95L or Fas ligand (FasL)], tumor necrosis factor (TNF)-a, and lymphotoxin-ß.

Tumor Necrosis Factor/Nerve Growth Factor Receptor Superfamily or Type III (TR Domain)

The extracellular region of these proteins contains a series of cysteine-rich repeats, or *TR domains*. These sequences are encoded by more than one exon. Members include CD27, CD30, CD40, CD95 (Fas), CD120a (TNFRI), and CD120b (TNFRII). The TR domain has two double-stranded ß sheets. It binds the TN domain. A trimer of TN domain binds three TNFR molecules.

Tetraspan Transmembrane Superfamily

The TM4 SF traverses the membrane four times with both the -NH $_2$ and -COOH termini inside the cell. Members include CD9, CD37, CD53, CD63, CD81, and CD82. CD20, which also crosses the membrane four times, does not belong to this group.

Integrin Superfamily

Members are heterodimers of an a- and a ß-chain (see CD29, CD41, CD49, CD61, and so forth).

Scavenger Receptor Superfamily (SR Domain)

Members of this SF are CD5, CD6, and CD36. They have three similar domains in the extracellular region.

Scavenger receptors are distinguished into class A and B, each divided into types I and II. The type A macrophage scavenger receptor and CD36 (class B-I) belong to the family of multiligand lipoprotein receptors, which recognize oxidized low-density lipoprotein. Both classes are also receptors for advanced glycation end products (AGE), which are important physiologically and are involved in aging, diabetic complications, and so forth.

Rhodopsin Superfamily

This SF contains more than 50 members that are characterized by the presence of seven hydrophobic sequences, indicating that they cross the membrane seven times. The -NH $_2$ terminus is on the extracellular side, and the -COOH terminus is on the intracellular side of the membrane. These proteins couple to various G proteins. Leukocyte antigens that are members of this SF are CD88 (receptor for C5a anaphylatoxin) and CD128 (receptor for IL-8).

Complement Control Proteins Domain

CCP has a ß-sandwich structure with an ellipsoid shape. Several hydrophobic and aromatic residues are buried in the core. A hypervariable loop extends from one side and may be involved in protein binding. Several of the domains exist in complement receptors (CRs) [i.e., CD21 (CR2) has 15 to 16 CCPs whereas CD35 (CR1) has 30 CCPs].

Fibronectin Type III Domain (F3)

FN type III domain is detected in many proteins. Its fold is similar to the Ig domains (i.e., a barrel of two ß sheets). The RGD loop in FN, which binds integrins, is between strands F and G.

CD1 (LEU-6, CD1A–E)

Structure: The CD1 family consists of two groups: Group I includes CD1a, CD1b, and CD1c; group II includes CD1d. Each of these proteins is encoded by genes CD1A, CD1B, CD1C, and CD1D.

CD1 molecules have significant homology to the major histocompatibility complex (MHC) molecules and are associated with the ß $_2$-microglobulin. The a $_1$ and a $_2$ domains adopt an antigen-binding site. The a $_3$ domain is associated with ß $_2$-microglobulin. The groove is formed by hydrophobic amino acids and thus has little or no potential for forming hydrogen bonds with its ligand ([1], [2]).

Gene Locus: 1q22.

Molecular mass (kd): CD1a: 49; CD1b: 45; CD1c: reduced, 43.

Distribution: CD1a: cortical thymocytes, DCs, epidermal Langerhans cells, astrocytes, cytokine-stimulated monocytes. CD1b: Langerhans cells. CD1c: thymocytes, B

cells, mantle zone and umbilical cord. CD1d: intestinal epithelium, kidney tubular epithelia, hepatocytes, thymus.

Function: CD1 antigens are antigen-presenting molecules for microbial antigens ([3], [4]). In this group belong the *Mycobacterium tuberculosis* mycolic acids and the lipoarabinomannan of *Mycobacterium leprae*.

These antigens are taken by antigen-presenting cells (APCs) and are delivered to acidic endosomes, where CD1b is detected (s). In the acidic endosomes, the a helices of the CD1b groove unfold and allow binding of the lipid component, which is buried within the groove, and only the carbohydrate portion is left exposed to react with the T-cell receptor (TCR). (For further details, see Chapter 18.)

CD2 (T11, LEU-5, SRBC RECEPTOR)

Structure: CD2 is a member of the IgSF, forming a subfamily, which includes CD48, CD58, CD84, CD150 (SLAM), CS1, CD229 (Ly9), and CD244 (2B4). All members have two Ig domains, a membrane-distal V-like and a C2-like domain.

The cytoplasmic region of CD2 contains a unique proline-rich segment. It is essential for binding of the CD2-binding protein, regulation of T-cell adhesion, and activation of phosphoinositide 3-kinase (PI3K).

Gene locus: 1p13.

Molecular mass (kd): 50.

Distribution: Expressed on thymocytes, peripheral T cells, and NK cells. It is also expressed on a subpopulation of B cells and, in rare cases, of B-cell acute lymphoblastic leukemia (B-ALL) and B-cell chronic lymphocytic leukemia (B-CLL).

Function: CD2 mediates adhesion of T cells to APCs, activation of T cells, resulting in production of cytokines or induction of cytolysis by T or NK cells ([1], [2]). (For further details, see Chapter 17.)

CD3 (T3, LEU-4)

Structure: CD3 consists of a complex of five proteins that are always associated with the TCR on the surface of T cells. Three of them, ?, d, and e, belong to the IgSF but ? and ? do not. Two heterodimers, ?-e and d-e are linked to TCR, as well as the ?-? (CD247) homodimer and ?-? heterodimer. The extracellular regions of ?-, d-, and e-chains have one C-Ig–like domain, whereas the intracellular region has one immunoreceptor tyrosine-based activation motif (ITAM). The extracellular region of the ?-chain is only nine amino acids long, whereas the intracellular region has three ITAMs. The transmembrane region of the CD3 chain has a conserved negatively charged amino acid, complementary to the positive charge of the transmembrane region of the a/ß-chains of the TCR.

Gene Locus: For ?, d, and e on 11q23; ?, ?:1q22

Molecular mass (kd): Reduced, 16, 20, 22, 25, 28; unreduced, 20, 25, 28, 32, 38.

Distribution: Present on thymocytes (double-positive stage), in mature T cells, and in the cytoplasm of immature T cells.

Function: Signal transduction ([1]). The ITAMs are phosphorylated on engagement of the TCR and adhesion molecules to the APC, thus becoming docking sites for protein tyrosine kinases (PTK) in the initiation of the signal transduction cascade. (For further details, see Chapter 17.)

CD4 (T4, LEU-3A, 3B)

Structure: Extracellular domain consists of four Ig domains (two V and two C). Cytoplasmic tail has three serine residues that can be potentially phosphorylated ([1]).

Gene locus: 12pter–p12.

Molecular mass (kd): Reduced, 59; unreduced, 59.

Distribution: Helper-inducer T cells, monocytes (lower density), hematopoietic stem cells, dendritic cells (DCs), and eosinophils (activated).

Function: Coreceptor for TCR. Binds to the MHC monomorphic portion of the class II molecules. CD4, as adhesion molecule, strengthens binding of TCR to target, augmenting the early phases of formation of the immunologic synapse ([2]). CD4 is located at the periphery of the synapse, whereas the TCR and the CD3-chains remain in the center; it also acts as activation molecule ([3]). Cytoplasmic tail is associated with PTK p56 ^{lck}. It is the receptor for human immunodeficiency virus (HIV), binding to the *C*-terminal of the envelope glycoprotein (gp) 120. However, for the entry of HIV, the chemokine receptor CCR5 is required as co-receptor. Expression of CD4 is down-regulated as a result of binding to Nef protein, which directs it to lysosomes after it is internalized ([4]). CD4 expression in microglia may contribute to brain degeneration in HIV infection. (For further details, see Chapter 17.)

CD5 (LEU-1)

Structure: The extracellular region contains three scavenger receptor cysteine-rich domains, an ancient family of proteins that binds polyanions and lipoproteins. The cytoplasmic region contains multiple Ser/Thr and Tyr residues. Tyrosine 429 is critical for inhibitory function mediated by CD5, independent of an immunoreceptor tyrosine-based inhibitory motifs (ITIM) motif ([1], [2]).

Gene locus: 11q13.

Molecular mass (kd): 67.

Distribution: Thymocytes, T cells, NK cells, and a subpopulation of B cells (B $_1$). It is expressed in the majority of cases of B-CLL. The CD5 $^+$ B cells are increased in rheumatoid arthritis.

Function: Monoclonal antibodies to CD5 stimulate phosphorylation of intracellular tyrosines and T-cell activation. However, CD5 may also mediate inhibitory effects. CD5 $^+$ B cells produce autoantibodies. CD72 is the counter-receptor for CD5 ([3], [4] and [5]).

CD8 (T8, LEU-2)

Structure: Heterodimer of CD8a- and CD8ß-chains. Each chain has one Ig-like domain (V) in the extracellular region, which is connected to the transmembrane region by a hingelike peptide rich in Pro, Ser, and Thr residues. The CD8a gene predicts that the peptide contains nine cysteines, three in the V domain and two each in the hinge, transmembrane, and cytoplasmic regions. The cytoplasmic region consists of 29 highly basic amino acids and is associated with p56 ^{lck} tyrosine kinase. The a-chain binds to the monomorphic a $_3$ domain of class I HLA molecules.

Gene locus: 2p12 for both chains.

Molecular mass (kd): Reduced, 32; unreduced, 70.

Distribution: Thymocytes, T cells (cytotoxic), and subpopulation of NK cells (especially CD57 $^{+}$).

Function: CD8 acts as a coreceptor for TCR. It binds to the same HLA molecule as the TCR (see Chapter 17) ([1], [2]).

CD10 (COMMON ACUTE LYMPHOCYTIC LEUKEMIA ANTIGEN, NEPRILYSIN)

Structure: Type II membrane protein (-NH2 terminus intracellularly), member of membrane metalloproteinases (i.e., CD13, CD26, CD73, and so forth). The large extracellular region contains twelve cysteines. Other amino acids critical for other functions have been identified by site-directed mutagenesis, such as for substrate binding (Arg 102 and Arg 747), zinc coordination (Glu 646), and catalytic activity (His 583 and His 587) contained within a characteristic pentapeptide.

Gene locus: 3q25.1.

Molecular mass (kd): 90 to 110, depending on the cell or tissue source—lymphocytes, 100; neutrophils, 110. Variations are due to degree of glycosylation (there are six glycosylation sites) or splice variants.

Distribution: CD10 is expressed in normal and malignant cells of hematopoietic origin as well as in nonhematopoietic tissues. It is present in the pro-B and pre-B cells but not in mature B cells, except for germinal center B cells; it is also present in terminally differentiated neutrophils. In malignancies, it constitutes the main marker in more than 70% of B-ALL and in a small number of T-ALL, as well as in Burkitt and follicular lymphomas and a small number of multiple myelomas. Other tissues include the brush border of proximal tubules of kidney, biliary canaliculi, bronchial epithelium, fibroblasts, breast myoepithelium, placental microvilli, endometrial stromal cells, and nonhematopoietic tumors such as melanomas, gliomas, retinoblastomas, and so forth ([1], [2]).

Function: CD10 is a neutral endopeptidase, also known as *encephalinase*. Its substrates are important peptides such as bradykinin, enkephalins, angiotensin I, oxytocin, substance P, and peptide f-MLP. Its activity depends on Zn binding, and it attacks peptide bonds involving the a-NH $_{2}$ groups of hydrophobic amino acids. Target cells express both CD10 and the receptor for the peptide, which is hydrolyzed by the enzyme. It regulates B-cell proliferation and differentiation and reduces inflammatory responses and enkephalin-mediated analgesia. Bombesinlike peptides are potent mitogens for bronchial epithelia and are autocrine growth factors for small cell carcinomas of the lung. Their concentration increases in cigarette smokers as a result of CD10 inactivation by the smoke. CD10 degrades amyloid ß-peptide, holding some promise for the treatment of Alzheimer disease ([3], [4], [5], [6] and [7]).

CD11a (LFA-1a: LYMPHOCYTE FUNCTION–ASSOCIATED ANTIGEN-1 a SUBUNIT; aL)

Structure: CD11a forms a heterodimer with CD18 (ß $_{2}$ integrin), which is known as *LFA-1*. It is a type I transmembrane protein with more than 1000 amino acids in the extracellular region, whereas the cytoplasmic region consists only of 53 residues. The extracellular region can be divided into the *N*-terminal half and the remaining membrane-proximal region. The *N*-terminal half of the molecule contains seven repeats of four antiparallel ß strands. The repeats are arranged like twisted blades of a propeller, and the whole structure is known as the ß *-propeller domain*. Within the propeller is inserted, as a result of exon shuffling (between sheets 2 and 3), a 200–amino acid segment known as the *I domain* (for *inserted*). It is homologous to the A domain of von Willebrand factor (vWF), a molecule that mediates adhesion between platelets and subendothelial matrix. The I domain has a fold similar to a structure that has been identified in nucleotide binding of small G proteins and the a subunits of the heterotrimeric G proteins. It is composed of six or seven a helices and six ß strands arranged in a Rossman type of fold.

The I domain contains a metal ion coordination site (or *MIDAS*, *m*etal *i*on- *d*ependent *a*dhesion *s*ite), with a conserved sequence DXSXS, and with surrounding residues is the major ligand-binding site. CD18 regulates opening of the I domain of the aL subunit. Ca $^{2+}$ binding is mediated by strands in the lower surface of the ß-propeller, and its removal activates ligand binding and destabilizes the a/ß subunit association. Ligand binding is supported by Mg $^{2+}$ or Mn $^{2+}$. The remaining membrane-proximal part consists of four to six ß-sandwich or ß-barrel folds ([1], [2]).

Gene locus: 16p11.2.

Molecular mass (kd): Unreduced, 170; reduced, 180.

Distribution: LFA-1 is expressed on all leukocytes but not in platelets or nonhematopoietic tissues.

Function: Cell-surface and cytoplasmic molecules regulate LFA-1 function. Plasminogen activator receptor is associated with LFA-1, and cytoplasmic proteins known as *cytohesins* regulate ligand binding by interacting with the cytoplasmic region of ß $_{2}$ integrins. Signaling molecules [i.e., phospholipase C? $_{1}$ (PLC? $_{1}$)] and Ca $^{2+}$ increases have been implicated. LFA-1 ligands are the intercellular adhesion molecules (ICAMs)-1, -2, and -3. It participates in all immune and inflammatory interactions between cells of the immune system and other cells.

In vivo, LFA-1 mediates adherence of (a) T cells to APCs, B cells, endothelial cells, synovial cells, fibroblasts, and so forth; (b) cytotoxic T lymphocytes (CTL) and NK cells to targets; and (c) macrophages to tumor cells, and so forth.

It contributes to the arrest, strong adhesion, and spreading of circulating lymphocytes on the endothelium, initiating transendothelial migration (see Chapter 15). Mutations of the ß2-chain (CD18) result in a profound immune deficiency known as *LAD-1* (leukocyte adhesion deficiency) as a result of lack of expression of LFA-1 (see CD18) ([3], [4] and [5]).

CD11b (aM, CR3, MAC 1)

Structure: Type I transmembrane proteins with a large extracellular region and a short intracellular region. The structure resembles that of the aL-chain [i.e., seven repeating subunits forming a ß-propeller domain, an I domain, and a MIDAS motif (see CD11a)]. The heterodimer CD11b/CD18 is known as *CR3* ([1]). (See Chapter 18.)

Gene locus: 16p11.2.

Molecular mass (kd): 165.

Distribution: Expressed on neutrophils, monocytes, macrophages, NK cells, subsets of T and B cells, and mast cells.

Function: CD11b possesses the ligand-binding site for iC3b (inactivated C3). Other ligands include fibrinogen, factor X, ICAM-1 (CD54), heparin, lipopolysaccharide (LPS), and CD23. The I domain is the major recognition site for at least four distinct ligands. Certain molecules, such as CD14, CD87, CD16, and CD32, are physically associated with the CD11b (i.e., co-capping), generating intracellular signaling. CD11b/CD18 on its own mediates phagocytosis of iC3b-opsonized bacteria in contrast to CR1, which requires cooperation with the Fc receptor. Mac-1 mediates adhesion and transmigration of neutrophils across the endothelium, homotypic adhesion of neutrophils, and chemotaxis. It can also bind to some yeasts without involvement of complement via its lectin domain, which also triggers the respiratory burst. In LAD-1, CD11b is not expressed, and patients suffer from serious bacterial infections (see CD18) ([2], [3], [4] and [5]).

CD11c (aX, P150, 95)

Structure: Similar to CD11a and CD11b. As a heterodimer with CD18 is known as *CR4*.

Gene locus: 16p11.2.

Distribution: Important receptor on macrophages, monocytes, neutrophils, DCs, NK cells, and hairy cell leukemia cells.

Function: Mediates leukocyte adhesion and spreading, chemotaxis, and fibrinogen binding. CD11c is strongly expressed in cells from hairy cell leukemia and, together with CD25, could be used for detection of minimal residual disease by flow cytometry ([1], [2] and [3]).

CD11d (aD)

CD11d is the newly added member of the a-chains of ß $_2$ integrins and forms a heterodimer with CD18, contains an I domain like all other a-chains of the ß $_2$ integrins, but it is more closely related to CD11b and CD11c. The I domain of aD binds with high affinity to vascular cell adhesion molecule-1 (VCAM-1), which is not a ligand for the other a-chains of the ß $_2$ integrins. VCAM-1 is the ligand for a $_4$ integrins that lack I domain. aD also binds to ICAM-3 but not to the other two ICAMs. It is expressed on eosinophils and strongly on macrophages (foam cells) found in aortic fatty streaks that may develop into atherosclerotic plaques. CD11d/CD18 is constitutively expressed by synovial macrophages and strongly in synovium from patients with rheumatoid arthritis ([1], [2]).

CD13 (MY7, AMINOPEPTIDASE N)

Structure: Type II membrane protein, which belongs to the family of metalloproteases (other members are CD10, CD26, CD73, and so forth). It exists as a non–covalently linked homodimer. The *C*-terminal domain contains the substrate binding site, and the *N*-terminal contains a pentapeptide, associated with the catalytic and the Zn-binding sites.

Gene locus: 15q25.

Molecular mass (kd): 150.

Distribution: It is expressed on normal myeloid and monocytic lineage cells and on most acute myelogenous leukemias (AMLs), as well as on a small number of lymphoblastic leukemias (5 to 10%). Expression of CD13 is regulated by cell–cell contact by stromal bone marrow cells. All CD13 $^+$ blasts cultured *in vitro* on stromal cells from normal bone marrow lose CD13 expression. CD13 is expressed on renal proximal tubules, intestinal brush border, endothelial cells, fibroblasts, brain, osteoclasts, bone marrow stromal cells, and so forth ([1], [2]).

Function: CD13 is a receptor for the RNA corona viruses, which cause upper respiratory infections in humans, as in severe acute respiratory syndrome. CD13 removes unsubstituted *N*-terminal amino acids with neutral side chains from peptides. Peptide bond preceding Pro is resistant to CD13. Natural substrates are vasoactive peptides (bradykinin, angiotensin III), neuropeptide hormones, cytokines, IL-8, tuftsin, and so forth. Frequently, it is coexpressed and cooperates with other ectopeptidases (i.e., CD10 or C26). It has been implicated in trimming peptides that protrude out of the groove of MHC molecules. In inflammatory conditions of the joints, CD13, CD10, and CD26 of synoviocytes provide an important source of peptide degradation.

CD13 regulates endothelial morphogenesis and cell motility, both critical in angiogenesis and in tumor progression. Endothelial cells release IL-8, which induces apoptosis of attached leukemic cells. Strong CD13 expression allows cells to survive by blocking apoptosis, probably as a result of IL-8 inactivation by the enzyme ([3], [4], [5], [6] and [7]).

CD14 [LIPOPOLYSACCHARIDE RECEPTOR (LPS-R)]

Structure: CD14 is attached to the membrane by a *C*-terminal GPI anchor. The extracellular region contains ten sequences with similarities to the leucine-rich repeats. It is also found as a plasma protein (soluble or SCD14, 1 to 6 µg/ml). There are two soluble forms: one released from the membrane and a second lacking the GPI anchor.

Gene locus: 5q23-31.

Molecular mass (kd): 53.

Distribution: CD14 is expressed on monocytes, macrophages, and weakly on granulocytes. It is also expressed in the liver, a primary organ in the acute phase response.

Function: CD14 binds bacterial LPS (endotoxin) and, as a component of a multimolecular complex, plays an important role in LPS-induced activation, inflammatory response, and innate immunity.

LPS is captured by a serum LPS-binding protein and is transported to CD14, which binds the complex. CD14, however, cannot trigger activation because it lacks an intracellular region. This function is mediated by one of a group of molecules known as *Toll-like receptors* (TLR), as they are structurally homologous to the Toll receptors of the fruit fly *Drosophila melanogaster*. One of the ten human TLRs, TLR4, is critical for transmission of LPS activation signals and requires a third molecule, MD2, linked to the extracellular region of TLR4. LPS links all three molecules and binds directly to all three members of the complex. The role of TLR4 has been conferred in TLR4 knock-out mice and in humans with TLR4 mutations. TLRs recognize pathogen-associated molecular patterns, and TLR4 specifically recognizes *Escherichia coli* LPS. TLR4 recruits an adaptor protein MyD88, which engages the IL-1 receptor–associated kinase, leading to activation of nuclear factor-?B (NF-?B) and production of cytokines (TNF-a, IL-1) and chemokines, as well as up-regulation of co-stimulatory molecules (CD80, CD86, and so forth). A conical lipid A interacts with TLR4, whereas cylindrical shapes interact with different TLRs for different responses. Soluble CD14 transfers LPS to high-density lipoproteins where it is neutralized. Liver expression of CD14 may function in the acute phase response. CD14 is also involved in the removal of apoptotic cells without inciting inflammation ([1], [2], [3] and [4]).

CD15 (Lewis ^{x}, Le ^{x}), CD15s (Sialyl Lewis ^{x}, sLe ^{x})

Structure: Antibodies, which recognize CD15, react with a trisaccharide: Galß?4[Fuca1?3]GlcNAc. The sialylated form (sLe ^{x}) has a sialic acid linked to Gal. These carbohydrate chains are O-linked on glycoproteins (known as *mucins* or *sialomucins*), which present them to the lectin domain of L-selectin. Three of these proteins, GlyCam-1, CD34, and MAdCAM (defined by the antibody MECA-79) were given the name *peripheral lymph node addressin* (PNAd). Sialyl Lewis ^{X} is modified by sulfation by two sulfotransferases; one of them, GlcNAc-6-sulfotransferase, is highly restricted to high endothelial venules (HEVs), and such sulfated sLe ^{X} structures are very potent L-selectin ligands. Because L-selectin binding is highly dependent on sulfation of sLe ^{x}, these two sulfotransferases play a critical role in controlling the migration of lymphocytes across capillary endothelia. (See details in Chapter 15.)

Distribution: Expressed on neutrophils, eosinophils, and monocytes but not on platelets, lymphocytes, and erythrocytes. CD15 is not (or is very weakly) detected on myeloid progenitors and AML blasts. This is due to the presence of strong 6'-sialyltransferase, which uses the precursor substrate at the expense of 3'-fucosyltransferase and prevents the synthesis of Le ^{X} and sLe ^{X}. CD15 is detected in HEV cells in association with L-selectin gp ligands.

Function: Sialylated and sulfacted Le ^{X} displayed by mucins are the ligands for L-selectin in lymphocyte homing ([1], [2]). These posttranslational modifications of Le ^{X} are mediated by sulfotransferases that are highly restricted to HEV ([3]). Fucose and sialic acid are critical components of the L-selectin ligands. These enzymes exert a fine-tuning of the influx of lymphoid cells in various inflammatory sites ([4], [5], [6] and [7]). High serum levels of sLe ^{X} were found to be an independent predictor for liver metastasis in patients with gastric carcinoma ([8]). CD15 has been detected in myeloma with phagocytic plasma cells ([9]). In LAD type II [CDG-IIc (congenital disorders of glycosylation) in the newer classification], a guanosine diphosphate (GDP)–fucose transporter deficiency is due to a defect in GDP–fucose import into the lumen of

the Golgi. Patients lack Le ^{X} and sLe ^{x}, and no H antigen is expressed on erythrocytes ([6], [7], [8] and [9]).

CD16 (FC?RIII)

Structure: CD16 exists in two isoforms: CD16a and CD16b. The extracellular region contains two type C2Ig-like domains. The transmembrane form, CD16a, requires coexpression with other molecules for efficient cell-surface expression. In macrophages, CD16 is associated with a homodimer of the ? subunit of the FceR and in NK cells, is associated either with a homodimer of Fce ? subunit or a heterodimer of the Fce? and the TCR-? of the CD3 complex ([1]). Soluble forms of both isoforms are formed by the action of serine proteases (CD16b) or metalloproteases (CD16a). The transmembrane region of CD16a has a conserved sequence of eight amino acids with a negatively charged aspartic acid unique to all FcR chains that associates with other molecules.

Gene locus: Both isoforms: 1q23.

Molecular mass (kd): Transmembrane (TM): 27; GPI: 21.

Distribution: CD16b (GPI-anchored) is expressed exclusively in neutrophils, whereas the transmembrane CD16a is expressed on macrophages and NK cells, some monocytes, and some T cells. Fc?RIII has also been detected in kidney mesangial cells and placental trophoblasts. It is detected in the mantle zone of lymph nodes and interfollicular areas. The GPI-anchored is up-regulated by IFN-? and GM-CSF and down-regulated by TNF-a. The transmembrane form is up-regulated by TNF-ß.

Function: Interaction with the Ig Fc domain is mediated primarily by the membrane proximal Ig domain, which binds between the two C? $_{2}$ domains of the Fc fragment ([2]). Fc?RIIIa binds monomeric Ig and has higher affinity than Fc?RIIIb.

One of the main functions of Fc?RIII is ADCC (antibody-dependent cell cytotoxicity) (i.e., through NK cells). It also mediates phagocytosis and generates superoxide production when it is cross-linked on monocytes or macrophages. Signal transduction is initiated by the ?/?-chains, which carry ITAM sequences. Residue 148 of Fc?RIIIa may be substituted with either valine (V) or phenylalanine (F). NK cells homozygous for V (VV) bind IgG more strongly than NK cells from FF persons ([3]). This is important because VV patients with lymphoproliferative diseases respond to chimeric anti-20 monoclonal antibody (rituximab) better than FF patients ([4]). A substitution at position 48 by histidine is associated with recurrent viral infections ([5]).

CD18 (ß $_{2}$ INTEGRIN)

Structure: CD18 is a transmembrane protein that forms heterodimers with CD11a, CD11b, or CD11c (a-chains). The extracellular region consists of an *N*-terminal region (NTR) followed by an I-like domain, a midregion, and, next to the membrane, a cysteine-rich region (CRR). The interrelationships of these domains and regions to the overall function (i.e., cell-surface expression and ligand binding of the heterodimeric ß $_{2}$ integrins) is quite complex ([1]). The I-like domain of the ß $_{2}$ subunit contributes to the heterodimer formation by interacting with the ß-propeller of the a subunits (see CD11a) ([2]).

The binding of the ligand by the heterodimer is contributed by the I-like domain of ß $_{2}$ with contributions from the I-domain of the a subunits.

By electron microscopy, the leukocyte integrins appear as having a globular “head” with two stalks joining the head to the cell membrane. The head is formed by the *N*-terminals of both chains, which includes the ß-propeller and I-domains. Therefore, the ligand binds to the top of the head. One stalk is formed by the remaining portion of the a subunit, whereas the second stalk is the CRR region of the ß subunit. Normally, the integrin is restrained to a resting state. Activation changes the “closed” to an “open” conformation, which is achieved by movement of the subunits similar to the opening of a scissor.

Gene locus: 21q22.3.

Molecular mass (kd): 90.

Distribution: Neutrophils, monocytes, macrophages, T and B lymphocytes.

Function: As a common chain to all four leukocyte integrins, CD18 participates in a great variety of immunologic and inflammatory responses ([3]). LFA-1 plays a major role in interactions of lymphocytes with other cells: (a) endothelial (homing to peripheral lymphoid organs and migration to sites of inflammation); (b) T-cell interaction with APCs in the formation of the synapse (see Chapter 17); and (c) CD8 $^{+}$ CTL with target cells. These interactions generate *outside-in* signals, which regulate reorganization of cytoskeletal elements, stimulate growth, and prevent apoptosis. The CD18 intracellular region interacts with several cytoskeletal proteins. The ß $_{2}$ integrins are also activated from signals generated by other receptors inside the cell (i.e., *inside-out* signaling). Engagement of TCR with antigen generates intracellular signals, which in turn act on LFA-1 at the cell surface, increasing its affinity, thus stabilizing further the T-cell interaction with APCs. Mac-1 (CD11b/CD18) regulates several functions of neutrophils (i.e., adhesion, migration, chemotaxis, phagocytosis, degranulation, and so forth). It cooperates with several other receptors such as LPS/LPS-binding protein (CD14) and with Fc?RIIIb (CD16) in ADCC.

Chemokines such as secondary lymphoid-tissue chemokine (SLC), Epstein-Barr virus (EBV)–induced molecule 1 ligand chemokine (ELC), and stromal cell–derived factor (SDF)-1a enhance LFA-1 affinity and induce lateral mobility of LFA-1 ([4]). Both of these changes result in a rapid arrest of lymphocytes rolling on the endothelial surface. LFA-1 function can be inhibited by small molecules ([5]), which bind to a pocket of the I domain, termed the *lovastatin-binding site* (L-site), named after the inhibitor of (3-hydroxy-3methyl 6-glutaryl-coA) HMG–coenzyme A. Several other compounds (hydantoin and so forth) bind to the same pocket and inhibit LFA-1 function.

Leukocyte Adhesion Deficiency

Mutations of CD18 have been identified that impair the cell-surface expression of all ß $_{2}$ heterodimers. Migration of neutrophils and monocytes is absent or drastically reduced at extravascular sites of inflammation. This deficiency is invariably fatal within the first few years of life. A variant form has been described with normal or moderately reduced levels of ß $_{2}$ integrins. In recombinant ß $_{2}$ integrins, substitution of Asp ^{134} resulted in loss of the adhesion properties of both a $_{L}$ß $_{2}$ and a $_{M}$ß $_{2}$, and substitution of Asp ^{128} or Ser ^{138} resulted in loss of surface expression of ß $_{2}$ integrins.

CD19 (B4)

Structure: The extracellular region contains two C-2 Ig-like domains. The cytoplasmic region is long and highly conserved and contains nine tyrosines. CD19 interacts with CD21 (CR2) through its extracellular and transmembrane regions, with CD81 (target for antiproliferative antibody-1) through the extracellular region only, and

with surface IgM through the first 17 amino acids of the cytoplasmic region ([1]).

Gene Locus: 16p11.2.

Molecular mass (kd): 120.

Distribution: CD19 is the earliest recognizable marker of B cells and is retained until the B cell becomes a plasma cell, when it is lost. It is also expressed on follicular DCs.

Function: CD19 amplifies B-cell activation and is itself phosphorylated after engagement of the B-cell receptor (BCR; surface IgM). The amplification involves successive tyrosine phosphorylations of CD19 and stepwise recruitment of PTK Lyn, Fyn, PI3K, and so forth ([2], [3]). The CD19 large cytoplasmic region (240 residues) acts as scaffolding, linking several signaling molecules.

The CD19 complex lowers the threshold of antigen required for B-cell stimulation severalfold ([3]). CD19 is necessary for the BCR-mediated activation of Bruton kinase, which is linked to X-linked agammaglobulinemia (Bruton) ([4]).

CD20 (B1)

Structure: CD20 spans the cell membrane four times, yet it does not belong to the tetraspan family of proteins (i.e., CD9, CD81, and so forth) but to the subfamily A, a new family named *membrane-spanning four domains* (MS4A). Other members are the ß-chain of the high-affinity IgE receptor (i.e., FceRIß), the HTm4 molecule, and sixteen other proteins recently added. MS4 proteins are divided into 12 subgroups: MS4A1 to MS4A12 ([1]).

CD20 is constitutively phosphorylated but is not glycosylated. Long *N*- and *C*-terminal ends are located within the cytoplasm, but only a minor portion of the molecule is exposed on the cell surface.

Gene locus: 11q13. The gene is near the site of the t(11;14)(q13;q32) translocation found in some B-cell malignancies ([2]). It is approximately 50 kb away from BCL-1, between the centromere of chromosome 11, and the 3' end of BCL-1, and its proximal location excludes it from being translocated to chromosome 14. The CD5 gene is in the proximity of CD20.

Molecular mass (kd): 33, 35, 37.

Distribution: CD20 is expressed on B cells after expression of CD19 and CD22 at approximately the pre–B-cell stage and remains throughout the B-cell life. It is strongly increased in germinal center B cells but then declines at the end of B-cell differentiation. It is not expressed on plasma cells and is only weakly expressed in B-CLL ([3]).

Function: CD20 is a Ca $^{2+}$ channel, and this property explains the role of CD20 in activation and proliferation of B lymphocytes ([4]). Engagement of CD20 by an antibody stimulates transmembrane Ca $^{2+}$ flux. CD20 is redistributed to membrane rafts on activation, where receptors and signaling molecules are gathered ([5]).

The CD20 in B-cell low-grade lymphomas is used as the target for immunotherapy with anti-CD20 chimeric monoclonal antibodies (rituximab) ([6], [7]). The antibody probably acts by a number of mechanisms (i.e., complement-mediated cytotoxicity, ADCC, and inhibition of proliferation or apoptosis) ([8]).

CD21 (CR2, EPSTEIN-BARR VIRUS RECEPTOR, C3D RECEPTOR)

Structure: Member of the family of regulators of complement activation characterized by the CCP domains (also known as *short consensus repeats*). CCPs are present in many other proteins not related to complement regulation, such as blood clotting factor XIIIb subunit, IL-2 receptor, a vaccinia virus protein, and so forth ([1]).

CCP consists of 60 to 70 amino acids, with a core structure made of antiparallel ß strands and short inter-CCP linker peptides. The extracellular region contains 15 (short isoform) or 16 (long isoform) CCPs. The first two CCPs form a V-shaped binding site for C3d, and variable orientations between them contribute to biologic diversity and specificity. The intracellular region contains tyrosine kinase phosphorylation sites ([2]).

Gene locus: 1q32.

Molecular mass (kd): 145.

Distribution: Present on B cells at the stage when they first become Ig $^{+}$. It is lost on activation. Present on follicular DCs and in a small number of T cells.

Function: CD21 is the receptor (CR2) for the C3d fragment resulting from C3b fragmentation (see Chapter 18) ([3]). It is also the receptor for EBV, interacting with the viral capsid protein gp 350/220 and mediating internalization of the virus, for which the intracytoplasmic region is necessary ([4], [5]). CD21 is a component of the CD19/CD21/CD81 complex, which binds antigen-antibody-complement complexes and amplifies B-cell responses as a result of cross-linking of the complex with the BCR complex ([6]). It localizes immune complexes (ICs) on follicular DCs, facilitating antigen presentation and cellular interactions in the lymph node follicles where B cells express strongly CD21. The CD19/21/81 complex lowers the threshold for B-cell activation 100-fold. CD21 effectively links innate and adaptive immunity. It forms complexes with CD35 (CR1) on B cells distinct from the CD19 complexes, as well as with CD23. Their role in B-cell function is not clear.

CD22 [B5, LEU-14, SIALIC ACID–BINDING IMMUNOGLOBULIN SUPERFAMILY LECTIN (SIGLEC)-2]

Structure: CD22 is a member of the *siglecs* family, which binds sialic acid (see CD33, CD164, CD170, and so forth) and belongs to the IgSF ([1], [2]).

There are two isoforms, one of which is the predominant form (CD22ß) and contains seven Ig-like domains in the extracellular region (one type V and six type C-2), and the other (CD22a) lacks domains 3 and 4 and has a truncated cytoplasmic region. CD22 recognizes only an a2?6–linked sialyllactosamine. The ligand binds to the V domain, which includes an arginine conserved on all siglecs.

The cytoplasmic region contains six conserved Tyr residues, two of which are within sequences, which conform with ITAMs ([3]), whereas the other four form potential ITIMs ([4], [5]). When ITIMs are phosphorylated, they associate with SH_2-containing phosphatases, SHP-1, SHP-2, or SHIP.

Gene locus: 19q13.1.

Molecular mass (kd): 140.

Distribution: Intracytoplasmic expression during the early B-cell development stages (pro– and pre-B cell) is a marker for B-lineage commitment. It is expressed on the cell surface during the mature cell stages and disappears on B-cell activation.

Function: CD22 is an adhesion molecule and possesses lectin activity mediated by the first *N*-terminal Ig-like domain ([5]). As lectin, it binds sialic acid linked by an a2,6 bond to the penultimate galactose residue of glycoproteins. CD22 binds to CD45RO and CDw75, both possessing a2-6–linked sialic acids. Binding of CD22

lectin to its ligands does not require bivalent ions (i.e., Ca^{2+} or Mg^{2+}), which are necessary for C-lectins.

PTKs Lyn and Syk mediate phosphorylations after BCR ligation. Two carboxyterminal ITIM tyrosines are required for SHP-1 phosphatase recruitment, which dephosphorylates signaling molecules and thus exerts an inhibitory effect ([6]). Other signaling molecules are also linked to CD22, such as SHIP (inositol phosphatase) and the adaptor molecules Shc ([7]).

CD22-deficient mice develop high titres of high-affinity autoantibodies (i.e., anti–double-stranded DNA, anticardiolipin, and so forth) ([8]).

CD22 is “masked” on resting B cells, unavailable for binding to its normal ligands. Release from this “masking” is necessary for CD22 to bind to its sialic acid ligands and exert the negative regulatory function on B-cell activation.

CD22 has been specifically targeted with monoclonal antibodies conjugated to cytotoxic RNAase for immunotherapy of lymphomas.

CD23 (LEU-20, BLAST-2, FceR-II)

Structure: Type II membrane protein (NH_2 terminal inside the cytoplasm). The extracellular region contains a C-lectin domain, three membrane proximal heptad repeats of hydrophobic residues forming an a-helical coiled-coil stalk as a trimer, and two clusters of cysteines ([1], [2] and [3]).

CD23 exists as two isoforms (CD23a and CD23b) resulting from two different transcription initiation sites. The CD23a promoter is stimulated only by IL-4, whereas the promoter of CD23b is stimulated by IL-4 and other stimuli ([4]). The isoforms differ by six cytoplasmic amino acids of the *N*-terminal cytoplasmic region: CD23a is restricted to B cells, and CD23b is expressed by other cells. CD23 is cleaved by an unknown metalloprotease releasing a soluble form (sCD23) of 37 kd, but all of them retain the lectin-binding head. CD23 is highly homologous to the C-lectin asialoglycoprotein receptor, pulmonary surfactant apoprotein, and mannose-binding protein.

Gene locus: 19p13.3.

Molecular mass (kd): 45.

Distribution: CD23 is expressed on several types of cells: B lymphocytes, where it appears to be associated with IgD; follicular DCs, especially those in the light zone of the germinal centers; transiently on some T cells in allergic individuals; Langerhans cells; monocytes; platelets; NK cells; nasopharyngeal carcinoma cells; B-CLL; and EBV-transformed B cells.

Function: CD23 is the low-affinity receptor for IgE ([3]). It also binds to CD21 and to the a-chains of the $ß_2$ integrins. Soluble CD23 (or IgE-binding factors) enhance IgE synthesis. Oligomeric, but not monomeric, forms of CD23 enhance IgE production by facilitating presentation of IgE/Ag complexes ([5]). The CD23b isoform is involved in IgE-dependent activities in inflammation (i.e., phagocytosis of IgE-coated particles, release of IL-1 and TNF-a, and generation of superoxide) ([6]). Soluble CD23 (sCD23) exerts various cytokinelike activities. In mice with experimentally induced arthritis, antibodies to CD23 decrease the severity of the disease. In humans with rheumatoid arthritis, there is an increase of CD23 expression.

CD23 and CD5 coexpression is the signature phenotype of B-CLL. Overexpression of CD23 in B-CLL is due to a deregulation of Notch 2 signaling ([7]). sCD23 is elevated in B-CLL and may have prognostic significance ([8], [9]) because its levels are a reflection of tumor mass ([10]). sCD23 long doubling time is found in patients with slow progression of the disease, and short sCD23 doubling time is associated with aggressive disease. CD23b is the predominant isoform in B-CLL and is capable of presenting antigen to T cells ([11]). Based on specific marker expression, the B-CLL cells, irrespective of V gene mutations, exhibit features of activated antigen-experienced B cells ([12]).

CD25 [TAC ANTIGEN, a-CHAIN OF INTERLEUKIN (IL)-2 RECEPTOR]

Structure: CD25 is the a-chain of the IL-2 receptor, which with the ß- (CD122) and ?c- (common, CD132) chains, forms the high-affinity receptor ([1]).

The extracellular region contains two CCP domains and is rich in O-linked carbohydrates. The cytoplasmic region is short, consisting of only 13 amino acids. The ligand (IL-2)-binding site is located in the NTR.

Gene locus: 10p14.

Molecular mass (kd): 55.

Distribution: The IL-2Ra-chain is expressed on activated, but not resting, T cells. It is strongly expressed on human T-cell leukemia virus type 1 T-cell leukemia. CD25 is also detected on B cells, monocytes, a subset of thymocytes, activated NK cells, myeloid precursors, activated eosinophils ([2]), and oligodendrocytes. CD25 is strongly expressed in hairy cell leukemia.

Function: CD25 binds IL-2 with low affinity (10^{-8} M) but with the trimolecular IL-2R, the affinity increases to 10^{-11} M ([3]). The IL-2R complex mediates the functions of IL-2 (i.e., induces progression of cell cycle from G_1 through S, G_2, and M phases), promoting proliferation and clonal expansion of T cells. Rapamycin and FK506 block the G_1 ?S progression and inhibit T-cell proliferation. The CD25 binds IL-2, but the signal transduction is mediated by the ß- and ?-chains (see details of signal transduction in Chapter 18). The ?c interacts with Jak 3 kinase and calpain, whereas the ß-chain interacts with Src kinases, Syk kinase, PI3K, and Jak 1. PI3K mediates the T-cell proliferation and prevention of apoptosis and is very likely recruited by Jak 1 kinase ([4]).

Mutations of the IL-2R?-chain lead to X-linked severe combined immunodeficiency (XSCID) in humans (see CD132). Because ?-chain is shared by several cytokines, the immunodeficiency is profound ([5]). Abnormalities of the IL-2Ra-chain gene have also been identified in patients with lymphoproliferative T-cell deficiency.

Humanized anti-CD25 antibodies have been shown to reduce the incidence of renal and cardiac allograft rejection and decrease the severity of graft-versus-host disease (GVHD) in patients undergoing HLA-matched allogeneic bone marrow transplantation ([6]). CD25 is expressed on a subpopulation of $CD4^+$ T cells with immunosuppressive properties in mice. These $CD25^+$ T cells can delay or even prevent GVHD in allogeneic hematopoietic stem cell transplantation. Human $CD4^+$ $CD25^+$ regulatory T cells block *in vitro* the proliferative response of T cells to allogeneic stimuli ([7], [8] and [9]). The suppressive activity of these $CD25^+$ T cells is due to transforming growth factor (TGF)-$ß_1$, and prevent a lethal autoimmune function in mice deficient in the IL-2Rß chain ([10]).

CD28

Structure: CD28 is a disulfide-linked homodimer with a single Ig-like V domain in the extracellular region ([1]), with two cysteines shared by the Ig heavy and light chain variable domains. There are five potential glycosylation sites. A third cysteine residue is involved in the homodimer formation. The cytoplasmic region has the YMNM motif that mediates the binding of CD28 to the *C*-terminal SH_2 domain of the p85 subunit of PI3K ([2]), and the same motif was found to bind Grb2 ([3]). Mutation of the tyrosine in this motif prevents binding of PI3K and induction of Bcl-X_L in response to CD28 co-stimulation, but proliferative responses are not affected ([4], [5]). Downstream from this motif are two proline-rich motifs, PRRP and PYAPPR. CD28 binds through proline residues to the SH_3 domains of Lck, triggering its activation.

Gene locus: 2q33.

Molecular mass (kd): Unreduced, 90; reduced, 44.

Distribution: Expressed constitutively on T cells and is up-regulated after activation. Plasma cells are CD28 $^{+}$.

Function: CD28 is a co-stimulatory receptor for T cells ([6]). Its engagement provides the second signal (first by TCR) required for expansion of T-cell clones. CD28 is an obligate co-stimulatory receptor because blocking its activation leads to anergy. Ligands for CD28 are the CD80 (B7-1) and B7-2 (CD86), which form homodimers ([7]). Both of these molecules are also ligands for CTLA-4 (CD152), which is an inhibitory receptor ([8]). Ligand binding to CD28 initiates multiple signaling events through PI3K, Lck, and Grb2 ([9]). The different proteins associated with CD28 regulate different functions [i.e., promotion of T-cell survival as a result of induction of the antiapoptotic protein Bcl-X $_{L}$, the release of cytokines, which then stimulate clonal expansion ([10], [11]), differentiation, and expression of other molecules (i.e., CTLA-4 and CD40L, which regulate further interactions)]. Blockade of co-stimulation has been used in a number of experimentally induced diseases as well as in clinical trials. In allogeneic bone marrow transplantation, GVHD is reduced. In psoriasis vulgaris, it reduces disease activity ([12]). Trials in renal transplantation and autoimmune diseases are still in progress ([13], [14] and [15]).

CD29 [ß $_{1}$ INTEGRIN CHAIN, VERY LATE ANTIGEN (VLA) ß-CHAIN, PLATELET GLYCOPROTEIN (GP) IIA]

Structure: CD29 is the ß-chain of heterodimers it forms with 11 a subunits. The heterodimers with six of these subunits (CD49a to CD49f, a $_{1}$ to a $_{6}$) are known as *very late antigens* (VLAs) because they appear on T cells late after activation ([1]). In nonlymphoid tissues, ß $_{1}$ is associated with a $_{7}$- to a $_{9}$-chains. In the extracellular region of the ß $_{1}$ subunit, there is an I domain–like structure (see CD11a), which contains a specificity-determining loop with several amino acids critical for ligand and cation binding ([2], [3]). This domain undergoes conformational changes on activation after ligand and Mn $^{2+}$ or Mg $^{2+}$ binding.

The membrane proximal region is a cysteine-rich domain that regulates anchoring of the ß $_{1}$ subunit to the cytoskeleton and is highly conserved across species. The cytoplasmic region is short (50 residues) and, as a result of alternative splicing of messenger RNA (mRNA), there are structural variations of this region, generating size isoforms ([4], [5]). These isoforms (ß1-A, -B, -C1, -C2, -D, and -E) affect tissue distribution and changes in the regulation of ligand binding and signaling activity. All isoforms share the same first 26 amino acids of the cytoplasmic region but differ in the membrane distal region ([6]).

Gene locus: 10p11.2.

Molecular mass (kd): Reduced, 130; unreduced, 115.

Distribution: It is universally expressed on all leukocytes and most other cells in association with 13 different a subunits. On memory T cells, it is present in higher densities as VLA1-VLA6. The a $_{8}$-ß $_{1}$ integrin is prominently expressed in the nervous system ([7]). Expression of the ß $_{1}$ isoforms varies. The ß $_{1}$A variant is expressed on all tissues, the ß $_{1}$B in the skin, liver, and skeletal muscle, and the ß $_{1}$C and ß $_{1}$C $_{2}$ in blood cells, and the ß $_{1}$D is specific for skeletal and cardiac muscle.

Function: The ß $_{1}$ subunit associates with 13 a subunits through the specificity-determining loop of the I domain–like structure ([8]). The cytoplasmic domain of CD29 interacts with cytoskeletal proteins (i.e., a-actinin, paxillin, talin, and filamin) and thereby links the outside environment with the inside of the cell ([9]).

As heterodimers, the ß $_{1}$ integrins mediate cell–cell and cell–matrix adhesions. The heterodimers form receptors for the extracellular matrix proteins, such as FN, collagen, laminin, and vitronectin. The ligand binding is contributed by both ß $_{1}$- and a-chains and is located in the aminoterminal end, which, by electron microscopy, appears as a globular head, made up by both the a and ß subunits, standing more than 10 nm above the cell surface ([10]). In response to matrix ligands, they generate intracellular signals [i.e., tyrosine phosphorylation, elevation of intracellular Ca $^{2+}$, and activation of focal adhesion kinase (FAK), which then acts as a docking site for cytoskeletal proteins and signaling molecules].

In response to mechanical forces arising from collagen matrices, ß $_{1}$ maintains the viability of fibroblasts, mediated by PI3K through the Akt/protein kinase B ([11]). Other signals lead to cytoskeletal reorganization and gene expression regulating cell migration, proliferation, differentiation, and survival (outside-in signaling). The cytoplasmic ß $_{1}$ domain initiates inside-out signaling, modifying the conformation of the extracellular domain and increasing ligand-binding affinity. Two highly conserved motifs of the ß $_{1}$ cytoplasmic tail (NPXY) are critical for adhesion to FN and localization to focal adhesion sites. The 14 *C*-terminal amino acids of the cytoplasmic region of the ß $_{1}$ subunit are associated with a 200–amino acid phosphoprotein known as *ICAP-1* (integrin cytoplasmic domain–associated protein) ([12]), which is constitutively phosphorylated and promotes ß $_{1}$-dependent cell migration. The ß $_{1}$ integrins determine collective movement of malignant cell clusters ([13]). In such clusters, “forerunner cells” open a path for cells following behind the “guiding” cells. In the absence of ß $_{1}$ integrin, cell dissemination follows an ameboid, crawling pattern.

For special functions of a-ß $_{1}$ heterodimers, see CD49. The a $_{7}$ß $_{1}$ heterodimer selectively binds to laminin and plays a role in skeletal muscle differentiation. The a $_{8}$ß $_{1}$ is expressed predominantly in the nervous system and promotes axon growth in spinal cord, optic, and auditory systems ([7]). The a $_{9}$ß $_{1}$ is detected in airway epithelium, basal layer of squamous epithelium, smooth and skeletal muscle, and hepatocytes ([14]). It binds to ADAM 15 (*a d*isintegrin *a*nd *m*etalloprotease), and the interaction mediates binding of sperm to oocytes. (For ADAM family of proteins, see CD156.) The a $_{10}$ß $_{1}$ integrin is expressed on chondrocytes, hyaline cartilage of joints, trachea, bronchi, and aortic and atrioventricular valves and plays a role in cartilage development ([15]). The a $_{11}$ß $_{1}$ integrin is expressed in the uterus, heart, and skeletal muscle ([16]). It is a receptor of interstitial collagens and has a role in organization of interstitial collagen matrices during development.

CD30 (Ki, BER-H2 ANTIGEN)

Structure: CD30 is a member of the TNF receptor (TNFR) SF ([1]). The extracellular region contains cysteine-rich repeats (five or six), each containing approximately 40 amino acids. A hinge sequence separates the third from the fourth repeat and may have derived from another repeat. The hinge and a sequence proximal to the membrane is rich in Ser, Thr, and Pro, potential sites for O-glycosylation.

The cysteine-rich motifs are found in many receptors of growth factors and are involved in ligand binding. Mapping the epitopes on CD30 with monoclonal antibodies (Ki 1, Ki 2), it is visualized that the *N*- and *C*-terminals of the extracellular region are in close proximity, and as a result, the trimeric form of CD30 on Hodgkin and Reed-Sternberg (H-RS) cells assumes a flowerlike structure ([2]). The cytoplasmic region is large but has no death domain (DD) and no tyrosine kinase sequences.

It binds the TNFR–associated factor (TRAF)-1, TRAF-2, TRAF-3 (or CRAF-1), and TRAF-5. TRAFs are signal-transducing molecules associated with the CD40 and TNFR type 2 ([3], [4]). They bind to the *C*-terminal 36-66 residues, which contain three distinct sites or subdomains, D $_{1}$, D $_{2}$, and D $_{3}$. Depending on the cell type, these molecules induce cell proliferation or cell death.

CD30 exists in a soluble form in the serum.

Gene locus: 1p36.

Molecular mass (kd): 120.

Distribution: Originally, CD30 was identified as *Ki-1 antigen* on Reed-Sternberg cells in Hodgkin lymphoma ([5]). It is not detected on resting peripheral blood B, T, and NK cells but is induced after activation. Monocytes and macrophages are negative, but cells around the lymph node follicles are CD30 $^{+}$. Epithelial cells and Hassall

corpuscles in the thymic medulla are CD30 $^{+}$. It is detected in large cell lymphoma, or Ki-1/CD30 $^{+}$ lymphoma (ALCL), which includes a number of lymphocytic neoplasms other than ALCL ([6]), including T-cell lymphomas. CD30 is expressed on T cells infected with HIV, and cross-linking of CD30 reactivates HIV production ([7]). Expression of CD30 is regulated by co-stimulatory signals from CD28 and IL-4.

Embryonal carcinoma and mixed germ cell tumors are CD30 $^{+}$.

Function: CD30 is a pleiotropic molecule and activates different signaling pathways on different cells ([8]). It induces Ig secretion (EBV-derived cell lines), proliferation (T-cell Hodgkin disease–derived lines), cytolytic cell death (ALCL cell lines) ([9]), and lymphocyte trafficking. The ligand for CD30 (CD30L or CD153) is a member of the TNF family of cytokines. The molecular mechanism of CD30 activity is overproduction of NF-?B, which can be constitutive or a result of overexpression of CD30 ([10], [11]). Induction of NF-?B by CD30 is mediated by TRAF-2 and TRAF-5, which bind to two of the three subdomains of the cytoplasmic tail of CD30 ([12]). However, NF-?B can also be induced in the absence of TRAFs.

In H-RS cells, overexpression of CD30 leads to its self-aggregation and recruitment of TRAF-2 and TRAF-5 ([13], [14]). Overproduction of NF-?B induces IL-13 secretion (in the absence of TCR engagement), and by this autocrine mechanism, IL-13 promotes survival of Hodgkin cells. In contrast to Hodgkin cells, CD30 ligation induces apoptotic death of ALCL cells, probably by the inability of these cells to activate NF-?B production ([15], [16]). IL-13 exacerbates allergic inflammation, and in this case, it is secreted through interaction of CD30 on primed T cells with CD30L on eosinophils. This interaction is TCR independent and is mediated by TRAF-2 with downstream activation of the MAP kinase (MAPK) pathway and c-Jun induction (not NF-?B). IL-13 promotes airway inflammation and tumor progression ([17]). In H-RS cells, confocal immunofluorescence has shown that TRAF proteins are aggregated near the cell membrane and are co-localized with IKKa and IKBa, whereas in lymphoma cells, these proteins are diffusely distributed.

CD31 [PLATELET ENDOTHELIAL CELL ADHESION MOLECULE-1 (PECAM-1)]

Structure: The extracellular region consists of six Ig-like domains of the C2 type, which are found in cell adhesion molecules ([1], [2]). Domain 2 contains a consensus recognition sequence for glycosaminoglycan binding. Both domain 2 and 6 are important for heterophilic adhesion. Domain 5 is incomplete as it lacks some of the ß strands ([3], [4]).

The cytoplasmic region contains ITIM motifs characteristic of inhibitory receptors. It plays an important role in ligand interactions mediated by the extracellular region. Deletion of the *C*-terminal third of the cytoplasmic region converts the adhesion interactions mediated by CD31 from heterophilic to homophilic.

Another role of the cytoplasmic region is in signal transduction. It contains Ser and Tyr residues, which are phosphorylated after cell activation. The protein-tyrosine phosphatases, SHP-1 and SHP-2, bind to two Tyr-containing sequences (ITIMs) found in inhibitory receptors ([5], [6]).

Several alternatively spliced variants have been identified, all of them involving the transmembrane and cytoplasmic regions. The cytoplasmic region is required for CD31 to localize to cell–cell borders and support aggregation. It is encoded by seven short exons, which may represent discrete functional entities.

Gene locus: 17q23.

Molecular mass (kd): 130 to 140.

Distribution: CD31 is widely distributed among cells of the vascular compartment. In endothelial cells (approximately 10^{6} copies/cell), it is concentrated at cell–cell junctions. It is expressed on platelets (approximately 5×10^{3}/cell), monocytes, neutrophils, a subset of naïve CD8 $^{+}$ and CD4 $^{+}$ T cells, bone marrow stem cells, and cell lines of myeloid and megakaryocytic lineage.

Function: CD31 mediates two basic cellular functions: (a) *adhesion*, which is homophilic (CD31-CD31) or heterophilic (CD31–another molecule); and (b) *signal transduction* through the protein tyrosine phosphatases SHP-1 and SHP-2, which bind to the cytoplasmic ITIMs ([7]).

- *Adhesion function*. CD31 is a key participant in extravasation of neutrophils and monocytes involving a homophilic interaction (i.e., CD31 of leukocyte and CD31 of the endothelial cell ([8], [9] and [10]). CD31 mediates transmigration of CD34 $^{+}$ cells across endothelium after activation by growth factors ([11]). Although heterophilic ligands have been identified, including the integrin a $_{V}$ß $_{3}$ and glycosaminoglycans found in heparin, these interactions could not be verified ([12]). Homophilic interaction, which causes CD31 aggregation, induces phosphorylation of Tyr residues on ITIMs, acting as docking sites for SHP-1 and SHP-2 protein tyrosine phosphatases. SHP-1 and SHP-2 are known as *inhibitory signaling molecules* because they dephosphorylate activating kinases, although depending on the cell type and the associated substrates, they can also transmit positive signals ([13], [14]). It is suggested that CD31 activation leads to modulation of affinities of integrins. This was shown for CR3 (CD11b/CD18), a ß $_{2}$ integrin on monocytes and neutrophils, and for ß $_{1}$ integrin modulating T-cell adhesions to endothelial cells. According to this view, homophilic interactions are always the primary event leading to CD31 activation and involvement of other adhesion molecules. Domains 1 and 2 of the extracellular region are implicated in the transendothelial migration of monocytes (diapedesis), whereas domain 6 is responsible for their passage through the extracellular matrix (interstitial migration).
- *CD31 as an inhibitory receptor*. The presence of ITIM sequences in CD31 places it in the subfamily of inhibitory receptors [i.e., KIRs (killer inhibitory receptors), Fc?RII (CD32), CTLA-4 (CD152), and so forth] ([15]). Indeed, CD31 exerts inhibitory regulation of signal transduction by TCR and production of autoantibodies by B cells ([16]). Mice deficient of CD31—lacking the normal inhibitory function of CD31—develop an autoimmune disease. CD31 is expressed on naïve T cells but is lost in memory T cells, which become more responsive to stimuli for production of IL-4.
- *Cellular functions*. In response to thrombin activation of platelets, CD31 is phosphorylated, associated with the cytoskeleton, and redistributed on the surface of the cell as the platelets spread ([17]). CD31 mediates responses of endothelial cells to H_2O_2, released by neutrophils, increases intracellular Ca^{2+}, and induces secretion of prostacyclin, thus regulating responses of endothelial cells to oxidant-mediated injury ([18]). CD31 generates signals that cause release of normal cells attached to macrophages, thus preventing phagocytosis of viable cells. However, this mechanism is lost in apoptotic cells, which are phagocytosed ([19]).
- *Other functions*. CD31 plays a role in angiogenesis ([20]), in normal and neoplastic tissues, and in cardiovascular morphogenesis in mice. CD31 mediates the endothelial interactions (tube formation) or interactions of endothelial cells with surrounding cells. CD31 is the target in drug-induced thrombocytopenias ([21]). Antibodies to carbimazole bind to CD31 on the addition of the drug. In thrombocytopenias induced by quinidine, the antibodies react with CD31 as well as with gpIb/IX and gpIIb/IIIa.

CD32 (FC?RII)

Structure: CD32 is a member of the IgSF and contains in its extracellular region two Ig-like domains of the C2 type ([1], [2], [3], [4], [5] and [6]). There are three genes in the order, A-C-R, which encode six isoforms, IIa $_{1-2}$, IIc, and IIb $_{1-3}$, with the same extracellular but different cytoplasmic regions. Additional heterogeneity is introduced by polymorphisms caused by variations of a single residue. The cytoplasmic region of IIa and IIc contains an ITAM motif, whereas IIb has an ITIM ([7]). The Fc?RII is a low-affinity receptor for the Fc fragment of Ig.

Gene locus: 1q23.

Molecular mass (kd): 40.

Distribution: CD32 is expressed on monocytes (IIA, IIB, IIC), granulocytes (IIA, IIB, IIC), macrophages (IIA and IIB), B cells (IIB only), NK cells (IIA, IIB), endothelial cells, platelets (IIA), eosinophils (IIA), mast cells (IIA, IIB), and Langerhans cells. When activating and inhibitory receptors are coexpressed, the ratio of the expression determines the cellular response.

Function:

- *Fc?RIIA*. Cross-linking of the activating Fc?RIIA results in degranulation, phagocytosis, ADCC, transcription of cytokine genes, and release of inflammatory mediators ([8], [9]). These functions are indicative of the central role of these receptors in mediating inflammatory responses by cytotoxic IgG and IgG ICs. The initial event is translocation of the receptor to lipid rafts (i.e., membrane cholesterol-rich microdomains, which are of low density and are detergent resistant) (see Chapter 17) ([10], [11]). It is followed by phosphorylation of ITAMs by Scr family of PTKs, such as Lyn, associated with the rafts, initiating the cascade for phagosome and superoxide formation ([12], [13]). The translocation of the receptor to the lipid rafts is followed by its degradation. A single tyrosine residue upstream of the ITAM motif is important for phagocytic signaling and interaction with the Syk kinase, which plays a critical role in phagocytosis ([3]). The next event is the formation of the phagolysosome, which depends on the cytoplasmic tail but not the ITAM sequence.
- *Fc?RIIB.* This isoform is expressed on B cells and functions as an inhibitory receptor ([14], [15]). Cross-linking of the receptor by the ligand induces raft reorganization and coalescence. The extracellular and transmembrane regions are important at this stage. The inhibitory activity of the IIB receptor is determined by the 13–amino acid sequence of the ITIM, which is necessary and sufficient to mediate cancellation of the activating signal initiated by the BCR. Phosphorylation of the ITIM leads to binding of inositol phosphatase SHIP (Scr homology 2–containing inositol polyphosphate 5-phosphatase) or of the protein tyrosine phosphatase SHP-1 (Scr homology 2–containing protein tyrosine phosphatase 1) ([16]). The binding of one or the other phosphatase depends on a particular amino acid on either side of the single Tyr of the ITIM. SHIP inhibits Ca^{2+} mobilization and blocks ADCC, cytokine, and proinflammatory mediator release. Arrest of proliferation of B cells is mediated through inactivation of MAP kinases. The IIB receptor maintains peripheral tolerance for B cells. It interacts with immune complexes (ICs) on follicular DCs and triggers apoptosis of B cells during the selection process of centrocytes in the light zone (see Chapter 16). Fc?RIIB knock-out mice produce autoantibodies and develop autoimmune diseases as a result of loss of normal inhibitory function for B cells. They exhibit exaggerated IC-mediated organ damage (i.e., alveolitis, arthritis, systemic anaphylaxis). IIB receptor sets the threshold for responses by other receptors such as BCR (autoantibodies), Fc?RIIB (cutaneous anaphylaxis by ICs), or FceRI (systemic IgE-mediated anaphylaxis).
- *Other functions*. The IIA receptor exists in two alleles, position 131 being His or Arg. The H-131 is the only Fc?R that recognizes IgG2 efficiently and is able, in the homozygous state, to clear IgG2 ICs, an essential function in systemic lupus erythematosus. The H-131 allele is decreased significantly in patients with lupus nephritis ([17]). The Fc?RIIB is important in treatment of malignancies by monoclonal antibodies ([18]). Trastuzumab (Herceptin) and rituximab (Rituxan) engage both activating (Fc?RIII) and inhibitory (Fc?RIIB) receptors. Ideally an antibody against tumors should bind preferentially to activating and minimally to inhibitory receptors.

CD33 [SIALIC ACID–BINDING IMMUNOGLOBULIN SUPERFAMILY LECTIN (SIGLEC)-3]

Structure: CD33 is a member of a new family of sialic acid–binding proteins ([1]). There are 11 members in the Siglec family ([2], [3]), and four of them, Siglecs 5, 7, 8, and 10, share a high degree of sequence homology with CD33 (approximately 50 to 80%), forming a subfamily of CD33-related Siglecs. CD33 has the smallest extracellular region of all Siglecs, consisting of two Ig-like domains, one NH_2 terminal V-type followed by one C2 type (Siglec 1 has 17 Ig-like domains). The two Ig-like domains are linked by a disulfide bond, and the V domain interacts with sialic acid through an Arg conserved in all Siglecs, forming a salt bridge. The cytoplasmic region contains two Tyr, one (Y340) located within an ITIM motif and the other (Y358) within a SLAM-like motif (TEYSEV). SLAM (*s*ignaling *l*ymphocyte *a*ctivation *m*olecule) allows the docking of SAP (SLAM-associated protein), which inhibits the binding of SHP-2 phosphatase and prolongs activation signaling.

CD33 has two serine phosphorylation sites catalyzed by protein kinase C, therefore it is also a phosphoprotein. Phosphorylation is augmented by IL-3 erythropoietin or GM-CSF ([4]). Inhibition of this pathway of CD33 activation shifts the dependence of CD33 function to its lectin activity.

Gene locus: 19q13.3.

Molecular mass (kd): 67.

Distribution: CD33 is a myelomonocytic marker that is absent in $CD34^+$ stem cells but expressed in the early precursors after CD34 ([5]). Its expression declines with myeloid differentiation and is weak in neutrophils. However, monocytes are strongly positive for CD33. It is a useful marker in distinguishing AML from ALL, but in occasional cases of mixed lineage acute leukemias, it is coexpressed with lymphoid markers.

Function: Each Siglec is expressed in a highly restricted manner [i.e., sialoadhesin in macrophages, myelin-associated gp (MAG) in oligodendrocytes and Schwann cells, CD22 in B cells, and so forth]. Their ligands are sialic acids (i.e., acidic monosaccharides) found on cell-surface glycoconjugates. Although CD33 prefers an a2-6–linked sialyllactose, it can also bind to an a2-3 bond. The presence of ITIM sequence in its cytoplasmic region places CD33 among the family of inhibitory receptors ([6]). Ligand binding triggers phosphorylation of the two tyrosines, which act as docking sites for SHP-1 and SHP-2 phosphatases ([7], [8]); however, only Tyr340 is critical for binding of the two phosphatases. Recruitment of SHP-1 and SHP-2 down-regulates calcium mobilization induced by CD64 (Fc?RI).

The function of CD33 in myeloid differentiation is unknown. CD33 inhibits generation of DCs from monocytes or $CD34^+$ myeloid precursors ([9]). Anti-CD33 antibodies inhibit differentiation of normal $CD34^+$ cells in cultures supplied with stem cell factor and GM-CSF ([10]) or proliferation of chronic myelogenous leukemia (CML) cells in the presence of GM-CSF. Similarly, AML cells displaying a high degree of *in vitro* proliferation in the presence of GM-CSF were inhibited by anti-CD33 antibodies ([11]), inducing apoptosis of AML cells ([12]). Antibodies to CD33 acted synergistically with etoposide or cytosine arabinoside at suboptimal doses of the drug.

A humanized murine anti-CD33 antibody linked to calicheamicin (gemtuzumab) is in use (phase II trials) in the treatment of relapsed AML ([13]).

CD34 (MY10, SGP^{90})

Structure: CD34 is a highly glycosylated type I transmembrane gp, member of the sialomucin family of proteins, and similar to leukosialin or CD43 ([1]). The extracellular region contains adhesion recognition sequences and has several N- and O-potential glycosylation sites in the first 130 amino acids ([2], [3] and [4]). This region is followed by a sequence, which has six cysteine residues and is expected to form a globular structure.

The cytoplasmic region has two PKC phosphorylation sites and one tyrosine phosphorylation site, which suggests that CD34 may be involved in signal transduction. A splice variant is generated by the insertion of an additional exon between exons 7 and 8. This introduces a stop codon and produces a truncated protein, retaining only 16 amino acids.

Gene locus: 1q32.

Molecular mass (kd): 116 (estimated by mobility of the natural protein). Based on amino acid sequence, it is only 40.

Distribution: It is expressed on hemopoietic stem cells with the capacity to repopulate bone marrow for all lineages ([5], [6] and [7]). However, $CD34^-$ stem cells also exist and have the potential for engraftment ([8]). CD34 expression disappears with differentiation to more mature stages of myelocytic and lymphocytic lineages. Its expression is up-regulated after PKC activation and is independent of transcription or translocation ([9]).

Outside the hemopoietic system, CD34 is expressed on endothelial cells ([10]). In murine tissues, CD34 is expressed in the vessels of all organs examined ([11]). CD34 is a major counter-receptor for L-selectin ([12]).

Function: The function of CD34 in hemopoiesis is still unknown. Interaction with L-selectin suggests that CD34 functions as an adhesion molecule and, possibly, through interaction with bone marrow stroma, mediates retention of stem cells in the bone marrow ([13]). In hematopoietic differentiation, CD34 may prevent terminal differentiation, which occurs only after its down-regulation. TGF-ß $_1$ influences $CD34^+$ Lin^- progenitor cell differentiation, maintaining these cells in an undifferentiated state ([14]). Curiously, CD34 knock-out mice suffer from only minor hemopoietic defects. CD34 is a useful marker for phenotypic identification of

various leukemias.

CD35 [COMPLEMENT RECEPTOR (CR) 1: CR1, C3bR, C4bR]

Structure: CR1 is a single-chain, type I transmembrane glycoprotein, a member of the family of regulators of complement activation, which includes CR2 (CD21), decay-accelerating factor (DAF; CD55), membrane cofactor protein (MCP; CD46), and so forth (see Chapter 18) ([1]). The extracellular region of the most common, A, allele, is composed of 30 domains known as *complement control protein (CCP) repeats* previously known as *short consensus repeats* (SCR), or *sushi domains* ([2], [3]). One CCP domain contains 59 to 75 residues. Four cysteines and one tryptophan occupy an invariant position. Disulfide bonds are formed between the cysteines, 1?3 and 2?4. The disulfide bonds fold the CCP domain in a globular conformation with ß sheets joined by hypervariable loops ([4]). All CCP domains, except the two carboxyterminals, form larger units known as *long homologous repeats* (LHRs). Each LHR consists of seven domains. There are four allelic variants of CR1: CR1-1 (or A, four LHRs), CR1-2 (B, five LHRs), CR1-3 (C, three LHRs), and CR1-4 (D, six LHRs). Starting from the NH_2 terminal end, the LHRs are known as *A*, *B*, *C*, and *D*. CR1 carries the Knops blood group antigens (1% in whites and 40 to 50% in African populations).

The CCP domains are characteristic of complement control proteins, but they are also found in other proteins without complement control function, such as IL-2 receptor and factor XIIIb. The cytoplasmic region consists of 43 amino acids versus the 1930 of the extracellular region.

Gene locus: 1q32.

Molecular mass (kd): A: 190; B: 220; C: 160; D: 250.

Distribution: Expressed on blood cells except platelets, NK cells, and most T cells. Because of their numeric superiority, the erythrocytes express 90% of CR1 in the blood. The number of CR1 per cell are as follows: neutrophils, monocytes, B cells: 20,000 to 40,000; subpopulation of T cells, 1000 to 5000; erythrocytes, 100 to 1000. It is expressed on follicular DCs, podocytes, and astrocytes. CD35 is released from cells, and in picomolar concentrations, it is found in a soluble form in blood. Neutrophils and monocytes can rapidly up-regulate CR1 expression, released to the membrane from an intracellular compartment. Up-regulation is induced by anaphylatoxin C5a, endotoxin, cytokines, and so forth. Expression on B cells is detected on pre-B cells and increases with maturation. In contrast, in the myeloid lineage, CR1 is detected on mature cells (i.e., neutrophils and bands) but only in 1% of myelocytes.

Function: CR1 is a multifunctional molecule. Its ligands are C3b, C4b, and, with lower affinity, iC3b and C3dg. It is also a receptor for C1q ([5]) and for mannan-binding lectin, a protein of the innate immune system, which recognizes carbohydrates on pathogens ([6]). The C3b- and C4b-binding sites are in the first three CCPs of LHR A (site 1), LHR B (site 2), and LHRC (site 3). Site 1 binds only C4b, whereas site 2 and site 3 bind both C3b and C4b complement fragments ([7], [8]).

The erythrocyte CR1 serves as an *immune adherence receptor* for complexes opsonized with C3b/C4b ([9]). This property plays an important physiologic role for removal of ICs, which are delivered to the liver or spleen. Removal of ICs by erythrocytes prevents their deposition to other tissues (i.e., vessels or kidney) and thus protects them from IC-mediated tissue damage ([10]). Another important function of this “shuttle” service by the CR1 of erythrocytes is in immunologic defense. Bacteria and viruses opsonized by complement are captured by CR1 of erythrocytes and are prevented from leaving the bloodstream to invade susceptible tissues, while at the same time, they are delivered to tissue phagocytes to be destroyed. In this process, phagocytes remove the opsonized particle and CR1 while sparing the erythrocyte. Clearance of infectious agents by erythrocytes in animals was achieved very rapidly using antibodies specific for the pathogen, cross-linked with anti-CR1 antibodies (heteropolymers). The anti-CR1 antibody in these complexes takes the place of complement. CR1 contributes to regulation of complement as a result of its two properties: decay-accelerating activity (DAA) ([11]) and cofactor activity (CA). CR1 accelerates the decay of all convertases, that is, the classical (C4b2a) and alternative (C3bBb), by displacing C2a and Bb, respectively ([1]). CR1 acts as cofactor for factor I, a serine esterase that cleaves C3b and C4b to hemolytically inactive forms. As cofactor, it promotes cleavage by factor I of C3b to $iC3b_1$, $iC3b_2$, and to C3dg and C3c ([1]). Only CR1 can generate C3dg fragments. C4b is similarly cleaved by factor I with CR1 as cofactor. Site 1 contains the DAA for both C3 convertases, whereas for C5 convertases, LHR A and LHR C are required. The CA activity resides in site 2. CR1 enhances phagocytosis mediated by Fc receptors on monocytes, especially after activation by cytokines, and also triggers secretion of IL-1a, IL-1ß, and prostaglandins from human monocytes. Individuals with the Hegelson blood group type have partial CR1 deficiency, that is, less than 50 copies of CR1/RBC, but no disease. In lupus erythematosus, however, reduced levels of CR1 correlate with disease activity.

As a result of its DAA and CA activities, CR1 inhibits inflammation induced by complement activation. Soluble CR1 has been used in clinical trials to reduce tissue damage in myocardial infarction, lung transplantation, adult respiratory distress syndrome, and in patients undergoing cardiopulmonary bypass ([12]).

Attachment to CR1 of the sialyl-$Lewis^X$ saccharide allows binding of CR1 to E and P selectins in inflamed endothelia, blocking extravasation of leukocytes while at the same time neutralizing complement by its DAA or CA activity. Mutations on site 1 generate CR1 with fourfold enhanced DAA activity for both C3 convertases, whereas other mutations, particularly replacement of Phe-82 (site 1) with Val, abrogates DAA.

CD35 and CD21 have a very important role in immunity. CD21 increases follicular retention and survival of B cells in germinal centers, and CD35 helps to trap antigen–antibody complexes on follicular DCs ([13]). However, CD35 only inhibits B-cell activation. Although the cytoplasmic region of CD35 has no signaling capacity, it is possible that it may associate with the Fc receptor ([14]).

CD36 (PLATELET GLYCOPROTEIN IV)

Structure: CD36 is a member of scavenger receptor class B, which includes scavenger receptor B-1, the receptor for cholesterol ester, and the lysosomal integral membrane protein II. It is a receptor for thrombospondin-1 (TSP-1), called *platelet gp IV* because it is detected in platelet granules ([1]). There are two transmembrane regions; one each on the *C*- and *N*-terminal ends of the molecule. The bulk of the protein is located extracellularly, whereas the two intracellular tails are short (9 to 13 amino acids). Most of the glycosylation sites are located within the *N*-terminal end, whereas the *C*-terminal is proline rich and contains six cysteines. The C-terminus has a sequence that may serve for signal transduction ([2]). TSP-1 binding is mediated by the sequence 93 to 120, oxidized low-density lipoprotein (oxLDL) binds to sequence 120 to 155, and apoptotic cells to residues 155 to 183.

Gene locus: 7a11.2.

Molecular mass (kd): 88/113.

Distribution: Expression is broad (i.e., detected in platelets, monocytes, macrophages, DCs, megakaryocytes, and erythroid precursors). Among other cells, it is expressed on the endothelium of small vessels (not large), epithelia of retina, breast, intestine, smooth and skeletal muscles, and adipocytes. CD36 is localized in caveolae (i.e., cholesterol- and sphingolipid-enriched membrane microdomains), which are considered to concentrate and integrate signaling molecules and are involved in cholesterol trafficking. Expression is up-regulated in monocytes by M-CSF, GM-CSF, IL-4, and native and modified LDL. It is down-regulated by corticosteroids, $TGF\text{-}ß_1$, high-density lipoprotein, and LPS. A critical regulator is PPAR-?, a nuclear hormone receptor that functions as a transcriptional regulator of genes linked to lipid metabolism.

Function: CD36 is a multifunctional receptor ([3]). Several ligands have been identified: long-chain fatty acids (LCFAs), oxLDL ([4], [5] and [6]), anionic phospholipids ([7]), collagens I and IV, and TSP-1. CD36 binds to apoptotic cells ([8], [9]), *Plasmodium falciparum*–infected RBCs ([10]), retinal photoreceptor outer segments, and sickle red cells. In performing its function, CD36 acts in concert with other proteins (i.e., fatty acid–binding protein, caveolin, integrins, cytoskeletal proteins, and signaling molecules).

Atherogenesis. CD36 plays a critical role in the formation of foam macrophages ([11]). Entrapped LDL becomes oxidized by inflammatory stimuli and is taken up by CD36 expressing phagocytic cells, which become foam cells. The cycle is perpetuated as a result of generations of lipid by-products activating CD36 and PPAR-? ([12]) genes in a positive feedback loop. Mice deficient in CD36 are defective in uptake of oxLDL and foam cell formation ([11]).

Phagocytosis of apoptotic cells. CD36 is involved in the clearance of apoptotic cells in cooperation with a $_Vß_3$ integrin. Phosphatidylserine, an anionic phospholipid

on apoptotic cells, may act as the ligand for CD36 for phagocytosis of apoptotic cells. By this function, CD36 plays an important role during development, infection, and immunity. Another function of CD36 related to clearance of apoptotic cells is the removal of photoreceptor rod outer segments (ROS), which are shed daily and must be phagocytosed to maintain normal vision. ROS membranes contain anionic phospholipids that are removed by CD36 expressed on retinal pigment epithelium.

Malaria and sickle cell disease. RBCs infected with *P. falciparum* are cleared by macrophages ([10]). CD36 binds to infected RBCs, and their removal depends on a $_{V}ß_{3}$ integrin. CD36 may also recognize RBCs with sickle hemoglobin. Because sickle cells move slower, adhesive interactions develop between CD36 and TSP-1, which may contribute to pathology of sickle cell anemia.

CD36 and transportation of LCFAs. LCFAs are important for energy production. CD36 acts as transporter of LCFA to skeletal muscle and heart and contributes to lipid homeostasis.

Antiangiogenic activity. TSP-1 is a potent inhibitor of tumor angiogenesis ([13]). CD36 mediates this function of TSP-1 as a result of activation of an apoptotic pathway via caspase-3.

CD36 and diabetes. AGEs derive from long exposure of protein to glucose and have been implicated in a number of degenerative diseases ([14]). CD36 is one of the receptors of AGEs and mediates their endocytosis. Whether this process contributes to microvascular changes in diabetes remains to be seen.

CD38 [ADENOSINE DIPHOSPHATE (ADP)–RIBOSYLCYCLASE, CYCLIC ADP–RIBOSE HYDROLASE]

Structure: CD38 is a non–lineage-restricted type II transmembrane protein (NH_2 terminus in the cytoplasm), which is an *ectoenzyme* ([1]). The extracellular region is large and contains two hyaluronate (HA)-binding motifs, and a third present in the cytoplasmic region. The HA motifs may function for attachment to the extracellular matrix. There are 12 conserved cysteines, 11 of which are located in the extracellular region, and four of them play an essential role in the cyclic adenosine diphosphate (cADP) ribose synthetic and hydrolytic activity. The *C*-terminal part and particularly Cys-275 contribute to the *nicotinamide adenine dinucleotide* (NAD) glycohydrolytic activity. The disulfide bonds are important for the catalytic activity because 2-mercaptoethanol, which splits disulfide bonds, inhibits the enzymatic function of CD38. A conserved pair of amino acids, Gly-146/Asp-147, endows the ADP-ribosyl transferase activity to the CD38 protein. A number of leucines within the transmembrane and extracellular regions potentially form leucine zipper motifs that mediate association of CD38 with other proteins.

Gene locus: 4p15.

Molecular mass (kd): 45.

Distribution: In hematopoietic cells, CD38 expression is discontinuous, that is, it is switched on and off several times during cell differentiation. Uncommitted stem cells are $CD38^-$, whereas committed $CD34^+$ cells are $CD38^+$. B-cell progenitors are $CD38^+$, but circulating naïve B cells are $CD38^-$. In LN follicles, centroblasts are $CD38^+$, giving rise to $CD38^+$ centrocytes in the light zone of germinal center. Centrocytes that survive apoptosis differentiate into memory B cells, which are $CD38^-$, or plasma cells that are strongly $CD38^+$. Early T-cell precursors of the subcortical area are $CD38^+$; expression is maintained through the double-positive stage then declines in naïve single-positive T cells in the periphery that regain expression during activation. Myeloid precursors are $CD38^+$, but neutrophils $CD38^-$. It is expressed on monocytes, NK cells, erythroid progenitors, erythrocytes, and platelets. Outside of the hematopoietic system, it is detected in skeletal and heart muscle, proximal convoluted tubules of kidney, thyroid, brain, prostate (but not in benign prostatic hypertrophy), and vascular endothelium.

Function:

- *Molecular mechanisms*. NAD^+ is an important coenzyme involved in many biological reactions ([2], [3] and [4]). NADases catabolize NAD^+ by breaking the bond between the nicotinamide and the adenosine diphosphoribose (ADPR). CD38 has a complex enzymatic function involving two or three enzymatic pathways: (a) Its favorite function (97%) is the conversion of NAD^+ to ADPR (*glycohydrolase activity*); (b) it cyclizes ADPR to cADP-ribose (cADPR) (*cyclase activity*); and (c) it hydrolyzes cADPR to ADPR (*hydrolase activity*) ([5], [6] and [7]). cADPR is an important second messenger because it raises intracellular calcium independent of IP3 through ryanodine-sensitive receptors in intracellular Ca^{2+} store. CD38 also functions as transferase of cADPR to cysteine or arginine on target proteins. There is a serious topologic problem regarding the function of CD38: Its catalytic site is extracellular, whereas its substrate is in the cytoplasm. Because CD38 is internalized on ligation, it is conceivable that CD38 and its substrate will come together ([8], [9], [10], [11] and [12]). Recently, it has been shown that a protein known as *connexin 43* (CX43) forms hexameric channels, which act as a transporter system for NAD^+ on the plasma membrane. These channels allow the entrance of NAD^+ into vesicles where CD38 catalyzes its conversion to cADPR, which in turn is actively transported to cytosol by “dimeric” or “tetrameric” CD38 channels. Other data indicate that cADPR is not required for initiation of its own signal transduction but is required for enhancing proliferation of already replicating cells. Extracellular regions altered by mutations do not affect the catalytic and signal transduction functions. The suggestion was made that CD38 is associated with an intermediary protein that communicates between CD38 and BCR extracellularly. This messenger protein, named *ARAP* (*a*ntigen *r*eceptor– *a*ssociated *p*rotein), is released after conformational changes occurring on ligation and associates with BCR. Thus, CD38 “borrows” the efficient signaling machinery of BCR.
- *Cellular functions.* Antibodies to CD38 act synergistically with submitogenic doses of endotoxin and augment proliferative responses of naïve B cells ([13]). CD38- and IgM-mediated signal transduction are probably linked, because B cells unresponsive to IgM-mediated stimulation are also unresponsive to stimulations through CD38. Signal transduction through CD38 probably is regulated by Bruton's kinase (Btk). Another example of the “functional” linkage with other molecules in signal transduction is its association in NK cells with CD16 ([14]) for control of Ca^{2+} fluxes and tyrosine phosphorylation. CD38 triggers cytotoxic responses in activated NK cells, whereas stimulation through CD38 induces cytokine production from T cells and prevents apoptosis of germinal center B cells ([15]). As a cell marker, CD38 is used in phenotyping acute and chronic leukemias. In B-CLL, expression of CD38 is an important prognostic marker and a predictor of clinical outcome ([16], [17], [18] and [19]). Quantification rather than percentages of positivity may have a better predictive value to identify B-CLL patients who are likely to progress ([20]). Patients with $CD38^+$ B-CLL have a significantly more aggressive disease regardless of clinical stage ([21]).

CD39 (E-NTPDase: ECTO-NUCLEOSIDE TRIPHOSPHATE DIPHOSPHOHYDROLASE, APYRASE, ECTO-ATPase)

Structure: CD39 belongs to the growing family of ectoenzymes known as *ecto-apyrases* or *ecto-ATPases* or *E-NTPDases*. Their main function is to hydrolyze nucleoside triphosphates (NTP) or diphosphates (NDP) acting on the ? and ß phosphate residues of nucleotides. Members of this family are separated into two subgroups according to their membrane topography ([1], [2], [3] and [4]). Group A includes E-NTPDases 1 to 4, and Group B includes ENTPD5 and putative member NTPD6 or CD39L2. CD39 and the other members have two transmembrane regions leading to the N- and C-termini inside the cell. The larger portion of the molecule forms an extracellular loop, which contains the catalytic activity. The enzymatic activity is determined by five conserved sequences known as *apyrase conserved regions* (ACRs). Mutations of ACRs affect the specificity of the enzyme, which is also regulated by the two transmembrane regions. Change of H59 in ACR1 converts CD39 to an ADPase. NTDPase5 is identical to protooncogene PCPH that mediates cellular responses to stress. It has only one transmembrane region because it lacks the *C*-terminal hydrophobic sequence. The putative NTPDase6 has only one (*N*-terminal) transmembrane region.

CD39 has six putative glycosylation sites essential for its surface expression. Oligomers may be formed as a result of intermolecular cross-linking between cysteines, which affects catalytic activity. The new classification of these enzymes as proposed by Zimmerman et al. during the Second International Workshop on ecto-ATPases and related ecto-nucleotidases is presented in the table below.

A posttranslational modification of CD39 involves addition of palmitic acid within the *N*-terminal cytoplasmic region, which contains one Cys. This preferentially targets CD39 to membrane caveolae and may facilitate signal transduction.

Gene locus: 10q24.

Molecular mass (kd): 55 to 60.

Distribution: CD39 is present on the cell surface of activated B cells, NK cells, T cells, Langerhans and DCs, macrophages, polymorphonuclear cells (PMNs), platelets, and erythrocytes ([5]). It is detected on endothelial cells, endocardium, and vascular smooth muscle. NTPDase2 is a specific marker of pericytes and is found in the adventitia of muscularized vessels and other cells of the subendocardial space. CD39L2 has a predominant expression in the heart. Not all members are located on the cell surface. NTPDase4 is located in the Golgi apparatus and lysosomal vacuoles.

Function: CD39 is not active within the compartments of the secretory pathway until it reaches the plasma membrane. Glycosylation is essential for its membrane localization. This mechanism prevents CD39 from depleting intracellular ATP stores while still being transported from the Golgi apparatus to the cell surface ([6]). Nucleotides are released from the cytoplasm of cells into the extracellular space or lumen of intracellular organelles. In those locations, they influence a variety of physiologic functions such as platelet aggregation, vascular homeostasis, immune functions, and neuronal signaling interacting with extracellular receptors ([7], [8]). Their function in the extracellular space or the lumen of intracellular organelles is regulated by the NTPDases ([9]).

The specificity of these enzymes, which is determined by the ACRs, varies. Some hydrolyze primarily NTPs, whereas others attack diphosphates. NTPDase2 hydrolyzes primarily ATP rather than ADP; NTPD-ase 4 and 5 are uridine diphosphatases (UDPases). Enzymatic activities depend on millimolar concentrations of Ca^{2+} or Mg^{2+}. In the cardiovascular system, NTPDases regulate the actions of ATP on vascular tone, blood flow, and platelet aggregation (at sites of vascular damage or inflammation) ([10]) and reverses platelet aggregation induced by ADP, collagen, or thrombin ([11]). Mice deficient in CD39 exhibit increased cerebral infarct volumes and reduced postischemic perfusion ([12]). Soluble CD39 rescues these mice from cerebral injury.

CD39 inhibits IL-1 release from stimulated endothelial cells, suppresses E-selectin expression, and protects endothelial cells from apoptosis ([13]).

In the immune system, blockade of ecto-ATPase activity results in loss of effector functions of B, T, and NK cells.

Proposed New Nomenclature of E-NTPDases

New Classification	Old Classification
NTPDase 1	CD39 ectopyrase
NTPDase 2	CD39L1, ecto-ATPase
NTPDase 3	CD39L3, HB6
NTPDase 4	UDPase, LLALP70
NTPDase 5	CD39L4, ER-UDPase
NTPDase 6	CD39L2

NOTE: Family name: E-NTPDases. Individual members: NTPDase 1–6.

From Zimmermann H, Beaudoin AR, Bollen M, et al. Proposed nomenclature for two novel nucleotide hydrolyzing enzyme families expressed on the cell surface. In: van Duffel L, Lemmens R, eds. Ecto-ATPases and related ectonucleotidases. Maastricht: Shaker Publishing BV, 2000:1–8, with permission.

CD40

Structure: CD40 is a type I transmembrane phosphorylated glycoprotein member of the TNF-R family, which includes NGFR, CD27, CD30, CD95 (FAS), CD120a (TNFR-I), CD120b (TNFR-II), CD134 (OX-40), and CDW137 (4-1BB).

The extracellular region contains 22 cysteines, which form four domains homologous to those of the TNF-R family ([1]). The cytoplasmic region mediates signaling through association with other molecules, such as members of the TRAF (TNF receptor–associated factor) family ([2]). CD40 interacts directly with TRAF-1, TRAF-2, and TRAF-3, involving sequence ^{250}PVQET, whereas TRAF-6 binds to a membrane-proximal site ([3], [4]). T-254 is essential for association of TRAF-2 and -3 with CD40. Other sequences of the cytoplasmic region of CD40 also influence the binding of TRAF-2 and -3. A cytoplasmic molecule known as *I-TRAF/TANK* associates with TRAF-1 and -2 and prevents their binding to CD40. Therefore, high levels of this protein may prevent ligand-dependent recruitment of TRAFs to CD40.

Gene locus: 20q12-q13.2.

Molecular mass (kd): 48.

Distribution: Expression of CD40 is ubiquitous: B cells, thymocytes, T cells, monocytes, DCs, hematopoietic progenitors, stromal cells, and basophils. In nonhematopoietic cells, it is expressed by epidermal, epithelial, and endothelial cells, microglia, hepatocytes, smooth muscle cells, and so forth, as well as carcinomas of urinary bladder (although lacking in normal bladder epithelium), melanomas, and so forth.

Function:

- *Molecular mechanisms*. Binding of the CD40 ligand (CD154) triggers several cooperating signaling pathways. Five TRAFs ([1], [2], [3], [5] and [6]) associate via their TRAF domains to the cytoplasmic region of CD40 and initiate signaling cascades ([5], [6] and [7]). TRAFs form homotrimers, which are required for high-affinity interaction with trimeric CD40. Overall, TRAFs control the terminal phases of CD40-induced B-cell differentiation (i.e., germinal center formation, affinity maturation, and long-lived humoral immunity). Non–TRAF-binding domains of the cytoplasmic region are important in inducing early events such as B-cell proliferation, up-regulation of surface molecules, and early differentiation. A sequence of the cytoplasmic region proximal to membrane (N226-L235) mediates NF-?B activation and antibody secretion. The binding site for TRAF-6 is in proximity with the membrane, and TRAF-6 signals for NF-?B activation. A further downstream sequence (H236-Q257) up-regulates CD23, CD80, LFA-1, ICAM-1, and FAS. After association with TRAFs, signaling cascades lead to nuclear translocation of specific transcription factors. CD40 ligation activates expression of several genes as a result of activation of three major transcription factors: NF-?B, CRE (cAMP response element), and AP-1 ([8]). The binding sites of these factors are in the promoters of the genes activated by CD40. NF-?B up-regulates CD23, CD54, CD80 expression, and production of cytokines (IL-6, IL-12, GM-CSF, and so forth). CRE regulates activation of cytokine genes (IL-6, TNF-a, IL-12), whereas AP-1 regulates expression of CD25, CD54, and secretion of TNF-a. Screening gene expression with high-density oligonucleotide arrays shows that individual signaling pathways regulate some of the genes (“independent control”), whereas expression of other genes depends on cooperation between signaling pathways (“collective control”) ([9]).
- *Immune functions*. Absence of CD40/CD154 interactions results in gross impairment of T-dependent B-cell functions: (a) initiation and propagation of germinal center reaction; (b) B-cell activation; (c) B-cell proliferation (clonal expansion); and (d) B-cell differentiation and, with the addition of cytokines, especially IL-10, production of large amounts of antibodies ([10]). Ligation of CD40 induces production of IL-10 from macrophages. Withdrawal of CD40/CD154 stimulation leads to plasma cell differentiation while prolonged stimulation to memory B cells.
- *Inflammation*. CD40/CD154 interactions induces maturation of DCs, expression of cytokines and chemokines, adhesion, and co-stimulatory molecules. In turn, inflammatory mediators induce CD40 on endothelial cells and CD154 on both endothelial cells and platelets, leading to a cascade of events favoring thrombosis. CD40/CD154 interactions down-regulate thrombomodulin and induce tissue factor expression on endothelial cells *in vitro*, which render endothelial cells procoagulant ([11]).
- *Immune deficiency*. The hyper-IgM syndrome is due to mutations of CD154 (the CD40 ligand). See CD154 and Chapter 16.
- *Other*. T-cell activation of macrophages releases nitric oxide, which protects from *Candida albicans*–disseminated infections ([12]). CD40/CD40 ligand interaction was suggested to lead to salivary epithelia activation in Sjögren syndrome ([13]).

CD41 (INTEGRIN aIIb SUBUNIT, PLATELET GLYCOPROTEIN IIb OF THE IIb/IIIa COMPLEX)

Structure: CD41 is the aIIb subunit, which, with CD61, forms the gpIIb–IIIa complex, the most abundant platelet protein (1 to 2% of the total platelet protein; 50,000 gpIIb/IIa complexes per platelet) ([1], [2]). The molecule is synthesized from one mRNA, but a posttranslational modification generates two fragments (125 kd and 22 kd) linked by one disulfide bond. The large fragment is located entirely outside the cell, whereas the small subunit forms the transmembrane and cytoplasmic regions. The large fragment contains four repeats, 30 amino acids long. Each repeat has Asp, Asn, and Gly residues properly spaced, characteristic of the Ca^{2+}-binding proteins, such as calmodulin. The overall folding is known as the *EF hand*. Ca^{2+} is necessary to maintain the heterodimeric complex.

The complex aIIb/ß $_3$ (CD61, IIIa) is formed within the endoplasmic reticulum (ER), where the chains are separately synthesized. It is then transported to the Golgi apparatus for glycosylation and cleavage of the aIIb subunit to its large and small fragments. The mature complex is exported to the cell membrane in the low-affinity state. Glycine ^{418}, a highly conserved residue that flanks the fourth Ca^{2+}-binding domain of aIIb, is critical for the transport to the membrane, as some patients with Glanzmann thrombasthenia (GT) have shown (see below).

Activation of the aIIb/ß $_3$ integrin complex probably involves several mechanisms, one of them through cytoplasmic proteins, which bind to the complex. Two such proteins have been detected. One, known as *calcium integrin-binding* (CIB) *protein*, binds through its hydrophobic *C*-terminal to the conserved *N*-terminal sequence of the cytoplasmic tail of the aIIb subunit, converting the resting state to an active state ([3], [4]). CIB contains two functional *C*-terminal EF-hand domains and two *N*-terminal EF-hand–like sequences. These sequences are homologous to other EF hand–containing proteins such as calcineurin B and calmodulin. CIB has an *N*-terminal myristoyl group, which promotes its association with the cell membrane. A second cytoplasmic protein called *ancient ubiquitous protein 1* (Aup1) binds also to the conserved *N*-terminal tail of the aIIb subunit and may play a role in inside-out signaling ([5]). Aup1 is ubiquitously expressed in human cells. It has structural similarities to acyltransferases, enzymes involved in phospholipid synthesis.

Gene locus: 17q21.32.

Molecular mass (kd): 140, unreduced.

Distribution: Megakaryocytes and platelets.

Function: The ligands for aIIb/ß $_3$ are fibrinogen, FN, vitronectin, TSP, and vWF. Both subunits contribute to ligand recognition specificity and to affinity of binding ([6], [7]). A highly conserved sequence DXSXS in the ß subunit is a portion of a structure analogous (but not identical) to MIDAS (see CD61 and CD11) ([8]) found in a polypeptide of the ß integrin. It is postulated that the binding pocket is formed by the MIDAS-like sequence of the ß $_3$ subunit and the second Ca^{2+}-binding site of the aIIb subunit.

Binding of the ligand with high affinity requires that the integrin is brought from its “resting” low-affinity state to its high-affinity state after activation ([9], [10]). This requires “inside-out” signaling, provided by conformational changes. Charge reversal mutations seem to disrupt a potential salt bridge, which may link the two subunits and induce a constitutive state of activation of the integrin. Under these conditions, the integrin is spontaneously associated with the cytoskeleton in the absence of ligand binding (i.e., the mutations induce a constitutive bidirectional transmembrane signaling). These findings imply that conserved sequences on each subunit act as a “hinge,” which normally constrains the integrins to a low-affinity state. Agonist stimulation increases intracellular Ca^{2+} such as from binding of thrombin through phosphoinositide hydrolysis.

CIB, a Ca^{2+}-binding protein, then attaches to the cell membrane and possibly mediates subunit separation for integrin activation ([11]). Under conditions of rapid blood flow, the gpIb/V/IX complex interacts with the A $_1$ domain of vWF, supporting tethering and rolling. This interaction elicits transient Ca^{2+} spikes through intracellular release of Ca^{2+}, resulting in reversible platelet adhesion ([12], [13]). gpIb activates aIIb/ß $_3$ integrin, which, through PI3K activation, mobilizes Ca^{2+} from intracellular stores, which is subsequently followed by a transmembrane calcium flux, leading to irreversible platelet adhesion. During platelet aggregation after outside-in signaling, two tyrosines, Y^{747} and Y^{759}, which exist in the integrin cytoplasmic tyrosine domain, are phosphorylated. The spacing of the tyrosines is similar to that of the ITAM domains recognized by signaling molecules. Two proteins bind directly to these tyrosines: myosin, a cytoskeletal protein, and Shc, a signaling adaptor protein.

- *GT*. GT is an autosomal-recessive disease that results from a deficiency of the aIIb/ß $_3$ integrin caused by mutations affecting either one of the two chains ([14], [15] and [16]). It is characterized by mucocutaneous bleeding (epistaxis and purpura) and severely reduced or absent platelet aggregation. One group has mutations around or within the Ca^{2+}-binding domains of the aIIb-chain, affecting the transport of the complex to the cell surface. Another group of mutations are close to the ligand-binding pocket. In the ß $_3$ subunit, mutations are located within the cation-binding sphere (the MIDAS-like structure), which participates in ligand binding. Other mutations are located within the cytoplasmic regions and interfere with integrin activation.
- *Drugs interfering with aIIb/ß $_3$ function* . A Fab fragment of a chimeric (human/mouse) monoclonal antibody, abciximab (ReoPro) binds to aIIb/ß $_3$ and inhibits platelet aggregation. It acts as an antithrombotic agent, which blocks interaction of fibrinogen with aIIb/ß $_3$.

CD42: CD42a (GPIX); CD42b (GPIba); CD42c (GPIbß); CD42d (GPV)

CD42a (GPIX)

Structure: GPIX is a 17- to 22-kd, 160–amino acid protein member of the leucine-rich gp family detected in the a $_2$ gp of human serum. GPIX has one leucine-rich repeat or leucine gp repeat (LGR) and a sequence of 24 amino acids. Based on x-ray crystallography, it looks like a horseshoe with a-helices in the periphery and ß strands in the center ([1], [2]). gpIX is acylated with myristic and palmitic acids and is a major myristoylated protein in megakaryocytes. The fatty acids may facilitate interaction with gpIb and lipids in the cell membrane.

The cytoplasmic region is six amino acids long with a membrane-proximal cysteine. Antiplatelet antibodies to quinine/quinidine are directed against GPIX.

Gene locus: 3q21.

Molecular mass (kd): 17 to 22.

Distribution: Megakaryocytes and platelets.

CD42b (GPIba)/CD42c (GPIbß)

gpIb consists of two chains, a (CD42b) and ß (CD42c), linked by a disulfide bond.

Structure: The CD42b-chain (610 amino acids) has an extracellular region containing seven LGRs and two hydrophilic areas, one rich in charged amino acids and one rich in serine and threonine residues containing the majority of O-linked sialylated hexasaccharide sites. These moieties are attached to the protein on every three to four amino acids and generate a rigid mucinlike stalk, called *macroglycopeptide*, which displaces the *N*-terminal ligand-binding globular domain by approximately 45 nm above the cell membrane. Three tyrosines (276, 278, and 279) are sulfated posttranslationally and seem to promote binding with vWF ([3], [4]). Mutations resulting in loss of these tyrosines abolish totally the binding to vWF in the presence of botrocetin. The crystal structure of the *N*-terminal domain has been determined.

Gene locus: 17pter-p12.

Molecular mass (kd): 67.

Distribution: Megakaryocytes, platelets.

CD42c

Structure: CD42c is a 206–amino acid transmembrane protein with an LGR flanked by the same sequences as in the a-chain and the a_2 glycoprotein. It is likely that the gene for LGR was duplicated in the a-chain, whereas the ß-chain retained its ancestral architecture. The extracellular region has nine cysteines, one of them forming the disulfide bond linking the two chains. Four of the cysteines are on the *N*-terminal side of LGR as compared to two for the GPIba. Two disulfide bonds between these cysteines form a cysteine knot, which is critical for the conformation that determines the binding of GPIbß to GPIX. Residues 15 to 32 are important for interaction with GPIX. The extracellular region has one glycosylation site at Asp41.

The cytoplasmic region (34 amino acids) is rich in arginine and alanine residues, which may help in anchoring the protein to the membrane. A single Cys close to the membrane is a potential acylation site. RLS and RAGT sequences are likely targets for phosphorylation by cAMP-dependent protein kinase.

Gene locus: 22q11.21.

Molecular mass (kd): 20.

Distribution: Both chains are expressed in megakaryocytes and platelets.

CD42d (GPV)

Structure: Single-chain transmembrane protein (544 amino acids), with 15 LGRs in the extracellular region and 16 amino acids in the cytoplasmic region. Thrombin binds to GPV.

Gene locus: 3q29.

Molecular mass (kd): 82.

Distribution: Platelets and megakaryocytes.

Function of the GPIX-GPIb-GPV "complex": The complex plays a central role in primary hemostasis, being the key receptor for platelet adhesion for exposed subendothelium on damaged vessel walls under conditions of shear ([5], [6], [7], [8] and [9]). The proteins of the multimolecular "complex," GPIX-GPIba-GPIbß-GPV, are members of the leucine-rich family. GPIba is the largest and has the receptor sites for both vWF and thrombin; it links the complex through filamin to cytoskeleton ([10], [11]), which is essential for anchorage at high shear and for regulation of the interaction of the complex with vWF. The A_1 domain of vWF binds to GPIba NTR, which includes the seven LGRs, the disulfide-looped flanking regions, and the anionic sulfated tyrosine sequences ([12]).

The major function of the complex is to mediate initial adhesion of circulating platelets to vWF in subendothelial matrix of damaged vessels. This leads to translocation ("rolling") and reversible aggregation, which becomes irreversible after activation of the aIIb/$ß_3$ integrin ([13]).

Complex–vWF interaction is also involved in platelet thrombus formation under arterial or venous flow. The complex on the surface of free-flowing platelets binds to vWF on immobilized platelets (reversible binding), followed by irreversible aggregation if the aIIb/$ß_3$ integrin is activated.

Ligand binding triggers signaling, some of which is mediated through the ? isoform of protein 14-3-3, which binds to four *C*-terminal amino acids of GPIba ([14]). Proteins 14-3-3 regulate several key signaling molecules like BCR, cbl, p85 unit of PI3K, the apoptotic protein BAD, and so forth.

Bernard-Soulier syndrome is characterized by prolonged skin bleeding time, enlarged platelets, and thrombocytopenia ([15]). Patients have frequent epistaxis, gingival bleeding, and so forth. The genetic defects are heterogeneous: (a) biosynthetic defects or (b) functional defects (failure to bind the ligand). Mutations of the genes of GPIba, GPIbß, and GPIX have been detected ([16], [17]).

CD43 (LEUKOSIALIN, SIALOPHORIN, WASP: WISKOTT-ALDRICH SYNDROME PROTEIN)

Structure: CD43 (WASP) is a transmembrane protein (502 amino acids), constituting the major sialoglycoprotein expressed on leukocytes and platelets ([1]). The extracellular region has an *N*-terminal hydrophobic region and is rich in prolines (15% of the entire sequence), with 46 serines and 47 threonines interspersed. There are several proline-containing sequences found in SH_3 domains of proteins involved in signaling and organization of cytoskeleton. Ser and Thr residues carry O-linked sialic acid (70–85), forming an extended (45 nm), rigid, acidic structure with a net negative charge. There are two WASP glycoforms, reflecting differences of the attached O-glycan structures. One, on resting T cells, has tetrasaccharides (115-kd glycoform), whereas activated T cells carry branched hexasaccharides (139-kd glycoform). The change results from the enzymatic activity of an acetylglucosaminyltransferase. The cytoplasmic region is highly conserved and has constitutively phosphorylated Ser residues.

WASP belongs to a family of proteins regulating the organization of cytoskeleton. There are two groups: (a) WASPs and (b) WAVES (-1, -2, -3) ([2]). A homolog of WASP was detected in the brain and is known as *neural-WASP* or *N-WASP* (see details in Chapter 14).

Gene locus: X p 11-23.

Molecular mass (kd): 115; 130.

Distribution: WASP is present in hematopoietic cells, whereas N-WASP and WAVE are expressed ubiquitously. CD43 is expressed in thymocytes, T cells, activated B cells, plasma cells, NK cells, neutrophils, monocytes, macrophages, platelets, and stem cells.

Function:

- *Molecular mechanisms*. The WASP/WAVE family members play critical roles in rapid organization of cortical actin filaments in response to external stimuli ([3], [4]). The C-terminus consists of a verpolin homology region (V) followed by a cofilin homology and an acidic region (CA). The V motif interacts with monomeric G actin, whereas the CA interacts with the Arp 2/3 complex, bringing these two molecules together to initiate actin nucleation. N-WASP is key to formation of filopodia, whereas WAVE-2 is needed for formation of lamellipodia and membrane ruffles in response to outside stimuli, such as platelet-derived growth factor (PDGF). Several proteins bind to WASP through specific binding sites [i.e., Rho guanosine triphosphatases (GTPases) through the GTPase-binding domain, Cdc42/Rac through their interactive binding motif]. Other proteins with SH_3 domains bind to proline sequences (i.e., Ttk, PLC-?1, Grb2, and so forth). WASP is distinguished into two homology domains, WH-1 (N-terminus) and WH-2 (C-terminus). N-WASP, through WH-1, binds phosphatidylinositol 4,5-biphosphate and is anchored to the membrane. WH-1 also binds WIP (WASP-interacting protein), a proline-rich protein, and coordinates the signaling cascades. WH-1 recruits N-WASP to sites of actin polymerization. Cdc42/Rac stimulates protrusions at the leading edge, whereas Rho induces retraction at the tail end. Coordination of these two processes moves the cell toward the target.
- *Cellular functions*. Data in the literature are controversial in regard to the function of CD43 as an adhesive molecule. Some data suggest that CD43 promotes adhesion and cell interactions, whereas other data bring evidence to the opposite. The properties of CD43 (long, rigid, and negatively charged) are considered to oppose cell interactions (antiadhesive, steric barrier model) ([5]). However, CD43 also promotes adhesion, as shown in CD43-deficient mice, in which leukocytes are impaired in their ability to emigrate out of the vasculature ([6]). Sialoadhesin (CD169) has been shown to act as receptor for CD43 ([7]). Of the two glycoforms of CD43, the 130-kd, but not the 115-kd glycoform, carries the antiadhesive properties of the molecule. Interactions may also be facilitated by CD43 removal from the area of interaction either by proteolysis or capping. Indeed, CD43 is actively and selectively excluded from the immunologic synapse (i.e., the contact area between the T cell and the APC) ([8], [9] and [10]). However, when CD43 was technically allowed to remain in the synapse, it did not interfere with T-cell interaction and activation, which indicates that it does not impose a physical barrier. Actually, TCR engagement activates WASP, which is recruited for the movement and clustering of rafts, which are important for T-cell activation ([11]). T cells from WAS patients have impairment of raft clustering. The importance of WASP in T-cell motility is shown by the change from the spherical to the polarized morphology, with CD43 co-localizing with the ezrin/moesin proteins in the uropod and cell–cell contact areas ([12], [13]). Memory T cells (CD45RO) express strongly CD43, which may facilitate interactions for their extravasation. Cell motility is profoundly disturbed in patients with WAS ([14]). WAS macrophages show no actin polymerization, defective phagocytosis ([15]), and no chemotaxis to CSF-1 stimuli. DCs are unable to traffic normally to T-cell areas and cannot extend dendritic processes ([16]). WASP is highly expressed on hematopoietic stem cells. Cross-linking by an antibody induces apoptosis of the most primitive, but not the more differentiated, cells ([17]). Thus, WASP and the other members of its family are critical for cell motility, cell trafficking, cell activation, and cell interactions. Disturbances in these functions provide an explanation of the symptoms and signs of patients with WAS (i.e., eczema, bleeding, and recurrent infections), which are manifestations of a defective WASP in a variety of cells and a variety of functions.

CD45 (LCA: LEUKOCYTE COMMON ANTIGEN, B220)

Structure: CD45 is a protein tyrosine phosphatase previously known as the *leukocyte common antigen*. The extracellular region, which is an extended rod, has two domains: an *N*-terminal, mucinlike structure, with multiple Ser/Thr providing potential O-linked glycosylation sites, and a cysteine-rich domain (16 cysteines) followed by three FN type III domains. The cytoplasmic region (705 amino acids) is highly conserved (85% homology with other species). There are multiple phosphorylation sites, notably the sequence Lys-Lys-Arg-Ser immediately next to the membrane, a pro-ser–rich sequence and a glu-asp-ser sequence, which are potential sites for glycogen synthase kinase-3 and -5, respectively ([1], [2]).

The cytoplasmic region consists of the membrane proximal, first phosphatase domain (D1) and a second phosphatase domain (D2) in the carboxyl tail. When recombinant domains were studied *in vitro*, D1 is catalytically active and forms homodimers, whereas D2 has no catalytic activity and associates and stabilizes the D1.

The signature sequence essential for catalytic activity is HCSAGXGRXG, and the WPD loops are present in the D1, but not the D2, domain. The D2 is missing the Arg (R) involved in substrate binding.

There are multiple isoforms of CD45 as a result of alternative splicing, which is highly regulated. Of the eight exons of the gene, exons 3 to 8 encode the *N*-terminal O-glycosylated domain, which is affected by variable exon use.

The default pathway of splicing does not include exons 4, 5, and 6. Isoform expression has been studied with antibodies (CD45R). Antibodies that recognize epitopes encoded by exons 4, 5, and 6 have been termed *CD45RA*, *-B*, and *-C*, respectively. Antibodies that recognize CD45 deprived of contributions of 4, 5, or 6 are CD45RO. CD45R antibodies recognize more than one isoform. The significance of isoforms is in allowing different expression in various cells (see below) and association with distinct groups of surface molecules.

Gene locus: 1q31-32.

Molecular mass (kd): 180 to 220; 220 has all A, B, C epitopes; 180 lacks A, B, C. Isoforms with one or two of the A, B, C epitopes have Mr in between the two extremes.

Distribution: Found in all hematopoietic cells except erythrocytes. B lymphocytes express the isoform with all ABC sequences. However, with activation, they express the low Mr isoforms. Most thymocytes express the low Mr isoforms but, during differentiation and positive selection, become $CD45R^+$. Peripheral blood naïve T cells are CD45RA, whereas memory (activated) T cells are CD45RO. NK cells have 210 to 220 Mr isoforms; monocytes express the whole range of isoforms and so do the DCs.

Function: CD45 plays an essential role in lymphocyte activation. Src family members, lck and fyn, have been implicated in the initial increase of tyrosine phosphorylation on TCR stimulation. These kinases have two conserved Tyr residues, one within the kinase domain and a second in the carboxyterminal end. CD45 positively regulates TCR signaling by priming lck kinase through dephosphorylation of the *C*-terminal inhibitory tyrosine ([3], [4] and [5]). However, CD45 exerts negative regulation of PTKs at sites of adhesion by integrins. The totally opposite effects are regulated by a distinct topologic distribution of CD45 during TCR engagement. CD45 first is excluded from the immunologic synapse, where it may inhibit integrin activation and adhesive functions. Later, it is recruited back adjacent to TCR site,

where it is able to maintain src-kinase activity ([6]) and eventually induces down-regulation of TCR ([7], [8]). CD45 suppresses JAK kinases and negatively regulates cytokine production ([9]). Different isoforms differentially regulate IL-2 production. Myeloma cells are CD45 $^{-}$, but a small number of immature cells are CD45 $^{+}$, and they proliferate in response to IL-6 ([10], [11]).

Deficiency of CD45 as a result of mutations of the CD45 gene results in SCID ([12], [13]).

CD46 (COMPLEMENT MEMBRANE COFACTOR PROTEIN: MCP)

Structure: CD46 is a member of the complement control protein (CCP) family ([1]). Its extracellular region has four contiguous CCP domains, each 60 amino acids long. CCP domains 2, 3, and 4 have the C3b/C4b-binding site. An N-glycosylation site on CCP-2 is essential for measles virus (MV) binding ([2]). The CCP domain region is followed by a sequence rich in Ser/Thr and Pro. The protein exists in several isoforms defined by differences in the extracellular and cytoplasmic regions ([3]).

Gene locus: 1q32.

Molecular mass (kd): 52 to 58.

Distribution: It is expressed on all peripheral blood cells except erythrocytes and is expressed widely on other tissues. Predominance of certain isoforms has been noted in brain, kidney, salivary glands, and fetal heart.

Function: MCP was initially identified based on its ability to bind C3b or iC3 (C3 with broken thioester bond). MCP possesses “CA,” that is, binding of MPC promotes the degradation of C3b and C4b by a plasma serine protease, known as *factor I* (see Chapter 18) ([4]). For the classical pathway, MCP is the cofactor for C4b cleavage, and for low level C3b deposition by the alternative pathway, MCP is sufficient to block alternative pathway activation.

Although the N-glycans of CCP domains 2 and 4 are not involved in ligand binding, they are necessary for MCP protective function. Because the ratio of deposited C4b to MCP is greater than 10:1, one MCP molecule must cleave more than one C4b for cytoprotection ([5]). The isoform with a larger glycosylation domain binds C4b more efficiently than isoforms smaller in size and less glycosylated ([6]).

The CD46 is a receptor for MV and supports infection by the virus ([7], [8]). The MV-binding site is formed by CCP domains-1 and -2, and both are required for successful binding and infection ([9]). The two domains twist around the longitudinal axis of the molecule, forming an angle of approximately 100 degrees so that the sequences of each CCP that bind to MV are brought on the same face. In macrophages and monocytes, the replication of MV ([10]) is highly restricted, due to nitric oxide production triggered by IFN-a/ß. Another MV receptor is CD150 (or SLAM), which uses overlapping but different sites ([11]).

CD46 is a receptor to a number of other pathogens, such as herpes virus 6 (binding site at CCPs 2 and 3) ([12]), the M protein of group A streptococci (binding site at CCPs 3 and 4) ([13]), and *Neisseria gonorrhoeae* (binding site, CCP-3).

CD46 is a co-stimulatory molecule for CD3-mediated T-cell proliferation, followed by morphologic changes, reorganization of the cytoskeleton, and acquisition of strong adhesive properties ([14]).

CD47 [INTEGRIN-ASSOCIATED PROTEIN (IAP), RH-ASSOCIATED PROTEIN, NEUROPHILIN]

Structure: The CD47 protein was first identified during isolation of integrins and as a result was called *integrin-associated protein* (IAP). It consists of an extracellular region, which is a V-type IgSF domain, followed by five membrane-spanning regions and a *C*-terminal short cytoplasmic region ([1]). The protein does not bind directly to integrins but probably regulates their function. The sequence of CD47 is homologous or identical to a tumor-associated protein, AO3, and to a vaccinia virus–encoded protein (VA38) ([2], [3]).

Four alternatively spliced forms of the C-terminus exist as a result of variable usage of three exons. Most widely distributed are two isoforms, one with a long cytoplasmic tail (mainly in neural tissue) and a second with a short tail (bone marrow cells).

Gene locus: 3q13.1

Molecular mass (kd): 45 to 55 (unreduced).

Distribution: CD47 is ubiquitously expressed on hematopoietic cells, lymphocytes, neutrophils, monocytes, platelets, and erythrocytes (except Rh null) and is identical to antigen 1D8, a protein associated with Rh antigens ([4]). It is possible that CD47 and Rh polypeptides share a common pathway of cell-surface expression, and lack of IAP may contribute to the abnormal cation permeability of Rh-null erythrocytes.

Function: CD47 is associated with integrins a $_{V}$ß $_{3}$ but also with a $_{2}$ß $_{1}$, and aIIb/ß $_{3}$ and is a receptor for TSP and cell-based ligand SIRPa (signal regulatory protein-a) ([5]). SIRPs are a family of transmembrane proteins (approximately 15 members) expressed on monocytes, macrophages, granulocytes, DCs, and bone marrow progenitors, but not on lymphocytes. SIRPs are divided into two groups according to the presence (SIRPa) or absence (SIRPß) in the cytoplasmic region of four tyrosines, considered to be within an ITIM motif.

After phosphorylation, ITIMs act as docking sites for the SH $_{2}$ domain of SHP-1 or SHP-2 phosphatases and so influence signaling pathways. SIRP-a1 binds to SHP-2 and, as a result, was named *SHPS-1* (SHP-substrate 1). It now includes other ligands, such as BIT (brain Ig-like molecule), p84 [a neural adhesion molecule (NCAM)], and MFR (macrophage fusion receptor).

Binding to a $_{V}$ß $_{3}$ integrin (the vitronectin receptor) plays a key role in regulation of several functions of PMNs, such as Fc receptor–mediated phagocytosis ([6]), chemotaxis, respiratory burst, and migration of PMNs through endothelial and epithelial barriers ([7]). The key role of CD47-mediated regulation of PMN functions is reflected in its importance in host defense. Mice deficient in CD47 succumb to *E. coli* peritonitis with inocula that their heterozygous littermates survive ([8]). CD47 and SIRP-a interactions are also necessary for monocytes' crossing of cerebral endothelium, an important stage in the development of neuroinflammatory diseases ([9]). Through similar interactions and in cooperation with a $_{4}$ß $_{1}$ integrin, CD47 regulates migration of B cells through nonactivated endothelia ([10]). T cells are arrested on inflammatory vascular endothelium under flow through binding to TSP and the SIRP-a1 ligands or through up-regulation of a $_{4}$ß $_{1}$ integrins ([11]). CD47 ligation blocks Th1 differentiation ([12]) and inhibits production of IL-12 from macrophages ([13]), as well as production of IL-6 from monocytes. CD47 and a $_{V}$ß $_{3}$ integrin are both receptors for the a $_{3}$-chain of the basement membrane collagen IV and for similar sequences on melanoma tumor cells. CD47/a $_{V}$ß $_{3}$ binding inhibits proliferation of the tumor cells, and CD47 induces apoptosis of CLL cells ([14]). CD47 is a counter-receptor to MFR and is involved in homotypic macrophage adhesion, triggering the onset of fusion and formation of multinucleated giant cells ([15]).

A study of a recently identified patient with hereditary spherocytosis as a result of deficiency of band 4.2 showed that CD47 was practically absent (1%) in the patient's erythrocytes ([16]). Thus, CD47 is linked to band 4.2, but it is also linked to the Rh complex because it is absent in Rh-null individuals, who also have spherocytosis and stomatocytosis. Rh polypeptides interact with the red cell cytoskeleton.

CD47 in erythrocytes also acts as a marker for self ([17]). RBCs from mice deficient in CD47 injected in CD47 $^{+}$ normal mice are removed from the circulation by splenic red pulp macrophages. In connection to this role of CD47 in red cell survival, it should be noted that nonobese diabetic mice, which are deficient in CD47, develop a lethal autoimmune hemolytic anemia at 180 to 280 days, whereas the CD47 $^{+}$ nonobese diabetic mice do not ([18]). TSP potentially mediates adhesion of sickle red cells and reticulocytes to blood vessel wall under flow conditions ([19], [20]). This may provide a mechanism for vasoocclusion in sickle cell disease. CD47, as

a counter-receptor to p84, an NCAM that promotes neurite growth and neocortical neurons, mediates synaptic adhesions.

The SIRPa1 and SIRPa2 are not detected in leukemic cells from AML and CML. CD47 regulates Ca^{2+} influx in endothelial cells, and being a multiple transmembrane molecule, suggests that it may act as a Ca^{2+} channel. Some of the multiple functions mediated by CD47 are triggered through activation of heterotrimeric G proteins ([21]) and is coprecipitated as a complex with the Gai subunit. This is an unusual pathway for initiation of signal transduction because the only receptors that activate GTPases are proteins with seven or eight transmembrane regions ([22]). It has been suggested that the five transmembrane regions of CD47 and two of the associated integrins generate the number associated usually with GTPase activation.

Fundamentally, ligation of CD47 triggers cytoskeletal reorganization, leading to cell adhesion, spreading, motility, chemotaxis, and migration ([23]).

CD48 (BLAST-1)

Structure: CD48 is a member of the CD2 family and contains two Ig-like domains in the extracellular region, one V (membrane distal, D1) and one C2 type (membrane proximal, D2). D1 has no disulfide bonds, whereas D2 has two. Other members of the CD2 family include CD58, CD80, CD86, CD102, CD150, and CD244. It possesses a GPI membrane anchor. It is the same as BLAST-1, the first B-cell antigen, which is up-regulated after EBV infection. The genes of the members of the CD2 family most likely arose from gene duplication.

Gene locus: 1q21.3.

Molecular mass (kd): 45.

Distribution: Widely expressed on hematopoietic cells with the exception of granulocytes, platelets, and erythrocytes. CD48 expression is up-regulated by the IFNs and on B cells after EBV infection. It is induced at high levels on the surface of resting B lymphocytes after infection with EBV. CD48 was first designated *BLAST-1*, which is overexpressed in EBV-infected B cells due to an enhancer element upstream of the CD48 gene, and has an NF-?B–binding site ([1]). Elevated levels of a soluble form of CD48 are detected in the blood of patients with lymphoproliferative diseases and arthritis ([2]).

Function: CD48 is a low-affinity ligand for CD2 and interacts with the same site of CD2 that binds LFA-3 (CD58) ([3]). The interaction of CD2 with CD48 requires the same distance between interacting cells as the TCR and its ligand (i.e., the MHC–peptide complex) ([4]). The interaction of CD2 and CD48 is head to head, and the binding site on CD2 comprises an area of at least $770Å^2$ formed by residues of several ß strands. Although this area is very similar to the high-affinity interactions in antibodies and in proteinases, the CD2/CD48 affinity is 10^5-fold lower, and the CD48/CD2 dissociation rate is exceptionally fast ([5]). The limited binding strength is due to lack of sufficient complementarity and the presence of charged and polar residues. This type of easily reversible CD48/CD2 interaction allows proofreading by TCR of the MHC–peptide complexes and formation of new interactions ([6]).

A ligand for CD48 on epithelial cells has been shown to be the glycosaminoglycan-binding site of the hematopoietic form of CD44 (CD44H) ([7]). Another ligand for CD48 is the 2B4 (CD244) molecule on NK and T cells ([8], [9]), which has five to ten times stronger affinity than CD2. Both CD244 and CD2 are expressed on the same lymphocytes.

In NK cells, engagement of CD244 with CD48 triggers NK cell–mediated cytotoxicity, and on memory/activated $CD8^+$ T cells, it stimulates proliferation even of the nearby $CD244^-$ T cells. Another ligand for CD48 is a bacterial adhesion molecule known as *Fim H*, which is a mannose-binding lectin present at the distal tips of filamentous appendages on *E. coli* (type I fimbriae). It mediates adherence of bacterial cells to host cells through binding on CD48 of mast cells, triggering release of TNF-a ([10]).

CD49: CD49a (VLA-1) TO CD49f (VLA-6)

CD49 includes six distinct a subunits (a $_1$ through a $_6$), noncovalently associated with the ß $_1$ subunit (CD29). The heterodimers are known as *VLA* (VLA-1 through VLA-6) because originally they were detected at a late stage of T-cell activation. They are generally known as ß $_1$ *integrins*, although the ß $_1$ subunit forms heterodimers with other a subunits.

Structure:

- *General features.* The ß $_1$ integrins are heterodimers of two noncovalently associated subunits: a and ß. Their extracellular region as seen by electron microscopy consists of a globular headpiece formed by both subunits, which is the ligand-binding site. Two long stalks connect the head with the interior of the cell. In the “resting” state, integrins have a “bent” conformation with the head closer to the cell membrane, but after activation, the integrin stands up with a switchbladelike movement.
- *a subunits*. The a subunits can be separated into two groups: those with an I domain (a $_1$, a $_2$) and those that undergo posttranslational cleavage (a $_3$ through a $_6$) ([1], [2], [3] and [4]). In subunits a $_3$, a $_5$, and a $_6$, the cleavage generates one large and one small fragment linked by a disulfide bond. However, a4 is unique in that it has a potential protease cleavage site but is only variably cleaved; it has one of the two cysteines, which forms the disulfide bond joining the fragments in the others. The *N*-terminal extracellular half of all a subunits consists of seven short repeats with a FG-GAP consensus sequences (phenyl-alanine, glycine, glycine, alanine, proline). The repeats are folded into what is known as the ß *propeller*, formed by a sheet of four polypeptide strands, slightly twisted like a blade of a propeller. The upper face of the propeller has the ligand-binding site and the putative Mg^{2+} ion; a $_1$ and a $_2$ subunits only have an insertion (240 amino acids) between repeats 2 and 3, known as the *I domain*. The I domain is located on top of the ß propeller, linked to it by a hinge. The I domain consists of a ß sheet in the center, surrounded by a helices, a structure known as *Rossmann fold*, similar to that found in nucleotide-binding enzymes, small G proteins, and the a subunits of heterotrimeric G proteins. The top of the I domain contains a metal ion dependent adhesion site (MIDAS), which lies in the *C*-terminal end of the central ß sheet. MIDAS contains a signature sequence DXSXS for cation binding, which is also coordinated by water molecules and a residue in the ligand. The remaining extracellular region forms the “leg” of the a subunit that contains three large ß-sandwich domains, the first one known as the “thigh,” then “calf-1” and “calf-2.” Between the thigh and calf-1 is a sequence called the “knee” (or “genu”). It is here that the “anthropomorphic” integrin bends toward the membrane, head down, for its resting state. The cytoplasmic tail is short, and a small conserved motif is important for adhesive activity.

Gene loci: a $_1$, 5q11.1; a $_2$, 5q23-31; a $_3$, 17q23.3; a $_4$, 2q31.32; a $_5$, 12q11-q13; a $_6$, 2q31.1.

Molecular mass (kd): a $_1$, 200; a $_2$, 150; a $_3$, 150; a $_4$, 145; a $_5$, 160; a $_6$, 150.

Distribution: All VLA antigens are detected on hematopoietic cells, and reports may vary, probably as a result of the nature of the sample, especially in relation to activation. Resting T cells express moderate amounts of VLA-4 and only traces of the others. All VLA antigens increase on T-cell activation to a different extent, especially the VLA-1 and VLA-2 integrins. Thymocytes are predominantly VLA-4–positive, B cells express primarily VLA-2 and VLA-4, monocytes are mainly VLA-3– and VLA-6–positive, with VLA-4 present in moderate amounts, and platelets are positive for VLA-6 and VLA-2; granulocytes express a $_5$ß $_1$. Outside the hematopoietic cells, a $_1$ is present abundantly on smooth muscle cells and a $_2$ on epithelial cells; a $_1$ and a $_2$ are detected on fibroblasts, osteoblasts, and chondrocytes, and a $_3$ is detected in glomeruli and blood vessels.

Function: The VLA ß $_1$ integrins are receptors for proteins of the extracellular matrix. As a result, they are involved in (a) assembly of extracellular matrix and its interactions with cells, (b) cell migration, (c) tissue repair, and ([4]) organogenesis. The a $_1$ and a $_2$ are the major collagen receptors ([5], [6] and [7]). They both recognize various types of collagens, primarily I, IV, and VI, but with different affinities: a $_1$ binds preferentially the network forming collagen IV, whereas a $_2$ binds better to fibrillar collagen type I ([8], [9]); a $_2$ and a $_6$ are also a laminin receptor. a $_3$ is a receptor for collagen, laminin, and FN; a $_4$ and a $_5$ are FN receptors.

VLA antigens, as receptors of matrix, mediate cellular functions induced by matrix, such as maturation, proliferation, migration, cytokine secretion, and so forth. FN

and probably laminin modulate B-cell and thymocyte maturation and growth of bone marrow precursors.

Extracellular matrix components stimulate cytokine secretions from monocytes and macrophages. TSP-1, a matrix component, modulates several T-cell functions through a_4: adhesion, chemotaxis, and matrix metalloproteinase (MMP) gene expression.

Fibroblast migration is regulated under physiologic conditions of Ca^{2+} and Mg^{2+} by the a_2 integrin, whereas the a_1 mediates adhesion and movement of intraepithelial lymphocytes through collagen ([10]). Migration of keratinocytes is mediated by the a_2 integrin, which induces MMP-1 (procollagenase) and “navigates” the cells through the collagenous matrix.

Special functions:

- *a_2 Integrin* . In addition to being a receptor for collagen and laminin, a_2 is also a receptor for the echovirus, and binding is mediated by the I-domain. a_2 mediates platelet adhesion to both fibrillar and nonfibrillar collagen. It bears the alloantigenic determinant known as *HPA-5*. Alloimmunization against HPA-5 is associated with neonatal alloimmune thrombocytopenia and thrombocytopenia due to passively transferred platelet antibodies after transfusion of blood products. Silent polymorphisms of a_2 are associated with variation in the density of a_2 on platelets, which affects the rate of platelet attachment to type I collagen. A mutation, Thr799 Met of a_2, gives rise to a new alloantigen, Sit^a ([11]). This mutation causes diminished responses of platelets to collagen. Deficiency of a_2 gives rise to bleeding tendency and impaired reactivity to collagen.
- *a_3 Integrin* . a_3 plays an important role in matrix remodeling, especially pericellular matrices. Two of its ligands are entactin and epiligrin, which are both ubiquitous glycoproteins, especially in basement membranes. Entactin acts as a bridging molecule for other components like FN. Overexpression of a_3 in cultured cells stimulates strong deposition of entactin and forms FN pericellular matrices. a_3 integrin is detected in glomeruli with a role in basement membrane modeling and kidney organogenesis ([12]). An important development in the function of a_3 integrin has been the discovery of its association with members of the tetraspanin family (i.e., CD9, CD82, CD151, and so forth). CD151 is associated through its extracellular region with a3 and is a key player in the function of a_3 for matrix remodeling. Loss of a_3 and CD9 was found to be a significant prognostic factor in colon and endometrial carcinomas ([13]) with collapse of the a_3 tetraspanin cell-surface complex. CD151, as well as other tetraspanins, links a_3, as adaptors to intracellular cytoskeleton, and signaling complexes such as phosphatidylinositol 4-kinase. Interference with the complex causes almost complete reduction of neutrophil motility to chemotactic stimulation ([14]). a_3 integrin is the receptor for the Kaposi sarcoma–associated herpes virus 8 and mediates entry of the virus into the cells.
- *a_4 Integrin* . a_4 is a FN receptor and counter-receptor for VCAM-1. Bacterial protein invasin is a ligand for a_4 and mediates pathogen adherence directly to cells of the immune system. It supports tethering and rolling on VCAM-1 of leukocytes, especially monocytes, as a result of its clustering, and therefore enhancement of its avidity, by chemokines ([15]). a_4 is essential for migration of T cells to Peyer patches and, in cooperation with $a_4ß_7$, mediates adhesion and locomotion of B lymphoma cells on FN. Cross-talk between a_4 and LFA-1 increases the adhesion of T cells on ICAM-1 as a result of up-regulation of LFA-1 avidity. a_4 is a receptor for ADAM-28, a member of the ADAM family (a disintegrin and metalloprotease) expressed on lymphocytes. ADAMs, through their disintegrin domain, function as integrin antagonists very similar to the small peptide disintegrins contained in the venom of some vipers. This interaction may target metalloproteases on the cell surface.
- *a_5 Integrin* . The main function of a_5 is the assembly of FN matrix. The binding of FN through the RGD site (Arg-Gly-Asp) is enhanced by its synergy sequence (Pro-His-Ser-Arg-Asn). PDGF-ß induces a transformed phenotype on fibroblasts and is associated with increase of a_5. A similar phenotype was induced by overexpression of the a_5 and a_2 subunits. Adherence of FN to a_5 promotes a program of gene expression–dependent NF-?B activation, which coordinates angiogenesis and inflammation.
- *a_6 Integrin* . a_6 is involved in the development of kidney tubules. A mutation of the a_6 gene, which causes complete absence of the a_6 subunit, was found in a patient with junctional epidermolysis bullosa ([16]). Astrocytes promote oligodendrocyte survival, and as shown in cultures *in vitro*, this protection is mediated by the $a_6ß_1$ integrin. a_6 function is required for early stages of lens development, an effect mediated through the insulin growth factor-1 receptor. a_6 has been reported to promote cancer progression. This effect may be the result of enhanced expression of the vascular endothelial growth factor in breast carcinoma cells. a_6, like a_3, is associated with tetraspanins, and this complex promotes angiogenesis.

CD50 [INTERCELLULAR ADHESION MOLECULE (ICAM) 3; ICAM RECEPTOR]

Structure: CD50 is a member of the ICAM family. It is a type I transmembrane protein with five heavily glycosylated Ig-like domains of the C2 type in the extracellular region. The first Ig-like domain binds to its ligand LFA-1. The cytoplasmic region contains serines, which are phosphorylated on activation. The molecule by electron microscopy appears as a straight rod approximately 15 nm in length.

Gene locus: 19.13.3.

Molecular mass (kd): 115 to 135.

Distribution: Expressed on most hematopoietic cells. It is highly expressed on naïve T cells and on DCs, Langerhans cells, and endothelial cells after activation.

Function: The ligands for ICAM-3 are the $ß_2$ integrin LFA-1 (low affinity) and DC-SIGN (*DC*- *s*pecific *I*CAM-3– *g*rabbing *n*onintegrin) (high affinity) ([1]). DC-SIGN (CD209) is a type II membrane protein with a mannose-binding, C-type carbohydrate recognition domain at the C-terminus of the molecule. CD50 is involved in the initial interaction of T cells with the APCs during the exploratory contact of T cells with APC and before antigen recognition. ICAM-3, which is heavily glycosylated and carries N-linked high mannose oligosaccharides, binds on DCs to DC-SIGN but not, as expected, to the LFA-1. ICAM-3/DC-SIGN mediates the initial T-cell–APC interaction necessary for the TCR to scan the surface for identification of MHC–peptide complexes ([2]).

During this period, ICAM-3 redistributes to the contact area and takes a position in the periphery of the immunologic synapse, as compared to LAT (linker for activation of T cells), which positions itself to the center. During T-cell locomotion, ICAM-3 is concentrated in the uropod, where it interacts with moesin, a member of the ERM group (exrin, radixin, moesin), which connects surface molecules with the cytoskeleton ([3]). Moesin is co-localized with ICAM-3 to the distal end of the uropod, and its interaction with ICAM-3 is mediated by serine residues in its cytoplasmic region.

In addition to its adhesive properties, ICAM-3 is a co-stimulatory molecule ([4]). On ligation, it supports primary responses and induces phosphorylation of PTKs lck and fyn, intracellular Ca^{2+} increase, and expression of T-cell activation molecules CD69 and CD25 ([5]).

On polymorphonuclear leukocytes, ICAM-3 activates ß2 integrins by an outside-in mechanism through PTK phosphorylation ([6]). It induces cell aggregation but without granule release ([7]).

CD50 is expressed on endothelial cells of skin vessels in cutaneous T-cell lymphomas but not in lymph nodes infiltrated by tumor cells ([8]). DC-SIGN binds with high affinity to the HIV envelope gp 120, both to the macrophage-tropic and T-cell–tropic viruses, and enhances transinfection of T cells ([9]). Binding of DC-SIGN to ICAM-3 is not necessary for HIV infection of T cells because the binding sites are different. ICAM-3 binding highly depends on N-glycosylation; furthermore, a DC-SIGN mutation abolishes the binding to ICAM-3 but not binding to HIV. Similarly, blocking DC-SIGN/ICAM-3 interactions by monoclonal antibodies does not interfere with DC-SIGN–mediated HIV transmission.

A related molecule, DC-SIGNR, strongly homologous to DC-SIGN, is expressed on liver sinusoidal cells and in lymph nodes but not on DCs. This molecule has also high affinity for ICAM-3 and HIV gp120 protein. It has been proposed that it be named *L-SIGN* for *l*iver/lymph node– *s*pecific *I*CAM-3– *g*rabbing *n*onintegrin.

LFA-1/ICAM-3 interaction triggers transmigration of infected, LFA-1–positive monocytes through mucosal epithelial cells overexpressing ICAM-3, particularly under inflammatory conditions ([10]).

CD51 (a_V: a SUBUNIT OF VITRONECTIN RECEPTOR, INTEGRIN a_V SUBUNIT)

Structure: CD51 is the a subunit of the integrin vitronectin receptor, $a_V ß_3$ (CD51/CD61). The structure of a $_V$ subunit has been solved at a 3.1 Å resolution, both with and without ligand binding ([1]). The crystallographic data show a ß propeller in the NH2 terminal half of the extracellular region, with seven blades corresponding to the seven FG-GAP repeats (Phe/Gly/Gly/Ala/Pro), each formed as a four-stranded antiparallel sheet. The a $_V$ subunit has no I domain, also referred to in the literature as *A domain* because it is homologous to the A domain of vWF. The $a_V ß_3$ with six Mn^{2+} ion sites binds a ligand with an RGD sequence, in a crevice between the a $_V$ propeller and the A domain of the ß $_3$ subunit. Each residue of the ligand participates in the binding, which is associated with tertiary and quaternary changes in the $a_V ß_3$ integrin structure, that is, the a $_V$ propeller and the ßA domain move closer together at the peptide-binding site (see animation in Reference [2]).

The a $_V$ leg consists of three ß-sandwich, Ig-like domains, type C2, named “thigh,” followed by “calf-1” and “calf-2,” that are mostly hydrophobic. The a $_V$ leg folds back, forming a V-shaped structure, “genu,” between the thigh and calf-1, which is capped by a divalent cation. On activation, the a $_V$ unfolds, extending straight up, forming a cylinder 160 Å long and 20 Å wide (see also CD49). The proteolytic site that generates the heavy and light disulfide-linked chains is located within calf-2 ([3]). In the heterodimer, the a $_V$ propeller contacts the ßA domain, forming the “head” of the integrin. The interface in the head between the two subunits is largely hydrophobic. Naturally occurring mutations causing ß $_2$ or ß $_3$ integrin deficiencies are located in the vicinity of the interface, whereas others are found in the propeller or ßA domains.

Gene locus: 2q31-32.

Molecular mass (kd): 125 reduced; 150 unreduced.

Distribution: In combination with CD61 (ß $_3$), it is expressed on platelets but at lower levels than CD41/61. It is also detected on activated leukocytes, NK cells, macrophages, and neutrophils. In nonhematopoietic cells, it is present on endothelial cells, smooth muscle cells, and osteoclasts.

Function: CD51/CD61 is the vitronectin receptor, but it also binds to other RGD-containing proteins, such as fibrinogen, FN, vWF, laminin, TSP, and osteopontin. $a_V ß_3$ serves also as receptor to adenovirus, foot and mouth disease virus, coxsackie Ag, and *Hantavirus*. It binds to tat regulatory protein of HIV, to fibroblast growth factor 2, and to a fragment from disintegrin ADAM-15. Most of the protein ligands have an RGD sequence. It is conceivable that some of these ligands use an “inactive” and others an “active” form of the integrin.

a $_V$ is detected in granulation tissue but not in the dermis or epithelium of normal skin from the same donor. It is also present in blood vessels during development or within tumors. Several studies in a variety of systems support the role of a $_V$ integrins in angiogenesis ([4]). $a_V ß_3$ is expressed on activated endothelial cells, and disruption of its function by antibodies or peptide antagonists disrupts blood vessel formation in chick chorioallantoic membrane, mouse retina, rabbit cornea, arthritic knee, and in tumor models, in which inhibition of new blood vessel formation caused tumor regression ([5], [6]).

a $_V$ integrin facilitates survival of endothelial cells by angiogenic growth factor because blocking its function induces apoptosis of angiogenic cells.

Coxsackie virus Ag interacts with high affinity with $a_V ß_3$ integrin ([6]). The binding site is located on the ß $_3$ subunit and does not require the RGD sequence present on CAV9 protein of the virus. The ß $_2$ microglobulin is involved in the binding. Another virus that uses the $a_V ß_3$ integrin as receptor is a virulent strain of foot and mouth disease virus for cattle, serotype A $_{12}$ ([7]).

Because of the involvement of $a_V ß_3$ in inflammatory angiogenesis, a humanized monoclonal antibody, Vitaxin (MEDI-522) is administered to patients with rheumatoid arthritis, and clinical trials are in progress ([8]). The antibody is specific for a conformational epitope formed by both a $_V$- and ß $_3$-chains and blocks binding of $a_V ß_3$ to vitronectin and osteopontin.

CD52 (CAMPATH-1)

Structure: CD52, also known as *CAMPATH-1*, is an unusually short protein (12 amino acids) linked to the membrane with a GPI anchor ([1], [2]). There are two CD52 proteins, CD52-I and CD52-II, which differ in the GPI anchor. CD52-I contains exclusively distearoyl-PI (phospholipase-sensitive GPI), whereas CD52-II contains a palmitoylated stearoyl-arachidonoyl-PI (phospholipase resistant). Both carry one N-linked oligosaccharide, which consists of sialylated polylactosamine units attached to a tetraantennary fucosylated mannose core. Because of its small size, it is likely that CD52 must exist as an aggregate or micelle to achieve high-affinity binding to the CAMPATH-1 antibody. CAMPATH antibody recognizes an epitope, which includes the GPI anchor and the last three amino acid residues of the core peptide.

Gene locus: 1p36.

Molecular mass (kd): 21 to 28.

Distribution: It is strongly expressed on lymphocytes (5×10^5 molecules/cell), monocytes, eosinophils, and peripheral blood DCs (but not on tissue DCs) ([3]).

It is also found in epithelial epididymal cells, seminal vesicles, and seminal plasma. It is not present in testicular sperm, but it is acquired either during the transit of the sperm in epididymis or after its capacitation, which takes place in the uterus (i.e., after ejaculation) ([4], [5]). This CD52 modulation on the sperm surface is probably related to acquisition of its fertilizing capacity.

In lymphocytes, the glycan is attached to Asp3, and the oligosaccharides are only tetraantennary, whereas the male genital tract contains bi-, tri-, and tetraantennary glycans.

Function: It is a major constituent of the sperm glycocalyx, and its acquisition by the sperm during epididymal passage is one of the few well-defined modifications that occur to the sperm. It modifies surface charge and lectin-binding patterns. A sperm agglutination antigen (SAGA-1) has a core peptide that is identical to CD52, but the glycans are different. A sperm inhibitory monoclonal antibody was immortalized from an infertile woman with specificity against sperm glycoforms of CD52 ([6]). This unique CD52 glycoform is localized to the entire sperm surface and potentially could be used as a target of immunocontraceptive vaccine development ([7]).

CD52 has been used as the target antigen for treatment of lymphocyte malignancies ([8], [9] and [10]). Several properties of CD52 make it a particularly good target for immunotherapy. It is present in high density, it is not internalized, and is not present in $CD34^+$ stem cells.

The antibody CAMPATH-1H (a humanized monoclonal antibody), under the name *alemtuzumab*, has been used in B-CLL ([11], [12]), various T-cell malignancies, stem cell transplantation for prevention of GVHD, rheumatoid arthritis ([13]), and multiple sclerosis. Patients with rheumatoid arthritis or non-Hodgkin lymphoma (NHL) after treatment with CAMPATH-1H had $CD52^-$ T cells for several months, and the expression of other GPI-linked molecules (CD48, CD59, CD55) was also down-regulated ([14], [15] and [16]). PIG-A (*p*hosphatidyl *i*nositol *g*lycan complementation gene class *A*) T-cell clones were established from two patients. The function of CD52 in normal cells is not quite clear. Cross-linking CD52 by CAMPATH-1 antibody activates T cells *in vitro* and induces tyrosine phosphorylation.

CD54 (ICAM-1: INTERCELLULAR ADHESION MOLECULE-1)

Structure: CD54 is closely related to CD50 (ICAM-3). It has five Ig-like domains type C2 in the extracellular region. Each C domain has two ß sheets formed by seven antiparallel ß strands. The C2 domains are present in Fc receptors and adhesion molecules (CD2, LFA-3, ICAMs, NCAM, and so forth), whereas the C1 domains are

involved in antigen recognition (i.e., Igs). The first domain binds to LFA-1, whereas binding to Mac-1 is by the third Ig-like domain. The binding site for human rhinovirus is located in the loops joining strands B to F of domain 1, which also binds the malarial parasite, *P. falciparum*, in venular endothelial cells. The binding sites for LFA-1, fibrinogen, rhinoviruses, and malaria-infected erythrocytes are overlapping but not identical ([1]).

LFA-1 binding requires the presence of Ca^{2+} or Mg^{2+} and a dimeric ICAM-1, whereas the rhinoviruses bind to monomeric ICAM-1 and do not require divalent cations.

Electron microscopy shows that ICAM-1 is like a rod, 190 Å long, with a kink between domain 1 and 3 at approximately 76 Å from the amino end.

ICAM-1 is homologous to NCAM (CD56).

Gene locus: 9p13.3-13.2.

Molecular mass (kd): 90.

Distribution: CD54 has a wide distribution on hematopoietic and nonhematopoietic cells. Expression is moderate on activated T cells, B cells and monocytes and on hematopoietic progenitors ([2]). It is constitutively expressed on certain epithelia and endothelia, but expression is high in activated endothelial cells. Inflammatory cytokines, TNF, IL-1, and IFN-?, enhance its expression.

Function: The ligands for ICAM-1 are the integrins LFA-1 and Mac-1, rhinoviruses, erythrocytes infected with *P. falciparum*, and fibrinogen. ICAM-1 has no RGD motif and binds to the integrins through a large extended surface. Dimerization, which is mediated through domain 1, enhances the binding to the I domain of the a-chain at LFA-1 ([3]). Dimerization generates a competent surface for one LFA-1 molecule to bind more efficiently.

ICAM-1 is associated with ezrin, a member of the ERM family (ezrin/radixin/moesin), which is a linker between membrane molecules with actin cytoskeleton, and regulates cell adhesion and cortical morphogenesis ([4]). The ezrin–ICAM-1 association is regulated by signaling involving phosphoinositides.

In small blood vessels in the brain, ICAM-1 ligation induces tyrosine phosphorylation of the cytoskeletal protein, contactin, which leads to cytoskeletal changes and transmigration of T cells. ICAM-1 is a member of the group of molecules that orchestrates leukocyte transendothelial migration. The VLA-4 integrin functions early in leukocyte adhesion to the endothelium, and through cross-talk to the ß $_2$ integrins, aL/Mß $_2$, triggers their clustering (i.e., increase of their avidity). Initial interaction with ICAM-1 assembles a docking structure, built through ezrin activation by the cytoskeleton, on which the leukocyte adheres firmly before transmigration ([5]). During this process, ICAM-1 is exclusively localized on the apical membrane of the activated endothelial cell.

ICAM-1 plays a role as an adhesion molecule in cell–cell interactions during the induction as well as in effector functions of the immune response, such as T-cell mediated cytotoxicity. ICAM is detected in approximately 50% of patients with myeloid and B-lymphoid, but not T-cell, malignancies, preferentially of an immature phenotype. High-grade NHLs express a higher level of CD54 than the lower grade ones.

CD54 is shed from malignant cells and is detected in a soluble form in the serum of patients with leukemia or lymphoma ([6]). Shedding is probably mediated through an MMP.

CD55 (DAF: COMPLEMENT DECAY– ACCELERATING FACTOR)

Structure: CD55 (DAF) is a GPI-anchored protein, which belongs to the CCP family ([1], [2] and [3]). The extracellular region consists of four CCP domains of approximately 60 residues, each followed by a sequence rich in serines and threonines, which are heavily O-glycosylated. An N-glycosylation site exists between the first and second CCP domain. The GPI anchor is attached posttranslationally after removal of the hydrophobic domain.

The O-linked oligosaccharides are also added posttranslationally in the Golgi apparatus and account for approximately 26 kd of the molecular mass. Two-thirds of them are sialic acid.

Domains 2 to 4 adopt an extended helical conformation, and a positively charged surface area on domains 2 and 3 is the primary site for recognition of DAF by the C3 convertases ([4], [5]). Classical convertase requires CCP domains 2 and 3, whereas the alternative requires 2, 3, and 4 ([6]). Mutations to three tandem lysines (125 to 127) impair DAF control of alternative convertase, whereas mutations to Leu-147 and Phe-148 abolish the function to both convertases ([7]).

DAF serves as a receptor for a number of pathogens. Binding of echoviruses requires CCP domains 2 to 4 ([8]), coxsackie virus B_3 requires domain 2, and enterovirus 70 binds to domain 1. Many strains of *E. coli* bind to DAF via proteins present in their fimbriae. CD97, a seven-transmembrane protein, homologous to the secretin peptide hormone receptors, is a counter-receptor for DAF ([9]). CD97 is a member of the EGF-TM7 family, with EGF tandem repeats and a seven-transmembrane region found in G protein–coupled receptors ([10]). The function of CD55–CD97 interaction is not known. Several forms of DAF have been reported.

Gene locus: 1q32.

Molecular mass (kd): 70 (lymphocytes); 55 (erythrocytes).

Distribution: Ubiquitously distributed on all cells of the body in contact with serum or body fluids. Widely expressed on epithelia of the gut and genitourinary tract and in the central nervous system. Erythrocytes have approximately 3300 molecules of DAF/cell, which decreases with age. On neutrophils, there are 10,000/cell, and the number doubles within minutes after activation, likely as a result of release of molecules in storage.

Function: The C3 convertases are the central amplification enzymes of the complement cascade. The protection of self-tissues from the action of these enzymes is assigned to several CCPs of two functional groups: (a) inhibitors of the action of the convertases or (b) cofactors of the proteolytic enzyme, factor I. DAF does not inhibit the initial binding of C2 to a cell with deposited C4b but leads to the rapid release of C2a from its binding site on C4b, thus dissociating the classical C3 convertase. Similarly, Bb is rapidly released from the alternative C3 convertase. DAF, however, can associate with C4b and C3b on the cell surface without requiring C2 or factor B. DAF interacts directly with the type A domain of Bb, especially close to the a helices 4 and 5 ([11]). The complement protective function of membrane DAF for cells is exerted only intrinsically (i.e., on C3 convertase assembled on the same cell as DAF). Soluble DAF cannot incorporate into cell membranes, and it has much lower efficiency in inhibiting complement activation on cell surfaces.

DAF function is abolished by deletions of the CCP-2 to -4 domains as well as the removal of the serine-threonine–rich region. It cooperates with MCP in protecting cells from autologous complement attack by enhancing its CA, especially in the presence of excess factors B and D.

Deficiency of DAF and other GPI-anchored proteins such as CD59, another member of CCPs, is associated with intravascular hemolysis in paroxysmal nocturnal hemoglobinuria (PNH). PNH is an acquired hematopoietic stem cell disorder, manifested not only with hemolysis but with venous thrombosis, aplastic anemia, and so forth. The genetic defect (point mutation, deletion, or insertion) of the PIG-A gene affects an enzyme, N-acetylglucosamine transferase, the product of the gene, which is involved in the first step of GPI anchor biosynthesis. In PNH, proteins dependent on a GPI anchor are absent in all hematopoietic cell lines. As a result, red cells are sensitive to lysis by complement activation (see Chapter 18 for details). Absence of CD59 is more critical than CD55.

The echovirus 7 can cause aseptic meningitis in humans using DAF as receptor for attachment but not for virus entry. DAF does not bind to the “canyon” site, a depression on the viral capsid required for uncoating and entry of the virus.

Rare individuals have been identified with absent or low expression of DAF as an inherited condition based on the human erythrocyte blood group system, Cromer,

which has been localized on DAF ([12]). The Inab phenotype is an inherited null allele (i.e., a DAF-null allele).

CD56 (NCAM: NEURAL CELL ADHESION MOLECULE)

Structure: CD56 is an isoform of the NCAM. There are several isoforms (20 to 30) as a result of posttranslational modifications and differential splicing of mRNA encoded by the NCAM gene. Modifications affect glycosylation, acylation, sulfation, or phosphorylation. NCAMs have different modes of attachment to the membrane or to various cytoplasmic domains. The main isoforms are two transmembrane forms, one 140 kd (NCAM-A) and another 180 kd (NCAM-B) and one GPI-anchored, 120 kd (NCAM-C) ([1]).

A polysaccharide unusual for vertebrates, that is, a-2,8 polysialic acid (PSA), attaches to the central part of the molecule and is expressed mostly during development of the nervous system ("embryonic" NCAM) and only in limited areas in mature central nervous system. The extracellular region consists of five tandem Ig-like domains (the first two type I and the other three type C2) and two FN III domains ([2]). A variable alternatively spliced exon, encoding approximately 10 amino acids, alters the structure of the fourth Ig domain so that NCAM inhibits axonal growth. An additional domain, called *muscle-specific domain* (MSD), because it is detected in myoblasts, is located between the two FN domains, and is rich in O-linked polysaccharides. The HNR-1 carbohydrate is attached to the MSD domain (see CD57). The leukocyte NCAM is structurally identical with the neural NCAM, but it does not mediate homophilic interactions, a property initially used to define the neural NCAM.

By electron microscopy, NCAM appears as a flexible rod, which has a hinged structure, and the bending regions are amino-terminal to the hinge. This hinge structure may facilitate transhomophilic binding in the presence of changes of cell shape ([3] , [4]).

Gene locus: 11q23.1.

Molecular mass (kd): Transmembrane: 140 (NCAM-A), 180 (NCAM-B); GPI-anchored: 120 (NCAM-C).

Distribution: On hematopoietic cells, CD56 is restricted to NK cells and a subpopulation of T cells (approximately 5%). Among hematopoietic malignancies, it is detected in a broad spectrum of lymphoproliferative diseases predominantly of large granular lymphocytes. It is also expressed on rare cases of acute myeloid leukemia $CD7^{+}/CD56^{+}$ (considered as precursor acute leukemia) ([5]), nasal cell lymphomas (associated with EBV infection), nonnasal lymphoma ([6]), and multiple myeloma ([7]). In AML, it has been identified in 15 to 20% of cases and has been associated with monocytic morphology, trisomy 8, t(8;21), t(15;17), and 11q23 rearrangements. $CD56^{+}$ malignancies with blastic morphology, skin infiltration, and myeloid or myelomonocytic phenotype have been reported.

In nonhematopoietic tissues, it is detected in embryonic and adult neural tissues throughout the central and peripheral nervous systems. It is widely expressed on neurons, glial cells, and skeletal muscle.

Function:

- *Neural functions.* The neural NCAM is involved in homophilic interactions, involving all five Ig domains. The domains are paired (i.e., I with V, II with IV, and III with III). The homophilic binding follows an antiparallel direction of the two interacting NCAMs. PSA influences adhesion because, in NCAM with high PSA content, it keeps membranes of apposing cells apart. Removal of PSA results in tight adherence along the entire length of the membrane. NCAM is involved in neuronal migration, neuritic outgrowth, formation of the synapse, and promotion of its plasticity ([8]) associated with learning and memory. For neurite outgrowth, NCAM requires the cytoplasmic region as a neuronal receptor. In the extracellular region of NCAM, there is an ATP-binding site, and an ecto-type ATPase (see CD39) activity is associated with NCAM ([9]). A second site close to the *N*-terminal end binds heparan sulfate proteoglycan, an interaction that modulates NCAM binding to extracellular matrix. This is important during the development of the nervous system for cell motility and growth ([10]). It requires a coordinated expression of NCAM and matrix MMPs.
- *NK cell functions*. CD56 is expressed only in NK cells and a small number of T cells. NK cells (interchangeably called *large granular lymphocytes*) are characterized by their large cytoplasmic granules. The CD56 of NK cells is not involved in homophilic or other adhesive interactions, although it is structurally identical to neural NCAM. $CD56^{+}$ NK cells are an important cellular component of the innate immune system and, as a major source of IFN-?, are involved in the early stages of defense against viral infections, as well as links of the innate and the adaptive immunity. NK cell–derived IFN-? drives T-cell differentiation to the Th1 pathway. NK cells are non–MHC-restricted cytotoxic cells, and this function is regulated by KIRs, which recognize HLA type of antigens (see Chapter 17). CD56 is used as a marker in phenotyping hematologic malignancies. $CD56^{+}$ lymphomas include the EBV-positive sinonasal lymphoma and other aggressive nonnasal lymphomas. A neoplasm with the $CD4^{+}/CD56^{+}$ phenotype with cutaneous manifestations, splenomegaly, and lymphadenopathy is considered to involve the type 2, or plasmacytoid DCs ([11]). CD56 is expressed in a small percentage of AML, sometimes with monocytoid morphology, t(8;21) translocation, or both. Normal plasmal cells are $CD56^{-}$, and its expression has been used to distinguish myeloma from monoclonal gammopathies of undetermined significance or reactive plasmacytosis. However, a small number of monoclonal gammopathies of undetermined significance cases have $CD56^{+}$ cells. CD56 expression correlates with osteolytic lesions in multiple myeloma. As an adhesion molecule, NCAM regulates adhesion of tumor cells to matrix ([12]).

CD57 (HNK-1: HUMAN NATURAL KILLER CELL-1 ANTIGEN, LEU-7 ANTIGEN)

Structure: CD57 is a carbohydrate antigen, originally recognized by a monoclonal antibody human natural killer cell (HNK)-1 as a marker for human NK cells. The epitope recognized by the HNK-1 antibody is a trisaccharide synthesized in a stepwise manner by the addition of $ß_{1–3}$-linked glucuronic acid (GlcA), to a precursor disaccharide, N-acetyllactosamine. This is followed by the addition of a sulfate group to position 3 of the GlcA. The complete formula is: $SO_4{}^{3}GlcAß^{1,3}Galß^{1,4}GlcNAc$. A $ß_{1–3}$ glucuronyl transferase (GlcAT-P) adds the GlcA, whereas an HNK-1 sulfotransferase (HNK-1ST), adds the SO_4 group, directing the synthesis of the HNK-1 saccharide epitope on both glycoproteins and glycolipids ([1] , [2] and [3]). The $ß_{1–3}$ glucuronyl transferase is highly specific for the *N*-terminal N-acetyllactosamine structure but has no preference on the number of acceptor sugar branches (i.e., bi-, tri-, or tetraantennary complexes).

Gene locus: 11q12-qter.

Distribution: The HNK-1 trisaccharide is widely distributed in glycoproteins, glycolipids, and proteoglycans. It is expressed on several cell adhesion molecules such as NCAM (second, third, and fifth Ig-like domains and MSD) (see CD56). The HNK-1 is preferentially added to N-glycans (over O-glycans in NCAM), such as on MAG, the P_0 myelin glycoprotein and the myelin-oligodendrocyte glycoprotein. The HNK-1 epitope is present on several glycolipids named *sulfoglucuronylglycolipid-1* and *-2*.

CD57 is found on migrating neuronal crest cells, cerebellum, and myelinating Schwann cells in motor, but not sensory, neurons.

HNK-1 was first detected on NK cells but is also present on cancer cells and was originally considered as an oncofetal antigen. It is detected in small cell carcinomas of the lung and the human neuroendocrine tumors of the amino precursor uptake and decarboxylation type (APUD). It has also been detected in neuroblastoma, medulloblastoma, retinoblastoma, and melanoma. Additionally, it has been shown to act as an autoantigen in peripheral demyelinating neuropathies associated with monoclonal IgM proteins.

Function: HNK-1 has been shown to serve several functions independently of the protein backbone. HNK-1 interacts with proteins of the extracellular matrix, such as laminin 1 and 2, and L- and P-selectins. HNK-1 associates with neural crest migration, neuron-to-glial cell adhesion, outgrowth of astrocytic processes, astrocyte migration, and outgrowth of neurites from motor neurons.

A neural recognition molecule that binds, as well as expresses, HNK-1 (i.e., acts both as receptor and ligand) is P_0, a major glycoprotein of myelin in the peripheral nervous system, and HNK-1 might be involved in spiraling loops of Schwann cell processes in myelin formation.

HNK-1 was identified as the major target in peripheral neuropathies of patients with lymphoma secreting large amounts of HNK-1–binding IgM monoclonal proteins ([4]

).

Mice deficient in HNK-1 epitope have gross defects in hippocampus-dependent spatial learning and memory formation (i.e., higher order brain functions) ([5]).

IL-6 possesses lectin activity and recognizes the HNK-1 epitope ([6] , [7]). IL-6 binds to MAG and P_0, and the binding is inhibited by oligosaccharides having the HNK-1 epitope. Site-directed mutagenesis disclosed three important sites of IL-6 functions, and only site 3 is the HNK-1 recognition site (see Chapter 18).

The implications of these new findings of IL-6 function relate to demyelinating diseases because IL-6 binds to important glycoproteins of the myelin, which display HNK-1 epitopes. IL-6 gene knock-out mice show suppression of experimental allergic encephalomyelitis.

CD57 in Hematology-Immunology

CD57 was discovered by immunologists as a marker of NK cells (hence, the name HNK-1 for human NK cell-1). Neuropathologists investigated its role in their own field because the HNK-1 was associated with MAG, and it could be related to demyelinating diseases. CD57 is sometimes coexpressed with CD56 (HNK-1 epitope is attached to NCAM:CD56), and it is also present alone in T cells, referred to as *T-large granular lymphocytes*. $CD57^+$ T cells are increased after bone marrow or kidney transplantation ([8]), in acquired immunodeficiency syndrome (AIDS) ([9]), in rheumatoid arthritis ([10]), and with aging. $CD57^+$ leukemias are actually associated frequently with rheumatoid arthritis. The $CD57^+$ $HLADR^{BRIGHT}$ cell is functionally considered as natural suppressor cell ([11]). Nucleosides isolated from these cells induce apoptosis in human carcinoma cells. Whether these apoptosis-inducing nucleosides are the same as the inhibitor of cytotoxic functions produced by $CD57^+$ cells from patients with AIDS or after bone marrow transplantation is not known. $CD57^+$ T cells produce increased amounts of INF-?. Increases of $CD8^+$ $CD57^+$ cells in normal individuals correlate with asymptomatic human cytomegalovirus (CMV) infection ([12]). $CD57^+$ T cells give rise to leukemias, which are associated with neutropenia, autoantibodies, rheumatoid arthritis, splenomegaly, and constitutional symptoms ([13]).

CD58 (LFA-3: LEUKOCYTE FUNCTION ANTIGEN-3)

Structure: CD58 is a ligand for CD2 and a member of the CD2 family. The extracellular region consists of two Ig-like domains: a V-type (membrane distal) and a C2 type. There are two CD58 isoforms: a transmembrane and a GPI-anchored. CD58 is the major ligand for CD2, and the two interact with the large surfaces of their *N*-terminal domains ([1] , [2]).

Electrostatic forces, rather than complementarity shapes, play a prominent role in the interaction. The crystal structure of the first CD58, with and without its carbohydrate, supports the “handshake” model of interaction in which the two domains approach each other from opposite ends.

The crystal structure studies support the suggestion that both genes arose from duplication of an ancestral gene. The binding affinity is low (kd, 10 to 20 µm) due to high dissociation constant ([3] , [4]).

Gene locus: 1p13.

Molecular mass (kd): 45 to 70.

Distribution: CD58 is expressed on most hematopoietic cells (including erythrocytes) and nonhematopoietic cells (i.e., fibroblasts, endothelial, and epithelial cells). Expression is high on DCs and monocytes. It is detected on medullary (but not cortical) thymus epithelial cells. Soluble CD58 is detected in the serum and in the synovial fluids from patients with rheumatoid arthritis.

Function: CD58 mediates interactions between T cells and APCs. As a GPI-anchored molecule, CD58 has increased lateral mobility and thus may be able to concentrate in smaller areas of cell–cell contacts.

CD2/CD58 interactions deliver a co-stimulatory signal but only on memory $CD4^+$ T cells. Repeated interactions of these cells involving CD58 lead to production of high levels of IL-5 and low IFN-? (a Th2 cytokine pattern) while simultaneously leading to the expression of CD60. The features of CD2/CD58 interactions provide functionally stable contacts (in contrast to CD2/CD48), suitable for interactions between T or NK cells and their targets ([5]).

CD59 (COMPLEMENT PROTECTIN; MIRL: MEMBRANE INHIBITOR REACTIVE LYSIS; HRF-20: HOMOLOGOUS RESTRICTION FACTOR 20)

Structure: CD59 is an inhibitor of the formation of the membrane attack complex (MAC) of complement and is attached to the membrane by a GPI anchor. There are ten cysteines in the extracellular region, resulting in extensive intrachain disulfide bonding, and a single glycosylation site.

The topology of CD59 is similar to snake venom neurotoxins, that is, like a disk with the cysteines clustered in the hydrophobic center from which four loops extend

outward ([1]). The site, which binds to C8 and C9, is located in the *N*-terminal half ([2]).

CD59 is also homologous to herpes Saimiri viral protein VSB-15.

Gene locus: 11p13.

Molecular mass (kd): 19.

Distribution: CD59 is widely distributed in blood cells (leukocytes, erythrocytes, and platelets), endothelial and epithelial cells, trophoblast placenta, and spermatozoa. It is also detected in neurons and glial cells, where it is up-regulated in neurodegenerative diseases, that is, Alzheimer and Huntington chorea, both associated with chronic complement activation ([3]). It is detected in body fluids, plasma, urine, seminal fluid, saliva, amniotic fluid, and so forth.

Function: CD59 inhibits the formation of MAC after the C5b-7 insertion stage ([4]). It incorporates into the forming MAC and blocks C9 polymerization, binding to a conformational epitope in human C8 a-chain. It also binds to the b domain of C9 in the "hinge" region, which unfolds when C9 is inserted into the membrane.

CD59 inhibits MAC formation of human C5b67 complex only if either C8 or C9 is human. This is the basis of homologous restriction, indicating that CD59 interacts with both C8 and C9. CD59 hinders partial unfolding of C9 necessary for C9 oligomerization, multiple C9 membrane incorporations, and large MAC ring formation. The small size MAC (C5b8 with single C9) forms ion channels with a size comparable to other ion channels (0.7 to 1.0 nm); however, these small MACs are not "leaky," probably as a result of "plugging" by the CD59. CD59 not only blocks formation of large MACs (5 to 10 nm in diameter) but also blocks leaky small MACs ([5]).

Among the CCPs that protect from complement-mediated cell damage, CD59 is more important than DAF (CD55) or MCP (CD46). Absence of DAF is not associated with intravascular hemolysis, so absence of CD59 is the key factor in PNH. Study of the expression of GPI-anchored proteins by flow cytometry suggested that immunophenotyping of monocytes and granulocytes is better in assessing the size of PNH clone, and CD59 evaluation is more accurate than CD55 ([6], [7]). A patient with PNH was shown to have a defect in CD59 gene consisting of single-base deletions at amino acids 16 and 96 from the N-terminus.

In patients with diabetes, CD59 is subject to glycation, and as a result, CD59 loses its inhibitory function of MAC formation, and red cells become sensitive to MAC lysis ([8]). In addition to cell lysis, MAC stimulates proliferation of fibroblasts, smooth muscle, and mesangial cells by releasing growth factors, like fibroblast and PDGFs.

CD59 is associated with a creatinine transporter, which plays an important role in muscle metabolism, and during sepsis, there is an increase of free creatine from myocellular sources, triggered by CD59 ([9]).

CD61 (INTEGRIN ß$_3$ SUBUNIT)

Structure: CD61 is the ß $_3$ subunit that forms two heterodimers, one with a $_V$ (vitronectin receptor) and a second with aIIb subunit (platelet integrin receptor for fibrinogen, vWF, and so forth).

The crystal structure of the a $_V$ß $_3$ integrin has been analyzed. a $_V$ß $_3$ consists of an ovoid head formed by the NH $_2$ terminals of the two subunits.

The ß $_3$ subunit has a "head," one "leg," and a "knee," and forms with the a $_V$ subunit an "anthropomorphic" structure ([1]). The head consists of the ßA domain, which is made from a ß sheet surrounded by eight helices ([2], [3], [4] and [5]). There is a MIDAS motif on top of the ßA domain, which has a metal-binding sequence DXSXS similar to the MIDAS motif of the a subunits with an A(I) domain. Adjacent to the MIDAS with the Mn $^{2+}$ stimulatory site, there is the ADMIDAS sequence with a Ca $^{2+}$-binding inhibitory site.

Another domain called *hybrid* is an Ig-like type I domain, which is formed by two sequences distantly located in the primary structure (one on each side of the ßA domain). The ßA domain is inserted between loops of the hybrid domain. The ß $_3$ subunit contributes to the interface of the heterodimeric ovoid head. The interface is largely hydrophobic, and it does not have "specificity-determining" residues, which may account for the association of ß $_3$ with a $_V$ or aIIß.

The ß $_3$ leg is formed by several domains: a PSI domain (plexin, semaphorin, integrin) and hybrid domains. The integrin PSI domain has seven cysteines, six of them forming disulfide bonds between themselves, whereas one forms a long-range disulfide bond to the *C*-terminal cysteine-rich EGF domain. The PSI domain is followed by four EGF-like domains called *integrin EGF* (I-EGF).

The typical EGF domains have six cysteines, but the cysteines in I-EGF are seven, with the extra ones forming interdomain disulfide bonds between consecutive I-EGFs. The ß $_3$ leg ends with a tail domain (ßTD). The knee of the ß subunit (ß genu) lies in the PSI/I-EGF1–2 region.

Gene locus: 17q21.3.

Molecular mass (kd): 90 to 105.

Distribution: Detected in platelets, megakaryocytes, monocytes, macrophages, and endothelial cells.

Function: In the resting state, the integrin assumes a bent, compact, V-shaped position with one leg of the V ending to the head, whereas the other to the tail. The tip of the V corresponds to the "knee" (genu). In the presence of Mn $^{2+}$, the integrin stands up and takes the extended conformation with a head and two legs ([1], [6]).

Because the aV chain in the a $_V$ß $_3$ integrin has no I(A) domain, the A domain of the ß-chain mediates both the ligand binding and the heterodimer formation. The ligand residues Arg-Gly-Asp (RGD) fit into a crevice between the propeller (see CD51 or CD41) and the ßA domains.

Inside-out signals activate integrins and change the affinity for their ligands from low to high (i.e., enable the integrin to bind the ligand). Activation induces conformational changes and reorientation of the ßA and propeller domains, which may be facilitated by the fact that the residues, which bind the ligand as well as the metal and form the heterodimer, are very close together.

It has been proposed that the conformational changes occurring in ßA, propeller, and MIDAS may be visualized as a bell being pulled down by a rope (the *bell-rope model*). This movement is triggered probably by the hybrid domain, which "pulls" down a linker sequence (the "rope") at the C-terminus of the ßA domain and opens the ligand-binding site. Binding of the ligand with high affinity triggers outside-in signaling, which initiates the integrin functions, such as platelet aggregation and adhesion to injured surfaces.

The ß $_3$-chain is associated with two a-chain partners: a $_V$ (CD51) and aIIb (CD41). All integrin a-chains are divided into two groups, those with an I(A) domain (see CD11, CD49a, CD49b), and those without (CD41, CD49–CD49f, CD51).

Both aIIbß $_3$ and a $_V$ß $_3$ are important platelet integrins functioning as receptors for fibrinogen, vitronectin, vWF, and so forth. Therefore, they have a major role in hemostasis.

Seen by electron microscopy, aIIbß $_3$ binds to its ligands in different locations (i.e., for fibrinogen, the site is located to the distal end of the molecule, for FN, two-thirds from the NH $_2$ terminus, and for vWF, near the central module) ([7]).

The contributions of the various domains of ß $_3$ to the expression, ligand binding, and function have been studied from mutations, natural or targeted. Mutations result in GT, which, depending on the severity of its symptoms, is divided into type I (severe, <5% of normal aIIbß $_3$) and type II (moderate aIIbß $_3$ deficiency, 10 to 20% of normal) ([8], [9] and [10]). There are 40,000 to 80,000 aIIbß $_3$ molecules/platelet and only approximately 100 of a $_V$ß $_3$.

Mutations in ß $_3$ may not affect the function of both integrins as one would have expected. A Leu196 Pro mutation within ß $_3$ MIDAS in a patient with type II GT affected the expression and functions of aIIbß $_3$ and a $_V$ß $_3$. The mutation interfered with aIIbß $_3$ expression (transport to the surface) but not adhesion to fibrinogen. However, the a $_V$ß $_3$ functions were inhibited, that is, platelet spreading, formation of focal contacts, phosphorylation of p125 ^{FAK}, and clot retraction ([11]).

In another patient, His280Pro in ß $_3$ impaired aIIbß $_3$ but not a $_V$ß $_3$ expression, whereas a Ser162Leu markedly impaired ligand binding in aIIbß $_3$ but not in a $_V$ß $_3$ ([12]).

The cytoplasmic tail of ß $_3$ has two tyrosines (Y747 and Y759), which are potential sites of phosphorylation and substrates for Src kinases mediating outside-in signaling. Subsequent interactions with other signaling molecules, such as Syk and Csk kinases, modulate effector functions of the integrins (i.e., reorganization of cytoskeleton, adhesion to fibrinogen, platelet spreading, and so forth) ([13], [14]). The inside-out signals, which modulate ligand-binding affinity, utilize small GTPases such as Rap1b ([15]).

Because of the importance of these two integrins in hemostasis, drugs and monoclonal antibodies have been used in clinical medicine to modulate their function. After vascular injury, the ß $_3$ integrins are up-regulated in endothelial cells. Their activation, through a series of complex cellular interactions, contributes to restenosis after percutaneous coronary interventions. Abciximab is a chimeric monoclonal antibody and is used for thrombotic complications in angioplasty and other conditions in which platelet activation and deposition on the endothelium are involved ([16]).

The ß $_3$ integrins contain a thiol isomerase activity predicted from the CXXC motif in each of the I-EGF motifs of the ß $_3$-chain ([17]) involved in disulfide exchange reactions.

Four ß $_3$ polymorphisms have been identified to be associated with neonatal alloimmune thrombocytopenic purpura. One, responsible for the alloantigen system Pen ^{a}/Pen ^{b}, results from G526A mutation, and the second, Thr140Ile, is associated with the Duv $^{a+}$ alloantigen ([18]). Both of these involve the RGD-binding site. The third is associated with the Oe ^{d} alloantigen (Lys611 deletion) ([19]) and the fourth, Leu33Pro, with the platelet alloantigens PI ^{A1} and PI ^{A2}.

CD62 (SELECTINS)

Selectins constitute a family of molecules that allow leukocytes to attach to vascular endothelium and migrate across the vessel wall. There are three members in the family: E-selectin, limited to endothelial cells (CD62E); L-selectin, expressed on all neutrophils, monocytes, and the majority of B and T cells (CD62L); and P-selectin, expressed on endothelium and platelets (CD62P) ([1], [2]).

CD62E (E-Selectin, ELAM)

Structure: The extracellular region consists of an *N*-terminal C-type lectin module (lec) followed by an EGF-like module (epidermal growth factor) and six CCP domains.

The lectin module is analogous to other C-type Ca $^{2+}$-dependent animal lectins, therefore the function of E-selectin is regulated by carbohydrate–protein interactions. The C-type lectin fold consists of two antiparallel ß strands, two a helices, and a number of irregular loops, some of them involved in the monosaccharide binding mediated by Ca $^{2+}$.

The EGF fold is very similar to other EGF modules, with six cysteines forming disulfide bonds, which maintain a compact structure. These EGFs are similar to clotting factor IX EGF domain and do not contribute directly to the binding of ligand but are necessary, probably because they are required to maintain the conformation of the lec domain. Crystal structure of E-selectin has shown that there is very little interaction between the EGF and lec domains. The selectin CCP domains have six conserved cysteines. The role of CCP domains in selectin function is not clear, but deletion of CCP domains drastically affects the E-selectin function.

Gene locus: 1q22-25, closely linked to the genes of the other selectins and the complement receptor genes.

Molecular mass (kd): 97 to 115.

Distribution: E-selectin is expressed on endothelial cells, but it is not stored in cellular granules and is up-regulated by inflammatory cytokines (i.e., IL-1, TNF-a, and endotoxin), reaching maximal levels within 3 to 4 hours.

E-selectin is constitutively expressed in postcapillary venules of the skin.

Function: CD62E binds the ligand within a finite region of the lectin domain in the vicinity of the bound Ca $^{2+}$. CD62E (and all selectins) binds the tetrasaccharide sLe ^{X} [Siaa2?3Galß1?4(Fuca1?3)GlcNac] with fucose being a critical component ([3]).

The majority of the interactions between sLe ^{X} and E-selectin are electrostatic (i.e., hydrogen bonds, water bridges, and a Ca $^{2+}$ metal ion bond). The Ca $^{2+}$ is bound probably by the 2- and 3-hydroxyls of fucose.

Synthesis of the carbohydrate ligands requires the enzymatic function of glycosyltransferases. The epithelial a1,3-fucosyl transferase (FucT-III) synthesizes the E-selectin sLe ^{X} ligand ([4]). FucT-VII plays a critical role in constructing ligands for E- and P-selectins.

After stimulation by inflammatory cytokines, E-selectin can support rolling and tethering of PMN and contributes to a later stage influx into inflamed tissues. Rolling adhesions on E-selectin are stronger than those on P-selectin.

Recently, memory T cells expressing the cutaneous lymphocyte-associated antigen, a carbohydrate epitope also detected on P-selectin glycoprotein ligand-1 (PSGL-1), were shown to be able to bind on both E- and P-selectins.

The CD8 $^+$ type 1 cytotoxic cells migrate to inflamed skin through E-selectin using PSGL-1 and play a critical role for tissue-specific homing of T cells to skin. CD44 is an E-selectin ligand for primitive CD34 $^+$ hematopoietic cells ([5]). CD44 may be considered as a “bone marrow homing receptor” for transplanted bone marrow stem cells and tissue distribution of myeloid progenitors.

E-selectin reduces the velocity of rolling sufficiently so that ß $_2$ integrin further decreases the velocity so that the leukocyte comes slowly to an arrest. In the absence of E-selectin, ß $_2$ integrins are unable to decelerate rolling smoothly, and after a long period of time, the cells come to an abrupt arrest.

Lack of E-selectin in a child with recurrent infections implicates its role in leukocyte recruitment in areas of inflammation ([6]). The E-selectin was not detectable on the endothelial cells, although E-selectin mRNA was present. A proteolytically cleaved soluble E-selectin was elevated in blood.

CD62L (L-Selectin, LECAM-1)

Structure: CD62L has an extracellular region that consists of a C-type (Ca^{2+}-dependent) module (lec), an EGF module, and two CCP domains. An amino acid spacer between the second CCP domain and the membrane contains a proteolytic cleavage site. The cytoplasmic region is short.

Gene locus: 1q23-25.

Molecular mass (kd): 65 to 74 (lymphocytes); 95 (neutrophils).

Distribution: Expressed in most hemotopoietic cells, neutrophils, monocytes, and eosinophils, and in the majority of naïve T and B cells but only in a minority of activated T cells and NK cells. It is lost on activation because of proteolytic cleavage and is detected in peripheral blood in a soluble form.

Function: L-selectin recognizes glycoproteins, which collectively are referred to as *peripheral lymph node addressins* (PNAd) and are expressed on the luminal aspect of HEV. The L-selectin ligands require O-linked carbohydrates with posttranslational modifications for optimal binding (i.e., sialylation, fucosylation, and carbohydrate sulfation, all of which can be found in the sLe^X tetrasaccharide).

The essential modification is sulfation on the C6 position of either Gal or GlcNA carried out by two sulfotransferases, which belong to the GST subfamily of carbohydrate sulfotransferases. These O-glycan branches extend from a trisaccharide known as *core 2* and require an enzyme known as *core 2*-ß *1,6-N acetylglucosaminyl transferase* (C2GnT). They are further modified by a 2,3-sialyltransferase, an a-1,3-fucosyltransferase VIII (FucT-VIII), and a sulfotransferase, but the order of modifications is not known. These oligosaccharides decorate several proteins, such as GlyCAM-1 (which was found to be a secreted molecule), a glycoform of CD34, MadCam, podocalyxin-like protein, and so forth.

All these proteins, for simplicity called *PNAd*, are recognized (and copurified) by a monoclonal antibody, MECA-79 (see details in Chapter 15) independent of sialylation and fucosylation.

Three sulfotransferases have been isolated; one transfers a sulfate group to Gal-6 and the other two on GlcNAc-6 positions. One, known as *LSST*, or L-selectin ligand sulfotransferase, is HEV-restricted and is involved in the synthesis of L-selectin ligand and the MECA-79 epitope, required for lymphocytic homing ([7]).

The function of L-selectin is capture (“tethering”) and rolling. Rolling of leukocytes consists of stepwise and smooth components. The former corresponds to dissociation of bonds between a cluster of receptors and their ligands. The latter corresponds to the elongation of the microvillous tethers. Rolling, although oscillating, is remarkably uniform under all conditions of shear stress ([8], [9]). Inflammation, which up-regulates L-selectin expression, tends to augment tether formation.

Ligands for L-selectin are induced in sites of chronic inflammation, as shown with MECA-79 antibody staining ([10]). HEV-like vessels have been detected in synovium, skin, gut, lungs, and so forth under various inflammatory conditions. MECA-79 epitopes have also been detected in intramuscular capillaries and venules in patients undergoing rejection of heart allografts ([11]). Two new monoclonal antibodies, G72 and G152, have now been developed with specificity to 6-sulfo sLe^X, which is accepted as the L-selectin ligand.

CD62P (P-Selectin, PADGEM)

Structure: The extracellular region contains an *N*-terminal C-lectin domain, an EGF domain, and nine CCP domains that form an extended rod 48 nm long ([12]). Alternative splicing results in variants lacking the seventh CCP domain or producing a soluble form.

The cytoplasmic tail is short and attaches to cytoskeleton through interaction with moesin that is essential for leukocyte rolling and directs targeting of P-selectin to specialized organelles and to lysosomes. The binding site is a groove on the surface of the C-domain formed by three of the domain's strands.

Gene locus: 1q21-q24.

Molecular mass (kd): 140.

Distribution: Expressed on megakaryocytes, platelets, and endothelial cells. It is stored in secretory granules in platelets and is translocated to the membrane on activation. After a short expression on the surface, it is internalized and degraded within lysosomes ([13]).

Function: The ligand for P-selectin is PSGL-1 (CD162), although it binds also to E- and L-selectins. It mediates the interactions of leukocytes and platelets with the endothelial cells ([14]). PSGL-1 is a mucinlike transmembrane homodimer. The extracellular region consists of 15 decameric repeats rich in prolines and threonines.

Binding to P-selectin requires the sLe^X oligosaccharide at residue 16, one or more sulfated Tyr, and four acidic residues closer to the N-terminus. Engagement of T cells on P-selectin induces tyrosine phosphorylation of p125 FAK and, in neutrophils, enhances tyrosine phosphorylation activation of MAPK and stimulation of IL-8 secretion.

P-selectin mediates the rolling of neutrophils and their recruitment to areas of inflammation, especially in the early stages of leukocyte recruitment. Heparin, which is used in human disease as an anticoagulant and antithrombotic agent, has in addition antiinflammatory activity in experimental animals mediated through inhibition of P- and L-selectins ([15]). The 6-0 sulfate group of glucosamine units of heparin is critical for antiinflammatory as well as anticoagulation therapy.

CD64 (FC?RI)

Structure: CD64 is the high-affinity receptor for IgG (binds monomeric IgG) and is a member of the Fc?R family, which has nine transmembrane and three soluble members ([1], [2] and [3]). The Fc?RI family is a heterogeneous group of proteins as a result of multiple genes (A, B, C) and alternative splicing. The A gene encodes the high-affinity Fc?RIa. The B and C genes have a stop codon in the exon that encodes the third Ig domain and transcribes soluble proteins with one or two domains (Fc?RIb $_1$, Fc?RIc).

The extracellular region of Fc?RIa contains three Ig-like domains of the C2 type. Only the first two are homologous to those of the other FcRs. The third domain confers the high affinity to Fc?RI.

The cytoplasmic region contains no sequences known to be involved in signaling. The receptor forms a heterodimer with the FcR ?-chain, which is essential for its expression and signal transduction with an ITAM sequence in its cytoplasmic tail.

Gene locus: 1q21.1.

Molecular mass (kd): Fc?RIa, 72.

Distribution: Fc?RI is constitutively expressed on monocytes and macrophages. It can be induced by IFN-? on neutrophils, eosinophils, and glomerular mesangial cells. Fc?RI is also expressed on DCs.

Function: Fc?RI binds monomeric IgG as well as aggregated IgG. The C?2 domain of IgG binds directly to Fc?RI, but the C?3 stabilizes the interaction. Crucial for the interaction is a sequence in the N-terminal region of the C?2 domain present in human IgG1 and IgG3 high-affinity binding and another region in the hinge of IgG. The binding of IgG to Fc?RI involves only one heavy chain.

Cross-linking of Fc?RI on monocytes induces phosphorylation of PLC-? and Syk kinases ([4]).

CD64 is important for phagocytosis of opsonized targets and ICs as well as for antibody-mediated cytotoxicity ([5]).

The importance of Fc?RI in body defenses, however, was questioned when four individuals within a family were identified as lacking Fc?RI without manifesting immunologic problems. The defect was due to the change of a single nucleotide within the exon encoding domain 1, resulting in a change to a termination codon.

Signals lead to cytoskeletal remodeling mediated by the small GTPase, Rac, leading to activation of the Arp 2/3 complex (see Chapter 14). PI3K is involved in several steps during signaling in phagocytosis. FcRs in general, and Fc?RI in particular, have been used in clinical medicine in immunotherapies. Fc?Rs are important in mediating ADCC when antibodies are used for treatment of malignancies (i.e., CAMPATH, CD20) ([6]). Biospecific molecules (BSMs) improve the recruitment of Fc?R activation. BSMs have one side specific for the target, whereas the other is directed against the FcR. Several BSMs have developed and are used for cancer immunotherapy. Antibodies directed against viruses direct the pathogen to the phagocyte (antibody-dependent enhancement).

A BSM (MDX-240), specific for gp41 of HIV and Fc?RI, decreased virus production and diminished formation of HIV proviral DNA in macrophages. Fc?R plays a role also in autoimmune diseases for clearance of ICs but also in mediating IC tissue damage ([7]). Cross-linking Fc?RI and Fc?RII on macrophages stimulates secretion of matrix MMP-1. Because such complexes exist in atherosclerotic plaques, the study suggests that MMP-1 potentially may contribute to plaque rupture in arterial walls, triggering an acute coronary event ([8]).

CD66 [CARCINOEMBRYONIC ANTIGEN (CEA) FAMILY]

The CEA family of proteins consists of two subfamilies: (a) CEA-CAM (carcinoembryonic cell adhesion molecules, C-CAM) with eight members; and (b) PSG (pregnancy-specific glycoprotein), with 11 members ([1], [2]).

The CEA-CAM group has eight isoforms as a result of alternative splicing, but also by differential glycosylation, and variation in the number and sequence of the C2 domains. The usual C2 domain has approximately 178 amino acids, but some isoforms have domains with 71 or 31 residues (non-C2 domains). Those very small domains are specific for the C-CAM family.

CD66a: C-CAM-1

Structure: C-CAM-1 is a transmembrane protein with four Ig-like domains in the extracellular region. The *N*-terminal is of V-type, and the other three are of C2 type. It is heavily glycosylated with more than 60% of the mass contributed by the N-linked glycans, which bear sLe^X (CD15) types of structures. C-CAM-1 occurs in two isoforms: C-CAM-1L with a long cytoplasmic region (71 to 73 amino acids) and C-CAM-1S with a short one (10 to 12 amino acids), as a result of alternative splicing leading to a stop codon. C-CAM-1L contains two tyrosine residues in an ITIM motif (YXXL), spaced 21 residues apart.

Gene locus: 19q13.2.

Molecular mass (kd): 140 to 180.

Distribution: C-CAM-1 is present in hematopoietic cells, mature granulocytes (up-regulated after activation) ([1]), macrophages, T cells, and NK cells, stratified epithelia (contact cell boundaries), simple epithelia (apical brush border), liver (bile canaliculi), and kidney (proximal tubules). Generally, C-CAM-1L is found in apical and lateral surfaces, whereas C-CAM-1S is located exclusively in the apical surfaces. Lateral localization requires homophilic antiparallel binding between adjacent cells mediated by the N-domain.

Function: C-CAM-1 is an adhesion molecule but is also involved in numerous other functions such as proliferation, tumor growth, angiogenesis, epithelial cell polarization, and apoptosis. It is also a receptor for gonococci and *E. coli* ([3]).

The presence of the ITIM motif and recruitment SHP-1 and SHP-2 phosphatases suggests that its basic signal transduction mechanism is inhibitory (see below) ([4]).

In cell adhesion, the C-CAM-1L (but not C-CAM-1S) associates with cytoskeletal proteins paxillin (neutrophils, epithelial cells), as well as G-actin and tropomyosin ([5], [6]). The association with the cytoskeleton and its localization in the cellular boundaries, where it participates with neighboring cells in homophilic interaction, is mediated by Rho GTPases.

C-CAM-1 is an inhibitor of tumor growth, and it is found down-regulated in several human malignancies ([7], [8]). Transfection of several tumor cell lines from different species with C-CAM-1 complementary DNA (cDNA) resulted in inhibition of tumor growth.

Essential for tumor inhibition is the long cytoplasmic tail (C-CAM-1L). SHP-1 and SHP-2 tyrosine phosphatases are recruited and required for the inhibition of Ca^{2+}

influx. In normal cells, the Rho GTPases direct the adhesion molecule to its proper destination, the cell boundaries, where it establishes homophilic interactions with neighboring cells. A link possibly exists between C-CAM-1 interaction with cytoskeleton and tumor growth. This is suggested by the fact that only C-CAM-1L, but not C-CAM-1S, is tightly associated with the cytoskeleton and functions as tumor cell growth inhibitor. Relocalization of C-CAM-1L contributes to loss of contact inhibition and proliferation.

The S to L isoform rates are different between quiescent and proliferating cells, with the S to L ratio being lower in proliferating cells ([9]).

It has also been suggested that C-CAM-1 inhibits tumor angiogenesis through the release of an inhibitor of endothelial cell growth and migration ([10]). However, other data indicate that C-CAM-1 supports the vascular endothelial growth factor function.

Melanoma cells expressing C-CAM-1 could not be killed by cytotoxic NK cells because the NK cells engaged in homophilic interaction with the melanoma cell, which inhibited the NK-cell cytotoxicity ([11]). Another important function of C-CAM-1 is in the inhibition of activated decidual lymphocyte functions ([12]). The decidual lymphocytes consist predominantly of NK cells, which make up 70 to 80% of the lymphocytes in this location. They are strongly CD56 $^{+}$ and CD16 $^{-}$. On activation, they become C-CAM-1–positive. The extravillous trophoblast expresses constitutively C-CAM-1, and interaction with C-CAM-1 $^{+}$ NK cells inhibits cytotoxicity. This mechanism may provide an explanation for the survival of the semiallogeneic fetus from attack of maternal NK cells.

C-CAM-1 has also been implicated in the function of insulin ([13]). Binding of insulin to its receptor leads to phosphorylation of C-CAM-1, which then binds to Shc, an adaptor protein, and interrupts the signaling pathway of insulin. C-CAM-1 down-regulates cell proliferation triggered by insulin, but C-CAM-1 also regulates insulin clearance ([14]). Phosphorylated C-CAM-1 binds to the insulin receptor and mediates insulin clearance by endocytosis in hepatic cells. Interference with C-CAM-1 phosphorylation in the liver leads to impaired insulin clearance and hyperinsulinemia.

C-CAM is used by *N. Gonorrhoeae* to induce neutrophil apoptosis. Gonococci express the opacity (opa) proteins, which are adhesins, and mediate binding of gonococci to the C-CAM family of proteins and the heparan sulfate proteoglycans, syndecan-1 and syndecan-4. Shuffling of the HV domains of opa by the gonococcus generates variants with new specificities.

The gonococci actively release membrane material (“blebs”), which, through a TLR, activate NF-?B and stimulate up-regulation of C-CAM expression and opa-mediated neisserial binding. This interaction plays a central role in the pathogenic process because urethral exudate consists primarily of PMNs with internalized opa $^{+}$ bacteria, which induce cell death. To fully protect themselves, gonococci also inhibit T-cell activation ([15], [16]).

The CEA members have been considered as targets for immunotherapy of cancer. Vaccines targeting CEA have been developed and used in clinical trials to stimulate humoral responses or cytotoxic responses. For humoral immunity, an antiidiotypic, anti-CEA antibody (AB2) is used mixed in alum. For the CTL response, a pox virus–based vector is used, incorporating CEA with or without co-stimulatory molecules. Another approach uses DCs loaded with a peptide from CEA. These vaccines are safe and immunologically active.

CD66b [Carcinoembryonic Cell Adhesion Molecule (CEA-CAM)-8, Former CD67] and CD66c (CEA-CAM-6, NCA)

Structure: The extracellular region in both members consists of three Ig-like domains, the *N*-terminal of type V and the other two of type C2, all heavily glycosylated (11 to 12 N-glycosylation sites). The molecular weight of CD66b is shifted from 95 to 40 after deglycosylation.

Gene locus for both: 19q13.2.

Molecular mass (kd): 95 and, after deglycosylation, 40.

Distribution: Present in neutrophils. CD66c is detected on epithelia. Soluble forms of both are present in plasma.

Function: CD66b exhibits only heterophilic adhesion with CD66c (C-CAM-6) and CD66e (C-CAMe). CD66c is capable of both homophilic and heterophilic (with CD66b) adhesions ([16], [17]). Subtle differences in the N-domain sequences determine the specificity for homophilic and heterophilic interactions as well as the interactions with opa proteins of gonococci. Both regulate adhesions of neutrophils to endothelial cells, which are blocked by CD18 antibodies.

Cross-linking of CD66b/CD66c/CD66a promotes their clustering with participation of the ß $_{2}$ subunit of the a $_{M}$ integrin. This leads to ß $_{2}$ integrin activation and, in turn, alteration of the affinity of ß $_{1}$ integrin, which enhances the adhesion of neutrophils to FN. CD66a and CD66b are receptors for galectin-3 and enhance neutrophil adhesion to laminin through galectin-3.

Expression of CD66c in colorectal carcinomas is inversely related to the degree of cellular differentiation. CD66c (but not CD66b) is a receptor for the opa proteins of *N. gonorrhoeae* and mediates the nonopsonized internalization of the bacteria by neutrophils (see above).

CD66d (CEA-CAM-3) and CD66e (CEA-CAM-5, Carcinoembryonic Antigen)

Structure: The extracellular region of CD66d consists of only one V-type Ig-like domain. It is a transmembrane protein, and the cytoplasmic region (as with CD66a) is either long or short. The long cytoplasmic tail contains two tyrosine motifs (YXXL), which resemble the ITAM sequences. There are three splice variants, one of which alters the reading frame and leads to loss of the ITAM motifs.

The extracellular domain in CD66e attaches to the membrane by a GPI anchor.

Gene locus: CD66d, 19q13.2; CD66e, 19q13.1-13.2.

Molecular mass (kd): CD66d consists of six C2 type and one V-type Ig-like heavily glycosylated domains. It is attached to 35; CD66e is attached to 180 to 200.

Distribution: CD66d is expressed on hematopoietic cells, and its expression in neutrophils is up-regulated after activation. It is also detected in a variety of epithelia. CD66e has not been detected in hematopoietic cells but is expressed in epithelia.

Function: CD66d is phosphorylated and participates in signal transduction, leading to neutrophil activation. It forms a complex with calprotectin in neutrophils ([19]), but the function of this interaction is unknown. Calprotectin is a heterodimer formed by two Ca2 $^{+}$-binding proteins that cross-link two homologous or heterologous target proteins.

CD66d mediates phagocytosis of opa $^{+}$ gonococci ([20]) (see details in CD66a).

CD66e is involved in both homophilic and heterophilic interactions; it binds to Kupffer cells in the liver and stimulates secretion of various cytokines. The detection of CD66e is useful as a marker for malignancies, and its determination in the serum has been used to monitor tumor progression.

CD66f (PSG: Pregnancy-Specific Glycoprotein)

Structure: CD66f is a member of the second subfamily of the CEA family of molecules, which consists of 11 members. It has one *N*-terminal V-type domain and two to three type C2 Ig-like domains.

Gene locus: 19q13.2.

Molecular mass (kd): 54 to 72.

Distribution: It is produced by the syncytiotrophoblast in the placenta and is found in fetal liver and myeloid cells ([21]). It is detected around the second or third week of pregnancy and increases as pregnancy progresses. It is also produced by the testes, intestine, and cultured fibroblasts.

Function: CD66f exerts an embryotrophic activity (i.e., has a stimulatory effect on embryogenesis in preimplantation embryos *in vitro*) ([22]). The RGD sequence has been implicated in giving positional cues and locomotive signals during development. PSG may have a role in embryo-maternal communication, but its role during early pregnancy remains to be elucidated.

CD70 (CD27L)

Structure: CD70 is a member of the TNF SF and a type II membrane protein. Its extracellular region contains four cysteines forming two disul-fide bonds (1?3 and 2?4). CD70 is homologous to TNF-a and is the ligand for CD27 ([1]).

Gene locus: 19p13.

Molecular mass (kd): 21.

Distribution: Resting T and B cells do not express CD70, which is induced after activation (i.e., in small numbers of B cells in germinal centers and in memory B cells). It is expressed on B-cell malignancies [i.e., B-CLL (50%), follicle center cell lymphomas (33%), large cell lymphomas (71%), and Burkitt lymphoma cells].

Function: CD70 expression on T cells is restricted, but it occurs after priming by APCs ([2]). CD70/CD27 interactions play a role in B-cell differentiation to plasma cells and Ig production. In cooperation with IL-4 and CD40 signaling, it promotes plasma cell differentiation and IgE secretion ([3]).

The CD27/CD70 interaction involves a distinct step, as compared with CD40/CD154 (CD40 ligand) interaction. It blocks IL-10–mediated apoptosis of differentiating B cells and directs their differentiation to plasma cells and Ig synthesis ([4]). The CD27/CD70 interactions normally are transient and may be harmful if they are prolonged, as shown by a model in which CD70 expression was constitutively expressed on B cells in CD70 transgenic mice. In these animals, peripheral T cells increased in numbers, while, at the same time, they were differentiated to an effector type with IFN-? production ([5]).

Whereas B cells gradually decline as a result of IFN-? production from effector T cells, B cells from patients with common variable immunodeficiency type I (i.e., low in $CD70^+$ B cells) remain subnormal even after T-/B-cell interaction *in vitro*, suggesting that there is probably a B-cell signaling defect in these patients ([6]). An unusual CD70 expression is that in glioblastoma, where expression is inducible by irradiation. $CD70^+$ glioma cells co-cultured *in vitro* with peripheral blood mononuclear cells induced T- and B-cell apoptosis and shedding of CD27 from the mononuclear cells ([7]) (see further details in Chapter 18).

CD71 [TRANSFERRIN RECEPTOR (TfR)]

CD71 is the receptor for transferrin (TfR). TfR-mediated endocytosis brings the transferrin–iron complex to endocytic vesicles, where iron is unloaded by a decrease in the endosomal pH.

Structure: TfR is a type II transmembrane protein that forms a homodimer linked by two disulfide bonds. It consists of a large extracellular region (residues 89 to 760), a single transmembrane region (residues 68 to 88), and the *N*-terminal cytoplasmic region (residues 1 to 67) ([1]).

The large extracellular globular domain is separated from the membrane by a thin stalk and forms proteoparticles when it is reconstituted in phospholipids, a property

that may facilitate its sequestration from other proteins within endosomes for its subsequent return to the cell surface.

The stalk contains a single O-linked oligosaccharide attached to Thr-104 near the transmembrane region. Removal of the oligosaccharide or targeted mutation of Thr-104 enhances susceptibility of the TfR to proteolysis at Arg-100 and its release in a soluble form ([2]). It is likely that the oligosaccharide may protect TfR from proteolytic cleavage. The soluble TfR resulting from cleavage at Arg-100 is a homodimer but is not disulfide linked. This cleavage occurs in the endocytic compartment and is constitutively mediated by a matrix MMP of the ADAM family

A second TfR, known as *TfR-2*, exists in two alternatively spliced forms, a and ß. TfR-2a cannot fully compensate for TfR-1 because its affinity for transferrin is 25-fold lower than that of TfR-1. Furthermore, TfR-2a does not bind the HFE protein of hemochromatosis (see below).

The cytoplasmic region is short (residues 1 to 67) and contains the internalization motif YTRF.

Gene locus: 3q26.2.

Molecular mass (kd): 90 to 95 (reduced); 180 to 190 (unreduced).

Distribution: TfR is ubiquitously expressed on all cells of the body and especially on proliferating cells. It is regulated in response to iron availability. The regulation is mediated by regulatory proteins interacting with mRNA. A hairpin structure on 3' UTR of mRNA is recognized by transacting proteins known as *iron-regulatory proteins* (*IRP*) that control the rate of mRNA translation or stability. The iron-regulatory proteins regulate the iron homeostasis within the cell, once it is brought by the TfR, as well as other iron-binding proteins such as ferritin (iron storage).

Function: For transferrin to take up iron, it has to be transported from the intestinal lumen across the enterocyte to its basolateral surface by the transporter DMT-1 (divalent metal transporter-1), cross the villous lumen surface, and then be taken by ferroportin to the basolateral surface. All iron is changed to the ferric (oxidized) state to be taken up by transferrin.

Transferrin transports the iron to the cells of the body, and needy cells are recognized by expression of TfR on their surface. TfR dimer binds two transferrin molecules. The apical domain of TfR provides the interface with two of the domains from transferrin. The complex is internalized through receptor-mediated endocytosis (clathrin-coated pits) and is transported to endocytic vesicles where iron is discharged at the low pH of the endosomes. Once in the cytosol, iron enters a chelatable pool from which it is used by several enzymes or is stored in ferritin. When cellular iron is plentiful, it stimulates the assembly of new ferritin baskets, thus controlling its own storage capacity within the cell.

The apotransferrin remains bound to TfR in the acidic milieu, and the complex is recruited to the cell surface, where apotransferrin is released in the extracellular fluid.

TfR and Hemochromatosis

A second ligand for TfR is the hemochromatosis protein HFE. It is encoded by a gene in chromosome 6 linked to human class I MHC cluster. The protein, also known as HLA-H, is homologous to MHC class I molecules, such as HLA-A2 and the nonclassical HLA-G ([3], [4]). It is predicted to consist of three domains, a $_1$, a $_2$, and a $_3$. Interaction of HFE with TfR involves the a $_1$ and a $_2$ domain helices of HFE and the two helices of the helical domain of TfR ([5], [6]).

Binding of HFE to TfR induces conformational changes of TfR that affect the movement and position of the helical domain in relation to the other domains of TfR, and this, in turn, affects transferrin binding.

The normal function of HFE in iron metabolism is not quite clear.

HFE is localized widely in the body but especially in the major sites of iron metabolism (i.e., intestine and liver). It is detected in the basolateral surfaces of epithelial cells of the stomach and colon, the sinusoidal lining cells of the liver, and in the deep crypt enterocytes of the small intestine, where it localizes with the TfR and probably modulates the uptake of transferrin-bound iron ([7]).

The effects of binding of HFE to the TfR are controversial regarding the affinity of transferrin binding to TfR and its ability for endocytosis and delivery of transferrin-bound iron. Because HFE binds near the transferrin-binding site, it inhibits the uptake of transferrin ([8]). Thus, some data suggest that HFE is a negative modulator of TfR function ([9], [10]).

Hereditary hemochromatosis (HH) is one of the most common autosomal-recessive disorders in whites and is characterized by defective regulation of dietary iron absorption, leading to excessive iron accumulation in various organs ([11], [12] and [13]). The carrier frequency has been estimated to be 1 in 8 to 1 in 10 in North America. In 83% of patients with HH, a single-base transition of G to A results in the mutation C260Y (numbering begins at the first residue of the mature protein), which disrupts the intradomain disulfide bond of the a $_3$ domain of HLA-H and changes its tertiary structure ([14]). This abrogates its interaction with the ß $_2$-microglobulin. As a result, the mutant HFE is retained in the ER, fails to undergo late Golgi processing, and is degraded and prevented from being expressed on the cell surface ([15]).

Some cases of hemochromatosis have been reported that are due to a truncation mutation (Y250X) of the TfR-2 (or *type 3 HH*, to distinguish it from the HH with HFE mutations known as *type 1* and the juvenile-onset HH or *type 2*) ([16]). TfR-2 does not bind to HFE.

CD73 (ECTO-5'-NUCLEOTIDASE, L-VAP-2: LYMPHOCYTE VASCULAR ADHESION PROTEIN-2)

Structure: CD73 or ecto-5'-nucleotidase (5'-NT) is a GPI-anchored protein member of a large family of enzymes involved in the hydrolysis of nucleotides; some of them are membrane bound (i.e., ecto-nucleotidases), whereas others are within the cell (cytosolic) ([1]).

These enzymes exist throughout evolution from bacteria to mammals, indicating a common evolutionary origin, and residues in the catalytic domain are strongly conserved. Nucleotides in general in mammals are hydrolyzed by membrane-bound ecto-enzymes, which include ATPases, apyrases (CD39), and 5'-NT (CD73) (for a new classification, see CD39).

The protein forms a dimer, and intact disulfide bridges are essential for enzyme activity. In addition to the membrane-bound enzyme, there are three human cytosolic 5'-NT (see below).

Gene locus: 6q14-q21.

Molecular mass (kd): 70.

Distribution: CD73 expression is detected on T cells ($CD4^+$, 10%; $CD8^+$, 50%) and B cells (75%), medullary thymocytes, and cortical thymocytes. The number of 5'-NT B cells in adult peripheral blood as compared to those in fetal or cord blood is double (69% vs. 32%), and the enzymatic activity per positive cell also doubles.

As a result of its pattern of expression during T- and B-cell development, CD73 is considered as a lymphocyte maturation marker. It is detected on follicular DCs of the germinal centers ([2]), thymic medullary reticular cells, and epithelial cells.

Expression of 5'-NT is abnormally low or completely devoid in lymphocytes from patients with congenital X-linked agammaglobulinemia, SCID, WAS, common variable immunodeficiency, selective IgA deficiency, Omenn syndrome, and AIDS.

CD73 is expressed in placenta, liver, and kidney, and in the brush border of jejunal and ileal enterocytes.

It is also expressed in adult T-cell leukemia and cutaneous T-cell lymphomas, and in $CD10^+$ ALL, is associated with poor prognosis in children and adults.

Function: 5'-NT hydrolyzes exclusively nucleoside 5'-monophosphate (AMP) and has no activity for 2'- and 3'-monophosphates. The final hydrolysis products are nucleoside and phosphate.

- *Lymphocyte functions*. Enzymatic activity of CD73 generates nucleosides, which reenter the cell and are reutilized, supplying the cell with purine requirements for cell division, even when *de novo* purine synthesis is blocked by aminopterin ([3]). Nucleotides, which normally are available only intracellularly, may become available from apoptotic cells and are used as substrates for 5'-NT outside the cell. Nucleotides cannot cross the membrane, but with removal of the phosphate group by 5'-NT, nucleosides reenter the cell and join in the metabolic pool. The function of 5'-NT is known as the *purine salvage pathway* and could provide the total purine requirements of mitogen-stimulated human T cells or rapidly dividing human B lymphoblastoid cells. In certain lymphoid organs with high cell turnover and high levels of apoptosis (thymus, germinal centers), 5'-NT plays an important role, contributing to the salvage mechanism. In the thymic cortex, extracellular levels of nucleosides must be delicately regulated ([4]). Although, in principle, they may contribute to a salvage pathway, deoxyadenosine is lymphotoxic, and in the absence of its deamination by adenosine deaminase, leads to SCID. 5'-NT activity is barely detectable in the thymic cortex, so that adenosine levels are kept very low. CD73 acts as a co-stimulatory molecule in T-cell stimulation in naïve ($CD45RA^+$) T cells, but the enzymatic activity is not required for T-cell activation, as shown by site-directed mutagenesis replacing codons His92 and His194 with alanine. CD73 mediates adhesion of B lymphocytes to follicular DCs in the light zone of the germinal center. It also promotes lymphocyte adhesion to vascular endothelial cells (CD73 is also known as *lymphocyte-vascular adhesion protein 2*), mediated through activation of the LFA-1 integrin ([5]).
- *5'-NT functions in nonlymphoid cells*. CD73 is expressed on endothelial, epithelial, and mesenchymal cells, and on cells of the nervous system. Vascular permeability is affected by normal activities (i.e., by transendothelial PMN migrations, inflammatory conditions, or ischemia). Nucleotides and nucleosides are released from cells and are converted by 5'-NT to adenosine. Adenosine activates the adenosine receptor A_{2B} and leads to endothelial cell functional reorganization, promoting endothelial barrier function ([6], [7]). This function minimizes increased vascular permeability in inflammatory conditions, as well as maintaining vascular integrity during the normal function of cell migration. Adenosine protects tissues from hypoxic or ischemic damage through activation of the A_1 and possibly A_{2A} adenosine receptors. Brief periods of ischemia, known as *ischemic preconditioning*, protect tissues from prolonged ischemic damage after infarction. Adenosine production during the ischemic preconditioning period is increased as a result of enhanced CD73 activity, which in turn results from transcriptional regulation of the CD73 gene by a hypoxia-inducible factor released during preconditioning ([8]). This factor binds to the CD73 gene promoter. In the nervous system, CD73 serves in the release of neurotransmitter in cholinergic synapses. After injury, it is up-regulated in microglial cells, Schwann cells, and so forth. The extracellular hydrolysis of nucleotides is of functional importance during synaptic transmission, but also in the survival and differentiation of neural cells *in vitro* and probably during neuronal development.
- *Cytosolic 5'-NT*. There are three cytosolic 5'-NT (c5'-NT), cN-I, cN-II, and dNT-1, and one mitochondrial dNT-2. cNI is not detected in peripheral blood leukocytes, but aberrant expression in malignant cells is associated with a nucleoside analog resistance in chemotherapy ([9]). cN-I is responsible for most of the adenosine production in hypoxic and ischemic heart disease. CN-II hydrolyses guanine- and hypoxanthine-containing nucleotides.

CD74 (INVARIANT CHAIN, IC)

Structure: CD74 type II integral membrane protein (i.e., *N*-terminal intracellularly). There are four distinct forms of CD74 as a result of alternative initiation of translation (p35) or alternative splicing (p41). A sequence in CD74 is homologous to the repetitive sequences of thyroglobulin. Alternative initiation of translation from this form generates another variant (p43) ([1]).

In the extracellular region, the membrane-proximal sequence has the class II–binding site (amino acids 81 to 109) and the *C*-terminal is a largely a-helical sequence and contributes to the formation of trimers (residues 163 to 183), whereas the transmembrane sequence contributes to the stability of the trimers and its trimerization ([2]).

The transmembrane region exists as a left-handed a-helical coiled coil, and Gln47 forms strong interhelical contacts within the trimers; it is also implicated in lysosomal targeting after internalization from the plasma membrane, in addition to dileucine signals from the cytoplasmic tail.

From the cytoplasmic region (residues 1 to 30), the EQLP sequence is essential for targeting the invariant (Ii) chain to the endosomal compartment, and in its absence, the Ii is directed to the membrane ([3]). The cytoplasmic region contains two dileucine-like signals required for trans-Golgi network sorting and endosomal targeting.

A single peptide (residues 81 to 104) of the p33 form binds to class II molecules and has been called CLIP (class II–associated invariant chain peptide). The CLIP peptides bind to the peptide-binding groove of the class II molecule ([4]). Synthetic CLIP inhibits peptide loading to the human class II *in vitro*.

Deletion or truncation of the region of Ii containing CLIP results in failure of association of the Ii and the MHC class II molecule. Expression of Ii has been detected on the cell membrane independent of concomitant expression at class II antigens.

Gene locus: 5q32.

Molecular mass (kd): 33, 33, 41, 43.

Distribution: CD74 is expressed intracellularly in MHC class II–expressing cells, moderately in B cells, and weakly on monocytes, some activated T cells, and epithelial cells.

Function: Ii transports class II molecules to the endosomal compartments for loading with antigenic peptides. In this function, it acts as a chaperon, that is, facilitates the assembly of class II dimer by binding and stabilizing partially folded subunits, preventing their misfolding during the assembly process. Chaperon duties of Ii for MHC II are discharged by CLIP, which binds to the groove of MHC II. In the absence of Ii, the class II polypeptide chains remain permanently aggregated in the ER. The transporting function of CD74 is regulated by the 16-residue *N*-terminal sequence of the cytoplasmic tail, which contains the ER retention signal. After leaving the ER, the Ii/class II complex traverses the Golgi, where sialic acid is added to the N-linked glycans on all three chains.

The next destination of the complex is the endocytic compartment and, specifically, vesicles, selectively enriched in class II molecules, which serve as intermediates in the transport of newly synthesized class II molecules to the cell surface. Those are distinct from conventionally defined endosomes and lysosomes. They have been called *class II–enriched vesicles* (CIIV) or MHC II vesicles (MIIC). MIIC appear more lysosomelike than CIIV. Release of CLIP from MHC II for peptide loading is mediated by HLA-DM.

Unlike classical HLA molecules, the HLA-DM, which are structurally related to MHC class II, reside in the MIIC vesicles but not on the cell surface. They catalyze the dissociation of CLIP by binding to class II molecules transiently in the acidic environment ([5]). DM exerts an editing effect on peptides loaded to class II.

Once dislodged from MHC class II, Ii is degraded by a cysteine protease, cathepsin S. Cathepsin S activity is tightly linked to Ii degradation and the trafficking of the Ii/class II complexes ([6]).

The invariant chain coprecipitates with a fraction of CD1d molecules when both are expressed in the same cell ([7]). It directs CD1d to an intracellular compartment that overlaps with Lamp-1 $^{+}$ late endosomes/lysosomes. In knock-out Ii $^{-/-}$ mice, CD1d does not associate with the Ii chain, which it normally does in the ER, and is unable to present to Va14 $^{+}$ NKT cells “self” lipids, structurally homologous to a-galactosyl ceramide. This translates into a defect of CD1d function with failure to select, activate, and expand the population of CD1d-dependent NKT cells, which regulate responses of adaptive immunity against mycobacterial infections ([8]).

A secreted form of the invariant chain, which lacks the sequences for targeting to the endosomal compartment but contains the CLIP sequence, inhibits T-cell activation in an *in vitro* system. This form acts directly on APCs and inhibits antigen presentation to T cells ([9]).

A 65–amino acid fragment of the p41 splice variant binds to the active site of cathepsin L and facilitates the maintenance of a pool of the mature enzyme in the endosomal compartment of macrophages and DCs. A complex of this fragment with cathepsin L is detected in cultured supernates of APCs, and the complex is up-regulated by inflammatory stimuli (IFN-?, LPS). This complex may have an important role in elastin degradation during inflammation.

CD79A [MB1, IMMUNOGLOBULIN (Ig)a] AND CD79b (B29, Igß)

Structure: CD79a and CD79b form a disulfide-linked heterodimer, which is noncovalently associated with the membrane Ig (mIg) on B cells. Recent evidence indicates that there is only one heterodimer per BCR ([1]).

Both CD79a and CD79b have one Ig-like domain in the extracellular region, type C2 for CD79a and type V for 79b.

A point mutation (pro to leu) in the extracellular region of the Iga impairs the ability of the Iga/ß heterodimer to bind to mIgM.

The transmembrane regions of Iga and Igß have Glu and Gln residues, respectively, opposing the polar retention sequence TTAST of the transmembrane region of the µ-chain, forming contact points. The same transmembrane regions of Iga and Igß associate with other Ig isotypes.

The cytoplasmic regions of each molecule have an ITAM, which links them to signaling molecules.

Gene locus: 79a, 19q13.2; 79B, 17q23.

Molecular mass (kd): 79a, 33; 79b, 38.

Distribution: Both are restricted to B lymphocytes, first appearing on the surface of pro–B cells and remaining throughout the stages of B-cell differentiation, except in plasma cells. This may be the reason that normal plasma cells and some myeloma cell lines lack expression of surface Ig ([2], [3]).

Function: The Iga- and Igß-chains are important during B-cell development and B-cell function.

- *B-cell development*. In Igß $^{-/-}$ transgenic mice, B-cell development is blocked at the pro–B cell stage. The expression of Iga/Igß during B-cell development is distinct from Ig expression and occurs before Ig gene rearrangements. Iga/Igß expression precedes the completion of Ig gene rearrangements, and pro–B cells express both Iga- and Igß-chains, whereas the µ-chain is first detected at the pre–B cell stage. In the absence of either molecule, B-cell development is arrested ([4]). Mutations of the Iga-chain result in complete arrest of B-cell development ([5]). The Iga/Igß complex associates with the pro-BCR and, later, pre-BCR complexes before the light chain genes start to rearrange. Several functions of the pro–B cell stage (i.e., expression of the early B-cell marker CD19, interactions with bone marrow stromal cells, and early stages of $V_H DJ_H$ gene rearrangements) are independent of Iga/Igß.
- *Expression of BCR*. Display of the BCR on the cell membrane requires an intact Iga/Igß heterodimer, because mIgM cannot travel to the cell membrane without the association in the ER with Iga/Igß. Mutation in the extracellular region of Iga abolishes the association of Iga with IgM and its ability to be recognized by the ER quality control system for export, through the secretory pathway, to the membrane.
- *Antigen internalization*. mIg binds antigen and triggers the internalization of the mIg–antigen complex. The efficacy of this function is ascribed to the Iga/Igß heterodimer ([6]). Antigen presentation is not effective in the absence of Iga/Igß, and the cytoplasmic region of the Igß-chain can restore this function of mIg ([7]).
- *Signaling*. BCR consists of the mIg, which constitutes the antigen-specific module, and the Iga/Igß heterodimer, which is the signal transduction module ([8]). The cytoplasmic region of mIgM is only three amino acids long and is therefore unable to link to intracellular signaling molecules. Cross-linking of IgM stimulates phosphorylation of the ITAMs in the Iga/Igß-chains. The Src PTKs, Lyn, and Fyn phosphorylate these ITAMs with initial preference for the *N*-terminal ITAM tyrosines of Iga and Igß, followed by the *C*-terminal tyrosines. Coupling of Syk to distal signaling molecules requires the linker protein BLNK ([9]).
- *CD79 as a marker for B-lymphocytic malignancies*. Because CD79 is restricted to B lineage, its detection has been suggested for identification of B-cell malignancies by flow cytometry or histochemistry ([10]). Although results originally were encouraging, with wider use of the technique, it was found that CD79 is weakly expressed in precursor T-cell lymphoblastic lymphomas ([11]), T-ALL ([12]), and precursor T-cell lymphoma as well ([13]) (see more details in Chapter 16).

CD80 (B7-1)

Structure: CD80 belongs to a family of co-stimulatory molecules critical in T-cell activation and immune regulation. T-cell activation and immunity require the delivery of two signals: one antigen-specific (signal 1) and a second co-stimulatory or antigen-nonspecific (signal 2) ([1], [2]).

The extracellular region of CD80 contains two Ig-like domains, *N*-terminal V-type and a membrane-proximal C1 type. The ß strands of V domain form two ß sheets with three and six strands. Overall, this domain is structurally similar to the CD2 *N*-terminal domain.

A conserved hydrophobic sequence of CTLA-4 and CD28 [99] provides a large surface in the interaction with a high degree of complementarity. Neighboring CD80 molecules form homodimers by side-to-side contacts ([3]) or possibly larger multimers bridging neighboring homodimers. A strong contact area between the T cell and the APC increases the avidity of interaction as a result of oligomerization.

Despite structural similarities between the V domain of CD80 and the first domain of CD2, CD80 interacts with CTLA-4 at right angles, which provides strong adhesion in contrast to CD2.

The C domain is linked to the membrane by eight hydrophilic residues, forming the stalk.

The transmembrane region has three cysteines, which may be involved in covalent interactions with other membrane proteins.

Gene locus: 3q13.3-q21.

Molecular mass (kd): 60.

Distribution: CD80 is detected on various cells with APC function (i.e., macrophages, DCs, B cells, Langerhans cells) after CD40/CD40L interaction. Adjuvants strongly up-regulate CD80 expression, which may form the basis of their potentiation of the immune response. CD80 is down-regulated by IL-10, TGF-ß, and cross-linking of CD32 (FcR?-II).

Function: CD80 binds with low affinity to CD28 and high affinity to CTLA-4 (CD152) ([4]). Through CD28, it delivers a co-stimulatory signal and, through CD152, an inhibitory signal. The co-stimulatory signal or signal 2 is not antigen specific or MHC restricted but is essential in triggering T-cell activation. In the absence of signal 2, T cells become anergic or unresponsive. CD80/CD28 co-stimulation results in T-cell proliferation (clonal expansion), secretion of cytokines, and promotion of cell survival (increase of expression of antiapoptotic protein Bcl-X $_L$) ([5]).

Co-stimulation is not required under strong and sustained antigenic stimulation, whereas it is essential for low levels of antigen because it decreases the threshold of T-cell activation. It is important for naïve, but not for primed, T cells, especially after prolonged, frequent, and intense exposures to antigen.

CD80/CD28 interaction regulates Th1/Th2 balance, is essential for Ig class switching and germinal center formation, and has an interdependent relationship with the CD40/CD40L pathway ([6]). CD80/CD28 and CD40/CD40L interactions are synergistic; the former up-regulates CD40L, and, in turn, the latter up-regulates CD80, thus strongly amplifying co-stimulatory functions. CD80/CD28 co-stimulation directly augments CD8 $^+$ CTL responses in the absence of CD4 $^+$ T-cell–derived cytokines ([7]).

In the thymus, CD80 may block negative selection and allow development of autoreactive cells. Perinatal blockade of CD80 also inhibits clonal deletion of lethal autoreactive T cells in mice ([8]).

CD80/CD28 co-stimulation is essential in the control of the development of spontaneous autoimmune diabetes in nonobese diabetic mice by immunoregulatory T cells ([9]). CD80-mediated co-stimulation has been studied extensively in transplantation and tumor immunity ([10]). Blockade of the CD80/CD28 pathway by CTLA-4 Ig, a high-affinity inhibitor of CD80-mediated co-stimulation, induces long-term tolerance in some models.

CD80 expression was detected on T cells from skin lesions of patients with psoriasis and mycosis fungoides ([11]).

CD81 (TAPA-1: TARGET FOR ANTIPROLIFERATIVE ANTIBODY-1)

Structure: CD81 is a member of the tetraspanin family, which spans the cell membrane four times. The extracellular region consists of two loops, a small (SEL or EC1) between transmembrane (TM) regions TM1 and TM2 and a large (LEL or EC2) between TM3 and TM4. LEL domain contains four invariant cysteines, two of which define the conserved sequence Cys-Cys-Gly. Each LEL is composed of five a-helices (A through E). The first and last form a stalk supporting a mushroom-shaped head domain. The head is stabilized by two disulfide bridges. Two hydrophobic patches in the head are indicative of a design for the purpose of protein–protein interactions in keeping with the propensity of CD81 to form multimolecular complexes with other tetraspanins and integrins. The sequence between TM2 and TM3 is the most conserved region in all tetraspanins, whereas LEL is the most variable. It is encoded by exon 6, containing within it the CCG sequence detected in all tetraspanins.

Gene locus: 11p15.5.

Molecular mass (kd): 26.

Distribution: It is detected on most human tissues, except RBCs and platelets.

Function: CD81 is associated in a multimolecular complex within the CD19, CD21 co-receptor, which reduces the number of BCRs necessary to trigger B-cell activation ([1] , [2]). It delivers a co-stimulatory signal for thymocyte proliferation through IL-2 induction and, in peripheral T cells, stimulates preferentially a Th2 cytokine response ([3]).

An important property of CD81, and of all tetraspanins, is the formation of multimolecular complexes with other tetraspanins, as well as with integrins forming the “tetraspan web,” a kind of molecular “organizer” ([4]). These tetraspanin complexes are facilitators of several functions related to cell adhesion and migration ([5] , [6]). Some associations of tetraspanins with integrins are selective (i.e., CD81/a $_4$ß $_1$, CD51/a $_5$ß $_1$, and CD151/a $_6$ß $_1$) ([7]). CD81 and CD151 are responsible for associating these integrins to other tetraspanins, probably through interactions with other tetraspanins.

All tetraspanins tested have palmitate attached on cysteines, and palmitoylation sites are conserved among members of the family. Palmitoylation is critical for formation of the “tetraspan web,” as well as for targeting to subcellular compartments and the maintenance of cell morphology.

The tetraspanin prototype complexes (i.e., CD81/a $_3$ß $_1$) form discrete units independent of lipid microdomains, although they may also associate with microdomains resembling lipid rafts ([8]).

The complexes with integrins are concentrated on punctate adhesion structures, which resemble the Rac-dependent, peripheral focal complexes and point contacts, related to cell migration. The CD81 and a $_3$ß $_1$ integrin clusters associate with talin and MARCKS and enhance tyrosine phosphorylation of the FAK or PI4K, forming complexes at the cell periphery. This signaling pathway plays a key role for cell motility and is distinct from the more conventional integrin signaling through FAK.

Tetraspanins link integrins to PKC with the extracellular large loop associating with the integrins, and the first two transmembrane regions and cytoplasmic tails connecting with PKC, which is activated and phosphorylates the a $_3$ integrin cytoplasmic tail ([9]).

CD81 forms important adhesion complexes with the tetraspanins CD9 and CD151 ([10] , [11]) and regulates integrin activation and adhesiveness, which control cell motility into matrix. Migration is accompanied by remodeling of the extracellular matrix (i.e., degradation of the preexisting and deposition of new components) and formation of capillary-like cords by migrating endothelial cells. The complexes are detected in the endothelial lateral junctions, a location important for the functions they regulate.

Polarized epithelial cells form strong intercellular adhesion, such as desmosomes and tight junctions, which are cadherin dependent. Tetraspanin–integrin complexes

support the cadherin-independent step of intercellular adhesions involving clustering of the appropriate receptors to bring about cell–cell and cell–matrix interactions ([12]). Both are strongly expressed in human keratinocytes along the filopodia and the lateral and apical surfaces and inhibit keratinocyte migration ([13]).

In nervous tissue, tetraspanin–integrin complexes contribute differentiation of immature neurons to assume polarized morphology, with extensions of distinct mature neurons and dendrites.

The functionally relevant complexes in this system are between the tetraspanins CD81, CD151, and the a $_3$ß $_1$ integrin. The neurite outgrowth depends on engagement of a $_3$ß $_1$ because it takes place only on laminin-5 substrate, the a $_3$ß $_1$ ligand, but not on laminin-1 ([14]).

CD81 in complex with CD9 promotes myogenesis; it stimulates myoblast differentiation, fusion, and myotube formation and maintenance ([15]).

CD81 participates in an intercellular trafficking communication system mediated by exosomes, which are small membrane vesicles (50 to 90 nm) ([16]). They were originally detected in association with terminally differentiating reticulocytes containing CD71. Subsequently, they have been identified in platelets, DCs, cytotoxic and activated T cells, and so forth. B cell–derived exosomes carrying MHC class II molecules have been identified on the surface of DCs. CD81-containing exosomes released from activated T cells were taken up by CD81 $^-$ cells co-cultured with T cells. The functional importance of intercellular CD81 transfer by exosomes remains to be seen, but existing data suggest that exosomes play an immunoregulatory role in the immune system.

Members of a small new family of proteins are the latest group of proteins, which are major partners of CD81 and CD9, and form highly specific stoichiometric complexes. These proteins belong to the IgSF and contain the Glu-Try-Ile motif (EWI with the amino acid letter code), which is not present in the usual IgSF members. They are EWI-2, EWI-3 (or PGRL for prostaglandin regulatory-like protein or IgSF-3) ([17] , [18]), EWI-F (or FPRP for prostaglandin Fa $_2$ receptor regulatory protein or CD9P-1) ([19]), and EWI-101 (or CD101).

EWI-2 is detected in every tissue tested so far. EWI-2 has an especially strong association with CD81 and CD9 and is a candidate for involvement in diverse functions ascribed to CD81 and CD9, such as tumor cell metastasis, nervous system development, cell proliferation, myogenesis, oocyte fertilization (CD9), and hepatitis C pathogenesis (see below). PGRL and FPRP have similar sequences and are negative regulators of PG and PGF $_{2a}$ receptors. PGs are inflammatory mediators produced from arachidonic acid by the action of cyclooxygenases (COX-1 and COX-2). PGE $_2$ is abundant in the thymus, its production being regulated by cortical and medullary epithelial cells, and facilitates differentiation of T cells from double-negative thymocytes. Inhibition of PGE $_2$ synthesis impairs adhesion of CD4 $^+$8 $^+$ thymocytes to stroma. PGE $_2$ from macrophages suppresses Th1 responses and augments Th2 responses. The role of PGRL and FRL on regulation of prostaglandin receptors through CD81/CD9 remains to be determined.

The chronic hepatitis C virus binds through its E2 envelope protein to the major ECL of human C81 ([20]).

Cross-linking of CD81 on NK cells by E2 inhibits cytokine and IFN-? production and NK cell cytotoxicity (granule release) ([21]). Insufficient production of IFN-? by NK cells in response to IL-12 and IL-15 could alter development of Th1 responses. A Th1 versus Th2 imbalance has been recently described in hepatitis C virus–infected individuals.

CD85: CD85a TO CD85m

Nomenclature

Under the cluster designation CD85 are 13 members, which act as receptors for MHC; they belong to the IgSF and are known by two additional terminologies: (a) Ig-like transcripts (ILTs) and (b) leukocyte Ig-like receptors (LIRs). They also are termed *monocyte/macrophage inhibitory receptors* (MIRs). They are encoded by genes forming a cluster in human chromosome 19q13.4, the leukocyte receptor complex (some disagree that the group of these genes is, genetically speaking, a “complex”). The leukocyte receptor complex contains two ILT gene clusters (separated by a group of genes with unknown function), and further telomeric to the second cluster is the KIR cluster. The gene for the Fc receptor for IgA (CD89) is on the telomeric side of the KIR cluster.

Between the two ILT clusters are the genes for two other receptors, LAIR1 and LAIR2 (leukocyte-associated Ig-like receptor). The ILTs/LIRs are detected on B cells, monocytes, macrophages, DCs, and so forth, whereas the KIRs are expressed on NK and T cells.

In the ILT/LIR/MIR system, some proteins have two (or even three) designations (i.e., ILT1/LIR-7, ILT2/LIR-1), whereas others have only one (i.e., ILT7, LIR-8, and so forth) ([1] , [2] , [3] and [4]).

The MHC receptors in general can be separated functionally into two categories: *inhibitory* or *activating*. The former have a long cytoplasmic tail with one or more ITIM motifs, which attract protein tyrosine phosphatases. The latter have a short cytoplasmic tail, lack ITIMs, and have a positively charged amino acid within their transmembrane region, and for signaling, they associate with ITAM-containing adaptor proteins like DAP12 or FcR?-chain (for ILTs). All these molecules show 63 to 84% identity with the prototypic LIR-1 sequence. The ILTs/LIRs are structurally related to human FcaR (CD89). (See table in CD39 for classification proposed during the seventh HLDA workshop, Harrogate UK, June 2000. See also http://www.gene.ucl.ac.uk/nomenclature/genefamily/lilr.html; http://www.ncbi.nlm.nih.gov/prow/; and Andre P, Biassoni R, Colonna M, et al. New nomenclature for MHC receptors. Nat Immunol 2001;2:661.)

ILT: Immunoglobulin-Like Transcript-1

ILT1 (LIR-7) has a short cytoplasmic tail and is selectively expressed on myeloid cells. It is associated with FceRI? rather than DAP12 and delivers an activating signal with Ca $^{2+}$ mobilization and release of serotonin.

It has been detected on macrophages and the synovium of patients with rheumatoid arthritis. In the same patients, however, ILT4, an inhibitory receptor, is also detected. It is likely that activating and inhibitory receptors regulate the activation of infiltrating leukocytes.

ILT-2

ILT2 (LIR1, CD85d) is the prototype of this group and contains four extracellular Ig domains and a cytoplasmic tail with four ITIM motifs. Two alternatively spliced forms exist, one lacking ITIMs. The cytoplasmic region is fully hydrophobic. ILT2 recognizes a broad range of class I molecules as compared to KIRs because it binds to many alleles of the HLA-A and -B and is not limited to one allele in each locus. It recognizes HLA-G1 and HLA-E, the nonclassical HLA molecules.

Through its *N*-terminal Ig domain, it interacts with the nonpolymorphic a3 domain of class I MHC. On engagement with its ligand, ILT2 associates with SHP-1 phosphatase, delivering an inhibitory signal.

The cytoplasmic region of ILT2 has four tyrosines, but only two are within ITIM consensus sequences. The docking sites for SHP-1 are tyrosine 644 (SIYATL) and tyrosine 614 (VTYAQL), whereas tyrosine 533 plays a pivotal role in promoting phosphorylation of the SHP-1 docking sites.

Recruitment of SHP-1 phosphatase reduces phosphorylation of TCR?-chain and LAT (see Chapter 17). As a result, ILT2 inhibits rearrangements of actin cytoskeleton. The inhibitory effect is concentrated at the APC–T cell interface because the TCR and ILT2 are polarized at the immunologic synapse. Cross-linking of ILT2 inhibits antigen-specific T-cell proliferation and increase of secretion of IL-10 and TGF-ß cytokines, which down-regulate immune responses. When ILT2 is not engaged, antigen-specific CD4 $^+$ T-cell activation leads to IL-2, IFN-?, IL-13 production, and T-cell proliferation.

ILT2 is detected on the surface of only a small number of CD3 $^+$ T cells, but it is present in the cytoplasm of all T cells. It inhibits CD3/TCR-mediated activation of both CD4 $^+$ and CD8 $^+$ T-cell clones and down-regulates antigen recognition by CD8 $^+$ T cells. ILT2 is detected not only on NK and T cells but also on myeloid and naïve B

cells. It inhibits Ca $^{2+}$ mobilization, triggered by BCR on B cells and on monocytic cells by surface-expressed HLA class II molecules. It is likely that ILT2 regulates the B-cell triggering threshold and inhibits killing by NK and T cells.

Human CMV infects 70 to 90% of adults. It occurs early in life and lasts as a latent infection for a lifetime. CMV triggers the synthesis of a protein, UL18, which is homologous to class I MHC; it is associated with ß $_2$M, and binds endogenous peptides on its peptide groove ([5]). It is displayed as class I decoy molecule on the surface of CMV-infected cells, which may have become targets for KIRs because of down-regulation of their MHC as a result of the infection. ILT2 inhibitory receptor binds to UM18 with greater than 1000-fold higher affinity than normal MHC, thus compensating for the very low levels of UM18 expression. Interaction of ILT2 with class I MHC at the molecular level resembles the interaction of CD4 with MHC class II, rather than KIR with class I MHC. ILT2 and CD4 interact with the nonpolymorphic domains of MHC, whereas KIR interacts with the polymorphic groove area. CMV infects monocytes, which are strongly ILT2 $^{+}$, and UL18 expression may limit antiviral monocytic functions as a result of the strong inhibitory signals from ILT2/UL18 interactions. A subpopulation of these monocytes is a major source of IFN-a, which is necessary for CMV-induced NK-cell cytotoxicity.

ILT2 was also detected in some cutaneous lymphoma cell lines and circulating malignant CD4 $^{+}$ T cells, which usually express KIR (CD158k) receptors. The ILT2 $^{+}$ CD4 $^{+}$ Sézary cells were less susceptible to anti-CD3 induced cell death.

ILT-3

ILT3 (LIR5) is closely related to FcaR and is expressed on B cells and DCs. It is inhibitory to APC function, is involved in antigen uptake, and targets ligands into processing and peptide-loading compartments.

ILT-4

ILT4 (LIR2) exists as six alternatively spliced variants, some with short cytoplasmic tails, which lack ITIMs. It binds tyrosine phosphatase SHP-1. Co-ligation with FcR?I (CD64) inhibits Ca $^{2+}$ mobilization and tyrosine phosphorylation of the associated ?-chain and Syk kinase.

It inhibits monocyte activation signals and regulates cytolytic and inflammatory responses that might be triggered against self-antigens by monocytes ([6]). It binds to HLA-G, a nonclassical class I antigen expressed by human trophoblasts of the placenta, protecting the developing embryo.

ILT-5

ILT5 (LIR3) shows striking diversity, with amino acid variants clustered in several distinct sequences of the extracellular region. Alternatively spliced forms exist, which lack ITIMs.

CD86 (B7-2, B70)

Structure: CD86 is a member of the IgSF, related structurally and functionally to CD80. It consists of two Ig-like domains, an *N*-terminal V-type and a membrane-proximal C2 type. As with CD80, certain amino acids in the ß strand G in the IgV domain and in the ß strand A of the IgC domain are critical for binding to CD28 and CTLA-4. However, the whole GFC'C? face of the IgV and ABED sheet of the IgC provides the complete requirements for binding.

The cross-linked IgV domain of CD86 has the most potent co-stimulatory activity at concentrations approximately 100-fold lower than cross-linked whole CD86 for proliferative activity and cytokine secretion. This indicates that variants or even truncated forms may regulate co-stimulation.

The crystal structure of a CD86/CTLA-4 complex has been solved at a 3.2-Å resolution. Direct observation of the complex shows that each molecule binds by its front sheet. The CD86 strands G, F, C, C', and C? form a shallow concave surface, and the FG loop of CTLA-4, which corresponds to the complementarity-determining region, CDR3-like segment, packs against it ([1]). CD86 interacts with dimers of CTLA-4 or CD28. CTL-4 and CD28 are homodimers, and the residues contributing to homodimer formation of CTLA-4 are distally located from those contributing to the CD86/CTLA-4 interface. More significantly, they are conserved, indicating that homodimerization has an important biologic function. CD86 interacts with other homodimers, thus forming an alternating periodic structure within the immunologic synapse that is able to provide distinct signaling mechanisms. Oligomerization of CD86 increases high affinity for binding the counter-receptors ([1]).

Gene locus: 3q21.

Molecular mass (kd): 80.

Distribution: CD86 is strongly expressed on resting monocytes and DCs and is weakly expressed on B and T cells and on eosinophils, which after activation by IL-3 are B7 $^{+}$. In other tissues, CD86 is expressed in salivary gland epithelia of patients with Sjögren syndrome ([2]), in bronchial epithelial cells after lung transplantation, and in glomerular endothelium from cats submitted to renal ischemia. Kidney biopsies from patients with interstitial nephritis showed expression of CD86 (and CD80) by the renal epithelial cells ([3]). CD86 expression is up-regulated in B cells by IL-4 and in monocytes by IFN-? and is down-regulated by IL-10. Soluble CD86 has been detected in blood from certain cases of AML or B-CLL.

Function: In general, CD86 (as well as CD80) provides the second signal for T-cell activation and has overlapping roles with CD80 in co-stimulation ([4]). B7 co-stimulation is critical for CD4 $^{+}$ and CD8 $^{+}$ cell activation and differentiation. Naïve, but not activated, T cells are highly dependent on Th2, but not Th1, cytokine production.

However, the strength and duration of CD28 engagement and cross-linking determine the differential effects of co-stimulation on the cytokine profile (strength of signal hypothesis).

Naïve T cells exposed *in vitro* to DCs in the absence of antigenic stimulation become CD86 $^{+}$. Similarly, T cells from peripheral blood of patients with thyroiditis or neoplastic ascites are also CD86 $^{+}$. CD86 $^{+}$ T cells reside in T-cell areas of lymph nodes or migrate to areas of inflammation in the periphery, where they may be able to provide co-stimulation to naïve T cells.

CD86 and CD80 play a critical role in cross-priming of CD8 $^{+}$ T cells. Cross-priming implies the sensitization to an exogenous antigen of CD8 $^{+}$ T cells by APCs (DCs) that have endocytosed the antigen. The initial step in cross-priming is the activation of APCs by CD4 $^{+}$ T cells through a CD40L/CD40 interaction, which in turn

up-regulates co-stimulatory molecules CD86 or CD80. In the second step, the APCs directly prime $CD8^+$ T cells for CTL function ([5]).

For humoral immunity, CD86 is important for initiating antibody response, even in the absence of the action of adjuvants, which enhance antibody responses by up-regulating expression of CD80. Class-switch and germinal center formation depend on CD86 expression.

Salivary gland epithelial cells from patients with Sjögren syndrome (autoimmune epithelitis) constitutively express CD86 (and CD80), which can stimulate T-cell proliferation and IL-2 production, and release soluble forms of CD86 ([2]). The findings suggest that epithelial cells potentially have a role in antigen presentation and thus regulate immune responses locally.

Results from mice deficient in CD86 have shown that co-stimulation is critical for the induction, as well as the effector phases, of experimental allergic encephalomyelitis.

The roles of the two co-stimulatory molecules differ. Anti-CD80 antibody reduces the incidence of the disease, whereas the anti-CD86 antibody increases disease severity. The anti-CD80 allowed the generation of Th2 clones, which, on transfer to other animals, prevented induction of the disease and abrogated established disease. The effect of these clones was, at least partially, due to IL-4 secretion ([6]).

Activated (but not resting) eosinophils express HLA-DR antigens and CD86 (but not CD80). They are capable of stimulating proliferation of T cells in response to superantigen toxic shock syndrome toxin 1 ([7]). T-cell clones to tetanus toxoid or influenza hemagglutinin also proliferate in response to antigenic peptides presented by activated eosinophils but not in response to naïve antigens. Activated eosinophils apparently have antigen-presenting but not antigen-processing capacity.

The heat labile enterotoxin from *E. coli* and the closely related cholera toxin have adjuvant activity for both systemic and mucosal immunity. These properties are due to the up-regulation of B7 molecules ([8]).

CD87 (uPAR: UROKINASE PLASMINOGEN ACTIVATOR RECEPTOR)

Structure: Plasminogen is activated to plasmin by three systems, one of which is called the *extrinsic*, and involves two activators: the tissue type (tPA) and the urokinase type (uPA). uPA is a disulfide-linked two-chain (A and B) protein with serine proteinase activity. CD87 is the receptor for this enzyme and binds to its chain.

Urokinase plasminogen activator receptor (uPAR) is a GPI-anchored protein, which consists of three cysteine-rich domains, D_1, D_2, and D_3.

In addition to uPA, CD87 is a receptor for several other proteins, that is, vitronectin, kininogen, gp130, and integrins. uPA cleaves plasminogen at the Arg^{560}-Val^{561} bond, and cleavage of uPAR occurs at a similar bond, Arg^{83}-Val^{84}, of the linker sequence between D_1 and D_2, with D_1 containing the uPA-binding site.

Gene locus: 19q13.

Molecular mass (kd): 35 to 59 (unreduced).

Distribution: CD87 is expressed on monocytes, granulocytes, activated T cells, and a subset of activated NK cells, and widely on nonhematopoietic tissues.

Function: uPAR is a pleiotropic molecule involved in multiple basic process, that is, adhesion, chemotaxis, and cell migration, which make uPAR an important player in inflammation, metastasis, and tissue repair ([1]).

- *uPA–uPAR interaction*. Proteolytically active uPA is generated by "reciprocal zymogen activation," that is, uPA binds to uPAR and activates cell-bound plasminogen for generation of plasmin. Through a positive feedback mechanism, plasmin converts uPA to a two-chain active enzyme that is susceptible to inhibition by the plasminogen activator inhibitor (PAI), which binds to the uPAR/uPA complex. The entire trimolecular complex is internalized by the low-density lipoprotein receptor–related protein (LRP) (see CD91); the uPA–PAI-1 is destroyed in the lysosomes, whereas uPAR recycles back to the cell surface ([2]). uPA binds to uPAR by its aminoterminal region of the A chain, whereas the catalytic domain is located in the B chain, cleaves the receptor, and releases the ligand-binding D_1 domain. uPA bound to uPAR activates plasminogen, and it forms plasmin at pericellular locations, at focal contact sites with extracellular matrix proteins, and at the leading edge of migrating monocytes. This is a fundamental mechanism, which underlies several types of cell migration.
- *Chemotaxis*. uPA cleaves uPAR at two sites in the D_1-D_2 linker sequence ([3]). Cleavage at the first site exposes residues 88 to 92 (SRSRY), which require a transmembrane adaptor to stimulate chemotaxis. The second site is at position 89/90 (i.e., within the chemotactic epitope) and destroys its chemotactic activity. The fact that intact GPI-linked uPAR, as well as the soluble uPAR, possesses chemotactic activity suggests that this activity depends on an adaptor molecule, which connects them to intracellular signaling pathways. The matrix MMP-12 cleaves uPAR, releases D_1 from D_2/D_3, and exposes the chemotactic epitope, which is down-regulated by the PAI-1 ([4]).
- *uPAR–integrin associations* ([5], [6] and [7]). The $ß_2$ integrins are transmembrane uPAR partners; uPAR binds to a site of the a-chain of Mac-1 (CD11b), close to the fibrinogen-binding site, and inhibits the fibrinogen binding. uPAR and Mac-1 are located in proximity on human monocytes and form functional complexes ([8]). MAC/uPAR association regulates the procoagulant and fibrinolytic functions of monocytes. Binding of uPAR to MAC-1 is mediated by non–I domain sites (atypical ligand), and the same interaction occurs with procoagulant factor X. Saturation of uPAR with uPA blocks factor X binding. Interaction of uPAR with MAC-1 is mediated by a site close to fibrinogen binding, which is degraded by the complex. uPAR/MAC-1 interactions are also important for the healing process in sites of inflammation, which facilitates leukocyte migration. uPAR is associated with other integrins (i.e., $a_3ß_1$, $a_Vß_3$, $a_4ß_1$, and so forth) ([9]). uPAR/$a_3ß_1$ integrin complexes stimulate uPA expression and enhance plasminogen activation. In turn, uPA proteolytically processes laminin-5, a major matrix protein, and reduces cell motility.
- *uPAR and adhesion*. Cell adhesion to extracellular matrix by uPAR is regulated by uPA-induced oligomerization and the increase of its affinity, as well as exposure of novel binding sites for vitronectin.
- *uPAR in cancer and human disease*. The enzyme seprase (gelatinolytic protease) and the uPA-uPAR system form complexes on the leading invasive edge of the tumor cells and degrade the extracellular matrix, promoting the metastatic ability of malignant cells ([10], [11]). Expression of uPAR is positively correlated with the rate of recurrence and mortality in patients, with adenocarcinomas of the endometrium constituting a useful prognostic marker ([12]). In leukemias, uPAR is fragmented on leukemic cells, and the soluble uPAR level correlates with the number of AML cells and with poor response to chemotherapy ([13]). uPAR is up-regulated in leukocytes of patients with HIV infection, and a high level of soluble uPAR in the serum is a major negative prognostic factor in HIV infection, independently of clinical status, viremia levels, and $CD4^+$ T-cell counts ([14]).

CD91 [a-MACROGLOBULIN RECEPTOR; LOW-DENSITY LIPOPROTEIN (LDL) RECEPTOR–RELATED PROTEIN: LRP]

The low-density lipoprotein receptor family consists of several members, and one of them is LRP1 or CD91. LRP1 is the receptor for native a_2-macroglobulin (a_2M). Activated or structurally modified a_2M binds to the a_2*M receptor or a a_2M signaling receptor (a_2MSR).

Structure: The mature LRP is a heterodimer consisting of an extracellular 515-kd chain (a-chain) and an 85-kd transmembrane ß-chain.

It consists of 31 complement type repeats arranged in four groups known as the *ligand-binding domain* (LBD). Each LBD is followed by an EGF-precursor homologous domain (EGF-phd), which consists of two EGF-like repeats separated from a third by a spacer region, which contains the YWTD motif.

Receptors that undergo endocytosis use any of four potential endocytosis signals that target surface proteins to clathrin-coated pits: (a) tyrosine-based motifs, (b) NPXY, (c) dileucine motifs, (d) serine phosphorylation, and (e) attachment of ubiquitin moieties.

The tail of LRP (of 100 amino acids) contains two NPXY motifs, one YXXF (F is any hydrophobic amino acid) and two dileucine motifs.

LRP does not conform to the “one receptor, one ligand” dictum, like the low-density lipoprotein receptor, but to “ *one receptor, multiple ligands*” ([1]). As a multiligand receptor, LRP binds to “remnant” lipoproteins, that is, lipoproteins modified by hydrolases and by association and dissociation of proteins (apolipoproteins) (i.e., apoE, a $_2$-macroglobulin/protease complexes, plasminogen activator/inhibitor complexes, toxins, clotting factors, lipases, lactoferrin, the amyloid precursor protein, and so forth).

Binding of one ligand does not inhibit binding of another, and ligands cross-compete for the same site.

A receptor-associated protein, a protein that functions intracellularly as a chaperon protein, facilitates LRP folding and trafficking within the secretory pathway.

Gene locus: 12q13-q14.

Molecular mass (kd): 600; a-chain, 515; ß-chain, 85.

Distribution: CD91 is widely distributed in tissues of the body but is expressed most abundantly in the liver, brain, lung, and placenta.

Function: Proteinase catabolism. CD91 was originally identified as a receptor for a $_2$M, best known as a proteinase inhibitor and a carrier of specific growth factors, including TGF-ß and NGF-ß. a $_2$M has three distinct binding sites: (a) for growth factors, including TGF-ß and NGF-ß, (b) for ß amyloid peptide, and (c) for LRP.

As a proteinase inhibitor, it functions as a molecular “trap,” which is sprung when proteinases attempt to cleave a highly susceptible to proteolysis sequence, the “bait region,” triggering a conformational change that entraps the proteinase. Entrapment forms covalent bonds with the trapped proteinase, which is inactivated. The complex binds to the a $_2$MR and is endocytosed.

a $_2$MR internalizes the uPA–PAI-1 complex, including the uPAR (see CD87).

a $_2$M binds ß amyloid peptide and delivers it to CD91 for internalization. a $_2$M gene polymorphisms have been associated with late onset of Alzheimer disease, and a $_2$M is expressed by microglia near amyloid plaques; LPR protects neuroblastoma cells from the toxic effects of ß amyloid ([2] , [3]).

Tissue factor, an integral membrane glycoprotein (CD142), is an essential cofactor in initiating the extrinsic pathway of blood coagulation. In response to injury, it gains access to the plasma, and its function is regulated by the tissue factor pathway inhibitor. Tissue factor pathway inhibitor binds to an unknown surface molecule, and then LRP mediates the cellular degradation of the complex ([4]).

Heat shock proteins (HSPs) are released from cells in stress. The HSPs perform the chaperon function for peptides, leading to their processing and presentation by MHC molecules. The complexes enter the APC but use the endogenous pathway of antigen presentation to CD8 $^+$ T cells (cross-priming or cross-presentation) ([5]).

All HSPs use CD91 as a receptor to enter the APC, even though they have no homology with each other ([6]). Because HSPs are released from necrotic but not apoptotic cells, CD91 is a sensor of necrotic cell death. a $_2$M forms complexes nonselectively with a great variety of proteins, and the captured proteins are rapidly removed from the circulation and delivered through CD91 to macrophages ([7]).

Antigen complexed with a $_2$M induces 500-fold higher titers of IgG antibody in the absence of adjuvant.

CD91 functions as receptor for apoptotic cells ([8]) through the family of collectins, that is, proteins of innate immunity such as surfactants and the mannose-binding lectin, which facilitate removal of microorganisms through opsonin-mediated phagocytosis. C1q is structurally and functionally related to collectins. SP-A and SP-D bind to apoptotic cells and facilitate their removal through CD91 ([9]).

CD93 (C1qRP: C1q RECEPTOR FOR PHAGOCYTOSIS)

Structure: The C1q receptor for phagocytosis (C1qRp) is organized in distinct domains. The large extracellular domain consists of a C-lectin–type domain, followed by a carbohydrate-binding domain, five EGF domains, and a membrane-proximal heavily glycosylated mucinlike domain ([1]). The cytoplasmic tail is short (47 amino acids) and contains a tyrosine kinase recognition motif. In addition to phagocytosis, C1q generates H $_2$O $_2$ and singlet O $_2$.

Gene locus: 22p11.2.

Molecular mass (kd): 126 (reduced); 97 (unreduced).

Distribution: It is expressed on endothelial cells, monocytes, and neutrophils but not on many tissue macrophages. It is detected on CD34 $^+$ stem cells, platelets, and microglial cells, as well as on immature DCs, where it is down-regulated with maturation ([2]).

Function: The best known function of C1q is the triggering of activation of the classical pathway of complement (see Chapter 18). However, C1q mediates other functions independent of the complement cascade activation, such as enhancement of phagocytosis, stimulation of respiratory burst, chemotaxis ([3]), antibody-mediated cell cytotoxicity, antibody production from B cells, and intercellular adhesion ([4]).

The C1qRp protein (CD93) has been reported to enhance phagocytosis by monocytes and neutrophils ([5]) and modulates intercellular adhesion binding through a ligand on vascular endothelial cells.

- *C1q binding proteins.* C1q is a hexameric structure that, on electron micrographs, appears as a “bouquet of flowers” (Chapter 18). Each monomer is composed of a globular head (gC1q) and a collagenous fibril-like region (cC1q). At least two proteins have been identified that interact with distinct C1q domains; one, gC1qR, binds to the globular heads of C1q, and a second, cC1qR, binds to the collagenous fibrillar structures ([6] , [7]). The gC1qR is a highly acidic 33-kd protein forming a trimer and binds with the *N*-terminal domain to the C1q ([8]). The protein is highly acidic (28 Glu, 20 Asp), suggesting that interactions with C1q may be primarily ionic. It has a protein kinase phosphorylation site and a tyrosine kinase recognition site. gC1qR is expressed on resting platelets and at higher concentrations on microparticles formed after platelet activation and aggregation ([9]). These particles, which contain aIIb/ß3 integrin, coagulation factors, TSP, and so forth, provide an important surface of initiation of coagulation. gC1qR binds to a great variety of proteins, such as vitronectin, thrombin, fibrinogen, high-molecular-weight kininogen, several proteins from viruses, and pathogenic bacteria. gC1qR as a “receptor” on platelets and endothelial cells plays an important role in blood coagulation with participation to a complex assembled by kininogen ([10]). The activation of this complex is independent of factor XII, although factor XII can also interact with this complex because it also binds to gC1qR through its aminoterminal region ([11]).
- *cC1qR (calreticulin).* The mature protein consists of 400 amino acids and is divided into three domains: (a) the *N*-terminal or *N domain*, which forms a ß globular sheet and contains the rubella virus–binding site, as well as the a integrin and steroid receptor–binding site; (b) a proline-rich or *P domain* with a nuclear localization site; and (c) the *C*-terminal or *C domain*, which is rich in acidic residues and binds Ca $^{2+}$ ([12]).

C1q binding to calreticulin (CRT) is mediated through sequences in its *N*-terminal half that show similarity to the putative C1q-binding region of the CH $_2$ domain of IgG.

CRT is an important chaperon in the ER, together with its membrane-bound homolog calnexin.

Several other functions have been attributed to CRT, such as adhesion (activates integrins), Ca $^{2+}$ binding and storage, development (cardiac, neuronal), assembly of

MHC class I molecules, gene expression (androgen-sensitive gene in prostatic cancer), and so forth. CRT has been implicated as an extracellular protein in autoimmunity ([13]). Autoantibodies are detected in 40% of patients with systemic lupus erythematosus and Sjögren syndrome.

CD94

Terminology: CD94 is a C-type lectin that forms disulfide-linked heterodimers with members of important NK-cell receptor proteins known as *NKG2* (see Chapter 17). In these heterodimers, the CD94 is the invariant chain, encoded by a single gene, whereas the NKG2 group is a multigene family of at least five proteins designated *NKGs A through E*. The cytoplasmic tails of the NKG2 proteins are either long (A/B) or short (C and E), corresponding to inhibitory or activating receptors, respectively. The inhibitory function of A/B depends on two ITIM sequences present in the cytoplasmic tail, which, on activation, recruit the phosphatases SHP-1 and SHP-2, which inhibit activation. The activating receptors do not have ITAMs but associate with a short ITAM-containing protein DAP12.

Structure: CD94 is a C-type lectin (i.e., it has a roughly spherical C-type module (C_L) of approximately 120 amino acids and a Ca^{2+}-dependent carbohydrate-reorganizing domain (CRD) ([1] , [2] , [3] and [4]). Some lack most of the conserved Ca^{2+}-binding residues, and the C-type domain has been renamed the *C-type lectin–like NK receptor domain*, or *NKD*.

CD94 is a type II transmembrane protein with a very short cytoplasmic tail.

Gene locus: 12p13.3-13.1. The CD94 and NKG2 genes are closely linked with the human “NK gene complex.”

Molecular mass (kd): 30.

Distribution: Expressed on NK cells and a subpopulation of ?d and aß T cells. After CD3 stimulation, some $CD4^+$ T cells express CD94/NKG2A receptors, which are up-regulated by IL-10 and TGF-ß. Expression of CD94/NKG2A on $CD8^+$ T cells is induced during T-cell antigenic stimulation.

Function: CD94 forms heterodimers with NKG2A/B (inhibitory) and with NKG2C and E (activating). The ligands for CD94/NKG2A are the nonclassical (class Ib) HLA-E molecules ([5]) loaded with a peptide from the leader sequence of the MHC class I heavy chain of most HLA class I ([6] , [7]). When an MHC molecule is missing from the cell surface, there is no leader peptide to be loaded on the HLA-E. This is recognized by the cell surface, surveying CD94/NKG2 receptors, as “missing self.” Under such circumstances, activating receptors assume the task of killing the cell. HLA molecules are “lost” as a result of malignant transformation or virus infections (missing self hypothesis, see Chapter 17 for details). However, in normal cells, the presence of HLA-E loaded with peptides is a signal for intervention by inhibitory CD94/NKG2 receptors to inhibit killing.

An interesting point for HLA-E is that the loading of signal peptides is dependent on *t*ransporter *a*ssociated with antigen *p*rocessing (TAP), in contrast to classical class I HLA molecules, which may accept signal sequence peptides without help from TAP (with a few exceptions). (TAP is the complex that transports the peptides to the ER to be loaded to the HLA molecules—see Chapter 18.) Variation in sialyl Lewis ^{X} expression by tumor cells seems to be recognized by CD94 receptors on NK cells, but the mechanism remains unknown. CD94 receptor binds more efficiently to sialyl Lewis ^{X} that is densely attached to carrier glycans ([8]).

The UL-40 glycoprotein of CMV is ligand for HLA-E and is recognized by the inhibitory receptors CD94/NKG2A; that prevents killing of CMV-infected cells ([9]).

CD95 (Fas ANTIGEN; APO-1; TNF RECEPTOR SUPERFAMILY, MEMBER 6, TNFRSF6)

Structure: CD95 is a member of the TNF family of receptors, which includes two TNFRs (TNFR1 and TNFR2), the receptor for lymphotoxin-ß, the NGF receptor (NGFR), CD40, CD27, and CD30.

CD95 is a transmembrane type I protein with an extracellular region consisting of three cysteine-rich domains (CRDs). The CRDs are stabilized by extensive intrachain disulfide bonds. Each CRD contributes to ligand binding; however, CRD1 is the primary ligand-binding site. CRD1 also mediates the preligand CD95 oligomerization and is known as *PLAD* (preligand assembly domain) (see below).

The cytoplasmic region contains a death domain (DD) mediating protein–protein associations.

Gene locus: 10q24.1.

Molecular mass (kd): 45 (reduced).

Distribution: Fas is constitutively expressed on $CD4^+$/$CD8^+$ (double-positive) human thymocytes, but Fas does not contribute to negative selection in the thymus because lpr/lpr mice (with defects in the apoptotic pathway, see below) have normal negative selection. Peripheral blood T and B lymphocytes express CD95 after activation, but Fas normally is detected on neutrophils, monocytes, and fibroblasts.

Signaling: Nonligated CD95 exists on the cell membrane in a preassociated form mediated by PLAD ([1] , [2] , [3] and [4]). This association, mediated by CRD1 before ligand binding, is necessary for the recruitment of signaling proteins. In the next step, through actin reorganization, the Fas recruits the Fas-associated DD (FADD), a cytoplasmic adaptor protein with a *C*-terminal DD and an *N*-terminal death effector domain (DED) ([5] , [6] , [7] and [8]).

FADD, through its own DD, interacts with the DD of Fas and, through DED, with the DED of procaspase-8 to form the *death-inducing signaling complex* (DISC).

Oligomerization of procaspase 8 leads to proximity-induced autocatalytic activation, followed by direct or indirect downstream activation of executionary caspases (i.e., caspase-3).

Fas cross-linking activates two sphingomyelinases, a neutral sphingomyelinase (NSM) located at the cytoplasmic membrane and an acidic sphingomyelinase (ASM) located in acidic membrane subdomains ([9] , [10]). The ASM pathway leads to accumulation of ceramide, a diffusible messenger for apoptosis in hematopoietic cells, generated from hydrolysis of sphingomyelin.

Ceramide is targeted to the Golgi apparatus and induces the synthesis of disialoganglioside GD3, a glycosphingolipid containing two sialic acid residues. GD3 induces ??m loss of mitochondria, leading to apoptosis.

In patients with Niemann-Pick disease, who are genetically deficient in ASM activity, the cells do not undergo normal Fas-mediated apoptosis because GD3 accumulation is impaired.

The role of ASM in Fas-mediated apoptosis has been shown for some but not all cells.

Fas signaling triggers T-cell co-stimulation through NF-?B and MAPK activation, leading to IL-2 secretion.

Function: CD95 is the major receptor for apoptosis, which morphologically is accompanied by condensation of cytoplasm, loss of plasma membrane microvilli, segmentation of the nucleus, and extensive degradation of chromosomal DNA into oligomers of approximately 180 bp.

Fas-mediated apoptosis occurs after primary activation of T cells (activation-induced apoptosis) and progressive differentiation of T cells is associated with increasing susceptibility to apoptosis, a mechanism contributing to maintenance of peripheral T-cell tolerance and prevention of the development of autoreactive T cells after activation.

- *Autoimmune lymphoproliferative syndrome (ALPS)* ([11], [12]) is characterized by massive lymphadenopathy and splenomegaly in children, accompanied by autoimmune hemolytic anemia, thrombocytopenia, other autoimmune manifestations, and polyclonal hypergammaglobulinemia. ALPS is associated with mutations of the CD95 gene (ALPS type Ia) or the CD95 ligand gene (CD178, ALPS type Ib) and a more severe clinical phenotype presumed to be caused by an undefined inherited gene defect in the absence of mutations in the CD95 or CD95L genes (ALPS type II). Type Ia corresponds to lpr and type Ib to gld murine syndromes. One major difference between ALPS and the murine model is the multiorgan autoimmune disease with renal involvement seen in mice, whereas autoimmune cytopenias predominate in ALPS. Chronic neutropenia is often associated with LGL leukemia. In these patients, the level of Fas ligand is elevated, and it has been shown that it triggers apoptosis of normal neutrophils *in vitro* ([13]). Levels of Fas ligand return to normal in treated patients at the same time as the disappearance of neutropenia. B- and T-cell lymphomas have been reported in families with ALPS and germ-line mutations of Fas. Fas mutations have been detected in other malignancies such as nasal T-cell lymphomas (7 out of 14) ([14]), mycosis fungoides ([15]), testicular germ cell tumors, and so forth. In chronically sun-exposed skin, CD95 is up-regulated in keratinocytes (solar elastosis, no dysplasia). However, in actinic keratosis, there is a loss of Fas proportional to the degree of dysplasia. In cases of myelodysplastic syndrome, the $CD34^{+}$ erythroid progenitors proliferate normally in cultures with erythropoietin, but further differentiation leads to Fas-mediated apoptosis, which may be responsible for impaired erythropoiesis ([16]).

CD99

Structure: CD99 is a transmembrane protein with limited similarity in the extracellular region to collagenlike proteins.

Gene locus: CD99 is encoded by MIC2 gene located in the pseudoautosomal region at the end of the short arm of X chromosome (MIC2X). MIC2 maps to the band between Xp22.3 and Xpter, and it escapes lyonization. A homologous locus was found on the Y chromosome in the euchromatin region Yq11.1-Ypter (MIC2Y). MIC2X and MIC2Y have closely related or identical sequences. MIC2Y is the most proximal autosomal locus to testis-determining factor ([1]).

Molecular mass (kd): 32.

Distribution: Within the hematopoietic cells, CD99 is expressed on all cell types except neutrophils. Expression is particularly high in subsets of plasma cells, in medullary cords of LN, and in cortical thymocytes. It is strongly expressed on Xg(a+) but low in Xg(a $^{-}$) erythrocytes. It is commonly expressed in AML, pulmonary, neuroendocrine, and gastrointestinal tumors.

Function: CD99 is involved in adhesion of erythrocytes to T cells in spontaneous rosette formation. It also triggers homotypic aggregation of double-positive thymocytes, which is Mg^{2+}-dependent and requires intact cytoskeleton, suggesting that it is likely to be mediated by an integrin. Indeed, ligation of CD99 up-regulates affinity/avidity of the $a_4ß_1$ integrin shown to be instrumental in adhesion of activated T cells to vascular endothelium ([2]). It regulates their extravasation in inflammatory sites. CD99 is constitutively expressed in lateral contacts of vascular endothelial cells, which are particularly active in the final step of transmigration of leukocytes. The CD99-mediated adhesion is operative after deep penetration of the migrating cells into the interendothelial junctions just before transmigration is completed.

CD99 transmigration is mediated through regulation of the function of integrins in the uropod. CD99 regulates LFA-1/ICAM-1–mediated adhesion of lymphocytes and triggers production of the Th1 type of cytokines. It induces up-regulation of TCR and MCH class I and class II molecules in thymocytes.

Engagement of CD99 induces apoptosis of Ewing sarcoma cells, although in this case, the apoptotic pathway follows mitochondrial permeability and transition pore opening, with a reduction of ??m and caspase activation.

CD99 transports MHC class I molecules from the trans-Golgi compartment to the cell membrane ([3]).

An intriguing function of CD99 involves its role in the generation of Hodgkin's Reed-Sternberg (H-RS) phenotype. Down-regulation of CD99 with antisense CD99 expression constructs, introduced in B-cell lines, induces morphologic (multiple nuclei) and immunologic (CD15 expression and decreased class I expression) characteristics of H-RS cells ([4], [5]).

These changes were believed to be induced through Rac, a member of the Rho family of proteins, which are involved in cytoskeletal organization. Constitutively active Rac rescues the CD99-deficient cells from morphologic abnormalities.

Viral latent membrane protein 1, which is essential for EBV transformation of normal B lymphocytes, plays a role in down-regulation of CD99 and leads to generation of H-RS cells ([6]).

CD100 (SEMAPHORIN 4D, SEMA4D)

Structure: Semaphorin (abbreviated SEMA) derives from the word “semaphore” used in railway track crossings to send signals of an approaching train. (Originally: Greek *sema*, sign, and *phero*, carry, convey.) Semaphorins are a large family of proteins consisting of more than 20 members, divided into eight subfamilies or subclasses: two invertebrates, five vertebrates, and one viral. CD100 is a member of subfamily 4. All semaphorins are defined by the presence of a signature domain, the *sema domain* at the aminoterminal. Semaphorins originally were characterized in the nervous system, where they were implicated in repulsive axon guidance and, more recently, in cardiac and skeletal development, angiogenesis, and tumor growth and metastasis. CD100 is the first semaphorin to be detected in the immune system ([1], [2]).

The extracellular region consists of an aminoterminal signal sequence, followed by a sema domain, which is a 500–amino acid sequence with 17 highly conserved cysteines; next is an Ig-like type C2 domain, and a lysine-rich stretch.

The cytoplasmic tail has tyrosine and multiple serine phosphorylation sites.

The transmembrane protein is proteolytically cleaved to release a soluble CD100 (sCD100). Proteolysis is well regulated and depends strictly on activation of T or B cells. It is probably mediated by an MMP.

Gene locus: 9q22-q31.

Molecular mass (kd): 300 (unreduced); 150 (reduced); 120 (soluble).

Distribution: CD100 is detected on T and B lymphocytes (especially after activation), NK cells, and myeloid cells, but not in RBCs, eosinophils, or endothelial cells. CD100 is also detected in the germinal centers (dark and light zones) but not in the mantle zone. It is present in lymphoid and myeloid leukemia cells.

Generally, it is not expressed in follicular NHL but is detected in high-grade small noncleaved B-cell NHL and in T-cell lymphomas.

Function: There are two receptors for CD100: (a) plexin B1 and (b) CD72.

Plexin B1 is a member of the plexin family of proteins, which are receptors for semaphorins, either alone or in combination with neurophilins ([3]). Plexin B1 is expressed in human brain, kidney, and liver and is the high-affinity receptor for CD100. Plexin B1 is linked to Rac, a small GTP-binding protein involved in cell morphology, aggregation, and cytokinesis.

CD72 is a low-affinity lymphocytic receptor for CD100 ([4], [5]). CD72 contains an ITIM in its cytoplasmic tail recruiting phosphatase SHP-1 and acts as an inhibitory receptor. CD100 blocks the association of CD72 with SHP-1 phosphatase, turning off the negative signals, which explains the enhancement of B-cell responses by

CD100. CD100 promotes aggregation and survival of B lymphocytes and inhibits spontaneous or chemokine-induced migration.

In humoral immunity, CD100 enhances proliferative B-cell responses and Ig production.

Soluble CD100 is released from activated lymphocytes ([6], [7]).

CD100 (Sema 4D) triggers invasive growth, a complex program characterized by dissociation of cells, growth, and branching morphogenesis (cells form tubules arranged like branches). This response was earlier detected by the scatter factors, a group of proteins with striking homology to plexins. The prototype of scatter factors is the hepatocyte growth factor (HGF) receptor (MET) encoded by the MET oncogene. Plexin B1 associates with MET, and binding of CD100 to plexin B1 stimulates tyrosine kinase activity of MET, resulting in phosphorylation of both plexin B1 and MET.

CD110 (THROMBOPOIETIN RECEPTOR, MPL, TPOR)

Structure: Member of hematopoietin receptor family. Encoded by the c-mpl gene, the homolog to the v-mpl virus oncogene of the murine myeloproliferative leukemia. There are two cytokine receptor domains in the extracellular region and two cytokine receptor box motifs in the intracellular region.

Gene locus: 1p34.

Molecular mass (kd): Unreduced, 85 to 92.

Distribution: Hematopoietic stem cells. Megakaryocyte progenitors as well as on megakaryocytes and platelets.

Function: CD110 regulates thrombopoiesis. Biochemically, it prevents apoptosis and stimulates growth and differentiation ([1], [2], [3] and [4]). Mutations of CD110 have been detected in some patients with congenital amegakaryocytic thrombocytopenia. Binding of thrombopoietin causes dimerization of CD110 and phosphorylation of JAK kinases and STAT transcription factors. MPL is markedly reduced or absent in platelets from patients with polycythemia vera and in most of the patients with idiopathic myelofibrosis. This finding may distinguish polycythemia vera from other conditions with erythrocytosis ([5]). CD110 (MPL) is expressed on the common myeloid progenitor but not on the common lymphoid progenitor ([6]).

CD117 (RECEPTOR FOR STEM CELL FACTOR, C-KIT)

Structure: Encoded by protooncogene c-kit and belongs to the class III tyrosine kinase receptor family. It is a transmembrane protein with five extracellular Ig-like domains (four C2 and one V). The intracellular region contains a tyrosine kinase domain that is split by a unique insertion of 77 amino acids and a consensus ATP-binding site. It is closely related to CSF-1 receptor (c-fms) and PDGF receptor.

Gene locus: 4q12.

Molecular mass (kd): Reduced, 145; unreduced, 145.

Distribution: Hematopoietic progenitors (except B-lineage precursors). Present on mast cells, melanocytes, spermatogonia, and oocytes.

Function: Stem cell factor or c-kit ligand binds to CD117. Binding of the ligand (Steel factor) triggers a variety of reactions, such as dimerization and internalization of the receptor, autophosphorylation and phosphorylation of other substrates, activation of MAPK and PLC-?, and protooncogene transcription. CD117 is crucial in hematopoiesis, activation, and development of mast cells. It prolongs survival of melanocytes and is necessary for survival and differentiation of type A spermatogonia. In humans, mutations of CD117 gene result in piebaldism, a disorder of pigmentation, in systemic mastocytosis, or in mast cell leukemia. Deletion or defects of CD117 gene in W mice result in anemia, lack of mast cells, pigmentation defects, and infertility ([1], [2] and [3]).

CD122 (IL-2 RECEPTOR, ß-CHAIN)

Details in Chapter 18.

Structure: CD122 is a cell-surface glycoprotein. The extracellular region contains one cytokine receptor domain [i.e., two pairs of conserved cysteines and the sequence Try/Ser/X/Try/Ser (WSXWS)] and one FN III domain. The cytoplasmic region contains serine-rich, acidic, and proline-rich domains. CD122 is associated with CD25 (a-chain) and CD132 (?-chain) to form the high-affinity IL-2 receptor. In the trimeric complex, CD25 binds the ligand (IL-2) and CD122/CD132 transmit the signal.

Gene locus: 22q11.2.

Molecular mass (kd): Reduced, 75; unreduced, 75.

Distribution: T cells, B cells, NK cells, monocytes, and macrophages.

Function: Binds IL-2 with low affinity as well as IL-15 ([1], [2]). Transmits growth signals (serine-rich domain is important). Two intracellular pathways of signal transduction for protooncogene induction: tyrosine phosphorylation (mediated by src-PTKs) and induction of c-myc. CD122 is associated with tyrosine kinases Syk, Lck, and JAK-1, as well as the transcription factor STAT-1. The IL-2 signaling follows several pathways. One involves Src kinases, with the path to the nucleus followed through Ras activation and MAPK cascade. A second is mediated by the P13K pathway and a third by the JAK kinases–STAT transcription factors. Stimulates growth and differentiation and cytokine secretion.

CD123 (IL-3 RECEPTOR, a-CHAIN)

Structure: The *N*-terminal is homologous to that of IL-5 and GM-CSF receptors. The extracellular region contains also a cytokine-receptor domain and a FN III domain.

Gene locus: Yp11.3 and Xp22.3.

Distribution: Hematopoietic progenitors, monocytes, and B cells.

Function: Binding of IL-3 results in tyrosine phosphorylation and promotes proliferation and differentiation of hematopoietic cells. It affects early stages of hematopoietic cell differentiation, especially at pluripotential stem cell stage ([1]).

CD124 (IL-4 RECEPTOR)

See details in Chapter 18.

Structure: Type I transmembrane protein of the hemopoietin receptor SF with a cytokine type I module (i.e., an *N*-terminal domain with two conserved disulfide bonds and a second with the domain, WSXWS motif, and membrane-proximal FN III domain). The cytoplasmic region is rich in Ser/Pro. Soluble form has been detected. It is also a component of the IL-13 receptor complex.

Gene locus: 16p12.1.

Molecular mass (kd): Reduced, 140.

Distribution: Present on B cells, T cells, hematopoietic progenitors, and bone marrow stroma. Also on mast cells, macrophages, epithelial cells, fibroblasts, and neuroblasts.

Function: The IL-4R a-chain binds IL-4 with high affinity and forms a heterodimer with the common ?-chain (?c) (CD132), which is required for activation of the signaling pathways ([1], [2]). The a-chain is associated with JAK-1 kinase and the ?c-chain with JAK-3. On binding of IL-4, the a-chain is phosphorylated and, through a unique sequence in its cytoplasmic region (shared also by the insulin receptor), binds a phospho-protein (see Chapter 18), which links the receptor to the PI3K pathway and other signaling pathways (Ras) leading to cell proliferation. Expression of many IL-4–responsive genes is mediated through the STAT-6 transcription factor activation. Functions of IL-4 include regulation of growth and differentiation of B cells, and it is a switch factor for IgE. It stimulates growth of T cells and mast cells and diverts T-cell differentiation to the Th2 pathway.

CD125 (IL-5 RECEPTOR, a-CHAIN)

Structure: Type I membrane protein containing in its extracellular region a cytokine type I module and three FN III domains. The cytoplasmic domain is short and rich in proline. Soluble IL-5R has been detected.

Gene locus: Chromosome 3p26.

Distribution: Widespread in hematopoietic cells, especially eosinophils and basophils.

Function: It binds IL-5. Signals are transduced by the nonbinding ?c-chain shared by other IL receptors. IL-5 activates the PI3K pathway and Vav protein. It stimulates eosinophil differentiation and B-cell growth and differentiation and enhances IgA production ([1]).

CD126: IL6 RECEPTOR

See Chapter 18.

CD128 (IL-8 RECEPTOR a, CXCR1; CD128B: IL-8 RECEPTOR ß, CXCR2)

Structure: Two receptors have been described, one with low and one with high affinity. Both have seven transmembrane regions and belong therefore to the rhodopsin SF of G protein–linked receptors.

Gene locus: 2q35.

Molecular mass (kd): Reduced, 58 to 67.

Distribution: Neutrophils, basophils, lymphocytes, keratinocytes, and melanoma cells.

Function: Binding of IL-8 induces chemotaxis of neutrophils, basophils, and T lymphocytes. Activates neutrophils and basophils and increases their adhesion to endothelial cells. Elicits respiratory burst. Signals transduced through IL-8R are similar to those transduced by other chemoattractant receptors. Increases cytosolic Ca^{2+} and activates PKC ([1]).

CD129 (RECEPTOR FOR IL-9)

Structure: The extracellular region contains one cytokine family domain and one FN III domain. Soluble forms exist. The receptor is associated with the ?-chain of the IL-2R.

Distribution: Found on T cells (helper), macrophages, and mast cell lines.

Function: Binds IL-9, which stimulates growth of T cells, mast cells, and megakaryoblastic leukemia cell lines ([1]).

CD130

See Chapter 18.

CD131 (COMMON ß-CHAIN)

Structure: Type I transmembrane protein. The extracellular domain contains two repeats of class I cytokine receptors.

Gene locus: 22q13.1.

Molecular mass (kd): Unreduced, 120 to 140.

Distribution: Present on early hematopoietic progenitors and pre-B cells.

Function: ßc (common) subunit, associates with the a-chains of IL-3R (CD123), GM-CSFR (CD116), and IL-5R (CD125) ([1]). It functions in signal transduction and is associated with the JAK-2 kinase. On binding of the cytokine to its receptor, the ßc is phosphorylated and allows docking on its cytoplasmic region of signal transducing molecules with SH_2 domains such as PI3K, Shc, and Grb2 adaptor molecules, and so forth. Some cases of pulmonary alveolar proteinosis have a reduced expression of ßc-chain and in one patient, a mutation was detected ([2]). Some of these patients develop AML, but all leukemic cells do not express the ßc-chain. Targeted deletion of ßc-chain gene in mice generates a pulmonary alveolar proteinosis–like syndrome.

CD132 (COMMON ?-CHAIN)

Structure: The extracellular region contains the four conserved cysteines and the WSXWS motif characteristic of class I cytokine receptors. The intracellular region contains two subdomains of the Src homology region 2 (SH_2), which are, however, insufficient to initiate downstream signal transduction.

Gene locus: Chromosome Xq13.1.

Molecular mass (kd): 64.

Distribution: Hematopoietic cell progenitors of T, NK, and B cells as well as the mature lymphocytes, neutrophils, and macrophages.

Function: It is a subunit for several cytokine receptors (i.e., IL-2, IL-4, IL-7, IL-9, and IL-15). The ?c-chain is not involved in ligand binding but in signal transduction. JAK-3 kinase is constitutively associated with ?c and is activated after binding of any cytokine sharing the ?c-chain with their receptors. JAK-1 as well as Syk and lck tyrosine kinases are activated by some of these cytokines. The JAK kinases phosphorylate members of the STAT family of transcription factors. The ?c-chain is critical for growth, maturation, and function of T and NK lymphocytes. This has been shown by experiments of nature (i.e., mutations of the ?c gene). Such mutations have been detected on all patients with XSCID, which constitutes 40 to 50% of all primary SCIDs. The mutations result in total absence of or abnormal ?c-chains and affect all eight exons of the gene. XSCID is characterized by profound lack of T and NK cells, but the number of B cells is either normal or slightly elevated. However, these B cells do not function normally (serum Igs are absent or diminished) even in the presence of normal T cells. They are, however, capable of class switching *in vitro* after stimulation with anti-CD40 antibodies. Bone marrow transplantation in the first 3 months of life offers greater than 95% chance of survival ([1], [2] and [3]).

CD133 (HEMATOPOIETIC STEM CELL ANTIGEN, PROML1: PROMININLIKE 1)

Structure: CD133 is a glycoprotein that spans the cell membrane five times (pentaspan) and is the first member to define this new family of proteins, which is distributed in several species from worms to humans. The extracellular region consists of two large loops, whereas the intracellular region consists of two small loops. The presence of tyrosines in the intracellular region suggests that the molecule may be involved in signal transduction. Cysteine residues are detected in the transmembrane domains.

Gene locus: 4p16.2-p12.

Molecular mass (kd): 120.

Distribution: It is expressed on primitive hematopoietic progenitors, which stain bright for CD34 and are also positive for CD117 (c-kit) and HLA-DR but are still negative for erythroid markers. It is also expressed in epithelium of developing embryos, endothelial cell precursors, retina, and neural stem cells. The protein is detected with certain antibodies in AMLs and in myelodysplastic syndrome. A mutation of the gene has been detected in a patient with retinal degeneration.

Function: Presently unknown ([1], [2], [3] and [4]).

CD138 (SYNDECAN-1, HEPARAN SULFATE PROTEOGLYCAN)

Structure: CD138 is a heparan sulfate proteoglycan consisting of a core protein, which, in its extracellular region, contains five sites for attachment of glycoaminoglycans, heparan sulfate in the distal three and chondroitin sulfate in the two proximal to the membrane. Its cytoplasmic region contains three tyrosines. It belongs to a family of syndecans that share similar transmembrane and intracellular regions but differ in the extracellular region, suggesting that they are tissue specific ([1], [2]).

Gene locus: 2p23.

Molecular mass (kd): 85 to 92, unreduced.

Distribution: Syndecan-1 is expressed strongly on plasma cells and myeloma cells and in the mouse on pre-B cells but not on mature B cells. It is also present on embryonic mesenchymal cells, vascular smooth muscle cells, endothelial, neural, and epithelial cells.

Function: It is an important regulator of myeloma cell behavior. On the cell membrane, it mediates adhesion between myeloma cells and collagen type I. On a subpopulation of motile myeloma cells, it is localized on the uropod, promoting homotypic cell adhesion ([3]). Cell-bound syndecan-1 promotes myeloma cell growth through binding of various cytokines and heparin-binding proteins, like the HGF produced by mesenchymal cells and myeloma cells ([4]). HGF thus acts as a paracrine and autocrine growth factor for myeloma cells. It binds to its receptor, c-Met kinase, a receptor tyrosine kinase, and furthermore stimulates activation of PI3K and the Ras pathway ([5]). Syndecan-1 is shed from the cell membrane and is highly elevated in a soluble form in the bone marrow of patients with myeloma ([6]). In the soluble form, it inhibits myeloma cell growth by inducing apoptosis and trapping HGF. However, this effect of syndecan-1 is concentration dependent because at low concentrations, it again promotes cell growth. Soluble syndecan-1 mediates decreased osteoclast and increased osteoblast activity. Thus, the action of syndecan-1, whether bound on myeloma cells or in the soluble form, exerts a complex regulatory role in myeloma.

CD140a (PDGFRa: PLATELET-DERIVED FACTOR RECEPTOR a) AND CD140b (PDGFRß)

Structure: The PDGFR-a and -ß are PTKs, subclass III, the members of which are characterized by several Ig-like domains in their extracellular region. The PDGFR are assembled as dimers of two polypeptide chains, which give rise to three isoforms, a receptor (homodimer), ß receptor (homodimer), and aß (heterodimer). Dimerization of the receptor chains is induced by their ligand, which is the PDGF, a disulfide-linked dimer of two chains, A and B. It exists as three isoforms, AA, BB, and AB. Ligand binding induces noncovalent dimerization of the receptor chains. AA induces only PDGFR-a, BB induces both PDGFR-a and PDGFR-ß, and PDGF-AB induces all three receptors, a, ß, and aß. PDGF forms two large loops, 1 and 3, pointing in one direction, and a smaller loop, 2, in the opposite direction. The site for binding to the receptor is contributed by loops 1 and 3, but loop 2 is also involved.

Each receptor chain contains five extracellular Ig domains, a transmembrane region, and an intracellular tyrosine kinase domain, which is split in two by an inserted sequence. This insertion contains a tyrosine that can be autophosphorylated and triggers the binding to intracellular signaling proteins. The site for high-affinity binding of PDGF-AA to the receptor is formed by Ig domains 2 and 3 and, for PDGF-BB binding, by domains 1 and 2. Domain 2 is probably the most important for ligand binding. Domain 4 mediates receptor dimerization.

Gene locus: CD140a, 4q11-q13; CD140b, 5q31-q32.

Molecular mass (kd): CD140a, 170; CD140b, 180.

Distribution: The PDGF ligand is expressed by many types of cells. The a-granules of platelets are the major source of PDGF. The receptors for PDGF are also expressed by a variety of cells and normally mediate the growth-promoting and other functions of PDGF. These soluble receptors can compete for ligand binding.

Function: The three PDGF receptors mediate overlapping but not identical signals.

- *Signal transduction* ([1], [2]). Dimerization of the receptors is the key event in PDGFR activation. The first step is autophosphorylation of the receptor chains. A tyrosine located within the kinase domain is important in kinase activation. Autophosphorylation provides docking sites for signaling molecules. The PI3K is important for actin reorganization and directs all cell movement, whereas PLC-? is involved in activation of Na^{+}/H^{+} exchanger. Grb-2 links the receptors to Ras molecules, leading to its activation and stimulation of cell growth.
- *Cellular processes:* (a) cell motility, (b) cell growth, (c) cell differentiation, (d) inhibition of apoptosis, and (e) cell transformation.
- *In vivo* functions. The ß receptor affects development of blood vessels, and the a receptor regulates development of alveoli and oligodendrocytes in the brain and spinal cord. PDGF and its receptors have been implicated in mesangial glomerulonephritis, idiopathic fibrosis of the lungs, kidney fibrosis, cirrhosis of the liver, scleroderma, myelofibrosis, and so forth ([3]). Involvement of PDGF and its receptors in the atherosclerosis process has been confirmed experimentally. The B-chain of PDGF is the c-sis prooncogene, and PDGF and its receptors promote growth and mitogenic functions and have a role in human malignant diseases ([3]).

CD141 (FETOMODULIN, THROMBOMODULIN)

Structure: Single-chain type I membrane protein divided into five domains. The *N*-terminal domain is a C-type lectin domain similar to the hepatic asialoglycoprotein receptor and members of the selectin family. The next domain consists of six EGF-like repeats. Two of these repeats bind thrombin, and three are necessary for

activation of protein C. The fifth is intracytoplasmic and contains potential phosphorylation sites and a cysteine that may be involved in forming polymers.

Gene locus: 20p12-cen.

Molecular mass (kd): 75, unreduced; 105, reduced.

Distribution: Present on endothelial cells, platelets, megakaryocytes, monocytes, smooth muscle cells, and synovial cells.

Function: CD141 is a component of a natural anticoagulant system. It binds thrombin with high affinity, leading to activation of protein C, which, in turn, inactivates factors V and VIII. Thrombomodulin–thrombin complexes are endocytosed, resulting in removal of thrombin from the endothelial surface. The lectin domain of thrombomodulin regulates endocytosis of the complex ([1], [2] and [3]).

CD 142 [TISSUE FACTOR (TF), THROMBOPLASTIN]

Structure: CD 142 is a transmembrane type I protein. The extracellular region consists of two type III fibronectin (FN) domains, joined at an angle of approximately 120 degrees ([1]). There are four cysteines forming two disulfide loops. The membrane proximal loop is important for TF function and the binding with high affinity to factor VII. The cytoplasmic tail has a single cysteine, which serves as an acceptor for palmitate or stearate, covalently linked via a thioester bond ([2]). Factor VII consists of a GAMMA–carboxyglutamic acid-rich domain (Gla), a hydrophobic or aromatic stalk, two epidermal growth factor domains, and a serine protease domain homologous to trypsin. The Gla domain has several Ca^{2} binding sites and three conserved hydrophobic residues. All domains make contact with TF, but the EGF-1 and the protease domains contribute most of the binding. The TF positions and orients VIIa protease and its catalytic center at 80 Å above the cell surface to allow optimal interactions with the substrate and the scissile peptide. The hydrophobic residues of the Gla domain point away and anchor VIIa to the membrane by insertion into the outer phospholipid layer. TF is homologous to class I cytokine receptors based on the conservation of the cysteines in the N-terminal domain and the WSXWS sequence of the C-terminal domain.

Gene locus: 1p21.

Molecular mass (kd): 45.

Distribution: CD 142 is expressed on the cell surface of a variety of cells that are physically separated from the circulating blood, and only vascular injury may initiate activation of coagulation. Blood cells and vascular endothelial cells normally do not express TF. It is detected in keratinocytes, glomerular epithelial cells (cytoplasmic inclusions), astrocytes, myocardium, stromal cells of the liver, pancreas, and spleen. In general, it is distributed around blood vessels, capsules surrounding various organs, and epithelial surfaces (i.e., it is strategically located with a distinct evolutionary advantage, forming a hemostatic barrier in cases of emergency). Expression of TF in monocytic cells is induced by inflammatory activation (i.e., cytokines, LPS, immune complexes, anaphylatoxin, etc.). Similar stimuli also induce TF expression in endothelial cells.

Function: CD142 is a receptor for factor VII and initiates the extrinsic pathway of coagulation. The initial proteolytic process after the binding of factor VII to TF consists of the conversion of factor VII to VIIa. The physiologically relevant protease for this change is likely Xa, which cleaves VII at the Arg152-Ile153 bond. TF acts as cofactor for Xa-mediated activation of TF-bound VII. The factor X substrate of TF-VIIa complex appears to be preferentially cleaved if associated with phospholipid. TF probably maintains a basal level of IXa and Xa from trace amounts of TF detectable normally in plasma. TF-VIIa complex produces intracellular signaling, such as changes of Ca^{2} concentration, tyrosine phosphorylation, MAPK activation, etc. TF plays important roles in venous and arterial thrombosis. It is detected in the macrophage foam cells of the atherosclerotic plaques and thus predisposes for arterial thrombosis. Induction of TF in monocytes by homocysteine may be a contributing factor in the mechanism by which high levels of homocysteine predispose to thrombosis ([3]). Its role in disseminated intravascular coagulation (DIC) has been documented in patients with sepsis and overwhelming infections, contributing to multiple organ failure and death. The release of elastase from activated neutrophils may be a contributing factor ([4]). TF directly augments macrophage activation by VIIa independently of the effects on the coagulation proteins ([5], [6]).

TF-VIIa complexes have been detected in the joints of patients with rheumatoid arthritis and may contribute to the chronic destructive process of the disease ([7]). TF is expressed on the surface of a variety of tumor cells, and the expression sometimes correlates with the grade of malignancy and metastatic potential ([8], [9]). Another possible role of TF in tumor survival is its contribution to angiogenesis as a result of its function in the maintenance of the integrity of the vascular wall ([10]). In tumors, TNF-alpha induces TF in the endothelial cells of the tumor vessels, and in the case of tumor necrosis, thrombosis may be triggered by the TF.

TF-induced coagulation is regulated by a protein that inhibits TF (TFPI) ([11], [12]). TFPI consist of an aminoterminal acidic region followed by three tandem Kunitz-type protease inhibitory domains and a basic carboxyl-terminal region. TFPI inhibits Xa especially in the complex Xa-Va-Ca^{2} embedded in a phospholipid layer (prothrombinase complex). However, Xa-independent inhibition also exists.

CD143 [ANGIOTENSIN-CONVERTING ENZYME (ACE), KININASE II, PEPTIDYL DIPEPTIDASE A]

Structure: Single polypeptide of type I transmembrane protein. It exists in two forms: one present on somatic cells (1306 amino acids) and a second in germ cells (testis) (732 amino acids). The two forms are generated as a result of differences in the transcription of a single gene initiated from two different promoters.

Gene locus: 17q23.

Molecular mass (kd): Somatic, 170 to 180; germinal, 90 to 110.

Distribution: The somatic form is present on endothelial cells, strongest in arterioles, and practically lacking in large arteries and veins. Expression is stronger in the blood vessels of the lung than in the kidney. It is also expressed on epithelial cells of proximal renal tubules and on several locations in the brain (basal ganglia, substantia nigra, and so forth). Finally, it is detected on mesenchymal cells, activated macrophages, and so forth. The germinal form is found only on differentiating germinal cells.

Function: CD143 acts as a dipeptide hydrolase with substrates of the angiotensin II and bradykinin, important vasoactive peptides ([1], [2]). It is necessary for spermatozoa to successfully penetrate the egg. The level of CD143 is regulated by glucocorticoids and thyroid hormones.

CD150 (SLAM: SIGNALING LYMPHOCYTE ACTIVATION MOLECULE)

Structure: Single polypeptide transmembrane type I protein with two extracellular highly glycosylated Ig-like domains. The cytoplasmic region contains three tyrosines, potential sites for binding of SH_{2} domains of signaling molecules. SLAM belongs to the CD2 subfamily of the IgSF. It includes CD2, CD48, CD58, CD150, CD229 (Ly-9), and CD244 (2B4). Two new members structurally related to SLAM have recently been described: SF2000 and SF2001.

Gene locus: 1p98 for CD2/CD58; 1q22 for the rest.

Molecular mass (kd): 70.

Distribution: It is expressed on thymocytes, B cells, T cells, and DCs.

Function: In T cells, SLAM ligation stimulates IFN-? and IL-2 secretion and, in B cells, proliferation and Ig secretion ([1]). A critical role for the function of SLAM is played by another molecule known as *SAP* (SLAM-associated protein) ([2]). SAP binds with high affinity to SLAM and controls its function. It inhibits binding of the protein tyrosine phosphatase SHP-2 and thus prolongs phosphorylation of SLAM and other signaling molecules. SAP also recruits and activates the PTK Fyn-T, establishing a new signal pathway involving the inositol phosphatase SHIP, adaptor molecules Dok 2, Dok 1, and Shc, and the Ras GAP protein. The importance of

SAP in the control of T-cell activation is further emphasized by the identification of mutations on SAP gene as the underlying mechanism in X-linked lymphoproliferative disease ([3], [4]). X-linked lymphoproliferative disease is a fatal disease that usually follows EBV infection and is characterized by fulminant infectious mononucleosis, B-cell lymphomas, and dysgammaglobulinemia.

CD151 (PETA-3: PLATELET-ENDOTHELIAL CELL TETRASPAN ANTIGEN-3)

Structure: Member of the TM4 SF (i.e., proteins with four transmembrane domains) ([1]). Short N- and C-termini end in the cytoplasm, whereas the extracellular region forms two loops, one 15 and the other 109 amino acids long. The TM4 family consists of over 20 members: CD9, CD37, CD53, CD63, CD81, CD82, and so forth.

Gene locus: 11p15.5.

Molecular mass (kd): 32, unreduced.

Distribution: Platelets, megakaryocytes, epithelial, and endothelial cells, Schwann cells, skeletal, smooth, and cardiac muscle ([2]). In the skin, it is expressed mostly in the basal cells of the epidermis. High levels of CD151 are detected in bile ducts, terminal bronchioles, and pancreatic intralobular ducts. CD151 is also localized in endosomal/lysosomal vesicles.

Function: CD151 associates with members of the ß1 and ß3 integrin family, as well as other members of the TM4 family ([3]). CD151 is involved in homotypic cell adhesions. Association with integrins and widespread expression in endothelia suggest that CD151 may be involved in adhesion events ([4]). Its presence in epithelia is restricted to the basal layers, suggesting that it may be involved in anchoring the cells to the basal lamina. Antibodies to CD151 induce platelet activation. Presence of high levels of CD151 on lung cancer cells is associated with poor prognosis.

CD152 (CTLA-4: CYTOTOXIC T LYMPHOCYTE–ASSOCIATED PROTEIN-4)

Structure: Disulfide-linked homodimer with a single Ig-like domain in the extracellular region of each polypeptide ([1]). Structurally, it is similar to CD28 and reacts with the same ligands, CD80 and CD86. The two genes are less than 150 kb apart, suggesting that they share a common ancestor. The cytoplasmic tail is short (36 amino acids) and contains two tyrosine-based motifs. It is 100% conserved between species, suggesting that this domain is important for function.

Gene locus: 2q33.

Molecular mass (kd): 33 reduced; 50 unreduced.

Distribution: Expressed on activated but not resting T lymphocytes. Ligation of CD28 strongly induces expression of CTLA-4. Even at the peak of its induction, most of CD152 is found intracellularly as a result of rapid internalization. One of the Tyr motifs (Y201) mediates internalization as a result of interaction with clathrin-associated adaptor complex, AP-2, which regulates endocytosis. The same motif associates with complex AP-1, which redirects excess of CD152 from Golgi to lysosomes for degradation, and when phosphorylated, serves as a docking site for signaling molecules.

Function: CTLA-4 inhibits T-cell responses ([2], [3], [4] and [5]). Blocking antibodies to CTLA-4 augments the immune response, enhances clearance of tumors and parasites, and exacerbates autoimmune disease activity. CTLA-4–deficient mice develop a massive lymphoproliferative disorder resulting in tissue destruction and death of the animals early in their life. The inhibitory effect of CTLA-4 results from multiple effects: (a) competition for B7 ligands (as a result of its higher affinity compared to CD28); (b) inhibition of production of cyclin D3, thus arresting progression through the cell cycle; (c) inhibition of IL-2 gene transcription (resulting from decreased accumulation of NF-AT in the nuclei); and (d) association with phosphatase SHP-2, which dephosphorylates TCR–CD28 activation complexes, thus blocking signal transduction. CTLA-4 plays a role in T-cell differentiation and predisposition toward Th2 development.

CD154 (CD40L)

Structure: CD154 is a member of the TNF SF. It is a type II transmembrane protein (NH_2 terminal inside the cell). It forms a trimer similar to TNF, and from its crystal structure, it is predicted that it binds three CD40 molecules ([1], [2] and [3]).

Gene locus: Xq26.

Molecular mass (kd): 33.

Distribution: CD154 is expressed on activated $CD4^+$ and $CD8^+$ T cells, monocytes, basophils, mast cells, eosinophils, and activated DCs.

Function: CD40/CD154 interactions regulate several aspects of the immune response, humoral and cell-mediated, by providing co-stimulatory signals: (a) it drives germinal center formation, B-cell proliferation, differentiation and Ig isotype switching; (b) it activates APC functions; (c) it stimulates T-cell priming and T-cell differentiation; (d) it stimulates cytokine production from monocytes (IL-1, TNF-a, IL-6, and IL-8), DCs, and macrophages (IL-12) ([4]); and (e) it activates NK cells. CD154 associates with two of the adaptor molecules known as *TRAFs*, TRAF-2 and TRAF-3. The former is critical for activation of NF-?B and the latter for isotype switching. CD40L is constitutively expressed by malignant B cells in lymphomas and on T and B cells in Hodgkin disease. CD40/CD40L interactions may provide survival signals to H-RS cells ([5]).

CD156 (ADAM-8: A DISINTEGRIN AND METALLOPROTEASE-8, MS2 HUMAN)

Structure: CD156 is a member of a large family of proteins (more than 30 members) known as *ADAM family* (*a d*isintegrin *a*nd *m*etalloprotease). It is a type I transmembrane protein with a long extracellular region consisting of five domains, which include a prometalloprotease domain, a metalloprotease domain, and a disintegrin domain ([1], [2]). The cytoplasmic region has an SH_3 domain (the SH_3 domain is involved in protein–protein interactions). It binds proline-rich protein sequences. The prometalloprotease domain must be removed by a protease for an active enzyme to be generated.

Gene locus: 10q26.3.

Molecular mass (kd): 60.

Distribution: Expressed on polymorphonuclear leukocytes and macrophages.

Function: The ADAM family of proteins performs several functions in a variety of cells and in several species. ADAMs 1 to 7 are expressed in reproductive organs and function in sperm-egg adhesion and fusion ([2]). ADAM-8 is involved in the degradation of vascular basement membrane. Through interactions of the disintegrin domain (competing with or binding to integrins), the ADAM proteins exert cell to cell and cell to matrix adhesion. It is important in PMN infiltration in areas of inflammation, and some members cleave and release important cell surface–bound molecules such as TNF-a (see CD156b), IL-6 receptors, Fas ligand, and so forth.

CD156B (ADAM-17, TACE: TUMOR NECROSIS FACTOR-a–CONVERTING ENZYME)

Structure: Transmembrane I protein, a structure similar to CD156.

Gene locus: 2p25.

Molecular mass (kd): 100 to 120.

Distribution: Expressed on all cells examined.

Function: CD156b is a Zn-dependent metalloprotease. It is essential for “shedding” from the cell surface of TNF-a and TGF-a or other important molecules ([1]). Enzymes of the ADAM family with “ectodomain shedding” properties of cell-surface molecules are known as *sheddases*. ADAM-17 participates in a great variety of normal and pathologic processes. It releases the growth hormone–binding protein, a circulating high-affinity binding protein generated by proteolysis of the extracellular domain of the GH receptor. It cleaves the extracellular region of Notch-1 receptor and plays an important role in activation of Notch pathway. Tumor necrosis factor-a–converting enzyme (and probably other members of the ADAM family) cleaves the amyloid precursor protein of Alzheimer disease and releases a large soluble form amyloid-B peptide, which aggregates and forms the amyloid plaques of the disease ([2]). Tumor necrosis factor-a–converting enzyme also cleaves normal or cellular prion (PrP^{c}) by its constitutive hydrolytic pathway and prevents the formation of the insoluble protease-resistant prion (PrP^{res}) resulting in neurodegenerative diseases ([3]). TACE mediates cleavage and shedding of fractalkine (CX3CL1) chemokine that functions as an adhesion molecule for leukocytes and chemoattractant in inflammatory reactions ([4]).

CD157 (BST-1)

Structure: CD157 is a single-chain GPI-anchored protein and is structurally and functionally similar to CD38.

Gene locus: 4p15.

Molecular mass (kd): 42 to 45.

Distribution: Expressed on B-cell progenitors before Ig gene rearrangements, as well as on T-cell progenitors. Also present on granulocytes, monocytes and macrophages, bone marrow stromal cells, endothelial cells, follicular DCs, and synovial cells from patients with rheumatoid arthritis.

Function: CD157 is a biofunctional ectoenzyme with two consecutive activities: (a) ADP-ribosyl cyclase, that is, it synthesizes cADP-ribose (cADPR) ([1]), and (b) cADPR hydrolase, (i.e., it converts cADPR to ADPR). As a cyclase, it splits NAD to nicotinamide and cADPR, which then is hydrolyzed to ADPR by the hydrolase activity. cADPR induces potent mobilization of Ca^{2+} from intracellular stores by two possible mechanisms: endocytosis of the ectoenzyme or channel formation ([2]). CD38 has also been detected intracellularly on ER and nuclear membranes. CD157 regulates pre–B cell growth and is down-regulated on mature B cells.

CD158

Structure: The CD158 contains 14 proteins, which, during the seventh HLDA workshop, were given a homogeneous CD nomenclature (i.e., CD158a through k and 158z). They belong to the KIRs. One family has two Ig-like domains in their extracellular region (KIR2D), and a second family has three (KIR3D). Each family is subdivided according to the length of its cytoplasmic tail: long (KIR2DL or KIR3DL) or short (KIR2DS) (see Chapter 17) ([1], [2]). The KIRDL members have two ITIMs in their cytoplasmic tail and functionally are inhibitory (i.e., CD158a or KIRDL1, and so forth). The KIRDS have no ITIM but have a positively charged amino acid (arginine or lysine) in their transmembrane domain, which is necessary to link to an adaptor with ITAM (DAP 12) for recruiting PTKs for activation.

Gene locus: 19q13.42.

Molecular mass (kd): Varies from 50 to 58, 70 or 140.

Distribution: NK cells and certain subpopulations of T cells.

Function: NK cells recognize HLA class I molecules and deliver signals that inhibit NK-cell function, avoiding killing normal cells. However, NK cells lyse targets that have lost some HLA molecules, as occurs with tumor cells or virus-infected cells. The ligand for CD158a is HLA-Cw4 and related alleles, whereas CD158b interacts with HLA-Cw3. Ligand binding to KIRD2L phosphorylates the ITIMs and recruits SHP-1 or SHP-2 tyrosine phosphatases, which initiate inhibitory signal cascade.

CD159A (NKG2A)

Structure: Type II transmembrane protein (NH_2 terminal intracellularly), which belongs to the C-lectin family of proteins ([1]). The NKG2 family binds proteins rather than sugars. NKG2A forms a covalently linked heterodimer with CD94. The cytoplasmic tail of NKG2A contains ITIMs, which recruit SHP-1 or SHP-2 phosphatases, and, as a result, the CD94/NKG2A receptor is inhibitory.

Gene locus: 12p13.2 to p12.3.

Molecular mass (kd): 48 (reduced); 70 (unreduced)

Distribution: The NKG2A is detected on NK cells and on some T cells, and the NKG2D is detected on NK cells, aß $^{+}$ and ?d T cells, and macrophages.

Function: The NKG2 proteins recognize nonclassical HLA class I molecules (i.e., HLA-E) ([2]). HLA-E binds peptides from leader sequences of classical HLA class I molecules. The NKG2C and E form heterodimers with CD94 but lack ITIMs and are activating. The NKG2D forms a homodimer and is also an activating receptor. Activating receptors have a charged amino acid in their transmembrane domain, which links them to adaptor proteins possessing ITAMs. NKG2D recognizes stress-induced MICA and MICB.

CD162 (PSGL-1: P-SELECTIN GLYCOPROTEIN LIGAND-1, PSGL)

Structure: CD162 is a disulfide-linked homodimer. The extracellular regions consist of a selectin-binding domain and 15 decameric repeats. PSGL-1 is extensively glycosylated with sialic acid and fructose containing O-linked glycans and sulfated on tyrosines. CD162 binds to P-selectin through the O-glycan attached to the threonine residue 16 of the mature protein but also to L- and E-selectin ([1]). All selectins bind to a tetrasaccharide known as *sialyl Lewis x* (sLe^{x}) and its isomer *sialyl Lewis a* (sLe^{a}). L- and P-selectin (but not E-) bind also to sulfated carbohydrates (i.e., heparan sulfate). A crucial role for the addition of the carbohydrates is played by two enzymes, a-2,3-sialyltransferase followed by an a-1-3-fucosyl transferase (Fuc T-VII) (see CD62 and Chapter 15).

Gene locus: Chromosome 12q24.

Molecular mass (kd): 250 to 160 unreduced; 120 reduced.

Distribution: Expressed on granulocytes, monocytes, most T cells, and some B cells. Some $CD34^{+}$ bone marrow cells are also positive. PSGL-1 is concentrated on the tips of microvilli, and PSGL-1 is down-regulated after leukocyte activation.

Function: It facilitates tethering and rolling of leukocytes, and when dimerized, it strengthens the bonds with P-selectin, which are important in shear flow ([2]). Binding of P-selectin to its ligand induces phosphorylation of signaling proteins such as the Ras MAPK pathway. It also stimulates IL-8 secretion, and so it further propagates the signaling cascade required for migration of leukocytes.

CD164 (MVC 24, MGC-24V)

Structure: It is a type I transmembrane protein of 178 amino acids, rich in serines and threonines (20%). The extracellular region contains two mucin domains (I and II) separated by a nonmucin cysteine-rich domain. At least 16% of the serines/threonines can serve for attachment of O-linked glycans. The carbohydrate component of the molecule (both O-linked and N-linked) constitutes 70% of the molecular mass of the mature protein. It is intriguing that CD164 has a cytokine-binding pocket. The intracellular region is short and hydrophilic and contains the YHTL motif of the type YXXF (letter code for amino acids, F, a hydrophobic residue). These motifs can be detected on the membrane proteins of endocytic vesicles. They bind the ? subunit of adaptor proteins involved in sorting proteins within transport vesicles. CD164 forms a homodimer of two disulfide-linked monomers.

Gene locus: 6q21.

Molecular mass (kd): 80 to 100.

Distribution: It is expressed on hematopoietic progenitors, which include clonogenic myeloid and erythroid cells, and more primitive precursors, generally $CD34^{+}$ $CD38^{-}$ strong ([1], [2]). It is also expressed on bone marrow stromal cells.

Function: CD164 belongs in the sialomucin adhesion receptor family, which includes CD34, CD162 (PSGL-1), CD43, GlyCAM, and so forth, with an adhesion receptor function. It also inhibits progression into cell cycle of primitive hematopoietic progenitors ($CD34^{+}/38^{-}$) ([1], [2]) and prevents development of myeloid and erythroid differentiated cells *in vitro* ([3]). Each of these functions is mediated by different glycosylated epitopes of the protein.

CD166 (ALCAM: ACTIVATED LEUKOCYTE CELL ADHESION MOLECULE, NEUROLIN, BEN)

Structure: Type I transmembrane protein, member of IgSF with five extracellular immunoglobin-like domains. Two V (*N*-terminal) and three C type. The cytoplasmic tail is short, but approximately 50% of its amino acids are positively charged residues. The CD166 binds to CD6 but is also involved in homophilic interactions. The molecule can be considered as consisting of two functional modules: *ligand binding*, comprising the V_1 domain, and *oligomerization module*, comprising the membrane-proximal C_2-C_3 domains. Both are needed for stable adhesion, although ligand binding in itself is independent of the C domains. The homophilic binding requires lateral homooligomerization through the C_1-C_2 domains.

Gene locus: 3q13.1.

Molecular mass (kd): 100 to 105.

Distribution: It is expressed on hematopoietic cells. On lymphocytes and monocytes, it is expressed only after polyclonal activation, and in the synovium of rheumatoid arthritis patients. It is also present on a subpopulation of $CD34^{+}$ bone marrow cells and stromal cells ([1]), metastasizing melanoma cells ([2]), neuronal cells, mesenchymal stem cells, and osteoblastic cells. It is detected in the endothelium of yolk sac and dorsal aorta but not in adult aorta.

Function: It is involved in various physiologic processes such as hematopoiesis, immune response, thymus development, vasculoangiogenesis, neural cell migration, osteogenesis, and so forth. CD166 is an adhesion molecule mediating interactions between identical or different cells through homophilic (CD166–CD166) or heterophilic (CD166–CD6) interactions ([3]–5). The adhesions are dynamically regulated through actin cytoskeleton, which is essential for clustering of the CD166 molecule. CD166 plays an important role in melanocytic tumor progression.

CD169 [SIALOADHESIN (SN), SIALIC ACID–BINDING IG-LIKE LECTIN-1 (SIGLEC-1)]

Structure: Type I transmembrane protein with a large extracellular region consisting of 17 Ig-like domains (one V at the NH_2-terminal and 16 C_2 domains) ([1]). It is a member of a family of proteins that bind sialic acid and containing ligands, specifically, the N-acetylneuraminic acid (Neu5Ac) portion of 3'-sialyllactose. The binding site is located in the V-domain (arginine 97) in the F strand of the ß sheet. Two groups of aromatic amino acids (tryptophan) are involved in hydrophobic interactions.

Gene locus: 20p13.

Molecular mass (kd): Approximately 200.

Distribution: Sn is expressed strongly on perifollicular macrophages in the spleen and sinusoidal and subcapsular macrophages in lymph nodes, as well as on stromal macrophages of bone marrow, and moderately on liver, gut, and lung macrophages. Inflammatory macrophages from rheumatoid synovium are strongly positive ([2]).

Function: The NH2 terminal V domain binds sialylated ligands, recognizing sialic acid in the a-2,3 glycosidic linkage of N- and O-glycans. Sn belongs to the Siglec family of sialic acid–binding lectins. Other members of the Siglec family are CD22 (Siglec-2) on B cells, CD33 (Siglec-3) on myeloid cells and monocytes, MAG (Siglec-4A) on Schwann cells and oligodendrocytes, Siglecs-5, -6, -7, -8, and -9 on various hematopoietic cells, and Siglec-10 on human DCs. Apart from Sn, the cytoplasmic regions of other Siglecs contain ITIMs and are involved in inhibitory functions (see CD33). Except for Sn, most of the other members are naturally masked (interacting with neighboring sialic acids) and are normally unmasked after cell activation or exposure to sialidases. Counter-receptors for Sn are the sialomucins, CD43 and CD162 (P-SGL-1) ([3]). The Sn from certain sources binds to the cysteine-rich domains of the mannose receptor. Macrophages interact through the Sn ligands on hematopoietic cells, mediating cell interactions important for hematopoiesis and their scavenging function. Neutrophils express high levels of Sn ligands. CD43 on T cells acts as counter-receptor for Sn, promoting cell–cell interactions. Sn binds strongly to autologous RBCs in a sialic acid–dependent manner. The reasons that RBCs escape adhesive interactions with the macrophages remain to be determined.

CD170 (SIGLEC-5)

During the seventh HLDA Workshop, CD170 was assigned to Siglec-5. The Siglec family, however, contains several members, and only five have been assigned a CD number: CD22, CD33, CD83, CD169, and CD170. The other members, Siglec-4a and -4b and Siglec-6 to -10, will likely be assigned their own numbers or be incorporated into one of the existing numbers (i.e., CD170 with a letter subscript: a, b, and so forth). In this section, Siglecs-5 to -10 are briefly summarized ([1]).

CD170 (Siglec-5) consists of four extracellular Ig-like domains, one V (NH_2-terminal) and three Cs. The V domain contains the sialic acid–binding site, with an Arg residue being essential, as for sialoadhesin (CD169). It expresses a high degree of homology with CD33 (subfamily CD33). However, Siglec-5 recognizes a2,3- and a2,6-linked sialic acids, in contrast to all other Siglecs, which bind either one but not both. The cytoplasmic tail contains two conserved tyrosines within potential ITIM sequences. All Siglec genes map to chromosome 19q13.41-43, closely linked to CD33. It is expressed at high levels on peripheral blood neutrophils (absent in immature stages of myeloid cells), on monocytes, and on B cells ([2]). The highly conserved ITIM-like motifs suggest that Siglec-5 may be involved in signaling as an inhibitory receptor, a member of the growing family of myeloid inhibitory receptors. These receptors are engaged with broadly expressed host-specific ligands and exert a protective effect by triggering inhibition of cytolytic functions of effector cells against the host.

Siglec-6 (OB-BP1)

Siglec-6 consists of three Ig-like domains, one NH_2-terminal V and two C_2. The cytoplasmic tail has two conserved tyrosines. The first tyrosine is within an ITIM, whereas the sequence of the second matches that found in SLAM, which is the docking site for SAP (see CD150). It is expressed in spleen cells, B cells, small intestine, and strongly in cyto- and syncytiotrophoblasts of the placenta. Siglec-6 selectively binds to sialyl-Tn (CD175s), a disaccharide formed by premature sialylation of N-acetylgalactosamine (see CD175). It is the only Siglec that binds a protein, leptin.

Siglec-7

Siglec-7 contains one V and two C_2 Ig-like domains in the extracellular region and two tyrosines in the cytoplasmic tail. It exhibits a high degree of homology with CD33, CD170, and Siglec-6 ([3]). It is expressed on granulocytes (low levels), monocytes (intermediate levels), NK cells, and $CD8^+$ T cells (high levels). It recognized the a2,3- or a2,6-glycosidic linkage. The gene is located on chromosome 19q13.41–43.

Siglec-8

Siglec-8 is expressed on eosinophils, the only Siglec family member so far to be identified on these cells ([4]).

Siglec-9

Siglec-9 contains three extracellular Ig-like domains (one V and two C_2). The cytoplasmic tail contains two tyrosines. Only one is within an ITIM. The sequence around the second tyrosine is similar to that on the SLAM (CD150) docking site for SAP. Siglec-9 recognizes sialic acid in either a2,3- or a2,6-glycosidic linkage to galactose and is expressed strongly on neutrophils and monocytes ([5]) and weakly on B cells, NK cells, and a subset of $CD8^+$ T cells.

Siglec-10

Siglec-10 is a transmembrane protein with five extracellular Ig-like domains (one V and four C_2) ([6]). The cytoplasmic tail contains three potential ITIMs. Siglec-10 is expressed on monocytes, B cells, NK cells, and eosinophils.

CD172a (SIRP-a: SIGNAL REGULATORY PROTEIN-a)

Structure: SIRP-a belongs to a new family of inhibitory/activating receptors. These molecules are also known as SHPS-1 (*s*rc *h*omology 2 domain–containing *p*hosphatase *s*ubstrate-1). The extracellular region of SIRP-a has three Ig-like domains, whereas the cytoplasmic region contains two ITIMs. There are approximately 15 members in this family in humans, which can be divided into two groups depending on the presence (SIRP-a) or absence (SIRP-ß) of the ITIMs. The ITIMs interact with protein tyrosine phosphatases SHP-1 and SHP-2 and thus are involved in negative regulation of signaling cascades. Members like SIRP-ß that lack ITIMs function as activating receptors.

Gene locus: 20p13.

Distribution: Strong expression on monocytes, granulocytes, DCs, myeloid progenitors, and stem cells ($CD34^+$ $CD117^+$), and on a subset of B cells. Expression is negative or reduced in AML and blasts of CML. It is also expressed in neuronal tissues.

Function: The ligand for SIRP-a is CD47, an IAP with multiple functions ([1]). Interaction of CD47 on T cells with SIRP-a on DCs inhibits maturation of DCs, decreases IFN-? production, and impairs development of Th1 cells. SIRP-a negatively regulates signaling by receptor of growth hormone ([2]), insulin, and EGF.

SIRP-ß is expressed in monocytes and DCs and lacks ITIM sequences. SIRP-ß associates with DAP-12, which contains an ITAM and acts as an activating myeloid receptor ([3]).

CD173 (BLOOD GROUP H TYPE 2)

Structure: Blood group antigens ABH derive from a common precursor that shows no ABH specificity. According to the terminal disaccharide structure of this precursor chain, they are distinguished into type 1 to type 6. Type 2 is the most common, with a structure of Galß$_1$?4GlcNAcß$_1$?X. The determinant *H* is generated by the enzyme H transferase that attaches a-fucose to carbon-2 of the terminal ß-galactose unit. H substrate is the immediate precursor of A and B antigens. Their specific determinants are generated by the addition of N-acetylgalactosamine (for A) or galactose (for B) to terminal galactose of substance H by appropriate transferase products of genes A or B. Differences between type 1 and type 2 ABH groups in the precursor substance are the linkage between galactose and N-acetylglucosamine (i.e., 1?4 for type 2 and 1?3 for type 1). In addition, in type 2, the terminal chain is perpendicular to the membrane, whereas in type 1, it is more or less parallel. Type 2 blood group H substance is CD173, the trisaccharide Fuca-1?2Galß$_1$?3GalNAc, which can be carried by a glycolipid or a glycoprotein ([1]). The gene (FUT-1) for the a1,2-fucosyltransferase, which generates the H determinant (H gene), is on chromosome 19q13.3.

Distribution: In addition to RBCs, H type 2 antigens are detected in hematopoietic $CD34^+$ cells carried by a 170-kd protein. It is also detected in pancreas, small intestine, mammary epithelium, and basal cell carcinomas. Peripheral blood lymphocytes are negative for CD173. Soluble forms of CD173 are present in plasma and urine.

CD174 (LEWIS Y)

Structure: The Lewis y (Le^y) determinant is based on type 2 chain core structure and carries two fucoses: one Fuca1?2 to the terminal galactose, and a second Fuca1?3 to the subterminal N-acetyl glucosamine (see also CD173). There are several genes regulating the expression of the antigens of the Lewis system, encoding fucosyl transferases. The Le^y antigen is generated by the transfer of a fucose to an already fucosylated H-substance intermediate. Le^y expression always depends on the secretor status of the individual.

Gene locus: The genes for the fucosyltransferases for the Le antigen system are located on chromosome 19p13.3 (FUT-3, FUT-5, and FUT-6), chromosome 11q21 (FUT-4), and 9q34.4 (FUT-7).

Distribution: Le^y glycolipids have been isolated from adenocarcinomas of the mammary glands and gastrointestinal tract, as well as from glycoproteins found in water-soluble substances of saliva, gastric mucosal mucins, and ovarian cyst fluids. They are expressed on granulocytes and small intestinal epithelial cells. Oligosaccharides carrying Le^y structure are present in milk and urine. Le^y has also been detected on *Helicobacter pylori*. This may represent a molecular mimicry phenomenon.

Function: The function of Le^y antibody is not well understood, but Le^x is involved in cell differentiation and embryonic development. Some members of the Le family are important ligands for adhesion molecules such as selectins. Adhesion of tumor cells on the endothelia involves Le members and therefore may play an important

role in hematogenous metastasis. Human epithelial tumors and leukemias have increased levels of transcripts from FUT-3 and FUT-6 genes.

CD175 (Tn)

Structure: The T antigen, also called *Thomsen-Friedenreich antigen*, appears *in vitro* in stored blood samples as a result of bacterial contamination and *in vivo* during infections. The T determinant is the disaccharide Galß1?3GalNAc. The Tn antigen is the precursor to T antigen, formed by the transfer of an a-GalNAc transferase of N-acetyl galactosamine to Ser or Thr of a protein (i.e., GalNAca1?O-Ser/Thr). The addition of a galactose to Tn antigen by a galactose-transferase generates the T antigen (i.e., Galß1?3GalNac-O-Ser/Thr). The T antigen is a common structure of glycoconjugates. In stored blood, it appears after bacterial contamination. It is also detected *in vivo* during infections with bacteria or viruses. Appearance of T antigen is caused by neuraminidases released by microorganisms and is known as the *T transformation*. T and Tn saccharides are carried by A and B glycophorins. A sialylated form of Tn (STn) also exists, formed by the addition of sialic acid to Tn determinant (i.e., Neu5Aca2?6GalNAc).

Distribution: Strong T-antigen expression is detected in malignant carcinomas of breast, stomach, and colon, teratocarcinomas, and acute leukemias ([1], [2]).

Function: T and Tn antigens represent precursors of biosynthetic pathways of glycoconjugates. Appearance of T antigens, Tn antigens, or both (T or Tn transformation) causes polyagglutination. The transformation usually is not accompanied by pathologic symptoms. However, leukopenia, thrombocytopenia, and hemolytic anemia have been observed. It has been suggested that Tn transformation may affect a hemopoietic stem cell because it affects not only red cells but also other blood cells. However, whereas the former (i.e., T) is acquired, the latter (i.e., Tn) is usually persistent and is believed to be due to a somatic mutation. These mutations affect genes involved in biosynthesis of glycoconjugates, altering the structure of red cell membranes. STn is one of the ligands for Siglec-6 (see CD170). Both T and Tn have been used as markers in malignancies. Detection of STn and Tn antigens on carcinoma cells or in the serum of patients indicates poor prognosis and distant metastases in colorectal, breast, and gastric cancers ([3]).

CD176 [T ANTIGEN, THOMSEN- FRIEDENREICH (TF) ANTIGEN]

Structure: The T or TF antigen (or epitope, glycotope) is generated from the addition, by a ß1?3 galactose transferase in the presence of a UDP-Gal, of a second galactose molecule to its precursor Tn (i.e., GalNAca1?O-Ser/Thr), forming the disaccharide: Galß1? 3GalNAca1?O-Ser/Thr (see CD175) ([1]). The T antigen generates the M or N histo-blood groups by the action of a-N-acetyl-neuraminic acid transferase.

Distribution: TF and its precursor Tn are accepted as tumor antigens, which are “cryptic” or “masked” in normal tissues, preventing their detection. The application of monoclonal antibodies (rather than lectins, which possess broader carbohydrate specificity) has permitted its detection in some normal tissues [i.e., pancreatic duct, apical membranes of renal distal and collecting tubules, salivary glands, stomach, and placenta (first and second trimester)]. T antigen has also been detected during the development of lungs and kidneys, placing it in the category of CEAs ([2]).

Function: Detection of the TF antigen has been used as a diagnostic and prognostic marker in various malignancies ([3], [4]). It has been suggested that it may serve as a target for immunotherapy. It mediates adhesion of malignant cells to vascular endothelium ([5]). However, others consider TF antigen as a differentiation-related antigen rather than a carcinoma-associated antigen.

CD178 [FAS LIGAND, CD95L, TUMOR NECROSIS FACTOR SUPERFAMILY-6 (TNFSF6)]

Structure: FasL is a cytokine and type II transmembrane protein that belongs to the TNF family. The NH_2-terminal cytoplasmic region is rich in proline, and the extracellular region has two cysteines in similar positions as TNF-a and TNF-ß with which FasL is highly homologous. The FasL is a homotrimer and is likely to have the same topology as TNF-a/TNF-ß.

Gene locus: 1q23.

Molecular mass (kd): 40.

Distribution: FasL is expressed primarily on activated T cells and nonactivated NK cells ([1]), as well as other cells and tissues such as neutrophils, astrocytes, microglia, mature erythroblasts, breast epithelia, placenta, and vascular endothelial cells. It is constitutively expressed on cells of immunologically privileged sites, such as stromal cells of retina and Sertoli cells of testis ([2], [3], [4], [5] and [6]). FasL is detected in a number of malignancies, including multiple myeloma and myeloid leukemias.

Function: After engagement of the TCR of a cytotoxic T cell, FasL appears on its surface (or is released in microvesicles) and reacts with Fas (CD95) on the target to bring about its demise by apoptosis ([7]). Expression of FasL on tumors and leukemias can induce death of T cells expressing Fas, considered as a tumor counterattack resulting in their escape from immune attack ([8]). Soluble FasL is elevated in patients with NK-cell (large granular lymphocyte) leukemia or NK lymphoma in patients with hemophagocytic syndrome, Diamond-Blackfan anemia, and aplastic anemia ([9]). Most of the patients with high levels of FasL are neutropenic because neutrophils are sensitive to FasL killing. FasL has been implicated in the negative control of erythroid differentiation. The gld inbred strain of mice have a spontaneous point mutation in the FasL gene (Ph273Leu) and suffer from an ALPS characterized by lymphadenopathy, splenomegaly, accumulation of $CD4^-/CD8^-$ (double-negative) T cells, and presence of high titers of autoantibodies.

CD179a (VPREB, VPREB1, IGVPB) AND CD179B (IGLL1, ?5, ?5 IMMUNOGLOBULIN OMEGA POLYPEPTIDE)

See also Chapter 16.

Structure: CD179a (or VpreB) and CD179b (or ?5) form the surrogate light (L) chain (SL) of the pre-BCR complex. The SL with the µ (IgM) heavy chain forms the pre-BCR. VpreB (CD179a) contains one V-like, and ?5 (CD179b) contains one C-like Ig domain. The VpreB lacks the sequence that corresponds to the J segment of the L-chain of mature B cells (ß7 strand), which is present in the ?5-chain. This ß strand in ?5 controls the folding of VpreB, the exit through the secretory pathway, and the assembly of SL by acting as an intramolecular chaperon ([1]). The SL chain is disulfide-linked to membrane-bound µ-chain to form the pre-BCR, which is associated with Iga (CD79a) and Igß (CD79b) heterodimer to form the pre-BCR complex.

Gene loci: 22q11.22 (CD179a) and 22q11.23 (CD179b).

Molecular mass (kd): CD179a, 16 to 18; CD197b, 22.

Distribution: Both proteins are expressed in the early stages of B-cell development and are detected on the surface of large and small pre-B cells.

Function: Pre-BCR complex interacts with several proteins on stromal cells (clusterin, matrix glycoprotein scl-1, and so forth) that promote survival, pre–B-cell proliferation, or both. Once the pre-BCR is formed, they cluster on lipid rafts, which promote activation of the PTK Lyn and phosphorylation of Igß-chain ([2]). This interaction leads to assembly of a number of signaling proteins in the raft essential for Ca^{2+} signaling, which leads to an orderly maturation of B cells, that is, turning off (a) genes of the Ig gene rearrangement machinery ensuring allelic exclusion and (b) the SL genes ([3]). Mutations of the genes of ?5 give rise to a syndrome similar to Bruton agammaglobulinemia ([4]). The availability of monoclonal antibodies for the VpreB-chain allows a more refined classification of B-ALL ([5]).

CD183 [$CXCR_3$, GPR9, CKR-L2, IP-10-R, MONOKINE INDUCED BY ?-Interferon Receptor (MIG-R)]

Structure: CD183 is a seven–transmembrane domain protein member of the G protein–coupled receptors. The extracellular domain consists of three extracellular loops, which bind the chemokine ligand. The intracellular region is composed of three loops. The C-terminus transduces the chemokine signal and regulates the

expression of the receptor. All chemokine receptors have a conserved amino acid sequence DRYLAIV in the second intracellular loop, which interacts with the G protein.

Gene locus: Xq13.

Molecular mass (kd): 40.

Distribution: CD183 is strongly expressed on activated/memory T cells but not in naïve T cells ([1]) and have a predilection for homing to inflammatory lesions. CD183 is also expressed by medullary thymocytes, DCs, plasmacytoid monocytes, eosinophils, and CD34 $^{+}$ hematopoietic progenitors activated by GM-CSF ([2]). CD183 is lacking on normal B cells but is expressed in all patients with B-CLL. In nonhematopoietic cells, CXCR $_3$ is detected on endothelial cells of small vessels of the skin, liver, and kidney, and on vessels of all lymphoid organs.

Function: There are three chemokines acting as ligands for CXCR $_3$: Mig (monokine induced by ?-IFN, CXCL-9); IP-10 (IFN-inducible protein 1b, CXCL-10); and I-TAC (inducible T-cell a-chemoattractant, CXCL-11). The activated Th1 type of cells strongly positive for CXCR $_3$ migrate to inflammation sites, such as rheumatoid joint, lesions of multiple sclerosis, sarcoidosis, hepatitis C, and autoimmune thyroids. CXCR $_3$ ligands secreted from alveolar macrophages in AIDS patients with alveolitis attract CD8 $^{+}$/CXCR $_3$ $^{+}$ T cells secreting IFN-? (consistent with Tc1 phenotype) ([3]). CXCR $_3$ expressed on endothelial cells of small vessels plays an important role in regulation of new blood vessel formation, which is fundamental for a variety of processes, such as wound healing and tumor growth. The ligands of CXCR $_3$ are angiostatic (i.e., oppose the angiogenic chemokines such as IL-8, GRO-a, and so forth) ([4]). Expression of CXCR $_3$ on endothelial cells is cell cycle–dependent, induced on activation, especially when they exhibit a high proliferative rate. CXCR $_3$ has also been detected on stellate hepatic cells and glomerular mesangial cells in culture, where ligands of CXCR $_3$ stimulate cell proliferation and up-regulate the expression of the receptor. These data suggest a role of CXCR $_3$ in tissue fibrosis.

CXCR $_3$ expression in B-CLL, but not in mantle cell lymphoma, is involved in chemotaxis of B cells ([5]) and may be used as a diagnostic marker ([6]). The intracellular signaling pathways after ligand binding to CXCR $_3$ involve phosphorylation of Src kinases and activation of PI3K and the Ras/ERK pathway ([7]). Continuous stimulation of CXCR $_3$ results in its own regulation as a result of rapid internalization induced primarily by the I-TAC ligand, and it occurs under physiologic settings.

CD184 (CXCR $_4$, FUSIN, LESTR, NPY3R, HM89)

Structure: CD184 is a seven–transmembrane domain protein linked to G protein. It has numerous Ser/Thr phosphorylation sites in the intracellular regions and cysteine residues in the NH $_2$-terminal region, likely forming disulfide bonds. Binding of its ligand requires the NH $_2$-terminus of the CXCR $_4$, whereas the activation is mediated by a distinct region of the second extracellular loop.

Gene locus: Chromosome 2q21.

Molecular mass (kd): 40.

Distribution: In contrast to other chemokine receptors, CXCR $_4$ is the only receptor expressed not only among hematopoietic cells but also widely on other tissue cells. It is detected on B and T cells, monocytes, neutrophils, platelets, macrophages, DCs, precursors of all lineages ([1]), endothelial and epithelial cells, and cells of nerve tissue.

Function: The only ligand of CXCR $_4$ is SDF-1, which was isolated from a bone marrow stromal cell line. Its gene has structural features considered characteristic of a “housekeeping” gene and is the only one among CXC chemokine genes to reside on chromosome 10, whereas all the others are on chromosome 4. CXCR $_4$ is involved in a wide variety of essential functions in embryogenesis, brain development, vascularization, hematopoiesis ([2], [3]), and cell migration. On binding, the ligand induces internalization of CXCR $_4$ and triggers a number of signaling pathways involving focal adhesion components and downstream diverse kinases ([4]). In hematopoiesis, CD184 mediates transendothelial migration of CD34 $^{+}$ stem cells and promotes B-cell lymphopoiesis and myelopoiesis in the bone marrow. In the thymus, SDF-1 is produced by epithelial cells, and its receptor is up-regulated on thymocytes by IL-7 to mediate their survival, expansion, and differentiation ([5], [6]). The CXCR $_4$/SDF-1 couple induces the development of new blood vessels, neuronal migration, and cerebellar development. CXCR $_4$ functions as a co-receptor for the T-cell–tropic HIV ([7]). The gp120 binds specifically to CXCR $_4$ of T cells. The binding site of gp120 differs from the site that permits the entry of the virus (“fusin” or co-receptor). Finally, CXCR $_4$ has been implicated in metastasis of breast ([8]) and prostatic carcinomas and migration of the myeloid and lymphoid leukemia ([9]).

CD195 (CCR5)

Structure: CD195 is a seven–transmembrane domain protein linked to G proteins. The conformation of the extracellular regions is maintained by two disulfide bonds, one linking the first and second extracellular loops, and a second linking the N-terminus and the third ECL. Conformational integrity is required for ligand binding and receptor activation. The second ECL is a major determinant for chemokine binding. CCR5 is the co-receptor for macrophage-tropic HIV-1. Sulfated tyrosines in the NH $_2$-terminal region of CCR5 interact with the HIV-1 gp120 envelope protein for the binding and entry of HIV ([1]). Other studies show that negatively charged and aromatic amino acids (some tyrosines being sulfated) are used for chemokine and HIV binding ([2]). For optimal CCR5 expression, a basic amino acid sequence and a cysteine cluster in the *C*-terminal intracellular region are required ([3]).

Gene locus: 3p21.

Distribution: CCR5 is expressed on activated (memory) cells, B cells, macrophages, and DCs as well as microglial cells. T cells collected from inflammatory sites and rheumatoid joints are predominantly (>80%) CCR5 $^{+}$. These cells are mostly CD45RO $^{+}$, a phenotype consistent with activated memory T cells. The CCR5 (and CXCR $_3$) may represent markers of inflammatory T cells, particularly of the Th1 type ([4]). Only small numbers of T cells within lymph nodes and peripheral blood are CCR5 $^{+}$.

Function: CCR5 is the receptor for several chemokines: MIP-1a (macrophage inflammatory protein-1a, CCL3), MIP-1ß (CCL4), RANTES (regulated on activation, normal T cell expressed and secreted, CCL5), MCP-2 (macrophage chemotactic protein 2, CCL8), and MCP-4 (CCL13). These chemokines and CCR5 play a major role in inflammatory responses ([5]). CCR5 is expressed primarily on Th1 cells that are involved in a number of inflammatory conditions, whereas virtually all T cells are CCR5 $^{+}$. Binding of the ligands (especially RANTES) results in phosphorylation of the CCR5 and association with JAK1 kinase, promoting the association of the STAT-6 transcriptional factor with CCR5. CCR5 is expressed on monocytes and immature DCs, which accounts for their capacity to extravasate and migrate into inflamed tissues. CCR5 is a major co-receptor for HIV-1 (macrophage-tropic on R5). Individuals lacking CCR5 because of homozygosity for the deletion mutant CCR5?32 (“knock-out”) allele show almost complete resistance to HIV infection.

CDW197 (CCR7)

Structure: A seven transmembrane domain–protein linked to G proteins.

Gene locus: 17q12-q21.2.

Distribution: CCR7 is strongly expressed on the vast majority of CD4 $^{+}$ T cells in the peripheral blood. In the lymphoid organs, CCR7 is detected on resting CD4 $^{+}$ and CD8 $^{+}$ T cells but usually not on activated T cells. Loss of CCR7 is usually accompanied by expression of the CCR5 receptor. T cells from skin, gut, lung, and liver are enriched in CCR7 $^{-}$ cells ([1]). CCR7 is expressed on mature DCs ([2]).

Function: There are two ligands for CCR7: (a) SLC, also known as TCA-4 (thymus-derived chemotactic agent 4), 6C kine, or exodus-2; and (b) ELC, also known as MIP-3ß or exodus-3. SLC and ELC are designated *CCL21* and *CCL19*, respectively. SLC is expressed by the cells of HEV, and binding to its receptor CCR7 arrests rolling T cells via activation of ß $_2$ integrin, which interacts with ICAM-1 around HEV (perivascular) ([3]). ELC, produced by cells in the paracortex, is transcytosed to the luminal surface of HEV and is detected in HEV vesicles and so cooperates with SLC for efficient T-cell homing through CCR7 ([4]). T cells, through ELC/CCR7 interactions, are retained in the paracortical area (see Chapter 14). The importance of CCR7 in lymphocyte homing was shown by CCR7 $^{-/-}$ mice, which are deficient in CCR7. These mice have increased numbers of T cells in peripheral blood, whereas the number of T cells in lymph nodes is reduced. A CCR7-independent homing pathway was recently shown with the use of FTY720, a novel immunosuppressant that induces marked reduction of T cells in blood ([5]). Treatment of CCR7-deficient mice with FTY720 accelerated T-cell homing and reduced the number of T cells in the blood. CCR7 is also important for the recruitment of antigen-loaded mature DCs to the paracortical areas, with the action of SCL expressed in the lymphatic endothelium. In this respect, CCR7 is crucial for establishing the functional microenvironments for cell interactions in the immune response. CCR7 mediates emigration of T cells from neonatal thymus. It is strongly expressed on H-RS cells, consistent with the interfollicular homing of these cells in classical Hodgkin disease, and mediates infiltration of lymphoid organs by leukemic cells in adult T-cell leukemia ([6], [7]).

CD204 (MACROPHAGE SCAVENGER RECEPTOR, MSR-A)

Structure: Transmembrane type II glycoprotein forming a trimer. The extracellular region (*C*-terminal) contains a cysteine-rich domain (scavenger receptor domain), a collagenlike domain, and an a-helical coiled-coil domain, important for the formation of the trimer. The collagenous domain mediates adhesions between the macrophage scavenger receptor (MSR-A) and denatured forms of type I and III collagens ([1]). Proximal to the membrane is a spacer, followed by the transmembrane region and the intracellular NH_2-terminal region.

Gene locus: 8p22.

Distribution: MSR is expressed on tissue macrophages and the high endothelial cells of postcapillary venules of lymph nodes.

Function: MSR-A belongs to a large family of scavenger receptors consisting of at least six classes. The best known are class A (I, II, III) and class B (CD36). MSR-A (type I and II) has broad ligand specificity ([2]). They bind oxidized, low-density lipoprotein, polyribonucleotides, sulfated polysaccharides, bacterial cell wall LPSs, ß-amyloid, and so forth. Their biologic activities include host defense (innate immunity), atherosclerosis (foam cell formation), cell–cell interaction, disorders of the nervous system, phagocytosis of apoptotic cells, and so forth. Macrophages adhere through MSR-A to basement membranes of vessels altered during aging by nonenzymatic glycation of the proteins [advanced glycation end products (AGE)]. Oxidized LDL is phagocytosed by macrophages and transformed to foam cells ([3], [4] and [5]). Because the ligands for MSR-A are altered endogenous or foreign molecules, the receptor's main function is the removal of unwanted or potentially dangerous products. Engagement by ligands of MSR-A induces release of inflammatory cytokines.

CD205 (DEC-205)

Structure: The extracellular region consists of an N-terminus cysteine-rich domain, FN type II domain followed by ten C-type lectin domains, one transmembrane, and a short intracellular region. The membrane-proximal region contains the sequence FSSVRY, which resembles the coated pit localization sequences. The distal or late endosome targeting is directed by the last three (EDE) amino acids of the cytosolic tail. This distal targeting sequence does not affect endocytosis or membrane recycling.

Gene locus: 2q24.

Molecular mass (kd): 205, reduced.

Distribution: DCs of all organs and Langerhans cells (skin), epithelial cells of thymic cortex, and intestinal villi. Low levels present on B cells, macrophages, T cells, bone marrow stromal cells, and epithelia of the lung.

Function: DEC-205 is an endocytic receptor used by DCs to deliver antigen captured from the extracellular space to late endosomes or lysosomes rich in MHC class II molecules ([1]). This contrasts with other receptors, such as the structurally homologous mannose receptor and the B-cell antigen receptor, which delivers captured antigens to the early endosomes. DEC-205 is a more efficient receptor, enhancing antigen presentation by 100-fold ([2]). A DEC-205 $^+$ cell with dendritic morphology that was isolated from nonparenchymal liver cells promotes differentiation of regulatory T cells (Tr) secreting IL-10, IFN-?, and TGF-ß but not IL-2 or IL-4 (i.e., a cytokine pattern consistent with Tr1-like cell) ([3]). These liver-derived DEC-205 $^+$ cells prolong cardiac allograft survival by an antigen-specific mechanism regulating donor-specific tolerance. The liver-derived DEC-205 $^+$ DCs home to the paracortical T-cell areas in the lymph node.

CD206 (MRC1, MACROPHAGE MANNOSE RECEPTOR, MMR)

Structure: The extracellular region has an *N*-terminal cysteine-rich domain, followed by a FN type II repeat and eight C-type lectin domains, which recognize carbohydrates (carbohydrate recognition domains, CRD) with high content of mannose and fructose ([1], [2]). In two other receptors (i.e., DEC-205 and phospholipase A_2 receptor), the C-lectin domains do not have conserved amino acids necessary for Ca^{2+}-dependent sugar. The *N*-terminal cysteine-rich and FN II domains increase the rigidity of the molecule, which has an extended conformation ([3]). Of the eight CDRs, CRD4 and CRD5 are the most crucial for mannose binding, yet they are in the middle of the receptor. This may be a more favorable place because, in the clathrin-coated pits filled with fluid, the mannose receptor is surrounded by ligands. CRD4 has a structure containing two a-helices and two small antiparallel ß sheets ([4]). CRDs 4, 5, and 7 are required for phagocytosis.

Gene locus: 10p13.

Molecular mass (kd): 166.

Distribution: CD206 is expressed mainly in macrophages and immature DCs, hepatic and lymphatic endothelial cells, mesangial cells, retinal pigmented epithelium, and inflammatory skin DCs (different from Langerhans cells). IFN-? decreases and IL-4 increases its expression.

Function: The main biologic functions of CD206 are (a) innate immunity: phagocytosis of bacteria, mycobacteria, yeast, and so forth ([5]); (b) adaptive immunity: antigen presentation; (c) removal of biologically active molecules from tissue fluids that may be potentially dangerous: myeloperoxidase, tissue plasminogen activator, lysosomal hydrolases; (d) removal of certain anterior pituitary hormones, such as lutropin and thyrotropin, clearing them from the circulation after they have acted on their targets; and (e) retinal epithelium: removal of proteins from outer segments of retinal rods.

CD208 (DC-LAMP: DENDRITIC CELL–LYSOSOME-ASSOCIATED MEMBRANE PROTEIN, LAMP-3)

Structure: Type I transmembrane protein member of the family of lysosome-associated membrane proteins (LAMP), which has two other members, LAMP-1 and LAMP-2, and is homologous to CD68. The extracellular region of LAMP-1 and LAMP-2 consists of two homologous lysosome-luminal domains separated by a proline-rich hinge region. In each of the domains, there are two conserved disulfide bonds and several O- and N-glycans, followed by the transmembrane and a short cytoplasmic region. The DC-LAMP has only one of these domains located in the membrane-proximal region. LAMP-1 and LAMP-2 carry large numbers of “sialyl-Le^X,” which serves as a ligand for E-selectin present on endothelial cells.

Gene locus: 3q26.3.

Molecular mass (kd): 70 to 90.

Distribution: Expressed only on interdigitating DCs located in the paracortical areas of the lymphoid organs and represents a specific marker for these cells. It is not expressed on immature DCs and first appears in the more mature stages, within acidic vesicles that intersect with endosomal components. These vesicles are rich in class II MHC molecules and HLA-DM ([1]). MIIC is considered to be the site for efficient peptide loading on class II molecules. DC-LAMP is not detected in Langerhans cells, considered to be immature DCs, or other dermal DCs. LAMP-1 and LAMP-2 are strongly expressed on malignant metastatic tumors ([2]).

Function: Probably involved in antigen presentation of class II MHC and remodeling of endosome/lysosome compartments by facilitating the translocation of class II to the cell surface. The genes of the LAMP molecules are on different chromosomes, LAMP-1 on 13q34, LAMP-2 on Xq24, and LAMP-3 (DC-LAMP) on 3q26, suggesting that they have diverged early in evolution and probably perform different functions.

CD209 (DC-SIGN: DENDRITIC CELL–SPECIFIC INTERCELLULAR ADHESION MOLECULE-3 GRABBING NONINTEGRIN)

Structure: Type II transmembrane protein (*N*-terminal cytoplasmic) that belongs to Ca^{2+}-dependent C-type lectins for ligand binding. The extracellular region consists of seven and a half tandem repeats of highly conserved 23–amino acid sequences. In the C-terminus, there is a globular carbohydrate recognition domain (CRD) consisting of twelve ß-strands, arranged in three ß sheets, and two a-helices, one on each end of the ß-sheet platform. There are two sites for Ca^{2+} binding on the CRD, but only site 1 is important for ligand binding ([1], [2] and [3]). The repeats in the extracellular region fold into a-helices and contribute to the formation of tetramers of DC-SIGN. The cytoplasmic tail contains dileucine motifs (which may mediate internalization) and an YXXY sequence, a site for tyrosine phosphorylation.

Gene locus: 19p13.3.

Molecular mass (kd): 44.

Distribution: Expressed on DCs in all mucosal surfaces and lymphoid tissues and in a small subset in peripheral blood. It is present in the fetus, which indicates that antigenic or environmental stimuli are not necessary for its expression ([4]). Macrophages are DC-SIGN negative, but IL-13 induces its expression. Expression of DC-SIGN on DCs is stimulated by IL-4 and negatively regulated by IFN-? and TGF-ß ([5]). DC-SIGN is detected in placenta and in the rectum throughout the entire thickness of the mucosa ([6], [7]).

Function: The ligands for DC-SIGN are ICAM-3 and the envelope HIV protein gp120. DC-SIGN binds with high affinity to highly complex mannose oligosaccharides in ICAM-3 and the HIV-gp120 but not to single mannose present at the end of oligosaccharide chains, as found in bacteria, which is the ligand for the macrophage mannose receptor. The clustering of CRD in the DC-SIGN tetramer facilitates binding to multiple high mannose–containing oligosaccharides spaced at appropriate distances, which provides specificity. DC-SIGN functions as a receptor for antigen presentation to naïve T cells, which strongly express ICAM-3, but not to activated T cells, which are weakly positive or negative for ICAM-3 ([8], [9]). Antigen internalized by DC-SIGN is targeted to late endosomes/lysosomes. DC-SIGN as receptor for gp120 protein of HIV binds multiple viral particles and enhances T-cell infection *in trans* ([10], [11]). How the virus escapes degradation after DC-SIGN–mediated internalization is not clear. The HIV protein Nef causes up-regulation of DC-SIGN to the cell surface, thus enhancing adhesion of several T cells around the DCs and facilitating virus transmission to T cells.

DC-SIGN R (DC-SIGN–related) is highly homologous to DC-SIGN protein (77%) with similar structure, specificity, and function. It has been detected in endothelial cells in approximately one-third of the capillaries in the terminal ileum. The same molecule has been found in liver on sinusoidal cells and in lymph nodes (called *L-SIGN*).

CD210 (IL-10 RECEPTOR)

Structure: The IL-10 receptor (IL-10R) consists of two subunits, IL-10R1 and IL-10R2. It belongs to a cytokine II receptor family related to the IFN-?R. The family includes tissue factor, the IFN-?, and IFN-a receptors ([1]).

The extracellular region of IL-10Ra (IL-10R1) consists of two FN type III domains followed by the transmembrane and the cytoplasmic regions. IL-10R1 binds with high affinity to IL-10.

IL10Rß (CRF2-4), originally described as *CRF2-4* (class II cytokine receptor family) or *orphan receptor* and a member of the IFN receptor family, is now shown to be an essential component of the IL-10R and is involved in signal transduction ([2]).

Gene locus: IL-10a, 11q23.3; IL-10ß, 21q22.1.

Molecular mass (kd): IL-10Ra, 90 to 120; IL-10Rß

Distribution: The IL-10a is expressed on most hemopoietic cells and in certain other tissues after induction. IL-10ß is detected in most cells and tissues.

Function: Binding of IL-10 to IL-10Ra initiates signaling through the IL-10Rß by engaging the Jak family of tyrosine kinases. Activation of the transcription factor STAT-3 is indispensable, but other pathways must be involved. The functions of IL-10 mediated by the IL-10R are multiple (i.e., inhibition of the production of inflammatory cytokines, IL-1, IL-6, IL-12, and TNF from macrophages and T cells). As well, it inhibits production of both CC and CXC chemokines implicated in inflammatory reactions. IL-10 has an important role in controlling systemic inflammatory responses, imposing some limits in the deployment of certain steps of innate or adaptive antipathogen responses, especially Th1 response by inhibition of INF-? production. IL-10 enhances Ig production and isotype switching and can be used in the treatment of certain immune deficiencies, such as common variable immunodeficiency and X-linked hyper IgM syndrome.

CD212 (IL-12 RECEPTOR-$ß_1$)

Structure: The IL-12R consists of two ß subunits, $ß_1$ (CD212) (high affinity) and $ß_2$ (low affinity) ([1], [2]). Both chains have a high degree of homology with the gp130 chain. The extracellular region of $ß_1$ consists of five FN III domains, followed by a transmembrane region and a short cytoplasmic tail. The $ß_2$ subunit is a transmembrane type I protein, and its cytoplasmic tail contains three tyrosines, suggesting that $ß_2$ is the signal-transducing component.

Gene locus: $ß_1$, 19p13.1.

Molecular mass (kd): $ß_1$, 100; $ß_2$, 130.

Distribution: It is expressed on activated $CD4^+$ and $CD8^+$ T cells and $CD56^+$ NK cells and macrophages. Expression of the $ß_2$ subunit is inhibited by IL-4 and induced by IFN-? (see below for significance). T cells from patients with Sézary syndrome with a heavy tumor burden do not express IL-12R under *in vitro* stimulation, indicating that treatment of these patients at a late stage of the disease with IL-12 will not be effective, although treatment is effective at an early stage of the disease ([3]).

Function: IL-12R mediates the functions of IL-12, which is a pleiotropic cytokine, and stimulates the production of several cytokines from T and NK cells (i.e., IFN-?, TNF-a, GM-CSF, IL-2, and so forth). The IL-12R$ß_2$-chain alone can transmit the IL-12 signals through the JAK2, Tyk 2 kinases, and STAT-4 protein. The most distinctive function of IL-12 is the regulation of Th1 versus Th2 differentiation. IL-12 stimulates early IFN-? production (from NK and T cells), which maintains IL-12R$ß_2$-chain expression and the IL-12 signal, promoting Th1 differentiation. In patients with tuberculoid but not lepromatous leprosy, the IL-12R$ß_2$ is up-regulated, and this

explains why only the former patients have resistance to *M. leprae* because of a strong Th1 response ([4]). IL-4 inhibits IL-12Rß $_2$, thus reducing or eliminating IL-12 signaling, and thus allows CD4-activated T cells to become Th2. Mutations in IL-12R have been associated with severe idiopathic mycobacterial and salmonella infections ([5]). IL-12 has also been implicated in the pathogenesis of experimental and human diseases (i.e., experimental allergic encephalomyelitis and multiple sclerosis). Synovial fluids from patients with rheumatoid arthritis have high levels of IL-12, and an abundance of IL-12–containing macrophages has been detected in colon biopsies from patients with inflammatory bowel disease. In patients with asthma (a Th2 response), IL-12 is reduced in bronchial biopsies.

CD213a $_1$ AND CD213a $_2$ (IL-13 RECEPTOR-a $_1$ AND -a $_2$)

Structure: The receptor complex that binds IL-13 consists of different polypeptide chains, and its composition varies with the type of cell ([1]). There are three (or probably four) combinations of a $_1$- and a $_2$-chains with the IL-4Ra and the ?c (common) chain: Type I consists of IL-13Ra $_1$/IL-13a $_2$ and IL-4Ra; type II consists of IL-13Ra $_1$ and IL-4Ra; and type III is similar to type II with the participation of the ?c-chain. The affinity of binding of IL-13 to IL-13Ra $_1$ is low, but for the IL-13Ra1/IL-4Ra complex, is high, and, furthermore, the complex transmits signals by IL-13 or IL-4 (i.e., it is both an IL-13 and IL-4 receptor). The IL-13Ra $_2$ binds IL-13 with high affinity but does not bind IL-4 ([2]).

- a $_1$-chain. In the extracellular region, the first two domains form the cytokine type I module (i.e., four conserved cysteines in the first and the WSXWS motif in the second). The cytoplasmic region contains a proline-rich domain proximal to the membrane and two tyrosines, which are involved in signal transduction ([3]).
- a $_2$-chain. The extracellular region has the cytokine I module, but the cytoplasmic region is short and is not involved in signal transduction. It contains a dileucine motif, which mediates internalization through clathrin pits, and a tyrosine motif, which plays a role in ligand binding ([4]).

Gene locus: IL-13Ra $_1$, Xq24l; IL-13Ra $_2$, Xq13.1.

Molecular mass (kd): IL-13Ra $_1$, 75; IL13Ra $_2$, 65.

Distribution: The a $_1$ receptor is widely expressed in human tissues (heart, brain, placenta, muscle, kidney, and so forth) and on hematopoietic and nonhematopoietic tumors. a $_1$ is detected on RS cells in Hodgkin lymphoma ([5], [6]). Transcripts of the a $_2$ receptor have been detected in B cells, basophils, eosinophils, monocytes, endothelial, and epithelial cells and in breast and pancreatic tumors.

Function: The IL-13R signal transduction involves the JAK-1, TYK-2, and STAT-6 pathway and mediates IL-13 and IL-4 functions. IL-13 promotes B-cell proliferation and enhances the antigen-presenting function of phagocytes. It blocks secretion of inflammatory cytokines from monocytes (IL-6, IL-8, IL-12, and so forth), and on endothelial cells, it increases expression of adhesion molecules (VCAM-1). IL-13 plays a central role in allergic asthma, inducing airway hyperresponsiveness, mucus overproduction, increase of IgE, and so forth ([7]).

CDW217 (IL-17 RECEPTOR)

Structure: The structure of IL-17R is not yet fully characterized ([1], [2]). Isolated cDNA from peripheral blood leukocytes indicates that it is a type I transmembrane protein, quite unrelated to receptors of other known families. Two IL-17Rs have been described: IL-17R and IL-17Rh1 (homolog). Another receptor, IL-17BR, is probably the same as IL-17Rh1. Several cysteines in the extracellular regions of IL-17R and IL-17Rh1 are conserved, as well as structures in the intracellular tail, suggesting that both use similar signaling pathways. The intracellular tail of IL-17R is long and physically connected to TRAF ([3]). IL-17RB has a much shorter intracytoplasmic tail than IL-17R.

Gene locus: IL-17R, 22q11.1; IL-17RB, 3p21.1; IL-17Rh1, 3p21.

Molecular mass (kd): IL-17R, 130 to 158.

Distribution: IL-17R is widely distributed in hematopoietic (NK cells, macrophages, neutrophils, and so forth) and nonhematopoietic cells (vascular endothelial cells, fibroblasts, synoviocytes, keratinocytes, epithelial cells, and so forth).

Function: IL-17R mediates the functions of IL-17 but binds IL-17A with low affinity. The IL-17 receptors promote secretion of IL-6, IL-8, IL-1, TNF-a, and nitric oxide and activate NF-?B (i.e., their main function is proinflammatory) ([4]).

IL-17 recruits neutrophils via IL-8 ([5]), which stimulates bronchial epithelial cells to release IL-6 and may play a role in severe exacerbations of asthma. IL-17 receptors are up-regulated in synovial endothelial cells and chondrocytes in patients with rheumatoid arthritis ([6]), and IL-17 is crucial for osteoclastic bone resorption ([7]).

IL-17 promotes cardiac and renal allograft rejection and through IL-8 may contribute to gastric inflammation in *Helicobacter* infection ([8]). IL-17R–deficient mice have a 100% mortality from pneumonia by *Klebsiella pneumoniae*, thus implicating a role of IL-17 in host defense. It is interesting to note that the locus 3p21 undergoes deletion in several cancers and frequently in CML.

CD231 (TALLA-1: T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA–ASSOCIATED ANTIGEN 1; TM4SF2: TRANSMEMBRANE 4 SUPERFAMILY MEMBER 2; MXS1: MEMBRANE COMPONENT X CHROMOSOME SURFACE MARKER 1)

Structure: Cell-surface glycoprotein member of the transmembrane 4 SF (tetraspanins). CD231 contains four transmembrane domains and two extracellular domains ([1]).

Gene locus: Xq11.

Molecular mass (kd): 150 (unreduced); 32 to 45 (reduced).

Distribution: Expression on cells of T lymphoblastic leukemia, neuroblastoma cells, and RNA detected in cerebral cortex and hippocampus.

Function: Unknown. The gene was found inactivated in X-linked mental retardation ([2]).

CD232 (VESP-R: VIRUS-ENCODED SEMAPHORIN PROTEIN RECEPTOR)

Structure: Type I transmembrane glycoprotein, member of the plexin family. The extracellular region contains (a) a subdomain highly similar to the semaphorin (“sema”) domain, thus shared by both receptor and ligand; (b) two plexin repeats (i.e., cysteine-rich sequences), also known as *MET-related sequences*, present in the oncoprotein MET (a receptor tyrosine kinase); (c) an IPT/TIG domain; and an Ig-like domain.

Gene locus: 12q23.3.

Molecular mass (kd): 220.

Distribution: T and B cells, monocytes, DCs, and brain, lung, placenta, heart, and so forth.

Function: Virus-encoded semaphorin protein receptor (VESPR) is a member of the family of proteins referred to as *plexins*, which are receptors for semaphorins, a

family with more than 20 members ([1], [2]). They are known for their role in neuronal, cardiac, and skeletal development, in the immune response (semaphorin CD100), and so forth but are expressed also by certain viruses. The plexins are now grouped into the A, B, C, and D subfamilies. VESPR is plexin C1, is induced by vaccinia virus, and is the receptor to the viral semaphorin A39R ([3]). The role of VESPR induction for pathogenesis of the infection is not clear. Recombinant A39R stimulated secretion of proinflammatory cytokines from monocytes and up-regulated ICAM-1 expression.

CD233 (BAND 3: ERYTHROCYTE MEMBRANE PROTEIN BAND 3; AE-1: ANION EXCHANGER 1; DIEGO BLOOD GROUP; SLC4A SOLUTE CARRIER FAMILY 4, ION EXCHANGER MEMBER 1)

Structure: Band 3 is the most abundant erythrocyte protein (25% of total membrane protein) and is present in the erythrocyte membrane at 1.2×10^6 copies per cell. It is a member of the anion exchanger gene family. It consists of two structurally and functionally distinct domains: an aminoterminal 43-kd cytoplasmic domain and a 55-kd membrane domain ([1], [2] and [3]). The amino terminal domain interacts with the cell cytoskeleton through ankyrin and binds protein 4-1 and 4-2, hemoglobin, enzymes of the glycolytic cycle, and the PTK p72 ^{SYK}. The carboxyterminal membrane domain spans the membrane 12 to 14 times, carries a number of blood group antigens, and especially the fourth segment is heavily glycosylated. The membrane domain is the anion exchanger ([4]). The extreme *C*-terminal tail ends intracellularly, and amino acids 886 to 890, LDADD, are the binding site of carbonic anhydrase II ([5]). Tyrosine-904, adjacent to the binding of CAII, is phosphorylated by p72 ^{SYK}, which seems to be triggered by a decrease in the cell volume. CD233 interacts with glycophorin A (GPA), which facilitates movement of CD233 to the cell surface. Band 3 exists as a dimer, but ankyrin binding forces a tetramer assembly.

Gene locus: 17q21-q22.

Molecular mass (kd): 95 to 110.

Distribution: Band 3 is expressed in the erythrocyte plasma membrane, and a truncated form (missing the first 65 residues) is detected in the basolateral membrane of the a-intercalated cells of the distal tubules and collecting ducts of the kidneys.

Function: CD233 is a major protein organizer center of the erythrocyte and, as a result, regulates several of its functions. Its major function is clearing from the body the CO_2 produced in the tissues. CO_2 enters the red cells, where it is hydrated by CAII to carbonic acid. The HCO_3^- diffuses out to the plasma in exchange for Cl^- (Hamburger shift). In the lungs, the opposite takes place, with HCO_3^- being transported back to the erythrocytes to be dehydrated by CAII. The bicarbonate transport by CD233/CAII across the membrane takes place within 50 milliseconds. The CD233/CAII complex functions as a HCO_3^- transport metabalon (i.e., an enzyme complex whose members channel metabolites from one site to the next) ([6]). In the kidneys, CD233 is involved in acid secretion and thus regulates pH homeostasis.

Other functions of CD233 include regulation of glucose metabolism, ion transport, maintenance of erythrocyte morphology, and removal of senescent cells ([7]).

Some mutations, such as amino acid substitutions, affect the overall folding of CD233 (i.e., band 3 Tuscaloosa, P327R), which is essential for the secondary structure of the erythrocyte, whereas other substitutions (i.e., band 3 Memphis, K56E) cause reduction in anion transport. Mutations or total loss of CD233 in humans leads to hereditary spherocytosis and renal tubular acidosis. Other mutations cause Southeast Asian ovalocytosis as a result of tight binding to ankyrin and increased erythrocyte rigidity, which resists invasion by malaria parasites ([8]). Ovalocytosis is asymptomatic and results from deletion of nine amino acids in the boundary between the cytoplasmic region and the first transmembrane segment. This causes entanglement of the skeletal network from inhibition of normal spectrin unwinding ([9]). One human is known with lack of CD233 who has severe anemia and nephrocalcinosis ([10]). Other mutations result in the Diego blood group system. The most prevalent Diego antigens (from approximately 18) are Di^b and Di^a.

CD234 (FY-GLYCOPROTEIN, DUFFY ANTIGEN, DARC: DUFFY ANTIGEN RECEPTOR FOR CHEMOKINES)

Structure: The Duffy antigen is a seven-transmembrane molecule that is a receptor for certain chemokines and malarial parasites. The aminoterminal end is extracellular (approximately 62 residues), contains two to three glycosylation sites, and is rich in acidic amino acid residues containing the blood groups Fy^a and Fy^b. The molecule has three extracellular loops with cysteine residues, three intracellular loops, and ends with the *C*-terminal cytoplasmic tail (28 residues), composed with approximately 50% serine and threonine residues, which are possibly targets for phosphorylation ([1]).

Gene locus: 1q21-q22.

Molecular mass (kd): 35.

Distribution: Erythroid cells, postcapillary venule endothelium, endothelial cells of red pulp spleen, and bone marrow sinusoids are main sites of CD234 expression. It is detected in the Purkinje neurons of the cerebellum and on neurons in diverse regions of the brain and spinal cord (i.e., hippocampus, dental nucleus, pontine nuclei, paraventricular nucleus, anterior horn, anteromediolateral cell column, and Clark column). Neurons that express CD234 are projection neurons or connecting neurons in different regions.

Function: CD234 binds human malarial parasite *Plasmodium vivax* and the simian parasite *Plasmodium knowlesi*. It also binds to members of the CXC chemokine family (i.e., IL-8, melanoma growth-stimulating activity, and neutrophil-activating polypeptide-2), and CC chemokine family members, MPC-1 and RANTES ([2]). CD234 is not coupled to trimeric G proteins, and ligand binding does not trigger intracellular signaling. As a result, it has been suggested that it should not be considered as a receptor but only as a binding protein: Duffy antigen chemokine-binding protein.

Ligands for CD234 on the malarial parasite are known as *erythrocyte-binding proteins*. The binding is mediated by the *N*-terminal cysteine-rich region II, which is conserved in these proteins, and referred to as *Duffy binding–like domain* after the *P. vivax* Duffy-binding protein ([3], [4]). Binding to CD234 is required for an irreversible junction between the merozoites and erythrocytes and is followed by the entry of the parasite into the Duffy-positive erythrocyte ([5]). The early steps of the Duffy binding–like domain ligand interaction with CD234 involve attachment, apical reorientation, and junction formation. In *P. falciparum*, a Duffy binding–like domain mediates adherence to multiple host receptors, including PECAM-1/CD31, CD36, and so forth, contributing to the virulence of this parasite ([6]). CD234 may play a role in angiogenesis in response to MIP-2 chemokine. The role of CD234 in the function of nervous and immune systems remains to be elucidated.

CD235a (GLYCOPHORIN A), CD235b (GLYCOPHORIN B), CD235ab (GLYCOPHORIN A/B, CROSS-REACTIVE MABS)

Structure: GPA and glycophorin B (GPB) are sialoglycoproteins encoded by two closely linked genes, GYPA and GYPB, respectively. A third gene, GYPE, encodes glycophorin E. Some of the structural features of these proteins are listed in the table below ([1]). Glycophorins A and B determine the serologic groups M and N, depending on the amino acids at positions 1 and 5 (see table below) ([2], [3] and [4]).

	Molecular					Serology			
	Gene Exons	No. of Residues	kd	No. of Mole- cules/ RBCs × 10^5	CHO (%)	M	N	S	s
GPA	7	131	37	50–90	60	S-1; G-5	L-1; E-5	—	—
GPB	5	72	24	0.8–3.0	50	—	Weak	M29	T29

GPE	4	59		20	—		—	S-1; G-5	—	—	—

CHO, chinese hamster ovary; GP, glycophorin; RBC, red blood cell.

Variants of these molecules arise from crossover between introns 3 of GYPA and GYPB, gene replacement events, or from deletions or alterations in the glycans attached to threonine or serine. Complete deletions of the genes result in lack of GPA or GPB. When MN group is not detected, the phenotype is known as En(a $^{-}$) ([5]).

- GPA: The extracellular region is heavily glycosylated, and although GPA constitutes 1.6% of the protein mass of the red cell, it provides approximately 67% of the neuraminic acid content. It contains only one N-linked tetrasaccharide at asparagine –26, whereas the rest are O-linked (serine or threonine). The intracellular region (residues 96 to 131) has a high content of acid amino acids and prolines.
- GPB: Highly homologous to GPA-group N with identical sequences in the first part of the extracellular region. It lacks N-linked carbohydrate. Cytoplasmic region is eight amino acids long.

Gene locus: The three genes are tandemly located (5'-GYPA-GYPB-BYPE-3') on chromosome 4q28-31.

Distribution: Red cells and red cell precursors.

Function: The morphology and other functions of the red cells in individuals with deficiency of GPA and GPB are normal.

Red cells with the EN(a $^{-}$) phenotype are resistant to *P. falciparum* malaria.

CD236 (GLYCOPHORIN C/D) AND CD236R (GLYCOPHORIN C)

Structure: Glycophorin C (GPC) is encoded by a gene, GYPC, in chromosome 2. The same gene encodes a truncated form, which is glycophorin D (GPD). The GPC protein has 128 amino acids (14 kd). Glycosylation, however, generates a posttranslational 32-kd protein. The GPD is shorter by 22 residues at the N-terminus. The GPC or GPD defines the Gerbich blood group antigens, which are Ge:1, Ge:2, Ge:3, and Ge:4 ([1], [2] and [3]). The most common phenotype expresses all four antigens, but some people lack one or more of these determinants as a result of deletions of one or more exons. In some individuals with the Leach phenotype (Ge1 $^{-}$2 $^{-}$3 $^{-}$4 $^{-}$), both GPC and GPD are not expressed ([4]). Lack of expression results from deletions of exons 3 and 4 which generate proteins without the transmembrane region. In another case, DNA sequence alterations resulted in frameshift and a premature stop codon formation, preventing expression of the aberrant protein. Other variants [i.e., Yussef (Yus) type (Ge1 $^{-}$2 $^{-}$3 $^{+}$4 $^{+}$) or Gerbich (Ge) type (Ge1 $^{-}$2 $^{-}$3 $^{-}$4 $^{+}$)], result from deletions of exons 2 or 3, respectively, generating a single protein expressed on the cell membrane with truncated extracellular regions. In the Ge and Yus phenotypes, GPD is not produced.

Gene locus: 2q14-21.

Molecular mass (kd): GPC, 32; GPD, 23.

Function: GPC is a minor component of red cell membrane (approximately 4% of the membrane sialoglycoproteins). Individuals with the Leach phenotype have elliptocytosis ([4]), suggesting that GPC and GPD contribute to the maintenance of the shape of red cells. GPC deficiency leads to deficiency of protein 4.1 and disruption of the junctional complexes, which weakens membrane deformability and stability.

CD238 (KELL BLOOD GROUP)

Structure and Function: Type II transmembrane protein, member of the family of zinc metalloglycoproteins with neutral endopeptidase activity. Other members include neutral endopeptidase EC.3.4.24.11 [common acute lymphoid leukemia antigen (CALLA-CD10)], endothelin-converting enzyme-2 and the PEX gene product for the M13 subfamily of neutral endopeptidases (neprilysin family). The homology of Kell and CALLA is most striking in the segment preceding the active catalytic site. The *C*-terminal extracellular region with 665 amino acids contains 15 cysteines and the transmembrane one. The intracellular *N*-terminal consists of 47 amino acids with the first one being blocked, suggesting that it is pyroglutamic acid.

All 23 Kell antigens are located on the same Kell protein encoded by the KEL gene, with point mutations accounting for the polymorphism ([1], [2]). For example, K1 phenotype is due to a C to T substitution in exon 6 that predicts a change T193M. This change prevents N-glycosylation in one of the five consensus glycosylation sites. In the Kp(a+) phenotype, there is weakened expression of Kell antigens.

This is due to a point mutation (R281W), which causes retention of Kell protein, in the pre-Golgi compartment and thus reduction of its expression on the cell surface ([3]). Lack of Kell protein is known as *Ko* or *Knull phenotype* ([4], [5]). Several different molecular defects have been identified. A mutation (G to A) in intron 3 causes aberrant splicing and a transcript without exon 3. Exon 3 encodes the transmembrane domain of Kell protein and thus abolishes the translation of the *C*-terminal segment in which all Kell antigens are located. The extracellular region displays two heptad arrays of leucine zipper motifs (starting amino acids 583 and 590) involved in protein–protein interactions, and several zinc-binding sites are present. The consensus sequence HEXXH is found in endopeptidases and is mandatory for catalytic activity.

The Kell protein is probably present as an oligomer and is also associated by a disulfide bond with the XK protein (Kell-72 to XK347) ([6]). The XK protein, which carries the Kx antigen, is a 37-kd polypeptide that spans the red cell membrane ten times and has structural characteristics of a membrane transporter. The XK protein is absent in patients with the McLeod syndrome, which is associated also with a depression of all Kell antigens ([7], [8]). In the McLeod phenotype, there is absence of the K_X ubiquitous erythrocyte antigen and decrease of the Kell antigen, resulting from mutations, some of them disrupting GT sequences present at RNA splice sites, as well as within exon 3 (i.e., the 746C > G mutations encoding the substitution R222G) ([9]). In the Ko phenotype, the XK protein is increased. The gene for XK protein is located in X chromosome. The McLeod syndrome locus is closely linked to loci that are defective in chronic granulomatous disease and muscular dystrophy of the Duchenne type, and individuals with the McLeod phenotype express various combinations with some features from these syndromes. They also have mild hemolytic anemia and acanthocytic red cells. Kell protein functions as an endopeptidase and shares substrates with the endothelin-converting enzymes ([10]). Kell has a narrow endopeptidase activity because it cleaves only big endothelin-3 (ET-3) to yield ET-3. ET-3 is a potent bioactive peptide, which maintains vascular tone and has multiple other biologic roles. The allele for the Kell protein (K) is known as *Cellano (k)*. This polymorphism is due to a point mutation resulting in substitution of M193T, which converts K to k. The Kell protein is second in importance after RLD as an immunogen in hemolytic disease of the newborn.

Gene locus: 7q33-35.

Molecular mass (kd): 93.

Distribution: Expressed primarily in red cells but also in myeloid progenitors, testis, and weakly in other tissues ([11]).

CD239 (B-CAM: B-CELL ADHESION MOLECULE, LUTHERAN BLOOD GROUP)

Structure: B-cell adhesion molecule (B-CAM) is a transmembrane type I glycoprotein. The extracellular region contains (a) Ig-like domains, linked by disulfide bonds, which, starting from N-terminus, are two V type and three C_2 type; and (b) consensus motifs for binding to integrins ([1]). The intracellular domain is short (59 residues) and has consensus motifs for Src SH_3-domain binding. These features suggest that B-CAM possibly functions as a receptor and signal transduction molecule. B-CAM is encoded by the same gene that encodes the Luth-eran (Lu) blood group antigens ([2]). B-CAM and Lu antigens derive from alternatively spliced transcripts of the same gene on chromosome 19q13.2. B-CAM lacks the majority of the cytoplasmic tail of Lu glycoprotein. Lu gene is organized into 15 exons, and

alternative splicing of exon 13 generates two transcript splice forms: a 2.5-kb (short cytoplasmic tail, B-CAM) and a 4.0-kb (long cytoplasmic tail, Lu glycoproteins). Antibodies generated against the Lu or B-CAM proteins react with both proteins, which is indicative that both antigenic determinants are present on the same molecule. Lu glycoproteins carry the same Ig-like domains in the extracellular region as B-CAM. The Lu glycoproteins' polymorphism is due to substitution mutations: R77H (i.e., Lu ^{b} or Lu2?Lu ^{d} or Lu1) in domain 1 ([3]). There are approximately 18 antigens in the Lu blood group system, and at least one Lu antigen is located in each Ig-like domain ([4]).

Gene locus: 19q13.2-13.3.

Molecular mass (kd): 85.

Distribution: B-CAM is widely expressed in normal tissues and highly expressed in ovarian and epithelial carcinomas. B-CAM is closely related to MUC18, an antigen whose expression in melanomas correlated with tumor progression ([5]). Lu glycoproteins are expressed in erythrocytes.

Function: B-CAM/Lu proteins are receptors for the extracellular matrix protein laminin ([6]). Lu glycoproteins are intercellular adhesion molecules and may contribute to vasoocclusion in sickle cell disease. Sickle cells bind to laminin isoforms containing the a5-chain, which are present in the subendothelium and bone marrow sinusoids.

CD240CE (Rh30CE); CD240D (Rh30D); CD240 DCE (Rh30D/CE CROSS-REACTIVE MABS); CD241 RhAG

Structure: The Rh antigens are encoded by two closely linked genes, the RHD and RHCE, encoding the RhD and RhCE (also known as RhCcEe) 33-kd proteins, respectively, which are highly homologous (90% amino acid identity) ([1], [2]). A third polypeptide, known as *Rh-associated glycoprotein* (RhAG) (synonym, Rh50), is encoded by a third gene *RHAG* (synonym, RH50) ([3], [4]). RhAG is 36% homologous to RhD and RhCE and does not carry serologically detectable Rh antigens but is essential for the expression of the other two on the cell surface ([5], [6], [7] and [8]). The predicted transmembrane topologies of the Rh proteins indicate that all three span the cell membrane 12 times, with only short loops connecting the transmembrane sections. Thus, the bulk of the proteins is “hidden” within the lipid bilayer. Both N- and C-termini are located in the cytoplasm. The Rh system is the most complex and polymorphic, compared to other blood group systems, with 50 different antigens so far described. The majority of the alleles originate from exon exchange or gene conversion. The D antigen consists of a collection of conformational epitopes over the entire RhD protein that defines the Rh $^{+}$ individuals (85% of the population). The D epitopes depend on residues located on extracellular loops 3, 4, and 6. In Rh $^{-}$ people, the RHD gene is not expressed. The weak $^{-}$D (D ^{u}) phenotype never induces antibodies in pregnancy. Amino acid substitutions have been detected in the intracellular and transmembranous regions.

The C and c alleles differ in three positions in exon 2, whereas the E/e dimorphism is located in the fourth extracellular loop. Amino acids 103 and 226 are crucial for C/c and E/e antigenicities, respectively ([9]).

The RhD and RhCE polypeptides are modified posttranslationally with the addition of palmitylate to free sulfhydryls on cysteine residues.

Two Rh-deficiency phenotypes exist, *Rh null* (amorph type, Rh-deficiency syndrome) due to silent alleles and *Rh mod* due to the presence of a suppressor gene, which is a mutant allele of the RHAG gene, impairing the synthesis of the RhAG glycoprotein ([10]). The Rh-null individuals not only lack RhD but are deficient in other proteins, Landsteiner-Wiener (LW), Duffy antigen, and CD47.

The Rh proteins are associated with other membrane proteins (i.e., glycophorin, LW protein, Duffy antigen, CD47, and RhAG).

The RhAG gene resembles the Rh genes, expressed only on erythroid cells. The RhAG protein has 12 membrane-spanning domains and directly interacts with the Rh proteins. All these proteins form a cluster, with the Rh proteins important for the integrity of the red cell membrane. The core of this complex is a tetramer made of two Rh proteins and two RhAG proteins.

Gene locus: RHD/RHCE, 1p36.2-34.1; RHAG, 6p21.1-p11.

Molecular mass (kd): D, 33; CE, 33; RhAG: 45–100.

Distribution: Expressed on cells of the erythroid series with increasing density during differentiation.

Function: Rh antigens are clinically the second most important of all blood groups, second only to ABO. The D antigen is highly immunogenic, and Rh incompatibility is a major cause of hemolytic disease of the newborn, which triggered the discovery of this blood group in 1939. In Rh deficiency, the individual has stomatocytosis, spherocytosis, increased osmotic fragility, altered phospholipid asymmetry, and mild hemolytic anemia. On the basis of their structure, the Rh proteins were believed to perform a transporter function ([11], [12] and [13]). RhAG shared homology with ammonium transporters in microorganisms.

It has now been conclusively demonstrated that RhAG as well as an Rh homolog, RhCG (synonym, RhGK), which is expressed only in kidney and testis, function as ammonium transporters ([14], [15]). The RhCG protein is a 58-kd membrane glycoprotein, and its gene contains 11 exons. The RhCG is the first nonerythroid Rh protein with similar membrane topology (i.e., spans the membrane 12 times).

CD242 [ICAM-4: INTERCELLULAR ADHESION MOLECULE-4, LANDSTEINER-WIENER (LW) BLOOD GROUP]

Structure: Type I transmembrane protein, with two Ig-like domains in the extracellular region, which contains four N-glycosylation sites and six cysteines. Two alleles, Lw ^{a} and Lw ^{b}, differ in amino acid 70, Gln versus Arg, respectively.

Gene locus: 19p13.3.

Molecular mass (kd): 42.

Distribution: Red cells.

Function: The LW blood group is ICAM-4 ([1]). Like the other ICAM molecules, LW binds to LFA-1 and mediates adhesion. Its expression depends on the expression of the Rh proteins ([2]). In Rh-null individuals, LW proteins are not detected.

CD243 (MDR-1: MULTIDRUG RESISTANCE-1, P-GLYCOPROTEIN)

Structure: P-glycoprotein (P-gp) consists of 1280 amino acids and belongs to the SF of ATP-binding cassette transporters ([1], [2], [3] and [4]). This SF is divided into seven subfamilies.

Multidrug resistance-1 or P-gp belongs to the multidrug resistance–TAP subfamily, and it consists of two structurally homologous halves, each with six transmembrane domains, one ATP-binding site, and the highly conserved “Walker A” and “Walker B” motifs. The two halves are linked by a flexible linker peptide. Both N- and C-termini are located inside the cell. There are three glycosylation sites in the first exoloop and four phosphorylation sites in the intracellular region.

Deletion of the linker peptide results in a nonfunctional protein, although it is still expressed in the membrane ([5]). Both nucleotide-binding sites are also essential for the function of the protein. The drug-binding site is within or near the transmembrane segments 5, 6 and 11, 12 and the extracellular loops connecting them.

As seen from above the cell surface (2.5 nm resolution by electron microscopy), P-gp is a cylinder with a central aqueous pore approximately 5 nm in diameter, which is open to the extracellular space but closed at the cytoplasmic face of the membrane ([6]). Two lobes of approximately 3 nm each are exposed at the cytoplasmic face of the membrane corresponding to the nucleotide-binding domains.

Gene locus: 7q21.1.

Molecular mass (kd): 170.

Distribution: Ubiquitous.

Function: P-gp is an active transporter with broad specificity for hydrophobic compounds. P-gp is best known for its role in the development of resistance to multiple cytotoxic drugs in cancer cells, which requires ATP hydrolysis ([7], [8]). There are two independent ATP hydrolysis events in a single catalytic cycle of P-gp. Binding of the drug and ATP is followed by the first hydrolysis event, which is accompanied by a conformational change bringing release of the substrate and ADP. This allows a second ATP binding and hydrolysis event, which returns the molecule to its original state for another ligand and ATP binding.

Various models have been suggested for the action of P-gp. Experimental evidence supports the “drug pump” of the “flippase” model (i.e., substrate is “flipped” from the inner to the outer membrane leaflet).

P-gp is probably important for its physiologic role in excretion of xenobiotics. Suitable for this role is its location on the mucosal surfaces of jejunum, ileum, and colon, and in the brush border and biliary face of proximal tubule cells and hepatocytes, respectively. P-gp may also play a role in forming the blood–brain barrier because it is located in the luminal surface of the capillary endothelial cells in the brain. P-gp can be seen to serve as a barrier for the entry of toxic compounds into the body and to protect cells from toxic substances that have left the circulation to enter the interstitial space. P-gp was shown recently to limit oral absorption and brain entry of protease inhibitors in HIV-1 patients ([9]).

Drug resistance development in hematologic malignancies is associated with increased expression of P-gp or other multidrug resistance genes ([10]). Reversal of the resistance may be achieved by blocking P-gp–mediated drug efflux with “modulators” such as verapamil, which inhibits the transport function without interrupting the catalytic function, and cyclosporin A, which inhibits transport by interfering with both substrate recognition and ATP hydrolysis.

CD244 (2B4, NAIL: NATURAL KILLER CELL ACTIVATION–INDUCING LIGAND)

Structure: CD244 belongs to the CD2 subset of the IgSF because of the homology of its extracellular region [other members are CD2, CD48, CD58, CD84, CD229 (Ly9), and CD150 (SLAM)]. The extracellular region contains one V and one C_2 domain, distal and proximal to the membrane, respectively ([1]). The C_2 domain has two conserved cysteines forming a disulfide bond. The cytoplasmic region contains four novel tyrosine-containing motifs (TxYxxV/I), which are similar to the ITIM. The CD244 gene contains nine exons; five of them encode the cytoplasmic region, and the remainder encodes the rest of the molecule. Differential exon usage leads to splice variants of the CD244, varying in the extracellular region, which has eight potential N-glycosylation sites.

Gene locus: 1q22.

Molecular mass (kd): 70.

Distribution: CD244 is expressed in NK cells, approximately 80% of $CD8^+$ T cells, 75% of ?d T cells, basophils, and monocytes.

Function: CD244 is the high-affinity receptor for CD48 ([2], [3]) and was originally identified as an activating receptor of NK cells ([4]). CD244 ligated by CD48 leads to rapid CD244 phosphorylation and enhances lysis of targets by NK cells and the release of cytokines. CD244 associates with several signaling molecules, such as the tyrosine phosphatase SHP-2 ([5]) (in NK cells), but in other cell types, CD244 binds SHP-1. The novel tyrosine motif is the target for phosphorylation by Lck, which follows linkage to LAT and signal transduction with similar pathways as the TCR (i.e., Ras, Raf, ERK, and so forth), leading to regulation of lytic function and cytokine production ([6]). SAP contains one SH_2 domain, and CD244 recruits SAP to its novel tyrosine-based motif.

In patients with X-linked lymphoproliferative disease due to a defect in SAP ([7], [8]), the interaction of CD244 with CD48 inhibits NK-cell activation and the killing of EBV-infected cells ([9]). It appears that CD244-mediated NK-cell activation requires a functional association with SAP, which prevents association with SHP-2 ([10]). In $CD8^+$ T cells, CD244 stimulates granzyme release and perforin expression, IFN-? production, and down-regulation of chemokine receptor CCR7.

CD246 (ALK: ANAPLASTIC LYMPHOMA KINASE)

Structure: The anaplastic lymphoma kinase (ALK) is a PTK (similar to the insulin receptor subfamily). The normal ALK is a transmembrane protein of 1620 amino acids, which has a low-density lipoprotein and a MAM domain in the extracellular region and the tyrosine kinase catalytic domain in the intracellular region. The gene for ALK is located in 2p23. A protein known as *nucleophosmin* (NPM, B23) is located in chromosome 5q35. The NPM is a multifunctional nucleolar protein and expresses the following activities: (a) nucleic acid binding, (b) ribonuclease, (c) chaperone, and (d) oligomerization.

A nonpolar region in the N-terminus, as well as an acidic segment in the center, mediates the chaperone activity. The cytoplasmic region has a core region of several acidic residues as well as several potential phosphorylation sites (Thr/Ser). The 37 *C*-terminal amino acids are important for nucleic acid binding and include five aromatic amino acids (two highly conserved Try), whereas the center of the molecule is required for ribonuclease activity. Oligomerization and chaperone activity are highly correlated, and the monomeric forms are not molecular chaperones. The secondary structure of NPM is predominantly ß sheet (40 to 50%) with some a-helix. NPM shares several structural features with the small HSPs.

In ALCLs, a t(2;5)p23;q35 translocation fuses the genes of ALK and NPM, and the fusion gene encodes the protein NPM-ALK, consisting of the *N*-terminal and transmembrane regions of NPM and the cytoplasmic regions of ALK ([1], [2], [3] and [4]).

Gene locus: ALK, 2p23; NPM, 5q35; NPM-ALK, t(2;5)p23;q35.

Molecular mass (kd): ALK, 200; NPM, 37; NPM-ALK, 80.

Distribution:

- ALK: mRNA is detected in the brain and spinal cord and in neurons of specific regions of the nervous system, such as thalamus, midbrain, olfactory bulb, and ganglia of embryonic and neonatal mice ([5], [6]). ALK is not expressed in lymphocytes.
- NPM: Ubiquitous—localized only in the nucleus.
- NPM-ALK: In cells of ALCL, in approximately 50 to 60% of the patients ([7]). With fluorescence techniques, the localization of the chimeric protein is difficult to determine, as fluorescence varies depending on the specificity of the antibodies (ALK or NPM, *C*- or *N*-terminal epitopes). However, with variant ALCLs (i.e., other than NPM as partner of ALK), fluorescence is detected in the cytoplasm.

Function:

- ALK: Development of nervous tissue.
- NPM: Multifunctional nucleolar protein with DNA binding, chaperone, and ribonuclease activities (see above) ([8]). NPM is a histone chaperone and mediates nucleosome, and ribosome biogenesis, and decondensation of sperm chromatin. The chaperone activities depend on the strongly acidic segments, and for its

functions, it shuttles between nucleus and cytoplasm. It plays a role in normal and abnormal growth. It is the target of CDK2/cyclin E in the initiation of centrosome duplication ([9]). Its gene is also the target of c-Myc, thus linking the increase of NPM with cell growth.

- NPM-ALK: NPM is the most common partner for ALK, but in some patients, other genes fuse with ALK: (a) TFG (TRK-fused gene), which generates three chimeric proteins: short, long, and extra-long; (b) TPM3; (c) CLTCL (clathrin heavy chain polypeptide) ([10]); (d) ATIC; and (e) MSN (moesin) ([11]).

RTKs normally are activated as a result of dimerization by the ligand, but with the NPM-ALK, the kinase is constitutively activated as a result of oligomerization of NPM, which thus imitates the ligand in bringing aggregation of the kinase.

The kinase activity of NPM-ALK depends also on its interaction with Hsp90, which maintains its folding and promotes its maturation ([12]). For the mitogenic effect, NPM-ALK utilizes PLC-?, stimulating proliferation ([13]). It also activates PI3K/AKT, triggering antiapoptotic signals ([14]), which through activation of STAT-3 increase the transcription of the antiapoptotic protein Bcl-X_L ([15]).

CD247 (CD32 ANTIGEN, ZETA POLYPEPTIDE)

Structure: Member of the invariant components of the TCR complex (i.e., CD3 ?, d, e, and ?). A nonglycosylated protein 163 amino acids long, with a short extracellular region (nine amino acids) and a unique positive charge (lysine at position 9). The ?-chains exist as a disulfide-linked homodimer (90%) or heterodimer (with the ?-chain) (10%). Recently, it was suggested that the ?-chain exists in a tetrameric form. The intracellular region contains seven tyrosines as potential phosphorylation sites, six of them arranged in ITAMs (i.e., the ?-chain has three ITAMs) ([1]).

Gene locus: 1q22-q23.

Molecular mass (kd): 16.

Distribution: T cells, with TCR, NK cells in association with CD16 (Fc?RIII), and basophils with FceR.

Function: It couples the TCR to the signal transduction pathways, even in the absence of the other invariant chains (?, d, e) of the TCR complex ([2]). Important in this context is the fact that ?-chain remains in the center of the contact area between T cell and APC [i.e., within SMAC (supramolecular activation cluster)], which contributes to the immunologic synapse, whereas the CD4, which initiates the early phase of T-cell activation, moves to the periphery ([3]). The short extracellular region loosely interacts with the TCR, as shown with mutation K9D. Activation of T cells leads to release of microvesicles (exosomes), which carry TCR/CD3/?-chain, but their function remains to be determined. Patients with low TCR expression and defects of humoral and cell-mediated response have impaired association of TCR with ?-chain. The ?-chain has also been shown to be down-regulated in tumor infiltration cells or peripheral blood T cells in patients with malignancies. It has been hypothesized that low ?-chain expression may underlie a poor T-cell response against the tumor as a result of the importance of this molecule in signal transduction and T-cell activation. CD3-?-chain is significantly reduced in patients with Hodgkin disease during the active stage ([4]). In patients with gastric carcinoma, low levels of CD3-?-chain were found to represent an independent prognostic marker. In myeloid malignancies, recovery of CD3-? levels correlated with successful remission induction ([5]).

Clinical Flow Cytometry

HISTORY

Flow cytometry (FC) is the measurement of numerous cell properties (cytometry) as the cells move in single file (flow) in a fluid column and interrupt a beam of laser light. The method allows the quantitative and qualitative analysis of several properties (multiparameter) of cell populations from body fluids.

Quantitative cytometry has its origins in the 1930s in the pioneering work of nucleic acid measurements of the cell by Caspersson ([1]). The need to make measurements of large cell populations rapidly and accurately stimulated the development of instruments that were the forerunners of present day flow cytometers. Light scattering was used as an indicator of the presence of a particle. A significant discovery was the report by Coons and Kaplan of the conjugation of fluorescein to antibodies ([2]), which opened the field of detection of tissue antigens by specific antibodies using fluorescence. The next important development took advantage of the low electrical conductivity of a cell with respect to saline solutions. The rise of electrical impedance was used as a measure of cell volume as cells, suspended in saline, passed through an orifice [Coulter counters (Beckman Coulter, Hialeah, FL)] ([3]). In the early 1960s, Kamentsky developed a *rapid cell spectrophotometer* ([4]). The instrument measured cell size (by light scattering at 410 nm) and DNA content (by absorption at 260 nm) using computer technology to make accurate statistical analysis of data possible.

New Era: Modern Flow Cytometry

The need for multiparameter analysis was satisfied by the introduction of fluorescent dyes for measurement of total DNA content in the detection of cancer cells and fluorescent antibodies specific for cell-surface markers in the separation of cell subpopulations. One of the early commercially available flow cytometers, the Hemalog D (Technicon; Bayer Diagnostic, Tarrytown, NY) found wide applications in hematology laboratories for differential blood counts. Light scattering was combined with absorption measurements at different wavelengths using dyes and chromogenic substrates of enzyme action to identify the blood cell populations.

FLUORESCENT ACTIVATED CELL SORTER The modern technology of FC is based on two seminal discoveries born of academic curiosity to obtain answers for fundamental questions in immunology. First came the birth of the fluorescent activated cell sorter by Herzenberg and colleagues ([5] , [6] and [7]), which was used to separate plasma cells based on intracellular fluorescence. This was followed by the demonstration that antigen-binding lymphocytes are the precursors of antibody-producing cells ([8]), and the allotype ([9]) and isotype ([10]) of an antibody molecule are the same as those detected on the surface immunoglobulin (Ig) of the lymphocytes. Human T and B cells were also studied by fluorescent activated cell sorter analysis ([11] , [12]), but highly specific antibodies and their conjugation with fluorescent dyes were difficult to prepare. Herzenberg's cytometer was trademarked by Becton Dickinson (Franklin Lakes, NJ) approximately a decade later. The earlier one-laser, water-cooled cytometers evolved into the modern three-laser sorter with multiple detectors referred to as the *Hi-D fluorescent activated cell sorter* ([13]). Now, other light sources besides the argon lasers (488 nm) are used, such as krypton (407 nm) and dye lasers (595 nm). The number of dyes available allows the simultaneous measurement of up to 11 colors of fluorescence ([14]). Of course, in a routine laboratory, the use of more than three or four fluorochromes demands a greater involvement in quality control, optimization, and color compensations. The name *polychromatic FC* has been suggested for the use of larger numbers of fluorochromes ([15]). The modern flow cytometer is a remarkable instrument that combines a blend of modern technologies such as fluidics, lasers, optics, analog and digital electronics, and computer software. With such combinations, it can measure cell size, structure, and cellular contents, as well as any particle down to a size of approximately 0.1 µm. Its detection limit is approximately 1000 molecules of a dye (i.e., 1×10^{-18} g/cell). It has been calculated that this is the amount of dye present in 1 g of water, if 1 g of the dye is evenly distributed in a volume of water with the dimensions of 3000 km × 3000 km × 300 m ([16]). The flow cytometer consists of three main compartments: (a) sample handling—flow cell and associated fluidics; (b) light sensing—light source, optics, and detectors of light scatter and fluorescence; and (c) signal processing—data collection and analysis ([17]).

MONOCLONAL ANTIBODIES The second important discovery complemented the first with the development of monoclonal antibodies by the Nobel Prize–winning discovery of Kohler and Milstein in 1975 ([18]). Fusion of an antibody-producing normal mouse spleen lymphocyte with a plasmacytoma (myeloma) cell generates a hybrid cell, called *hybridoma*, capable of producing unlimited quantities of monoclonal antibodies. Monoclonal antibodies revolutionized modern medicine from the laboratory to the bedside. Some of the problems related to the commercial impact of this discovery were briefly outlined by Cesar Milstein ([19]). The production of monoclonal antibodies is a relatively simple procedure, as shown in Figure 3.1. A mouse is injected with an antigen having several distinct epitopes. The mouse immune system responds to each epitope (A to D) by producing antibodies specific for each epitope (anti-A to anti-D). Each antibody is produced by the progeny of a single antigen-specific lymphocyte. The progeny of this lymphocyte is a *clone*, and, as a result, the antibody produced is *monoclonal*. Mouse spleen suspension is mixed in a test tube with plasmacytoma cells, which have no capacity to produce Ig. Addition of a fusion agent, such as polyethylene glycol, generates hybrids, each formed from the fusion of one antibody-producing lymphoid/plasmacytic cell and one plasmacytoma cell. The fused cell inherits the property of producing an antibody of a single specificity (monoclonal) from the antibody-producing cell (parent I). At the same time, it also inherits from parent II the property to be “immortal.” The fused cell is called *hybridoma*.

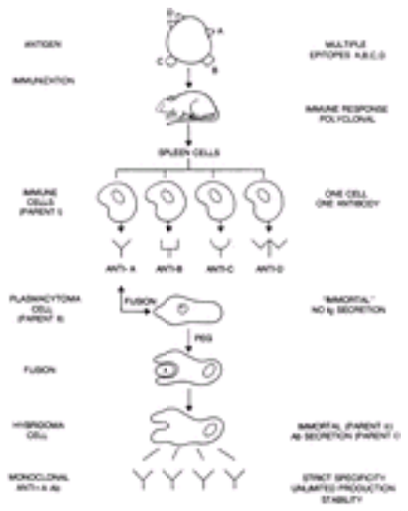

Figure 3.1. Production of hybridomas. Ig, immunoglobulin; PEG, polyethylene glycol.

The advantages of monoclonal antibodies are their homogeneity, predictable specificity and affinity, and availability in very large quantities. Monoclonal antibodies have become an indispensable tool for diagnostic procedures, especially in FC, in bacteriology, for tumor localization by means of radioimmunoassays, and so forth. The application of monoclonal antibodies by investigators created a crisis, which resulted from a plethora of designations given for the same molecule. The confusion called for a universal notation for cell antigens and the establishment of Workshops on Human Leukocyte Differentiation Antigens (HLAD). The first HLAD Workshop convened in Paris in 1982, and the last was the seventh HLAD Workshop in Harrogate, United Kingdom in June 2000 ([20], [21] and [22]). The molecules are given a number following the designation *CD* (clusters of differentiation) (see Chapter 2). The seventh HLAD Workshop added 110 new specificities, the last number being 247, the v?-chain of T cells. However, some gaps in the numbering still remain (i.e., between CDw197 and CD200). Also, multiple specificities are included under one designation [i.e., 13 for CD85 (CD85a to CD85m), the ILT/LIR family (Ig-like transcripts/leukocyte inhibitory receptors) and 14 for CD158s, the KIR family of receptors (killer-cell Ig-like receptors such as CD158d to CD158k with some numbers consisting of two specificities, i.e., CD158b1 to CD158b2 and so forth)]. Access to CD nomenclature and brief descriptions of CDs are available online at PROW: Protein Reviews on the Web: http://www.ncbi.nlm.nih.gov/prow/.

PRINCIPLES AND INSTRUMENTATION

Fluidics

For reliable analysis, the specimen must be a monodisperse suspension. Failure to meet this requirement results in technical inaccuracies and causes blocking of the flow. From a reservoir, isotonic fluid under pressure is forced into a tubing that delivers it to the flow cell. The flow cell is called by some the “heart of the flow cytometer.” The isotonic fluid within the flow cell generates a fluid column with laminar flow and a high flow rate of 10 m/second. This is known as *sheath fluid*. The sample is introduced in the flow cell by a computer-driven syringe in the center of the sheath fluid, thus creating a coaxial stream within a stream, the *sample core stream*. The shape of the tip of the sample insertion needle affects the orientation of the cell, which in turn may affect measurements. For example, an asymmetrically shaped tip improves orientation of epithelial cells and sperm cells, resulting in more accurate measurements. There is no mixing of the sheath and sample streams. The pressure of the sheath stream hydrodynamically aligns the cells so that they are presented to the light beam in single file (i.e., one at a time). The cells trigger the scattering of the light and, at the same time, are excited by the beam and emit fluorescent light. As the flow cell narrows, the velocity of the fluid increases and the diameter of the sample stream decreases to a very narrow cross section of the approximate size of the cells being measured. The velocity of the core stream is controlled by the sheath pressure, and its diameter is controlled by both the sheath pressure and the volumetric sample delivery rate. Resolution and sensitivity depend on both of these parameters, and their control is paramount for good analysis. Resolution is expressed as the *coefficient of variation* [CV; i.e., the relative standard deviation of the signal produced by identical cells or particles (CV = 100 × standard deviation/mean of the peak)]. *Sensitivity*, on the other hand, is a product of the intensity of the excitation, which is determined by the time spent by the cell in the excitation focus (which depends on the flow velocity) and the shape of the laser beam. Resolution is a function of the diameter of the sample core, whereas sensitivity changes with its velocity. Under constant sheath pressure, increasing the sample delivery increases the core diameter. This results in poor resolution. Under constant sample delivery rate, an increase in the sheath pressure results in increase of the velocity of the sample, which decreases the sensitivity.

Light Source and Light Beam

Sensitivity and resolution also depend on the shape and intensity of the laser beam. The diameter of the beam is approximately 650 µm, but it is narrowed by two cylindrical lenses that reduce the dimensions significantly. The first lens (vertical) results in an elliptical beam with a longer vertical dimension (perpendicular to the axis of flow) and a shorter horizontal dimension (along the axis of flow). The second lens (horizontal) changes the beam so that its horizontal dimension is longer than the vertical. Lengthening the horizontal axis increases the resolution of the instrument as determined by the CV and the amount of light illuminating the particle. Shortening the axis enhances sensitivity because the intensity of light over the sample core stream is increased. Thus, depending on whether resolution is more important (DNA quantitation) than sensitivity (immunophenotyping, platelet counts), the horizontal axis should be kept longer or shorter, respectively. The vertical axis controls the discrimination between two closely spaced cells such as doublets ([23]). Cells can be close together as a result of clumping or a fast running sample. In such cases, the beam should be as narrow vertically as possible. The particles intersect the beam within the flow cell (closed flow) or after they exit the flow cell (sense-in-air). At the intersection (interrogation point), two events take place: *light scattering* and *emission of fluorescent light*, assuming that the particle is tagged by a fluorescent dye.

Signals: Collection and Sensors

Alignment is critical because the light intensity is higher at the center of the beam, and the particle should intersect the beam at its center. In the newer instruments, the need for daily mechanical alignment has been eliminated.

LIGHT SCATTERING *Light scattering* is the result of laser light reflecting and refracting off the cells ([24]). Light scatter signals are used to set the threshold for separating platelets, erythrocytes, and debris from viable leukocytes. Light scattered along the axis of the beam is known as *forward angle scatter* (FS), and light scattered at greater angles is known as *90-degree light scatter* or *side scatter* (SS). Light scattering is related to the intrinsic properties of the cell such as size and granularity. It is not necessary to treat the cells with any reagents. Extrinsic properties of the cell are those requiring the aid of external reagents to be revealed, such as DNA content with the use of fluorescent dyes. The FS has been shown to be proportional to the size of the cell. Typically, FS is light scattered between 1 to 10 degrees. FS is very useful in discriminating between cells and debris of cells. Other properties of the cell besides size may influence FS, such as the index of refraction and the absorptive properties of the cell. The index of refraction is higher in fixed and stained cells. Discrimination between live and dead cells is better at lower angles (0.5- to 12.5-degree). Live cells scatter more light than apoptotic cells, and best separation occurs between angles 0.5 and 12.5 degrees ([25]). The sensor for FS is usually placed beside the flow cell on the other side of the entry of the beam. A beam “dump” prevents the high-intensity laser beam from entering the sensor. SS is due to light reflected from internal structures of the cell and correlates with granularity of the cell. The SS is collected together with the fluorescent light at right angles to the beam. The light collection optics and sensors for SS and fluorescence are described later in this chapter. As a result of differences in cell size and granularity, light scattering (FS and SS) separates blood cells into three major populations: lymphocytes, monocytes, and granulocytes. In a two-parameter histogram (Fig. 3.2) of FS versus SS (when red blood cells have been lysed during sample preparation), we distinguish the three main leukocyte populations. For routine flow cytometric analysis of peripheral blood and bone marrow, this histogram can be used to gate for a particular cell population under study, or either one of these parameters could be used in combination with a fluorochrome (see below).

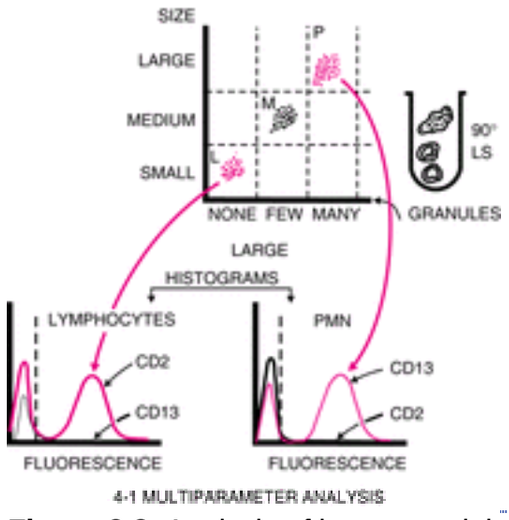

Figure 3.2. Analysis of human peripheral blood cells by flow cytometry. Blood cells are separated on the basis of their size, which scatters light in a forward direction, as well as on the basis of their granularity, which scatters light at a 90-degree angle (LS). Lymphocytes (L) (small and nongranular) occupy the lower left area of the screen, polymorphonuclear leukocytes (P) (large with many granules), the upper right. The monocytes (M) are detected in an intermediate position. Identification of these populations is achieved with monoclonal antibodies specific for markers present in one but not the other population. For example, the lymphocyte population shows strong fluorescence for the antibody to CD2 (a T-cell marker) (*continuous line*) but not for the CD13 (a myeloid-cell marker) (*interrupted line*). The opposite is true for the polymorphonuclear neutrophil (PMN) population. The vertical interrupted line separates the background fluorescence (at *left*) from specific fluorescence (at *right*) in the histogram.

FLUORESCENT LIGHT: MULTICOLOR ANALYSIS Certain dyes (fluorochromes) absorb the laser light and emit light at longer wavelengths. This is known as *fluorescence*. Various fluorochromes have distinct wavelengths for excitation (absorption of light) and emission. The flow cytometers used in clinical laboratories usually have two lasers; one is an argon ion laser that emits light at 488-nm wavelength (blue to blue-green). The argon laser is capable of exciting several commonly used fluorochromes and dyes. A second laser can include a helium-neon (633 nm), helium-cadmium (325 nm), or red diode laser (634 nm). With increase in laser power, the fluorescence signal increases (and thus sensitivity). However, with very high power, the signal to background difference may be reduced, and, thus, sensitivity is reduced. For the fluorochrome to be useful, the fluorescent wavelength must be longer than the excitation light (the difference is known as *Stoke shift*) so that it can be separated. The light that is scattered at wide angles (SS) and the fluorescent light are collected together at right angles to the laser beam by a pickup lens/spatial filter assembly. Optical filters are used in a flow cytometer to separate the light collected into usable spectral components for the quantitation of the respective fluorescence or scatter signals. Two types of optical filters are used in FC: absorption and interference filters. Absorption filters are usually made of colored glass. They absorb the unwanted light and pass the light with the desired wavelength. As a result of light absorption, these filters tend to fluoresce, especially after light absorption of short wavelengths. Interference filters attenuate or reflect the unwanted light. This is accomplished by depositing specific series of metals and dielectrics onto the substrate. There are five types of interference filters: the band pass, notch, long pass, short pass, and dichroic filters. The dichroic filters are designed to reflect a specific range of light wavelengths and to pass all others. The individual components of light are separated using the appropriate combination of filters that pass light of a certain wavelength (long and short pass filters) and dichroic filters, which reflect some wavelengths while allowing others to pass (Fig. 3.3). A dichroic filter at a 45-degree angle to the collected light path reflects the SS (488 nm) to the SS sensor while allowing the fluorescent light (higher wavelength) to pass. Subsequently, the light passes through a filter that absorbs any remaining 488-nm light that may have passed through the first dichroic filter. The fluorescent light is then separated successively by a series of dichroic filters (Fig. 3.3). Each dichroic filter reflects to a sensor light of a certain wavelength while allowing the remaining light to pass to the next dichroic filter, and so on. By this method, the light is separated progressively into bands of increasing wavelength (yellow, green, red), which correspond to fluorochromes used to tag the cells.

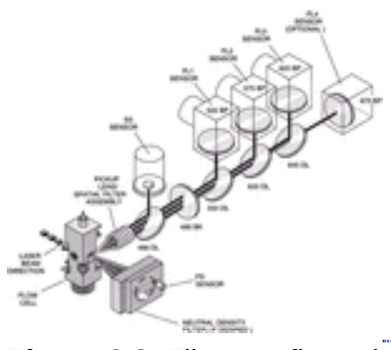

Figure 3.3. Filter configuration for four fluorescence sensors. Side scatter (SS) and fluorescent light (FL) are collected together and then separated by the use of a series of filters. Combinations of absorption and interference dichroic filters allow the separation of the incident (488 nm) from emitted (fluorescent) light. The incident light is directed by a dichroic filter to the SS sensor. Subsequently, the fluorescent light is separated by a combination of filters into its individual components, corresponding to wavelengths of light emitted from the fluorochromes used. FS, forward angle scatter. (From Epics XL Reference Manual, Coulter Corporation, 1993, with permission.)

The sensors convert the photons to electrical impulses that are proportional to the number of photons received, which in turn are proportional to the number of fluorochrome molecules bound to the cell. The fluorescent emissions are of low intensity and thus necessitate the use of photomultiplier (PMT) tubes to be detected. The PMT produces photoelectrons, which are released by the interaction of photons with the photocathode. The photoelectrons are accelerated onto the surface of a dynode through a voltage potential and successively release enough electrons to generate an electrical impulse.

Signal Processing

The electrical impulses are analog signals that are converted to digital signals with converters. The sensor may process either the brightest signal emitted from the cell or all signals, which measure total cell fluorescence. Electrical pulses are very weak and must be amplified. Amplification is either linear or logarithmic.

The linear form of data presentation more accurately represents differences in fluorochrome concentrations between cells. In linear amplification, the output signal is directly proportional to the input signal. Each channel represents the same increment in signal value. Thus, a peak at channel 200 represents an intensity twice that of a histogram peak at channel 100 (i.e., the relationship is straightforwardly linear). Histograms using linear amplification find applications in quantitation of fluorescence of DNA, RNA, and light scatter of cell size and granularity.

In logarithmic amplification, the output is proportional to the logarithm of the input pulse. This is important when we need to review cell populations that vary widely in their characteristics, such as cell-surface markers. Because the logarithmic amplification compresses a wide input range, populations with similar intensities cannot be resolved. Immunophenotyping is the most common application of logarithmic amplification.

The digitized data are stored either as histograms or as list-mode. When data are collected as histograms, the abscissa represents a preassigned parameter (i.e., intensity of fluorescence), and the ordinate represents the number of cells analyzed. More widely used is the list-mode method of data collection. In this method, various parameters (e.g., scatter, fluorescence, and so forth) are stored as a list. The software then allows the data to be reanalyzed and presented as histograms. This form of analysis allows for the reprocessing of data, especially in complex specimens with heterogeneous cell populations.

An important aspect of FC is the selection of only a certain cell population for analysis. This is called *gating* and is done electronically. In other words, the software allows the selection of cells within a limited range of certain parameters to be analyzed. Gates are rectilinear, amorphous, or numeric. The amorphous are the most versatile because they can be of any shape or form and allow better selection of cells.

Cell Sorting

Some flow cytometers may physically separate the cells (sorting) based on differences of any measurable parameter. Sorting is achieved by droplet formation. The basic components of any sorter are a droplet generator, a droplet charging and deflecting system, a collection component, and the electronic circuitry for coordinating the timing and generation of droplet-charging pulses. Fundamentally, the flow chamber is attached to a piezoelectric crystal, which vibrates at a certain frequency so that when the fluid carrying the cells passes through the nozzle, forming a jet in air with a velocity of 15 m/second, the vibration causes the jet to break up in precisely

uniform droplets, typically 30,000 to 40,000/second. Each droplet, when separated from the jet, can be charged and then deflected by a steady electric field and is collected to a receptacle. Almost every cell is isolated in a separate droplet.

When a cell is analyzed and a decision for sorting is made, until the proper electrical charge pulse is applied to the droplet containing this cell, there is a transit time that is determined by several factors, such as flow velocity, droplet separation, and the cell preparation that sometimes may cause perturbations of the jet. Sophisticated circuitry coordinates all functions during this transit time so that the electrical charge pulse is applied to the selected droplet. If two cells are so close together in flow that they cannot be isolated, the sorting is aborted. Poor sample preparation may cause doublets or coincident cells that cannot be recognized as separate cells. This results in contamination of the sorted fraction.

Fluorochromes and Conjugates

For a fluorochrome to be used in clinical practice, it must meet certain requirements ([26]). The light absorption spectrum should match the wavelength of the light emitted from the argon ion laser, which is 488 nm (Table 3.1). They should have a reasonably high *extinction coefficient*, a measure of the probability of absorbing a photon of light and therefore being "bright." Extinction coefficients vary between fluorochromes. They should have a high *quantum yield*, a measure of the efficiency of the conversion of the absorbed light to emitted light. For example, the quantum yield of fluorescein is 0.50 (i.e., fluorescein has a probability of emitting one photon, on average, for two photons absorbed), whereas the quantum yield of R-phycoerythrin is 0.98 (i.e., it emits one photon for every photon absorbed). Because R-phycoerythrin also has a very high extinction coefficient (2×10^6 L/mole·cm at maximum absorption) as compared to fluorescein (67,000 L/mole·cm), it is a much more sensitive fluorochrome. The fluorescence intensity from a fluorochrome is proportional to the product of the extinction coefficient and quantum yield. Other desirable properties are lack of interaction with cellular or biologic components and very little overlap with the spectrum of other fluorochromes to be used concomitantly. Fluorochromes that bind to organic matter give high background or nonspecific fluorescence, which sometimes may create problems in analysis of weakly fluorescent cells. For fluorochromes with spectral overlaps, a careful selection and appropriate filters minimize the problem. Furthermore, *compensation* [i.e., subtraction of signals (fluorescence) from detectors that are not supposed to detect this fluorochrome] minimizes the problem.

TABLE 3.1. Spectral Properties of Certain Fluorochromes

Parameter	Probe	Absorption Maximum	Extinction Maximum	Emission Maximum	Quantum Yield
Covalently	FITC-NH-Ab	490	67	520	0.10–0.40
Labeled	Phycoerythrin	480–565	1960	578	0.98
Reagents	TRITC-amines	554	85	573	0.28
Phenotyping	XRITC-NH-Ab	580	—	604	0.08
	Texas Red-NH-Ab	596	85	620	0.01
	Allophycocyanin	650	700	660	0.68
DNA-RNA	Propidium iodide	536	6	623	0.09
Content	Ethidium bromide	510	3	595	—
Reticulocyte count	Thiazole orange	453	26	480	0.08

FITC, fluorescein isothiocyanate; TRITC, tetrarhodamine isothiocyanate; XRITC, X-rhodamine isothiocyanate.
Modified from Waggoner AS. Fluorescent probes for cytometry. In: Melamed MR, ed. Flow cytometry and sorting, 2nd ed. New York: Wiley-Liss, 1990:209–225.

The fluorochromes most commonly used for conjugation with monoclonal antibodies are

1. *Fluorescein isothiocyanate* (FITC) has a molecular weight of 389 d and an absorption maximum at 495 nm. With excitation by 488 nm, it emits fluorescence with a maximum around 520 nm. Approximately three to five molecules of FITC are usually conjugated for each antibody molecule. Higher numbers result in fluorescence quenching, which occurs when fluorochromes are in close proximity and reduces the brightness of the labeled species. FITC is a popular fluorochrome because of its reasonably high extinction coefficient and quantum yield, its water solubility, and its emission at 515 to 520 nm, which can even be detected by the human eye. Among its disadvantages are its relative photoinstability, loss of fluorescence below a pH of 8, and its wavelength of excitation, which produces autofluorescence.
2. *Phycoerythrin* is a member of the natural dyes of phycobili-proteins, which derive from *Cyanobacteria* or red algae. In nature, it transfers light energy to chlorophyll during photosynthesis. It has a molecular weight of 240 kd (larger than the antibody molecule) with 34 phycoerythrobilin fluorochromes per molecule. Its absorption maximum is 564 nm, and its emission maximum is approximately 576 nm. R-phycoerythrin is more suitable than the B form because it is more efficiently excited at 488 nm. For conjugation to the antibody molecule, certain cross-linking groups are used. Phycobili-proteins are water soluble, fluorescent at neutral pH, readily conjugated with antibodies, and have high quantum yields.
3. *Texas red* is a sulfonyl chloride derivative of sulforhodamine 101 with a molecular weight of 605 d. It is a more soluble rhodamine derivative with an absorption maximum of 596 nm. Its emission maximum is 620 nm. In multicolor analysis using Texas red and phycoerythrin, it is recommended that a dual-laser flow cytometer be used.
4. *Allophycocyanin* is a member of the phycobiliprotein family. It has a 105-kd molecular weight and six phycocyanobilin chromophores per molecule, which are similar to phycoerythrobilin, the chromophore of phycoerythrin. Allophycocyanin absorbs maximally at 650 nm and emits at 660 nm. It can be excited by a dye laser or a helium-neon laser.
5. *Peridinin-chlorophyll-a protein* is a dinoflagellate protein, can be excited at 488 nm, and emits light at greater than 600 nm. It is easily bleached and can be used only by low-power bench-top instruments. New fluorochromes are continuously introduced, such as Cas B and Cas Y excited by krypton lasers (407 nm), APC, the Alexa series (430, 595), and ECD (or Red 613). ECD has some overlap with PE channel but is brighter than Cy5PE.
6. *Tandem fluorochromes* are two fluorochromes covalently conjugated. Only one of them absorbs light at 488 nm from the argon ion laser that is most commonly used in single-laser flow cytometers. Energy from this fluorochrome is transferred to the second fluorochrome, which cannot be directly excited at 488 nm. This second fluorochrome, in turn, emits fluorescent light at a wavelength higher than that of the first one. For example, in a covalent conjugate of cyanin with phycoerythrin, 488-nm light excites phycoerythrin, which transfers the energy to the cyanin molecule. Cyanin, in turn, emits light at a longer wavelength than phycoerythrin (at 670 nm). The efficiency of energy transfer between the two fluorochromes is very effective, with less than 5% of the light absorbed by phycoerythrin being lost as fluorescence at 575 nm. These tandem fluorochromes allow the use of one argon ion laser (488 nm), and, thus, the need for dual lasers is eliminated. Tandem fluorochromes have opened the way for three-color fluorescence systems in combination with FITC and phycoerythrin using one laser light source. Texas red can also be conjugated to phycoerythrin, giving a tandem fluorochrome with an emission maximum above 600 nm.

Monoclonal antibodies with exquisite specificity are conjugated with fluorochromes. The structure recognized by the antibody is known as an *epitope*; any complex protein possesses several epitopes, and it is possible that several monoclonal antibodies produced against the same protein may detect different epitopes and give different results. These antibodies are recognized as being specific for a marker, but their binding may be different, and the number of cells detected may also differ.

Sensitivity of immunophenotyping depends on qualities of the monoclonal antibody, such as its specificity and affinity, and on the properties of the fluorochromes. Minimizing the background fluorescence by decreasing the nonspecific binding of the conjugates to the cells is mandatory. Nonspecific binding of the antibody is mediated through its Fc fragment and is especially prominent on cells expressing Fc receptors (natural killer cells, monocytes, neutrophils, B cells). Interaction of Fc receptors with Igs is non–species-specific. Therefore, all monoclonal antibodies (usually mouse Igs) bind to human cells to different extents depending on their class. The nonspecific binding may be reduced by pretreating the samples with human plasma to saturate the Fc receptors with human Ig. Strong nonspecific binding can occur with samples containing malignant cells, such as lymphoma cells in lymph node preparations. Nonspecific binding may also be the result of conjugates with high dye to antibody ratio, which results in the formation of aggregates. Each antibody molecule has an optimum number of fluorochrome molecules that yields maximum fluorescence as a result of specific binding with minimum nonspecific binding. The size of the conjugate is also important, particularly with the phycobiliproteins. Conjugates with large size are insoluble. Thus, conjugation of phycoerythrin (240 kd) to IgM (900 kd) has not been successful.

Flow Cytometer Settings

In modern flow cytometers, basic features are not adjustable. However, a number of variables need to be set by the operator, such as setting the PMT sensitivity, the gains, selection of linear versus logarithmic amplification, color compensation, and so forth ([27]).

Increasing the voltage applied to the PMTs increases the sensitivity and the value of the signal collected. When the voltage changes, all populations change by the same number of channels, thus there is no change in the relationship of two peaks or populations.

Changing the gain settings, however, alters the relationship of different populations. Increase of the gains spreads populations located close together farther apart. Although this may appear as an advantage, it is a disadvantage for certain populations with relatively bright fluorescence. It may push them to the maximum channel (i.e., 1024 channel) and thus make them unable to be included in the analysis. At the maximum channel, the value measured is equal to or greater than the maximum.

Color compensation is required when two fluorochromes used have overlapping spectral properties. For example, FITC emits light over a wide range of wavelengths and thus is detected by other than the green PMT (i.e., the yellow and the red PMTs). Subtraction of the color detected by other than the green PMTs is known as *color compensation*. Compensation is usually done by compensation beads labeled by individual fluorochromes.

The voltages are set first with individual beads, followed by a run with all beads mixed. It is then determined whether the voltages are accurate.

Finally, it is important to set the thresholds, which exclude small-sized particles such as erythrocytes, platelets, and cell debris. Occasionally, debris with strong SS and weak FC signals is encountered, probably from disintegrated neutrophils.

Reporting Results

One method of reporting the results for specific subpopulations, such as $CD4^+$ cells, is as a percentage of the total lymphocytes. This presupposes that lymphocytes can be well separated from monocytes by FC and SS. If the total $CD3^+$ population can be determined, then the subpopulation can be reported as a percentage of that population. Most flow cytometers cannot provide absolute numbers because they do not measure fluid volumes. A computerized system has been used to report results in an attempt to obtain diagnostic and prognostic information in leukemias ([28]).

FLOW CYTOMETRY IN HEMATOLOGY

Some common practical applications of FC in hematology are described briefly here. Detailed descriptions of these and other applications can be found in several monographs ([29] , [30] and [31]).

Sample Preparation

For cell-surface marker analysis, the sample is incubated with the appropriate monoclonal antibodies, and the red blood cells are lysed with lysing reagents (several are commercially available; some also contain fixatives). Nonspecific binding of the monoclonal antibody is determined by a species- and isotype-matched Ig without antibody activity that is conjugated to the same fluorochrome. This control is set to exclude 98 to 99% of all cells. The data are usually collected in list-mode. In a routine analysis, the first histogram displays the data of FS versus SS. In normal blood or bone marrow samples, three main leukocyte types are distinguished: lymphocytes, monocytes, and granulocytes (Fig. 3.4). On simple inspection, this histogram also shows whether the sample is normal or abnormal. Appropriate gating (rectangular or amorphous) allows the analysis of the various populations. In the presence of one large population (as in cases of leukemias or lymphomas), detailed analysis is possible by selecting with small gates (“bitmaps”) cells that are small or large (FS) versus cells that are nongranular, moderately granular, or heavily granular (SS). Thus, a differential count based on “intrinsic” cell properties is achieved. Although in the majority of cases, cell separation based on light scattering is adequate, to answer special questions, it is necessary to combine other approaches such as a combination of one light scatter parameter with fluorescent antibodies against a cell-surface marker. Frequently, CD45, a marker expressed by mature leukocytes, is used.

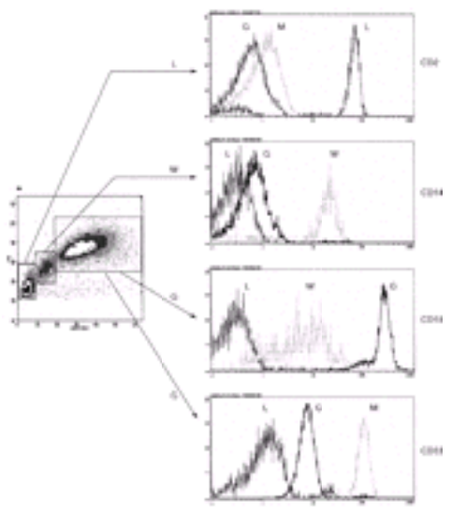

Figure 3.4. Two-parameter analysis (forward angle scatter vs. side scatter) of normal peripheral blood. Three populations are distinctly separated. These populations can be identified as lymphocytes (L), monocytes (M), and granulocytes (G) using lineage-specific (or associated) markers such as CD2 (lymphocytes), CD14 (monocytes), and CD15 and CD33 (granulocytes). Expression of CD15 is weaker in monocytes (vs. granulocytes) and varies widely among them (*broad peak*, i.e., large coefficient of variation). In contrast, expression of CD33 is stronger and more homogeneous (*narrow peak*, small coefficient of variation) in monocytes as compared with granulocytes. Thus, a marker not only identifies a cell simply as a result of its presence or absence, but also as a result of its intensity and heterogeneity of expression as defined by the coefficient of variation. The horizontal line separates the positive cells (to the *right*) from the negative (to the *left*). For comparison, each histogram to the right shows all three cell populations.

Immunophenotyping

NORMAL HEMATOPOIESIS The development of monoclonal antibodies against cell-surface markers of blood cells and their conjugation with certain fluorochromes markedly contributed to the application of FC to the study of normal hematopoiesis ([32] , [33] , [34] , [35] and [36]). Multiparameter FC has been used for characterization of normal hematopoietic differentiation. The changes in the expression of lineage-specific or lineage-associated cell-surface and cytoplasmic markers provided data for the reconstruction of the differentiation pathways along distinct lineages. Uncommitted hematopoietic progenitors reside within the population of bone marrow cells that are strongly $CD34^+$ and $CD38^-$. CD38 is expressed in early progenitors with potential for lineage commitment as assessed functionally and by lineage-associated antigens ([35]). A detailed description of differentiation of the hematopoietic lineages is given in Chapter 6, Chapter 16, and Chapter 17. This chapter provides a brief outline of the appearance of lineage-specific and lineage-associated markers.

Lymphocytic Differentiation

B Lineage Commitment to B-cell differentiation is indicated by the appearance of CD19 and CD10 (Chapter 16) ([33]). Expression of CD19 is B cell–specific, whereas CD10 is also expressed at the early stages of T-cell differentiation. Expression of CD34 and CD10 ceases by the time the cell expresses IgM on its surface. Appearance of surface IgM is also associated with other B-cell markers such as CD20, CD21, and CD22. B cells make up approximately 20% of peripheral blood lymphocytes, and the typical phenotype is $CD19^+$, $CD20^+$, $CD21^+$, and $CD22^+$. B-cell activation is associated with the reappearance of CD10 marker in B cells of the germinal center. CD23 is also considered an activation marker. With further differentiation, expression of CD45 declines and disappears at the stage of plasma cell. Plasma cells may also lose expression of CD19, while at the same time becoming strongly positive for CD38. A phenotype $CD45^-/CD38^{3+}/CD138^+/CD19^-$ is the signature of a plasma cell.

T Lineage Pre–T cells express CD34, CD7, and CD2 while still in the bone marrow. When these T-cell progenitors migrate to the thymus, the characteristic phenotype of the subcortical thymocyte develops in contact with thymic stroma. T cells in the subcapsular cortex are the most immature, and their phenotype is CD34 $^{+}$/CD2 $^{+}$/CD7 $^{+}$/CD4 $^{\pm}$/CD8 $^{\pm}$ (“double negatives”). Coexpression of CD4 and CD8 with CD1 is detected in the next stage (“double positives”) (Chapter 17), followed by the gradual appearance of CD3 and the a/ß T-cell receptor (TCR). Subsequently, the CD4 $^{+}$/CD8 $^{+}$ thymocytes give rise to the single-positive CD4 and CD8 cells. The majority of peripheral blood lymphocytes (approximately 60 to 80%) are CD2 $^{+}$/CD3 $^{+}$/CD7 $^{+}$ and express either CD4 or CD8. A small number are CD4 $^{-}$/CD8 $^{-}$, but these are not immature cells because they express the TCR.

Erythroid Differentiation On commitment to the erythroid lineage, CD71 appears on the cell surface with loss of CD34 and CD33 and decrease of CD45 ([32]). With further differentiation, expression of CD71 declines as the expression of glycophorin is up-regulated. CD45 disappears in the final stages.

Myeloid Differentiation CD33 is one of the earliest antigens to appear ([34]). The CD34 $^{+}$CD33 $^{+}$ cells can give rise to burst-forming unit erythroid and colony-forming unit granulocyte-monocyte. Immature myeloid cells become CD13 $^{+}$ followed by the appearance of CD15 and CD11b. Only at the final stages are CD16 and CD10 expressed. Granulocytes are strongly positive for CD15 and only weakly positive for CD33, with a heterogeneous distribution or large CV. CD13 and CD11b are of intermediate expression. In contrast, monocytes are strongly CD33 positive [with small CV (i.e., homogeneous expression in the population)] but weakly CD15 positive and CD4 positive. Expression of CD4 easily distinguishes monocytes from CD4 $^{+}$ T cells. In the monocytes, expression of CD4 is weak with a large CV, whereas in the T cells, expression of CD4 is strong with a small CV. Thus, intensity of fluorescence and CV are important parameters, in our experience, for cell identification. The signature phenotype for monocytes is CD33 ^{high}, CV-small/CD15 ^{low}, CV-large/CD4 ^{low}, CV-large.

IMMUNOPHENOTYPING OF HEMATOLOGIC MALIGNANCIES Markers specific for hematologic malignancies exist only when a new protein is encoded by a gene resulting from the fusion of two normal genes (i.e., bcr/abl). However, diagnosis by immunophenotype can still be accurately made by the usual leukocyte antigens and other proteins expressed on the cell surface (Ig light chains). It is based on the presence of a marker in numbers significantly larger than normal or on the presence of an aberrant phenotype resulting from (a) expression of a marker on a lineage on which it is not normally expressed, or (b) asynchronous antigen expression (i.e., presence of a marker at a stage of differentiation where it does not normally belong). Diagnosis based on large numbers of cells expressing a specific marker may lead to erroneous diagnoses, as past experience has taught us. The classic example is the common acute lymphocytic leukemia (ALL) antigen or CALLA (CD10), which was first believed to be specific for leukemic cells but later was found on bone marrow B-cell progenitors and on peripheral B cells (germinal center), as well as on cells from other lineages and even on nonhematopoietic cells. If the bone marrow is replaced by leukemic cells, the diagnosis is straightforward because the number of CD10 $^{+}$ cells in normal adult bone marrow is less than 5% of the lymphoid cells. Earlier, some investigators accepted a number of CD10 $^{+}$ cells greater than 20 to 30% of the bone marrow cells as an abnormal finding suggestive or diagnostic of ALL. It has been shown, however, that in children with thrombocytopenic purpura, the number of CD10 $^{+}$ cells may be up to 60% in the absence of ALL ([37]). As shown in Figure 3.5, the bone marrow contains large numbers of CD10 $^{+}$ cells, which are heterogeneous in terms of expression of CD10, CD20, or CD45. Furthermore, with the decline of CD10 expression, the CD20 and CD45 density increases, which is evidence of maturation. Therefore, high levels of one particular marker may not necessarily indicate a neoplastic disease. The same applies for the CD34 marker associated with immature hematopoietic cells.

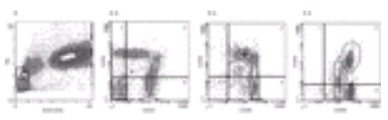

Figure 3.5. The patient had idiopathic thrombocytopenic purpura, and the bone marrow showed increased numbers of immature lymphoid cells (23%). By flow cytometry, these cells are CD10 $^{+}$. Some are CD10 $^{-}$, whereas the remaining cells express CD20. As CD10 expression declines, the expression of CD20 increases and merges with the cells, which are CD20 $^{+}$ but CD10 $^{-}$. This is a pattern characteristic of B-cell maturation. A similar pattern is shown with expression of CD45. SS, side scatter.

More than the high percentage of a rare cell marker, it is the composite phenotype that should be considered. For example, the association of CD34 with another marker not normally seen, such as CD7, CD4, or CD56, is more suggestive of a proliferative disorder (see Appendix). These very rare phenotypes confirm the diagnosis whether one accepts that leukemia is a “frozen window” of normal hematopoiesis, and therefore the cells with the unusual phenotype correspond to normally infrequent cells, or whether one believes that the phenotype is aberrant as a result of interlineage or intralineage “infidelity” indicative of misprogramming or illegitimate gene expression. These rare markers, however, have a very important application after diagnosis if they can be used as patient-specific probes for monitoring minimal residual disease. For example, the expression of CD56 on CD34 $^{+}$ blasts could be readily identified in one out of 10 ^{4} blasts in 20% of cases of childhood acute myelogenous leukemia (AML) ([38]). In progenitor cells of chronic myelogenous leukemia in chronic, accelerated, and blastic phases, CD56 is again coexpressed with CD34 ([39]). Despite these difficulties, immunophenotypic diagnosis of leukemia has increasingly become an indispensable tool in laboratories, although the morphologic diagnosis and classification still remain the indisputable standard for the study of patients with hematopoietic malignancies. In the following situations, immunophenotyping is clearly important: (a) determination of lineage (myeloid vs. lymphoid) if it cannot be decided on the basis of morphology and cytochemistry, (b) distinction between B- and T-cell acute leukemias, (c) detection of mixed lineage leukemias, and (d) detection of monoclonality in B-cell lymphoproliferative disorders on the basis of expression of Ig light chains. The application of increasingly greater numbers of monoclonal antibodies allows a more precise classification and will make it possible to associate genetic subgroup **s** with a distinct immunophenotype such as leukemias with t(8;21), t(15;17), and so forth ([40]). Light scattering can provide useful information. Figure 3.6 shows representative examples of AML of the first four French/American/British (FAB) classifications, FAB M0 to M3. The light scattering histograms show gradual increase of SS from M0 to M3, indicative of the gradual increase in the granularity of the leukemic cells. Immunophenotyping reveals that expression of the stem cell marker (CD34) is retained even in some M2 leukemias. Furthermore, the M2 group is immunophenotypically heterogeneous in the expression of other markers, such as CD4. The significance of these immunophenotypic findings remains to be determined.

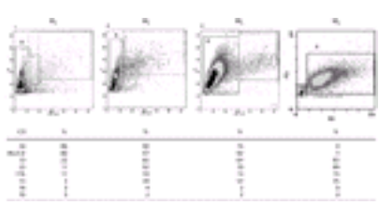

Figure 3.6. Light scatter histograms and the phenotype are shown using the main myeloid markers with examples from the four French/American/British (M0 to M3) classes of acute myelogenous leukemia. The phenotype refers to the main cell population (*A*) in each forward angle scatter (FS) versus side scatter (SS) histogram. Numbers are percentages.

Immunophenotypic analysis of acute leukemias allows the identification of mixed lineage leukemias. Figure 3.7 shows the phenotype of a patient with AML-FAB M1 with the aberrant expression of CD2 and CD7. Rare forms of leukemia can only be identified by analysis of cell-surface markers. Figure 3.8 shows the phenotype of a case of ALL of B lineage with the expression of CD2. This case of biphenotypic leukemia reveals the existence of common lymphoid precursors that have also been detected in fetal liver ([41]) (see below). Immunophenotyping has advanced our understanding of the origin of acute leukemias, but the impact on various clinical aspects, such as prognosis and therapy, still needs to be better evaluated.

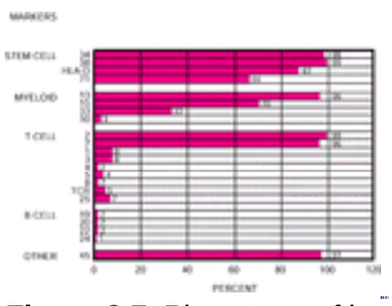

Figure 3.7. Phenotype of bone marrow cells from a patient with acute myelogenous leukemia (French/American/British–M1). The bone marrow contains one main population (98%) of cells that are heterogeneous in size, and only the larger cells are slightly granular. These cells show distinct evidence of myeloid differentiation and the coexpression of two lymphoid (T-cell) markers, CD2 and CD7. Although CD7 may be accepted here as a stem cell marker, the expression of CD2 is certainly aberrant. This is an example of mixed lineage leukemia. TCR, T-cell receptor.

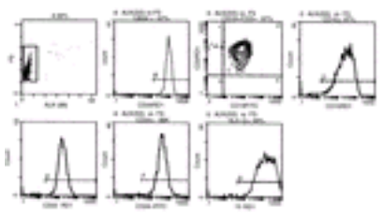

Figure 3.8. The phenotype of a case of acute lymphocytic leukemia that shows the expression of CD2 on all blasts. Mixed lineage leukemias can only be identified by immunophenotyping. The clinical significance of such cases remains to be evaluated. FITC, flouroscein isothiocynate; FS, forward angle scatter; SS, side scatter.

The use of three or more monoclonal antibodies permits a more precise identification of the phenotype of a cell population. This is particularly important when a marker is expressed not only on the leukemic cells, but also on normal cells. For example, CD33 is expressed on all stages of myeloid differentiation. Gating on the basis of light scattering, which excludes the most granular (and, therefore, the most mature) cells, is not sufficient. Combination of CD33 with CD34 identifies the most immature cells (those likely to represent the leukemic blasts), and their identification may further be improved with the addition of a third marker such as CD4, CD7, or HLA-DR, which have now been identified as markers of primitive hematopoietic progenitors (stem cells) ([42], [43]). The use of CD45 with a combination of two other monoclonal antibodies further facilitates the identification of blasts because it is known that CD45 is either lacking or expressed only weakly in the most immature hematopoietic cells and increases in density with maturation ([44], [45], [46] and [47]). In Figure 3.9A, the blasts from a case of ALL show weak expression of CD45. The presence of relatively large numbers of $CD10^+$ cells after treatment may indicate residual disease or bone marrow regeneration. A combination of CD10 with CD45 in this case reveals that, in contrast to the diagnostic pattern, CD10 expression is heterogeneous, and, as CD10 is down-regulated, expression of CD45 is up-regulated, suggesting bone marrow regeneration (Fig. 3.9B). A two-parameter histogram of CD45 versus SS (Fig. 3.10) allows the selection of all immature cells that are low in CD45 and that are also low in SS because they lack granularity.

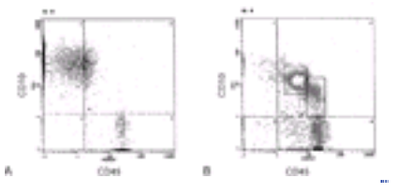

Figure 3.9. A two-parameter histogram, CD10 and CD45, identifies two different populations of $CD10^+$ cells. **A:** $CD10^+$ blasts from a patient with acute lymphocytic leukemia show no or little coexpression of CD45. **B:** $CD10^+$ cells after chemotherapy show progressive increase of CD45 as CD10 is down-regulated. These cells are normal, regenerating $CD10^+$ cells.

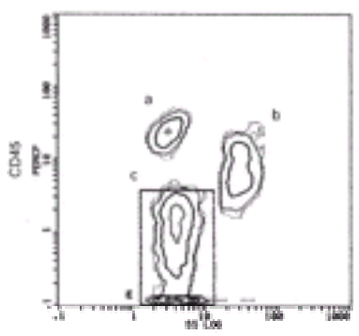

Figure 3.10. A two-parameter histogram [CD45 vs. side scatter (SS)] shows the presence of cells with low CD45 expression and low SS, which represent immature cells from a patient with acute leukemia. The ungated histogram clearly shows three main populations: (*a*) small numbers of cells with strong CD45 expression and low SS (lymphocytes); (*b*) high to intermediate CD45 expression and high SS (granulocytes); and (*c*) low SS with decreasing expression of CD45. These are immature cells, and gating can be used to determine their phenotype.

The combination of two to three monoclonal antibodies may be used for the detection of residual disease. Combinations of monoclonal antibodies must be used cautiously because, for certain markers, the presence of one antibody may interfere with the detection of another, probably on the basis of steric hindrance. Evaluation of the density of a specific marker has been attempted to determine whether it can be used as a prognostic indicator. Quantitative variation of CD10 in ALL has been demonstrated ([48], [49]). Patients with levels of CD10 less than the median of the $CD10^+$ group had a higher rate of failure. Overexpression of CD10 suggested the diagnosis of ALL even with low $CD10^+$ numbers. Different CD10 levels were associated with different chromosomal abnormalities; for example, high CD10 levels were associated with hyperdiploid cells and low CD10 levels with the t(4;11) translocation ([48]). Quantitative ratios of two markers may also be used to identify stage of differentiation. Parallel quantification of CD24 and CD45 allows identification of B-cell differentiation stage and may also be relevant clinically ([50]). High CD24 and low CD45 values are found in ALL, and, in these patients, low CD24 to CD45 ratios were associated with good prognosis.

Acute Lymphocytic Leukemia Immunophenotyping of cases of ALL is one of the most important applications of FC and provides an easy and definite diagnosis and a distinction between B-ALL and T-ALL ([51]).

B-Cell Acute Lymphocytic Leukemia Diagnosis of ALL in children by FC is based primarily on the expression of CD34, CD19, HLA-DR, and CD10. Expression of CD45 (low or negative) and CD24 (strong) is particularly useful not only at diagnosis but also during the follow-up period of bone marrow regeneration for detection of residual disease. From an earlier study, 69% of the cases are $CD34^+$ and 75% are $CD10^+$ ([52]). In our experience, the combination of CD45, CD34, CD10, and CD24 is particularly useful in two-parameter histograms for the identification of normal B blasts of regenerating cells versus leukemic blasts. Other B-lineage–specific markers are cytoplasmic detection of CD79a (mb1) ([53]), CD22, and TdT. Monoclonal antibodies specific for the V-preB and ? ^{5} subunits of the pre-BCR reacted with cells in 53 of 56 cases classified as non-B non-T-ALL, thus identifying them as B-cell ALL ([54]). In a small number of cases, CD2 is coexpressed with other B-cell markers ([55]). $CD2^+$ B-cell precursors have been identified in fetal life ([41]). These leukemias may represent malignancies derived from such an early B-lymphocytic precursor. Approximately 1 to 2% of B-ALL in children express surface Ig absence of CD34 and TdT, with some expressing an L3 morphology.

T-Cell Acute Lymphocytic Leukemia T-cell ALL comprises approximately 15 to 20% of childhood ALL. The phenotype of T-ALL corresponds to early stages of T-cell differentiation within the thymus. Cases corresponding to stage I of T-cell differentiation are $CD34^+/CD7^+/CD2^+$, and some of them are also $CD10^+$. This phenotype corresponds to the pre–T cell, a precursor detected in the bone marrow. More mature phenotypes are characterized by lack of CD34 and CD10, and, through a transitional stage, which is negative for CD4 and CD8 (stage II), the cell normally becomes double positive (i.e., $CD4^+/CD8^+$ and $CD1^+$) (stage III). The cells are also TdT positive. Expression of cytoplasmic CD3 is specific for T-cell lineage. Expression of several T-cell markers may not be detected (i.e., CD2, CD4, or CD8). However, if the cells are CD7 positive and other T-cell or myelomonocytic markers are absent, the phenotype is diagnostic of T-ALL. CD7 is the most important marker for T-ALL. However, in our experience, it is the composite phenotype that is important for diagnosis. It has been suggested that diagnosis of T-ALL should not be made in the absence of CD7 expression ([51]).

Acute Myelogenous Leukemia Markers useful for the diagnosis and classification of AML are CD34, CD117, CD33, CD13, CD15, CD4, CD11b, HLA-DR, and cytoplasmic myeloperoxidase. Immunophenotyping contributes to diagnosis in cases that are difficult to diagnose morphologically.

Acute Myelogenous Leukemia with Minimal Myeloid Differentiation The cells are agranular and show low FS and SS. They strongly express CD34, HLA-DR, and usually CD38 and CD117 (c-kit), as well as CD33, CD13, or both ([56]).

Acute Myelogenous Leukemia without Maturation The blasts have low FS and SS, they are $CD45^+$ and $HLA\text{-}DR^+$, and a high proportion of them are $CD38^+$ and $CD117^+$. Antigens associated with more mature stages of myeloid differentiation (i.e., CD15, CD11b, CD16) are not expressed. A minimum of 3% of blasts demonstrate expression of myeloperoxidase.

Acute Myelogenous Leukemia with Granulocyte Differentiation Maturation at least to the level of promyelocytes and myelocytes is evident. The cells show a stronger SS pattern, and CD45 is moderately to weakly positive, whereas HLA-DR is negative. If there are small numbers of immature cells, they can be separated by their FS/SS properties with or without CD45 combination from the more mature leukemic cells. CD33 expression decreases as more mature markers gain in intensity (i.e., CD15, CD11b). Intracellular myeloperoxidase is strong.

Acute Myelogenous Leukemia with Monocytic Differentiation In the monocytic type of AML, the blasts are large with strong FS signal. They are strongly $CD33^+$ and express CD13 and HLA-DR. They are usually negative for CD34, CD117, and CD11b. CD64 and CD14 are monocytic-related markers and may help in diagnosis, as does expression of CD4. In the myelomonocytic type of leukemia, markers of immature cells are negative. The typical phenotype is expression of CD33, CD13, CD11b, CD4, and HLA-DR.

Megakaryoblastic Leukemia The blasts are positive for CD41 (aIIb) and CD61 (ß $_3$), which are the a- and ß-chains, respectively, of integrin aIIb/ß $_3$, one of the main platelet integrins.

Acute Myelogenous Leukemia with Recurrent Genetic Abnormalities In a group of AMLs, there are certain genetic abnormalities that recur regularly. These forms of AML often have a high rate of complete remission and favorable prognosis (see reference [166]). Most commonly identified abnormalities are reciprocal translocations: t(8;21), inv 16 or t(16;16), t(15;17).

Acute Myelogenous Leukemia: t(8;21)(q22;q22), AML1/ETO In some patients (diagnosed as M2 AML by the FAB classification), there is a translocation t(8;21)(q22;q22), one of the most common karyotypic abnormalities in AML ([57]). The blast cells in these cases are CD34 $^+$CD19 $^+$ and HLA-DR $^+$ and express weakly CD13 and CD33 ([58]). CD56 is often expressed but not as often as CD19. The nonblastic cells have a more mature phenotype (i.e., CD11 $^+$/CD15 $^+$) without immature markers. In AML with a similar translocation in children, CD19 was detected in 81% of the cases and CD56 in 63% ([59]). The CD19/CD56 markers are coexpressed. This translocation involves the AML1 gene at 21q22 and ETO in 8q22.

Acute Promyelocytic Leukemia (AML t15;17)(q22;q12) Acute promyelocytic leukemia (APL) is diagnosed in less than 10% of all AML cases. A variant of APL is known as *microgranular M3* (or *hypogranular*) because the granulation is significantly less than in the traditional M3. Accurate diagnosis of APL is important because of the danger of potentially fatal disseminated intravascular coagulation, which can be initiated by procoagulants contained in the granules. Background fluorescence is high, probably as a result of proteins associated with the granules. In APL, the CD33 expression is strong, whereas CD13 is heterogeneous. The early myeloid markers, CD34 and HLA-DR, are negative, as well as the mature marker CD15. Frequently, there is coexpression of CD2 or CD19.

CD7 + Leukemia Leukemias positive for CD7 but negative for CD4/CD8 were identified as hematopoietic malignancies involving immature cells ([60]). Subsequently, CD7 expression was identified in patients with classical AML phenotype ([61]). CD7 expression was detected in cases of undifferentiated cells with only CD13 $^+$ expression ([62]), and we had a case in which CD7 was the only marker. It is now clear that CD7 is a marker of very primitive hematopoietic precursors detected during the stages of liver hematopoiesis ([63]) and on normal human myeloid progenitors ([43], [64], [65]), as well as on B-lineage precursors ([66]). Cell lines derived from fetal bone marrow B-cell precursors transformed by the Epstein-Barr virus express CD7 and correspond to pre-B or early B stage of differentiation ([67]).

Down Syndrome Children with Down syndrome have an increased incidence of acute leukemia, commonly AML (approximately 10 to 20 times that of the general population). Some patients, however, develop myeloproliferation that resembles leukemia and undergoes spontaneous durable remission ([68]). A unique myelodysplastic syndrome referred to as *transient abnormal myelopoiesis* (TAM) has been reported in children with Down syndrome. The phenotypic characteristic of TAM is the expression of platelet-associated antigens, CD9, CD36, CD41, and CD42 ([69]). In some cases, CD33 and HLA-DR or CD3 and CD7 are also detected, whereas the TCRß is clonally rearranged ([70]). TAM is sometimes called *acute megakaryocytic leukemia*. The phenotype is frequently mixed with expression of megakaryocytic/platelet myeloid or T-cell markers. The abnormality in TAM seems to involve a multilineage precursor ([71]).

Lymphoproliferative Disorders FC contributes significantly to the study of lymphoproliferative disorders through (a) identification of clonality and (b) identification of cell lineage ([72], [73]). Clonality for B cells requires the demonstration of light-chain restriction if surface Ig is expressed. A panel of lineage-specific antibodies provides the answer to the question of cell lineage.

B-Cell Chronic Lymphocytic Leukemia In B-cell chronic lymphocytic leukemia (B-CLL), there are two important and characteristic markers in the majority of the cases (i.e., CD5 and CD23), usually used in combination with CD19 (to exclude T-cell lineage). CD23 expression differentiates B-CLL from mantle cell lymphoma. The combination of CD5/CD23 could also be used for easy identification of residual disease. As shown in Figure 3.11A, all cells are CD5 $^+$/CD19 $^+$ at diagnosis. These cells are monoclonal, as shown in Figure 3.12, because they express only ?–light chains. During therapy, however, residual leukemic cells can be detected easily by FC. As shown in Figure 3.11B, the majority of the cells in this patient are normal T cells (i.e., CD5 $^+$/CD19 $^-$). However, a small cluster of cells with the CD5 $^+$/CD19 $^+$ cells located in the same position as the leukemic cells at diagnosis indicates residual disease. The antibody FMC-7 is useful for identification of prolymphocytic leukemia or prolymphocytoid changes of B-CLL. The term *prolymphocytoid transformation* has been applied to cases of CLL with increased numbers of nucleolated lymphocytes ([74], [75]). Increased numbers of FMC-7 $^+$ cells are sometimes noted in patients with B-CLL in the absence of morphologic changes of prolymphocytic leukemia. It appears that immunologic changes are regulated independent of morphology. In 78 cases of B-CLL with atypical phenotypes, 61% showed increased FMC-7 expression ([75]).

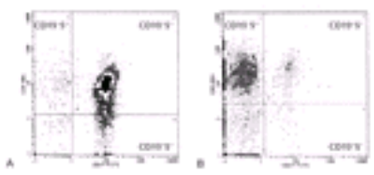

Figure 3.11. A two-parameter histogram of peripheral blood from a patient with B-cell chronic lymphocytic leukemia. **A:** At the time of diagnosis, all cells are CD5 $^+$CD19 $^+$. **B:** Four months after treatment, a very small number of CD5 $^+$/CD19 $^+$ cells still remains.

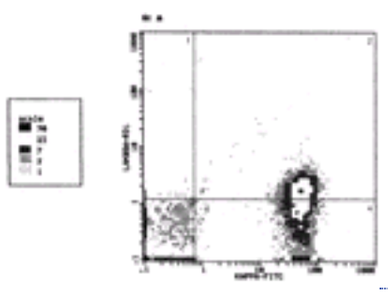

Figure 3.12. Two-parameter histogram (? vs. ?) identifies a mono-clonal population of B cells from a patient with B-cell chronic lymphocytic leukemia. There are no ? $^+$ cells. The small number of cells weakly coexpressing ?-chains together with strong ? expression is likely due to artifacts (passive immunoglobulin adsorption or nonspecific binding of the anti-? monoclonal antibody).

Somatic mutations of the CD79b gene in patients with B-CLL affect the expression of its protein ([76]). CD79b is one of the chains that, together with CD79a, form the co-receptor for surface Ig. Surface Ig is not expressed in the absence of the co-receptor. This may explain the fact that mIg expression is markedly decreased or even undetectable in B-CLL. Expression of CD11c in B-CLL is somewhat controversial and may indicate variants of B-CLL, as is the case with FMC-7 ([77], [78]). Recently, the expression of CD38 in B-CLL has raised significant discussion about whether it can be used as a prognostic factor and whether it identifies a group of patients in whom the genes in the B cell have undergone somatic hypermutations. It was first reported that patients with high percentages of CD38 $^+$ cells had V genes that were unmutated ([79]) and that these patients had a more aggressive form of disease ([80]). The majority of the reports consider CD38 expression as a predictor of poor clinical outcome and an important prognostic marker ([81], [82], [83], [84] and [85]). High levels of CD38 and unmutated genes predicted shorter survival ([80], [86]). Others pointed out that p53 dysfunction has predictive value and all CD38 $^+$ patients had p53 dysfunction, but the two are not associated ([87]). In a multivariate analysis of prognostic factors in B-CLL, deletion of chromosome 11q23, atypical morphology, and more than 30% CD38 $^+$ cells are associated with the presence of unmutated Ig VH genes and poor prognosis ([88]). CD27 has been shown to be expressed in normal memory B cells, which carry somatically mutated Ig VH genes ([89]). CD27 is also expressed in B-CLL ([90]), but whether CD27 in B-CLL is also associated with mutated genes has not been examined. High-grade lymphoma developing in patients with B-CLL is known as *Richter transformation* or *Richter syndrome lymphoma*. It is considered to be clonally related to, or evolving from, the original B-CLL clone. Phenotypically, the cells are CD5 $^-$ ([91]).

Hairy Cell Leukemia Hairy cell leukemia shows a unique phenotype with characteristic expression of CD103 ([92]), the a $_E$-chain, which forms a heterodimer with the ß $_7$-chain. Expression of the integrin a $_E$ß $_7$ is important for homing of lymphocytes to the Peyer patches. A small subpopulation of B cells expresses a $_E$ß $_7$. CD11c may not be unique to hairy cell leukemia, but its expression is strong. The hairy cell leukemia cells are CD5 $^-$/CD23 $^-$ and express CD25 (Fig. 3.13).

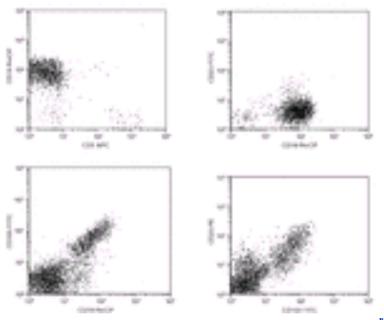

Figure 3.13. The phenotype of hairy cell leukemia differs from the phenotype of chronic lymphocytic leukemia in several aspects. The hairy cell leukemia cell is CD5 $^{-}$/CD23 $^{-}$, and it is positive for CD11c, CD25, and CD103. CD103 is the aE (*E* for epithelial associated) of the a $_{E}$ß $_{7}$ integrin. a $_{E}$ß $_{7}$ binds to E-cadherin on epithelial cells and is important for homing of lymphocytes to intestinal epithelia. APC, allophycocyanin; FITC, fluorescein isothiocyanate; PerCP, peridinin-chlorophyll-a protein. (Courtesy Dr. Carmen Morales.)

Mantle Cell Lymphoma Mantle cell lymphoma has a characteristic genetic marker as well as an immunophenotype. In our experience and in that of others ([93]), FC has shown that the distinguishing phenotype is CD5 $^{+}$/CD23 $^{-}$. CD10 distinguishes mantle cell lymphoma (CD10 $^{-}$) from follicular cell lymphoma (CD10 $^{+}$).
Marginal Cell Lymphoma The majority of the B cells in the marginal zone of the spleen are memory B cells (both T-dependent and T-independent specific for type I antigens). The marginal zone of the lymph node is a rim of lymphocytes located in the outer zone of the mantle of the secondary lymphoid follicles. Marginal zone B cells are larger than naïve B cells and express high levels of IgM. These lymphocytes are negative for CD5, CD23, and CD10, which differentiate marginal lymphoma from other B-cell lymphomas ([94]). The marginal zone B cells are hypermutated, indicative of their postfollicular center nature ([95]). A B cell known as *monocytoid B cell* is detected in large numbers in Hodgkin disease and in lymphadenopathies caused by *Toxoplasma gondii*. It has the same phenotype as the marginal zone B cell but has not undergone mutations (i.e., is a naïve B cell) ([96]).
Follicular Cell Lymphoma Follicular lymphoma (FL) is characterized by the t(14;18)(q32;q21) translocation. The BCL-2 oncogene at chromosome 18q21 is juxtaposed to the Ig heavy chain gene locus at 14q32. As a result of the translocation, the BCL-2 is deregulated ([97]). The phenotype that distinguishes FL from other B-cell lymphomas in the majority of cases is CD10 $^{+}$CD5 $^{-}$CD23 $^{-}$. A combination of CD10 with antibodies to light chains provides evidence of monoclonality. A variant of FL known as *floral FL* has been shown to express CD5 ([98]).
Burkitt Lymphoma In addition to the usual markers associated with B cells, the tumor cells are CD10 $^{+}$ and sIgM $^{+}$.
Peripheral T-Cell Lymphoma The usefulness of FC in T-cell proliferative diseases is to confirm the nature of the lineage. Clonality markers for T cells, equivalent to light chains on B cells, do not exist ([99]). Clonality may be suspected by phenotypic abnormalities of major T-cell markers such as CD4, CD8, or both. For example, expression by all cells of only one of these markers instead of the normal ratio or the expression of both on the same cell is strong evidence of an “abnormal” population. Lack of CD7 is suggestive of malignancy but is not conclusive. In adult T-cell leukemia/lymphoma (human T-cell leukemia virus type 1 infection), CD25 is expressed in high levels. In a study of 50 cases of peripheral T-cell lymphomas, one to five aberrations were detected in 92% of the cases. Abnormal expressions most frequently involved CD3 (66%), followed by CD7 (58%) ([85]). Unique expressions of a particular marker in other T-cell lymphoproliferative diseases include the CD30 (large cell lymphoma, cutaneous or noncutaneous) and the CD4 in Sézary syndrome. However, immunophenotyping is only contributory to the diagnosis. A rare T-cell lymphoma, known as *hepatosplenic T-cell lymphoma*, is a malignancy of the ?d T cells and is CD4 $^{-}$/CD8 $^{-}$/CD16 $^{+}$ ([100]).

Staging of B-Cell Lymphoma

The standard practice for determining the stage of non-Hodgkin lymphoma is the morphologic examination of bone marrow. Results from the application of FC for this purpose remain controversial. One study questioned the usefulness of FC because in only 3 of 273 samples did FC improve the diagnosis, and two of these cases were morphologically suspicious ([101]). Considering the cost difference between FC and morphologic examination of bone marrow, FC does not offer significant advantages ([102]). In this study, FC on peripheral blood provided results that were as good as those from the bone marrow. On the other hand, FC was found to be superior to morphology in patients with low bone marrow involvement because the morphologic evaluation can detect only cases with greater than 5% bone marrow involvement. These results need to be reevaluated with larger numbers ([103]). It is likely that improvements in the protocols for FC evaluation are needed, as shown by another study in which CD19-based gating was successfully used to detect light-chain restriction ([104]). Although morphology and FC provided concordant results in 82% of the cases, all 18 samples were positive by FC except for one with discrepant results.

Minimal Residual Disease by Flow Cytometry

It is well known that, in patients with complete remission as shown by morphology, relapses frequently occur due to persistence of small numbers of leukemic cells that remain undetectable by morphology or cytochemistry ([105]). Several reports in the literature regarding the feasibility of FC for detection of minimal residual disease show a disappointing level of agreement. Some of the reasons are methodology, differences in interpretation, and, more specifically, the inability to identify clonogenic cells by immunophenotyping ([105] , [106] , [107] and [108]). There is also no consistency among centers in identification of leukemia-associated phenotypes. Expression of myeloid-associated antigens in ALL and lymphoid-associated antigens in AML varies greatly (i.e., 7 to 54% in the former case and 4 to 60% in the latter) ([106]). Another possibility is that the expression of lymphoid markers such as CD7, CD4, and CD2 in cases of AML is not, strictly speaking, an aberration, but rather leukemias arising from progenitors expressing these markers normally, as has been shown for CD7 and CD4. However, in some cases in which a “leukemic phenotype” can be confirmed, FC is a convenient method to detect rare leukemic cells. Asynchronous antigen expression is useful when two markers are normally well separated by their expression at distinct maturational stages but are coexpressed in the leukemic cell, such as CD34 and CD20 in B-ALL ([52]). This particular combination does not apply to all cases because only 38% of B-ALLs are CD20 $^{+}$ ([52]). In our experience with certain markers, their density and, therefore, intensity of fluorescence are strikingly higher in the leukemic population as compared to normal. For example, intensity of CD24 expression is much stronger in B-ALL blasts than in normal pre-B cells. In combination with CD10, the CD10 $^{+}$/CD24 $^{+}$ blasts are in a unique position on the histogram, well separated from CD10 $^{+}$/CD24 $^{+}$ normal B cells during bone marrow regeneration (*unpublished observations*). Fluorescence intensity has been used successfully to identify leukemic cells in B-ALL, and the leukemic nature of these cells was confirmed by polymerase chain reaction and Ig heavy chain gene rearrangements ([109]).

In general, in spite of methodologic differences, FC is sensitive enough to detect small numbers of leukemic cells. Among 53 ALL patients, persistence of gradual increase of the number of leukemic cells in the bone marrow is associated with a higher incidence of relapse (90% vs. 22%) and a shorter disease-free survival (median of 12 months vs. not reached) ([108]).

Detection of minimal residual disease by FC requires carefully controlled technique, proper marker protocols, and significant expertise for definition of the leukemic phenotype at diagnosis, and the interpreter must be able to later identify this phenotype on rare residual leukemic cells.

Platelet Function

FC offers distinct advantages in the study of platelet activation in whole blood with minimal manipulation ([110]). Platelet activation is detected by antibodies specific for epitopes exposed after granule secretion (i.e., P-selectin) or ligand binding. Ligands induce conformational changes to their receptors; fibrinogen, for example, induces conformational changes to its receptor GPIIb/IIIa (CD41/CD61) integrin ([111]). In either case, these activation-specific antibodies do not react with resting platelets. Antibodies against the GPIb-IX-V complex (CD42a, a, ß), the receptor for von Willebrand factor, bind to resting platelets and only very weakly to activated platelets ([112]). On activation, there are changes in the size and granularity of platelets as reflected in the reduction of forward light scatter (size) and granularity (SS). Because activation of platelets may occur during preparation for FC, samples need to be handled with specific procedures and inhibitory compounds.

As a result of activation, intracellular Ca $^{2+}$ increases rapidly. Clinically approved Ca $^{2+}$ indicators are Fluo-3 and Fura Red (Molecular Probes, Eugene, OR). Binding of free intracellular Ca $^{2+}$ to Fluo-3 increases the intensity in green wavelengths and decreases wavelengths in the red range (Fura Red). The ratio between the two intensities gives the relative Ca $^{2+}$ concentration ([113]). Microparticles frequently overlap with nonspecific background or “electronic” noise but technically may be separated with the use of an antiplatelet antibody and linear SS.

In thrombocytopenia patients, FC helps to determine whether the low platelet count is the result of accelerated destruction or decreased production. With normal bone marrow capacity, loss of platelets triggers compensatory platelet production. Newly released platelets are larger and contain RNA, which can be detected by thiazole

orange (reticulated platelets) ([114]). Diagnosis of idiopathic thrombocytopenic purpura by detecting platelet-bound IgG is difficult because Ig bound to platelets is found in other conditions and because platelets have Fc receptors that may carry normal Ig ([115]).

Interaction of platelets with leukocytes is increased in inflammatory conditions and has also been detected in cardio-pulmonary bypass, acute coronary syndrome, and so forth. Such interactions are easily detected by FC because the “cluster” has the scatter properties of leukocytes that bear both leukocyte- and platelet-specific markers ([116]).

Platelet studies by FC have been used in clinical conditions, such as Glanzmann thrombasthenia, to demonstrate the degree of lack of GPIIb/IIIa on the cell surface (see Chapter 2, sections CD41 and CD61). In family members who may be heterozygotes, FC has the advantage of determining the subpopulation of platelets with lack of GPIIb/IIIa.

Erythropoiesis and Red Blood Cell Disorders

Reticulocytes can be differentiated from mature red blood cells on the basis of their RNA content. Usually, counts of reticulocytes are done using thiazole orange dye. Analysis of data requires discrimination from mature red blood cells and platelets ([117]). The intensity of green fluorescence provides accurate estimates if the “discriminator” value is set appropriately to exclude fluorescence of mature erythrocytes. The threshold level, or discriminator, is set from normal blood with known reticulocyte values. The fluorescence increases on binding to RNA, with thiazole orange by a factor of 3000, with other dyes, such as thioflavin T, by a factor of 100. The excitation and emission maxima for thiazole orange in complex with RNA are 500 nm and 533 nm, respectively. Gating is usually set on size (FS), and fluorescence intensity is recorded on a logarithmic scale. Measurements of the immature reticulocyte fraction (IRF) provide an accurate assessment of erythropoietic activity. IRFs are reticulocytes recently released and have a higher RNA content. IRF measurements allow for detection of significant changes in red blood cell production after bone marrow transplantation or chemotherapy. Several methods, including FC, are used to obtain IRFs ([118]).

Feto-maternal hemorrhage can be detected by FC with the use of anti–hemoglobin F antibodies (F cells) ([119]). Enumeration of F cells is important in sickle cell anemia and thalassemia, in which patients receive treatment intended to stimulate increase of F cells, which is usually associated with clinical improvement. Monitoring levels of F cells is important for optimal treatment schedules because some of the drugs used have toxic side effects. F cell levels may be of prognostic value in myelodysplasia, and, therefore, their levels need to be monitored ([120]).

In paroxysmal nocturnal hemoglobinuria, the glycosylphosphatidylinositol-anchored proteins CD55 (decay-accelerating factor) and CD59 (membrane inhibitor of reactive lysis) are decreased. The decay-accelerating factor is an inhibitor of the classical C3 convertase and inhibits its function by splitting C4b and C2a. CD59, on the other hand, is a regulator of the membrane attack complex. It prevents insertion of the C9 component during the formation of the membrane attack complex and blocks polymerization of C9 (see Chapter 18).

FC has distinct advantages over other methods in the study of red blood cells: sensitivity, ability to quantitate fractions of red cells with defects, and accurate monitoring during the management of the patient ([118]). It can also identify the lack of markers on leukocytes at the same time. FC allows the analysis of markers on red blood cells and leukocytes with the use of triple-staining techniques ([121]). Decreased expression of CD55 does not always correlate with *in vivo* hemolysis, whereas loss of CD59 is associated with a high degree of hemolysis ([122]).

Intracellular Cytokines

FC has recently been used in monitoring cytokine production. These methods have distinct advantages but also several disadvantages ([123]). Functional subsets of T cells can be identified by this method, which allows the identification of cells producing more than one cytokine.

A disadvantage of this method is the permeabilization of the cells, which increases nonspecific fluorescence. Blocking the Fc receptors with polyclonal Ig tends to minimize the problem. A specificity control also requires blocking the intracellular cytokine by an unlabeled anticytokine antibody. Positive controls are available commercially. Cells need to be activated for increased production of cytokines. Usually, a polyclonal activator is used, such as phorbol myristate acetate and ionomycin, but this raises the question of immunologic specificity. Cell-surface markers like CD4 are down-regulated during activation, which makes cell identification difficult. Because the amount of cytokines produced is small, it is customary to block their secretion with the use of brefeldin A so that the cytokine is retained within the Golgi apparatus.

One of the main applications of this methodology is the identification of Th1 versus Th2 cell populations ([124] , [125]). Despite the limitations of this approach, the reported results seem to be consistent with pathogenic mechanisms of human disease. These studies have identified T-cell subsets producing predominantly transforming growth factor-ß ([126]) as well as the immunoregulatory T cells, which secrete mainly interleukin-10 ([127]).

Major Histocompatibility Complex–Peptide Tetramers

The innovation of HLA class I tetramers has revolutionized our understanding of cytotoxic T cells. Soluble HLA molecules are made in *Escherichia coli* by recombinant technology. A 15–amino acid peptide containing a single lysine residue is attached to the COOH terminus of an HLA-A $_2$ molecule. The lysine-containing peptide is biotinylated by the BirA enzyme. Folding of the HLA heavy chain is achieved in the presence of ß $_2$ microglobulin and the ligand peptide of HLA-A $_2$. Biotinylation of the tag peptide at the COOH terminus correctly orients the HLA molecule for recognition by the TCR, which binds to the NH $_2$ terminus of the HLA. Tetramers are produced by mixing the HLA tagged with the biotinylated peptide with phycoerythrin-labeled deglycosylated avidin. Because avidin has four biotin-binding sites, it produces tetramers of HLA molecules that bind to the T cells with appropriate TCR (Fig. 3.14). The tetramers have far greater avidity for T cells than the sum of the individual affinities of the four HLA molecules ([128] , [129] and [130]). Variations of this method have been developed with covalently bound peptides ([131]) or using silent mutated sequences, which bacteria prefer in order to initiate synthesis of the HLA molecule ([132]). Tetramers for HLA class II are now available ([133] , [134]). Tetramer studies have been done mainly on major histocompatibility complex class I–mediated responses in viral infections ([135]) and malignancies ([136] , [137]). These studies have shown that the CD8 $^+$ T-cell antigen–specific responses involve 40 to 80% of the circulating CD8 $^+$ T cells, which persist for many years. Class I HLA tetramers are also used in bacterial infections and autoimmune diseases ([138]).

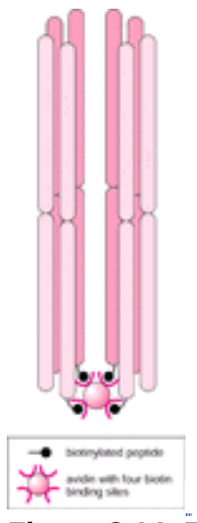

Figure 3.14. For formation of HLA class I or class II tetramers, the HLA molecules are tagged with a lysine-carrying peptide in their C-terminus. The molecules are biotinylated (i.e., biotin is attached on the lysine of the tag peptide). Addition of phycoerythrin-labeled avidin, which has four biotin-binding sites, associates four HLA molecules to form a tetramer.

Low frequency cytotoxic T cells have been detected by this method in some individuals who lyse chronic myelogenous leukemia cells ([139]). The HLA tetramer assay has been applied to detect cytotoxic T lymphocytes specific for Epstein-Barr virus ([140]) or cytomegalovirus ([141]) in recipients and donors of stem cell transplants. The technique can also be used *in situ* ([142]) to detect with exquisite specificity cytotoxic T cells in Epstein-Barr virus–exposed individuals ([143]). A new application of the tetramer technology is the simultaneous detection of antigen-specific T cells and identification of cytokine secretion. Tetramers with proper agonist peptides have the capacity to stimulate T-cell activation programs secreting interferon-?, tumor necrosis factor-a, or both ([144]).

In an important new application, tetramers conjugated with a tumor-specific antibody targeted tumor cells (CEA^+ cell lines, $CD20^+$ B-cell lymphoma cells) to be attacked and lysed by antigen-specific cytotoxic T lymphocytes ([145]). These studies open the field for use of tetramers for specific immunotherapy. Tetramer assays can be combined with detection of intracellular cytokine, opening the way for the study of antigen-specific immune responses ([146], [147]).

Tetramers made from CD1d have been tested for the detection of CD1-restricted T cells. CD1 is an HLA-like molecule that presents lipids or glycolipids to T cells. CD1d tetramers identified natural killer T cells unambiguously ([148]). Natural killer T cells have been implicated in the defense against certain infectious diseases as well as in the regulation of insulin-dependent diabetes mellitus.

Phagocytosis

All aspects of phagocytosis can be studied by FC (i.e., opsonization of the particle to be phagocytosed, engulfment, and oxidative burst) ([149]). The particles used are bacteria, zymosan, fungi, or latex labeled with FITC. For opsonization, the particles are incubated in serum that is normal or from a patient who has recovered from a specific infection. Oxidative burst is studied with substances that are converted from nonfluorescent to fluorescent products under the influence of the intracellular reactive oxygen radicals. This conversion reflects the amount of oxidative burst induced. Among the most common substances are 2',7'-dihydrochlorofluorescein diacetate, dichlorofluorescein, and dihydrorhodamine-123/rhodamine-123.

Dihydrorhodamine-123/rhodamine-123 is a more sensitive indicator system. Lymphocytes and nonlymphocytes are discriminated by FS and SS. The number of phagocytosing nonlymphoid cells is calculated as a percentage of gated cells. The parameter *phagocytosis product* is defined as the percentage of phagocytosing nonlymphocytes multiplied by the mean number of targets per phagocytosing nonlymphocyte.

Cell Cycle Analysis

Cell cycle analysis is the simplest method to reveal the frequency of cells in each cell cycle phase. Cells are permeabilized and stained with the nucleic and specific fluorochrome, propidium iodide or 4'6'-diamidino-2-phenylindole. The results are displayed as DNA content–frequency histograms, which show the proportions of cells in the respective phases of the cell cycle. Univariate analysis of DNA content is most frequently used in clinical studies of tumors or proliferative disorders. The proportion of cells in the S- and G_2/M-phases is considered indicative of the increased proliferative potential, which in tumors is accepted as a poor prognostic feature. This simple analysis does not provide information about cell kinetics (i.e., the duration of cell cycle or doubling time). Cells in G_2- and M-phases have the same DNA content and cannot be discriminated by univariate analysis. For this purpose, mitotic markers can be used ([150]). DNA replication is measured by a bivariate analysis of DNA content versus incorporation of 5-bromo-2'-deoxyuridine (BrdU) ([151]). Live cells are exposed to this thymidine analog, which is incorporated into DNA as the cell divides. BrdU is detected by a monoclonal antibody tagged by fluorescein. The DNA content is measured by propidium iodide. In the histogram, green versus red fluorescence provides information not only on the DNA content, but also on the number of cells in division.

Detection of Apoptosis

During apoptosis, there are changes in the cell size (smaller) and nuclear fragmentation. Shrinkage of the cell, which occurs early in apoptosis, can be detected by FS ([152]). Late in apoptosis, the SS also decreases. However, light scatter is not specific for apoptosis, and it should be combined with other methods.

Detection of phosphatidylserine in the outer leaflet of the cell membrane can be determined with annexin-V conjugated with fluorescein, which binds with high affinity to phosphatidylserine ([153]).

Other methods of evaluation of the apoptotic process by FC include measurements of mitochondrial transmembrane potential, ??m. This is measured by rhodamine-123, a lipophilic green fluorochrome that permeates normal membranes and accumulates in the mitochondria. High intensity of green fluorescence indicates normal mitochondrial transmembrane potential. The combination with propidium iodide discriminates apoptotic from live cells. The permeable membrane of apoptotic cells allows penetration of propidium iodide (red-staining), whereas rhodamine-123 penetrates only normal membranes (green-staining) ([154]).

Another method is based on the detection of DNA fragmentation. The 3'-OH ends of the DNA breaks are detected by a fluorochrome-tagged deoxynucleotide. The BrdUTP is the most advantageous, and when it is attached to the DNA breaks, it is detected by a specific antibody ([155]). The attachment of BrdUTP is mediated by the enzyme deoxynucleotide transferase (TdT). The method is known as TUNEL (*T*dT-mediated deoxy *u*ridine triphosphate-biotin *n*ick- *e*nd *l*abeling).

HLA Cross-Match by Flow Cytometry

For a successful cross-match, the detection of antidonor antibodies in the recipient and antirecipient antibodies in the donor is critical. FC is one of the most sensitive techniques for the detection of IgG antibodies ([156], [157]). Another advantage of FC versus the cytotoxic method, in addition to sensitivity, is the multiparameter analysis. T and B cross-matches for antibody activity against class I or class II can effectively be distinguished. T and B cells are identified by appropriate monoclonal antibodies. A human IgG anti-HLA antibody, bound to the cells, is detected by anti–human IgG antibody conjugated with fluorescein (Fig. 3.15). A significant shift of fluorescence over the control is a positive result, indicating that anti-HLA human IgG is bound to the cells. If both T and B cells are positive, transplantation is contraindicated ([158]).

Figure 3.15. Flow cross-match. Testing for antidonor HLA antibodies is based on incubation of the recipient's serum with donor cells expressing HLA class I or class II antigens. The binding of the antibody is detected by fluorescein-conjugated anti–human immunoglobulin (Ig) by flow cytometry. FITC, fluorescein isothiocyanate; MHC, major histocompatibility complex; PE, phycoerythrin; PerCP, peridinin-chlorophyll-a protein. (Courtesy of Dr. Peter Nickerson, Director, Immunogenetics Laboratory, Winnipeg Centre, Manitoba, Canada.)

In earlier years, a panel of cells of known HLA type were tested against the patient's serum. This was known as *panel-reactive antibody*, or *PRA*. The percentage of positive reactions (i.e., the number of cells in the panel that reacted with the serum) was called *percentage PRA*. By this method, the specificity of the antibody is known as well as the possibility of obtaining a negative cross-match. PRA values predict the possibility of a positive cross-match between the recipient and prospective donors (i.e., a PRA value of 50% indicates that a positive cross-match will occur with 50% of organ donors). Thus, PRA value and specificity would exclude certain potential donors and expedite organ allocation.

Flow cytometric PRA using cells was introduced in an attempt to replace the serologic method, but several problems were encountered. Recently, microparticles

coated with purified HLA class I or class II proteins have been introduced instead of cells ([159], [160]). In the test, 20 to 50 µl of the patient's serum is added to a mixture of HLA class I and class II beads. After 30 minutes of incubation, they are washed, and a goat anti–human IgG fluorescein-conjugated reagent is added. The mixture is washed again after a short incubation, and the beads are passed through the cytometer. The beads of class I and class II antigens can run simultaneously (Fig. 3.16).

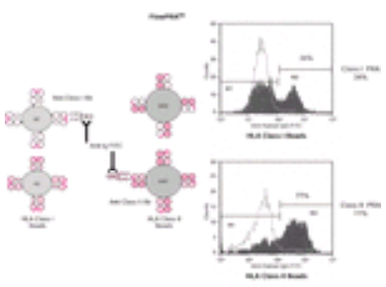

Figure 3.16. Flow panel–reactive antibody (PRA). Beads coated with purified HLA class I or class II molecules are incubated with the patient's serum. After washing, fluorescein-conjugated anti–human immunoglobulin (Ig) is added **(A)**. The beads are examined by flow cytometry for identification of the presence of anti-HLA antibodies **(B)**. Multiple single-antigen–coated beads of different color are now mixed in the same tube for the simultaneous detection of anti-HLA antibodies of different specificities. FITC, fluorescein isothiocyanate. (Courtesy of Dr. Peter Nickerson, Director, Immunogenetics Laboratory, Winnipeg Centre, Manitoba, Canada.)

The flow cytometric PRA can detect more antibody than the cytotoxic method and, in addition, can detect class I and especially class II antibodies simultaneously, which is difficult with the customary methods. Once the presence of anti-HLA antibody is established, the identification of the specificity can be accomplished with flow-specific beads (i.e., expressing a particular HLA antigen) ([158]). These improvements in detection of anti-HLA antibodies have also shown that detection of antidonor antibody during the posttransplant period has a poor prognosis ([161]) and identifies patients in need of new approaches to treatment ([162]).

The last step in the evolution of this technology is the use of single–antigen bead panel. These single antigen beads are coated with different color and are mixed in one tube for the simultaneous detection of HLA antibodies against eight different antigens per test ([163]). In a group of ten patients who had rejected a kidney transplant, this method identified antibodies to 31 of 35 antigens that were mismatched in the donor.

Three methods, antiglobulin-enhanced complement-dependent cytotoxicity (AHG-CDC), enzyme-linked immunosorbent assay, and FC were compared in 264 sera from 88 patients ([164]). Discordant results were found in 32 sera. None of the 32 sera was positive by AHG-CDC, 20 of 32 were positive by enzyme-linked immunosorbent assay, and 32 of 32 were positive by FC. In another group of 302 patients who exhibited 0% PRA by AHG-CDC, 25% had class I or class II antibodies detectable by FC. These striking differences between the two methods will certainly redefine the concept of sensitization in organ transplantation.

APPENDIX: IMMUNOPHENOTYPING HEMATOLOGIC MALIGNANCIES IN THE FUTURE: DEFINING THE IMMUNOPHENOTYPIC SIGNATURE

Clinical flow cytometry has been in existence for just over 25 years, but its applications are still growing ([13]). At this point, it has gone from the cell surface deep inside the cell to intracellular molecules and signaling pathways and is poised to explore the genome. The prospects for combinations of immunophenotyping with molecular phenotyping have been reviewed ([165]).

In the clinical setting of studying hematologic disorders, flow cytometry has not yet reached its potential, mainly because of the limitations of the number of fluorochromes used with the one-laser or two-laser cytometers. Some laboratories have now reached the concomitant use of 11 ([14]) or 12 ([13]) markers combined with the two parameters of light scattering. Less information is obtained when reagents are used alone or combined in small sets (i.e., “two two-color stains are not equivalent to one four-color stain”) ([14]).

The possibility of identifying larger numbers of cell-surface markers combined with the identification of intracellular molecules is exemplified in Figure 3.17. It shows the analysis of naïve and memory CD8 $^{+}$ T cells activated by phorbol myristate acetate, ionomycin, and monensin. Dead cells were separated by ethidium monoazide bromide, and the viable cells were examined for 10-color 12-parameter (two scatters) cytometric analysis ([14]).

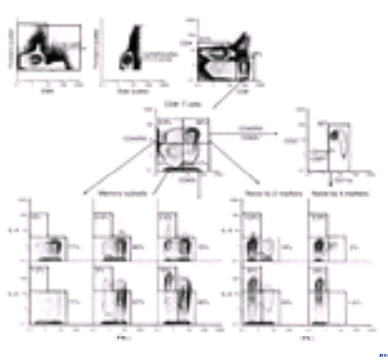

Figure 3.17. Immunophenotypic analysis of CD8 $^{+}$ human T cells by 10-color 12-parameter fluorescent-activated cell sorter analysis. Human peripheral blood mononuclear cells were incubated with phorbol acetate, myristate, ionomycin, and monensin and then stained for detection of several markers and intracellular cytokines. The analysis demonstrates the separation of naïve versus memory CD8 $^{+}$ T cells by phenotype and their differences in production of interleukin (IL)-2, IL-4, and interferon (IFN)-?. Naïve CD8 $^{+}$ T cells do not produce IFN-?. However, separation by two markers shows IFN-?–producing cells in the naïve T cells as a result of contamination by memory cells. EMA, ethidium monoazide bromide. (Courtesy of Dr. Leonard A. Herzenberg, Professor, Department of Genetics, Stanford University School of Medicine, CA. From Herzenberg LA, DeRosa SC, Herzenberg LA. Monoclonal antibodies and the FACS: complementary tools for immunobiology and medicine. Immunol Today 2000;21:383–390, with permission.)

Analysis to this extent is not yet available in most of the clinical laboratories. However, with the development of new instruments and new fluorochromes, flow cytometry is poised to define precisely the immunophenotypic signature for the disease or for the patient. This will be a kind of proteomics by flow cytometry to complement the new technology of functional genomics by the microarrays. The examples presented here are an attempt to outline, albeit crudely, some of the principles that may significantly add to a complete immunophenotype. In the future, immunophenotype will include not only protein identification, but also quantitative and functional aspects of their expression. Figure 3.17 is a glimpse into the future. In the examples shown here, we have used two- to four-color analysis with two scatter parameters. We define (a) the lineage of the malignant cell (not always possible with the available data); (b) “asynchronous” intralineage expressions (i.e., detected in a stage of differentiation in which it does not belong) or “aberrant” interlineage expressions; (c) intensity of fluorescence, which provides a gross but still useful parameter of expression of a particular marker; and (d) degree of homogeneity in the expression of the marker as measured by the CV. This distinguishes the homogeneous expression of a marker by the clonal malignant cell from the usually heterogeneous expression by the normal cells as a result of their normal differentiation. As some examples show, however, there is frequently a differentiation potential within the malignant clone, and the heterogeneity of the marker could be used as a unique characteristic of the patient rather than of the lineage or the stage of differentiation.

CASE 1: Acute Myelogenous Leukemia

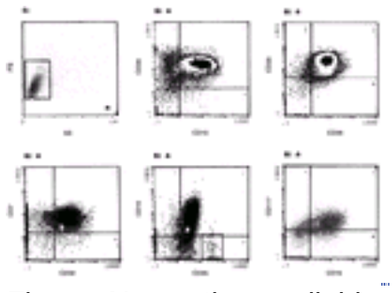

Figure. No caption available.

Size	Small to medium.
Granularity	Nongranular with only the larger cells weakly granular.
Immunophenotypic signature	Stem cell: CD34 $^{+}$, CD117 $^{+}$, CD7 $^{+}$; myeloid: CD33 $^{+}$, CD15 $^{+}$, CD11b $^{+}$.
Comments	Immature myeloid precursor with expression of CD7. Asynchronous expression of markers (i.e., coexpression of CD117 $^{+}$/CD15 $^{+}$) constitutes an important component of the signature for this patient. FS, forward angle scatter; SS, side scatter.

CASE 2: Acute Myelogenous Leukemia with Maturation

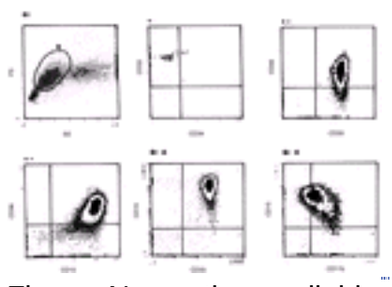

Figure. No caption available.

Size	Medium.
Granularity	Medium (monocytic area).
Immunophenotypic signature	Stem cell: CD34 $^{-}$, CD117 $^{-}$; myeloid: CD33 $^{+}$/CD15 $^{+}$, CD11b $^{+}$; others: CD56 $^{+}$.
Comments	AML with maturation. Aberrant expression of CD56. Heterogeneous expression of CD15 (CV 102.6) as compared to CD33 (CV 46.7). Probably indicates some degree of differentiation and forms an important component of identification of this clone. Note: CD33 $^{+}$ cells in histogram 2 accumulated along the vertical axis. FS, forward angle scatter; SS, side scatter.

CASE 3: B-cell Acute Lymphocytic Leukemia

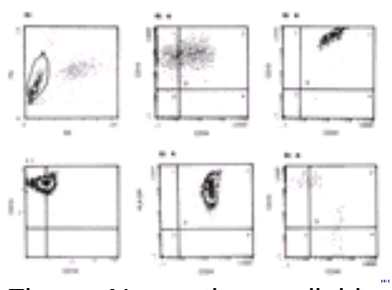

Figure. No caption available.

Size	Small to medium.
Granularity	None in small cells; rare in larger cells.
Immunophenotypic signature	Stem cell: CD34 $^{\pm}$, CD38 $^{+}$; B-lymphoid: CD10 $^{3+}$, CD24 $^{2+}$, CD19 $^{-}$, CD20 $^{-}$; other: HLA-DR $^{2+}$, CD45 $^{-}$.
Comments	Very strong CD10 expression (small CV). Most of the cells are CD34 $^{-}$ and CD19 $^{-}$, and all of them are CD20 $^{-}$ and CD45 $^{-}$. Heterogeneous HLA-DR expression (large CV). Double: CD10/CD24, CD10/CD20, and CD10/CD38 (not shown) will be very useful for minimal residual disease. Note: CD10 $^{+}$ cells in histogram 6 clustered along vertical axis. FS, forward angle scatter; SS, side scatter.

CASE 4: B-cell Acute Lymphocytic Leukemia

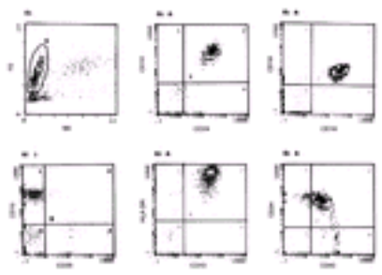

Figure. No caption available.

Size	Heterogeneous.
Granularity	None.
Immunophenotypic signature	Stem cell: CD34 $^{-}$; B-lymphoid: CD10 $^{2+}$, CD24 $^{2+}$, CD19 $^{+}$, CD22 $^{+}$, CD20 $^{-}$; other: HLA-DR $^{3+}$, CD45 $^{+}$.
Comments	Some evidence of maturation (i.e., CD34 $^{-}$, intermediate CD10 and CD24 expression with expression of CD45). Comparison with Case 3 makes the point. FS, forward angle scatter; SS, side scatter.

CASE 5: B-cell Acute Lymphocytic Leukemia

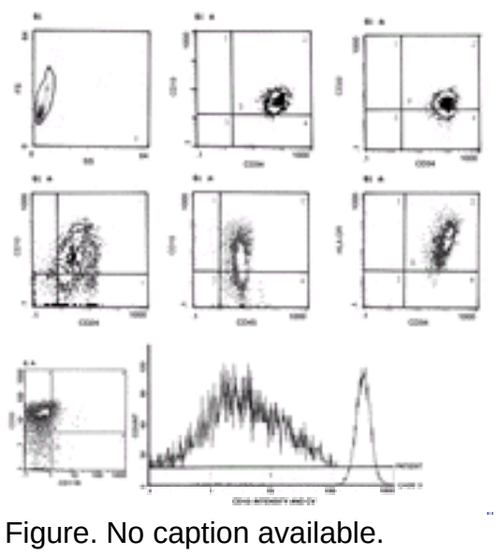

Figure. No caption available.

Size	Small.
Granularity	None.
Immunophenotypic signature	Stem cell: CD34 $^{2+}$, HLA-DR $^{2+}$, CD71 $^{-}$; B-lymphoid: CD10 $^{2+}$, CD19 $^{+}$, CD24 $^{+}$, CD22 $^{+}$, CD20 $^{-}$, cCD79a $^{-}$; myeloid: CD33 $^{+}$, CD13 $^{\pm}$, CD11b $^{-}$.
Comments	The striking heterogeneity (very large CV) of CD10 expression is the most characteristic point in this patient. For comparison, see single-parameter histograms with the usual acute lymphocytic leukemia. CD24 expression is also heterogeneous and, relative to the usual cases, weak. The striking type of CD10/CD24 expression combined with CD33 is the main characteristic of this case. FS, forward angle scatter; SS, side scatter.

CASE 6: B-cell Acute Lymphocytic Leukemia

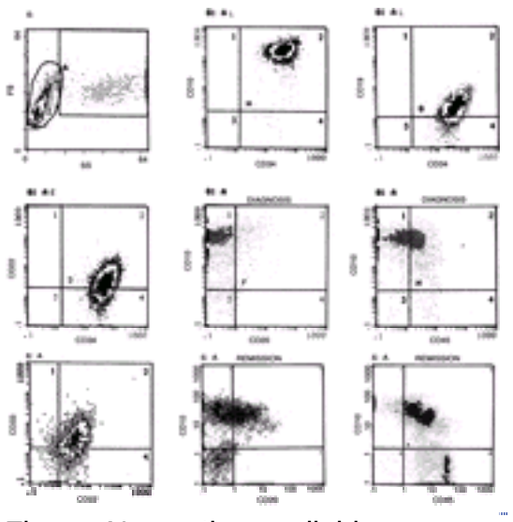

Figure. No caption available.

Size	Small to large.
Granularity	Light on the larger cells.
Immunophenotypic signature	Stem cell: CD34 $^{2+}$, CD117 $^{-}$; B-lymphoid: CD10 $^{3+}$, CD24 $^{2+}$, CD19 $^{+}$, CD22 $^{+}$, CD20 $^{-}$; myeloid: CD33 $^{+}$.
Comments	Characteristic feature is the strikingly strong expression of CD10 and CD34, placing the cell in the upper right corner of the histogram where no normal cells are usually located. Therefore, the CD10/CD34 combination will be very useful for minimal residual disease, as will the almost total lack of CD45. Expression of CD33 is another characteristic of this immunophenotype. The combinations CD10/20 and CD10/45 are shown for both diagnosis and remission. Although CD10 intensity is lower in remission as compared to diagnosis, the most critical criterion is the pattern of differentiation in remission, which does not exist in the leukemic population. FS, forward angle scatter; SS, side scatter.

CASE 7: Acute Monocytic Leukemia

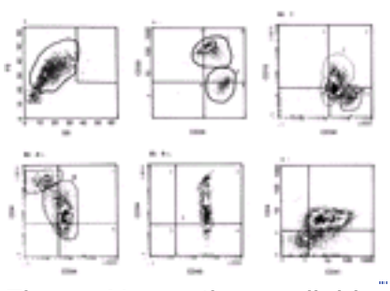

Figure. No caption available.

Size	Heterogeneous.
Granularity	Heterogeneous; large cells, heavily granular.
Immunophenotypic signature	Stem cell: CD34 $^{+}$, CD117 $^{\pm}$, CD38 $^{2+}$; myeloid: CD33 $^{2+, CD15+}$, CD13 $^{\pm}$, CD11b $^{+}$ (not shown); monocytic: CD14 $^{+}$, CD4 $^{+}$, HLA-DR $^{2+}$; others: CD45 $^{+}$, CD2 $^{+}$ (not shown).
Comments	Acute leukemia with monocytic phenotype. Characteristics in this case are the two cell populations: (a) CD34 $^{2+}$, CD4 $^{-}$, CD15 $^{-}$ and (b) CD34 $^{+}$, CD4 $^{+}$, CD15 $^{+}$, CD45 $^{2+}$. Heterogeneity of CD34 expression (CV 166.7). CD4 and CD41 expression show pattern of differentiation. FS, forward angle scatter; SS, side scatter.

CASE 8: Bone Marrow Regeneration versus Acute Lymphocytic Leukemia

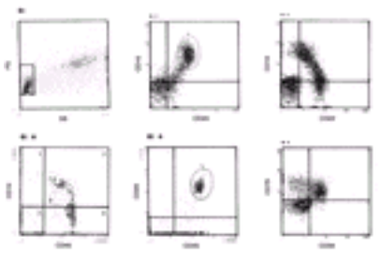

Figure. No caption available.

Size	Small.
Granularity	None.
Immunophenotypic signature	Stem cell: CD34 $^{+}$; B-lymphoid: CD10 $^{2+}$?CD10 $^{+}$, CD22 $^{+}$, CD21 $^{+}$, CD20 $^{+}$, cCD79 $^{+}$.
Comments	This 3-month-old child was suspected to have leukemia by morphology. However, the strong regeneration pattern by immunophenotype could not support the diagnosis. In addition, expression of CD45 and CD20 is strong, which is not usually seen in B-cell acute lymphocytic leukemia. This case shows that strong pattern of differentiation by several markers is very helpful in distinguishing normal bone marrow regeneration from a proliferative disease, especially when morphology indicates a relatively large number of immature cells. The child is now 4 years old and has no signs of leukemia. FS, forward angle scatter; SS, side scatter.

Cytogenetics

Cytogenetics is the study of chromosome structure. Cytogenetic analysis has become increasingly important in the diagnosis, classification, management, and scientific investigation of hematopoietic and lymphoid disorders. Classic cytogenetic analysis studies cells in metaphase, or dividing cells. However, with the advent of molecular cytogenetic techniques such as fluorescence *in situ* hybridization (FISH), cytogenetic analysis now includes the study of interphase, or nondividing, cells.

Cytogenetic techniques established over the last five decades have become a routine part of the analysis of abnormal hematopoiesis and lymphopoiesis and, hence, play a prominent role in the clinical practice of hematology and oncology. The use of cytogenetics in the diagnosis and management of each disease depends on selection of the appropriate tissue and cell type for analysis, availability of cells for karyotyping, and proper interpretation of cytogenetic findings.

From a scientific point of view, the identification of recurring chromosomal abnormalities has guided the search for genes involved in malignant transformation and has helped to elucidate alterations in the structure and expression of these genes. Identification of genes involved and elucidation of their structural changes have, in turn, led to an understanding of mechanisms of malignant transformation that is beginning to foster the development of targeted therapies.

This chapter focuses on cytogenetic methodology and terminology, general principles of cytogenetics, and the application of cytogenetic analysis in hematology and hematologic oncology. Cytogenetic findings in specific diseases are discussed in greater detail in the chapters devoted to these diseases.

BACKGROUND

Because cytogenetic analysis is the study of chromosome structure, it requires that chromosomes be visualized microscopically as discrete structures. Every human cell contains deoxyribonucleic acid (DNA) packaged into chromosomes, normally consisting of 22 pairs of autosomes and 1 pair of sex chromosomes. Chromosome morphology varies markedly during the cell cycle, which is the process of cell replication.

The cell cycle consists of interphase, the period between cell divisions, and mitosis, or cell division. Cells that are in a resting state and not cycling are said to be in G_0.

Interphase is the portion of the cell cycle in which the nucleus is most metabolically active and undergoes chromosome duplication in preparation for mitosis. Interphase includes three distinct stages: G_1 phase (gap one), S phase (synthesis of DNA), and G_2 phase (gap two).

Mitosis (M phase), or cell division, is divided into five phases: prophase, prometaphase, metaphase, anaphase, and telophase. During prophase, the chromatin, which has already doubled, undergoes progressive coiling and thickening. In prometaphase, the nuclear membrane breaks down, releasing the chromosomes into the cytoplasm, and the chromosomes move to the center of the cell, or the equatorial plane. During metaphase, the chromosomes line up in the center, or metaphase plate. This is when the chromosomes are the most contracted and the least metabolically active. Anaphase occurs when the centromere divides, leading to the separation of the chromatids (sister chromosomes). Once separated, the chromatids move to the opposite ends of the cells. In telophase, the final stage of mitosis, the chromosomes uncoil, the nuclear membrane reappears around each set of chromosomes, and the nucleus takes on the morphology seen in interphase. During, or directly after, telophase, new cell membranes are formed (cytokinesis) and divide the cytoplasm, creating two identical daughter cells.

The appearance of cells during the different phases of the cell cycle is shown in Figure 4.1. Interphase chromosomes are uncoiled and cannot be resolved as discrete structures. Chromosomes first become visible as discrete structures during prophase. Prometaphase chromosomes are almost maximally condensed and are visualized as two identical chromatids. Maximal chromosome condensation occurs during metaphase. The chromosomes then become less condensed during anaphase and telophase; individual chromosomes can no longer be visualized. Cytogenetic analysis must be performed on cells in prometaphase or metaphase.

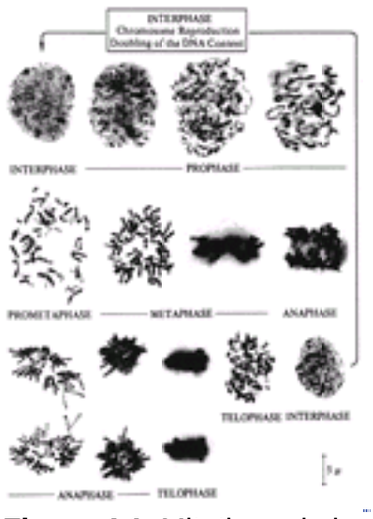

Figure 4.1. Mitotic cycle in cultured human lymphocytes. (From Therman E, Susman M. Human chromosomes, 3rd ed. New York: Springer-Verlag, with permission.)

Successful cytogenetic analysis depends on a number of factors. Cells must be available in adequate numbers. Analysis must be performed on viable cells that are undergoing division. Sufficient numbers of cells must be present in the phases of the cell cycle in which chromosome morphology is appropriate for analysis. Chromosomes must be separated from one another within the cell so that each chromosome can be resolved as a distinct entity. Finally, each chromosome must be able to be identified and characterized as normal or abnormal. For cytogenetic analysis of malignancies, it is critical that the analysis be performed on malignant cells rather than on coexisting normal cells.

The ability to study chromosomes depended on the development of methods for growing normal and malignant cells in tissue culture, arresting cells at the appropriate phases of the cell cycle, and separating chromosomes from each other within cells.

HISTORY

The presence of 46 chromosomes in normal human cells was demonstrated for the first time in 1956, first by Tjio and Levan and subsequently by Ford and Hamerton ([1], [2]). Normal male cells were found to contain 2 copies of each of 22 autosomes and 1 copy of each of the sex chromosomes, X and Y. Normal female cells contained 2 copies of each of the 22 autosomes and of the X chromosome, and contained no Y chromosome.

Associations between abnormal numbers of chromosomes and congenital anomalies were initially reported in 1959. Three copies of one of the smallest human chromosomes, rather than the normal two, were found in cells of children with Down syndrome ([3]). The presence of two copies of the X chromosome, along with one copy of the Y chromosome, was reported in cells of males with Klinefelter syndrome ([4]), and a single copy of the X chromosome, without a Y chromosome, was found in cells of females with Turner syndrome ([5]). The era of clinical cytogenetics had thus begun.

In 1960, before banding techniques became available (see below), Nowell and Hungerford reported the first chromosomal anomaly associated with cancer ([6]). The presence of an unusually small chromosome was detected as a consistent abnormality in unbanded bone marrow metaphases from patients with chronic myelogenous leukemia (CML) (Fig. 4.2). This small chromosome was called the *Philadelphia chromosome*, after the city in which it was discovered. The Philadelphia chromosome was initially abbreviated Ph ^{1}; the designation Ph ^{1} was subsequently changed to Ph ([7]).

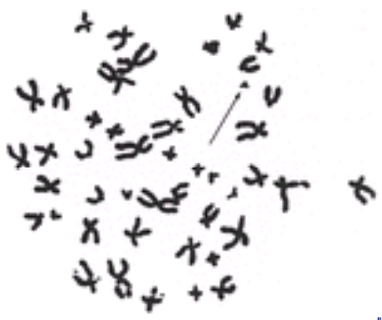

Figure 4.2. An unbanded metaphase spread from bone marrow cells of a patient with chronic myelogenous leukemia, with the Philadelphia chromosome (*arrow*). (From Sandberg AA. The chromosomes in human cancer and leukemia, 2nd ed. New York: Elsevier, 1956, with permission.)

In the late 1960s, the staining of metaphase spreads with quinacrine mustard was found to produce unique patterns of fluorescence on each chromosome ([8]). This was the first chromosome banding technique, and the first banded human karyotype was published in 1970 ([9]). However quinacrine banding (Q-banding) required fluorescence microscopy and could be cumbersome, as the fluorescence tended to "quench" rapidly. Other banding techniques were subsequently developed that produced similar bands using pretreatment with alkali and saline followed by staining with Giemsa, a compound that had been developed to stain blood smears for the identification of the protozoan that causes malaria ([10]). Light microscopy could be used to visualize Giemsa banding (G-banding), which soon became the most commonly used banding technique. The nomenclature for chromosome bands was established in 1971 ([7]).

Banding allows chromosomes to be visualized as a continuous series of light and dark regions. *Bands* are defined as regions of chromosomes that are distinguished from adjacent regions by virtue of appearing darker or lighter with one or more banding techniques. Unique banding patterns thus allow chromosomes to be distinguished from one another. Identification of individual chromosomes had not previously been possible.

The use of chromosome banding allowed more accurate and precise identification and description of cytogenetic abnormalities. In 1973, Rowley reported that the recurring cytogenetic abnormality described earlier in CML was a reciprocal translocation between chromosomes 9 and 22, t(9;22)(q34;q11) ([11]). Ph was an abnormally small chromosome 22 resulting from translocation with chromosome 9. The use of chromosome banding also resulted in a rapid increase in the numbers of recurring cytogenetic abnormalities reported. The t(8;21) in acute myeloid leukemia (AML) was reported in 1973 ([12]), and the t(15;17) in acute promyelocytic leukemia (APL) was described in 1977 ([13]).

The late 1970s saw the development of high-resolution banding procedures ([14]). High-resolution banding is achieved by analyzing the more elongated prophase and prometaphase chromosomes. Banding of these longer chromosomes allows visualization of 500 to 2000 bands on chromosomes, whereas metaphase banding yields only approximately 300 bands. The availability of sufficiently large numbers of prophase and prometaphase cells for analysis is achieved by cell cycle synchronization. Cells are cultured with methotrexate (MTX), which arrests DNA synthesis. MTX acts by inhibiting dihydrofolate reductase, the enzyme that catalyzes conversion of folic acid to tetrahydrofolic acid, which is a coenzyme for one-carbon unit transfers, including methylation of deoxyuridylic acid to thymidylic acid. Inhibition of DNA synthesis arrests the cell cycle in interphase. The cell cycle block is subsequently released by transferring the cells to an MTX-free, thymidine-rich medium. Cells enter mitosis simultaneously and are arrested in prophase and prometaphase by brief colchicine treatment. High-resolution banding allowed the identification of more subtle chromosome rearrangements, resulting in the identification of abnormal karyotypes in larger numbers of cases ([15]) and the recognition of subtle structural chromosomal abnormalities such as inv ([16])(p13q22) in AML ([16]).

The last 20 years have seen a very rapid expansion of the number of recurring cytogenetic abnormalities reported in malignant cells, as documented in the serial editions of Mitelman's *Catalog of Chromosome Aberrations in Cancer* ([17]). Cytogenetic databases are now available on-line. The two most commonly used are the *Mitelman Database of Chromosome Aberrations in Cancer* (Mitelman F, Johansson B, Mertens F, eds., 2002) at http://cgap.nci.nih.gov/Chromosomes/Mitelman and the *Atlas of Genetics and Cytogenetics in Oncology and Haematology* at http://www.infobiogen.fr/services/chromcancer/. The majority of cytogenetic abnormalities have been described in hematologic malignancies. Data on cytogenetic abnormalities in lymphomas and solid tumors are limited in comparison, reflecting the difficulty

of obtaining analyzable dividing cells from lymph nodes and tumor tissue compared to bone marrow samples.

In the 1980s, molecular technology was combined with cytogenetic methodology to create molecular cytogenetic techniques, or *in situ* hybridization. The most widely used is FISH, in which specific DNA or RNA sequences indirectly or directly labeled with fluorochromes are made to bind to the complementary target sequences within metaphase or interphase cells and are subsequently visualized by fluorescence microscopy ([18], [19]). Four major types of DNA sequences are used as probes in clinical FISH studies. Locus-specific probes are used to detect the presence and location of a particular gene. Centromeric probes are highly repetitive sequences that detect alpha satellite DNA primarily located in the centromeres. Subtelomeric probes contain unique sequences from the telomere region of chromosomes. Whole chromosome paints are mixtures of numerous unique and repetitive sequences homologous to many sites on a single chromosome ([20]). Chromosome painting is performed by hybridizing cells with pooled DNA probes for sorted human chromosomes ([20]). These chromosome-specific probes label entire chromosomes and are particularly useful in identifying the origin of chromosomal material that is not identifiable in banded metaphases. FISH can be performed simultaneously with different probes labeled with different fluorochromes, permitting the detection of several target sequences. Applications of FISH are demonstrated in the sections Numerical Chromosomal Abnormalities and Structural Chromosomal Abnormalities.

Competitive genomic hybridization, described in the early 1990s, is a molecular cytogenetic technique that allows efficient screening of cells for losses and gains of chromosomal material ([21], [22]). Genomic DNA from the cells to be studied (test DNA) is labeled with a fluorochrome, and DNA from normal cells (control DNA) is labeled with a different colored fluorochrome. Labeled test DNA and genomic DNA are simultaneously hybridized to metaphase chromosome spreads from normal cells. The fluorescent signals generated by the test DNA and the control DNA along the normal chromosomes are compared as a means of detecting and identifying chromosomal material that has been lost or gained in the test DNA. Computerized image analysis is used to measure and compare signal intensities.

Finally, recently developed specialized imaging procedures have allowed for the simultaneous visualization of all the chromosomes in a cell. These techniques, called *multiplex fluorescence in situ hybridization* ([23]) and *spectral karyotyping* ([24]), use combinatorial labeling and digital imaging microscopy to create a unique color for each chromosome within a cell, so that all chromosomes, each with unique labeling, can be detected simultaneously. These techniques have become extremely useful in identifying the chromosomal origins of marker chromosomes and genetic material that are otherwise unidentified.

CYTOGENETIC METHODS

Conventional cytogenetic techniques are described in a number of books ([25], [26], [27] and [28]). The techniques are briefly summarized here.

Samples

For successful cytogenetic analysis of malignancies, it is critical that malignant cells, rather than contaminating normal cells, be studied. Bone marrow is the tissue of choice for cytogenetic analysis of leukemias, myelodysplastic syndromes (MDSs), and myeloproliferative disorders. In cases of leukemia in which marrow cannot be aspirated, blood may be used if it contains more than 10% blasts. A bone marrow core biopsy sample can sometimes be processed successfully to allow study of cells in mitosis. Blood is generally not appropriate for cytogenetic analysis of MDSs.

A sample of 1 to 2 ml of bone marrow is generally adequate for cytogenetic analysis. The sample must be aspirated into a sterile syringe coated with preservative-free sodium heparin to prevent clotting and then transferred into a sterile tube containing preservative-free heparin or a medium such as RPMI 1640, McCoy's 5A, or Hanks' balanced salt solution with preservative-free heparin. Antibiotics (penicillin, streptomycin) may be added to the transport medium. When peripheral blood is to be studied, 10 ml of blood should be drawn aseptically into a sterile heparinized syringe and transferred to a sterile tube also containing heparin.

Cytogenetic analysis of lymphomas is performed on lymph node tissue. Lymph nodes obtained aseptically are transported in sterile tubes containing medium and antibiotics. They are then transferred to sterile Petri dishes with medium, where they are minced using sterile scissors and then triturated using a Pasteur pipette, creating a cell suspension. Processing of this cell suspension is similar to that of bone marrow and blood cells.

Samples should be processed for cytogenetic analysis as soon as possible after they are obtained. Delays in processing may compromise cell viability. Additionally, normal cells may survive better than malignant cells, so that only normal karyotypes are obtained. The likelihood of successful analysis of acute lymphocytic leukemia (ALL) samples, in particular, is adversely affected by delays in processing. Samples with very high numbers of cells are also less likely to be successfully studied following delays in processing ([27]). If bone marrow or blood samples cannot be processed immediately or must be mailed overnight to be processed, cell viability can be maintained by keeping samples at room temperature in culture medium. Lymph nodes may be refrigerated. Cytogenetic samples should not be frozen.

Sample Processing and Cell Culture

Marrow, blood, or lymph node cells are centrifuged and then resuspended in a medium such as RPMI 1640 or McCoy's 5A. They are then counted with a Coulter counter or a hemocytometer and resuspended at 1×10^6 cells/ml of medium, which is the optimal cell concentration for cell culture for cytogenetic analysis.

Cytogenetic analysis may be performed on uncultured or cultured cells. Chromosome preparations from cells that have not been cultured are called *direct preparations*, whereas preparations from cultured cells are called *indirect preparations*. Bone marrow cells can be studied in direct preparations because dividing cells are present in bone marrow aspirates. The advantage of direct preparations is that they allow rapid karyotyping of the cells that are undergoing division *in vivo*. The disadvantages of direct preparations are that they have a low mitotic index because *in vivo* cell proliferation rates are generally low and that chromosome morphology is generally poor. Additionally, compared to indirect preparations, direct preparations more often yield normal rather than abnormal metaphases ([29]). The normal metaphases seen in direct preparations may derive from erythroblasts ([30], [31]). In APL, in particular, analysis of indirect preparations demonstrates the t(15;17) translocation in virtually all cases ([32]), but direct preparations often yield normal karyotypes ([33]). Cell culture increases the mitotic rate, improves chromosome morphology, and generally promotes proliferation of malignant cells, but normal cells may also proliferate in culture. To maximize the likelihood of successfully karyotyping the abnormal population, both direct and indirect preparations should be studied, several culture conditions should be used including cell cycle synchronization, and cell cultures should be harvested at several different times.

Mitogens may be useful in stimulating proliferation of abnormal cells in some circumstances. In particular, unstimulated chronic lymphocytic leukemia (CLL) cells have a very low mitotic rate, and cytogenetic analysis in cases of CLL studied without mitogens often reveals normal metaphases that are derived from coexisting normal cells rather than from CLL cells. The use of B-cell mitogens increases the frequency with which cytogenetic abnormalities are detected in cases of CLL. To optimize the success of cytogenetic analysis, B-cell CLL cells should be cultured with a polyclonal B-cell activator such as 12-0-tetradecanoylphorbol-13-acetate, Epstein-Barr virus, lipopolysaccharide, or protein A to stimulate B-cell proliferation ([34]). T-cell CLL cells may be cultured with a combination of phytohemagglutinin (PHA), 12-0-tetradecanoylphorbol-13-acetate, and pokeweed mitogen to stimulate cell division. CLL cells should be cultured for long periods of time, in the range of 3 to 5 days. The likelihood of successful cytogenetic analysis in cases of multiple myeloma is also increased by cell culture with combinations of cytokines, including granulocyte-macrophage colony-stimulating factor, interleukin-3, and interleukin-6 ([35]).

Cells are incubated (direct preparations) or cultured (indirect preparations) in a medium such as RPMI 1640 or McCoy's 5A supplemented with fetal calf serum, L-glutamine, penicillin, and streptomycin; mitogens are added in selected cases. The cell density should be 1×10^6 cells/ml of medium. Colchicine (Colcemid) is used to arrest cells in metaphase. In direct preparations, colchicine is added to the cell suspension without prior cell culture, and cells are harvested after incubation in medium with colchicine at 37°C for 1 hour. In overnight colchicine-treated cultures, cells are cultured overnight in medium with colchicine and are harvested the next morning. In short-term cultures, cells are cultured in medium without colchicine at 37°C, generally for 24 to 72 hours. Before harvesting cells after short-term culture, colchicine is added to the cultures, usually at 0.01 µg or 0.02 µg/ml for 1 hour. Longer colchicine exposure times result in greater numbers of metaphases, but longer colchicine exposure times and higher colchicine concentrations compromise chromosome morphology.

Cell cycle synchronization in the early stages of cell division yields elongated chromosomes, allowing high-resolution chromosome banding. To achieve cell cycle synchronization, cell division is blocked by incubation with an antimetabolite, and the block is then released, producing synchronization of cell division in early mitosis, when chromosomes are longer than in metaphase. Moreover, because cell division is synchronized, the duration of colcemid treatment can be significantly reduced, resulting in better chromosome morphology. The most commonly used technique is MTX synchronization. MTX, an inhibitor of thymidine biosynthesis, arrests cells in S phase. Cells are initially cultured in medium without MTX. MTX is added after an initial culture period; after approximately 17 hours, most of the dividing cells have accumulated in S phase. At this point, thymidine is added to the culture, releasing the MTX block. The cells then proceed synchronously to mitosis. Colchicine is then

added for 10 to 15 minutes, and the cells are harvested. Shortened colcemid treatment, in addition to MTX synchronization, produces elongated chromosomes, allowing detection of subtle abnormalities such as small deletions and rearrangements.

To increase the likelihood of successful cytogenetic analysis and identification and accurate characterization of abnormal clones, a variety of culture conditions should be used, including synchronization of cell division. Optimizing cell density and using different culture conditions are particularly important in maximizing the likelihood of successful cytogenetic analysis of ALL cells.

Stimulated peripheral blood is most often used to establish the constitutional karyotype. Peripheral blood cells are cultured at 1×10^6 cells/ml in culture medium supplemented with 2% PHA, a T-cell mitogen. Colchicine is added after 72 to 96 hours, generally at a concentration of 0.01 µg/ml. Cultures are harvested after 1 hour of colchicine exposure.

Hypotonic Treatment

After colchicine treatment, hypotonic treatment is used to produce cell swelling, allowing chromosomes to spread within cells. Chromosome spreading serves to optimize visualization of each chromosome and to minimize overlapping of chromosomes in metaphase spreads. A dilute solution of KCl (0.075 mol) may be used for hypotonic treatment; other hypotonic solutions are also in use. After colchicine treatment, cells are centrifuged, resuspended in prewarmed hypotonic solution, and incubated at 37°C. The optimal duration of incubation in hypotonic medium varies; it is generally in the range of 10 to 45 minutes.

Fixation

After the hypotonic treatment, cells are fixed in a modified Carnoy fixative (3:1 methanol to acetic acid volume per volume). Fixation causes denaturation and precipitation of proteins and nucleic acids, resulting in hardening of chromatin, which enhances morphology. The cells are centrifuged, gently resuspended in fixative, incubated at room temperature, and then centrifuged again. This is repeated until a cell suspension that is only slightly cloudy is obtained. Slides may be prepared immediately for cytogenetic analysis, or the cells may be stored in fixative and prepared for analysis at a later time.

Slide Preparation

Fixed cells are dropped onto cleaned glass slides under several different conditions. The angle at which the pipette and slide are held is varied. Slides may be wet, cold, or dry and are then dried with steam, air, or flame. After the slides are dried, they are examined for cell density and quality of metaphase spreads by phase contrast microscopy. If the slides are not optimal, new slides are made, altering the density of the cell suspension or the dropping technique, as appropriate.

Staining

Since 1968, several protocols have been developed that yield staining of chromosome regions with variable intensity based on their nucleotide and protein composition. Staining with these dyes produces a unique banding pattern on each chromosome that is specific for that chromosome.

Q-banding, the first banding method developed, uses quinacrine mustard or quinacrine dihydrochloride to create fluorescent transverse bands when excited with the proper wavelength of light. Quinacrine is a fluorescent dye that intercalates into the DNA helix. Q-band analysis requires fluorescence microscopy. Moreover, Q-bands fade over time, and Q-banding is therefore not conducive to routine work.

G-banding uses pretreatment with an enzyme (trypsin) followed by staining with the Giemsa dye to also produce transverse bands, called *G-bands*, which are identical to Q-bands. G-banding is generally preferred over Q-banding because G-band analysis is performed by light microscopy and G-banding is permanent. G-banding is the most widely used banding technique for routine chromosomal analysis. Other G-banding techniques use stains other than Giemsa, such as Wright and Leishman's stains.

The most widely used G-banding technique is called *GTG banding* (G-bands by trypsin using Giemsa). In this technique, air-dried slides aged by heating in an oven are treated with a dilute solution of the proteolytic enzyme trypsin (0.05% trypsin for 5 to 10 minutes) and then stained with Giemsa. The relative importance of DNA and proteins in G-banding is not well understood. Treating chromosomes with a hot alkaline solution before Giemsa staining produces bands that are the reverse of G-bands, called *R-bands*. R-banding methods are useful for analyzing rearrangements involving the terminal ends of the chromosomes.

In contrast to Q-, G-, and R-banding, which produce bands distributed along the entire length of each chromosome, other staining methods are adapted to demonstrate specific chromosomal structures, including constitutive heterochromatin (C-banding), telomeric regions (T-banding), and nucleolus-organizing regions (NOR-banding). C-bands are primarily in the centromeric regions of chromosomes. C-band size and position are unique for each chromosome. C-banding is particularly useful in studying chromosomal translocations involving the centromeric regions.

Microscopy

After banding, slides are scanned under a light microscope to locate chromosome spreads that are of adequate quality for karyotyping (Fig. 4.3). The coordinates of these metaphases are recorded.

Figure 4.3. Banded metaphase.

For cytogenetic analysis to be considered adequate, at least 20 chromosome spreads should be analyzed. In particular, whereas abnormal clones are sometimes demonstrated by analysis of small numbers of cells, demonstration of 20 normal chromosome spreads is required for a case to be considered cytogenetically normal. Demonstration of 20 out of 20 normal metaphases excludes the presence of 14% abnormal cells with 95% confidence ([36]).

Cytogenetic analysis of cases of ALL presents particular difficulties. Chromosome spreading is more difficult to accomplish, chromosome morphology is fuzzy, and bands are often suboptimal. Thus, metaphase spreads are often considered nonanalyzable. Two morphologically different populations of metaphases may be present. When two populations are present, the population with better spreading and better chromosome morphology often represents cells with normal karyotypes. If the metaphases that are easiest to study are selected for analysis, the case is inaccurately characterized as cytogenetically normal. Therefore, it is imperative to examine both populations.

Karyotyping

Chromosomes are counted in each of the chosen metaphase spreads to determine whether they are present in normal numbers. Chromosomes are then identified and characterized as structurally normal or abnormal. To facilitate analysis, chromosomes from each metaphase spread are arranged in a prescribed order, called a *karyotype* (Fig. 4.4A and Fig. 4.4B). On completion of the microscopic analysis, the cells are ready to be photographed or electronically imaged, printed, and karyotyped. The selected metaphases are photographed onto black and white film, and prints are generated. Karyotyping is performed by cutting out chromosomes

from the photographic prints of each chromosome spread and arranging them in prescribed order. Once the karyotype is finalized, the chromosomes are pasted onto a sheet of paper.

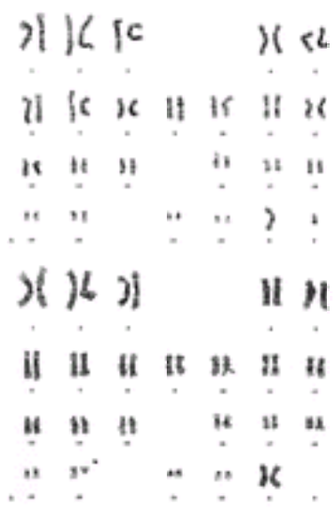

Figure 4.4. Normal male **(A)** and female **(B)** karyotypes.

The ability to detect subtle cytogenetic abnormalities depends heavily on the experience of the cytogeneticist. Examples of subtle structural abnormalities that may be easily missed by cytogeneticists without extensive experience include inv(16)(p13q22) and t(9;11)(p21;q23), both of which are clinically significant cytogenetic abnormalities seen in AML. The ability to accurately karyotype metaphases with multiple or complex abnormalities is also a function of experience. Cytogenetic analysis of cancer cells should optimally be performed in laboratories staffed by groups of cytogeneticists with expertise in this specialized area.

Automated Karyotyping

In recent years, automated karyotyping systems have become available, greatly increasing the efficiency of karyotyping in laboratories that handle large numbers of samples. Automated karyotyping relies on computerized image analysis. Software programs have been created that allow chromosome spreads identified by light microscopy to be karyotyped on a computer screen. The karyotype is then printed directly from the computer. Both chromosome spread and karyotype images are archived as digital files.

Automated karyotyping obviates the need to photograph metaphases, develop film, print negatives, and cut and paste chromosomes. The number of steps and the amount of time required for cytogenetic analysis are thereby significantly decreased, allowing more rapid analysis and reduction of labor costs.

CYTOGENETIC NOMENCLATURE

Human chromosome nomenclature was initially established at an international conference in 1960. It has been serially updated to include terminology developed to describe chromosomal abnormalities, chromosome bands, high-resolution bands, and, most recently, results of FISH analysis. The most recent guidelines for cytogenetic nomenclature were published in 1995 ([7]).

For karyotypic analysis, each chromosome is visualized as two chromatids that are joined at a central constriction called the *centromere*. The centromere is the region where the chromosome attaches to the spindle during mitosis. The centromere divides the chromosome into two arms: a short arm, designated the p-arm (*p* stands for *petit*), and a long arm, designated the q-arm (*q* was chosen simply because it is the letter after *p*). By convention, chromosomes are always shown with the p-arm on top.

Chromosomes were initially described based on their size and the position of the centromere. Size was characterized as large, medium, or small. The position of the centromere was used to classify chromosomes as metacentric, acrocentric, or submetacentric. A chromosome with the centromere in the middle is designated as *metacentric*, one with the centromere closer to one end is *submetacentric*, and one in which the centromere is almost at one end is called *acrocentric*.

In 1963, before the advent of chromosome banding, human chromosomes were divided into seven groups, A through G, based on their size and the position of the centromere. Group A includes chromosomes 1, 2, and 3, which are large, metacentric chromosomes. Group B includes chromosomes 4 and 5, which are large and submetacentric. Group C chromosomes, including numbers 6 through 12 and the X chromosome, are medium-sized and metacentric or submetacentric. Group D, chromosomes 13 through 15, includes medium-sized acrocentric chromosomes with satellites. Group E, chromosomes 16 through 18, consists of small metacentric (chromosome 16) and submetacentric (chromosomes 17 and 18) chromosomes. Group F chromosomes, numbers 19 and 20, are small and metacentric. Group G chromosomes, including 21, 22, and Y, are small and acrocentric; 21 and 22 have satellites, whereas the Y chromosome does not. Without chromosome banding, chromosomes within some groups could not be distinguished. Banding allowed the chromosomes in each group to be uniquely identified and distinguished from each other.

Nomenclature was subsequently established to describe the structure of individual chromosomes. The term *landmark* is used to designate distinct morphologic features important in identifying chromosomes. Landmarks include the centromere, the ends of the chromosomes (called *telomeres*), and prominent chromosome bands. *Chromosome regions* are defined as areas lying between adjacent landmarks. The number of regions on the short and long arms of individual chromosomes ranges between one and four. Regions of each chromosome arm are numbered sequentially, moving outward from the centromere toward the telomere (Fig. 4.5).

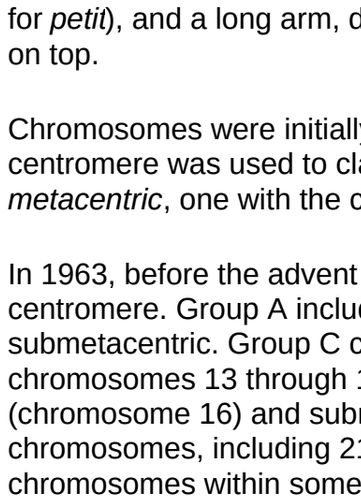

Figure 4.5. Diagrams of normal human G-banded chromosomes showing banding at the 400, 550, and 850 band levels of resolution. (Adapted from ISCN 1995. Basel: Karger, 1995.)

Bands are defined as chromosome segments that are clearly distinguishable from adjacent segments by virtue of appearing lighter or darker with the use of one or more banding techniques. Chromosome regions, defined above, are divided into bands. The bands within regions are also numbered sequentially, also moving outward on each arm from the centromere toward the telomere (Fig. 4.5). To designate chromosome bands, one specifies the chromosome number, the chromosome arm, the region number, and the band number within the region, given in order, without spacing or punctuation. For example, 1p31 (chromosome 1, short arm, region

3, band 1) designates the first band of the third region of the short arm of chromosome 1.

High-resolution banding divides chromosome bands into sub-bands, which are light and dark regions constituting finer structure within chromosome bands. Sub-bands are also numbered from the centromere toward the telomere of each arm. Sub-band numbers are given after band numbers, separated by decimal points. For example, band 1p31 includes sub-bands 1p31.1, 1p31.2, and 1p31.3. Figure 4.5 shows normal human chromosomes with sub-bands as well as bands.

Karyotypes are described according to the International System for Human Cytogenetic Nomenclature ([7]). The description of a karyotype starts with the total number of chromosomes, including the sex chromosomes. The total number of chromosomes is followed by a list of the sex chromosomes present in the cell and then a list of abnormalities of autosomes listed in ascending numerical order. This system represents a change from older nomenclature, in which numerical chromosomal abnormalities were listed first, followed by structural abnormalities. A normal male karyotype is 46,XY, and a normal female karyotype is 46,XX. Common abbreviations and symbols used in describing karyotypes are listed and defined in Table 4.1.

TABLE 4.1. Common Symbols and Abbreviations Used in the Description of Chromosomes and Chromosomal Abnormalities

Symbol or Abbreviation	Meaning
add	Additional material of unknown origin
Brackets [ ]	Surround numbers of cells
c	Constitutional anomaly
cen	Centromere
Comma (,)	Separates chromosome numbers, sex chromosomes, and chromosomal abnormalities
Decimal point (.)	Denotes sub-bands
del	Deletion
der	Derivative chromosome
dic	Dicentric chromosome
dmin	Double minute
dup	Duplication
i	Isochromosome
idic	Isodicentric
ins	Insertion
inv	Inversion
mar	Marker chromosome
Minus (–)	Loss
p	Short arm of chromosome
Parentheses ( )	Surround chromosomes and breakpoints
Plus (+)	Gain
q	Long arm of chromosome
Question mark (?)	Questionable identification of a chromosome or chromosome structure
r	Ring chromosome
Semicolon (;)	Separates chromosomes and breakpoints in rearrangements involving more than one chromosome
Slash (/)	Separates clones
t	Translocation
ter	Terminal (end of chromosome)

Chromosomal abnormalities may be numerical or structural and may be constitutional or acquired. The term *numerical chromosomal abnormality* refers to a karyotype with an abnormal number of chromosomes. Numerical chromosomal abnormalities may include chromosome losses or chromosome gains. Structural chromosomal abnormalities are alterations in the structure of individual chromosomes, including loss, rearrangement, or gain of chromosome segments. Numerical and structural chromosomal abnormalities may coexist in malignant cells.

NUMERICAL CHROMOSOMAL ABNORMALITIES

A cell with a normal complement of chromosomes is called *diploid*. Cells with 46 chromosomes, but with numerical chromosomal abnormalities (for example, the loss of one chromosome and the gain of another) are called *pseudodiploid*. The presence of an abnormal number of chromosomes is called *aneuploidy*. Cells with more than 46 chromosomes are called *hyperdiploid*, whereas the presence of fewer than 46 chromosomes is called *hypodiploidy*. Loss of one copy of a chromosome results in monosomy for that chromosome; loss of both copies results in nullisomy. Gain of an additional copy of a chromosome results in trisomy for the chromosome that has been gained. When two additional copies of a chromosome are gained, it is referred to as *tetrasomy*.

Chromosome loss is indicated in the karyotype by a minus sign followed by the number of the missing chromosome, whereas chromosome gain is indicated by a plus sign followed by the number of the chromosome that has been gained. The number of chromosomes in the cell, given in the karyotype, reflects the chromosomes that have been lost or gained. For example, 45,XY,-7 indicates a male cell with loss of one copy of chromosome 7 (monosomy 7); 47,XX,+8 indicates a female cell with an extra copy of chromosome 8 (trisomy 8); and 48,XY,+13,+13 indicates a male cell with two additional copies of chromosome 13 (tetrasomy 13).

The chromosomes that are most commonly lost in acquired cytogenetic changes include 5, 7, X, and Y ([37]). Loss of the Y chromosome may be seen as an age-related phenomenon in bone marrow cells of normal males ([38]), but it also occurs as a primary cytogenetic abnormality ([39]) as well as a secondary change, particularly in AML with t(8;21) ([40]). Loss of a chromosome has as its obvious molecular consequence loss of one copy of the genetic material on that chromosome. The genes whose loss is critical in the monosomies that are seen as recurring cytogenetic abnormalities in AML and MDS have not been identified.

The most common acquired trisomy is +8, seen in AML, MDS, and CML in blast transformation ([37]). Trisomy 8 occurs as both a primary and a secondary cytogenetic abnormality in AML. Other trisomies in myeloid disorders include +4, +6, +9, +11, +13, +19, +21, and +22 ([37] , [41] , [42]), whereas the most common trisomies in ALL are +4, +6, +10, +14, +17, +18, +20, +21, and +X ([43]).

The obvious molecular consequence of a trisomy is the presence of an additional copy of all of the genetic material on a chromosome. Nevertheless, the relationship between trisomies and malignant transformation has remained unclear. A partial tandem duplication of the ALL-1 or MLL gene at 11q23 has been demonstrated by molecular techniques in one of the three copies of chromosome 11 in AML with trisomy 11, although all three copies appear structurally normal by conventional cytogenetic analysis ([44] , [45]). Exons 2 through 6 or 8 of the ALL-1 gene are duplicated, and the partially duplicated ALL-1 gene encodes novel partially duplicated RNA and protein species. Demonstration of partial tandem duplication of ALL-1 as a consistent finding in AML with trisomy 11 represents the first identification of a specific molecular change associated with a recurrent trisomy in human cancer. Molecular abnormalities have not yet been demonstrated in association with other trisomies. In particular, trisomy 8 has been shown not to be associated with abnormalities in structure or expression of the c-myc oncogene at 8q24 ([46]).

Numerical chromosomal abnormalities are particularly common in childhood and adult ALL, and their presence is prognostically significant ([43] , [47]). *Near-haploid* or *hypodiploid ALL* is defined by multiple chromosome losses ([48]). Hypodiploid ALL most commonly has 45 chromosomes ([49]). Hyperdiploid ALL is divided into *moderate hyperdiploidy*, defined by the presence of 47 to 50 chromosomes ([50]); *massive hyperdiploidy*, which is more than 50 chromosomes ([51]); and *near triploidy*

or *near tetraploidy*, defined by a marked increase in chromosome number, in the range of 69 to 96 chromosomes ([52]). Hyperdiploidy and moderate hyperdiploidy are common in childhood ALL, representing 27% and 16% of cases, respectively. Hyperdiploidy is prognostically favorable, whereas moderate hyperdiploidy correlates with an intermediate prognosis ([43]). In contrast, near haploidy and hypodiploidy are prognostically unfavorable ([48], [49]).

FISH with probes hybridizing with the centromeric regions of specific chromosomes allows the detection of numerical chromosomal abnormalities in interphase cells ([53]). FISH may be performed on blood smears as well as on bone marrow samples prepared for cytogenetic examination ([54]). Moreover, the presence or absence of numerical chromosomal abnormalities, determined by FISH, may be directly correlated with cellular morphology and cell-surface antigen expression ([55], [56]).

FISH with a probe specific for the centromere of chromosome 12 (Fig. 4.6) is more sensitive than conventional cytogenetic analysis for detecting trisomy 12, the most common cytogenetic abnormality in CLL ([57], [58]). Based on analysis of normal controls, fresh and archived CLL samples are considered to be positive for trisomy 12 by FISH if three chromosome 12 signals are present in more than 4% and 7% of cells, respectively ([57], [58]). The incidence of trisomy 12 in the largest published study of CLL cases studied by FISH was 35%, compared to only 6% by conventional cytogenetic analysis ([55]). Moreover, patients with trisomy 12 detected by FISH had shorter survival times than those without trisomy 12 ([58]).

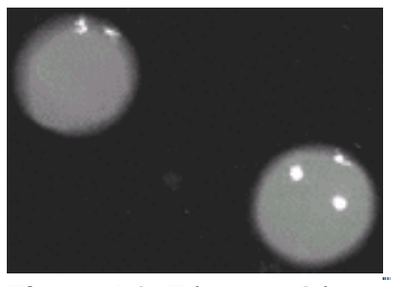

Figure 4.6. Trisomy 12 in an interphase cell (*right*) demonstrated by fluorescence *in situ* hybridization with a chromosome 12 centromeric probe. An interphase cell with two chromosome 12 signals is also seen (*left*). See Color Plate.

Multiple myeloma cells are also difficult to karyotype because of low proliferative rates even with B-cell mitogens ([35]), and FISH demonstrates a significantly higher incidence of aneuploidy than is found with conventional cytogenetic analysis ([59]). Interphase FISH analysis of myeloma cells from 32 patients with probes for chromosomes 1, 3, 7, 8, 11, 12, 16, 17, 18, and X demonstrated aneuploidy in 90% ([59]). Chromosome gain was more common than chromosome loss; chromosomes 3, 7, and 11 were most frequently gained. The X chromosome was most frequently lost in females but not males. Chromosome 17 loss was also common.

In contrast to CLL and myeloma cells, myeloid cells can generally be karyotyped with ease, and results of conventional cytogenetic and FISH analysis of AML cells with numerical chromosomal abnormalities such as monosomy 7 and trisomy 8 are more similar than is the case for CLL ([60], [61]). FISH may be used to demonstrate numerical chromosomal abnormalities in cases in which they are not demonstrated by conventional cytogenetic analysis, in which only one metaphase with the abnormality is detected by conventional cytogenetic analysis, or in which conventional cytogenetic analysis is inadequate ([61]).

STRUCTURAL CHROMOSOMAL ABNORMALITIES

A variety of structural chromosomal changes may be present in tumor cells. Precisely defined terms are used to describe these changes. Structural chromosomal abnormalities seen in hematopoietic and lymphoid neoplasms include deletions, isochromosomes, isodicentric chromosomes, inversions, rings, translocations, dicentric chromosomes, additions, insertions, duplications, double minutes, and marker chromosomes.

Deletion

A *chromosomal deletion* (del) is loss of a chromosome segment. Deletions may be either interstitial or terminal. In an interstitial deletion, an internal chromosome segment is lost, and the chromosome segments that are proximal and distal to the deleted segment become juxtaposed. In a terminal deletion, the tip of a chromosome arm is deleted. del(5q) and del(7q) refer to any deletions of the long arm of chromosome 5 and chromosome 7, respectively. In contrast, del(5)(q13q33) specifically designates an interstitial deletion of the long arm of chromosome 5 between band q13 and band q33, and del(7)(q22) designates a terminal deletion of chromosome 7 with a break at band q22 and loss of all chromosomal material between band 7q22 and the 7q telomere.

Common chromosome deletions include del(5q), del(7q), and del(20q) in AML and MDS; del(13q) in MDS; del(6q) and del(9p) in ALL; and del(13q) in CLL ([37]). del(13q) in CLL, studied by FISH, is illustrated in Figure 4.7. The critical molecular changes associated with most chromosome deletions are unknown, but it is hypothesized that chromosomal deletions result in loss of tumor-suppressor genes ([62]). Genes on 5q that may be deleted in del(5q) include a number of growth factor and growth factor receptor genes, including granulocyte-macrophage colony-stimulating factor, interleukin-3, interleukin-4, interleukin-5, interleukin-9, the macrophage colony-stimulating factor receptor c-fms, and the glucocorticoid receptor ([62]). In some cases of MDS with del(5q), the c-fms gene has been found to be deleted from both the del(5q) chromosome and the copy of chromosome 5 without visible structural abnormalities ([63]). The smallest commonly deleted region on 5q is the small segment of band 5q31 that has been demonstrated to contain the early growth response-1 protein gene ([64]) or the interferon regulatory factor-1 gene ([65]). A case of AML has been described with deletion of one interferon regulatory factor-1 allele as part of a del(5q) and an inactivating rearrangement of the other allele in the structurally normal chromosome 5 ([65]). Of note, del(9p) in ALL has been associated with deletion of the interferon genes ([66], [67]). The retinoblastoma gene is deleted in del(13), and the remaining retinoblastoma gene on the cytogenetically normal copy of chromosome 13 may be inactivated ([68]). The commonly deleted region in del(6q) in ALL is 6q21; the critical gene has not been identified ([69]).

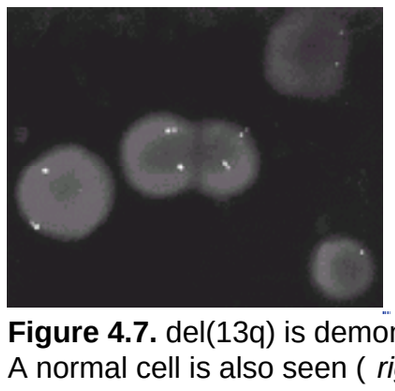

Figure 4.7. del(13q) is demonstrated by fluorescence *in situ* hybridization with locus-specific probes to two regions of chromosome 13q in two cells (*left* and *center*). A normal cell is also seen (*right*). See Color Plate.

Isochromosome

An *isochromosome* (i) is a structurally abnormal chromosome that consists of two chromosome arms positioned as mirror images of each other. Isochromosomes may be monocentric (one centromere) or dicentric (two centromeres). A dicentric isochromosome is called an *isodicentric* chromosome (see below). The most common isochromosomes in hematologic malignancies are i(11q), i(17q), and i(21q) in AML; i(7q), i(9q), and i(17q) in ALL; i(9q), i(17q), and i(22q) in CML; and i(X)(q13), i(17q), and i(21q) in MDS, whereas i(1q), i(6p), i(7q), i(8q), i(9p), i(17q), and i(21q) are recurring isochromosomes in lymphoproliferative disorders and lymphomas ([70]).

Isochromosome formation leads to both loss and gain of genetic material. As an example, i(17q), which occurs frequently as a secondary cytogenetic abnormality in blast crisis of CML, consists of two chromosome 17 long arms, without short arms. Cells with i(17q) generally also have one normal chromosome 17; thus, they have

one copy of 17p and three copies of 17q. One important molecular consequence of i(17q) formation is loss of genetic material on 17p, including the p53 tumor-suppressor gene. Cells with i(17q) have a single copy of p53, which is on the structurally normal chromosome 17. This copy of the p53 gene often has point mutations or other molecular changes that result in p53 inactivation ([71], [72]). i(17q) with inactivating molecular changes in the remaining copy of the p53 gene may also be seen in AML and MDS ([73], [74]). i(17q) also occurs as a secondary chromosomal abnormality in ALL ([75]).

Isodicentric Chromosome

An *isodicentric chromosome* (idic) is an isochromosome in which there are two copies of the centromere. Isodicentric chromosomes are rare. An example is idic(7p) in AML ([76]). idic(7p) consists of two copies of the short arm and the centromere of chromosome 7, positioned as mirror images of each other.

Inversion

A *chromosomal inversion* (inv) is a structural chromosome change consisting of a 180-degree rotation of a chromosome segment. Inversions may be pericentric or paracentric. In pericentric inversions, the segment that undergoes 180-degree rotation includes the centromere. In paracentric inversions, the inverted segment is entirely within either the short or the long arm of the chromosome and does not include the centromere. inv(16)(p13q22) is a pericentric inversion, whereas inv(3)(q21q26) is paracentric. Both of these inversions occur in AML ([37]). Another example of a paracentric inversion is inv(14)(q11q32), which is the most consistent chromosomal change found in T-cell CLL and T-cell prolymphocytic leukemia ([77], [78]).

The molecular consequence of chromosome inversion is juxtaposition of genes on the long and short arm of a chromosome (pericentric inversion) or on the same arm of a chromosome (paracentric inversion) that are not normally juxtaposed. inv(16)(p13q22), a structural chromosomal abnormality seen in AML ([16]), is a pericentric inversion that juxtaposes MYHII, the smooth muscle myosin heavy chain gene at 16p13 with the core-binding factor-ß (CBF-ß) gene at 16q22 ([79]). The reciprocal chromosomal translocation t(16; 16)(p13;q22) juxtaposes the same two genes from the two different copies of chromosome 16, rather than the same chromosome 16. inv(3)(q21q26) is a paracentric inversion, also found in AML, that juxtaposes the ribophorin I gene at 3q21 and the EVI I gene at 3q26. Again, the t(3;3)(q21;q26) juxtaposes the same two genes from the two different copies of chromosome 3, rather than the same chromosome 3. inv(11)(p13q23) is an uncommon pericentric inversion in ALL cells that has been shown not to involve the MLL or ALL-1 gene at 11q23 ([80]).

inv(16) in AML, illustrated in Figure 4.8, is associated with bone marrow eosinophilia ([16]). Moreover, eosinophil morphology is abnormal, with large irregular granules that stain a deep purple with May-Grünwald-Giemsa stain and also stain with naphthol-AS-D-chloroacetate-esterase, in contrast to normal eosinophils ([16]). Interphase FISH was used to demonstrate the chromosome inversion in bone marrow eosinophils from patients with AML with inv(16) ([81]).

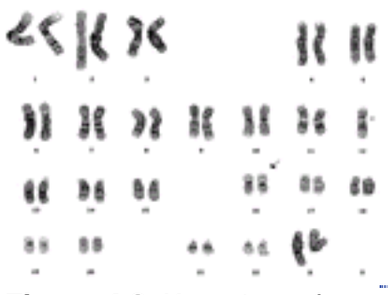

Figure 4.8. Karyotype demonstrating inv(16)(p13q22).

Ring Chromosome

A *ring chromosome* (r) is an abnormal chromosome in which breaks have occurred in both the short and the long chromosome arms, and the breakpoints in the short and long arms have joined together, creating a closed circle, or ring. Ring chromosomes are uncommon in hematologic malignancies; they have been reported primarily in AML and CML. There are only rare reports of ring chromosomes in lymphoid malignancies ([37]).

Translocation

A *chromosomal translocation* is a relocation of material from one chromosome to a different chromosome. Translocations are usually reciprocal. A reciprocal translocation is an exchange of material between different chromosomes. Reciprocal translocations generally occur between two chromosomes, but rarely may involve more than two chromosomes. Nonreciprocal translocations are also rare.

Large numbers of chromosomal translocations have been described in hematopoietic and lymphoid neoplasms. In many instances, the associated molecular changes have been identified, and mechanisms of malignant transformation have been elucidated ([82]). Some translocations result in synthesis of novel fusion proteins. Examples include the t(9;22) in CML, which results in synthesis of an aberrant tyrosine kinase, and a variety of translocations in AML and ALL, which result in synthesis of aberrant transcription factors. Alternatively, translocations may result in relocation of an oncogene to a locus that is highly transcribed in a particular cell type, resulting in activation of the oncogene. Examples include the t(8;14)(q24;q32) in Burkitt lymphoma, the t(8;14)(q24;q11) in T-cell ALL, and the t(14;18)(q32;q21) in follicular non-Hodgkin lymphoma.

The t(9;22)(q34;q11) in CML, illustrated in Figure 4.9, is a reciprocal translocation between the long arms of chromosome 9 and chromosome 22, with breakpoints at 9q34 and 22q11. The significant molecular change in t(9;22)(q34;q11) is a relocation of the abl oncogene from 9q11 to the bcr locus on 22q11 ([83], [84]). A novel bcr/abl fusion gene is created that encodes novel fusion bcr/abl RNA and protein species ([85]). bcr/abl expression results in increased tyrosine kinase activity, which appears to be sufficient to induce malignant transformation ([86], [87]).

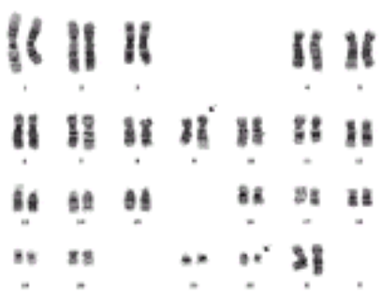

Figure 4.9. Karyotype demonstrating t(9;22)(q34;q11).

Variant translocations may be seen in CML ([88], [89], [90] and [91]). Simple variant translocations are translocations between 22q11 and a chromosome breakpoint other than 9q34, but with bcr/abl fusion at the molecular level. An example is t(17;22)(p13;q11) with bcr/abl rearrangement. Complex variant translocations are three-way translocations between 9q34, 22q11, and a third chromosome breakpoint. An example is t(3;9;22)(q13;q34;q11), which is a three-way translocation between 3q13, 9q34, and 22q11, also with bcr/abl fusion.

A number of translocations in acute leukemia result in synthesis of aberrant transcription factors. In the t(8;21) in AML, the AML-1 or CBF-a gene on chromosome 21 is juxtaposed to the ETO gene on chromosome 8 ([92], [93]). The product of the normal CBF-a gene dimerizes with the product of the normal CBF-ß gene, which is the gene on 16q22 that is involved in inv(16). CBF-a and CBF-ß form the heterodimeric transcription factor CBF. The AML-1/ETO fusion product is an aberrant CBF-a

protein. Reciprocal translocations with 11q23 breakpoints in AML and ALL also result in the synthesis of fusion proteins that are aberrant transcription factors. The gene at 11q23 that is involved in 11q23 translocations is ALL-1 or MLL, and reciprocal chromosome breakpoints include 1p32, 1q21, 4q21, 6q27, 9p22, 10p12, 17q21, 19p13.1, and 19p13.3 ([94], [95] and [96]). In the t(15;17)(q22; q11–12) in APL, illustrated in Figure 4.10, the retinoic acid receptor (RAR)-a gene from chromosome 17 is fused to the PML gene at 15q22. A hybrid PML/RAR-a gene is created, encoding an aberrant transcription factor that inhibits promyelocyte differentiation ([97], [98], [99], [100], [101] and [102]).

Figure 4.10. Karyotype demonstrating t(15;17)(q22;q12).

Examples of translocations resulting in oncogene activation include t(8;14)(q24;q32) in Burkitt lymphoma, t(8;14)(q24;q11) in T-cell ALL, and t(14;18)(q32;q21) in follicular non-Hodgkin lymphomas. In t(8;14)(q24;q32), the c-myc oncogene at 8q24 is juxtaposed to the immunoglobulin heavy chain gene at 14q32, resulting in dysregulation of c-myc transcription ([103]). In t(8;14)(q24;q11), the c-myc oncogene is activated by juxtaposition to the T-cell receptor a/d locus ([104]). In t(14;18)(q32;q21), the BCL-2 gene at 18q21, which inhibits apoptosis, is overexpressed by virtue of juxtaposition to the immunoglobulin heavy chain gene at 14q32 ([105]).

Robertsonian translocations are whole arm transfers, almost always between acrocentric chromosomes, that usually occur as constitutional chromosomal abnormalities ([106]). They are very rarely seen as acquired abnormalities associated with malignancy ([107]).

Two-color probe systems have been created for the identification of chromosome translocations by FISH ([108], [109]). Some of these are available commercially and are used in clinical cytogenetics laboratories. FISH may be used to rapidly identify translocations such as t(15;17); a fusion signal is seen, representing juxtaposition of the two probes in the translocation region (Fig. 4.11). Early confirmation of the diagnosis of APL can help guide the choice of induction therapy. A commercially available locus-specific probe to the MLL gene serves to confirm involvement of this gene in 11q23 chromosome translocations; splitting of the signal is seen (Fig. 4.12). The chromosomal origins of translocations can also be demonstrated with the use of paint probes. FISH with translocation breakpoint probes is also being explored as a technique for monitoring residual disease after therapy ([110], [111], [112] and [113]).

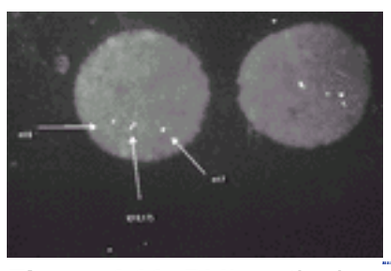

Figure 4.11. PML–retinoic acid receptor (RAR)-a fusion demonstrated in an interphase cell (*left*) by fluorescence *in situ* hybridization with locus-specific probes for the PML and RAR-a genes. A normal cell is also seen (*right*). See Color Plate.

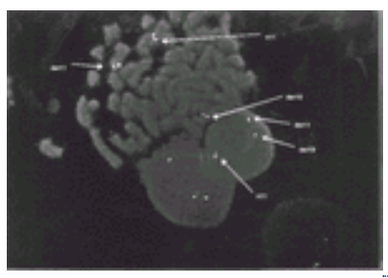

Figure 4.12. Chromosomal translocation involving the MLL gene on chromosome 11 (11q23) demonstrated by fluorescence *in situ* hybridization with a locus-specific probe for MLL. The normal MLL gene is seen as overlapping or adjacent red and green signals. When MLL is involved in a translocation, the red and green signals separate. See Color Plate.

Dicentric Chromosome

A *dicentric chromosome* (dic) is a structurally abnormal chromosome that has two centromeres. Dicentric chromosomes result from reciprocal translocations in which one of the resulting derivative chromosomes contains the centromeres of both of the chromosomes involved in the translocation. FISH can be helpful in confirming the identity of the centromeres and the other chromosomal material in dicentric chromosomes. Examples of dicentric chromosomes include dic(9;12)(p1?1;p1?2), dic(7;12)(p11;p11), and dic(9;20)(p11;q11.?1) in ALL ([114], [115] and [116]).

Addition

A *chromosomal addition* (add) is a gain of chromosomal material of unknown origin, in contrast to a gain of chromosomal material of known origin, which is called a *translocation* ([7]). A plus sign after a chromosome arm is a general designation indicating the gain of chromosomal material, resulting in lengthening of the arm. For example, 14q+ indicates the presence of additional chromosomal material on 14q. An abnormal chromosome 14 with extra material on its long arm is a common finding in CLL ([34]). The abnormal chromosome 14 in CLL can often be identified as resulting from a reciprocal translocation involving the 14q32 breakpoint, such as t(11;14)(q13;q32). However, when a reciprocal translocation is not identified, the designation 14q+ is used to describe an abnormal chromosome 14 with extra chromosomal material of unknown origin on its long arm.

Insertion

Insertion (ins) is the presence of a chromosome segment in a new position within the same or another chromosome. Insertions are very uncommon. In some instances, structural chromosomal abnormalities that were previously described as insertions have been reinterpreted as translocations. For example, ins(3;3)(q26;q21q26), which describes insertion of the segment of chromosome 3 between bands q21 and q26 into the other chromosome 3 at band 3q26, has been reinterpreted as a reciprocal translocation, t(3;3)(q21;q26) ([37]).

Duplication

Duplication (dup) is the presence of an extra copy of a segment of a chromosome, so that there are two copies of the duplicated segment, juxtaposed with one another within the chromosome. An example of a duplication is dup(1)(q31p12), which is an uncommon secondary chromosomal abnormality in ALL ([37]). A chromosome duplication results in a structurally abnormal chromosome, whereas a molecular duplication such as the partial tandem duplication of the MLL gene ([117]) or the FLT-3

gene ([118], [119]) is detectable only by molecular techniques.

Double Minutes

Double-minute chromosomes (dmin) are marker chromosomes without centromeres or banding patterns, which usually result from gene amplification. They are small spherical structures that usually occur in pairs, similar in appearance to diplococci. Double-minute chromosomes are more common in solid tumors than in hematologic or lymphoid malignancies ([37]). Double-minute chromosomes in AML have been shown to contain amplified copies of the c-myc gene ([120]) or the ALL-1 gene ([121]) or identified material from chromosome 19 ([122]).

Marker Chromosomes

The term *marker* (mar) is used to designate a structurally abnormal chromosome that has no part that can be identified. Karyo types may include one or more markers. The presence of one marker chromosome in a karyotype is designated by +mar. The presence of several different markers is indicated by +mar1, +mar2, +mar3, and so forth. The presence of multiple copies of the same marker is indicated by multiplication signs, as in +marx2, +marx3, and so on ([7]). The use of FISH with chromosome paint probes to study marker chromosomes is illustrated in Figure 4.13, and the use of spectral karyotyping to study marker chromosomes is illustrated in Figure 4.14.

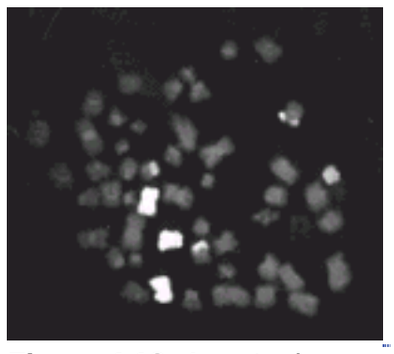

Figure 4.13. A metaphase spread showing the use of whole chromosome paints to confirm the origin of marker chromosomes. Chromosome 11 (*green*) is present as three intact chromosomes and as two translocation regions. Chromosome 20 (*red*) is seen as one intact chromosome and as a translocation region. See Color Plate.

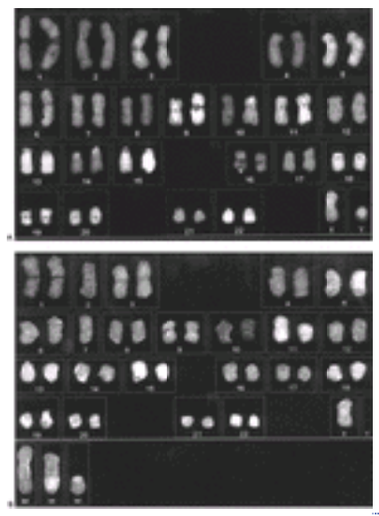

Figure 4.14. Spectral karyotype of a normal male cell **(A)** and of a cell with marker chromosomes **(B)**. See Color Plate.

CONSTITUTIONAL VERSUS ACQUIRED CHROMOSOME CHANGES

Numerical and structural chromosomal abnormalities may be either constitutional or acquired. *Constitutional chromosomal abnormalities* are abnormalities that are present in all or almost all cells in the body and exist at the earliest stage of embryogenesis. Acquired chromosomal abnormalities are abnormalities that develop in somatic cells, usually in association with malignant transformation.

The constitutional karyotype of 99% of people is normal ([106]). Constitutional chromosomal abnormalities may be associated with congenital genetic syndromes (e.g., trisomy 21 with Down syndrome) or may be normal variants that are not associated with somatic changes. The most common constitutional abnormality found in apparently normal patients is a pericentric inversion of chromosome 9, inv(9)(p11q13), which is present in approximately 1% of the population. Other constitutional abnormalities include reciprocal translocations, pericentric inversions of chromosomes other than chromosome 9, and Robertsonian translocations ([116]). A constitutional abnormality is designated by *c* in a karyotype ([7]). For example, the karyotype of cells from a female with Down syndrome is 47,XX,+21c.

Blood samples are used to determine constitutional karyotypes. Peripheral blood lymphocytes are stimulated to divide by culturing them with the T-cell mitogen PHA. Blood cells are cultured for 72 or 96 hours in medium with fetal calf serum and PHA. The cells are then processed for cytogenetic analysis using a standard technique. To confirm that an abnormality is constitutional, PHA-stimulated lymphocytes may be studied either at the time of active disease or in remission. Constitutional abnormalities are also present in a patient's malignant cells, and, unlike acquired abnormalities associated with malignant transformation, they remain present when cytogenetic studies are performed after treatment of the malignancy (e.g., when remission bone marrow is studied after treatment of acute leukemia).

Acquired chromosomal abnormalities may develop in cells that previously had a normal karyotype or may develop as new changes in patients with constitutional chromosomal abnormalities. The karyotype 47,XX,+21 designates an acquired trisomy 21 in female cells with a normal constitutional karyotype. In contrast, 47,XX,+21c describes a cell from a female with Down syndrome without acquired cytogenetic abnormalities. The karyotype 47,XX,t(8;21)(q22;q22),+21c would be that of a cell of a female with Down syndrome with an acquired t(8;21)(q22;q22).

CYTOGENETIC DEFINITION OF CLONALITY

Once acquired chromosomal abnormalities develop in a cell, the cell and its progeny may have a proliferative or a survival advantage, creating a clone, which is a cell population derived from a single progenitor cell. Cytogenetically, a *clone* is defined by a minimum of two mitotic cells with the gain of the same chromosome or with the same structural abnormality, or three mitotic cells with the loss of the same chromosome. Cytogenetic changes occurring in an insufficient number of cells to define a clone are considered to be random changes. Alternatively, if apparently random changes are ones that can be detected by FISH, FISH may be used to determine their frequency in larger numbers of metaphase spreads and in interphase cells.

PRIMARY VERSUS SECONDARY ACQUIRED CHROMOSOME CHANGES

Acquired chromosomal abnormalities may be either primary or secondary. Primary cytogenetic abnormalities are aberrations that are often found as sole chromosomal changes in malignancies. Moreover, they are often associated with specific tumor types. Examples of primary cytogenetic abnormalities include t(8;21)(q22;q22) and inv(16)(p13q22) in AML, t(15;17)(q22;q11–21) in APL, t(9;22)(q34;q11) in CML, and t(8;14)(q24;q32) in Burkitt lymphoma. Secondary chromosomal abnormalities are changes that generally occur not by themselves but in addition to primary changes. The chromosomes most commonly involved in secondary cytogenetic abnormalities in acute leukemia include 1, 5, 7, 8, 9, 21, 22, X, and Y ([37]). Secondary changes include del(5q), del(7q), -7, +8, del(9q), +21, +22, -X, and -Y. Secondary abnormalities associated with blast transformation of CML include +8, i(17q), +t(9;22)(q34), and +19, occurring in addition to

t(9;22)(q34;q11). Development of i(17q) correlates with the loss of activity of the tumor-suppressor gene p53.

Primary cytogenetic abnormalities are changes that are thought to be associated with the pathogenesis of malignant transformation, whereas secondary chromosomal changes likely correlate with tumor progression. Some secondary changes, such as +8, occur in association with a variety of primary changes. Other secondary changes are associated with specific primary abnormalities. Examples include the association of del(9q), -X, and -Y with t(8;21). Thus, it appears that certain secondary changes may confer a proliferative or survival advantage to any cell, whereas others may confer an advantage only to cells with specific primary abnormalities. Trisomy 8 is an example of a chromosomal abnormality that may occur as either a primary or a secondary cytogenetic change.

The prognostic significance of secondary chromosomal abnormalities is unclear. Several studies have addressed the prognostic significance of secondary chromosomal abnormalities with t(15;17)(q22;q21) in APL ([123], [124] and [125]). Secondary chromosomal abnormalities are present in approximately one-third of APL patients. An adverse prognostic significance was demonstrated in one recent study ([123]) but not in two others ([124], [125]). Secondary chromosomal abnormalities present at diagnosis may alter the prognosis of Ph $^{+}$ ALL, which has a poor prognosis ([126]). The presence of monosomy 7, in particular, as a secondary abnormality worsens the prognosis of Ph $^{+}$ ALL ([126], [127]). The presence of secondary chromosomal abnormalities worsens the prognosis of Ph $^{+}$ CML ([128]).

MOLECULAR CYTOGENETIC ANALYSIS OF CASES WITH NORMAL KARYOTYPES

Although AML, ALL, and MDS cases with normal karyotypes are categorized as having an intermediate response to treatment ([175], [176] and [177], [187]), treatment response and clinical course are actually heterogeneous. In AML, recurring molecular abnormalities have been identified that define subsets of karyotypically normal cases with adverse prognoses. These include internal tandem duplications of the FLT-3 and MLL genes and FLT-3 mutations ([117], [118] and [119]).

Recent studies have applied spectral karyotyping and FISH with specific probes to the analysis of karyotypically normal cases. Using FISH with eight locus- and chromosome-specific probes, Cuneo et al. ([129]) did not find abnormalities in 55 adult *de novo* AML cases, but they found abnormalities in 8 (30%) of a group of 27 elderly patients with AML and patients with AML after MDS. Abnormalities included 5q31, 7q31, and 17p13/p53 deletions and trisomy 8. Using FISH with specific probes, Rigolin et al. ([130]) found abnormalities in 18 (18%) of 101 karyotypically normal MDS cases. Abnormalities included trisomy 8, del(5)(q31), del(7)(q31), monosomy 7, and del(17)(p13) and were an independent predictor of worse prognosis. Using spectral karyotyping, Zhang et al. ([131]) detected abnormalities in 2 (7%) of 28 karyotypically normal AML cases; the abnormalities included a cryptic 11q23 translocation and a minor monosomy 7 clone. Competitive genomic hybridization is currently being applied to the analysis of normal karyotypes. These techniques are research tools; their clinical application has not been validated.

CLINICAL APPLICATIONS OF CYTOGENETICS

Diagnosis

The presence of a clonal chromosomal abnormality serves to establish the diagnosis of a clonal bone marrow disorder. Cytogenetic analysis is particularly helpful in the establishing the diagnosis of MDS in patients who present with mild cytopenias and in whom the bone marrow aspirate shows minimal or no dysplasia. Similarly, the presence of t(9;22) provides early confirmation of the diagnosis of CML in patients presenting with slight elevations of the granulocyte count.

Classification

In contrast to the earlier French-American-British classification of hematologic malignancies, the more recent World Health Organization classification of neoplastic diseases of the hematopoietic and lymphoid tissues ([132]) considers cytogenetic analysis to be an essential element of the diagnostic evaluation of neoplastic diseases and incorporates cytogenetic findings into the definition of a number of subtypes. Specifically, the presence of t(8;21), inv(16), t(15;17), and 11q23 abnormalities serves to define distinct subsets of AML, and in the presence of t(8;21), inv(16), or t(15;17), the diagnosis of AML is made regardless of the percentage of marrow blasts. Similarly, isolated presence of del(5q) serves to define a distinct subset of MDS.

The presence of specific chromosomal abnormalities also serves to define disease entities that are amenable to specific therapies (see the section Specific Therapies). The prime example is the use of the t(15;17) to distinguish APL from other subtypes of AML. In the t(15;17)(q22; q11–12) in APL, the RAR-a gene from chromosome 17 is fused to the PML gene at 15q22, creating a hybrid PML/RAR-a gene that encodes an aberrant transcription factor that inhibits promyelocyte differentiation ([97], [98], [99], [100], [101] and [102]). Classic hypergranular APL is easy to distinguish on the basis of morphology, but hypogranular APL is more difficult to diagnose ([133]). Both hypergranular and hypogranular APL with t(15;17)(q22;q11–21) respond to induction therapy with all- *trans*-retinoic acid. The converse problem is the presence of classic APL morphology but the absence of the t(15;17) by conventional cytogenetic analysis ([134]). In a study of 60 such patients ([134]), molecular analyses revealed PML/RAR-a rearrangements in 42, presence of promyelocytic leukemia zinc finger/RAR-a rearrangements in 11, and t(5;17) in 2; only 5 had no evidence of RAR-a rearrangement. In t(11;17)(q23;q21), the RAR-a gene from chromosome 17 is fused to the promyelocytic leukemia zinc finger gene at 11q23, which encodes a transcription factor, rather than to the PML gene at 15q22. The ALL-1 or MLL gene at 11q23 is not involved. APL with t(11;17)(q23;q21) rather than t(15;17) is resistant to all- *trans*-retinoic acid induction therapy ([135], [136]).

The t(9;22)(q34;q11) translocation is present in the bone marrow and peripheral blood cells of approximately 95% of patients who are diagnosed with CML on the basis of their clinical presentation. Patients whose cells do not carry the translocation and in whom the corresponding gene rearrangement is not detected by molecular techniques have an atypical clinical picture, commonly with anemia, thrombocytopenia, or massive splenomegaly, and early disease acceleration and shorter survival ([137], [138] and [139]). Cases of chronic myeloid leukemia without the translocation should not be classified as CML, but rather as chronic myelomonocytic leukemias or atypical myeloproliferative syndromes. The presence of t(9;22) demonstrated by cytogenetic, molecular cytogenetic, or molecular biologic techniques also provides the data necessary for the decision to treat with imatinib mesylate (Gleevec), the inhibitor of the bcr-abl tyrosine kinase ([140], [141] and [142]).

Etiology

A variety of environmental and occupational exposures have been associated with an increased risk of AML, and there is a high frequency of cytogenetic abnormalities in these cases ([143], [144], [145], [146], [147], [148], [149] and [150]). Cytogenetic abnormalities associated with occupational exposure to organic solvents, petroleum products, and pesticides include -7, del(7q), and del(5q) ([144], [145] and [146], [149]). Smoking is associated with -7, del(7q), -Y, and +13 in AML and with t(9;22)(q34;q11) in ALL ([150]).

The incidence of clonal cytogenetic abnormalities in cases of AML in patients treated with chemotherapy or radiation therapy for prior malignancies (therapy-related AML) is very high, ranging from 75 to 90% in various series ([151], [152] and [153]). Abnormalities of chromosomes 5 or 7 are seen in most cases of leukemia in patients previously treated with alkylating agent–based chemotherapy regimens. del(5q), del(7q), or -7 has been detected in 72 to 83% of cases of AML in patients with Hodgkin disease, multiple myeloma, ovarian carcinoma, and other malignancies treated with regimens containing mechlorethamine, melphalan, nitrosoureas, or cyclophosphamide, with or without radiation therapy ([153]). t(3;21)(q26;q22) has also been reported as another recurring chromosomal abnormality associated with alkylating agent therapy ([154]).

Acute monocytic or myelomonocytic leukemias with cytogenetic abnormalities involving 11q23 are seen as cases of treatment-related leukemia associated with therapy with topoisomerase inhibitors, such as anthracyclines and epipodophyllotoxins, rather than alkylating agents ([155], [156] and [157]). These leukemias have developed after therapy for non–small cell carcinoma of the lung, small cell carcinoma of the lung, ovarian carcinoma, neuroblastoma, osteosarcoma, and ALL ([155], [156] and [157]). Development of AML with abnormalities of 11q23 is highly associated with epipodophyllotoxin therapy in patients with T-cell ALL; the cytogenetic findings at the time of development of AML differ from those seen at presentation of ALL ([157]). Like most *de novo* acute leukemias with 11q23 abnormalities, treatment-related acute leukemias with 11q23 abnormalities involve the ALL-1 gene, also called MLL or HRX ([158], [159], [160] and [161]).

Rare cases of acute leukemia that develop in patients treated with chemotherapy for prior malignancies have chromosomal abnormalities that are usually seen in *de novo* leukemia, such as t(8;21), inv(16), and t(15;17) ([162], [163]). Whereas treatment-related leukemias with abnormalities of 5, 7, or 11q23 have a poor prognosis,

treatment-related leukemias with chromosomal abnormalities typically seen in *de novo* disease have a more favorable prognosis ([162], [163]).

Prognosis

An extensive literature documents the prognostic significance of recurring chromosomal abnormalities in AML ([164], [165], [166], [167], [168], [169], [170], [171], [172], [173], [174], [175] and [176]), ALL ([43], [47], [48], [49], [50], [51] and [52], [178], [179], [180], [181], [182], [183], [184], [185], [186] and [187]), MDS ([188], [189], [190] and [191]), CML ([128]), CLL ([192], [193]), and non-Hodgkin lymphoma ([194], [195], [196] and [197]). The prognostic significance of recurring chromosomal abnormalities in each disease is detailed in the chapters devoted to each of these diseases in this book and is not reiterated here.

Recent studies have addressed the impact of these chromosomal abnormalities on treatment outcome after allogeneic bone marrow transplantation for AML in first remission or at later times ([175], [198], [199] and [200]). The chromosomal abnormalities that are prognostically unfavorable with respect to outcome of chemotherapy are also prognostically unfavorable with respect to outcome of transplantation.

Assignment of Treatment

Because of the demonstrated prognostic significance of cytogenetic findings in acute leukemia ([43], [47], [48], [49], [50], [51] and [52], [164], [165], [166], [167], [168], [169], [170], [171], [172], [173], [174], [175], [176], [177], [178], [179], [180], [181], [182], [183], [184], [185], [186] and [187]), they are in increasing use in guiding the management of acute leukemia patients. In particular, they guide the choice of postremission therapy. Patients with AML with the prognostically favorable abnormalities t(8;21) and inv(16) may be managed with chemotherapy rather than transplantation, with the expectation of prolonged disease-free survival and a high cure rate. Conversely, the presence in pretreatment marrow samples of chromosomal abnormalities that predict a low likelihood of long-term disease-free survival with chemotherapy-based treatment strategies is used as a basis for proceeding to bone marrow transplantation in first complete remission. Outcome for patients with unfavorable cytogenetics does appear to be improved by allogeneic stem cell transplantation ([175]). In particular, treatment outcome for Ph $^{+}$ ALL patients is superior after allogeneic bone marrow transplantation, compared to the results of chemotherapy ([201], [202]).

Given the importance of cytogenetic findings in acute leukemia for determining prognosis and guiding management, recent studies have sought to compare the sensitivity of molecular cytogenetic and molecular techniques to that of conventional cytogenetic analysis in detecting abnormalities. Cytogenetics and the reverse-transcriptase polymerase chain reaction are almost always concordant in the detection of t(8;21) and inv(16) ([203]), although the t(8;21)-associated gene rearrangement may sometimes be detected in AML with a normal karyotype ([204]). 11q23 abnormalities do not always involve the MLL gene, and the MLL gene may be rearranged in the absence of 11q23 chromosomal abnormalities ([205]).

Specific Therapies

The most striking aspect of recent progress in the therapy of hematologic malignancies is the development of specific therapies, targeting genetic abnormalities identified at the cytogenetic, molecular cytogenetic, or molecular level. All- *trans*-retinoic acid is an effective agent in the treatment of APL with t(15;17), but APL with t(11;17)(q23;q21) rather than t(15;17) is resistant to all- *trans*-retinoic acid induction therapy ([135], [136]). Imatinib mesylate is a specific inhibitor of the BCR-ABL tyrosine kinase that has activity in Ph $^{+}$ CML and ALL ([140], [141] and [142]). Imatinib mesylate also inhibits the platelet-derived growth factor and kit kinases and was recently shown to have activity in chronic myeloproliferative disorders with t(5;12)(q33;p13), in which rearrangement of the platelet-derived growth factor receptor ß gene on chromosome 5q33 results in its constitutive activation ([206]).

Residual Disease

Cytogenetic analysis of remission bone marrow after therapy for acute leukemia generally shows the exclusive presence of normal metaphases ([207], [208] and [209]). In one study, however, one or more abnormal metaphases identical to those present in pretreatment marrow were found in first remission marrow samples of 20 of 71 patients (28%), and all of these patients subsequently relapsed, as compared to 50% of patients whose remission marrows did not show metaphases with chromosomal abnormalities that had been present in pretreatment marrow ([210]). Most recently, FISH has been found to detect residual disease in posttreatment samples ([110], [111], [112] and [113], [211], [212], [213], [214] and [215]). FISH can be used to evaluate both metaphase and interphase cells. In hypermetaphase FISH, cells are cultured with colchicine for 24 hours, producing large numbers of metaphases that are of insufficient quality to be evaluated by banding studies but are suitable for residual disease analysis by FISH ([213]).

Engraftment

Cytogenetic techniques are used to monitor engraftment of donor cells and persistence or recurrence of host cells after sex-mismatched allogeneic bone marrow transplantation. FISH with probes for the X or Y chromosome allows efficient screening of large numbers of cells with respect to donor or host origin ([216], [217], [218] and [219]).

CONCLUSION

Cytogenetic analysis has become increasingly sophisticated and has played a progressively larger role in the diagnosis and management of hematologic and lymphoid disorders over the last four decades. This role is expected to expand as a reflection of technical innovations that facilitate cytogenetic analysis and greater knowledge of the clinical and molecular implications of chromosomal abnormalities.

Molecular Biology and Hematology

BASIC PRINCIPLES

Current practice in hematology has been profoundly influenced by advances in molecular biology. These have produced an understanding of disease at the most fundamental level, had a tremendous impact on diagnostic capabilities, and led to a large number of recombinant proteins for therapy. The contribution that hematology has played in the development of this knowledge has been significant. The thalassemias, for example, were the first genetic disorders analyzed with the tools of molecular biology, and current knowledge of genomic organization and transcriptional control has come in part through studies of the ß-globin gene cluster. Further, a hematologic disorder, sickle cell anemia, was the first for which a molecular description was obtained, and the initial attempt at human gene therapy involved hematopoietic cells from patients with an inherited immunodeficiency.

DNA Chemistry and Structure

The human genome is comprised of 3.1×10^9 base (3.1 gigabase) pairs of DNA packaged into 23 pairs of chromosomes. Less than 2% actually encodes proteins, with the remainder believed to regulate DNA replication, transcriptional activity, attachment to the nuclear matrix, and packaging ([1]). The deoxyribonucleotide building blocks of DNA are covalently joined by phosphodiester bonds linking the fifth carbon on one pentose ring (5') to the third carbon on the adjacent pentose ring (3') (Fig. 5.1). This configuration imparts a directionality to each polynucleotide chain, with the double helical structure of DNA resulting from pairing of strands that run in opposite, or antiparallel, directions. The energy underlying their interaction comes from interstrand base pairing between adenine (A) and thymine (T), involving two hydrogen bonds, and guanine (G) and cytosine (C), mediated by three hydrogen bonds. The two strands form a right-handed helix with a major and a minor groove.

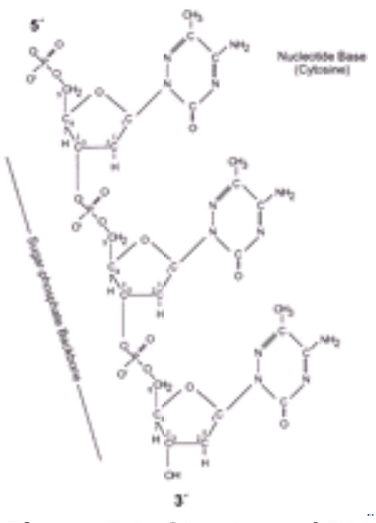

Figure 5.1. Structure of DNA. DNA is comprised of two complementary polynucleotide chains, each possessing a sugar-phosphate backbone in which the 5' position of one pentose ring is linked by a phosphodiester bond to the 3' position of the adjacent base. Sequence shown here is CCC.

Messenger RNA (mRNA) transcribed from DNA specifies an amino acid sequence through a series of base pair triplets, or codons (Table 5.1). This type of protein-coding mechanism has two important features. First, its degeneracy, with almost every amino acid represented by several codons, minimizes the effect of DNA mutation by reducing the probability that any single base change will produce an amino acid substitution. Second, although the code is translated in nonoverlapping triplets from a fixed starting point, three translational reading frames potentially exist for each nucleotide sequence. Thus, insertion or deletion of a single base alters the amino acid sequence encoded from that point and, in some cases, results in synthesis of a truncated protein product.

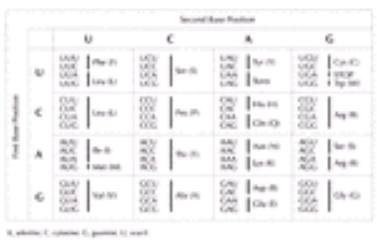

TABLE 5.1. Genetic Code

From Chromosomes to Genes

Before the development of molecular-based methods to characterize DNA structure, light microscopy revealed that the human genome is packaged into 46 chromosomes. Each chromosome, present as a pair, is unequally divided by a centromere into short and long arms, designated *p* and *q*, respectively. It was also recognized that the chromosomes were not uniform in appearance and that their distinctive banding patterns could be used to resolve specific pairs. With further refinements in staining technique, recurring abnormalities were recognized in the complement of chromosomes, or *karyotype*, of malignant cells. In fact, the first specific cytogenetic abnormality associated with a human neoplasm came from analysis of blasts of patients with chronic myelogenous leukemia ([2]). The association

between the Philadelphia chromosome, named for the city in which it was discovered, and this disease provided one of the earliest indications of the clonal nature of cancer.

Even the smallest human chromosome contains more than 5 × 10 ^{7} base pairs, which, if fully extended, would stretch some 1.4 cm. Because the average nucleus is microns in diameter, the cell compacts these large DNA molecules into a protein-bound form termed *chromatin*. The fundamental unit of chromatin is the *nucleosome*, which is comprised of a short stretch of DNA associated with highly basic histone proteins acting in part to neutralize the negative charge of the nucleic acid. Two copies each of histones H2A, H2B, H3, and H4 make up a protein octamer core around which the DNA is wrapped. Nucleosomes are separated by less highly protein-bound linker DNA that varies in length from 8 to 114 base pairs. As a result of this organization, a 10-nm chromatin fiber is formed whose appearance under electron microscopy has been likened to beads on a string. In turn, the 10-nm fiber is coiled into a 30-nm fiber possessing approximately six nucleosomes per turn. In addition to histones, there are nonhistone proteins associated with chromatin that function in DNA packing, replication, and transcription. The end result is that chromatin contains up to twice as much protein as DNA (Fig. 5.2).

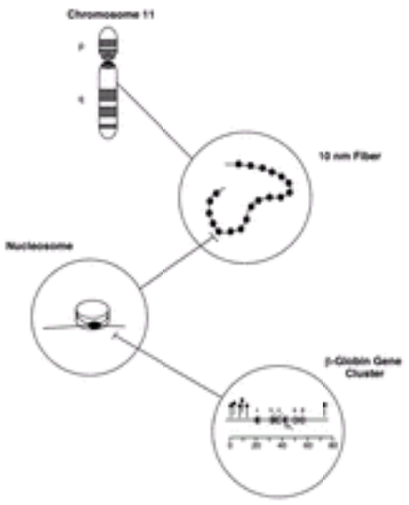

Figure 5.2. Genomic organization from the gene to the chromosome. DNA complexed with histones and nonhistone proteins is packaged into a highly organized structure whose core unit is the nucleosome. As a result of this organization, a 10-nm chromatin fiber is evident on electron microscopy that resembles beads on a string. This is assembled into a chromosome, each of which possesses a short (*p*) and long (*q*) arm. Transcriptionally active regions of DNA are less protein-bound and show hypersensitivity to digestion with DNAse I. These DNAse I hypersensitive sites are denoted in the bottom panel by  .

An additional challenge in genomic organization comes in copying the ends, or *telomeres*, of chromosomes. Because DNA polymerases are unable to replicate the termini of DNA molecules, long stretches of a tandemly repeated sequence, 5'-TTAGGG-3' in humans, are maintained in this region to ensure that essential subtelomeric genes are not deleted during DNA replication. The number of these repeats decreases with every somatic cell division, whereas, with some important exceptions ([3]), telomere length is maintained by the action of an unusual RNA-dependent DNA polymerase, telomerase, in cells that become immortalized or transformed.

The structure of the genome is dynamic, with some regions only transiently complexed with protein. Transcribed DNA is known to have an altered structure as evidenced by an increased sensitivity to cleavage with the enzyme deoxyribonuclease (DNAse) I. This DNAse hypersensitivity is also a property of origins of replication and centromeres. The DNA-binding affinity of histones can be altered by acetylation, and recent work has revealed that certain transcriptional coactivators possess histone acetyltransferase activity.

The small fraction of the human genome that encodes proteins shows the most complex organization, as exemplified by the globin genes. In the adult, the tetrameric hemoglobin A molecule is comprised of two nonidentical a- and ß-chains. The human a-globin genes are located on chromosome 16, whereas the ß-globin genes are clustered on chromosome 11. The ß-globin gene cluster actually contains five functional genes (ϵ, G?, A?, d, and ß) spanning over 50 kilobase pairs of DNA (Fig. 5.2). Each gene contains protein-coding segments, or *exons*, which are interrupted by sequences, *introns*, that must be removed from the transcribed mRNA before translation. In addition, each contains a promoter and other regulatory regions upstream of its transcriptional start site essential for its proper expression. This organization is illustrated diagrammatically in Figure 5.2.

Genomic Diversity

The early view of the genome of one gene encoding one protein was upset by the discovery of introns in 1977 ([4], [5]). It soon became apparent that multiple proteins could be derived from a single gene either through utilization of multiple promoters or an “exon shuffling” mechanism in which different exons are spliced in or out of the transcribed RNA. These processes are illustrated schematically in Figure 5.3. The amino acid sequence of the encoded protein is thus necessarily altered when exons are substituted, added, or deleted. In addition, even when the coding region is unaffected, the abundance of a protein can be altered as a result of changes in the rate of transcription or in the stability of the transcribed mRNA.

Figure 5.3. Generation of multiple proteins from a single gene: alternative splicing and alternative promotion. After transcription, heteronuclear RNA is processed by removal of the noncoding introns (splicing) and by addition of a polyadenylic acid tail (polyadenylation). This processed or messenger form of RNA is then translated into protein in the cytoplasm of the cell. Translation begins at a start codon (ATG) and terminates at one of several possible stop codons, leaving regions of the RNA 5' and 3' to the coding region untranslated (UTR). Variation in RNA and, consequently, protein sequence can occur if there is more than one promoter or if portions of the protein coding regions (exons) are differentially incorporated into the final, processed form of RNA.

A further level of complexity exists for the antigen-receptor genes, those encoding T-cell receptors and immunoglobulins, in which somatic recombination accompanies immune cell differentiation (Fig. 5.4) ([6]). The class to which an immunoglobulin belongs is specified by the type of heavy chain gene used in its synthesis—?, µ, a, d, and ϵ. Each heavy chain contains *N*-terminal variable (V $_{H}$) and *C*-terminal constant (C $_{H}$) regions encoding the variable and constant domains of the immunoglobulin molecule, respectively. The constant domain is invariant for every antibody of a given type, whereas the variable domain, which is subdivided into three hypervariable regions, is responsible for antigen recognition and binding. The heavy chain also contains a hinge region important for the

characteristic Y shape of the assembled molecule.

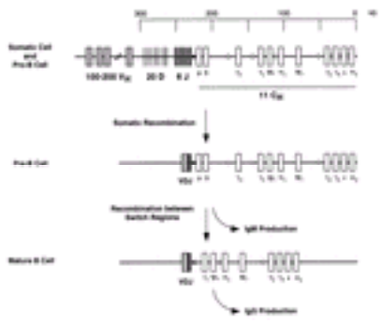

Figure 5.4. Intrachromosomal gene rearrangement: somatic recombination in the immunoglobulin (Ig) heavy chain locus. The Ig heavy chain is generated by the joining of a single V gene to a D segment, which is fused to a J gene. This process of somatic recombination occurs in the immature B cell. VDJ-joining triggers expression of the C $_{\mu}$ gene. Ig class switching occurs through further recombination involving switch regions, designated by the open and closed circles.

The genes that encode the antigen receptors are present as discrete, noncontiguous segments distributed over large distances at their particular chromosomal locations. The immunoglobulin heavy chain locus, for example, is comprised of at least two megabase pairs of DNA on chromosome 14 and includes more than 100 V genes, each with its own leader sequence and promoter region, at least 12 functional diversity (or D) genes, six functional joining (or J) genes, and nine functional C genes. Additional nontranscribed versions of each of these, termed *pseudogenes*, also exist. Each V gene contains two exons, and each C gene contains multiple exons, corresponding to the constant, hinge, and transmembrane domains, and cytoplasmic tail.

To assemble a functional heavy chain molecule, intrachromosomal gene rearrangements join selected V, D, and J genes, following which the recombined VDJ locus is fused to a specific C gene. As a result of these events, the arrangement of DNA in a B cell that produces a specific immunoglobulin molecule becomes distinct from that of all other somatic or germ cells, and up to 38,880 (or 60 × 12 × 6 × 9) different heavy chains can be generated by this mechanism alone. Further variability is introduced by addition of nucleotides at the junctions between segments, by alternative splicing of the mRNA, and, in the immunoglobulin—but not T-cell–receptor genes—by somatic mutation. In this way, the organism becomes capable of mounting an immune response of extraordinary specificity.

Somatic recombination represents a specialized strategy to achieve genomic diversity. In the germline, recombination is accomplished by meiosis. Interchromosomal exchange of DNA occurs in this process as the result of the two copies of each chromosome coming into register. The crossing-over events facilitated by this mechanism cause a shuffling but, normally, no loss of genetic information. The greater the distance between two genes, the higher the probability that they will become separated after meiosis, whereas genes in such proximity that they consistently cosegregate are said to be *linked*. In addition to meiosis, random mutation can alter DNA sequence, both in coding and noncoding regions. If not deleterious, these sequence polymorphisms are inherited and in this way increase genetic diversity.

Pathologic Changes in the Genome

The processes that promote genomic diversity are also prone to error. These are manifested as translocations of chromosomal segments, deletions, insertions, or inversions of smaller regions, or mutations of individual nucleotides. The proteins affected may be altered in their expression or have diminished or even novel function. Burkitt lymphoma, thalassemia, and sickle cell disease are specific examples of disorders resulting from pathologic alterations in the genome.

Even under normal circumstances, it is estimated that only one in three lymphoid progenitor cells productively rearranges its antigen-receptor genes and successfully develops into a mature lymphocyte. If rearrangement occurs between rather than within chromosomes, as in Burkitt lymphoma, a cell may obtain a growth or survival advantage. The endemic form of Burkitt lymphoma is associated with a translocation of the c-myc protooncogene on chromosome 8 to the immunoglobulin heavy chain locus on chromosome 14 so that it is effectively decapitated and fused to the J $_{H}$ gene promoter. In other patients, the c-myc locus is brought under the regulatory control of the powerful immunoglobulin enhancer. Both types of translocations cause unscheduled or dysregulated expression of c-myc protein.

The thalassemias provide another example of hematologic illness with a genetic basis. The underlying defect in this group of diseases lies in the synthesis rather than the sequence of the globin protein made. Hemoglobin (Hb) Lepore is particularly illustrative of the errors that occur when there is unequal crossing-over between nonallelic members of a gene cluster, which in this case differ in sequence by only 7% overall. This nonreciprocal rearrangement generates recombinant chromosomes in which one has a duplication and the other a deletion of the sequences between the genes involved, effectively fusing them together. The protein ultimately synthesized contains *N*-terminal sequence derived from the d-globin gene and *C*-terminal sequence from the ß-globin gene. The unequal crossing-over events believed to cause this form of thalassemia are illustrated in Figure 5.5.

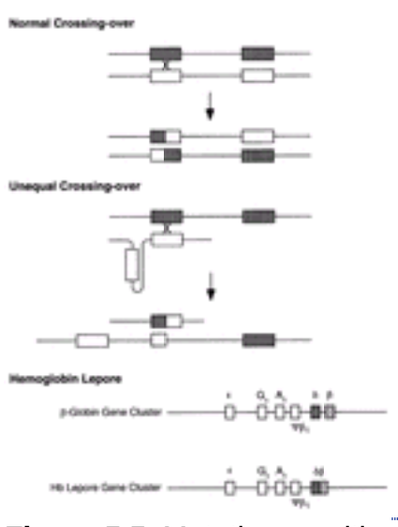

Figure 5.5. Mutation resulting from abnormal crossing-over: hemoglobin (Hb) Lepore. Genetic recombination occurs physiologically during meiosis and requires precise alignment of the corresponding sequences in homologous chromosomes. Abnormal alignment can occur when there are two or more copies of homologous genes, as in the ß-globin gene cluster. Hb Lepore likely results from this kind of misalignment, as illustrated.

Finally, disease can result from the substitution of even one base pair. This can effect an amino acid substitution, which changes the properties of the encoded protein, as illustrated by the sickle cell mutation, or a stop codon that terminates protein chain elongation (nonsense mutation). The first molecularly characterized disorder, sickle cell anemia, results from a missense mutation in the sixth codon of the ß-globin gene, causing the substitution of the amino acid valine for glutamic acid ([7]) (Fig. 5.6). The abnormal Hb molecule resulting from this mutation shows a marked decrease in solubility when deoxygenated and becomes polymerized into ropelike fibers. These structures are responsible for the abnormal cell shape characteristic of this disease and the hemolytic and vasoocclusive phenomena that produce its clinical manifestations. At least 300 other point mutations in the a- or ß-globin genes have also been described.

Figure 5.6. Mutation resulting from base substitution: hemoglobin S (sickle hemoglobin). Hemoglobin S results from a homozygous A to T transversion in codon 6 of the human ß-globin gene, causing the substitution of valine (Val) for glycine (Gly) in the resulting protein. Glu, glutamic acid; Pro, proline.

GENE DISCOVERY AND MOLECULAR ANALYSIS

Restriction Enzymes and Vectors

Molecular analysis of hematologic disease has been greatly facilitated by the use of a number of powerful techniques and the knowledge of gene structure and expression gained from their application. A pivotal discovery was that of *restriction enzymes*, endonucleases that cut double-stranded DNA at specific sequences. By reducing the genome to experimentally manipulable pieces, or *restriction fragments*, these enzymes made it possible to clone and propagate genes. Restriction endonucleases recognize specific four– to eight–base pair sequences that in many cases are palindromic, or have the same order of bases read from either strand. *Eco*RI, for example, recognizes the sequence

5'… GAATTC… 3'
3'… CTTAAG… 5'

and cleaves between G and A with the creation of two new ends:

5'… G AATTC… 3'
3'… CTTAAG… 5'

Although the DNA in this example is left with overhanging ends, other enzymes can generate blunt ends, depending on their recognition sequence. Since the discovery of the first restriction enzyme in 1970, hundreds have been characterized and made commercially available ([8]).

In addition to restriction endonucleases, a variety of other nucleic acid–modifying enzymes are used in preparing recombinant DNA. One of the more commonly used is T4 DNA ligase, which catalyzes the formation of a phosphodiester bond between two free ends of DNA. The ends created by *Eco*RI, for example, can be rejoined by the action of this enzyme.

Another important tool of the molecular biologist is the *vector*. In its simplest form, it is the vehicle by which a foreign DNA molecule is introduced into bacteria, amplified, and ultimately purified. Standard vectors contain multiple restriction enzyme sites to simplify subcloning of DNA fragments, an antibiotic resistance gene for selection of cells that have taken up the vector, and a sequence (or origin) permitting replication in the bacterial host. Additional features allow some vectors to replicate in eukaryotic cells and serve as templates for *in vitro* transcription. Cells are rendered capable of taking up this or other forms of DNA by treatment with divalent cations or exposure to a pulsed electrical field. These methods are applicable to both prokaryotic and eukaryotic cells.

Molecular Cloning

A frequent objective in molecular biology is the isolation of a gene or its mRNA, and a number of the techniques required for what is termed *molecular cloning* were pioneered for the globin genes. Depending on whether the nucleic acid of interest is DNA or RNA, the initial step in this process involves generating a genomic or complementary DNA (cDNA) library, respectively. For the former, the source of DNA is the entire genome, which is initially reduced to smaller fragments by restriction enzyme digestion. As many genes are interrupted by introns and span substantial distances, it is usually desirable to obtain large DNA fragments for this purpose. Their size is determined by the frequency with which a given restriction site occurs in the genome and the proportion of these sites actually cleaved by the enzyme. For example, genomic DNA is frequently digested for library construction with *Sau*3AI, which recognizes the sequence GATC. The frequency with which any specific four–base pair sequence occurs is 1/4 × 1/4 × 1/4 × 1/4, or 1/256, so that complete digestion with *Sau*3AI would produce fragments that are, on average, 256 base pairs in length. The extent of digestion can be controlled, however, so that products in the range of 15 to 20 kilobase pairs can be produced. These are then introduced into a vector that can replicate in bacteria, typically one derived from bacteriophage d. The complete collection of these fragments constitutes a genomic library.

The original source of nucleic acid for construction of a cDNA library is mRNA, which must first be converted to its corresponding DNA form by an RNA-dependent DNA polymerase (reverse transcriptase). Because mRNA in eukaryotic cells is polyadenylated, it is frequently purified with a homopolymeric thymidine [oligo(dT)] affinity resin. Either oligo(dT) or random hexanucleotides are used as primers for the enzyme, resulting in synthesis of a DNA/RNA hybrid. Ribonuclease H is used to digest the RNA component, followed by DNA polymerase to fill in the gaps, resulting in replacement of the RNA strand by its DNA counterpart. Next, T4 DNA ligase is added to join any regions still unlinked, and the ends of the newly synthesized cDNA are ligated to synthetic oligonucleotide linkers containing specific restriction enzyme sites. The resulting pool of clones subcloned into a vector constitutes the cDNA library.

Synthetic oligonucleotides, larger DNA fragments, or in some cases antibodies can be used for screening the library. If a portion of the protein-coding region is known, oligonucleotide mixtures encompassing all or the most likely nucleotide sequences can be synthesized based on this amino acid sequence. For the peptide sequence methionyl-glutamyl-threonyl-serine, for example, up to 1 × 2 × 4 × 6, or 48, different oligonucleotides might be used, as there is one codon for Met, two for Glu, four for Thr, and six for Ser. The cDNA from another species can also be used for screening if the corresponding sequence is conserved evolutionarily.

The conditions under which a nucleic acid probe is used to screen a library, as well as nucleic acid hybridization in general, are affected by the processes of DNA strand separation (denaturation) and renaturation. The temperature at which a molecule of DNA becomes denatured is dependent on the proportion of G + C and, to a lesser extent, by the number of A + T base pairs. For mammalian genomes with GC contents, typically, of 40% the temperature at which half their DNA denatures, or the *melting temperature* (T_m), is approximately 87°C. The composition of DNA also dictates the T_m of smaller, double-stranded oligonucleotides and can be estimated from the following equation:

$$T_m = 2(A + T) + 3(G + C)$$

where *A*, *T*, *G*, and *C* represent the specific number of these nucleotides in the probe.

Renaturation is affected by DNA composition as well. The two strands of the DNA duplex base pair in their entirety. However, if two polynucleotides are mixed that are not completely complementary, both the T_m of the renatured molecule and its rate of reassociation are decreased in proportion to the mismatch between the two molecules. The process by which such molecules renature is termed *annealing* or, in an analytical context, *hybridization*. Hybridization can be carried out with nucleic acids in solution or immobilized on filters. For library screening, radioactive nucleotides are typically incorporated into the oligonucleotide or cDNA probe, and the bacterial colonies containing the desired clone are visualized with autoradiography.

Isolation of Genes without Prior Knowledge of Sequence

Often there is insufficient information, particularly with disease-related genes, to permit the use of standard library screening techniques in molecular cloning. Using a combination of genetic and physical maps, it has proven possible to isolate genes from their location within the genome without prior knowledge of their sequence or function. This approach, termed *positional cloning*, relies on the segregation of a trait or disease over several generations of kindreds and uses the technique of linkage analysis to identify the gene's probable chromosomal location ([9]). This is followed by isolation and analysis of the genes from this region for mutations that cosegregate with the disease. The availability of the complete sequence of the human genome has greatly facilitated the application of this method.

The development of yeast artificial chromosome and, more recently, bacterial artificial chromosome vectors has played a major role in the development of this technology ([10]). It had proven difficult previously to incorporate fragments larger than 10 to 15 kilobase pairs into plasmid vectors, both because of the difficulties in generating large circular DNAs and because of their relatively inefficient uptake by bacterial cells. The use of yeast artificial chromosomes, which can accommodate fragments larger than 500 kilobase pairs, became possible after the *cis*-acting sequence elements required for chromosome stability in yeast were defined. This technology has also been applied to bacterial artificial chromosome vectors, which have proven particularly useful for sequence analysis of large DNA fragments. The utility of positional cloning strategies is borne out by the success in a number of genetic disorders in identifying the genes involved.

Genomics

Knowledge of nucleotide sequence underlies all understanding of a gene's normal function, as well as how it might be altered in disease. The most common method for DNA sequence analysis is the *chain-termination method* developed by Sanger in which a DNA polymerase catalyzes the synthesis of new DNA strands of varying lengths, each originating with a specific oligonucleotide primer complementary to the single-stranded DNA template ([11]). Chain elongation is terminated at all possible positions by incorporation of a dideoxynucleotide triphosphate lacking a 3' hydroxyl group. In practice, four independent reactions are carried out with a mixture of deoxynucleotide triphosphates plus a limiting amount of one dideoxynucleotide triphosphate. The ratio of deoxynucleotides to dideoxynucleotides is adjusted to allow for incorporation of the dideoxynucleotide along the whole length of the molecule. The products of the four reactions are fractionated by size using denaturing polyacrylamide gel electrophoresis, and the DNA sequence is determined from an autoradiogram of the gel if a radiolabeled nucleotide is incorporated or by fluorography if fluorescent nucleotides are used. The Sanger method is still widely used, although DNA sequence analysis has been made more amenable to automation and less expensive to carry out ([12]).

Once the nucleotide sequence of a gene is established, one of the first ways in which it is analyzed involves some type of computer-assisted database search ([13]). This can reveal whether the gene has previously been isolated, either in its full-length form or as an anonymous sequence, if homologs exist in other species, and, frequently, some indication of function. The GenBank database maintained at the National Center for Biotechnology Information of the National Library of Medicine contains all publicly available information on gene and protein sequences. User-friendly search engines, the most widely used being the Basic Local Alignment Search Tool, or BLAST ([14]), enable interrogation of the compiled database and are accessible over the World Wide Web (http://www.ncbi.nlm.nih.gov/).

As a result of a concerted effort worldwide, a draft sequence of the human genome was obtained in 2000, with over 90% available in its final form in September 2002 ([15]). Unexpectedly, a total of only 30,000 to 35,000 genes appear to be present in our genome, although, as a result of alternative splicing, this is sufficient to encode more than 100,000 proteins. It has also been found that protein-coding regions are unevenly distributed through the genome, with some chromosomes and chromosomal regions being more gene dense than others.

In addition, effort has been made to comprehensively sequence cDNAs, termed *expressed sequence tags*, from a number of different sources of RNA, and estimates indicate that more than half of all human genes are represented in the expressed sequence tag databases. The complete sequencing of the genomes of several model organisms has also been accomplished, including the 1.8–megabase pair genome of *Haemophilus influenzae*, the 1.66–megabase pair genome of *Methanococcus jannaschii*, and the 4.6–megabase pair genome of *Escherichia coli*.

MOLECULAR DIAGNOSTICS

Molecular techniques have revolutionized the diagnosis of disease, particularly in inherited disorders. Two of the earliest applications of these methods were in the prenatal diagnosis of a-thalassemia ([16]) and in identification of the causative mutations in ß-thalassemia ([17]). Since that time, highly sensitive and specific techniques have been developed to analyze abnormalities in both RNA and DNA.

Southern Blot Analysis

Southern blot analysis, named for its originator, E. M. Southern ([18]), enables the copy number, organization, and internal structure to be determined for any gene. The technique involves immobilization of nucleic acids on a filter as described above for library screening, except that total genomic DNA represents the target of the probe rather than a library of individual clones. Briefly, high-molecular-weight genomic DNA is treated, typically, with a panel of restriction enzymes, and the resulting digests are fractionated by agarose gel electrophoresis. These restriction fragments are denatured within the gel and transferred, or blotted, to a filter replica. The gene of interest is then identified by hybridization with a labeled probe and its structure analyzed from the hybridization patterns.

Although supplanted by the polymerase chain reaction (PCR) for most purposes, Southern blot analysis has been invaluable in diagnosis of a number of hematologic disorders. The mutation in sickle cell anemia, for example, can be specifically recognized with this technique. Substitution of T for A in codon 6 of the ß-globin gene in Hb S results in the loss of an *Mst*II restriction site as shown:

Hb ACCTGAGGAG
Hb SCCTG *T*GGAG
*Mst*II CCTNAGG

As a result, the size of the hybridizing band in Southern blot analysis of *Mst*II-digested DNA differs for an individual with this mutation and one with a normal ß-globin sequence.

A similar approach can also be used to determine genetic relatedness and to analyze the extent of chimerism after allogeneic bone marrow transplantation, although PCR has effectively replaced Southern blot analysis for both these applications. It was recognized that differences in nucleotide sequence can exist naturally between individuals, and provided they alter a restriction enzyme recognition site and a probe to the region is available, such restriction fragment length polymorphisms are detectable by Southern blot analysis. Southern blot analysis can also be carried out using probes for highly polymorphic regions consisting of tandemly repeated nucleotide units of 20 to 40 base pairs ([19]). The number of these variable number of tandem repeats varies between individuals as a result of recombination, resulting in unique bands on hybridization analysis.

Northern Blot Analysis

Because mRNA is susceptible to alkaline hydrolysis and does not bind well untreated to nitrocellulose, Southern's method for DNA analysis could not be applied directly to mRNA. With the inclusion of a denaturant like glyoxal or formaldehyde in the gel, it became possible with what is now termed *Northern blot analysis* to similarly analyze RNA fractionated by agarose gel electrophoresis and transferred to a filter ([20]). Although it is infrequently used in diagnostics, an important attribute of this technique is its ability to quantitate the abundance of specific RNA species.

In Situ Hybridization

Northern blot analysis relies on hybridization of a labeled probe to RNA immobilized on a solid support. By incubating the probe with specially prepared cells or tissue sections, information can also be obtained about the specific location and identity of the cell types that transcribe that mRNA. This technique, termed in situ *hybridization*, can be used for the localization of viruses or viral messages ([21]) in addition to cellular transcripts ([22]).

In situ hybridization can also be used to assign a gene to an individual chromosome and to localize it within a particular subchromosomal segment ([23]). If the DNA probe is biotinylated, avidin-conjugated fluorescent molecules can be used to amplify the hybridization signal in an application of the technique termed *fluorescent* in situ *hybridization* ([24]). The fluorescent *in situ* hybridization technique has been invaluable in detecting loss, gain, or rearrangement of specific chromosomal regions in tumor cells.

Comparative genomic hybridization is an adaptation of *in situ* hybridization in which a genome-wide analysis is carried out to identify regions with tumor-specific gains or losses ([25]). This technique involves hybridization of metaphase cell preparations with equal amounts of subject and reference DNA labeled with dyes that fluoresce in the red and green wavelengths. Regions that hybridize equally well with subject and reference DNA appear yellow (red + green), whereas regions hybridized with under- or overrepresented DNA appear red or green.

Microarray Analysis

An increasingly applied approach to characterizing gene expression uses nucleic acids spotted or stamped on inert supports, or *microarrays* ([26]). This microarray technique involves extraction of RNA from a biologic sample, its conversion to cDNA with incorporation of either fluorescent nucleotides or tags that can be detected

later by fluorescence, hybridization of these labeled cDNAs to a very large number of cDNAs or oligonucleotides affixed to a glass slide or filter, and laser scanning of the hybridized array. A reference RNA is similarly processed but labeled with a different fluorochrome, and the two cDNA populations are mixed and competitively hybridized to the array. Spots appear yellow (red + green) if the subject and reference cDNAs hybridize equally and red or green if there is a difference in the abundance of one or the other cDNA (Fig. 5.7). The technique provides information on the abundance of as many different RNAs as there are unique cDNAs or oligonucleotides on the array, which can number in the tens of thousands. Microarray experiments generate a massive amount of data and require sophisticated informatic methods to extract biologically useful information ([27]).

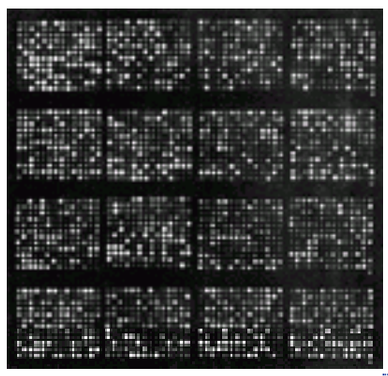

Figure 5.7. Microarray analysis. Shown is a portion of a complementary DNA (cDNA) microarray that has been competitively hybridized with cDNA made from human leukemic cell RNA and labeled with the fluorochrome Cy3 and cDNA prepared from a pool of human RNAs (reference RNA) and labeled with a different fluorochrome, Cy5. Each spot corresponds to one of a total of 11,000 cDNAs affixed on this array. Its color (red, green, or yellow) on laser-scanning analysis provides information about the abundance of specific RNAs in the leukemic blasts. See Color Plate.

Gene expression profiling has been used to identify the involvement of specific genes, microorganisms, or pathways in disease. Microarray analysis has, in addition, led to new, molecular-based classifiers for known diseases (class discovery) and for previously unclassified disorders (class prediction). In addition to their use in large-scale gene expression analysis, microarrays have been used to screen for genomic imbalances (array comparative genomic hybridization), small mutations, insertions, or deletions, and for single-nucleotide polymorphisms. Besides nucleic acids, array technologies are being developed for proteins, protein-binding molecules, and even small tissue sections.

Polymerase Chain Reaction

Although Southern blot analysis and, particularly, fluorescent *in situ* hybridization are useful diagnostically, their application is largely restricted to circumstances in which there are sizeable deletions or rearrangements, and they are not generally useful for detecting small insertions, deletions, or base substitutions. PCR, first reported by Mullis and colleagues in 1986 ([28]), has been essential for this purpose and has found wide utility in numerous areas of cell and molecular biology.

PCR is, fundamentally, a method to amplify genomic or cDNA sequence. In its usual application, two oligonucleotides oriented in opposite directions and complementary to sequences at either end of the region of interest function as primers for a DNA polymerase in the manner described above for sequencing. A reaction mixture containing a DNA template, primers, and deoxynucleotide triphosphates is heated to a temperature of 94 to 95°C to effect DNA strand separation and then cooled to allow the oligonucleotides to anneal. Primer extension is effected at high temperature, typically 72°C, by inclusion of a heat-stable DNA polymerase, and these reactions, which comprise one complete cycle, are then repeated some 20 to 40 times. As a result of its exponential nature, 2^n copies are generated of the sequence encompassed by the two primers, where *n* represents the total number of cycles carried out. The technique is extraordinarily sensitive and capable of detecting, for example, the presence of a single malignant cell within a million normal ones. PCR is outlined in schematic form in Figure 5.8.

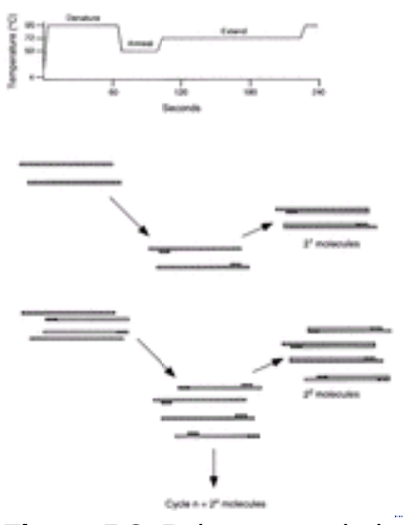

Figure 5.8. Polymerase chain reaction. The polymerase chain reaction is a method to exponentially amplify defined regions of DNA. The technique consists of a series of repeated steps (cycles) involving, in sequence, denaturation of the DNA target, binding (or annealing) of specific oligonucleotides (primers) complementary to the region of interest and delimiting the region to be amplified, and DNA synthesis (or extension) from the primers by the action of a heat-stable DNA polymerase. Denaturation, annealing, and extension are carried out at different temperatures (*top*) in a dedicated piece of equipment known as a *thermal cycler*. A total of two molecules are synthesized after the first cycle, four molecules after the second cycle, and 2^n after n cycles, where *n* represents the total number of cycles.

PCR is often combined with other techniques, including some of those described earlier, to determine whether the amplification products contain a mutation. Although dideoxynucleotide sequencing can be carried out to confirm mutations, restriction enzyme digestion, allele-specific oligonucleotide hybridization, and single-strand conformation polymorphism analysis represent more efficient methods to screen for their presence. The first approach takes advantage of the sequence specificity of restriction enzyme digestion and was illustrated in the example of sickle cell disease above. The approach is simplified and more widely applicable, however, if a short fragment of amplified DNA is analyzed rather than the entire genome. The second method involves hybridization of an allele-specific oligonucleotide to PCR product immobilized on a filter. Because the T_m of a short oligonucleotide is dependent on the extent of complementarity, conditions can be controlled so that only exact matches result in binding of a labeled probe to the DNA sample immobilized. In single-strand conformation polymorphism analysis, the DNA of interest is denatured by heat or alkali treatment and, with a control sample, subjected to electrophoresis in a nondenaturing polyacrylamide gel ([29]). The technique relies on a mutation affecting the secondary structure and thereby the electrophoretic mobility of either of the denatured strands relative to that of the control.

ANALYSIS OF GENE FUNCTION

Clues to a gene's function are sometimes apparent from its amino acid sequence. The ability of transcription factors, a class of proteins essential for regulated gene expression and frequently targeted by leukemia-associated translocations, to act as sequence-specific DNA-binding proteins can be detected with the widely used *electrophoretic mobility shift assay*. In this technique, also referred to as a *gel* or *band shift assay*, short double-stranded oligonucleotides of defined sequence are labeled, typically radioactively, and mixed with purified transcription factor or nuclear extracts ([30]). The mixtures are fractionated electrophoretically under nondenaturing conditions, and if a protein–DNA complex formed, the mobility of the labeled probe is retarded (Fig. 5.9). Specificity is assured by the ability of unlabeled oligonucleotide to compete with the labeled probe for binding and by the elimination or further retardation (“supershift”) of the labeled band by an antibody to a component of the complex.

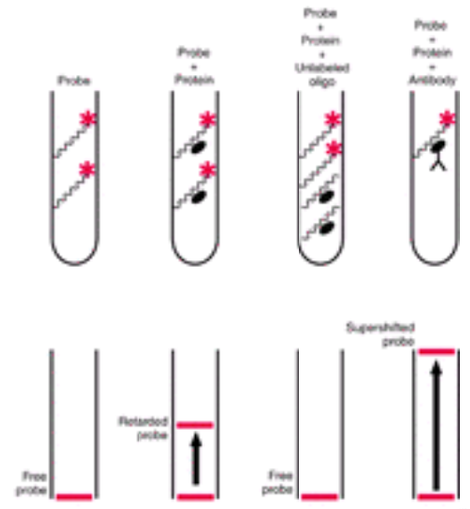

Figure 5.9. Electrophoretic (or gel) mobility shift assay of DNA binding activity. A radiolabeled, double-stranded DNA probe is mixed **(A)** with putative DNA-binding protein in the form of purified protein or nuclear extract, and the resulting mixture is subjected to electrophoresis under nondenaturing conditions. Protein–DNA complexes are detected on an autoradiograph of the dried gel **(B)** as a result of retardation of the labeled probe. Specificity of binding is ensured by elimination of the retarded band by an excess of unlabeled probe in the binding mixture and by its elimination or further retardation ("supershift") by an antibody to the protein constituents of the binding complex.

Even when knowledge of a protein's actions is known, it may be desirable to determine its function within a cellular or even organismal context. Once the nucleotide sequence of a gene has been determined, it is often possible to selectively inhibit its actions through use of synthetic oligonucleotides or RNA species complementary to the encoded message. Although these antisense reagents may not always be specific, they are believed to inhibit the translation or accelerate the destruction of the transcript targeted and are predictably more effective against proteins of short half-lives ([31]). A more potent and potentially more specific approach involves the use of double-stranded RNA molecules from 21 to 23 base pairs in length that are complementary to the RNA of interest ([32]). These small, interfering RNAs effect posttranscriptional silencing by a series of steps that culminate in degradation of the targeted mRNA by cellular ribonucleases. In addition to their use in probing gene function, both antisense inhibition and RNA interference are under investigation for therapeutic purposes.

A more secure method of inhibiting protein function involves the germline inactivation of its gene such that a functional product is never expressed (Fig. 5.10). This approach, referred to as *gene targeting* or *knock-out*, involves the introduction into pluripotent embryonic stem (ES) cells of a targeting vector containing, typically, a neomycin resistance gene flanked by sequences of exact homology to the gene of interest and linked to a viral thymidine kinase gene ([33]). ES cells in which homologous recombination at the targeted locus occurs integrate the neomycin resistance gene without the thymidine kinase gene and, as a result, are resistant to concurrent selection with the neomycin analog G418 and the drug ganciclovir. Cells surviving this "positive-negative" selection are microinjected into blastocysts of mice, which are then implanted into a foster mother. Any chimeric offspring that result, usually identified on the basis of coat color, are interbred. If the targeted ES cells have contributed to the germline, mice homozygous for this induced mutation can be generated by breeding, provided that the gene is not required in embryonic development. The technology to create knock-out mice has provided important insights into the *in vivo* function of numerous genes and led to the development of mouse models for a number of hematologic disorders. The establishment of human ES cell lines ([34]), with their ability to differentiate into hematopoietic progenitors ([35]), suggests that these cells could be useful therapeutically.

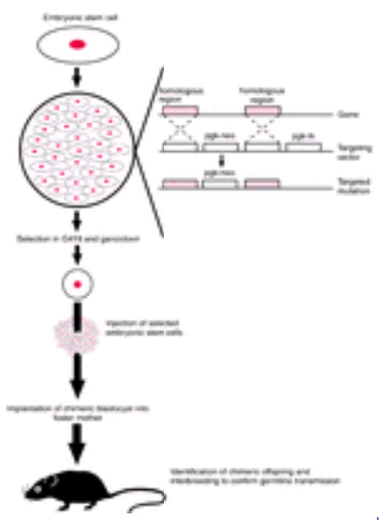

Figure 5.10. Generation of mice with targeted mutation (knock-out mice). Embryonic stem cells are pluripotent, or capable of contributing to every cell type in the animal. They are transduced in culture with a targeting vector (*inset*) in which a neomycin resistance gene (*neo*) driven off a phosphoglycerate kinase (*pgk*) promoter is flanked by portions of the gene to be targeted. Linked to this is a *pgk*-promoted thymidine kinase (*tk*) gene, which converts the drug ganciclovir to a toxic, phosphorylated product. In embryonic stem cells that undergo homologous recombination (*arrows*), the *pgk-neo* gene is incorporated into the targeted locus, thereby inactivating it, without insertion of the *pgk-tk* gene. These cells are selected in culture by their resistance to both the neomycin analog G418 and ganciclovir, analyzed by Southern blot analysis to verify disruption of the targeted gene, and injected into blastocysts of mice with a distinctive coat color. These are implanted into a foster mother, and the chimeric mice resulting are identified by coat color. Mice are then mated to verify germline transmission of the targeted mutation.

A complementary approach to elucidating a gene's function involves its selective overexpression, either *in vivo* in transgenic animals (Fig. 5.11) or *in vitro* with a plasmid or viral vector. The transgene is constructed to contain all components necessary for efficient and tissue- or cell type–specific expression, including a promoter, polyadenylation site, and, typically, one or more introns. It is introduced by microinjection into fertilized eggs, which are implanted into the reproductive system of a pseudopregnant female mouse. If successful, the transgene becomes incorporated into the germline of the resulting offspring. Sequential matings of these animals, termed *founders*, are typically carried out with nontransgenic mice and then with heterozygotes to generate a line homozygous for the transgene. In addition to analysis of any phenotype resulting from expression of the introduced gene, transgene copy number and tissue distribution are usually determined ([36]).

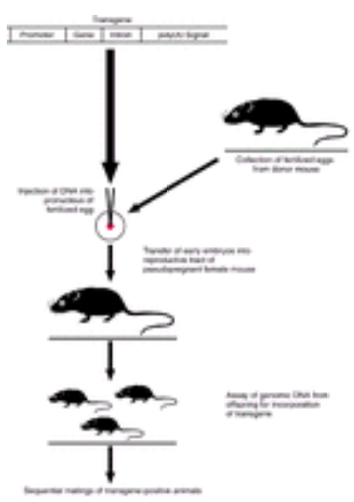

Figure 5.11. Generation of transgenic mice. The transgene construct, which contains a promoter, the coding sequences of the gene of interest, a polyadenylation signal, and, typically, one or more introns, is microinjected into the pronucleus of a fertilized egg. The resulting embryos are surgically transplanted into the

reproductive tract of a pseudopregnant female mouse. The pups born are tested for incorporation of the transgene by Southern blot or polymerase chain reaction analysis of genomic DNA, usually from their tails. Sequential matings of transgene-positive animals (founders) are then carried out to verify that the transgene can be passed through the germline and to establish a line of mice homozygous for the transgene.

A variety of vectors are used to transduce cells with specific genes, either in transient fashion or for derivation of permanent cell lines. This approach is rapid, avoids potential toxicities resulting from expression of a transgene during embryonic development, and is useful in targeting expression to specific cell types when a tissue-specific promoter is unavailable. The techniques used in this approach are the same as those used in gene therapy and are described in detail in Chapter 26.

Although the technology can be expected to change, it is a safe prediction that molecular biology will continue to impact the practice of hematology.

Origin and Development of Blood Cells

BLOOD CELLS

The blood contains several different types of cells. Each of these cell types is quite distinct in appearance, and each has a specific biologic function. *Erythrocytes* are anucleate, biconcave discoid cells filled with hemoglobin, the major protein that binds oxygen. The erythrocytes transport the respiratory gases oxygen and carbon dioxide. *Granulocytes* and *monocytes* are cells that can exit from blood vessels and migrate among the cells of many tissues. These two cell types play key roles in inflammation and phagocytosis. *Platelets* are very small, anucleate cells that contain molecules required for hemostasis. In addition, platelets provide hemostasis through their abilities to adhere, aggregate, and provide a surface for coagulation reactions. Lymphocytes mediate highly specific immunity against microorganisms and other sources of foreign macromolecules. B lymphocytes confer immunity through the production of specific, soluble antibodies, whereas T lymphocytes direct a large variety of immunity functions, including killing cells that bear foreign molecules on their surface membranes. Despite these extreme structural and functional differences among the cells of the blood, strong evidence exists that all of the blood cells are the progeny of a single type of cell: the hematopoietic stem cell (HSC). The processes involved in the production of all of the various cells of the blood from the HSCs are collectively called *hematopoiesis*. These processes of hematopoiesis include the self-renewal of stem cells, the commitment of most progeny of stem cells to differentiate ultimately into a particular cell type, and the proliferation of the progenitor cells and their differentiation along a pathway leading to a particular kind of mature blood cell. A process implicitly prerequisite to the generation of mature cells is the maintenance of a local environment permissive for the survival of at least some portion of each cell lineage (e.g., the production of necessary protein survival factors or growth factors).

Hematopoiesis begins early during embryogenesis, and the process undergoes many changes through fetal and neonatal development. Unlike some organ systems that form in early life and are not continually replaced, turnover and replenishment of the hematopoietic system continue throughout life. The cells of the blood have finite lifespans, which vary depending on the cell type. In humans, granulocytes and platelets have lifespans of only a few days, whereas some lymphocytes can exist for many months. Thus, cells are replaced as the older cells are removed and the newly formed, mature cells are added. The numbers of the various cell types in the blood are normally kept in relatively constant ranges. In particular, variations in the erythrocyte number are normally minimal, and values 50% above or below the norm for the population have significant health effects. Although the numbers of other blood cell types are not nearly as constant as the number of erythrocytes, the production processes of other blood cells are also highly regulated. The regulation of hematopoiesis is complex. For each cell lineage, there are particular regulatory growth factors that play a key role in fostering the production of cells of that lineage. Lineage-specific regulation is necessary because of the widely varying lifespans and widely varying functions of the different mature blood cell types. However, there are also regulatory factors that influence overall hematopoiesis by working on very early progenitor cells: the HSCs or cells that have not undergone commitment to a single lineage, or both.

This chapter presents an overview of hematopoiesis in humans. However, much of the experimental work on hematopoiesis has been done using mice, and many of the conclusions presented here are based on that work. All cell lineages that compose the blood are discussed. There are, in addition to the blood cells, several cell types that are derived from the HSCs but are not found in the blood. The final steps of differentiation of these latter cells occur in the tissues in which they reside. Such cells include dendritic cells of the lymphoid tissues and the skin (Langerhans cells), specialized macrophages of all types, and mast cells. Figure 6.1 is an illustration of the cell types associated with hematopoiesis and their distribution among bone marrow, blood, and lymphatic tissues.

HEMATOPOIETIC ORGANS

Development of Hematopoietic Organs

During prenatal development, the sites of hematopoiesis change several times ([1], [2], [3], [4], [5], [6], [7] and [8]). The hematopoietic tissue arises from the mesodermal germ layer that forms at the time of gastrulation in vertebrate embryos. Beginning in late gastrulation, two types of hematopoiesis are established. The first is termed *primitive hematopoiesis*. It arises in the blood islands of the extraembryonic yolk sac on embryonic day 7.5 in mice and day 19 in humans and continues through day 13 in mice and week 8 in humans. The second is termed *definitive hematopoiesis*. It arises slightly later than the primitive hematopoiesis and begins in the splanchnopleura/aorta-gonad-mesonephros of the developing embryo. Primitive hematopoiesis is transient, lasting during the respective embryonic periods described above, whereas definitive hematopoiesis persists throughout postnatal life. These two forms of hematopoiesis also differ in that the primitive blood cells are mainly erythrocytes, whereas the definitive blood cells are all types including granulocytes, lymphocytes, monocytes, and platelets as well as erythrocytes. The primitive erythrocytes are nucleated and have reduced erythropoietin (EPO) requirements during their development compared to definitive erythroid cells ([9]), and their hemoglobin is composed of the embryonic forms of the “alpha family” and “beta family” of globin chains ([10]). The definitive erythrocytes, on the other hand, are anucleate and require EPO for survival during differentiation, and their hemoglobins contain the fetal and adult forms of globins.

Primitive hematopoiesis arises in the yolk sac blood islands where visceral endoderm induces both endothelial and blood cell development in the adjacent mesoderm. This induction appears to be mediated by a member of the hedgehog family of proteins (Indian hedgehog) and leads to the expression of bone morphogenic protein (BMP)-4 in the developing mesodermal cells ([11]). BMP-4 expression, in turn, leads to the development of both endothelial cells that assemble to form blood vessels and the primitive blood cells located in these blood vessels ([8], [11]). Slightly later in development, but in a similar manner, BMP-4 is expressed in the endothelial cells in the ventral portion of the developing dorsal aorta and the subjacent mesoderm. This BMP-4 induction of definitive hematopoiesis occurs at embryonic days 10 to 13 in mice and weeks 4 to 6 in humans. Thus, the BMP-4 induction of definitive hematopoiesis is later by approximately 2 days in mice and approximately 2 weeks in humans as compared to the analogous BMP-4 induction at the initiation of primitive hematopoiesis. Like primitive hematopoiesis, the first definitive hematopoiesis occurs in newly formed blood vessels, specifically in the ventral part of the dorsal aorta and in the proximal vitelline and umbilical arteries.

By embryonic day 10.5 in mice, long-term repopulating HSCs that can rescue lethally irradiated adult mice can be found in the splanchnopleura/aorta-gonad-mesonephros region ([12]). These HSCs increase in number and can be found by day 11 in the fetal liver and yolk sac blood islands. However, their origin appears to be in the ventral wall of the dorsal aorta where both endothelial and hematopoietic cells are present. Furthermore, multiple cellular markers are displayed by both the endothelial and hematopoietic cells. These include CD34, FLT3 ligand (FL), Flk-1, TAL-1, GATA-2, LMO-2, AML-1, and CD31 [PECAM-1 (*p*latelet- *e*ndothelial *c*ell *a*dhesion *m*olecule-1)] ([6], [7], [13], [14] and [15]). The close physical and temporal association of endothelial and hematopoietic cells during their differentiation in the embryo, as well as the numerous shared markers, has led to the concept of a common mesodermal cell type termed the *hemangioblast*. Studies with embryonic stem cells *in vitro* also support the existence of the hemangioblast, but direct evidence of this cell type *in vivo* has not been demonstrated ([15], [16]). Alternative possibilities are that mesodermal cells in the splanchnopleura/aorta-gonad-mesonephros directly differentiate into endothelial or hematopoietic cells without a hemangioblast stage or, more likely, that some endothelial cells are hemato-genic and give rise to hematopoietic cells ([17], [18] and [19]).

Once the definitive hematopoietic cells have been formed, they rapidly seed the fetal liver, which is the major site of hematopoiesis in the midgestational period. The spleen also participates in hematopoiesis during this period. The erythrocytes produced in the fetal liver of mammals are anucleate like the erythrocytes of the adult, and they have the same alpha family hemoglobin chains as in adults, but, in the case of humans and some other species, the beta family chains of the hemoglobin are a fetal type that is different from the major type of ß-globin chain in adults. In the latter phases of mammalian fetal development, the bone marrow becomes the main site of hematopoiesis. In the human, the bone marrow is the exclusive site of postnatal hematopoiesis under normal circumstances, whereas in the mouse, the spleen is also a hematopoietic organ throughout life. In humans, during late fetal development, erythrocytes begin to be produced that contain adult types of beta family chains in their hemoglobin molecules, and by the end of the first year of postnatal life, this type of erythrocyte is the only one normally produced.

From naturally occurring and experimentally induced mutations in various murine genes known to be expressed in developing hematopoietic cells, a number of proteins that regulate blood cell development have been identified. Among these are several proteins that are required at various stages of hematopoietic development (i.e., the null state leads to prenatal death) ([6], [8]). Among those proteins that are essential for blood island development in the yolk sac are the vascular endothelial growth factor receptor Flk-1 and the transcription factor TAL-1, which are expressed in both the endothelial and the hematopoietic cells, and GATA-1 and Rbtn-1, which are transcription factors required for primitive erythroid cell development. Definitive hematopoietic cells have additional proteins that are required for their development. These proteins include transcription factors GATA-2, c-myb, AML-1, and GATA-3 that are required by hematopoietic cells when they first are formed in the dorsal aorta. Other transcription factors or growth factors and their respective cell-surface receptors are required during prenatal hematopoiesis for the survival and growth of more differentiated cell types. Examples are the myeloid transcription factor PU.1, the erythroid transcription factor EKLF (erythroid Kruppel-like factor), stem cell factor (c-kit ligand) and its receptor c-kit, and EPO and its receptor.

Structure of Hematopoietic Organs

The hematopoietic organs can be considered in terms of several operational components. First, there is the anatomic structure—the three-dimensional organization of different tissue types and their component cells; for example, the structure of the blood vessels in proximity to the hematopoietic cells. A second operational component of hematopoietic organs is the stroma. *Stroma* is the term used to refer to the various cells as well as the extracellular macromolecules that occupy the hematopoietic tissue along with the hematopoietic cells. The stromal cells include specialized fibroblasts, adipocytes, macrophages, and lymphocytes, as well as the endothelial cells of capillaries and sinuses (only the macrophages and lymphocytes are derived from HSCs). The stroma thus constitutes the microenvironment in which the hematopoietic progenitor cells grow and differentiate, and there is strong evidence that various stromal cells as well as extracellular matrix molecules play critical and diverse roles in hematopoiesis. Third, there are the hematopoietic progenitor cells: the HSCs and their progeny that become the blood cells of all lineages. The characterization of the hematopoietic progenitor component and its various differentiation processes are the main focus of this chapter.

Some Functional Aspects of Bone Marrow Anatomy

Studies of the marrow by electron microscopy have greatly refined our knowledge about the structures present and the topologic associations between the various cell types ([20], [21], [22] and [23]). Largely, the roles of the anatomic features of hematopoietic organs are unknown. However, some functions of the cells of the venous sinuses within the marrow are understood in general terms. The venous structure of the marrow cavity is a complex maze of sinuses that eventually drains into central veins. In the marrow or fetal liver of mammals, hematopoietic progenitors differentiate outside the sinuses, unlike in the marrow of birds, in which hematopoiesis occurs within the sinuses. The sinuses of the marrow in mammals are formed by a continuous layer of endothelial cells that, on the extraluminal side, are partially covered by a discontinuous layer of adventitial reticular cells: fibroblast (myofibroblast) cells that have processes forming a network throughout the extraluminal space of the marrow cavity. The endothelial cells of the sinuses are thought to play a role in the selective exiting of mature blood cells from the marrow into the bloodstream. These mature cells apparently pass through the cytoplasm of the endothelial cells rather than between cells at their borders ([22], [23]). The mechanisms involved in this

remarkable process are not well understood. The endothelial cells are also presumed to play a specific role in the movement of circulating hematopoietic progenitor cells from the blood into the marrow stroma (homing).

Stroma of Hematopoietic Organs

The stroma consists of myofibroblasts (adventitial reticular cells); adipocytes, which are derived from the myofibroblasts; macrophages; lymphocytes and plasma cells; the endothelial cells of the marrow sinuses; and stem cells of various types other than the HSCs. These other stem cell types can give rise to mesodermal-derived cells ([24]), endothelial cells ([25]), or even diverse cell types associated with multiple embryonic germ layers ([26]). In addition to the cellular components, the stroma contains a large variety of extracellular macromolecules including fibronectin, collagens, thrombospondin, tenascin, and others. One very critical type of interaction between the marrow stromal cells and the hematopoietic progenitor cells is the synthesis and presentation by stromal cells of hematopoietic growth factors. One example has been discovered from studies of mice that have mutations in either of two particular genes ([27]): the white spotting locus (nonfunctional allele W) and the steel locus (nonfunctional allele Sl). Each of these genes is essential for hematopoiesis. Mouse embryos that are homozygous for null alleles of either of these genes die at an early stage of embryogenesis without forming any blood cells. However, mice have been found and bred that bear mutant alleles of each of the two genes that retain partial function (W^{v} and Sl^{d} alleles). Heterozygous mice of the Sl/Sl^{d} or the W/W^{v} genotypes are phenotypically similar, with a lack of cutaneous pigment, sterility, and congenital anemia ([27]). Reciprocal bone marrow transplantation studies between normal, wild-type mice and heterozygous mice, Sl/Sl^{d} and W/W^{v}, revealed that W/W^{v} mice have defective HSCs but a functional microenvironment that can support transplants of normal stem cells. Conversely, the Sl/Sl^{d} mice have functional stem cells and can thus serve as donors for marrow transplants, but these mice have a defective microenvironment (stroma) for hematopoiesis; thus, their defect cannot be corrected by the receipt of stem cells from normal donor mice. Detailed understanding of the function of these two genes was achieved after the cloning of the genes at the W and Sl loci. The W gene encodes the cell-surface receptor protein Kit (gene designated *c-kit*) ([28] , [29]), and the Sl gene encodes the ligand for that receptor, which is variably called *steel factor*, *kit ligand* (KL), or *stem cell factor* ([30] , [31] and [32]). The Kit protein is a cell-surface receptor on hematopoietic progenitor cells for the growth factor product of the Sl gene expressed by stromal cells. KL is produced in two forms due to alternative splicing of the mRNA: a soluble form and an integral membrane form ([33] , [34]). It has been shown that the stromal cell membrane–bound form of KL can stimulate hematopoietic progenitor cells by cell–cell contact and thus may be as important functionally as the soluble form. Activation of the Kit receptor is essential for the survival and development of immature hematopoietic progenitors. Kit and KL are also produced in certain other developing tissues, hence their roles in pigmentation and gonadal function. In addition to the production of KL, stromal cells produce a large number of other hematopoietic growth factors, some of which also exist in soluble and membrane-bound forms, including FL ([26] , [35] , [36]) and macrophage colony-stimulating factor [colony-stimulating factor-1 (CSF-1)] ([37] , [38] , [39] and [40]).

Besides providing a source of growth factors, the stroma of hematopoietic organs has other functions in hematopoiesis. Interactions with stromal elements play a role in the egress of mature blood cells from the hematopoietic organs. Stromal elements are important in the “trafficking” of immature hematopoietic cells or HSCs into and out of hematopoietic organs and the blood. This trafficking occurs during embryonic development as the primary organs of hematopoiesis change. Also, some HSCs and other immature progenitors migrate continuously between bone marrow and blood in normal adult animals ([41]). The processes by which hematopoietic cells leave the bloodstream and specifically move into hematopoietic organs are collectively called *homing*. Homing occurs not only for hematopoietic progenitor cells that are circulating normally, but also for such cells that are introduced into the bloodstream artificially through stem cell transplantation. It is not clear whether the homing mechanisms are the same for transplanted cells and for those circulating normally, although in both cases an adhesive interaction between circulating progenitors and the endothelial cells of the venous sinuses is followed by a transmigration of the progenitors through the endothelium.

The molecular interactions between the hematopoietic cells and the stromal cells or extracellular matrix involve ligand-receptor relationships between so-called adhesion molecules on the surfaces of the hematopoietic and stromal cells or between such molecules on the cell surfaces with specific domains within certain extracellular matrix molecules [see reviews ([42] , [43])]. There are many cytoadhesion molecules known, and they generally can be classified into several families: sialomucins, selectins, integrins, and members of the immunoglobulin superfamily ([42]). CD44 is an additional adhesion molecule, not belonging to one of the above families. Numerous interactions are possible, and there appears in some cases to be redundancy in the systems involved in trafficking, homing, and the other processes within the hematopoietic microenvironment.

Integrins are heterodimeric molecules composed of two subunits, a and ß, joined noncovalently. Sixteen types of a subunits and eight types of ß subunits are known, although only a few of the possible heterodimer combinations have been found on hematopoietic or stromal cells and implicated in hematopoiesis. The integrins are transmembrane proteins, each subunit having extracellular and intracellular domains. The integrin subunits a_4 and $ß_1$ clearly have important functions in hematopoiesis. Although they each can pair with certain other subunits of the heterologous type, the $a_4ß_1$ pair [very late antigen (VLA)-4] appears to be the most important. Chimeric mouse embryos, in which the integrin a_4 subunit gene was deleted in a substantial portion of the cells, formed no a_4-null erythrocytes, almost no B-lymphoid cells, and few myeloid cells ([44] , [45]). *In vitro* hematopoietic colony formation of a_4-null cells appeared normal, so the defect is likely due to impaired interaction of the hematopoietic progenitors with the stroma. Likewise, chimeric mouse embryos containing $ß_1$-null cells demonstrated an essential role for the $ß_1$ integrin subunit during hematopoietic development ([46]). $ß_1$ integrin is not essential for the generation of hematopoietic progenitor cells in the aorta-gonad-mesonephros or the yolk sac or for their differentiation *in vitro*, but it is necessary for their colonization of the fetal liver, spleen, and bone marrow during embryogenesis. HSCs rendered $ß_1$-null by conditional gene ablation are unable to colonize hematopoietic organs or to rescue lethally irradiated mice on transplantation ([46]). Nevertheless, conditional deletion of the $ß_1$ gene in adult mice does not lead to defects in stem cell retention in the marrow or in hematopoiesis ([47]).

The integrin $a_4ß_1$ (VLA-4) is widely expressed on hematopoietic progenitor cells, and it binds to the vascular cell adhesion molecule (VCAM)-1, an adhesion molecule of the immunoglobulin superfamily present on stromal cells, macrophages, and venous sinus endothelium in bone marrow [reviewed in ([48])]. VLA-4 also binds to fibronectin ([42] , [48] , [49]). Treatment of animals with antibodies to VLA-4 or VCAM-1 induces release (mobilization) of HSCs and more differentiated progenitor cells from the bone marrow ([50] , [51]) and inhibits hematopoietic progenitor cell homing after transplantation ([52] , [53]). However, like the conditional deletion of the $ß_1$ integrin subunit gene, conditional deletion of the VCAM-1 gene ([54] , [55]) does not disrupt bone marrow retention of HSCs or hematopoiesis, although it affects migration, specifically of T cells, to the bone marrow ([54]). Thus, these VLA-4 and VCAM-1 experiments indicate that molecules critical for homing in the transplant model or in mobilization by growth factors or drugs may not be essential for maintaining adult hematopoiesis because of overlapping functions of adhesion receptors. Yet, individual cytoadhesion molecules may play very specific roles such as that of VCAM-1 in T-lymphocyte homing.

The selectin family of cytoadhesion molecules has functions in the lymphocyte homing to lymphoid tissues and in leukocyte rolling and adhesion to activated endothelial cells. The selectin family members are designated E, P, and L. HSCs have receptors for the selectins, and they can exhibit the rolling phenomenon similar to that of leukocytes ([56] , [57]). Some data also indicate that the selectins might be important for stem cell transmigration across endothelium ([58]) and homing. Mice in which genes for two or all three selectins have been deleted are viable, although several aspects of their marrow hematopoiesis are abnormal ([59] , [60]). These mice also are defective in hematopoietic progenitor cell homing to the bone marrow but not the spleen after transplantation ([59] , [61]).

The adhesion molecules of all families are transmembrane proteins, and many can act as receptors that activate specific intracellular signaling pathways. These adhesion molecules/receptors, in turn, may be regulated by other intracellular signaling pathways ([48] , [62] , [63]). Thus, the interactions of the hematopoietic cells with stromal cells and matrix can be highly modulated by the adhesion receptors, both in transmitting signals from the microenvironment into the cell and in translating the state of intracellular signaling pathways into changes in the number and affinities of adhesion molecules. Activation of Kit by its ligand (KL) modulates adhesion functions that are apparently mediated by integrins $a_4ß_1$ (VLA-4) and $a_5ß_1$ (VLA-5) ([50] , [64] , [65]). Another example is the chemotactic cytokine (chemokine) receptor CXCR4 and its ligand stromal-derived factor-1a (SDF-1). SDF-1 is the only known chemokine that elicits directed chemotactic response in HSCs ([66] , [67]). Mice lacking SDF-1 or CXCR4 have defective hematopoiesis in fetal bone marrow ([68] , [69]). Antibodies against CXCR4 block engraftment of severe combined immunodeficiency (SCID) mouse bone marrow by transplanted CD34-enriched HSCs and hematopoietic progenitor cells ([70] , [71]). SDF-1 is expressed on bone marrow endothelium and appears to induce binding of circulating progenitors to the vascular endothelium by activating the integrins lymphocyte function-associated antigen, VLA-4, and VLA-5 ([72] , [73] and [74]).

The stroma also contains an extracellular matrix that provides a structural network to which hematopoietic progenitors and stromal cells are anchored. This matrix is composed of various fibrous proteins, glycoproteins, and proteoglycans that are produced by the stromal cells ([75]). These include collagens (types I, III, IV, V, and VI) ([76] , [77] and [78]), fibronectin ([79] , [80] , [81] , [82] and [83]), laminin ([84]), hemonectin ([85] , [86] and [87]), tenascin ([88]), thrombospondin ([89] , [90] , [91] , [92] and [93]), and proteoglycans ([86] , [94] , [95] , [96] and [97]). Several of the adhesion molecules on hematopoietic cells specifically bind to sites on particular matrix macromolecules. For example, HSCs and

more mature progenitors bind to fibronectin, primarily through interaction with the integrin receptors a $_4$ß $_1$ and a $_5$ß $_1$ ([42], [48], [49], [75], [98]). Another cytoadhesion molecule that interacts with several matrix macromolecules is CD44, which binds with glycosaminoglycans (hyaluronic acid being the major CD44 ligand) ([99]). The *proteoglycans*, proteins with extensive sulfation such as heparan sulfate and chondroitin sulfate, are extracellular matrix proteins that may contribute to adhesion between the stroma and the hematopoietic progenitor cells ([86], [94], [95], [96] and [97]). The proteoglycans can also concentrate soluble growth factors. For example, granulocyte-macrophage colony-stimulating factor (GM-CSF) binds to heparan sulfate in the marrow matrix ([100], [101]).

HEMATOPOIETIC STEM CELLS

Age of Morphologists

The ideas in this chapter have evolved from a long history of experimental work and often conflicting interpretations by many investigators. Fascinating accounts of much of this history are presented in *Blood, Pure and Eloquent*, edited by M.M. Wintrobe ([102], [103]). One milestone in understanding the origins and development of blood cells was the realization by Ernst Neumann and Guilio Bizzozero in the mid-nineteenth century that the bone marrow is a site of red blood cell production in adult animals and that such production is a continuous process throughout postnatal life. Another major advance made in the late nineteenth century by Paul Erlich and later by Artur Pappenheim and others was the application of synthetic dyes and various staining/fixing techniques to blood and marrow preparations and the consequent precise morphologic characterization and classification of cells of the blood and marrow.

A third milestone in hematology was the development of the idea of a pluripotent stem (ancestral) cell that gives rise to all of the mature blood cell types through extensive proliferation and multiple differentiation steps. By use of refined staining methods, Pappenheim observed various transitional cells and organized them into a relational scheme—a tree whose various branches when traced backward converged to a type of mononuclear cell that had none of the distinct features of the end-stage blood cells or the transitional stages. He proposed the notion that this cell was so morphologically primitive that it could be the common ancestor of all blood cells. Although most morphologists between 1900 and 1940 accepted the idea of ancestral cells in a hematopoietic series leading to progressively more mature types, there was much debate about how many ancestral cell types there were. Many workers believed that lymphocytes had a separate origin from myeloblasts and thus that there were dual or perhaps plural ancestral cells. Reviews of the conflicting concepts of the origin of hematopoietic cells as of the late 1930s are presented in detail in *Handbook of Hematology*, edited by Downey ([104]).

Advent of Hematopoietic Progenitor Transplantation

In the late 1940s and the 1950s, experimental hematologists applied several new approaches to the study of hematopoiesis. Among them were radiation exposure followed by grafting of hematopoietic tissue, use of chromosome cytogenetics, and use of radioactive materials. Lorenz et al. ([105]) showed that mice and guinea pigs may be protected against otherwise lethal whole-body irradiation by injections of bone marrow from other animals of their respective species. In similar experiments, Ford et al. ([106]) used bone marrow from donor mice that had a morphologically identifiable chromosomal marker to show that hematopoiesis in the irradiated recipient mice was reconstituted by cells from the donor marrow—that is, the protected animals were chimeras with respect to their hematopoietic tissues. The experiments of Ford et al. did not settle the question about how many types of ancestral cells there were, but experiments generating radiation chimeras have since been used with great power to study the nature of stem cells and their progeny.

Till and McCulloch ([107]) used radiation/grafting experiments to prove directly the existence of an ancestral cell that has multilineage potential. They examined spleens of mice at 1 week after transplantation and found growth of macroscopic colonies containing cells of multiple hematopoietic lineages. These colonies were the progeny of individual transplanted cells that were called *colony-forming units spleen* (CFU-S). Because the cells in these spleen colonies could, in turn, be injected into secondary, irradiated mice and give rise to spleen colonies, the CFU-S apparently replicated themselves within the colonies. When the observation time for CFU-S assays was extended from 1 week to 2 weeks after transplantation, a series of evanescent colonies was found, and those appearing on later days had greater self-replication and multilineage differentiation capacities ([108], [109]). Although early studies could not demonstrate the clonal growth of lymphoid cells in the spleen colonies ([110], [111]), a recent study indicates that most such colonies derived from CFU-S do contain lymphoid progenitors as well as myeloid progenitors ([112]). However, several studies showed that cells with the capacity for long-term hematopoietic reconstitution of irradiated mice can be separated from most CFU-S by their size and density ([113]). Thus, many CFU-S, although multipotent, do not have long-term repopulating capacity.

Hematopoietic Repopulating Unit

Investigators sometimes use the terminology *long-term hematopoietic repopulating unit*. Its operational definition is a cell or group of cells that provide long-term hematopoietic reconstitution of ablated animals, including repopulation of all myeloid and lymphoid cell lineages. This function, if it can be accomplished by a single cell, is the operational definition of a pluripotent HSC. The identification of hematopoietic repopulating units requires hematopoietic cell transplantation into an ablated host. The most suitable experimental animal is the mouse. However, the analyzed cells are not spleen colonies but rather the reconstituted hematopoietic tissues after an extended period of time after transplantation.

To make progress in the purification and characterization of hematopoietic repopulating units, it was essential to develop quantitative assays to measure them. To quantify hematopoietic repopulating units by transplantation, it is necessary to transplant serial dilutions of a test cell population into a group of animals. Even if repopulating units are present in the transplant inoculum, ablated animals receiving no short-term sustaining progenitor cells would die with a lack of hematopoiesis before the transplanted cells could reconstitute the animal. Therefore, “competitive repopulation assays” ([114], [115] and [116]) are used in which the recipient animals survive in the short-term because they contain or are given an additional source of progenitor cells that can be distinguished from the donor test population. In one form of this assay, one mixes various dilutions of the test population of hematopoietic cells bearing a distinguishable genetic marker with a constant number of hematopoietic cells (source of short-term reconstituting support cells) from a congenic mouse strain. One then transplants the mixtures into ablated host mice of the congenic strain used to procure the supportive cells. The reconstituted mice are hematopoietic chimeras with progenitor cells derived from both of the hematopoietic cell sources in the transplant. Using the genetic marker, one can determine the fraction of hematopoietic cells derived from each cell genotype in the chimeric animals at various time points after transplantation. From these ratios and the known dilutions of test cells given in the transplants, one can calculate the number of hematopoietic repopulating units in the test population by binomial correlation and covariance methods ([114]) or by using limiting dilution analysis and Poisson statistics ([115], [116]). A variation of this assay uses limiting dilutions of genotypically distinct donor cells to transplant into stem cell–deficient W/W ^{V} mice that can be used as hosts rather than hematopoietically ablated mice ([117]). A second variation uses, as hosts, mice that have been transplanted previously and thus have a reduced or weakened endogenous stem cell competition capacity ([115]).

Using these competitive repopulation assays in mice, it has been shown that the hematopoietic repopulating unit is extremely rare, with an incidence in murine marrow of 1 per 10 ^{4} ([115]) to 1 per 10 ^{5} nucleated cells ([114]). As discussed in the section Definitive Evidence for a Pluripotent Stem Cell, the minimal hematopoietic repopulating unit has been proved to be a single, pluripotent stem cell (HSC). Thus, the competitive repopulation assays can be used to measure enrichment of murine HSCs after purification schemes ([118]) and also to analyze possible replication of HSCs during *in vitro* culture.

Definitive Evidence for a Pluripotent Stem Cell

Animal reconstitution experiments with hematopoietic cells that were individually marked genetically have verified the existence of HSCs and demonstrated their capacity for extensive self-renewal ([119], [120] and [121]). In these marking experiments, hematopoietic cells were infected *in vitro* with a recombinant retrovirus that was able to integrate its DNA (provirus) into a cell but could not replicate and spread to other cells. The one-time, random integration of the provirus into the DNA of an individual cell provides a specific marker for the progeny of that cell that develop in an animal after transplantation. Random integration assures that each provirus has unique flanking sequences of DNA and thus has a high probability of yielding a DNA fragment of a distinguishable size after cutting with a restriction enzyme that does not cut the provirus. Several months after transplantation of the genetically marked cells and establishment of hematopoiesis, it is typically observed that all types of cells in the blood and lymphoid organs contain progeny of an individually marked cell, proving that it was pluripotent. Often, these clones of marked cells continue to contribute to all of the hematopoietic lineages in the animal for an extended period. Also, when these primary recipient animals are subsequently used as donors for secondary recipient animals, frequently the same clones of HSCs are apparent in these secondary recipients. This persistence can even be demonstrated in tertiary recipients ([119], [120]). Thus, clearly many HSCs reproduce themselves (self-renew) over a long period. Yet not all clones of HSCs are so long lived; some produce progeny for varying periods and then apparently become extinct. Finally, marked clones have been observed to begin contributing to hematopoiesis after some period of posttransplantation latency, indicating that dormancy is possible. Thus, these studies have demonstrated that, after transplantation, some HSCs

contribute continuously to hematopoiesis for a long time—in mice, apparently for the whole lifetime of the animal. Other HSCs contribute and then become extinct, and finally, some may remain dormant for some period and then contribute. Additional transplantation studies of marked HSCs in mice ([116]) have suggested that polyclonal hematopoiesis is more common and that long-term contribution by individual stem cells is more rare than the earlier studies indicated ([119] , [120]). To what extent these possible behaviors are manifest in a normal, nontransplanted mouse or in larger animals is not yet clear. Mice differ from humans and other large animals in the demand for hematopoietic cell production, in lifespan, in the turnover of stem cells, and in other factors ([122] , [123]). Studies using retroviral insertion site analyses for larger animals, particularly nonhuman primates, have recently shown progress ([122] , [124]). It appears likely that questions about the longevity of function of stem cell clones and about the overall kinetics of hematopoietic cell production in a primate model may soon be answered.

In Vitro Assays for Hematopoietic Stem Cells

There are many scientific questions about hematopoietic progenitor cells that can only be pursued with cell culture–based manipulations of such cells. Also, with the advent of hematopoietic tissue transplantation in humans, there is great need for an *in vitro* assay that identifies human cells capable of long-term hematopoiesis in patients. To infer that any *in vitro* assay measures HSCs, one must correlate the properties of the cells analyzed *in vitro* with those of repopulating units tested *in vivo*. Such comparisons can presently only be done for mouse cells because *in vivo* assays of repopulating units transplanted into hosts of the same species as the test cells are not feasible or are not fully proven for other species. Progress in the development of murine xenograft models to assay human stem cells may lead to satisfactory quantification in the future (see Human Hematopoiesis in Animal Hosts after Xenografts).

In vitro systems have been developed for culturing murine and human hematopoietic cells, and the assayed human cells are presumed to represent the same stages in the hematopoietic hierarchy as their mouse cell counterparts. *Culture of Hematopoietic Cells*, edited by R.I. Freshney, I.B. Pragnell, and M.G. Freshney ([125]), is a good reference book describing many of the cell culture methods for assaying hematopoietic progenitor cells alluded to in the foregoing sections. One type of *in vitro* assay, which is an assay for early-stage hematopoietic progenitors, quantifies cells in a test population that are capable of initiating long-term hematopoiesis in culture after seeding them onto irradiated stromal cell monolayers [human ([126] , [127]); mouse ([128] , [129])]. Such cells are called *long-term culture-initiating cells*, or LTC-ICs ([126]). LTC-ICs can initiate cell cultures that sustain production of multilineage progenitors for many weeks. This continued production of hematopoietic progenitors of multiple lineages in individual cultures is measured after several weeks by harvesting the cultured cells and doing secondary assays for various types of lineage-committed progenitors. By using a limiting dilution assay and Poisson statistics, one can accurately quantify LTC-ICs in a test cell population. In the long-term cultures, islands or colonies of hematopoietic cells can be recognized morphologically *in situ* and have been termed *cobblestone area-forming cells*, or CAFCs ([128]). Some investigators use limiting dilution assays in long-term cultures and count CAFCs as the endpoint of the assay ([127] , [128] and [129])—that is, they examine mouse cell cultures on day 8 (day 8 CAFCs) or day 28 (day 28 CAFCs) ([128]) or after 6 weeks (6-week CAFCs) ([130]).

Assays of murine bone marrow cells for LTC-ICs and for day 28 CAFCs yield estimates of 1 to 4 LTC-ICs or CAFCs per 10^5 marrow mononuclear cells—a value comparable to that obtained for HSCs in repopulation assays ([114] , [115]). A modification of the mouse LTC-IC assay ([131] , [132]) has led to a demonstration that some LTC-ICs form lymphoid as well as myeloid progenitors *in vitro*. However, evidence obtained more recently indicates that LTC-ICs do not correspond 1:1 to hematopoietic repopulating units. For example, several studies have shown that *ex vivo* expansion of hematopoietic cell populations with growth factors in culture leads to a loss of *in vivo* repopulating cells ([133]), although measured LTC-ICs do not decrease in parallel. Some studies have suggested that *in vitro* culture leads to loss of homing due to down-regulation of certain adhesion molecules ([133]). One study suggests that there is an unknown defect in repopulating function correlated with S/G_2/M phases of the cell cycle ([134]) and that noncycling stem cells from tissue sources quickly enter the cell cycle under most *in vitro* culture conditions. Measured LTC-IC numbers are not dependent on the initial cell cycle status. Finally, HSCs are so-called side population (SP) cells, a phenotype indicating that they have low levels of labeling by flow cytometry when stained with the Hoechst dye 33342 due to the presence of a verapamil-sensitive (efflux) transporter ([135] , [136] , [137] and [138]). Transplantable human HSC activity in human fetal liver cells, detectable in nonobese diabetic (NOD)/SCID mice (see below), is associated exclusively with the SP cells, whereas a large majority of LTC-ICs in the fetal liver lack the SP phenotype ([139]). In bone marrow and liver of adult mice and some other studied species, LTC-ICs are highly enriched in SP cells, but even in those tissue sources, a smaller majority of LTC-ICs are in the non-SP fraction ([136] , [140]).

Human Hematopoiesis in Animal Hosts after Xenografts

Two animal models have been explored that can support xenografts of human hematopoietic cells and support multilineage, long-term human hematopoiesis. Murine models that are commonly used are derivatives of the NOD/SCID strain ([141] , [142] , [143] and [144]) or strains deficient in the RAG1 or RAG2 genes necessary for T- and B-cell receptor rearrangements ([145] , [146]). Another system, useful for such xenografts, is a fetal ovine system ([147] , [148]).

NOD/SCID/ß $_2$-microglobulin ^{null} mice have recently been used for supporting proliferation and differentiation of primitive human hematopoietic progenitors ([141] , [142] , [143] and [144]). Such murine systems now appear to offer the best estimates of human stem cell numbers in a transplanted cell population—more accurate than *in vitro* culture methods for enumerating such cells. Using a limiting dilution protocol and analyzing the fraction of mice that achieve long-term engraftment of both lymphoid and myeloid human cells, one can quantify SCID repopulating units in a source of human cells. One issue remains problematic in determining whether SCID repopulating units are the equivalent of human HSCs. The multilineage hematopoiesis in these mice can only be evaluated for 4 to 5 months at most, because the animals later develop thymic lymphomas. This limited period for evaluation of engraftment may result in some progenitors being scored as stem cells that cannot self-renew and could not support long-term engraftment in humans. Further backcrossing of the NOD/SCID derivative mice with other strains may lead to further improvement in the longevity of engraftment evaluation.

Enrichment of Hematopoietic Stem Cells

There are approximately 1 to 4 HSCs per 100,000 nucleated cells in hemopoietic tissues, and it has not been possible to isolate a pure population of HSCs. However, several procedures have been developed to enrich greatly the proportion of HSCs in isolated cell populations from mouse and human sources. Although there are variations used by different investigators, each procedure consists of a series of steps that discriminate and select cells based on experimentally determined properties of stem cells ([128] , [129] , [149] , [150] , [151] , [152] , [153] and [154]). In general, the steps consist of combinations of the following:

1. Density gradient isolation of low-density mononuclear cells (excludes erythrocytes and mature granulocytes).
2. Fractionation of cells based on sedimentation rate by elutriation.
3. Flow cytometry sorting using forward and perpendicular light scatter windows to exclude many large blasts, monocytes, and granulocytes.
4. Incubation of cells with a panel of antibodies to specific antigens on differentiated cell types and subsequent removal of the cells bearing those antigens (see Table 6.1 for listing of antibodies used for this removal). After removal of the antigen-bearing cells, the remaining population is referred to as *lineage negative* or *Lin* $^-$.

TABLE 6.1. Summary of Reagents and Procedures That Discriminate Cell Populations Enriched in Stem Cells

Stem Cells	Other Cells
Negative selection: removal of lineage-committed (Lin $^+$) cells bearing antigens listed below	
Negative	Human: CD2 (T cells), CD3 (T cells), CD19 (B cells), CD14 (monocytes), CD15 (granulocytes), CD16 (natural killer cells), glycophorin A (erythroid cells), CD24, CD56, CD66b
Negative	Mouse: Mac-1(monocytes, macrophages, granulocytes), B220 (B cells), GR-1 (granulocytes), TER119 (erythroid cells), Lyt-1 (CD5, T cells)
Positive selection: collection of cells bearing certain antigens	
Human cells: CD34 antigen; most stem cells in unstimulated bone marrow are negative, but stem cells that have been “mobilized” are positive; stem cells from fetal liver or umbilical cord blood are positive	More than 99% of total marrow cells are CD34 negative, yet among the positive cells, only a small fraction are stem cells
Mouse cells (some strains); most are Sca (Ly-6A/E) $^+$	Most are Sca $^-$, but as in the case of CD34, a large fraction of the Sca $^+$ cells are not stem cells

Stem Cells	Some Contaminating Cells
Other discriminatory properties	
A verapamil-sensitive ability to efflux Hoechst 33342 due to an ABC transporter protein (ABCG2/Bcrp1) (termed *side population cells*) (references 138, 139)	
Positive	Negative
Another verapamil-sensitive ABC transporter (MDR-1) responsible for efflux of rhodamine 123 (references 138, 139)	
Positive	Negative
HLA-DR display (human)	
Low	High
Thy-1 (CD90) antigen display (mouse, human)	
Positive	Negative
Wheat germ agglutinin binding (mouse)	
Low	High

5. Isolation of cells that display on their surfaces an antigen associated with stem cells but not widely expressed on other hematopoietic cells. In humans, CD34 (My10) has been commonly used (see paragraph at the end of this section). In some strains of mice, the Sca antigen (Ly-6A/E) is selectively expressed on stem cells. Kit is highly expressed on stem cells of both mice and humans but is widely distributed on other cell types.
6. Flow cytometry sorting of cells based on retention of rhodamine 123 or Hoechst dye 33342 (SP cells) or on binding of fluoresceinated wheat germ agglutinin or of fluoresceinated antibodies to Thy-1 (human) or to HLA-DR antigen. Stem cells stain at low levels with rhodamine 123, Hoechst 33342, or fluoresceinated wheat germ agglutinin. They display little HLA-DR antigens but most express Thy-1 antigen.

Table 6.1 summarizes reactivity of HSCs to antibodies and other molecules commonly used in their enrichment. Recent evidence showed that many HSCs in normal bone marrow of adult animals do not express CD34 ([155]). In adult mice, its expression is, however, induced in virtually all HSCs mobilized into the blood by growth factors, and this appears also to be the case in humans. CD34 is expressed on HSCs of human and murine fetal livers ([156] , [157]) and likely on all HSCs from tissues from fetuses or neonates, including HSCs of umbilical cord blood ([155]).

Stem Cells in Culture

Repopulation studies in irradiated mice, as well as experience with bone marrow transplantation in humans, provide strong evidence that HSCs can replicate and expand extensively *in vivo* (self-renewal). Obviously, it would be very useful if transplantable HSCs could be expanded substantially *in vitro*. Such expansion has not yet been achieved. In studies of murine bone marrow cells in culture, repopulating units (HSCs) generally decline substantially relative to input numbers over a period of 1 to 4 weeks in culture ([150] , [158] , [159]), even though clonal analysis does indicate that some HSC clones proliferate ([158]). In cultures of murine and human HSCs, there is a loss of repopulating activity associated with the entrance of the cells into the active cell cycle ([134]). The reason for this loss due to cell cycle activation is not clear. Another phenomenon that occurs during culture *in vitro*, however, is the reduction of expression of several adhesion molecules on the cell surface and a resulting loss of ability of progenitors to home to the hematopoietic organs ([133] , [160]). Whether the cell cycle effect is related to the loss of adhesion molecules is not clear.

In contrast to our current inability to expand transplantable HSCs *in vitro*, the various studies all indicate that one can greatly expand more mature types of progenitors, including those with multilineage or single lineage potential. Thus, cell expansion technology may be useful to obtain high numbers of hematopoietic progenitor cells that may support patients in the short term after high-dose chemotherapy or marrow transplantation.

Question of Stem Cells with Potential to Form Other Tissues in Addition to Hematopoietic Elements

During the last several years, data have been reported that suggest a “plasticity” in the differentiation potential of stem cells for various tissues. Interpretations were made that HSCs can give rise to muscle cells, neural cells, and liver parenchymal cells. Conversely, some experiments suggested that “muscle stem cells” or stem cells for other types of tissues could reconstitute the hematopoietic cells of lethally irradiated mice. For detailed discussions of this area of investigation, the reader is referred to several recent reviews ([161] , [162] , [163] and [164]). More recent studies have provided strong evidence that some of the interpretations of the earlier data concerning stem cell plasticity were wrong, whereas others must be reevaluated more stringently. Kawada and Ogawa ([165]) did secondary transplants of lethally irradiated mice with hematopoietic reconstituting cells isolated from muscles of mice that had previously been lethally irradiated and reconstituted with bone marrow of donors whose cells could be distinguished from these primary hosts. The results showed that the muscle-derived hematopoietic reconstituting cells in the secondary recipients were derived from the original donor strain for the primary transplant; that is, they were derived from the bone marrow HSCs transplanted from the original (primary) donors that were itinerant in the muscles, not from any “true” muscle stem cells of the secondary donors (donors for the secondary transplants). Wagers et al. ([166]) have examined the ability of single, marked HSCs to give rise to cells of nonhematopoietic types in mice made chimeric in the hematopoietic tissues by amplification of those single stem cells. These workers found no evidence that the HSCs contributed to nonhematopoietic cells, except possibly to extremely rare, individual hepatocytes. It remains to be tested fully whether the apparent origin of the hepatocytes from HSCs was due to differentiation or possibly due to a rare fusion of hepatocytes with hematopoietic cells. Likewise, the study did not fully address the possibility that HSCs could, in some tissues, be recruited to differentiate into other cell types under the stress of acute tissue injury. However, that possibility was tested in the case of acute recoverable intestinal injury, and no regenerating intestinal epithelium could be shown to be derived from HSCs.

Thus, current evidence indicates that traditionally defined stem cells for a particular tissue type do not likely transdifferentiate interchangeably under normal conditions *in vivo*. Broader questions, however, remain as to whether there are stem cells more primitive than HSCs in bone marrow and elsewhere that can give rise to tissue-specific stem cells or whether tissue-specific stem cells might be induced to dedifferentiate and reprogram into another type under conditions not yet understood. Reyes et al. ([167]) have purified and expanded cells *in vitro* from the bone marrow of adult mice, termed *mesodermal progenitor cells*, that can differentiate *in vitro* into various cells of limb-bud mesodermal origin and also appear to form cells of visceral mesoderm (endothelial cells). In follow-up studies ([168]), evidence was obtained that, after expansion under defined growth conditions, single cells of this type contributed to many somatic cell types of all three embryonic germ layers when injected into an early blastocyst. When the expanded cells were transplanted into a nonirradiated host, they contributed to hematopoietic cells as well as epithelial cells of the liver, lung, and gut. The authors of these studies now refer to these cells as *multipotent adult progenitor cells*, and cells with similar properties *in vitro* were also isolated from human tissues. These very recent findings thus indicate that a cell type exists in marrow and other tissues at an unknown frequency that can give rise to HSCs through a differentiation process. If so, our ideas and research on generation and self-renewal of HSCs will include extensive new possibilities.

COMMITTED HEMATOPOIETIC PROGENITOR CELLS

Committed hematopoietic progenitor cells are progeny of HSCs that have begun to differentiate and can no longer convey long-term reconstitution of all hematopoietic lineages in ablated animals—that is, committed cells cannot give rise to HSCs. The term *commitment* is also used to denote other irreversible differentiation events that lead to further limitation of potential for development into terminal cell types. The latter idea is consistent with the observation that cell colonies grown *in vitro* from individual progenitor cells (or spleen colonies grown *in vivo*) contain a single mature cell type or limited combinations of mature cell types. Figure 6.2 is an illustration depicting recognized stages of committed hematopoietic lineages. Each progenitor cell stage depicted in Figure 6.2 represents a cell that gives rise to a definite, limited repertoire of mature cells as observed in various *in vitro* and *in vivo* assays. Although space in Figure 6.2 does not permit the representation of cell proliferation, the cells undergo multiple cell divisions between the stages shown. Thus, small numbers of HSCs give rise to greater numbers of the earlier committed progenitors that in turn are amplified through cell division at each subsequent point in the differentiation process. According to this scheme, each successive stage has a more restricted differentiation potential, and there is a succession of commitment steps. Just as the molecular processes in cells that determine whether a stem cell undergoes self-renewal or commitment to differentiate are not understood, neither are the molecular events that lead to subsequent commitment steps.

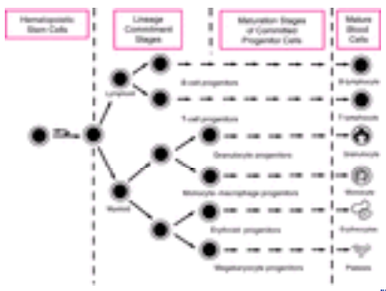

Figure 6.2. Diagram of hematopoietic cell differentiation. Hematopoietic stem cells can duplicate themselves during cell division (self-replicate), as indicated by the curved arrow. Most descendants of the stem cells are committed to differentiate. This commitment process occurs through a series of steps or stages, each of which leads to further restriction of lineage choice, until finally, the descendent cells are limited to a single lineage. After lineage commitment, the progenitor cells continue to differentiate and mature into the terminally differentiated cells found in the blood. The diagram shows only the steps of commitment and does not depict the proliferation of cells that occurs throughout the process. The amplification of cell numbers accompanying differentiation is very large. (From Koury M, Bondurant M. Prevention of programmed death in hematopoietic progenitor cells by hematopoietic growth factors. News Physiol Sci 1993;8:170–174, with permission.)

Multilineage Progenitors

When the HSCs give rise to progeny that are committed to differentiate, early generations of these progeny have the potential to give rise to descendants representing multiple lineages. The majority of the murine CFU-S are examples of hematopoietic progenitors that are not capable of long-term reconstitution of ablated animals but are multipotential because they can grow into a spleen colony containing multiple cell lineages *in vivo*. Under culture conditions in semisolid medium with adequate supportive growth factors, these progenitor cells can form colonies of multiple cell lineages *in vitro* ([169], [170]). Similar multilineage colonies can also be demonstrated *in vitro* in human hematopoietic cell populations ([171]). When the hematopoietic cells reach maturity, the lineage composition of the colonies can be determined by picking out the colonies and spreading the cells on microscope slides followed by conventional staining techniques or by immunostaining using lineage marker antibodies. Not all multilineage colonies that appear in *in vitro* or *in vivo* assays contain all cell lineages; several combinations of cell lineages are characteristic. For example, some colonies contain granulocytes, erythrocytes, macrophages, and megakaryocytes (GEMM colonies), other colonies contain granulocytes and macrophage (GM colonies), and so forth. Table 6.2 lists a variety of hematopoietic progenitor stages that are defined by *in vitro* assays. Table 6.3 lists the names and abbreviations of growth factors and their receptors that are discussed in this chapter.

TABLE 6.2. Listing of Hematopoietic Progenitors Defined *In Vitro*

Name	Abbreviation	Progenitor Stage/Potential	Factors
Cobblestone area-forming cell	CAFC (No.) [a]	Mouse CAFC (28–40), possibly stem cell Mouse CAFC (<28), multilineage	Irradiated marrow forming cell stromal cell layer; medium for long-term marrow culture, including horse serum and hydrocortisone
Long-term culture-initiating cell	LTC-IC	Multilineage, possibly stem cell	As above for CAFC
	$LTC\text{-}IC_{ML}$	Multilineage, myeloid and lymphoid, possibly stem cell	
CFU that produces colonies with myeloid and lymphoid cells	B-Mix	Multilineage, possibly stem cell	Kit ligand, IL-7, EPO (IL-11 or G-CSF)
CFU that produces colonies of neutrophils, eosinophils, erythrocytes, macrophages, megakaryocytes, and mast cells in various combinations	CFU-GEMM CFU-myeloid	Multilineage, myeloid restricted	Kit ligand, IL-11, GM-CSF, EPO, or often pokeweed mitogen-stimulated spleen cell-conditioned medium and EPO
CFU that produces colonies of granulocytes and macrophages	CFU-GM	Granulocytes and macrophages	Kit ligand, GM-CSF
CFU that produces			
Erythrocytes	CFU-E	Late stage, restricted to erythrocytes	EPO, IGF-1
Erythrocytes	BFU-E	Early stage, restricted to erythrocytes	EPO, Kit ligand, IGF-1
Granulocytes	CFU-G	Restricted to granulocytes	G-CSF
Macrophages	CFU-M	Restricted to macrophages	CSF-1
Megakaryocytes	CFU-MK	Restricted to megakaryocytes	TPO, IL-3, Kit ligand
B lymphocytes	CFU-preB	Restricted to B cells	Kit ligand, IL-7
Dendritic/Langerhans cells	CFU-DL	Restricted to dendritic/Langerhans cells and macrophages	GM-CSF, tumor necrosis factor-a

BFU-E, burst-forming unit erythroid; CFU, colony-forming unit; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IGF-1, insulinlike growth factor-1; IL, interleukin.

NOTE: Besides added factors, medium for progenitor cell growth usually contains fetal calf serum and bovine serum albumin. The combinations of factors shown are generally not the only ones that support colony development from the indicated progenitors. However, some factor combinations may be inhibitory or may influence the lineage spectrum of colonies that appear.

[a] No. indicates day after plating colony counted.

TABLE 6.3. Abbreviations for Growth Factors and Their Receptors

Factor	Abbreviation	Receptor
Erythropoietin	EPO	EPOR
Kit ligand	KL	Kit
Interleukin-1, -2, etc.	IL-1, IL-2, etc.	IL-1, IL-2, etc. receptor
Granulocyte colony-stimulating factor	G-CSF	G-CSF receptor
Granulocyte-macrophage colony-stimulating factor	GM-CSF	GM-CSF receptor
Macrophage colony-stimulating factor	M-CSF, CSF-1	CSF-1R
Interferon-a, -ß, -?	IFN-a, -ß, -?	IFN-a, -ß, -? receptor
Thrombopoietin	TPO	Mpl
Leukemia inhibitory factor	LIF	LIF receptor
Oncostatin M	OSM	OSM receptor
Ciliary neurotropic factor	CNTF	CNTF receptor
Transforming growth factor-a	TGF-a	ERBB1 (EGF receptor)
Insulinlike growth factor	IGF-1	IGF-1R
FLT3 ligand	FL	Flk-2/FLT3
Flk-1 ligand, vascular endothelial growth factor	VEGF	Flk-1

The observation that colonies with various combinations of lineages occur has been interpreted in several ways (models) in explaining how cells are committed to become a particular type of blood cell ([172]). The data favor the idea that there are multiple commitment steps and that these steps lead to loss of specific lineage potential in a definite order. The first lineage commitment step separates lymphoid from myeloid potential, then granulocyte/macrophage potential is separated from erythroid/megakaryocyte potential, and so on, until finally, a descendant cell has only one lineage capability. This idea of successive commitment steps is embodied in Figure 6.2. Although this idea is probably generally correct, there are variant models that differ somewhat in their interpretation ([172]). Also, it must be remembered that *in vitro* growth conditions may not be permissive for all possible lineages to appear in a colony. Thus, caution must be exercised in interpreting the exact lineage commitment pathways. Multilineage progenitors, CFU-S and *in vitro*–derived multilineage colonies, had been thought to be incapable of generating lymphoid cells. However, several relatively recent studies have shown that lymphoid cells are produced by several such progenitors, but that they were not observed previously because growth factor support for colony development was not permissive for descendent lymphoid cells ([112], [131], [173]).

Single Lineage Progenitors

The descendants of the multilineage colony-forming cells are ultimately restricted to a single lineage potential. The more mature, single lineage–committed progenitor cells are assayed *in vitro* by their ability to form colonies. These progenitor cells include (Table 6.2) CFU-G, CFU-M, CFU-E, CFU-MK ([174], [175] and [176]), CFU-preB ([131], [177]), and CFU-DL ([178], [179]) for colony-forming units granulocyte, macrophage, erythrocyte, megakaryocyte, B lymphocyte, and dendritic/Langerhans cell, respectively. In some lineages, it is possible to observe stages of maturity within the lineage-committed progenitors. For example, the single lineage producing burst-forming unit erythroid (BFU-E) is a more immature erythroid progenitor than the CFU-E, forming colonies of many more mature erythroid cells after a longer period of time than the CFU-E.

Terminal Phases of Differentiation

Cells in the final stages of hematopoiesis are sufficiently differentiated that they can be identified by morphology using light microscopy with preparations of hematopoietic tissue. These cells are erythroblasts, myelocytes, monocytes, and megakaryocytes, and, because of the vastly amplifying cell divisions that occur by the time the final stages are reached, these cells are by far the most prevalent cells seen in hematopoietic tissues. They are only capable of a few cell divisions, on the order of one to four, yet they are undergoing dramatic specialized changes associated with terminal phases of differentiation/maturation. The erythroblasts rapidly accumulate hemoglobin and begin to assemble a unique membrane skeleton that later maintains the shape and deformation properties of the mature erythrocytes. The nucleus of the erythroblast becomes condensed and is extruded from the cell, leaving an irregular, organelle-containing reticulocyte. Subsequently, over the course of a few days, extensive remodeling occurs within the reticulocyte that eliminates the internal organelles and changes the membrane so that the biconcave erythrocyte is formed. This remodeling process involves extensive, selective proteolysis and is not yet well understood. In myelocytes, granules that contain specific proteolytic enzymes are formed in the cytoplasm. The nuclei undergo a condensation process that ultimately results in a multilobular nucleus that is retained in the mature cell. Maturing monocyte precursors undergo similar changes. The terminal-stage megakaryocytes replicate their DNA and undergo several nuclear divisions without cytokinesis; thus, they become polyploid. Dense granules and a-granules form in the cytoplasm, and the cytoplasm becomes highly compartmentalized by demarcation membranes. Platelets form as small portions of the demarcated megakaryocyte cytoplasm separate from the whole cell.

THEORIES OF COMMITMENT

Extrinsic Regulation versus Stochastic Mechanisms

There are two contrasting ideas about the general nature of the commitment process. Evidence for and against each of these two views has been reviewed by Metcalf ([180]) and Enver et al. ([181]). One view is that a commitment step is determined from outside the cell by a specific signal or combination of signals. Most likely, these signals are initiated by ligands for which the cell has specific receptors. When activated, these receptors generate signals that cause specific initial changes in gene expression. In turn, these resultant changes initiate a sequence of further irrevocable changes in expression of genes that characterize a subsequent differentiation state. The hematopoietic cell and its progeny may then proceed through a predefined program of changes until, at some point, new signals are received that redirect another sequence of gene expression changes—a second commitment step and so on. In this deterministic model of commitment, the choices of the alternative possible pathways of differentiation are regulated by either interaction with ligands on stromal cells and matrix or interactions with soluble hematopoietic growth factors. A second model of commitment proposes that the critical, irreversible gene expression changes that establish the alternative differentiation events are stochastic; the alternative initial changes are probabilistic, and the probabilities for the alternative changes are unaffected by the cellular environment. A stochastic model for commitment to differentiation versus self-renewal of stem cells was first proposed by Till et al. ([182]). Later, Ogawa and Porter ([183]) proposed that commitment of multipotential hematopoietic progenitors to individual myeloid lineages is also a stochastic process. The role proposed for hematopoietic growth factors in the stochastic model is that of providing a permissive or selective environment for progenitor cell growth. The factors support survival or proliferation of the progenitors that bear the cognate receptors on the cell surface.

One often reads statements about a growth factor “inducing cells to differentiate along some pathway.” However, definitive proof that any hematopoietic growth factor can induce differentiation is lacking. In one experimental approach to resolving this issue, populations of undifferentiated, multipotential hematopoietic cells (usually an immortal cell line) are cultured in the presence of one or another mixture of test growth factors. After a time period of several days, a cell population emerges that is composed of a high percentage of cells recognizable as one or several particular lineages, and the lineage composition of the emergent population depends on the particular growth factors used in the culture ([184], [185]). In such experiments, the initial population of undifferentiated hematopoietic cells is undergoing cell division and cell death at unknown comparative rates. Because a differentiated population takes several days to become predominant, it is difficult to determine if the cells were induced to differentiate by the test growth factors or were rather selected for survival or growth by permissive conditions.

Another basic approach to attempt to distinguish between the models of commitment is to plate hematopoietic progenitor cells such that each culture initially contains a single cell. One then can micromanipulate the two daughter cells after an initial cell division and replate them individually into cultures with the same or different growth factors. Several studies of this type have been done ([172], [186], [187], [188] and [189]), and it has been shown that a significant fraction of paired daughter cells each gives rise to subsequent progeny representing different combinations of lineages. The type of progeny of these asymmetric divisions does not appear to be influenced by cytokines ([189]). Thus, so far, experiments manipulating single cells have yielded data consistent with the stochastic model of lineage commitment. Yet such experiments require analysis of the fate of hundreds of cell pairs under various conditions, and experiments have not yet been done that have completely resolved the issue. Whether cytokines can have any direct influence on differentiation is not clear. It is clear that *in vitro*, many cells do commit to differentiation into particular lineages and do differentiate without a detectable influence of cytokines. This latter conclusion was recently supported by a study that showed that clones of a multipotential cell line, when engineered to express a gene that protects the cells from apoptosis (*bcl-2*), can undergo spontaneous differentiation into multiple lineages in the absence of any added growth factors ([190]).

Molecular Mechanisms of Differentiation

From a molecular mechanistic standpoint, based on current ideas about gene transcription, it is easier to propose molecular schemes to explain a deterministic model of commitment than a stochastic one. One can suppose that a receptor signal activates a specific transcription factor (among several possible ones), and that specific factor turns on or represses a gene, which, in turn, activates or suppresses other specific genes. Irreversible sequences of gene expression can be hypothesized that are fixed in daughter cells of the original, affected cell ([191]). One is less accustomed to thinking about how transcription of alternative genes might be stochastic and how such alternatives might result then in different sequences of gene transcriptional changes that are passed on to progeny cells. Two familiar examples, of course, are the stochastic gene rearrangements that occur in lymphocytes to form the T-cell and B-cell antigen receptors. No such rearrangements of genetic material are known to occur in connection with commitment of other hematopoietic progenitors, but the possibility does exist for as yet unidentified genes. Another way in which expression of critical genes might be stochastic is through competition of transcription factors for the genetic elements that control the expression of the genes or through competition at some critical time between nuclear matrix-associated proteins for sites on the DNA in the vicinity of various genes. Aside from the binding of transcription factors, there are modifications of DNA and chromatin structure that regulate gene expression either reversibly or irreversibly. These modifications include DNA methylation and chromatin acetylation and methylation. How the specificity of these processes for particular gene regions is controlled has yet to be determined.

Role of Particular Transcription Factors

Some specific transcription factors exhibit hematopoietic lineage-restricted expression, and some are known to be essential for the complete differentiation of individual lineages. Among the transcription factors that have been shown to influence lineage decisions are several members of the homeobox (HOX) family and the Ikaros proteins ([192], [193]). Also, the mammalian Polycomb group of genes that regulates expression of various HOX genes probably plays roles in lineage decisions ([194]). Two examples of transcription factors whose lineage associations are more fully understood are GATA-1, which is essential for terminal erythrocyte and megakaryocyte differentiation, and PU.1, which is essential for B-lymphocyte as well as macrophage development ([163], [195]). Specific factors not only play a direct role in the expression of lineage-specific genes but, in some cases, appear to antagonize transcription factors important for other lineages; thus, they can repress the expression of genes characteristic of other lineages. For example, GATA-1 can suppress PU.1 activity, and PU.1 can suppress GATA-1 activity by direct protein interactions that block the function of each other ([163]). PU.1 and GATA-1 play positive roles in the transcription of their own genes (autoregulatory loops) ([196], [197]). Thus, hypothetically, an excess of GATA-1 over PU.1 could down-regulate PU.1 expression at the level of transcription, and excess PU.1 could likewise down-regulate GATA-1. In multipotent cells, it is known that there is expression at low levels of sets of genes characteristic of multiple hematopoietic lineages ([198]). Thus, commitment appears to occur not only by up-regulation of a single lineage program of gene expression but also by the irreversible suppression of competing differentiation programs. Because of observations such as those described above for GATA-1 and PU.1 and because the forced overexpression of particular transcription factors can cause lineage switches in certain *in vitro* cell systems, some investigators have proposed that the transcription factor profile (stoi-chiometry relationships) of multipotent cells directs their lineage commitment decisions through cross-antagonism mechanisms ([163], [199]). How variations in transcription factor stoichiometry occur could be either by extrinsic signals or by stochastic mechanisms. It should be pointed out that much of the evidence for this model was obtained in permanent cell lines that may not accurately represent normal primary cells, and also, many of the observations occurred in cells in which the expression of specific transcription factors at high levels was forced through genetic manipulations. Although these studies can provide useful information about the functions of specific transcription factors, it is premature to determine whether stoichiometric relationships among some of these factors in primitive cells are a major determinant of commitment and, if so, which factors are involved. In one of the best-studied cases, GATA-1, it is clear that erythroid lineage commitment and progression of differentiation to the proerythroblast stage occur in hematopoietic cells in which the gene has been deleted ([195]).

REPLICATION POTENTIAL OF COMMITTED PROGENITORS: A QUESTION OF IMPORTANCE FOR LEUKEMIA

During hematopoiesis, the numbers of more differentiated cells are amplified by cell divisions of the progenitors. Experience with *in vitro* cultures and with *in vivo* transplants indicates that, for most lineages, progenitor cells at each stage of development have an upper limit to the number of cell divisions that their progeny can undergo before terminal maturation occurs; the further along the commitment differentiation pathway the progenitor is, the lower the cell division potential becomes. However, such a limitation is not clear in some lineages. For example, lymphocytes may have vast, if not unlimited, proliferation potential. It is possible to achieve continuous proliferation of explanted T cells in culture if they are constantly provided interleukin (IL)-2 and cognate antigen ([200]). Also, there is evidence of long-term persistence and great amplification of B- and T-cell clones *in vivo*. Even in the cases of other lineages besides lymphocytes, it is not yet clear how flexible the overall amplification may be or to what degree it can be controlled by environmental influences. Some progenitors of granulocytes and macrophages can give rise to quite large numbers of progeny in the presence of combinations of growth factors ([201], [202]). Likewise, there is evidence that committed erythroid progenitor cells can be greatly expanded in culture while maintaining an immature phenotype in serum-free medium in the presence of high levels of KL and EPO or the presence of those two factors plus dexamethasone and ß-estradiol ([203], [204] and [205]). Even greater expansion of chicken erythroid progenitors can be achieved in the presence of transforming growth factor-a ([206]). To what degree the cell amplification process varies *in vivo* due to physiologic conditions is not known. Even less is known about the degree of amplification that occurs at the earliest stages of development.

One possible mechanism for limiting cell division potential is the successive shortening of the repetitive DNA at the ends of chromosomes (telomeres) at each cell division due to lack of ability of the DNA replication mechanism to replicate the very ends of the DNA. Without a special mechanism to maintain the telomeres, the chromosome ends would be shortened to the point of losing essential genetic material after a certain number of DNA replicative cycles. The cell presumably could sense these telomeric shortenings and prevent further replication ([207]). Some eukaryotic cells have an enzyme (telomerase) that can regenerate the repetitive DNA at chromosome ends and is believed to be responsible for telomere maintenance. Generally, cells of tumors and of immortal cell lines have demonstrable telomerase activity, whereas cells of most somatic tissues do not ([207]). However, this presumed distinction between immortal cells (including cancer) and normal cells does not always apply. Telomerase activity is present in some peripheral blood leukocytes and some bone marrow cells of normal human beings, including cell fractions enriched in granulocytes, T lymphocytes, and B lymphocytes/monocytes ([208], [209] and [210]).

The mechanism of control of cell division potential is important in considering the properties of leukemic cells *in vivo*. Depending on the kind of leukemia, the cell populations usually express markers of one or more normal hematopoietic cell lineages. Even though the combination of markers expressed may not correspond to those of known normal progenitors, they usually indicate that some degree of lineage commitment has occurred. However, some portion at least of the leukemia cell population exhibits the property of unlimited cell division potential—a property not known to exist, at least in normal committed myeloid progenitors. Thus, how cell division potential is restricted in normal hematopoietic progenitors and how this control is abrogated in some leukemic cells is a question of great theoretical and, possibly, practical importance.

HEMATOPOIETIC GROWTH FACTORS

In the course of development of *in vitro* assays for the various multilineage and single lineage hematopoietic colony-forming cells, it became clear that several different growth factors exist, each capable of supporting a particular spectrum of hematopoietic cell types. Initially, most of these factors were discovered to exist in “conditioned media” that had been used to culture specific cell lines or specific primary cell types. Such conditioned media were necessary or greatly stimulatory for hematopoietic cell colony growth. An example of a conditioned medium source is medium from pokeweed mitogen-stimulated murine spleen cells ([125]). The number of known hematopoietic growth factors has now expanded greatly and undoubtedly will continue to increase. The known growth factors have been purified, and the genes that encode them have been cloned. These growth factors, which are glycoproteins, are now available as pure, recombinant factors due to the successful cloning and expression of their genes at high levels in modified eukaryotic cells. The availability in abundance of pure growth factors has led to the identification and cloning of genes for their specific cell receptors. Conversely, in some cases, discovery of a putative receptor molecule through molecular cloning has led to the identification of previously unidentified growth factors.

Hematopoietic Growth Factor Receptors

Based on certain structural and functional features of the receptors for hematopoietic growth factors, two families of ligands/receptors have been recognized: the cytokine receptor family and the tyrosine kinase receptor family (Table 6.4). It was noted by Bazan ([211]), through modeling of the secondary structures of receptors for several hormones and hematopoietic growth factors, that predicted structural similarities existed among a particular receptor group. This group is called the *cytokine family of receptors*. These receptors have an approximately 200–amino acid extracellular binding segment composed of two discrete folded domains (modules) of approximately 100 amino acids. These modules share significant sequence and similar predicted secondary structure. Predicted secondary structure of these domains includes seven beta strands folded into antiparallel beta sandwiches with a similar topology. Bazan ([211]) proposed a model of cytokine binding to these receptors in which the cytokine fits into a generic structural framework formed by the relatively conserved topology of the ß-sheet faces and the connecting loops between the beta strands. Because the member receptors of the cytokine group have these structural similarities, it was expected that the binding domains of their ligands, the cognate growth factors, would have some common structural features, which is the case. Several of the cytokine growth factors have had their structures determined by x-ray crystallography: growth hormone, IL-2, macrophage colony-stimulating factor (CSF-1), GM-CSF, interferon-?, granulocyte colony-stimulating factor (G-CSF), IL-10, IL-5, IL-4, and murine leukemia inhibitory factor. The determined structure in each case includes a topologic feature consisting of a “bundle” of a helices ([212], [213], [214], [215] and [216]). There are variations in how these structures are formed from portions of the peptide chains, but they are, nevertheless, similar. For reviews of this cytokine growth factor/receptor group, see references [217], [218], and [219]. The receptor protein chains have a single membrane-spanning domain, and their intracellular domains have no areas of amino acid homology to tyrosine kinases or guanosine triphosphate–binding domains that are found in other classes of signal-transducing receptors. Most of the functional receptors for the cytokine growth factors consist of complexes of two or more protein chains of the cytokine receptor family (Table 6.4), and functional receptors for different cytokine growth factors sometimes contain a common cytokine receptor peptide chain. For example, IL-3, GM-CSF, and IL-5 receptors consist of a ligand-specific a-chain and a common gp140 $ß_c$ subunit. Similarly, the so-called IL-6 family of cytokines (Table 6.4) uses receptor complexes consisting of one or two common gp130 chains plus an additional ligand-specific subunit ([220]). Although receptors of several subunits are common among the cytokine receptor group, several members apparently consist of a single cytokine family protein chain. These

are the receptors for EPO, thrombopoietin (TPO), G-CSF, growth hormone, and prolactin.

TABLE 6.4. Classification of Hematopoietic Factors Based on Their Receptor Types

Hematopoietic growth factors using cytokine type of receptors
Cytokines with receptors consisting of a single unique peptide chain.
Erythropoietin, thrombopoietin, granulocyte colony-stimulating factor, growth hormone, [a] prolactin hormone [a]
Cytokines with receptors consisting of complexes containing gp130, which serves as the signal transducer, plus an additional ligand-binding subunit.
IL-6, IL-11, IL-12, leukemia inhibitory factor, oncostatin M, ciliary neurotropic factor [a]
Cytokines with receptors consisting of a ligand-specific a subunit and a common gp140 ß $_c$ subunit.
IL-3, granulocyte-macrophage colony-stimulating factor, IL-5
Cytokines with receptors consisting of a common ? $_c$ subunit and ligand-specific a and/or ß subunits.
IL-2, IL-4, IL-7, IL-9, IL-15
Cytokines with receptors consisting of two or more unique subunits.
IFN-a, IFN-ß, IFN-?
Hematopoietic growth factors using receptors of the tyrosine kinase (RTK) superfamily
Factors using RTKs of the epidermal growth factor (EGF) family (sometimes called *type I receptors*).
TGF-a, which uses EGF receptor [EGFR (ERBB1)]; TGF-a has a profound effect on primitive hematopoietic progenitors of some avian species; no effect on hematopoietic cells of mammals has been documented.
Factors using RTKs of the insulin family (sometimes called *type II*).
Insulinlike growth factor-1
Factors using RTKs of a subfamily of the platelet-derived growth factor family with five immunoglobulin-like domains (sometimes called *type III*).
Kit ligand, colony-stimulating factor-1, FLT3 ligand
Factors using RTKs of another subfamily of the platelet-derived growth factor family with seven extracellular immunoglobulin-like domains (sometimes called *type V*).
Flk-1 ligand (vascular endothelial growth factor)
Expression of several additional RTKs has been reported on hematopoietic cells. These include receptors designated *TIE*, *TEK*, and *MRK*. The effects of their ligands have not been reported.

gp, glycoprotein; IFN, interferon; IL, interleukin; TGF, tumor growth factor.

[a] Members of the cytokine superfamily that do not have known effects on hematopoietic cells.

The signal transduction mechanisms for the cytokine family of receptors are currently being investigated by many groups ([217], [218] and [219]). In general, each of these receptors interacts with several intracellular proteins. When their ligand binds, they activate one or more members of the Janus kinase (JAK) family of protein tyrosine kinases. They also bind the Shc proteins, which become phosphorylated on tyrosine and initiate a cascade of further tyrosine phosphorylations on other proteins. Also, when bound to ligand, these receptors activate the enzyme phosphoinositol 3-OH kinase. It is not yet fully understood what the roles of each of these receptor functions are in causing the final cellular effects. In the case of JAK kinase activation, it is clear that one result is subsequent activation of a STAT (signal *t*ransducer and *a*ctivator of *t*ranscription) family protein that moves from the cytoplasm to the nucleus and acts as a transcription factor through sequence-specific binding to DNA. In the case of most cytokine receptors, the *ras* signaling pathway is also activated.

The second group of known hematopoietic growth factors consists of members whose receptors are themselves protein tyrosine kinases ([221]) (Table 6.4). The factors of this group that are best understood in hematopoiesis are KL and CSF-1. The respective receptors are products of the *c-kit* and *c-fms* protooncogenes. One widely distributed receptor tyrosine kinase/ligand system that is important in hematopoiesis is insulinlike growth factor (IGF)-1 and its receptor IGF-1R. IGF-1 has specifically been shown to be important for erythroid cell differentiation *in vitro* in culture systems without added serum ([222]), although it is probably important for other lineages as well. The receptor tyrosine kinase FLK-2/FLT3 (mouse) or STK-1 (human) has been identified on early hematopoietic progenitors ([223], [224] and [225]), and its cognate ligand, FL ([226]), has multiple effects in hematopoiesis ([2[illegible]], [225], [227], [228] and [229]). Finally, there are reports of expression of additional receptor tyrosine kinases on some hematopoietic cells, but their significance in hematopoiesis has not been extensively studied. These include FLK-1 ([230], [231]), MRK ([232]), and TIE and TEK ([233], [234]). In chickens, the Erb-B receptor, through binding of transforming growth factor-a, has a profound effect on expansion of early erythroid progenitors ([206]).

The receptor tyrosine kinases comprise a large group of receptors that have been subdivided into types based on structure ([221], [235]) (Table 6.4). Kit, CSF-1R, and FLK-2/FLT3 are receptors of a subfamily of the platelet-derived growth factor receptor family [or type IV ([235])] that are characterized by five immunoglobulin-like domains in the extracellular portion. FLK-1 is a member of the other subfamily of the platelet-derived growth factor receptor family [or type V ([235])] that has seven such immunoglobulin domains. The genes for the related type III and type V receptors are clustered together in three locations in the human genome ([235]). IGF-1R is a member of the insulin family of receptor tyrosine kinases.

The intracellular mechanisms by which the receptor tyrosine kinases trigger their biologic effects are, like those of cytokine receptors, under intense investigation ([236], [237]). Interestingly, many of the same intracellular pathways appear to be stimulated by both types of receptors—for example, Shc activation and phosphoinositol 3-OH kinase activation. It remains to be elucidated whether or how these various receptors can initiate specific intracellular functions not common to all of the other receptors.

Factors That Act on Multilineage Progenitors

In vitro cultures of hematopoietic colony-forming cells have continued to be very useful in defining growth factor effects on various lineages of cells ([2[illegible]], [238], [239], [240], [241] and [242]). Many of the hematopoietic growth factors exhibit positive growth effects on HSCs or progenitors with multilineage potential, or both. These include KL, GM-CSF, G-CSF, CSF-1, IL-3, IL-4, IL-6, IL-11, IL-12, FL, leukemia inhibitory factor, oncostatin M, and TPO ([243], [244], [245] and [246]). In addition, some members of this same group can support differentiation of certain cell types to late stages or even to full maturity. For example, G-CSF, GM-CSF, CSF-1, IL-3, KL, and IL-6 can all support formation of small neutrophilic granulocytic colonies, and CSF-1 and GM-CSF can also support macrophage colonies and mixed granulocyte/macrophage colonies ([243]). Other members of this group do not support formation of colonies of mature hematopoietic cells alone but exert their effects in combinations with other factors. They may affect only early-stage progenitors, and their partner factors support the later differentiation, or they may act simultaneously with other factors on cells at any development stage that yields enhanced cell production as a result of a combination of different stimulatory signals. Such enhancement or potentiating effects are not restricted to those factors that have no effect alone but are rather observed with particular combinations of all members of the group listed above.

Potentiation of hematopoietic cell production in *in vitro* assays by combinations of growth factors can occur in two basic ways. A combination of growth factors may allow proliferation and differentiation of individual cells that would otherwise die or remain dormant in the presence of a single factor. Second, potentiation can occur by enhanced proliferation in the presence of the combined factors. The latter effect appears to apply to the examples of the combined effect of KL with G-CSF, GM-CSF, IL-3, IL-6, or EPO on expansion of populations of progenitors ([203], [247], [248]). The numbers of colonies formed in the presence of the combinations are not increased greatly, but there is a large increase in the size of the colonies. The proliferation of HSCs, however, appears to be an example of a requirement of a combination of factors for recruitment of dormant cells into proliferation and differentiation ([172], [243], [249], [250] and [251]).

When growth factors with effects on multilineage progenitors act alone or in combination, the result of early rounds of proliferation and differentiation is the generation of progeny that become committed individually to form different lineages of mature cells. For some lineages, the resultant single lineage progenitors cannot complete

differentiation and maturation without lineage-specific factors; late committed erythroid progenitors (CFU-E) require EPO, or they die. Likewise, appearance of lymphoid cells requires IL-7, and maturation of megakaryocytes and formation of platelets is greatly enhanced by TPO. Thus, the full development of hematopoietic cells from stem cells or early-stage progenitors requires the action of growth factors (alone or in combination) that support the multilineage progenitors and, in addition, growth factors that support terminal differentiation of committed single lineage progenitors.

Granulocyte and Macrophage Growth Factors

In addition to affecting multilineage progenitors, several growth factors also support terminal differentiation of granulocytes and macrophages. GM-CSF supports growth and development of both granulocytes and monocytes/macrophages ([174], [252], [253]). G-CSF, CSF-1, and IL-5 selectively support differentiation of neutrophilic granulocytes, monocytes/macrophage ([174], [252]), and eosinophilic granulocytes ([254], [255]), respectively. Dendritic/Langerhans cells arise from progenitor cells that also give rise to monocytes. *In vitro* culture of these progenitors in the presence of tumor necrosis factor-a plus GM-CSF or IL-3 favors generation of dendritic cells ([178], [179], [256], [257], [258] and [259]). Mast cell differentiation is supported by KL ([260], [261], [262] and [263]).

G-CSF, GM-CSF, and CSF-1 not only support differentiation of late-stage progenitors, but also can activate the resulting mature blood cells, stimulating such functions as phagocytosis ([264], [265], [266], [267], [268] and [269]). KL also activates mature mast cells, causing them to release histamine ([260]).

IL-5 is produced by T lymphocytes, whereas GM-CSF, G-CSF, KL, and CSF-1 are produced by multiple cell types including fibroblasts, endothelial cells, and macrophages. Thus, all of the cell types that produce the granulocyte and macrophage growth factors are distributed throughout the body, and T cells and macrophages are concentrated at the site of inflammation. Circulating late-stage granulocyte and macrophage progenitors as well as mature granulocytes and macrophages could thus be exposed to these factors at areas of inflammation as well as in the bone marrow stroma. It is plausible that these growth factors may play important roles in activation of granulocytes and macrophages as well as supporting final maturation stages at locations of inflammation. There is no evidence at present that production of granulocytes or macrophages is regulated systemically through a mechanism that senses the mature cell numbers in the body and causes elaboration of a factor that works in the marrow.

Megakaryocyte Growth Factors

In vitro colony assays have been developed for quantifying megakaryocyte progenitor cells, termed *colony-forming units megakaryocyte* (CFU-MK). As in the case of other early committed progenitors, the growth of such colonies is augmented by several of the CSFs with multilineage activity such as IL-3, IL-6, GM-CSF, KL, and IL-11 ([176], [270], [271]). However, in the case of platelets, there is evidence that their production is regulated by the number of platelets in the blood. Reduction of platelet numbers in rodents by antiplatelet antibodies or by exchange transfusion of platelet-poor blood causes an increase in the number of megakaryocytes in the hemopoietic tissues as well as an increase in their size and ploidy; platelet transfusion decreases these parameters ([176]). Such manipulations do not affect CFU-MK numbers in the hematopoietic tissues ([272]). These observations led to the speculation that the differentiation of megakaryocytes and the production of platelets are controlled by an unidentified thrombopoietic factor that is induced by thrombocytopenia ([176], [273]).

A growth factor has been identified that has some properties of a physiologic regulator of platelet production. This factor, TPO, exerts its effect through the activation of a cytokine receptor termed *Mpl* ([274], [275] and [276]). Mpl was identified earlier as the viral oncogene product of the mouse retrovirus, myeloproliferative leukemia virus ([277]). Recombinant TPO increases megakaryocyte and platelet numbers *in vivo* and stimulates CFU-MK growth *in vitro* ([278], [279]). Mice that bear homozygous, nonfunctional alleles of the *c-mpl* gene are viable but have greatly diminished platelet number ([244]). This latter result indicates that TPO is not essential for all platelet production but that it is a strong *in vivo* regulator. There is evidence that TPO production is regulated by blood platelet number ([279]) and that platelet number regulates the mRNA for TPO in the marrow and spleen but not in the liver and kidney ([280]). It is not yet clear that the modulation of TPO mRNA in these organs is responsible for the regulation of overall TPO protein levels. Several studies indicate that TPO is constitutively synthesized in the liver and that its level in blood is determined by its removal from circulation by binding to c-Mpl receptor on platelets and bone marrow megakaryocytes ([274]).

Growth Factors for B Lymphocytes

Methods for culture of B lymphocytes and their progenitor cells were originally described by Whitlock and Witte ([281]). Subsequently, a colony assay for B-cell progenitors, CFU-preB, was described, in which it was found that IL-7 is a very potent growth stimulatory factor for such progenitors ([177]). The role of IL-7 in lymphoid cell development *in vivo* was demonstrated by generating mice in which the genes for the IL-7 receptor are nonfunctional. Such mice have a profound reduction in thymic and peripheral lymphoid cellularity with defects in both B- and T-cell development ([282]). Because of the realization of the importance of IL-7 in B-cell growth *in vitro*, it has been incorporated into culture media when examining the lineage potential of early multilineage progenitors ([131], [132], [173]). Progenitors with both myeloid and lymphoid potential can now be observed and quantified, and it has become clear that such progenitors are more prevalent than previously thought. Thus, it appears that loss of this potential occurs at stages significantly beyond the commitment of the HSC to differentiate.

Growth Factors for Erythroid Cells

The physiologic regulator of erythrocyte production is EPO, and this regulation is very precise, keeping the red cell mass within very narrow limits ([283]). EPO acts on committed erythroid progenitors to support the later phases of erythroid differentiation ([283]). The regulation is achieved by EPO's action to modulate apoptosis of these progenitors. The production of EPO is regulated by the O_2 activity in the vicinity of specialized EPO-producing cells in the kidney. These cells are peritubular cells, located in the renal cortex ([284], [285] and [286]). By sensing O_2 activity, they essentially measure the oxygen delivery capacity of the blood, and they adjust EPO production to achieve the number of erythrocytes needed for normal tissue O_2 tension. The liver also contains specialized cells that can produce EPO in an oxygen-dependent manner, although in adult animals, the contribution of the liver to total EPO production is much less than that of the kidney. In the specialized kidney and liver cells, the transcription of the EPO gene is controlled by an oxygen-dependent transcription factor, hypoxia-inducible factor, that interacts with DNA sequences corresponding to the 3' untranslated sequence of the mRNA and also with sequences in the promoter region ([287]). In addition, tissue specificity of expression in the kidney requires specific, *cis*-acting DNA sequences far upstream (between 6 kilobase pairs and 14 kilobase pairs) of the coding sequence ([288], [289]).

KL is also specifically required for erythroid cell development as shown by its requirement for growth of human BFU-E *in vitro* under serum-free conditions ([290]). The Kit receptor is present on multilineage progenitors and on the BFU-E, and it persists on erythroid progenitors up to the proerythroblast stage. KL thus has a stimulatory effect on erythroid progenitors throughout most early stages, including those of the CFU-E and proerythroblast, when EPO stimulation becomes essential for further development. IGF-1 also appears to have a specific role in erythroid development, as it also appears necessary for proper erythroid differentiation in serum-free cultures ([222], [291]). Other multilineage growth factors, such as IL-3 and GM-CSF, have a stimulatory effect on BFU-E growth *in vitro*, although there does not appear to be a specific requirement for these factors.

IN VIVO SIGNIFICANCE OF KNOWN HEMATOPOIETIC GROWTH FACTORS

With the exception of EPO, the growth factors were initially discovered and studied because of their support of hematopoietic cells *in vitro*. An important question is what is their physiologic role *in vivo*? This question has been studied by several approaches, but perhaps the most revealing is to understand the phenotype of animals resulting from loss of function mutations in the genes for the growth factors or their specific receptors. Mice bearing spontaneous mutations in some of the growth factor genes have been identified. In additional cases, mutant animals were created by using the genetic engineering technique of homologous recombination-directed mutagenesis (gene knock-out) in murine embryonic stem cells and using these cells to generate mouse strains bearing the mutation ([253]).

Table 6.5 summarizes the phenotypes of mice bearing loss of function mutations for several growth factors. Of the factors with effects on multilineage cells, the significance of KL is the most clear. As discussed in the section Stroma of Hematopoietic Organs, the spontaneous mutations at the W locus and the Sl locus affect Kit and its ligand, respectively, and complete loss of function of either is lethal at an early embryonic stage. Certain partially functional alleles in these genes are compatible with life, but animals bearing them have hematopoietic deficits in several cell lineages. The gene encoding CSF-1 is the gene that is defective in the spontaneous mutant op/op mice. These young mice lack teeth and develop osteopetrosis due to failure to develop osteoclasts derived from macrophages ([292]). They also have great deficiencies in macrophage populations in some but not all tissues. Interestingly, with age, the op/op mice undergo significant correction of their macrophage deficiency. GM-CSF–deficient mice appear to have numerically normal production of granulocytes and monocytes. However, they have alveolar

proteinosis because of defective functioning of alveolar macrophages ([293], [294]). This condition leads to bacterial and fungal pneumonias. In summary, CSF-1 appears to be important for normal production of some macrophage types, and GM-CSF is important for the function of alveolar macrophages. Nevertheless, the production of some macrophages, even in the absence of function of both genes ([295]), indicates that there are yet unknown regulators that are important for monocyte/macrophage production and function. G-CSF function is important for maintenance of normal neutrophil numbers and granulocyte/macrophage progenitors in the bone marrow. Only 20 to 30% of normal neutrophil numbers are present in mice lacking G-CSF; they have reduced capacity to mobilize neutrophils on demand; and deficient mice are more susceptible to some bacterial infections ([296]). Although IL-3 is one of the most potent stimulators of hematopoietic colony growth *in vitro*, several mouse strains lack functional IL-3 a-receptor subunits and no IL-3 binding or demonstrable function in the cells of the animals. However, such animals are hematologically normal ([297]). Mice deficient in the Flk-2/FLT3 receptor develop into healthy animals with largely normal mature cell populations derived from hematopoietic tissues. They do have some specific deficiencies in primitive B-cell progenitors and in the transplantability of their stem cells ([298]). Mice deficient in the ligand for FLT3 have a more severe phenotype than those deficient in the receptor itself ([299]). The physiologic role of other multilineage factors remains to be clarified.

TABLE 6.5. Phenotypes Caused by Nonfunctional Mutations in Genes for Hematopoietic Growth Factors or Their Receptors

Factor	Observed Effects
Kit ligand	No functional alleles: embryonic death associated with no production of fetal hematopoietic cells and other developmental failures. Partially functional allele: deficiency of hematopoiesis, anemia, and also other defects in pigmentation and in gametogenesis.
IL-3	Lack of function does not appear to affect hematopoiesis.
Granulocyte-macrophage colony-stimulating factor	Alveolar proteinosis.
Colony-stimulating factor-1	Osteopetrosis, alveolar proteinosis.
Granulocyte colony-stimulating factor	Neutrophil deficiency; approximately 20% of normal numbers; impaired mobilization of neutrophils; demonstrated to be susceptible to some infections.
IL-5	Eosinophil deficiency.
Thrombopoietin	Platelet deficiency, approximately 10% of normal numbers.
Erythropoietin	Embryonic death; failure to produce fetal erythrocytes due to apoptosis of the late progenitors in the fetal liver; production of some embryonic blood cells.
FLT3 ligand	Deficiencies in immune system and in myeloid progenitors; more severe defects in the case of knock-out of the ligand than knock-out of the receptor (FLT3).
IL-7	Reduced thymic and peripheral lymphoid cellularity, including B- and T-cell development.

IL, interleukin.

Mutant mice have been generated that lack function of factors affecting more restricted lineages. Mice lacking IL-7 exhibit a profound reduction in B- and T-cell development ([282]), and those lacking TPO only have approximately 10% of the normal number of platelets ([244]). Loss of function of EPO or the EPO receptor leads to embryonic death at approximately day 13 of gestation due to failure of production of fetal erythrocytes ([300], [301]).

Thus, with some exceptions, the hematopoietic grow factors discovered because of their effects *in vitro* appear to be important *in vivo* in maintaining some aspects of hematopoiesis or in the function of some subclasses of mature hematopoietic cells. The roles of some of the factors that affect progenitors with multilineage potential have not yet been fully evaluated *in vivo*. The evidence from mutant mice also indicates that there are as yet undiscovered factors—in particular, factors that regulate production and function of macrophages and related cells.

MECHANISMS OF ACTION OF HEMATOPOIETIC GROWTH FACTORS

The process by which mature blood cells are formed from specific progenitor cells of the hematopoietic organs has largely been analyzed by *in vitro* culture of bone marrow or other cells in semisolid media in the presence of various combinations of growth factors. In such experiments, individual progenitor cells undergo multiple rounds of cell division and concomitant differentiation over a period of time, eventually producing colonies of mature cells. The roles of growth factors in the processes of colony development and differentiation into mature cells are unknown. Because colony formation requires cell proliferation and differentiation, “stimulation” of colony formation has been inferred to be synonymous with initiation of cell cycling or induction of a differentiation program in progenitor cells, or both. However, there is another mechanism of growth factor support of hematopoietic cell development: promotion of cell survival by prevention of programmed cell death (apoptosis). This function has only been recognized more recently as a definite, specific function of growth factors and hormones.

In this chapter, evidence has been presented for the existence of pluripotent stem cells, multilineage progenitors, and single lineage–committed progenitors representing a continuum of immature to mature phases. Also, numerous growth factors have been discussed; some act on all of the above types of progenitors, some act on only stem cells and multilineage cells, and some act on late stages of lineage-committed cells and are apparently necessary during the final differentiation phases. Thus, it is possible that in some instances, growth factors cause proliferation in a particular type of progenitor, whereas in another instance, a growth factor acts to prevent apoptosis. The developmental stage of a cell may determine its response to a growth factor. Finally, combinations of factors may be required for a particular cell response.

Induction of Differentiation

With the exception of the Indian hedgehog and BMP4 inductions of hematopoiesis in embryonic development, little evidence exists that growth factors are directly responsible for inducing the gene expression changes that are critical for the commitment of cells to a particular lineage pathway. Although some hematopoietic growth factors are known to activate certain transcription factors, no data have yet proved that those specific transcription factors directly control a differentiation step. Nevertheless, ongoing research into the possible roles of particular transcription factors and growth factor receptors in directing differentiation (see section Theories of Commitment) may clearly establish such roles for some of them in the future.

Mitogenesis

It is difficult to determine whether a particular growth factor is a mitogen for a specific type of normal hematopoietic progenitor cell—that is, to determine whether it causes the cell to enter an active cell cycle from an initially resting state. To make such a determination requires that one has a nearly pure population of the cells in question, that the cells remain alive for at least 24 hours without the test factor (to distinguish proliferation effects from survival effects), and that culture conditions can be found such that the test factor can be assessed in the absence of other factors or such that each factor can be assessed independently. These conditions can occasionally be met using purified populations of explanted, late-stage hematopoietic progenitors ([302]), but they cannot yet be achieved with stem cells or early multilineage progenitors. In lieu of using normal progenitors, numerous studies have used transformed hematopoietic cell lines that are dependent on a hematopoietic growth factor for continuous growth. One can often put such cells into a quiescent cell cycle state without initiating apoptosis by transient growth factor depletion. Thus, although such lines can meet the above criteria, they may be abnormal. Their transformed phenotype may be the result of selection for mutations in genes that control the cell cycle or apoptosis.

As indicated above, the notion that a growth factor acts as a mitogen implies that the target cell exists in an inactive cell cycle state without the factor. Such a state appears to apply to some hematopoietic progenitors *in vivc* but not to others. For the majority of progenitor types, we do not have a firm answer as to their ability to exist in such an inactive state. One type of evidence indicates that many HSCs are quiescent: *In vivo*, or when freshly isolated, most of them are resistant to 5-fluorouracil, an agent that selectively kills cells that are undergoing DNA synthesis ([131], [303], [304] and [305]). However, recent experiments designed to measure the cell cycle status of LTC-ICs in humans indicate that circulating and bone marrow–derived LTC-ICs are different in this regard; a high percentage of bone marrow LTC-ICs

appear to be in cycle ([306]), whereas circulating LTC-ICs are quiescent. For committed progenitors of most types, there is little evidence that they can remain latent. In the mouse, they are sensitive to killing by 5-fluorouracil treatment over a 2-day period ([131], [303]). Studies of the cycling status of several stages of committed erythroid progenitor cell types have been done by ^{3}H-thymidine (or hydroxyurea) suicide methods in which a high dose of these agents is given in a pulse and kills cells that are in active DNA synthesis during the pulse. One then assays the fraction of particular progenitors surviving such a pulse by colony formation or other biologic assays. In the committed erythroid lineage, early progenitor populations (the BFU-E) on average have a smaller fraction of cells in DNA synthesis at a given time (approximately 30%) than the later stage CFU-E (approximately 70 to 80%), suggesting that some BFU-E may spend time in a latent state or may be cycling slower ([307], [308], [309] and [310]). There is also some evidence that exposure of BFU-E to EPO can increase the fraction of such cells in DNA synthesis ([309], [310]), although other studies have concluded that EPO has no effect on the cell cycle status of BFU-E ([307], [308]). In the case of CFU-E, the fraction of cells in DNA synthesis is unmodified by EPO exposure. However, EPO is absolutely necessary for the survival of CFU-E and for progression of CFU-E into mature erythrocytes.

One case in which mitogenic effects of a growth factor have been clearly demonstrated on primary normal progenitors is that of CSF-1 action on macrophage progenitors from mouse bone marrow ([302]). These cells require CSF-1 for survival, but at low levels of CSF-1, they remain alive but are quiescent in regard to cell cycle. Higher doses of CSF-1 induce these quiescent progenitors to reenter the cell cycle and proliferate. Thus, these two effects of CSF-1 are separable, and the observed effect on cells depends on the dose of growth factor. Potentially, each of these effects could come into play *in vivo*, depending on the concentration of CSF-1 in the target cell's environment.

Prevention of Apoptosis

A large body of evidence suggests that most or all normal hematopoietic progenitor cells require specific growth factors to prevent apoptosis ([311], [312], [313], [314], [315], [316] and [317]). There appears to be several mechanisms by which growth factors can prevent apoptosis, and more than one of these mechanisms can be supported simultaneously by a single growth factor operating on a cell. One general mechanism of apoptosis suppression is the increased synthesis of antiapoptotic proteins encoded by the members of the *bcl-2* gene family ([318], [319], [320], [321], [322], [323], [324], [325], [326], [327], [328], [329], [330] and [331]). In neutrophils and macrophages, the antiapoptotic proteins Mcl-1 and A1 are regulated ([322], [323], [324] and [325], [332]). In progenitors of macrophages, megakaryocytes, erythrocytes, eosinophils, and B and T lymph-ocytes, the anti-apoptotic protein Bcl-x plays a key role in survival at particular developmental stages ([318], [319], [320] and [321], [326], [328], [329], [330], [331] and [332]). A second mechanism of apoptosis suppression by growth factors is the activation of the protein kinase Akt-1 through the activation of phos-phoinositol 3-OH kinase ([333]). It is not fully understood how Akt-1 prevents apoptosis, but one possible way is through phosp-horylation and inactivation of BAD, an apoptosis-promoting member of the Bcl-2 protein family ([333]). Still other mechanisms undoubtedly exist by which growth factor receptors send antiapoptotic signals.

In control of erythrocyte production, much evidence suggests that the physiologically relevant function of EPO is regulation of apoptosis in late-stage progenitors, not regulation of cell cycling ([312], [334], [335] and [336]). As stated above, there is mixed evidence for a proliferative function of EPO in human BFU-E ([307], [308], [309] and [310]), and there is some evidence that EPO is mitogenic for some erythroid cell lines ([337], [338]). *In vivo*, most CFU-E and proerythroblasts are in DNA synthesis (i.e., the majority of these progenitors are in S phase of the cell cycle) regardless of the EPO levels in the animals from which they were obtained. In other words, CFU-E and proerythroblasts, which are the cells with the greatest number of EPO receptors and are highly dependent on EPO, are in active cell cycle under all conditions; therefore, EPO does not induce them into cell cycle. Several studies using CFU-E and proerythroblasts of mice and humans have shown that they undergo prompt apoptosis in the absence of EPO ([312], [334], [335] and [336]). In a proerythroblast population, the fraction of cells that undergoes apoptosis is dependent on the concentration of EPO over an extensive range of concentrations ([335]). Studies using cultures of purified human CFU-E under serum-free conditions with added combinations of pure growth factors indicated that the number of cell divisions that occur during late erythroid maturation depends on the concentration of KL, but that EPO by itself can keep the cells alive ([291]). Finally, studies of mice in which either the EPO gene or the EPO receptor gene has been knocked-out show that the homozygous fetuses die because of failure of definitive erythropoiesis. In the livers of these fetuses, CFU-E develop, but there is evidence of extensive apoptosis of erythroid cells ([300], [301]).

EPO causes increased transcription of the *bcl-x* gene during late stages of erythroid differentiation, and it also stimulates the Akt kinase pathway. One recent study suggests that the induction of *bcl-x* by EPO is sufficient to explain completely the antiapoptotic function of the hormone in erythroid progenitors ([339]), although this conclusion warrants further study. It is not yet known how EPO or other hematopoietic growth factors induce transcription of *bcl-x*, although roles for several transcription factors have been suggested ([340], [341], [342], [343] and [344]).

A model of erythropoiesis has been proposed based on EPO preventing apoptosis in late-stage erythroid progenitors (Fig. 6.3) ([312], [345]). In the model, it is postulated that there is a period during the differentiation of red cell progenitors during which EPO is required to prevent apoptosis. This period includes the CFU-E and subsequent proerythroblast stages and, possibly, the immediate predecessors of the CFU-E, the mature BFU-E. The model also requires that individual progenitors within the EPO-dependent population exhibit a range of sensitivities to EPO such that there is an extended dose range of EPO over which individual progenitors may survive and continue proliferation and differentiation. Thus, the level of EPO ultimately controls erythrocyte production by regulating the number of dependent progenitors that survive or die.

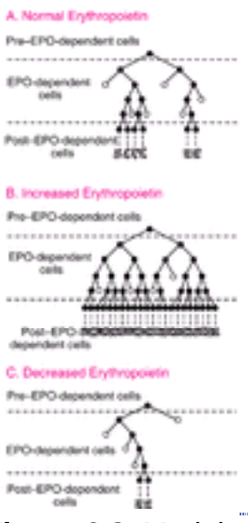

Figure 6.3. Model of erythropoiesis based on erythropoietin (EPO) suppression of programmed cell death (apoptosis). Erythroid progenitor cells enter a period of development in which they are dependent on EPO for survival (EPO-dependent cells). Surviving viable cells are indicated by solid dots; cells undergoing programmed cell death caused by insufficient EPO are indicated by open circles. Before entering the EPO-dependent period, the progenitors can survive without EPO (pre–EPO-dependent cells). Cells surviving transit through the EPO-dependent period can complete maturation into reticulocytes without EPO and ultimately become red cells (post–EPO-dependent cells). The number of cell generations encompassed by the EPO-dependent period is uncertain, but the stages of colony-forming unit erythrocyte and proerythroblast are in the EPO–dependent period. The model implies that the cells are heterogeneous in their concentration requirement for EPO, during the period of EPO dependence. (From Koury MJ, Bondurant MC. Control of erythrocyte production: the roles of programmed cell death (apoptosis) and erythropoietin. Transfusion 1990;30:673–674. Reprinted with permission from Transfusion, published by the American Association of Blood Banks.)

The two examples discussed here, CSF-1/macrophage progenitors and EPO/erythroid progenitors, indicate that different cellular mechanisms may be important in the regulation of particular types of progenitors. Also, different growth factors or combinations may activate different cellular mechanisms in a given cell type (e.g., KL plus EPO supports survival and proliferation of human CFU-E, whereas EPO by itself supports survival without proliferation) ([291]). For most progenitor types and growth factor combinations, we do not yet know which cellular functions are regulated because pure cell systems are not readily available. It is also not known how the cellular processes of proliferation, apoptosis, and differentiation are related mechanistically or if apoptosis regulation by growth factors is achieved by a mechanism common to all cell types and all factors or if there are several different mechanisms.

Erythropoiesis

CONCEPT OF THE ERYTHRON

The entire process by which red cells are produced in the bone marrow is termed *erythropoiesis.* For descriptive purposes, this process can be divided into various stages, including the *commitment* of pluripotent stem cell progeny into erythroid differentiation, the *erythropoietin-independent* or *early phase* of erythropoiesis and the *erythropoietin-dependent or late phase* of erythropoiesis. Under normal conditions, the whole process of erythropoiesis results in a red cell production rate such that the red cell mass in the body stays constant. This indicates that there must be control mechanisms by which the size of the red cell mass is tightly regulated. These control mechanisms are better understood for the later rather than the earlier phases of erythropoiesis. The glycoprotein hormone *erythropoietin* (EPO) has been established as the major humoral regulator of red cell production ([1], [2]).

Erythropoiesis involves a great variety and number of cells at different stages of maturation, starting with the first stem cell progeny committed to erythroid differentiation and ending with the mature circulating red cell (Fig. 7.1). The whole mass of these erythroid cells has been termed the *erythron* ([3]), a concept that emphasizes the functional unity of the red cells, their morphologically recognizable marrow precursors, and the functionally defined progenitors of erythroid precursors. The concept of erythron as a tissue has thus far contributed significantly to the understanding of the physiology and pathology of erythropoiesis.

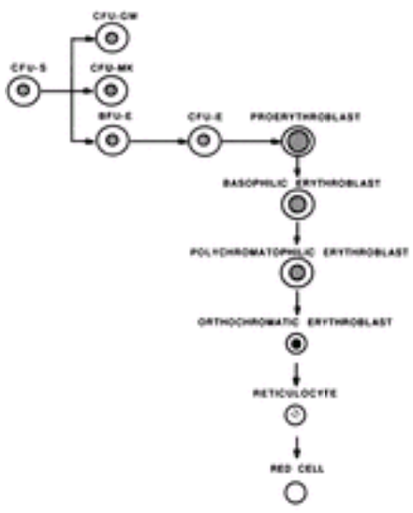

Figure 7.1. Schematic representation of the various stages of erythroid differentiation. BFU-E, burst-forming unit erythroid; CFU-E, colony-forming unit erythroid; CFU-GM, colony-forming unit granulocyte-monocyte; CFU-MK, colony-forming unit megakaryocyte; CFU-S, colony-forming unit spleen.

ERYTHROID CELLS

Commitment of Stem Cell Progeny to Erythroid Differentiation

The work of Till and McCulloch ([4]) has provided experimental evidence for the presence in the bone marrow of cells capable of both self-renewal and production of progenies with potential for differentiation into red cells, granulocytes, and megakaryocytes. Injection of murine bone marrow cells into a sublethally irradiated syngeneic mouse leads to the formation of colonies of hematopoietic cells in the spleen of the recipient mouse after 8 to 12 days. The day 12 colonies contain cells of all three hematopoietic lineages and, in addition, cells that maintain their self-renewal capacity in the sense that they are capable of restoring hematopoiesis in a second group of sublethally irradiated mice. The cell that gives rise to these colonies was termed *colony-forming unit spleen* and represents a cell identical or closely related to multipotent hematopoietic stem cell ([5]). Recently, the pluripotent murine hematopoietic stem cell has been purified and characterized ([6]). The murine stem cells morphologically resemble small immature lymphocytes, and injection of as few as 30 of these cells can rescue 50% of sublethally irradiated mice. These stem cells can restore not only the hematopoiesis but also the lymphopoiesis of the recipient mice ([6]).

Factors that affect commitment of stem cell progeny into a specific differentiation pathway are poorly understood and generally undefined. Although expression of lineage-specific transcription factors is the earliest molecular event associated with commitment toward a specific line, the stimuli responsible for their expression remain undefined. It is generally accepted that commitment and differentiation are irreversible events. A differentiated cell cannot regress to an undifferentiated stage or change into another differentiation pathway. Under normal conditions, once commitment occurs, differentiation proceeds fully to the stage of mature cell, which, in the case of blood cells, has a limited lifespan. Thus, differentiation is a process that leads to cell death. These concepts are generally well proven for the mature, morphologically recognizable hematopoietic cells and their progenitors, such as the marrow erythroblasts and their erythroid progenitors, but whether they apply equally well to more immature cells is less well known.

There are three major theories that address the process of commitment of stem cell progeny into a specific differentiation pathway ([7]). According to the *stochastic theory*, commitment is a random event that progressively restricts the potential for differentiation ([4]). This theory allows for regulatory factors to act only at later stages of hematopoiesis. This model derives its experimental support from the nonnormal (non-Poisson) distribution of lineage-specific cells in colony-forming unit spleen–derived colonies ([4]) and in colonies derived from multilineage progenitor cells ([8]), as well as from the identification *in vitro* of progenitor cells with bipotent differentiation potential such as erythroid/megakaryocytic, erythroid/eosinophil, or neutrophil/erythroid ([9], [10] and [11]). The second theory, that of *hemopoietic-inductive microenvironment*, proposes that commitment of stem cell progeny to a specific pathway depends on the environment that surrounds each hematopoietic stem cell ([12]). This model is based on the sequential analysis of colony type in spleen colonies (colony-forming unit spleen) and received further support by recent experiments with purified stem cells ([6]). The third theory proposes that commitment depends on *humoral factors* that compete among themselves at the stem cell progeny level in promoting differentiation toward one specific pathway ([13], [14]).

Erythroid Progenitors

Erythroblasts in the bone marrow are generated from proliferating and differentiating earlier, more immature erythroid cells termed *erythroid progenitors*. These progenitor cells cannot be identified morphologically, but they are detectable functionally by their ability to form *in vitro* colonies of erythroblasts ([15]). The development of tissue culture techniques for cloning hematopoietic progenitor cells in semisolid culture media *in vitro* has led to the recognition and assay in the human and murine bone marrow of at least two erythroid progenitors, the *colony-forming unit erythroid* (CFU-E), and the *burst-forming unit erythroid* (BFU-E). Under the influence of EPO, these progenitors can grow in semisolid culture media and give rise to colonies of well-hemoglobinized erythroblasts.

COLONY-FORMING UNIT ERYTHROID The CFU-E is an erythroid cell closely related to the proerythroblast ([16]). Under the influence of low concentrations of EPO, it gives rise (in 2 days in murine and in 5 to 8 days in human marrow) to colonies of 8 to 32 well-hemoglobinized erythroblasts ([17], [18] and [19]) (Fig. 7.2). The clonal origin of these colonies has been demonstrated by glucose-6-phosphate dehydrogenase–isoenzyme analysis ([20]). Morphologically, CFU-Es purified from progenitor cell cultures appear as immature cells with fine nuclear chromatin, a well-defined, large nucleolus, high nuclear-cytoplasmic ratio, a perinuclear clear zone, and basophilic cytoplasm with pseudopods ([21]). On electron microscopy, this cell appears as a primitive blast with dispersed nuclear chromatin, a prominent nucleolus, and an agranular cytoplasm containing clumps of mitochondria and frequent pinocytotic vesicles ([21]).

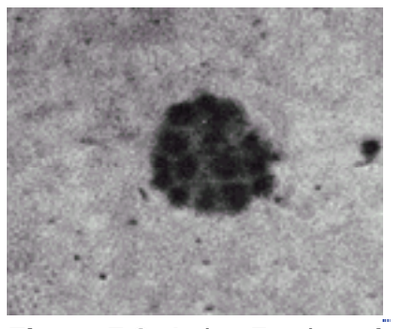

Figure 7.2. A day 7 colony-forming unit erythroid–derived colony of erythroblasts containing 16 cells.

The number of CFU-Es in the human marrow ranges from 50 to 400/1 × 10^5 light-density, nonadherent, nucleated cells and varies significantly with the methods used for cell separation and the culture conditions. The majority of the CFU-Es are in a phase of active DNA synthesis (S-phase) as demonstrated by a 70 to 90% killing of cells after short exposure to ^{3}H-thymidine *in vitro* (^{3}H-thymidine suicide) or after administration of cycle-specific chemotherapeutic agents *in vivo* ([22], [23] and [24]). The size of CFU-E compartment in intact animals depends on the levels of circulating EPO. Anemia associated with high EPO levels or administration of EPO leads to expansion of the CFU-E compartment, whereas transfusion-induced polycythemia leads to low EPO levels and to significant reduction of the CFU-E compartment ([24]). From a number of *in vitro* studies, it has been well established that the CFU-E is the most EPO-sensitive cell, carrying the highest density of EPO receptors (EPORs) on its surface, and it is also absolutely dependent on EPO for its survival. In the absence of EPO, CFU-Es undergo programmed cell death (apoptosis) ([21], [25], [26], [27] and [28]).

BURST-FORMING UNIT ERYTHROID The BFU-E is an erythroid progenitor that is much more immature than the CFU-E, and it is more closely related to the multipotent hematopoietic stem cell, as indicated by its cell size and buoyant density and the relatively low percentage of these cells in active DNA synthesis (0 to 25%) ([23], [24], [29], [30]). BFU-E can be separated from CFU-E by its slower velocity sedimentation at unit gravity ([31]). Morphologically, the BFU-E appears as a very immature blast cell with slightly oval, moderately basophilic cytoplasm with occasional pseudopods, very fine nuclear chromatin, and large nucleoli ([27]). On electron microscopy, the cytoplasm is abundant and contains polyribosomes, and the nucleus contains small amounts of clumped heterochromatin and prominent nucleoli ([27]). In the presence of EPO and under the influence of other factors acting on early hematopoietic cells, such as interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor, thrombopoietin, and stem cell factor, it gives rise in 5 to 7 days in mice and in 14 to 16 days in humans to clusters of many erythroid colonies containing a total of 500 to more than 5000 well-hemoglobinized erythroblasts (Fig. 7.3). The clonal origin of the BFU-E–derived erythroblasts has been demonstrated by characterization of the type of hemoglobin produced by cells in single colonies in co-culture experiments of bone marrow cells from a patient with homozygous hemoglobin C and marrow cells from another patient with homozygous hemoglobin S disease ([32]).

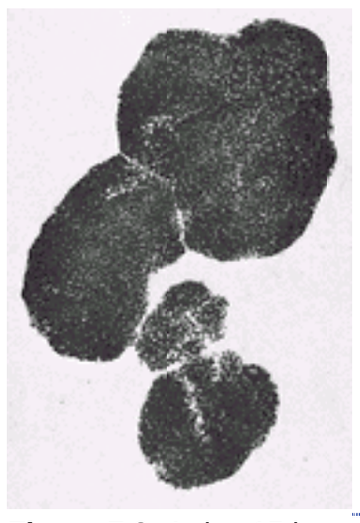

Figure 7.3. A day 15 human bone marrow burst-forming unit erythroid–derived burst (group of colonies) or erythroblasts containing over 1000 cells.

The BFU-E can be considered as a progenitor of the CFU-E. Indeed, after 6 to 7 days in culture, cells generated from human BFU-E have all the functional characteristics of CFU-E ([21]). The concentration of BFU-E in the human bone marrow varies from 10 to 50/1 × 10^5 nucleated cells; however, this number fluctuates widely depending on the cell separation methods and the culture conditions. In contrast to CFU-E, BFU-Es are also detectable in the peripheral blood at a concentration of 0.02 to 0.05% of light-density (<1.077), mononuclear blood cells ([33], [34] and [35]). From both *in vitro* and *in vivo* experiments, it has been well established that the early stages of BFU-E proliferation and differentiation are EPO-independent ([24], [27], [30]). BFU-Es can survive *in vitro* (for 48 to 72 hours) in the absence of EPO, but they are absolutely dependent on IL-3 for their survival ([27]). Only 20% of blood BFU-Es express a very low density of EPORs detectable by autoradiography ([27]). The size of BFU-E compartment in the marrow of animals remains unaffected by the acute changes in the levels of circulating EPO induced by anemia or transfusional polycythemia ([24]). Anemia can induce an increase in the cycling of BFU-Es without affecting their numbers ([36], [37]), and *in vitro* EPO can induce BFU-Es into DNA synthesis ([38]). In humans, chronic administration of EPO is associated with an increase in the concentration and cycling status of marrow BFU-Es; however, these changes are also seen in granulocytic-monocytic, megakaryocytic (CFU-MK), and multilineage-progenitors, indicating that, at the early progenitor cell level, the marrow responds to EPO as an organ in a non–lineage-specific manner ([39]). All this evidence indicates that the early stages of erythropoiesis at the BFU-E level are EPO-independent, and dependence on EPO develops at a stage between BFU-E and CFU-E ([27]). The distinction between early (BFU-E) and late (CFU-E) erythroid progenitors, although valid, is by itself artificial. There are a variety of cells between BFU-E and CFU-E that form a continuum of erythroid progenitors at different stages of differentiation with properties between those of BFU-E and those of CFU-E. As an example, a subclass of erythroid progenitors termed *mature* BFU-Es has been described in human and murine marrow ([22], [23]). These cells share properties from both CFU-E and BFU-E. They have a proliferative potential lower than BFU-E but higher than CFU-E, their cycling status is also intermediate between CFU-E and BFU-E, and they do not exhibit IL-3–dependence, but they show relative EPO-dependence ([22], [23], [26]). Thus, it becomes clear that, during erythroid development, early progenitors of high proliferative potential in a relatively low cycling status with absolute dependence on IL-3 and responsiveness to but not dependence on EPO differentiate progressively through various stages into later progenitors of low proliferative potential with a high cycling status that are IL-3–independent and totally EPO-dependent.

Erythroid Precursors

Erythroblast is a term first used by Ehrlich to refer to all forms of nucleated red cells, pathologic as well as normal. He classified erythroblasts into two main categories: a normal series, the *normoblasts*, and a pathologic series, the *megaloblasts*. He had observed the latter in pernicious anemia during relapse, as well as in early embryonic blood. The term *megaloblast* is used in this book in the pathologic sense given by Ehrlich. These abnormal cells are described and discussed in

Chapter 43.

The least mature recognizable erythrocyte precursor cell is known as the *pronormoblast* or *proerythroblast*. Cells characteristic of subsequent stages of maturation are called *normoblasts* or *erythroblasts*. The various stages of maturation, in order of increasing maturity, are known as *pronormoblasts*, *basophilic normoblasts*, *polychromatophilic normoblasts*, and *orthochromatic normoblasts*. Morphologic characteristics of each stage, as seen with ordinary light microscopy after staining with Romanowsky dyes, are widely agreed on. Cytoplasmic maturation can be assessed by the change in staining characteristics, as the deep blue color from the high RNA content of immature cells gives way to the red color characteristic of hemoglobin. Nuclear maturation is evaluated by the disappearance of nucleoli and the condensation of chromatin as nuclear activity ceases. The use of these features in defining stages of maturation is described in more detail in ensuing paragraphs.

Electron microscopy has added a number of details to the understanding of normoblast structure (Fig. 7.4). At the pronormoblast stage, ferritin can be found in the cytoplasm. On electron microscopy, this large, iron-containing protein has the characteristic appearance of a tetrad, making positive identification possible. Ferritin may appear as isolated molecules within the cytoplasm, or it may be found in pinocytotic vesicles or in larger structures (often surrounded by a membrane) that have been called *siderosomes*. The sources and metabolic fate of ferritin are discussed in Chapter 28. Its morphologic importance depends on the fact that the presence of ferritin helps to distinguish erythrocyte precursors from other immature cells.

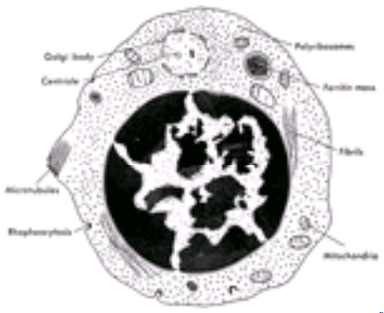

Figure 7.4. Schematic diagram of the ultrastructure of the normoblast as visualized by electron microscopy. (Courtesy of Dr. Marcel Bessis.)

The cytoplasm of erythrocyte precursors contains ribosomes, but, for the most part, these remain free within the cytoplasm rather than being part of a well-defined endoplasmic reticulum. In the stages that are actively synthesizing hemoglobin, the ribosomes are found in units known as *polyribosomes*; these consist of two to eight individual ribosomes joined together by a strand of messenger RNA (mRNA). Ribosomal RNA accounts in large part for the deep blue staining that is characteristic of younger cells (pronormoblast to polychromatophilic erythroblast). Mitochondria in erythroid cells are round or oval, and the cristae are less distinct than in other cell lines. They are most numerous in the earlier stages of maturation. Many small vesicles that are approximately 50 nm in diameter are seen throughout the cytoplasm. They have a single membrane with an indistinct inner layer, and they sometimes contain ferritin particles ([40]). These vesicles are believed to arise by a process termed *pinocytosis* or *rhopheocytosis* (Fig. 7.4), whereby macromolecular substances are brought into the cell. The vesicle is formed from an invagination of the cell membrane, followed by closure to form a vacuole, which later separates from the membrane. Other cytoplasmic structures found in the young normoblast include a Golgi apparatus and occasional, randomly oriented microtubules. The latter are of unknown function but may represent remnants of the marginal band, a cytoskeletal structure characteristic of erythrocytes of lower species ([41]). Alternatively, they may be remnants of mitotic spindles ([40]).

Stages of Normoblastic Differentiation

The pronormoblast or proerythroblast is a round or oval cell of moderate to large size (14 to 19 µm diameter) (Fig. 7.5A and Fig. 7.6A). It possesses a relatively large nucleus, occupying perhaps 80% of the cell, and a rim of basophilic cytoplasm. The nucleus of the youngest cells in this group may differ little from that of the myeloblast. Nucleoli are present and may be prominent. There is a very thin or delicate membrane penetrated by pores, which connect the nucleoplasm to the cytoplasm ([40]).

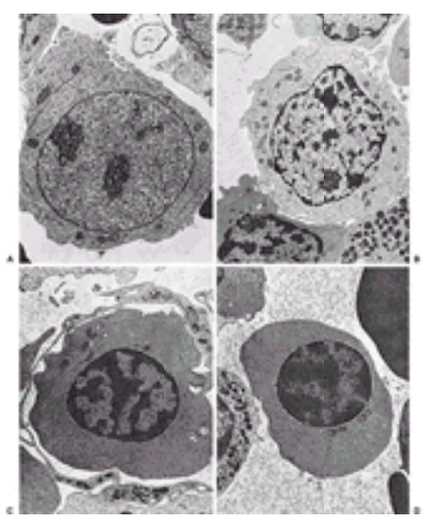

Figure 7.5. Maturation of normoblasts as seen with transmission electron microscopy. Pronormoblast **(A)**, basophilic normoblast **(B)**, polychromatophilic normoblast **(C)**, and orthochromatic normoblast **(D)**. (Courtesy of Dr. Carl Kjeldsberg.)

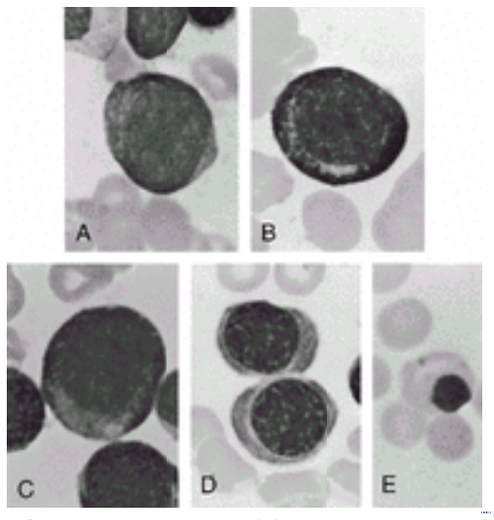

Figure 7.6. Normoblasts. Pronormoblast **(A)**; basophilic normoblast **(B)**; early **(C)** and late **(D)** polychromatophilic normoblasts; orthochromatic normoblast with stippling **(E)**. Magnification, ×1000; Wright stain. See Color Plate.

At this stage, only very small amounts of hemoglobin are present that cannot be detected by Giemsa stain. With the electron microscope at very high magnification (×100,000), ferritin molecules may be detected. As compared with that of myeloblasts and lymphoblasts, the cytoplasm has a tendency to be more homogeneous and condensed and may appear granular. A small, pale area may be found in the cytoplasm, probably corresponding to the Golgi apparatus ([40]). The nuclear chromatin is somewhat more coarse than that in myeloblasts or lymphoblasts. A number of mitochondria are seen in the cytoplasm with supravital stains or electron microscopy.

The basophilic normoblast or basophilic erythroblast is similar to the pronormoblast except that the nucleoli are no longer visible and the cell is somewhat smaller (12 to 17 µm in diameter) (Fig. 7.5B and Fig. 7.6B). Condensation of chromatin (formation of heterochromatin) begins in this stage. On light microscopy, the chromatin may appear coarse and granular; thus, there is little resemblance to the myeloblast. The nuclear structure may assume a wheel-spoke arrangement, and there tends to be sharp contrast between chromatin and parachromatin. The ribosomes reach their maximum number during this stage, and, as a consequence, the cytoplasm is deeply basophilic, even more so than in the pronormoblast. The color changes during subsequent stages reflect the increasing cytoplasmic concentration of acidophilic hemoglobin and the decreasing number with eventual disappearance of ribosomal RNA.

The first faint blush of hemoglobin, as indicated by one or more pink areas near the nucleus in dry fixed preparations, introduces the next stage, which is called the *polychromatophilic normoblast or erythroblast* (Fig. 7.5C, Fig. 7.6C, and Fig. 7.6D). Increasing condensation of nuclear chromatin is observed during this stage. Irregular masses of chromatin are formed, which may stain very deeply. Nucleoli are not visible. The nucleus is smaller (7 to 9 µm) as is the cell as a whole (12 to 15 µm). The maximum number of mitochondria is found in the early phases of this stage, but as hemoglobin becomes more plentiful, mitochondria decrease in number.

When the cytoplasm possesses almost its full complement of hemoglobin, the cell is termed an *orthochromatic normoblast or erythroblast* (Fig. 7.5D and Fig. 7.6E). Strictly speaking, normoblasts are rarely orthochromatic in the sense that their color is the same as that of mature red cells, but this term is convenient in distinguishing the more acidophilic from the distinctly polychromatophilic stage. The orthochromatic normoblast is the smallest of the nucleated erythrocyte precursors (8 to 12 µm in diameter).

In this stage, the nucleus undergoes pyknotic degeneration, the chromatin becomes greatly condensed, and the nucleus shrinks. The nucleus may appear to be an almost homogenous mass. It may assume various bizarre forms such as buds, rosettes, clover leaves, or double spheres, or only a faint ring may remain. The changing pattern of the nuclear chromatin is not an artifact produced by fixation as it has been shown by studies with the electron microscope ([42]). Distortions of this process have been described. Finally, the nucleus is extruded ([43]) (Fig. 7.7).

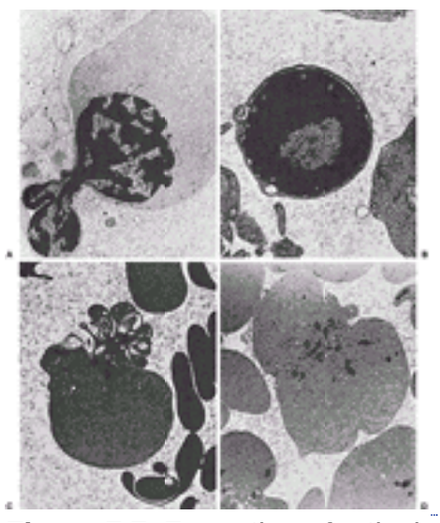

Figure 7.7. Formation of reticulocytes. **A:** Normoblast expelling nucleus; **B:** normoblast nucleus after expulsion, with rim of cytoplasm; **C:** reticulocyte immediately after expulsion of nucleus; **D:** reticulocyte. (Courtesy of Dr. Carl Kjeldsberg.)

After the nucleus has been extruded, the cell is known as a *reticulocyte*. These cells are somewhat larger than mature erythrocytes, perhaps 20% greater in volume ([44]). They contain certain cytoplasmic organelles, such as ribosomes, mitochondria, and the Golgi complex (Fig. 7.7C and Fig. 7.7D), and have special staining characteristics. Methyl alcohol or similar fixative agents used in staining cause a uniform precipitation of the ribosomal RNA. Such cells may appear uniformly blue or gray (diffuse basophilia), or various basophilic shades may be intermingled with pink-staining portions (polychromatophilia or polychromasia). Certain supravital staining techniques (see Chapter 1) cause the ribosomal RNA to precipitate or aggregate into a network of strands or clumps that have been termed *reticulum*. The presence of “reticulum” led to the term *reticulocyte*. Both terms are misleading because true endoplasmic reticulum does not exist in reticulocytes.

The “reticulum” may appear as a narrow band traversing the cell, it may be evenly distributed throughout the cell, or it may be so densely packed as to give the appearance of a nucleus. Generally speaking, the amount of reticulum in reticulocytes decreases as the cells mature, and, in “old” reticulocytes, only a few granules or scattered threads may be found ([45]). The shape and density of the network also depend, however, on a number of physical factors. Thus, the stronger the concentration of the dye, the larger and less broken up is the reticulum. Drying of the film tends to produce a fine reticulum ([46]). Heating tends to destroy the reticulum, with only rods and granules being demonstrable. A change in the pH of the staining mixture toward the acid side results in a finely granular reticulum, whereas treatment with dilute alkali produces a stippled form ([47]).

With transmission electron microscopy, the mitochondria in reticulocytes are found to be grouped together, whereas the ribosomes are more evenly distributed ([48]) (Fig. 7.7C and Fig. 7.7D). There may or may not be visible ferritin molecules and pinocytotic vesicles in the cytoplasm. After supravital staining with cresyl blue, the ribosomes agglutinate into a network, and the mitochondria become swollen and distorted and their cristae disappear. As the reticulocyte matures, the various organelles decrease in number. Usually the mitochondria disappear first and the ribosomes last. At times, “autophagic vacuoles” (auto-phagosomes or secondary lysosomes) are found. These structures contain the degenerated organelles and may represent a mechanism whereby the unneeded cellular components are discarded.

The shape of the reticulocyte, as revealed by the scanning electron microscope, differs considerably from that of the mature erythrocyte. The reticulocyte is irregular and polylobulated, and regions of apparent cytoplasmic retraction may be found (Fig. 7.8). Only in the late stages does the bilaterally indented disc shape of the mature red corpuscle appear.

Figure 7.8. Reticulocyte as seen by scanning electron microscope.

Reticulocytes are more adhesive than adult corpuscles and move about in currents at a much slower rate than do mature cells ([49]). They appear to have a coating of globulin, at least part of which is transferrin ([50]). Their specific gravity is lower than that of adult corpuscles ([51]), and they tend to collect in the upper portions of suspensions of corpuscles. They vary in their resistance to hypotonic solutions ([52]). They have metabolic pathways that are lacking in mature red cells, including an intact tricarboxylic acid cycle ([53]).

Proliferation and Maturation of the Erythron

Within the erythron, cellular maturation and proliferation proceed simultaneously. All identifiable erythroid progenitors and the morphologically identifiable erythrocyte precursors are functionally destined to mature; thus, they are incapable of self-maintenance. Maintenance of the erythron at a given size and its expansion on demand are functions of the stem cell compartment (see Chapter 6). A scheme of the proliferation of the erythron and its various stages of development is presented in Figure 7.1. It takes approximately 12 to 15 days for a cell at the BFU-E stage to mature into erythroblasts. Within 6 to 8 days, a BFU-E proliferates and differentiates into a CFU-E, which needs another 5 to 7 days to proliferate and develop into basophilic erythroblasts, a period during which the CFU-E undergoes three to five successive divisions. Probably, three to five cell divisions also occur during the maturation of erythroid precursors ([54]). Thus, 8 to 32 mature red cells are derived from each pronormoblast. Cell division ceases at the stage of polychromatophilic erythroblasts. Orthochromatic normoblasts cannot synthesize DNA and, therefore, cannot divide.

Two events may decrease the theoretic yield of cells. One of these is the death of the cell before or shortly after its release from the marrow (ineffective erythropoiesis) (Chapter 27). The second is a skipped cell division, a phenomenon that results in a large hemoglobin-poor cell (Chapter 27). These events occur to only a limited extent in normal subjects but may occur much more frequently under pathologic circumstances.

The biochemical events that occur at the stem cell progeny during its commitment to erythroid differentiation are unknown. The same holds true for the earlier identifiable erythroid progenitor BFU-E. This cell is totally IL-3–dependent and shows a small number of EPORs ([27]). Within 72 hours in culture, these cells become fully dependent on EPO (mature BFU-Es) and, in its presence, proliferate and differentiate into CFU-Es ([21] , [27]). At this stage, a number of differentiation events can be detected. From studies in murine erythroid cells, it has been established that EPO induces an increase in the synthesis of RNA and that this is closely followed by the induction of murine ß-globin gene transcription ([55]). Other biochemical events associated with terminal erythroid differentiation include increased uptake of calcium and glucose, synthesis of transferrin receptors, increased iron uptake, hemoglobin synthesis, and appearance of erythrocyte membrane proteins (band 3 and 4.1) ([56] , [57] , [58] and [59]). Hemoglobin synthesis continues as the cell matures further into the stage of basophilic erythroblast, and, at the polychromatophilic erythroblast stage, enough hemoglobin has accumulated in the cytoplasm to give the cell the mild acidophilic reaction detected by Romanowsky stains. Hemoglobin synthesis continues through the orthochromatic stage and persists at a very low rate in the reticulocyte after denucleation. Mature red cells, being devoid of ribosomes, are unable to synthesize hemoglobin.

As previously noted, morphologic evidence of nuclear degeneration (heterochromatin formation) can be seen as early as the basophilic normoblast stage. By the orthochromatic stage, the nucleus is completely inactive, unable to synthesize either DNA or RNA. The factors leading to cessation of nuclear activity are not fully understood, but there is evidence that they may be related to intracellular hemoglobin concentration ([60]). Hemoglobin is found within the nucleus, possibly gaining entrance through pores in the nuclear membrane ([60] , [61] and [62]). After reaching a critical concentration (possibly 20 g/dl) ([60]), nuclear hemoglobin may react with nucleohistones, thereby bringing about chromosomal inactivation and nuclear condensation. According to this hypothesis, the number of cell divisions and the ultimate erythrocyte size are related to the rate of hemoglobin synthesis. For example, microcytic cells are produced in iron deficiency because it takes longer to reach the critical hemoglobin concentration and the generation time is unaffected; hence, more cell divisions occur before nuclear inactivation, and the resulting cell is small. In contrast, the macrocytes observed when erythropoiesis is stimulated may be the end results of an EPO-induced acceleration of hemoglobin synthesis, which in turn leads to an earlier onset of nuclear degeneration and a reduced number of cell divisions. Also consistent with this hypothesis is the observation that the mean corpuscular hemoglobin concentration remains relatively constant in a variety of mammalian species, even though erythrocyte size varies greatly ([63]).

After the nucleus degenerates, it is extruded from the cell ([64]). This process, which has been observed in living normoblasts by phase contrast microscopy ([65]), is completed in 5 to 60 minutes. During the extrusion process, mitochondria and cytoplasmic vesicles accumulate near the nuclear border ([40] , [66]). The role of these structures in nuclear extrusion is not entirely clear, but supravital staining with Janus green B, a mitochondrial toxin, inhibits denucleation ([64]). The extruded nucleus carries with it a rim of cytoplasm, including ribosomes, hemoglobin, and occasional mitochondria.

Enucleation is a process similar to cytokinesis and does not seem to depend on either the presence of extracellular matrix proteins or accessory cells ([67]). Among the various cytoskeletal proteins, filamentous actin plays an important role in the process of enucleation, accumulating between the extruding nucleus and incipient reticulocyte. Supporting the major role of filamentous actin in the process of enucleation is the fact that low concentrations of cytochalasin D cause complete inhibition of enucleation ([67]).

Within the marrow, denucleation may sometimes occur as the erythroblast traverses the endothelial cell that forms the sinus wall ([68]). The normoblast cytoplasm and small organelles (ribosomes and mitochondria) squeeze through endothelial, cytoplasmic pores 1 to 4 µm in diameter, but the more rigid nucleus cannot conform to this pore size. The nucleus thus becomes caught and “pitted” from the cell. Passage through the endothelial pores is not essential to denucleation, however, because the whole process can be observed *in vitro* ([65] , [67]).

Soon after denucleation, the nucleus is engulfed by a macrophage. The cell may remain within the marrow as a reticulocyte for several days. Factors controlling release into the circulation are discussed in Chapter 6. After release, the reticulocyte may be sequestered for 1 to 2 days in the spleen ([69]). Here, additional maturation may occur, and the composition of the membrane lipids may be altered.

As the reticulocyte matures to an adult erythrocyte, it loses its ability to synthesize hemoglobin ([70]). Both particulate and soluble RNA fractions appear to be catabolized by a ribonuclease. The resulting oligonucleotides are probably further degraded by phosphodiesterases and phosphatases to pyrimidine nucleotides. A specific pyrimidine 5'-nucleotidase found in reticulocytes dephosphorylates these nucleotides, and the free pyrimidine bases then can leak out of the cell ([71]). If the pyrimidine 5'-nucleotidase is lacking because of hereditary deficiency ([71]) or lead poisoning ([72]), RNA degradation is greatly retarded, and basophilic stippling due to retained RNA aggregates becomes very prominent.

BIOSYNTHESIS OF HEMOGLOBIN

Because hemoglobin accounts for approximately 90% of the dry weight of the erythrocyte, the biosynthesis of hemoglobin is intimately related to erythropoiesis. As detailed in the previous section, many of the morphologic criteria used in staging the maturation of erythrocyte precursors are related to hemoglobin production and content. Furthermore, the initial events associated with the differentiation of CFU-Es into erythrocyte precursors include the activation of genes relating to hemoglobin synthesis ([55]).

Three complex metabolic pathways are required for synthesis of hemoglobin, corresponding to the three structural components of hemoglobin: protein (globin), protoporphyrin, and iron. The first two of these are discussed in the pages to follow. Iron metabolism is described in Chapter 28.

Globin Synthesis

GLOBIN GENES AND THE STRUCTURE OF CHROMATIN Distinct structural genetic loci exist for each of the known normal polypeptide chains in hemoglobin. Thus, there are a, ß, ?, d, and ϵ genes. In most human populations, the a genetic locus is duplicated, and there are four (two pairs) of identical a genes in normal subjects ([73] , [75]). There are also at least two different pairs of ? genes, one (^{G}?) coding for a ?-chain with glycine at position 136 (H14) and another (^{A}?) coding for a ?-chain with alanine at the same position ([76]). In contrast, there appears to be only one pair of genes coding for ß- and d-chains, respectively. (See also Chapter 8 and Chapter 42.) Genetic evidence has indicated that the a and ß genes are not linked, and it is now clear that they are located on different chromosomes ([77]). The a-gene cluster (approximately 30 kb) is located on the short arm of chromosome 16 and contains also the locus encoding for the ?-chain ([78]). The ß-gene cluster (approximately 50 kb) is located on chromosome 11 and includes the genes for the G?-, A?-, d-, and ϵ-globins ([78] , [79]). A schematic representation of the a- and ß-gene clusters is shown in Figure 7.9.

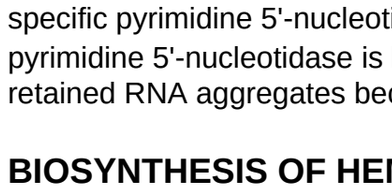

Figure 7.9. Organization of the human globin gene clusters on chromosomes 16 and 11. Solid areas within genes represent coding sequences; open areas represent

intervening sequences. Each cluster includes pseudogenes (??,?a, ?ß), which have sequence homology to functional genes but include mutations that prevent their expression.

Only 5 to 10% of the genetic material in erythroblasts is transcriptionally active, and the globin structural genes are included in this fraction ([80]). These active genetic regions of DNA make up the open portion, or euchromatin, of nuclear material, whereas unexpressed genes are included in the condensed, or heterochromatin, fraction. Differentiation of erythroid progenitors to erythroblasts is accompanied by the activation of the genes involved in erythroid differentiation, including the globin genes ([55], [81]). The modulation of expression of genes is imposed by chromatin structure, which includes not only strands of DNA but also histone and nonhistone proteins. The structure of chromatin by electron microscopy has been compared to beads on a string ([80], [81]). The beads represent nucleosomes, each of which consists of eight histone molecules, an octamer, associated with approximately 200 base pairs of DNA. These nucleosomes are distributed randomly along the DNA double helix and are joined by “spacer regions” of DNA, 40 to 100 base pairs long, associated with a specific histone (H1). In general, the association with histones is believed to limit accessibility to the genetic material by RNA polymerase, thereby preventing or retarding transcription. However, most current evidence suggests that active globin genes in erythroid cells are incorporated into structures at least resembling nucleosomes ([80]). Genes that are not transcriptionally active are closely associated with chromatin and may have an increased number of methylated nucleotides ([82], [83] and [84]). Under these conditions, the genes are insensitive to nuclease digestion. Activation of these genes is associated with modification of the chromatin structure induced by transacting factors. Thus, genes associated with erythroid development are resistant to nuclease digestion in nonerythroid or early noncommitted hematopoietic cells. As the cell matures within the erythroid line of differentiation, these genes are progressively activated as indicated by the appearance of nuclease-sensitive sites in areas encoding for globin genes that include also a number of regulatory sequences ([80], [81], [85], [86]).

TRANSCRIPTION AND MESSENGER RNA PROCESSING Synthesis of RNA takes place under the influence of large complex enzymes (or groups of enzymes) called *RNA polymerases* ([87]). Three such enzymes (or groups of enzymes) have been described: type I(A), which transcribes the genes for most ribosomal RNA and is found largely in the nucleolus; type II(B), which transcribes genes for “unique sequence” RNAs, including the globin messenger; and type III(C), which transcribes genes for transfer RNA (tRNA) plus a low molecular weight (MW) (S) fraction of ribosomal RNA. Types II(B) and III(C) RNA polymerase are found in the nucleoplasm outside of the nucleolus. Of the two DNA strands in the double helix, only one, the “sense strand,” appears to be translated *in vivo*. Globin mRNA, like most eukaryotic mRNAs, is synthesized in a precursor form that is two to three times as long as the molecule that ultimately serves as the template for protein synthesis ([73], [80], [81]). These precursor molecules are called *heterogeneous nuclear* RNAs. They have relatively short half-lives, on the order of 15 to 30 minutes. The heterogeneous nuclear RNA molecule undergoes “processing” to be converted into the final mRNA ([88]). Processing includes at least three posttranscriptional events: “capping” at the 5' end of the molecule, polyadenylation at the 3' end, and “splicing,” which results in removal of so-called intervening sequences or introns. The last are untranslated sequences of unknown function that interrupt a translated sequence ([89]). In mouse ß-globin heterogeneous nuclear RNA, for example, a long intervening sequence occurs between the codons for amino acids 104 and 105. This “unnecessary” segment must be “edited out.” The final mRNA molecule contains 675 to 750 nucleotides. The primary structure of mRNA can be divided into four regions: the 5' untranslated region (which includes the cap), the translated or coding region, the 3' untranslated region, and the polyadenosine region. The “cap” is characterized by an atypical 5'-triphosphate-5' linkage with guanosine-5-triphosphate (GTP) and methylation of adjacent nucleotides. This structure appears to be essential for maximal translational activity, presumably because it affects the initiation of translation; however, its exact role has not been determined. The cap is followed by an untranslated region of 36 nucleotide bases in a-globin mRNA and 53 bases in ß-globin mRNA. The difference may explain the observation that ß-mRNA is translated more efficiently than a-mRNA ([80], [81]). Normally, this relatively inefficient translation of the a-chain is compensated for by an increased amount of a-mRNA. The translated sequence begins with an initiator sequence of three bases (AUG) followed by a sequence of triplet codons, each of which corresponds to an amino acid in globin, according to the genetic code. The translated sequence ends with a terminator codon (UAA), which is followed by a noncoding area of undefined function. Finally, the molecule ends with a polyadenosine region, of variable length, that probably affects the stability or half-life of the molecule. The number of adenosine residues appears to decrease as mRNA ages ([90]); in older reticulocytes, mRNA may contain little or no polyadenosine.

TRANSLATION Translation is a ribosomal process whereby a polypeptide chain is synthesized according to the pattern provided by the sequence of codons in mRNA. The process has been divided into four major stages: activation, initiation, elongation, and termination. The activation step involves formation of an ester linkage between amino acids and specific tRNAs in the cytoplasm. This process requires adenosine triphosphate, magnesium, and specific enzymes known as *aminoacyl-tRNA synthetases*. Initiation of polypeptide chain formation occurs when a special, methionine-bearing, initiator tRNA (tRNA $^{met}_{F}$) becomes aligned with the initiator codon (AUG) in mRNA on the ribosome ([80], [81]). This complex step requires at least eight protein initiation factors ([91]). One of these [erythrocyte initiation factor (eIF)–2] forms a complex with GTP and tRNA $^{met}_{F}$, which attaches to the small (40S) ribosomal subunit. Next, mRNA and the larger (60S) ribosomal subunit are added under the influence of other initiation factors. The methionine molecule that begins the polypeptide chain at the *N*-terminal is eventually cleaved from the protein. As the polypeptide chain elongates, specific amino acid–bearing tRNAs become attached to the ribosomes ([80], [81]). Each tRNA has an anticodon sequence corresponding to the specific codon in mRNA. As each tRNA is positioned, its amino acid becomes attached by a peptide bond to another amino acid previously bound to the ribosome. Formation of the peptide bond is a property of peptidyl transferase activity associated with the large ribosomal subunit. At least two factors are required for ribosomal binding of tRNA. The other (“translocase”) is necessary for the movement of codons along the ribosome, a process using energy from GTP. A single mRNA molecule may have several ribosomes attached to form polyribosomes. When the terminator codon (UAA) is reached, the polypeptide chain is completed and released from the ribosome. This termination step requires GTP and one or more “releasing factors” ([91]).

TETRAMER FORMATION Once the polypeptides are released from the ribosomes, they quickly and spontaneously form aß dimers and a $_2$ß $_2$tetra-mers. Apparently, no enzymes or cofactors are involved in this process.

REGULATION OF GLOBIN SYNTHESIS Heme is of particular importance in controlling the rate of globin synthesis ([92], [93]). It stimulates globin synthesis in intact reticulocytes and cell-free systems, and, in its absence, polyribosomes disaggregate ([94], [95] and [96]). The major effect of heme is exerted on the chain-initiation step in translation. In the absence of heme, an inhibitor of globin synthesis accumulates ([97], [98]). This inhibitor acts by phosphorylating the initiation factor (eIF-1) that promotes binding of tRNA $^{met}_{F}$ to ribosomes ([99], [100]). Heme not only inactivates the inhibitor ([100]) but also stimulates an enzyme that dephosphorylates eIF-2 ([80]). Heme may also exert effects on transcription, on mRNA processing, or on both ([101]). In mouse erythroleukemia cells, hemin behaves as an inducer. The role of heme in mammalian protein synthesis appears to extend beyond the erythrocyte; heme-dependent factors for the initiation of protein synthesis have been demonstrated in liver and brain ([102], [103]).

Heme Biosynthetic Pathway

Strictly defined, *heme* is the ferrous iron complex of protoporphyrin IX; however, the term *heme* is also used in the generic sense to indicate iron protoporphyrin IX without regard to the oxidation state of the iron. Thus, hemoglobin, peroxidase, and cytochrome *c* are all “heme” proteins even though the iron is ferrous in hemoglobin, ferric in peroxidase, and either ferric or ferrous in cytochrome *c* ([104], [105], [106], [107], [108] and [109]).

Protoporphyrin IX is a tetrapyrrole, a complex structure (“macrocycle”) made up of four pyrrole rings joined together (Fig. 7.10). The four pyrrole rings are designated A, B, C, and D. At the periphery of the tetrapyrrole, there are eight sites where side chains may be located. Positions 1 and 2 are on the A ring, 3 and 4 on the B ring, and so forth. The four bridge carbons (methene groups) are designated a, ß, ?, and d. Thus, protoporphyrin IX may be described as 1,3,5,8 methyl, 2,4-vinyl-6,7, propionic acid–porphyrin, or porphine. Porphine, the so-called parent compound, is a hypothetical tetrapyrrole with only hydrogen atoms at the eight peripheral positions.

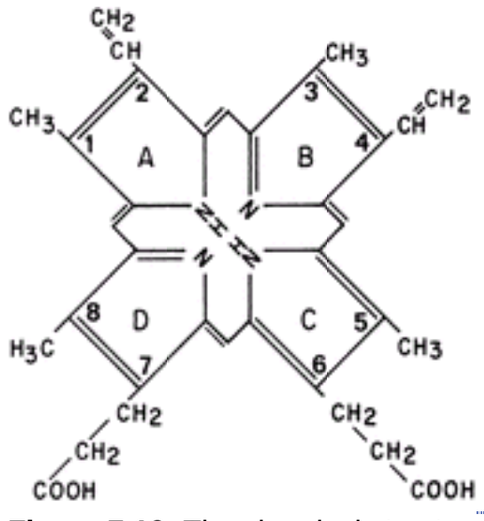

Figure 7.10. The chemical structure of protoporphyrin IX.

The designation *protoporphyrin IX* arises from the fact that, of the 15 possible isomers of protoporphyrin, the ninth one that Hans Fischer (who developed the foundations of porphyrin chemistry) and his co-workers synthesized was the same as the protoporphyrin that they prepared from heme. The IX isomer is the only one found in nature.

Porphyrins, by definition, are cyclicly conjugated tetrapyrroles. As such, they have a number of common properties. They are very stable, essentially flat molecules. The macrocyclic ring itself has little or no affinity for water. Porphyrins might be compared to phonograph records—both are flat, have a hole in the middle, and tend to stack and stick together. In the case of phonograph records, the sticking together is largely electrostatic; in stacked porphyrins, the attractive forces are the consequence of p bonding (interchange of p electrons) as well as van der Waals forces.

All porphyrins are intensely colored and have many common light absorption characteristics. All have an extremely intense absorption band at approximately 400 nm, the so-called Soret band. In addition, they all have four absorption bands in the visible region of the spectrum. All porphyrins fluoresce, but fluorescence is characteristically lost when metals are bound to form metalloporphyrins. Exceptions include Mg-porphyrins and Zn-porphyrins, which fluoresce despite their metal content (Chapter 44).

Of all the known porphyrins only five are of importance in human physiology and pathophysiology: uroporphyrin (two isomers), coproporphyrin (two isomers), and protoporphyrin (one isomer).

If, under appropriate conditions, a porphyrin is reduced to the fullest extent (e.g., with sodium amalgam or sodium borohydride), a total of six hydrogen atoms are added to the molecule—four to the bridge carbon positions and two to the pyrroline rings. (Compare the structures of protoporphyrinogen III and protoporphyrin IX in Figure 7.11.) The fully reduced compounds are called porphyrinogens. They are colorless, do not fluoresce, cannot bind metal ions, and are extremely unstable with regard to oxidation. Only the fully reduced compounds, uroporphyrinogen and coproporphyrinogen, are true intermediates in heme biosynthesis. Once these porphyrinogens are oxidized to their corresponding porphyrins, they can no longer function as substrates for the heme biosynthetic enzymes and must eventually be excreted in the urine and stool.

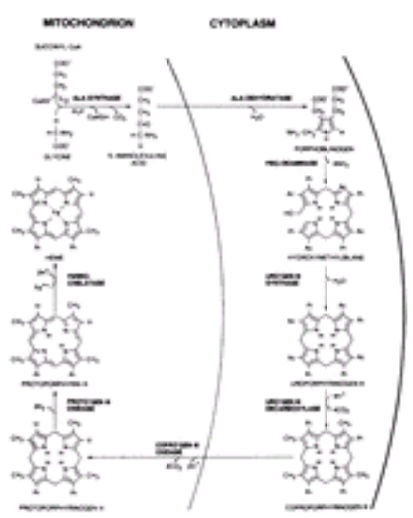

Figure 7.11. Heme biosynthetic pathway. Ac, acetate; ALA, d-aminolev-ulinic acid; CoA, coenzyme A; CoAS, succinyl-CoA; CoASH, uncombined coenzyme A; COPRO'GEN, coproporphyrinogen; PBG, porphobilinogen; PLP, pyridoxal 5'-phosphate; Pr, propionate; PROTO'GEN, protoporphyrinogen; URO'GEN, uroporphyrinogen; Vi, vinyl. (Modified from Bottomley SS, Eberhard Muller U. Pathophysiology of heme synthesis. Semin Hematol 1988;25:282.)

Uroporphyrinogen and coproporphyrinogen can occur in four isomeric forms. Of these, only two are known to occur naturally in mammalian tissues, namely, the I and III isomer forms. Without exception, all biologically functional tetrapyrroles are derived from uroporphyrinogen III. Uroporphyrinogen I and coproporphyrinogen I are useless by-products of heme synthesis. They are biologic anomalies and can be thought of as biochemical mistakes (see Chapter 31). Once formed, most uroporphyrinogen I is enzymically decarboxylated to coproporphyrinogen I and excreted as the oxidized compound, coproporphyrin I.

The difference between the type I and type III isomers is apparent on examination of the D ring. In the type I isomer, the 7 and 8 positions are occupied by acetate and propionate, respectively (as are positions 1 and 2, 3 and 4, and 5 and 6). In the type III isomer, the order in the D ring is reversed, and propionate and acetate are at positions 7 and 8, respectively. In the case of protoporphyrin IX, propionate is at position 7, and position 8 is occupied by a methyl group derived from the decarboxylation of an acetate group.

The first committed step in the biosynthesis of heme (Fig. 7.11) is the condensation of glycine and succinyl coenzyme A to yield d-aminolevulinic acid (ALA). This reaction is highly exergonic, because it involves the cleavage of the thio-ester bond of succinyl coenzyme A and is essentially irreversible. These features suggest that the enzyme catalyzing this reaction (ALA synthase) plays a key regulatory role in the biosynthesis of heme. Indeed, considerable experimental evidence supports this contention.

In the next reaction, two molecules of ALA undergo condensation, catalyzed by the enzyme ALA dehydrase or dehydratase, to yield the monopyrrole porphobilinogen with the concomitant loss of two molecules of water. This is the only known biologic reaction in which two identical molecules combine in such a way that the product is not simply a dimer but a distinctly different molecule. The product, porphobilinogen, is the primary building block for all natural tetrapyrroles, including the hemes, the chlorophylls, and the vitamin B_{12} derivatives (cobalamins).

The third reaction occurs in the presence of a pair of enzymes acting in concert (uroporphyrinogen I synthase or porphobilinogen deaminase and uroporphyrinogen III cosynthase or uroporphyrin III synthase). Four molecules of porphobilinogen condense to yield first an intermediate compound called *hydroxymethylbilane* (HMB), which, under the action of uroporphyrin III synthase, is rapidly converted to the first macrocyclic precursor of all tetrapyrroles, uroporphyrinogen III.

While remaining fully reduced, uroporphyrinogen III then undergoes a series of four decarboxylation steps catalyzed by the enzyme uroporphyrinogen decarboxylase. All four acetate side chains are sequentially decarboxylated at positions 1, 3, 5, and 8, yielding in turn CO_2 and methyl groups. All of the intermediate decarboxylation products have been isolated and identified. The final product of this series of decarboxylation reactions is coproporphyrinogen III, again a fully reduced tetrapyrrole.

Coproporphyrinogen III is transported by an unknown mechanism from the cytosol into the mitochondrion for the three subsequent reactions that yield heme. First, the propionic acid side chains at positions 2 and 4 are oxidatively decarboxylated by the enzyme coproporphyrinogen oxidase, resulting in the formation of vinyl groups. The product of this reaction is protoporphyrinogen IX. Protoporphyrinogen IX undergoes spontaneous oxidation to protoporphyrin *in vitro*, but, *in vivo*, an enzyme, protoporphyrinogen IX oxidase, is required to catalyze this reaction.

Protoporphyrin IX next combines with ferrous iron to yield the final product, the metalloporphyrin ferrous-protoporphyrin IX (heme). This reaction is catalyzed by the enzyme ferrochelatase or heme synthase.

BIOSYNTHESIS OF d-AMINOLEVULINIC ACID The first committed precursor of protoporphyrin IX is an aminoketone, ALA ([110]). Isotopic labeling studies demonstrated that the precursors of ALA are succinyl-coenzyme A (CoA) and glycine ([111]). Succinyl-CoA is generated mainly by the oxidative decarboxylation of a-ketoglutarate in the citric acid cycle. The direct formation of ALA from succinyl-CoA and glycine was first demonstrated in avian erythrocytes and in photosynthetic bacteria ([112] , [113]). The enzyme responsible for catalyzing the condensation of succinyl-CoA and glycine is ALA synthase (EC 2.3.1.37). The products of the condensation reaction are ALA, CO_2, and uncombined CoA. That pyridoxal phosphate is a cofactor in the reaction was first suggested by nutritional studies in pigs ([114]). Subsequently, the specific defect in heme biosynthesis caused by pyridoxine deficiency was demonstrated ([115] , [116]). The deficient synthesis of heme from glycine in erythrocytes from pyridoxine-deficient animals was corrected by the addition of pyridoxal phosphate ([116]), whereas the synthesis of heme from exogenously supplied ALA was normal in the pyridoxine-deficient cell and was unaffected by the addition of pyridoxal phosphate ([116]). In mammalian cells, ALA synthase first appears in the cytosol where it is synthesized on polyribosomes ([117]). The enzyme is then transported by an unknown mechanism to its functional site inside the mitochondria. In the process, the enzyme is modified so that the apparent MW of the mitochondrial enzyme is much less than that of the cytosol enzyme. The cytosol enzyme is probably a precursor of the mitochondrial enzyme and either is multimeric or exists in association with other proteins ([118]). The genes encoding for human ALA synthase have been identified and cloned ([119]). There are two forms of this enzyme, one specific for erythroid cells and the other present in all other tissues. The erythroid-specific enzyme is encoded by a gene present in chromosome X, whereas the nonerythroid form of the enzyme is encoded by a gene on chromosome 3 ([120] , [121]). An alternative way of generating ALA similar to one found in plants may exist in mammals. Plants form ALA directly from a five-carbon precursor by a transamination reaction ([102] , [122]) starting with a-ketoglutaric acid. This reaction is not confined to plants because an enzyme catalyzing such a transamination has been found in mammalian liver, as well as in plants, algae, and bacteria. The mammalian enzyme, alanine-dioxovalerate aminotransferase, has been highly purified from mitochondria ([102]). The capacity of this enzyme to form ALA is far greater than that of ALA synthase from the same mitochondria, but its physiologic significance in mammals remains unknown.

BIOSYNTHESIS OF PORPHOBILINOGEN The monopyrrole porphobilinogen is well established as a precursor of the hemes, the chlorophylls, and the cobalamins ([123]). Because all known forms of life require at least one of these classes of tetrapyrroles, it follows that porphobilinogen is biologically ubiquitous. Porphobilinogen is formed by the condensation of two molecules of ALA and the loss of two water molecules. The enzyme that catalyzes this reaction is ALA dehydrase (EC 4.2.1.24). Throughout the animal kingdom, ALA dehydrase is a soluble enzyme found in the cytosol ([105]). It is abundant in tissues such as bone marrow and liver where heme biosynthesis is active. It is also active in mature, circulating erythrocytes, even though these cells are not actively synthesizing heme. Its persistence results from the enzyme's inherent stability. It is inhibited by heavy metals, particularly lead, and under properly controlled conditions can serve as an index of environmental pollution by lead ([124] , [125]). The mammalian enzyme is an octamer of 31-kd subunits containing eight atoms of zinc required for stability and activity ([120]). Free sulfhydryl groups (-SH) are also essential for activity of ALA dehydrase from all sources ([118] , [126]), and these -SH groups seem to be protected by the zinc. Three isoforms of this enzyme have been reported, and the gene encoding for the enzyme has been identified and located on chromosome 9 ([127] , [128]). The quantity of enzyme present in most organisms greatly exceeds the amount needed by the organism to synthesize ALA ([108]). Thus, it would appear not to play a regulatory role in heme synthesis. However, several of the characteristics of ALA dehydrase are similar to those “expected” of regulatory enzymes. It is, for instance, inhibited by heme ([105] , [129]), and its kinetic properties suggest that the binding of the first molecule of ALA to the enzyme surface influences the affinity of the enzyme for the second molecule of ALA ([130]).

BIOSYNTHESIS OF UROPORPHYRINOGENS I AND III Porphobilinogen is a rather unstable, chemically reactive molecule. Within a few hours, a solution of porphobilinogen exposed to air and light develops a deep orange-red color. The color results from the formation of porphobilin, a poorly defined mixture of mono-, di-, and tripyrrolic oxidation products ([105]). This phenomenon can be observed in the urine of patients with acute intermittent porphyria, who excrete large quantities of porphobilinogen (Chapter 31). If porphobilinogen is incubated in solution at an acid pH, nonenzymic condensation occurs and uroporphyrinogen is formed ([105]). All four possible isomers of uroporphyrinogen are formed under these conditions. The reaction is often referred to as a “head-to-tail” condensation because of the apparent orientation of the precursor molecules. The penultimate reaction product apparently is an open-chain tetrapyrrole called *HMB*. On loss of the amino group attached to ring A, the $-CH_2^+$ can attack the free a-position on the D-ring pyrrole, thus forming the tetrapyrrole macrocycle. *In vivo* at neutral pH, this series of reactions is catalyzed by the cytosolic enzyme HMB synthase, formerly known as *uroporphyrinogen I synthase* or *porphobilinogen deaminase* (EC 4.3.1.8.). Two tissue-specific isoenzymes have been reported for HMB synthase, an erythroid tissue–specific and a nonerythroid form, both of which are products of a single gene located on chromosome 11q23 ([105] , [131] , [132] and [133]). *In vivo*, however, this enzyme works in concert with a second enzyme, uroporphyrinogen III cosynthase ([134]), to form uroporphyrinogen III, the precursor of all known functional tetrapyrroles. The molecular mechanism by which uroporphyrinogen III cosynthase effects the “turning around” of the D ring has been studied intensively ([105] , [135] , [136]). Uroporphyrinogen III cosynthase does not actually isomerize uroporphyrinogen I: The cosynthase does not use uroporphyrinogen I as a substrate nor does it use porphobilinogen. The molecular mechanism involved in this reaction has been clarified by nuclear magnetic resonance spectroscopy ([123] , [135] , [136] , [137] and [138]). Studies involving this technique have made it apparent that HMB synthase first catalyzes the head-to-tail condensation of four porphobilinogen molecules, yielding the aminomethyl tetrapyrrole. The tetrapyr-role is then deaminated, yielding a macrocycle that has been termed *preuroporphyrinogen* ([137] , [138]). Two structures for preuroporphyrinogen have been proposed ([137] , [139]). Filtration experiments have shown that preuroporphyrinogen is released from the surface of uroporphyrinogen I synthase and serves as the substrate for uroporphyrinogen III cosynthase ([138]). The cosynthase opens the bond linking the methylene bridge carbon to the D ring, allowing the D ring to rate 180 degrees about the carbon-nitrogen bond linking rings A and D. A new carbon-carbon bond is formed linking rings C and D (1,3-sigmatropic shift). The carbon-nitrogen bond then opens, and a new carbon-carbon bond is formed linking rings A and D (1,5-sigmatropic shift) and yielding uroporphyrinogen III ([138]).

BIOSYNTHESIS OF COPROPORPHYRINOGEN III The formation of coproporphyrinogen III is accomplished by the enzymic decarboxylation of the four acetic acid side chains of uroporphyrinogen III ([106] , [140]), a reaction catalyzed by what has been assumed to be a single cytosolic enzyme, uroporphyrinogen decarboxylase (EC 4.1.1.37). The decarboxylation proceeds in a clockwise fashion, starting with the acetic acid on the D ring of uroporphyrinogen III and continuing with the successive decarboxylations of the acetic acid residues on rings A, B, and C ([141]). The precise definition of the substrate for the enzyme, as well as for the reaction product, remains unsettled. Partially decarboxylated porphyrins containing seven, six, and five carboxyl groups are demonstrable in small amounts in both the urine and feces of humans. All of these partially decarboxylated porphyrinogens also can serve as substrates for uroporphyrinogen decarboxylase ([141]). Although uroporphyrinogen I and uroporphyrinogen III appear to be used equally well as substrates ([142] , [143] , [144] and [145]), there does appear to be isomer preference for the 7-carboxyl substrate (the I isomer is the preferred) ([144] , [146]) and the 5-carboxyl substrate (the III isomer is the preferred) ([112]). Multiple “substrates” and multiple “reaction products” suggest that multiple enzymes may be involved in the four decarboxylation steps. However, studies with purified preparations of uroporphyrinogen decarboxylase have shown that this enzyme catalyzes all four decarboxylations ([145] , [147] , [148] , [149] and [150]).

BIOSYNTHESIS OF PROTOPORPHYRINOGEN IX The formation of protoporphyrinogen IX from coproporphyrinogen III is catalyzed by the enzyme coproporphyrinogen oxidase, a mitochondrial enzyme distributed in two fractions, a major fraction in the intermembrane space and a minor one in the inter-membrane-matrix complex ([151]). This enzyme has an absolute requirement for molecular oxygen ([152] , [153]). It sequentially and oxidatively decarboxylates the propionic acid side chains in rings A and B of coproporphyrinogen III to form vinyl groups ([154]). At the same time, the propionic acid groups in pyrrole rings C and D are not decarboxylated. It has been assumed that they are essential for binding of the substrate to coproporphyrinogen oxidase ([118]), but more recent studies make this assumption unlikely ([155]). For coproporphyrinogen III to be metabolized, it must cross the outer mitochondrial membrane. It is not known if crossing the membrane is the result of a passive transfer or an energy-requiring step.

BIOSYNTHESIS OF PROTOPORPHYRIN IX The product of the coproporphyrinogen III oxidase reaction is protoporphyrinogen IX. To serve as a substrate for the final enzyme in the pathway, heme synthase (ferrochelatase), protoporphyrinogen IX must first be oxidized to protoporphyrin IX, the only time in the heme biosynthetic pathway that the oxidized porphyrin serves as substrate. Although protoporphyrinogen IX is easily oxidized nonenzymatically to protoporphyrin *in vitro*, an enzyme is required to catalyze this reaction *in vivo*. A membrane-associated, mitochondrial, oxidizing enzyme—protoporphyrinogen IX oxidase—was first found in yeast ([156]) and later was demonstrated in mammalian cells, including rat liver, human fibroblasts, reticulocytes, and leukocytes ([157]). The enzyme is heat labile and is inactivated by proteolytic digestion.

BIOSYNTHESIS OF HEME The insertion of ferrous iron into protoporphyrin IX to form heme is catalyzed by the enzyme heme synthase (ferrochelatase, protoheme ferrolyase, EC 4.99.1.1). Heme synthase is either tightly bound to or is an integral part of the inner mitochondrial membrane ([158]). Heme synthase activity has been partially purified from avian erythrocytes ([158] , [159]), human and rat liver ([158] , [160]), rabbit reticulocytes ([161]), human bone marrow ([162]), microorganisms ([163]), and

plant tissues ([164], [165]). Although no cofactors have clearly been demonstrated to be required by heme synthase, a number of studies have suggested a role for pyridoxal-5-phosphate ([166]). It seems clear that the *in vivo* substrates for heme synthase are ferrous iron and protoporphyrin. However, *in vitro*, the enzyme catalyzes the incorporation of several metals (iron, cobalt, and zinc) into several dicarboxylic porphyrins (protoporphyrin, mesoporphyrin, and deuteroporphyrin) ([105]). Under strictly anaerobic conditions, the ferrous iron–protoporphyrin chelate can be formed nonenzymatically ([156], [167]). This finding has led to the speculation that nonenzymic formation of heme may occur *in vivo*, but most evidence supports a catalytic role for the enzyme heme synthase. In addition, there is evidence that heme synthase may play a regulatory role in the biosynthesis of heme.

REGULATION OF THE HEME BIOSYNTHETIC PATHWAY

d-Aminolevulinic Acid Synthase The regulation of a biosynthetic pathway is generally effected at the first enzymic reaction synthesizing a precursor compound committed to ultimate incorporation into the final product ([168]). Frequently, such reactions are strongly exergonic and essentially irreversible. These generalizations hold true for the heme biosynthetic pathway. Control of the pathway is exerted through ALA synthase. The amount of ALA synthase present is regulated by induction and repression of enzyme synthesis ([118]). In higher organisms, this enzyme has a short half-life, allowing a rapid response to changes in the demand for heme and, thus, ALA ([169]). Most studies involving the induction of mammalian ALA synthase have used hepatic tissue as the source of the enzyme, but ALA synthase has also been shown to be inducible in Friend leukemic cells ([170], [171]), adrenal gland ([172]), kidney ([173], [174]), and bone marrow ([175]). Hepatic ALA synthase may be induced by a number of chemicals, drugs, and nonglucocorticoid steroids ([118]). The amount of enzyme may increase by a factor as great as 300 ([176]). Conclusive immunochemical data have demonstrated that inducing agents do not merely increase the activity of preformed ALA synthase; rather, they bring about an increase in the absolute amount of enzyme ([177]). Compounds that inhibit protein synthesis block the expected effects of inducing agents ([161], [178]). In erythroid cells, however, the erythroid-specific dALA synthase is constitutively produced at such high levels that this step in heme synthesis does not seem to be rate-limiting, and enzymes involved in later steps of the heme biosynthetic pathway may play a more important regulatory role ([179]). Heme plays a critical central role in the regulation of ALA synthase activity. Heme directly inhibits the catalytic activity of the preformed enzyme in a classic example of negative feedback inhibition ([140], [180]). In addition, the concentration of heme within the cell appears to regulate the synthesis of this enzyme ([181]). When the amount of heme is high, new synthesis of the enzyme is repressed. When the amount of heme is low, new synthesis of the enzyme is induced. Thus, agents that interfere with the synthesis of heme can lead to the induction of ALA synthase, and agents that induce the synthesis of hemoproteins can produce a similar effect ([182], [183]). Agents that exert these effects on the induction of ALA synthase are clinically important, for they can precipitate acute attacks in patients with acute intermittent porphyria and other closely related disorders of porphyrin metabolism (Chapter 31).

Secondary Control Mechanisms The regulation of heme biosynthesis appears to be sufficiently important in nature that additional control points have been incorporated during the process of evolution. Although the actual *in vivo* importance of the several secondary control mechanisms has not been fully established, available evidence suggests that they may play some role.

d-Aminolevulinic Acid Dehydrase ALA dehydrase from many species is inhibited by heme ([184]). When ALA synthase is present in excess, ALA dehydrase becomes the regulatory enzyme in the heme biosynthetic pathway. The demonstration of an alternative route for the synthesis of ALA (see above) indicates consistency in nature, because control points come after rather than before “committed” compounds are formed.

Uroporphyrinogen I Synthase Uroporphyrinogen I synthase, partially purified from human erythrocytes, consumes porphobilinogen and forms uroporphyrinogen I in accordance with classic Michaelis-Menten kinetics. The addition of uroporphyrinogen III cosynthase increases the affinity for the substrate of the dual enzymatic system, but the maximum velocity of the reaction leading to the synthesis of uroporphyrinogen III is decreased ([136]). The changes in affinity for the substrate of the dual enzyme system suggest that a conformational modification of uroporphyrinogen I synthase is produced on its association with the cosynthase ([185]). These findings, coupled with studies using crude liver homogenates, suggest that enhanced porphyrin synthesis from porphobilinogen occurs when cosynthase is inactivated ([186]). Thus, the activity of uroporphyrinogen I synthase increases when the activity of the cosynthase decreases. The mechanism of this regulatory effect of cosynthase on uroporphyrinogen I synthase is unknown.

Heme Synthase This enzyme also exhibits characteristics suggesting that it may play a regulatory role in heme biosynthesis. Heme synthase is subject to both substrate inhibition by protoporphyrin IX ([187]) and feedback inhibition by heme ([188]). Heme synthase can also be induced by several agents ([189], [190]). Finally, studies using Friend leukemia cells ([171]) and cultured human skin fibroblasts ([191]) have suggested a rate-limiting step in the formation of heme at the level of heme synthase.

CONTROL OF ERYTHROPOIESIS

It is evident that a well-balanced mechanism exists that maintains the erythron within “normal” limits and mediates the response to a variety of normal and abnormal situations. In broad outlines, this control system operates in the following manner. Alterations in the concentration of hemoglobin in the blood lead to changes in tissue oxygen tension within the kidney. In response to hypoxia, the kidney secretes a hormone called *EPO*. This hormone induces erythroid progenitor cells to differentiate into pronormoblasts, thereby bringing about expansion of the erythroid marrow and an increase in red cell production. This, in turn, leads to an increase in the size of the erythron and an increase in tissue oxygen levels. Each of the major steps in this process is discussed in greater detail in the sections that follow.

Tissue Oxygen

Tissue oxygen tension depends on the relative rates of oxygen supply and demand. Oxygen supply is a complex function of interacting but semiindependent variables, including (a) blood flow, (b) blood hemoglobin concentration, (c) hemoglobin oxygen saturation, and (d) hemoglobin oxygen affinity. Each of these functions may be altered to compensate for a deficiency in one of the others. For example, in severe anemia, cardiac output and respiratory rate may increase, and hemoglobin oxygen affinity may be reduced through the 2,3-diphosphoglycerate effect. Conversely, in respiratory insufficiency, secondary polycythemia occurs.

Despite the influence of cardiovascular and respiratory adjustments, tissue oxygen tension decreases roughly in proportion to the degree of anemia. Conversely, induced polycythemia of moderate degree leads to normal or increased tissue oxygen tension and to increased tolerance to hypoxia. These changes occur despite the increase in blood viscosity that accompanies polycythemia, suggesting that peripheral vascular resistance decreases to compensate for increased viscosity. However, with advanced degrees of polycythemia, the increase in viscosity may be great enough to negate the advantages of increased oxygen-carrying capacity.

Tissue hypoxia is the fundamental stimulus to erythropoiesis, as was first suggested by Miescher in 1893. This concept has been amply confirmed ([1]). However, it now seems clear that hypoxia does not exert its effects by a direct action on the marrow, as Miescher believed, but instead acts by inducing the elaboration of a hormone, EPO. The nature of the tissue oxygen receptors has been recently described (see Site and Regulation of Erythropoietin Production. These receptors are located within the kidney because production of EPO can be induced by renal artery constriction or by hypoxic perfusion of the isolated kidney.

Erythropoietin

STRUCTURE OF ERYTHROPOIETIN EPO is a glycoprotein hormone produced by the kidney, and it is the major humoral regulator of red cell production. EPO was originally purified from the urine of patients with aplastic anemia ([192]). It has an MW of 34,000 daltons as determined electrophoretically and contains 30% carbohydrate, of which 11% consists of sialic acid, 11% total hexose, and 8% *N*-acetylglucosamine ([193]). The potency of EPO is expressed in units, with one unit being equal to the amount of EPO present in one-tenth of the International Reference Preparation ([194]). This unit had been originally defined as the amount of EPO that produced in the starved rat the same erythropoietic response (increase in serum EPO level) as 5 µmol of cobalt ([1]). The potency of the purified human urinary EPO has been determined to be 70,400 U/mg of protein or 50,000 U/mg of total weight ([192]). Purification of human urinary EPO has allowed the isolation and cloning of the human genomic DNA encoding for human EPO ([195]). The gene encoding EPO has been localized on human chromosome 7 (7 pter-q22) ([196]). The EPO gene exists as a single copy in a 5.4-kb DNA fragment and contains four introns and five exons for the 193–amino acid polypeptide ([195]). The gene also includes a 27–amino acid signal peptide (leader sequence), which is cleared during EPO secretion, and a 166–amino acid peptide with an MW of 18,398 ([195]). The *C*-terminal arginine is absent from both recombinant and natural hormone, presumably because of posttranslational modification by a carboxypeptidase ([197]). The human EPO contains four cysteine residues linked by disulfide bonds, which, when reduced or alkylated, lead to significant loss of activity ([198], [199]). Recombinant EPO synthesized by mammalian cells is highly glycosylated, and the carbohydrate structure of the recombinant hormone is similar to but distinct from that of the natural hormone ([197]). Recombinant EPO has an MW of 30,000 by velocity sedimentation ([200]) and contains approximately 39% carbohydrate ([201]); however, recombinant EPO migrates slightly slower on sodium dodecyl sulfate–electrophoresis than urinary EPO, which suggests a slightly higher apparent MW of 40,000 compared to an MW of 34,000 of the native urinary EPO ([202]). The discrepancy between the electrophoretically obtained apparent MWs of natural and recombinant hormone is almost certainly due to distinctly different glycosylation of recombinant EPO in the Chinese hamster ovary cell line compared to the glycosylation of native EPO in kidney cells. Recombinant EPO must have additional carbohydrate, less negatively charged carbohydrates, or both compared to urinary EPO to result in reduced electrophoretic mobility. Glycosylation of the hormonal peptide is absolutely necessary for its *in vivo* activity. The bulk of glycosylation of EPO is at a single site of *N*-linked carbohydrate. Asialated EPO and non-glycosylated recombinant EPO produced in bacteria have no activity *in vivo*, which can be at least partially attributed

to rapid clearance of the hormone by the liver via the galactose receptors of hepatic cells ([200], [203]). The importance of glycosylation of EPO to EPO's *in vivo* activity and half-life led to modification of the EPO gene/protein to make a more effective pharmaceutical. The gene coding for EPO was modified by adding a second site of *N*-linked gly-cosylation, such that when the gene is expressed in Chinese hamster ovary cells, the amount of carbohydrate attached to the modified EPO peptide is almost doubled. The new product was called *darbepoetin* or *novel erythroid-stimulating protein*. Darbepoetin is highly related to EPO, such that it binds to the same receptor, but it has a longer *in vivo* half-life than recombinant EPO so that fewer injections/week than recombinant EPO are required for therapeutic use ([204]). Studies on the amino acid sequences of human and murine EPO have shown a very high degree of conservation of the molecule structure in these two species ([205], [206]). Which part(s) of the EPO molecule is primarily responsible for its function is not known, although results of studies with monoclonal antibodies have indicated that the amino acids in positions 99 to 129 may play an important role in the binding of EPO to cell membrane ([207]).

SITE AND REGULATION OF ERYTHROPOIETIN PRODUCTION Almost 50 years ago, Jacobson et al. established that the kidney is the major organ of EPO production in adult rats ([208]). Also, humans with end-stage renal failure were found to have low serum EPO concentrations, which were restored to normal after successful renal transplantation ([209]). The cloning of the murine EPO gene has allowed studies on the production of EPO-specific mRNA in anemic mice. Induction of anemia leads, within 1 hour, to the appearance of EPO-encoding mRNA in the kidney and liver of anemic mice and rats ([210], [211]). After bleeding, the EPO-mRNA in the kidney increases 500 to 1000 times compared to normal kidney, whereas the liver produces only 7% of the total EPO-mRNA ([211]). In no tissue other than the kidneys and the liver is EPO-mRNA detectable, even in the presence of severe anemia ([211]). These changes in EPO-mRNA were followed by parallel changes in serum EPO concentration determined by radioimmunoassay, indicating that EPO production in response to anemia represents *de novo* synthesis rather than release of preformed hormone ([212]). More recent evidence indicates that the anemia-induced increase in EPO-mRNA is at least partially due to an increased transcription ([213]). Murine EPO-mRNA was detected by ribonuclease protection assay at 14 days of gestation in the liver and almost a week later in the kidneys, which assume a major role in EPO production after birth ([214]). In cases of paraneoplastic erythrocytosis, EPO-mRNA has been detected in the neoplastic cells ([215], [216]). Specialized cells producing EPO have been identified in renal and hepatic parenchyma by the technique of *in situ* hybridization using radioactive probes specific for EPO-mRNA (Fig. 7.12) ([217], [218] and [219]). These rare EPO-producing cells are found in the interstitium of the renal parenchyma, outside the tubular basement membrane, mostly in the inner cortex and outer medulla. The nature of these intestinal peritubular EPO-producing cells remains controversial; however, the bulk of experimental evidence indicates that these cells are fibroblastlike type I interstitial cells ([220], [221]). In liver, mRNA is detected in hepatocytes. The number of the interstitial renal EPO-producing cells increases in response to anemia, indicating that increased demands for EPO are met by an increase in the number of EPO-producing cells rather than by an increased synthesis of EPO by a preset number of cells ([212]). Thus, it appears that EPO is synthesized *de novo* in response to hypoxia and that there is no detectable storage of the hormone. Increased levels of circulating EPO do not seem to exert any negative effect on EPO production.

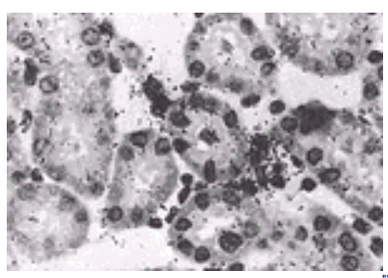

Figure 7.12. *In situ* hybridization of murine kidney using a probe specific for murine EPO-mRNA. EPO-producing cells are found in the interstitium, covered heavily with grains. Arrows indicate peritubular interstitial cells not producing EPO. (Courtesy of Dr. Stephen Koury.)

The mechanism by which hypoxia leads to EPO synthesis has only recently been understood. Results of several studies have shown that the EPO gene contains sequences that are oxygen sensitive and are involved in the regulation of EPO gene expression ([222]). By the use of plasmid constructs, transgenic mice, and cell transfection, it has been shown that these oxygen-sensitive sequences, located at the region flanking the 3' end of the EPO gene, can confer to cells the ability to respond to hypoxia by an increase of the protein encoded by the reporter gene ([223]). In the same area of the EPO gene, an enhancer has been identified with sequences suggesting that it belongs to the family of the nuclear hormone receptor superfamily ([224]). The ligand for this oxygen-sensitive enhancer was identified as a protein of 120 kd termed *hypoxia inducible factor 1* (HIF-1) ([225], [226] and [227]). This DNA-binding protein is tightly regulated by the oxygen tension and is considered to be the physiologic regulator of EPO transcription ([228]). HIFs are heterodimeric, helix-loop-helix, transcription factors consisting of two subunits, HIF-1a and HIF-1ß. The concentration and transcriptional activity of HIF-1a increase in a geometric fashion on exposure to hypoxia. In addition to EPO, a large number of genes (glucose transporters, glycolytic enzymes, vascular endothelial growth factors, and many others) are activated during hypoxia to aid the cell in adapting to hypoxic conditions ([229]). HIF-1a is constitutively expressed under normoxic conditions, but it is rapidly degraded via the ubiquitin proteosome complex after it is tagged with the protein of von Hippel-Lindau. Binding of the protein of von Hippel-Lindau to HIF-1a requires hydroxylation of the latter by a proline hydroxylase ([230], [231], [232] and [233]). Prolylhydroxylase is an oxygen- and iron-dependent enzyme. Under hypoxic condition, little or no proline hydroxylation takes place; thus, the protein of von Hippel-Lindau does not bind to HIF-1a, which accumulates, heterodimerizes with HIF-ß, and recruits the p300/CREB-binding protein transcriptional coactivator, and the whole complex binds to EPO enhancer to promote EPO gene transcription. Recruitment of p300 is inhibited by asparagine hydroxylation that is catalyzed by an oxygen-sensitive asparaginyl-hydroxylase ([234]). It seems that these two amino acid hydroxylases, by their dependence on normal intracellular oxygen for their function, act as the oxygen sensor in the EPO-producing interstitial cells in the kidney, and they regulate the function of HIF-1 at least at two distinct points ([233]).

ACTION OF ERYTHROPOIETIN

Erythropoietin Receptors EPO binds to specific molecules on the cell surface, the EPORs. Expression of both EPO and EPORs is necessary for adult life. Deletion of either the genes that code for EPO or the EPOR in mice results in identical phenotypes of fetal death at day 12 to 13 as a result of severe anemia ([235]). Arguably, the most important control point of erythropoiesis is the interaction of EPO with the receptor for EPO. The activation of the EPOR generates an intracellular signal in immature erythroid cells that promotes the survival of these cells that would otherwise undergo apoptosis. EPO may also promote proliferation. A direct instructive effect of EPO on either primitive hematopoietic cells or mature erythroid cells to direct differentiation is not supported by most data. Specific EPORs are expressed on hematopoietic cells that respond to EPO and have been identified on human ([21]) and murine erythroid cells ([236]), erythroleukemic cell lines ([237]), fetal liver tissue rich in erythroid elements, in mouse and rat placenta ([238], [239]), and in megakaryocytes ([240], [241]). The density of EPORs on erythroid cells is relatively small (approximately 1000 molecules/cell) and varies correlating with the cell's responsiveness to and dependence on EPO ([241]). EPORs are detectable by autoradiography on human BFU-Es; their density increases as the BFU-E matures to CFU-E ([27]). Erythroid cells at a stage between CFU-E and proerythroblast seem to have the highest density of EPORs, which decrease as the proerythroblast matures and eventually disappear at the stage of orthochromatic erythroblast ([27], [236]). EPORs are not expressed on reticulocytes or red cells. Whereas functional EPORs were detected in mouse and rat placenta ([238], [239]), these placental EPORs apparently cannot function to transport significant amounts of EPO from the maternal circulation to the circulation of the fetus. The deletion of the EPO gene in a mouse fetus results in severe anemia and death at days 12 to 13 postinception ([235]). If sufficient EPO from the mother were transported across the placenta to the fetus, one would expect normal birth of the mice missing the EPO gene (EPO–/–) but death by anemia shortly afterward. Thus, the fetal death of EPO–/– mice proves that fetal EPO production is necessary for survival. The detection of receptors for EPO in megakaryocytes ([240], [241]) is understandable because EPO concentration can affect platelet levels. In contrast, the physiologic significance of the presence of receptors for EPO in neurons, the kidneys, endothelial cells, embryonic muscles, and breast cancer cells is not yet established. Receptors for EPO may be required for normal embryonic development of the brain because the brains from day 12–EPOR–/– mice are abnormal ([242]). Cloning of murine erythroleukemia EPOR gene revealed a DNA sequence encoding a 507–amino acid peptide of 62 kd with a single membrane–spanning domain in a direction such that the amino-terminal site is located extracellularly and the carboxy-terminal site is located intracytoplasmically ([243]). The EPOR has undergone glycosylation and phosphorylation before being incorporated into the cell membrane as a 70- to 78-kd protein ([243]). Cells transfected with this gene express both high- and low-affinity EPORs ([243]). The human EPOR gene has been localized in the long arm of chromosome 19 ([244]). After the cloning of the EPOR gene, other receptor genes were cloned that were similar in sequence, such that it is now recognized that the EPOR is related to a large family of receptors, the hematopoietic receptor superfamily, that includes receptors from interleukins 2 through 9, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor, and receptors for other factors such as growth hormone and prolactin that do not modulate hematopoietic cells ([245]). After binding of EPO to its receptor, the hormone is rapidly endocytosed and degraded ([241], [246]). Whether the receptor is also degraded or recycles to the membrane is not known, although experimental evidence favors degradation ([237]). Crystallographic studies confirm that, as is the case for other members of the hematopoietic superfamily of receptors, one molecule of EPO may simultaneously bind to two receptors for EPO. It is clear that activation of the receptors by the hormone leads to formation of receptor homodimers ([247]); however, evidence suggests that EPOR dimers likely exist even before the binding of EPO. EPO binding shifts and stabilizes an active receptor conformation that brings the two EPORs in closer contact ([248], [249]). Tyrosine phosphorylation of the EPOR ([250]) is the first observable event after EPO binding. Because the EPOR lacks a kinase domain, a tyrosine protein kinase must associate with the receptor. The tyrosine protein kinase JAK2, a member of the Janus family of kinases, is a very likely candidate to be the primary EPOR-associated kinase because it can bind to conserved sequence of amino acids found in cytoplasmic domains of the EPOR ([251], [252]) and other receptors related in a sequence to the receptors for EPO. JAK2 is also implicated as the only significant EPOR-interacting kinase because deletion of the JAK2 kinase gene in mice results in a phenotype of day 12 to 13 fetal death and severe anemia that mirrors the phenotype after either deletion of EPO gene or the gene coding the receptor for EPO ([253]). To summarize the current view of this

research, two EPOR molecules bind to one EPO molecule. JAK2 kinase molecules associated with each receptor are activated by the physical process of bringing the inactive (or low-activity) kinases in close proximity by a shift in receptor conformation, such that these low-activity kinases cross-phosphorylate each other to gain full activity. The activated JAK2 kinase then phosphorylates all eight tyrosine residues of the EPOR cytoplasmic domain. These phosphorylated tyrosine residues of the receptor become docking sites for signaling molecules that may be phosphorylated by JAK2 to become active, such as the signal-transducing activators of transcription (STAT) proteins. STAT1 and STAT5 become phosphorylated, dimerize, and are transported to the nucleus to mediate gene transcription. Alternatively, the translocation of active signaling molecules from the cytoplasm to the plasma membrane via docking to the phosphorylated EPOR activates a signaling cascade. Examples include the translocation of phosphatidylinositol-3-kinase (PI3-kinase) from the cytoplasm to phosphorylate plasma membrane lipids at the cell surface ([254]). Domains of the receptor for EPO, the specific tyrosine residues of the receptor, or both are apparently important in activation of distinctive signaling pathways. For example, tyrosine residue 343 is required for EPO-dependent activation of STAT5 signaling ([255]), whereas the distal end as well as tyrosine residue 479 of the EPOR are required for activation of both PI3-kinase and MAP kinase cascade. The importance of EPOR tyrosine phosphorylation is difficult to reconcile with a study that showed that transgenic mice expressing receptors for EPO without any cytoplasmic tyrosine residues are essentially normal regarding erythropoiesis and hematocrit ([256]). Thus, the tyrosine residues of the receptor for EPO are likely important in more subtle ways than previously believed. This is suggested also by the fact that all eight tyrosines are conserved in both number and alignment between the murine and human EPOR genes. If these residues served no important purpose, one would expect differences in either tyrosine numbers or alignment between the mouse and human genes. The distal end of the EPOR acts as a negative regulatory domain to which tyrosine protein phosphatases dock to phosphorylated tyrosine residues to attenuate EPO signaling. This is suggested by the findings in a transgenic mouse created to express a truncated human receptor EPO, replacing the murine EPOR. This mouse was found to have a severe erythrocytosis, mimicking the disease state noted in humans with polycythemia vera who have elevated red cell mass due to mutations in the negative regulatory domain of the EPOR gene ([257]). The role of the transcription factor, STAT5, in signaling after phosphorylation and activation by binding to the receptor for EPO is controversial. STAT5 is expressed from two very similar genes, STAT5a and STAT5b. In transgenic mice in which both genes for STAT5a and STAT5b were deleted or "knocked-out" (STAT5a/b–/– mice), STAT5a/b was found to be neither essential nor significant for erythropoiesis ([258]). However, other investigators obtained and studied the same STAT5a/b–/– mice and reported a marked fetal anemia in the STAT5–/– mice and lesser but significant anemia in newborn and adult STAT5–/– mice ([259]). Erythropoiesis in STAT5a/b–/– mice was then reexamined by the initial investigators, who reported that the hematocrit was slightly reduced at fetal and newborn stages, but comparison of photographs of the STAT5–/– fetus did not appear to be significantly different from wild-type fetus ([260]). Thus, STAT5 seems to have some role in erythropoiesis, different from the initial conclusion that STAT5 has no effect, but it also plays a less significant role in fetal erythropoiesis than was initially claimed ([259]). EPO is known to weakly activate STAT1 and to strongly activate STAT5 in primary erythroid cells, such that STAT1 activation may partially compensate for STAT5 and explain why deletion of STAT5 in mice results in a relatively mild inhibition of erythropoiesis ([261]). A large body of evidence now shows that both the MAP kinase cascade and PI3-kinase cascade are activated after EPO activation of the EPOR. Although EPO may act to (a) promote the survival of immature progenitors by preventing apoptosis or programmed cell death, (b) drive the proliferation of progenitor cells, and (c) direct the differentiation of progenitor cells along erythroid maturation, it is not clear if some intracellular signaling pathways distinctly activate only one of these events. Some data suggest that the EPO-dependent activation of the MAP kinase pathway is more important in directing proliferation, whereas the PI3-kinase pathway is equally important in survival and proliferation ([254]).

Mechanism of Action EPO is a hormone that promotes erythroid differentiation ([1]). The role of EPO during the very early stages of erythropoiesis is still undefined. Cell lines with features of multipotent hematopoietic progenitor cells ([262] , [263]) and purified human blood BFU-Es ([27]) express a small number of EPORs, suggesting a possible role of EPO for their survival and differentiation. Although, *in vivo*, the BFU-E pool is unaffected by acute changes of the level of serum EPO and BFU-Es are EPO-independent for their survival, they can respond to EPO by increasing their cycling, which is part of the process of erythroid differentiation ([38]). Chronic administration of recombinant EPO to humans with end-stage renal disease results in global stimulation of the bone marrow with an increase in the concentration and cycling of all types of hematopoietic progenitors, but this effect is most likely indirect ([39]). The erythroid cell that is the most sensitive to EPO is a cell between the CFU-E and the proerythroblast ([27] , [236]), and this erythroid cell can be considered the primary target of EPO action. These cells express the highest density of EPORs on their membrane and are absolutely dependent on EPO for their survival ([27] , [264] , [265]). Studies on murine splenic erythroid cells infected with the anemia strain of Friend virus ([266]) have shown that binding of EPO is followed by a series of biochemical events, including increase in Ca^{2+} uptake ([267]), internalization of the hormone ([246]), increase in total RNA synthesis ([268]), glucose and iron uptake ([241]), rate of transcription of the a- and ß-globin gene ([211] , [269]), expression of transferrin receptors ([270]), and eventually increase of hemoglobin synthesis as well as of membrane bands 3 and 4.1 ([265] , [271]). All of these changes result in an increased rate of erythroid differentiation, ending with an increase in the reticulocyte production and an eventual increase in the red cell mass. One of the most impressive effects of EPO on the erythroid cells is the ability of the hormone to maintain the viability of these cells irrespective of any effect on cycling and differentiation ([264] , [265]). In the absence of EPO, erythroid cells die. It has been shown that EPO retards the cleavage of DNA that occurs normally in CFU-Es ([272]). In the absence of EPO, DNA cleavage is rapid and proceeds to cell death. The pattern of rapid DNA cleavage occurring in erythroid cells deprived of EPO is characteristic of cells undergoing apoptosis (programmed cell death) ([272]). In the presence of EPO, cell death is avoided and the erythroid cells are allowed to differentiate and form red cells. These findings suggest that the hormone promotes erythroid differentiation simply by allowing cell survival, which is a prerequisite for both cell proliferation and maturation. This model also suggests that, under normal conditions, a large number of generated CFU-Es are not surviving, but, under conditions of high EPO levels, expansion of the erythroid marrow is seen simply by allowing survival of more CFU-Es, resulting in an increased rate of red cell production. Within the same context, once the red cell mass is restored to normal, the ensuing decrease of EPO levels leads to a rapid turn-off of erythropoiesis by allowing programmed cell death to occur ([272]). The observation that relatively mature erythroid precursor cells continue to develop in fetal mice in which either the gene for EPO or the gene coding for the EPOR has been deleted ([235]) supports the model that EPO acts primarily by promoting survival of more mature erythroid cells and that EPO has no or a less significant role in proliferation of erythroid progenitors or in directing erythroid differentiation of immature hematopoietic cells. These abundant erythroid cells (proerythroblasts near the CFU-E stage of erythroid development) from spleens of either EPO–/– or EPOR–/– mice undergo apoptosis or programmed death unless these spleen cells are either cultured *in vitro* in EPO (EPO–/– mice) or forced by transfection with complementary DNA to express the EPOR (EPOR–/– mice) and then cultured in the presence of EPO. Thus, neither EPO nor receptors for EPO are necessary for the proliferation and differentiation of stem cells and early progenitor cells into relatively mature erythroid cells. Both EPO and the receptors for EPO, however, are absolutely required for erythroid cells to survive the transition from proerythroblasts/CFU-Es to mature erythroblasts, suggesting a clear role of EPO in directing the survival of these cells. In addition to erythroid cells, EPO affects megakaryocytes and their progenitors CFU-MKs. EPO acts as a colony stimulation factor for murine CFU-MK ([273]), whereas, in humans, it potentates the effect of megakaryocyte colony-stimulating factors present in lymphocyte-conditioned medium ([274]). It also promotes the differentiation of murine megakaryocytes ([275]), which express EPORs ([276]), and, when injected at high doses into mice, it increases platelet production ([277]). In patients with end-stage renal disease treated with EPO, a minor increase in the platelet count, averaging approximately 30,000/µl, has been noted ([278]). EPO does not seem to contribute in a significant way to the regulation of platelet counts because anephric patients can maintain a normal platelet count ([278]). Its various effects on megakaryopoiesis and thrombopoiesis may be explained by the extensive homology between EPO and thrombopoietin, the major humoral regulator of platelet mass ([279]).

ASSAYS FOR ERYTHROPOIETIN AND LEVELS IN HEALTH AND DISEASE The presence of EPO in serum, urine, or other body fluids can be detected by bioassays or immunoassays. Historically, EPO was detected by the polycythemic mouse assay in which the serum sample was injected with ^{59}Fe into polycythemic mice and the amount of ^{59}Fe incorporated into newly released red cells was measured ([1] , [280] , [281]). This method has low sensitivity and is affected by factors influencing erythropoiesis *in vivo* that are present in the injected sample. *In vitro* bioassays have been described ([280] , [281]), but none has received wide clinical application. Radioimmunoassays for EPO were developed initially by using purified human urinary EPO as antigen and standard ([282] , [283] , [284] , [285] , [286] and [287]); these have been replaced by purified human recombinant EPO ([284] , [285] and [286]). Using the same principles of immunologic detection of the protein, an enzyme-linked immunosorbent assay was developed, which is commercially available and currently used as the method for determining serum EPO concentrations. The immunoassays have the advantages of being quick, accurate, relatively inexpensive, and capable of quantifying very low EPO levels ordinarily not detectable by bioassays. Normal serum EPO levels, although variable with the type of assay, usually range between 5 and 30 mU/ml. An inverse correlation has been established between the logarithm of serum EPO concentration and the concentration of hemoglobin in the blood ([282] , [285]); however, the magnitude of the increase in the serum EPO concentration in response to anemia is variable among individuals. A disadvantage of the immunoassays is that they detect immunoreactive but not necessarily bioactive hormone. Thus, in renal failure, when serum EPO levels are low or undetectable by bioassays, the immunoassays detect higher levels ([284] , [286] , [287]). The clinical utility of a single serum EPO measurement has not yet been well established. A low value in the presence of anemia, not associated with renal failure, indicates an abnormal response to anemia, but a normal or elevated level of EPO does not allow any firm conclusion as to whether the increase is appropriate for the severity of anemia. A better approach in interpreting serum EPO levels is a comparison of EPO response to various degrees of anemia between groups of patients with anemia of established etiology. Using such an approach, a blunted EPO response has been described in patients with rheumatoid arthritis ([288]), solid and hematopoietic malignancies ([289] , [290]), sickle cell disease ([291]), and acquired immunodeficiency syndrome ([292]) and in premature neonates ([293]). Conflicting results have also been published regarding the use of serum EPO levels in the differential diagnosis of polycythemia ([74] , [294] , [295] and [296]). In the presence of an increased red cell mass, an elevated serum EPO value indicates that the polycythemia is secondary to chronic stimulation of the marrow by the hormone, which excludes the diagnosis of polycythemia vera. A normal value in an individual case of polycythemia, however, cannot rule out secondary polycythemia. In this group of patients with polycythemia, there is such an overlap in serum EPO levels that a single EPO value cannot always distinguish with confidence between polycythemia rubra vera and secondary polycythemia ([295]).

The Mature Erythrocyte

EVOLUTION OF OUR UNDERSTANDING OF THE ERYTHROCYTE

Erythrocytes were first described in the seventeenth century. The Dutch microscopist, Leeuwenhoek, took note of them, as did Malpighi, who mistook them for fat globules “looking like a rosary of red coral.” For many years, erythrocytes were not believed to be of any importance. The presence of iron in blood was demonstrated by Lemery in the seventeenth century, but not until 1851 did Funke isolate hemoglobin in crystalline form. The functional significance of red corpuscles was only appreciated, however, when Hoppe-Seyler demonstrated that hemoglobin has the property of readily taking up and discharging oxygen. This, then, was considered the primary or even sole function of the red cell (along with CO_2 exchange) until the late twentieth century. Now, however, our understanding of erythrocyte function has broadened to include O_2, CO_2, and nitric oxide (NO) exchange as well as immune clearance and, possibly, clearance of other soluble blood components such as cytokines.

STRUCTURAL FEATURES

The uniquely anuclear mature human erythrocyte is one of the most highly specialized of cells. Lacking such cytoplasmic organelles as nucleus, mitochondria, or ribosomes, the red cell is unable to synthesize new protein, carry out the oxidative reactions associated with mitochondria, or undergo mitosis. More than 95% of the cytoplasmic protein is hemoglobin. The remainder includes those enzymes required for energy production and for the maintenance of hemoglobin in a functional, reduced state. However, the erythrocyte expresses a perhaps surprising number of proteins that subserve functions we associate with other cells, including a variety of transport proteins, adhesion molecules, receptors, and signaling pathways. Thus, the red cell is now recognized to perform a number of crucial and complex functions in the human body.

Shape and Dimensions

At rest, the normal human erythrocyte is shaped like a flattened, bilaterally indented sphere, a shape often referred to as a *biconcave disk* (Fig. 8.1). In fixed, stained blood smears, only the flattened surfaces are observed; hence, on fixed blood films, the erythrocyte appears circular, with a diameter of approximately 7 to 8 microns and an area of central pallor corresponding to the indented regions.

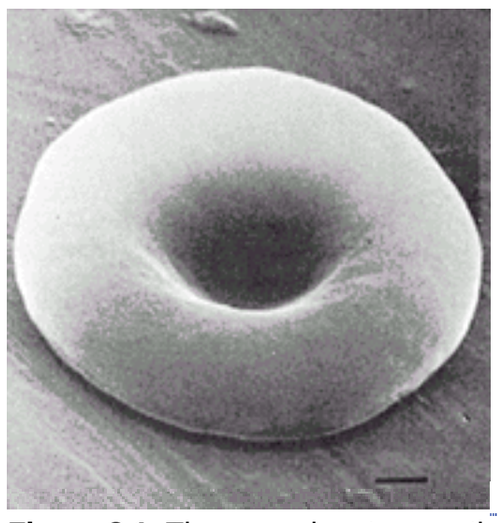

Figure 8.1. The normal mature erythrocyte as visualized by the scanning electron microscope (×9800). (Courtesy of Dr. Wallace N. Jensen.)

The dimensions of the red cell in the living state have been estimated by measurements made in photomicrographs (Fig. 8.2) ([1], [2] and [3]). For this purpose, the cells are suspended in isotonic solutions and photographed on edge. With ordinary light microscopy, the potential error associated with imprecision of focus is approximately 0.50 microns. This value can be reduced to 0.02 microns by means of holography with the interference microscope ([2]). Dimensions obtained by the latter method are somewhat smaller than those reported in earlier studies ([1]). With drying and staining, the cell shrinks so that diameters measured in fixed preparations are somewhat smaller than those of cells in isotonic solutions. The painstaking studies of Price-Jones yielded an average normal value for red cell diameter of 7.2 to 7.4 microns ([4]).

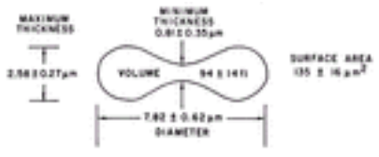

Figure 8.2. Dimensions of a cross section of the erythrocyte in isotonic solution. Values are means ± one standard deviation. (From Evans E, Fung YC. Improved measurements of erythrocyte geometry. Microvasc Res 1972;4:335, with permission.)

Indirect measurements of cell volume are consistent with values obtained using the microscopic method. Average values for the mean cellular volume in normal subjects range from 85 to 91 fl, depending on the combination of methods used. The variation in cell size can be documented by means of a frequency distribution curve of red cell volumes generated from the output of a Coulter counter (Fig. 8.3). Although some studies have suggested that red cell volumes are lognormally distributed ([5]), the size distribution is symmetric ([6]). Ninety-five percent of normal red cells are between approximately 60 and 120 fl in volume ([5]). However, some workers have challenged these values using transmission electron microscopy and stereology. They estimate that the true volume of mature red cells is only 44 fl, and that only 51% of the volume of the red cell column observed in a hematocrit tube is occupied by erythrocytes ([7]). It is interesting that these newer methods also calculate that erythrocytes have 44% more membrane surface area than necessary to accommodate cytoplasmic contents in a sphere ([7]), a figure very close to that estimated using earlier techniques ([8]).

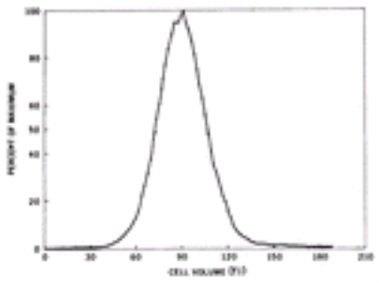

Figure 8.3. Frequency distribution curve of erythrocyte volume. The cells are normally distributed about a mean volume of 90 fl. (Modified from Bessman JD, Johnson RK. Erythrocyte volume distribution in normal and abnormal subjects. Blood 1975;46:369.)

Total hemoglobin content and red cell volume vary considerably more than does hemoglobin concentration ([9]). It has been proposed that mature red cell size and hemoglobin content are primarily dependent on erythroid precursor cell size at the last cell division during erythropoiesis. Reticulocytes are 24 to 35% larger than mature red cells, although they have similar total hemoglobin content (and thus a lower hemoglobin concentration) ([10]).

The disk shape is well suited to erythrocyte function. The ratio of surface to volume approaches the maximum possible value in such a shape ([11]), thereby facilitating both gas transfer and deformability as the red cell traverses the microcirculation ([12]). When red cell movements within small blood vessels were observed by cinemamicrography ([13]), the plane of the biconcave disk was found to be oriented in the direction of flow. The leading edge became pointed and the following edge blunted (Fig. 8.4); thus, the shape was similar to that of a parachute or torpedo viewed from the side. When deformed in this way, the erythrocyte can pass through a vessel of approximately 4 microns in maximum diameter. Erythrocyte shape may also vary between large and small vessels and under conditions of high or low shear stress. Circulating erythrocytes rarely appear to be biconcave disks in the murine abdominal aorta, whereas typical biconcave discoid shapes were common in the inferior vena cava ([14]).

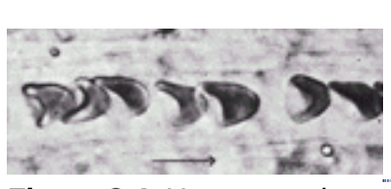

Figure 8.4. Human erythrocytes flowing through a vessel approximately 7 µm in diameter. Direction of flow is indicated by the arrow. (From Skalak R, Branemark P-I. Deformation of red blood cells in capillaries. Science 1969;164:717, with permission.)

Deformability

The erythrocyte is remarkable for its ability to maintain membrane integrity while exhibiting extreme deformability under normal physiologic circumstances ([15]). Without undergoing extensive remodeling, the erythrocyte membrane withstands high shear stresses, rapid elongation and folding in the microcirculation, and deformation as the erythrocyte passes through the small fenestrations of the spleen. Cell deformability depends on both the membrane and the cytoplasm; however, the cytoplasm of normal erythrocytes (as opposed to sickled erythrocytes, for example) acts as an ideal liquid and, at physiologic concentration, has very low viscosity ([15]). Thus, it is the elasticity and viscosity of the membrane that are crucial for deformability.

At least three sets of circumstances result in a spherical erythrocyte shape: osmotic (hypotonic) swelling, discocyte–echinocyte transformation, and discocyte–stomatocyte transformation. To a point, all three types of shape change are reversible. Osmotic swelling ([1]) occurs when erythrocytes are suspended in hypotonic solutions. Under such circumstances, the cell acquires water and swells, first becoming cup-shaped and then spherical. These changes are associated with an increase in volume, whereas the cell-surface area remains the same or increases only slightly ([2]).

Discocyte–echinocyte transformation ([16]) takes place when intracellular adenosine triphosphate (ATP) is depleted ([17]), when intracellular calcium content is increased ([18]), when the cell is exposed to stored plasma, high pH, anionic detergents, lysolecithin, or fatty acids, or when the cell is washed and placed between a glass (not plastic) slide and coverslip ([1]). ATP depletion reversibly transforms erythrocytes to spiculated spheroechinocytes; restoration of ATP leads to gradual resumption of normal shape ([17]). Transformation because of ATP depletion or other factors proceeds through several recognizable stages (Fig. 8.5). First, the disk becomes irregularly contoured (echinocyte I); second, crenations (regularly spaced spicules or projections) appear on the flat surface (echinocyte II); third, the cell becomes ovoid or spherical, with approximately 30 evenly spaced spicules projecting from the surface (echinocyte III); fourth, the cell becomes more distinctly spherocytic, with tiny spicules (spheroechinocyte I); and ultimately, these spicules become so small that they can be appreciated only with the scanning electron microscope (spheroechinocyte II) ([19]). The last stage is irreversible and is sometimes referred to as a “prelytic” sphere.

Figure 8.5. Shape transformations of the discoid erythrocyte. Erythrocytes may undergo transformation from a biconcave disk to an echinocyte or to a stomatocyte. Each transformation occurs via different intermediate shape changes. (From Bull BS, Brailsford D. Red blood cell shape. In: Agre P, Parker JC, eds. Red blood cell membranes—structure, function, clinical implications. New York: Marcel Dekker Inc, 1989, with permission.)

Discocyte–stomatocyte transformation ([20]) occurs when red cells are exposed to low pH, cationic detergents such as *polysorbate 80*, or phenothiazines. As the change proceeds, the cell loses the indentation on one side, and the opposite dimple increases in depth, producing a bow tie, then cup-shaped cell. Because such cells appear on fixed smears to have a mouthlike “stoma” instead of a round area of central pallor, they are known as *stomatocytes*. As the change progresses, the cells become spherostomatocytes and, finally, spherocytes with only a small hilum remaining at the former site of the stoma. Such cells lack the small spicules that

characterize the end-stage prelytic spherocyte resulting from discocyte–echinocyte transformation.

Although many circumstances can lead to transformation of the red cell from a disk to a sphere, some of them appear to act through effects on the erythrocyte plasma membrane anion transporter (AE1, described more fully below) ([21]). AE1 also provides a critical linkage to the membrane skeleton, and it is the interrelationship of these two functions that is proposed to account for these shape transformations. Spherocytic transformation is linked to the ratio of chloride ion influx and efflux (Cl^-_i/Cl^-_o), and many if not all conditions that lead to spherocytic transformation alter this ratio. It is thus theorized that the same conformational change that determines whether AE1 facilitates the inward or outward flow of Cl^- also alters the interaction of AE1 with ankyrin (and thus with spectrin), major components of the erythrocyte cytoskeleton.

Thus far, the factors acting within the membrane to maintain its elastic properties, as well as those that act on it, are still only partially understood. Among the factors that affect membrane deformability and stability are membrane lipid content, cytoskeletal proteins, and transmembrane proteins.

A large body of evidence supports the role of lipid type and distribution in maintenance of membrane integrity and normal function, and abnormalities in distribution of lipids between the inner and outer leaflets are associated with changes in mechanical properties of membranes as well as with the strength of association between the membrane and the cytoskeleton ([22]). The cytoskeleton, formed by a latticelike network of proteins, undoubtedly contributes to the bending energy necessary for assumption of the biconcave shape, as well as to membrane stability ([23]). Abnormalities in cytoskeletal proteins cause a variety of pathologically shaped red cells, including spherocytes and elliptocytes ([24]). Abnormalities of both expression and function of transmembrane proteins, such as AE1, also affect membrane mechanical properties ([25] , [26]). In addition, proteins adsorbed to the outer surface of the red cell, especially albumin, may also play a role in both maintaining normal cell shape and effecting changes in that shape under some conditions. Red cells suspended in isotonic medium tend toward an echinocytic shape until albumin is added, and increasing amounts of albumin move cells toward the discoid shape ([27]).

ERYTHROCYTE MEMBRANE AND CYTOSKELETON

Membrane Structure

The central feature of membrane structure is a matrix formed by a double layer of phospholipids. The lipid bilayer hypothesis, first proposed in 1925 ([28]) and refined by Danielli and Davson in 1935 ([29]), is now generally accepted ([30] , [31]). Lipid molecules in the bilayer are oriented with the nonpolar groups directed toward one another, forming hydrophobic interactions. The hydrophilic polar-head groups are directed outward, where they interact with the aqueous environment on both the cytoplasmic and plasma surfaces.

The best-accepted concept of how proteins fit into the lipid membrane structure is the so-called fluid mosaic model ([32]). The lipid bilayer may be thought of as a two-dimensional, viscous solution. Within this “sea of lipids” float globular proteins, some that penetrate the membrane completely and others that penetrate the membrane only partially and may be exposed at only one surface. Some proteins appear to have considerable lateral mobility, but in the red cell, many proteins interact with other membrane components, giving them a degree of immobility. Some proteins traverse the lipid bilayer once, whereas others have multiple membrane-spanning domains. On the cytoplasmic side of the membrane lies a network of structural proteins that form a cytoskeleton. Certain membrane-spanning proteins appear to interact with various cytoskeletal proteins ([33]). Some transmembrane proteins also appear to become covalently linked to lipid ([34]), and the so-called glycosylphosphatidylinositol-anchored class of proteins have no membrane-spanning domain but instead have their own phospholipid “tails” by which they are attached to the membrane ([35]).

Ultrastructure

In thin sections of erythrocyte membrane fixed with either osmium tetroxide or potassium permanganate, three distinct layers are observed. Two electron-dense (osmophilic) layers approximately 2.5 nm (25 Å) in thickness are separated by an electron-penetrable layer approximately 2.0 nm thick, for a total thickness of some 7.0 nm ([36]). This appearance has often been cited in support of the lipid bilayer structure, with the electron-dense areas representing either membrane protein layers or the polar ends of the phospholipids ([37]).

With air-dried, metal-shadowed red cell membranes, features of the surface are made apparent ([38]). In such preparations, plaques approximately 3.0 nm thick and 10 to 50 nm in diameter are randomly distributed over the surface. These observations have been used to suggest the existence of lipid-protein subunits.

Still another technique used in electron microscopic analysis of membranes is that of “freeze-cleaving” ([39]). Erythrocytes are frozen rapidly at -150°C and fractured with a razor blade. The cleavage plane follows pathways of least resistance, often exposing large areas of membrane. These surfaces are replicated with condensed carbon and platinum, and the replicas are examined with the electron microscope. Two types of membrane surfaces are observed with this technique. Both surfaces are characterized by the presence of particles approximately 10 nm in diameter. The two surfaces differ in that one has four to five times as many of these particles as the other (2600 to 3800/μm^2 as compared with 575 to 1400/μm^2). Membrane cleavage likely occurs in the nonpolar region between the two lipid layers, the particles representing proteins suspended in the lipid layer, as predicted by the fluid mosaic model.

The “quick-freezing” and “deep-etching” method of examining unfixed erythrocytes by electron microscopy has succeeded in providing a three-dimensional picture of the membrane cytoskeleton, whose proteins are organized into structured but deformable arrays ([40]).

Chemical Composition of the Membrane

Much that is known about red cell membranes is derived from studies of the insoluble portion of the cell remaining after hemolysis induced by osmotic rupture. This material has been called *stroma* and, if the membrane remains intact after hemolysis, red cell “ghosts.” It consists largely of components of the membrane, including the cytoskeleton. With careful attention to pH and osmolarity, one can prepare ghosts with only small amounts of residual hemoglobin ([44]). Approximately 230 to 300 mg of such relatively hemoglobin-free material can be extracted from 0.1 liter of erythrocytes. Such preparations contain approximately 52% protein, 40% lipid, and 8% carbohydrate by weight ([44]). Most of the carbohydrate is accounted for by the oligosaccharide portion of glycoproteins, but a small fraction (approximately 7%) is carried by glycolipids ([44] , [45]).

LIPID COMPOSITION Virtually all of the lipids in the mature erythrocyte are found in the membrane ([41]). Qualitative and quantitative analyses have been performed, and the data have been the subject of several reviews ([43] , [44] , [45] , [46] and [47]). These results are summarized in Table 8.1. Values in children differ only slightly from those found in adults ([48]).

TABLE 8.1. Lipids of the Normal Human Erythrocyte Membrane

Lipid	Molar Concentration (45)		Weight Concentration (44)	
	μmol/10^{10} cells	% of Total	mg/10^{10} cells	% of Total
Phospholipids				
Phosphatidylcholine (lecithin)	1.30		1.0	
Phosphatidylethanolamine (cephalin)	1.20		0.9	
Sphingomyelin	1.00		0.8	
Phosphatidylserine	0.60		0.4	
Lysolecithin	0.04		—	
Others	0.07			
Total phospholipids	4.20	49.5	3.1 (1.7–3.2) [a]	69

Cholesterol	4.00	47.1	1.3 (1.1–1.4) [a]	29
Glycolipids (globoside)	0.21	3.4	0.1	2
Total lipids	8.41	100	4.5 (3.9–5.2) [a]	100

[a] Range in parentheses.

The majority of erythrocyte membrane lipids are either phospholipids or unesterified cholesterol, which are present in approximately equimolar quantities. Four classes of compounds account for most of the phospholipid: phosphatidylcholine (lecithin), phosphatidylethanolamine (PE), sphingomyelin, and phosphatidylserine (Table 8.1). Two fatty-acid side chains are attached to all of these lipids except sphingomyelin, which has only one. In addition, trace amounts of other phospholipids containing only one fatty acid ("lysophospholipids," e.g., lysolecithin) or having a vinyl ether (plasmalogens) in place of a fatty acid are found. Phospholipids are distributed asymmetrically between the two lipid layers of the membrane ([49], [50]). Eighty percent or more of the aminophosphatides (PE and phosphatidylserine) lie within the inner (cytoplasmic) monolayer, whereas the choline-containing lipids (phosphatidylcholine and sphingomyelin) are the major components of the outer monolayer (Fig. 8.6). Little or no phosphatidylserine is detectable in the outer lipid layer of normal, nonsenescent red cells. The functional importance of the asymmetric distribution of phospholipids in the two erythrocyte membrane lipid layers is not completely understood, although study of certain pathologic conditions and experimental models has provided clues to both the role and regulation of this asymmetry. For example, when erythrocytes containing hemoglobin S and little or no hemoglobin A are subjected to reduced oxygen tension (PO_2), the outer lipid layer shows increased amounts of PE and phosphatidylserine, whereas the distribution of sphingomyelin is unchanged ([45]). The change in lipid sidedness correlates with loss of the ability to undergo echinocyte transformation, implicating a role for lipid distribution in regulating shape and also implying that the regulation of distribution of some phospholipids may be independent of the regulation of distribution of others. Maintenance of normal asymmetry results in improved mechanical membrane stability under applied shear stress and further appears to supply additional means for cytoskeleton attachment to the lipid bilayer through spectrin–phosphatidylserine interaction ([26]).

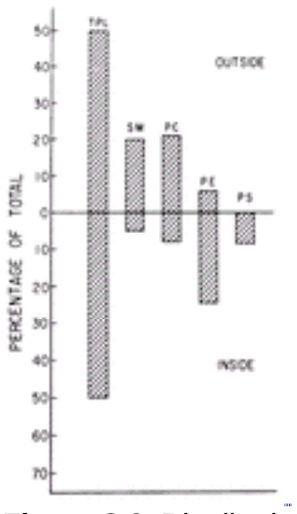

Figure 8.6. Distribution of erythrocyte phospholipids between the inner and outer layers of the membrane. PC, phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine; SM, sphingomyelin; TPL, total phospholipid. (From Rothman JE, Lenard J. Membrane asymmetry. Science 1977;195:743, with permission.)

The lateral mobility of lipids in the outer membrane layer exceeds that of lipids in the inner layer. Although cholesterol is known to restrict lipid lateral mobility ([51]), the outer lipid layer likely is relatively enriched in cholesterol ([52]). Some investigators believe that lipids in the inner layer are restricted in their mobility because of interactions of phospholipids with cytoskeletal proteins ([26], [53], [54]). An additional effect on lipid mobility and membrane deformability may come from the fact that the fatty acids found in erythrocyte phospholipids also are not distributed evenly between the two bilayers ([49], [55], [56] and [57]). Overall, approximately one-half of the fatty acids in the membrane are unsaturated (Table 8.2). Unsaturated fatty acids, however, and particularly the polyunsaturated acyl chains with four or more double bonds, are a disproportionately large part of the inner leaflet phospholipids, PE and phosphatidylserine. In contrast, phosphatidylcholine, which is predominantly in the outer lipid layer, contains most of the shorter-chain saturated fatty acids. Sphingomyelin is especially enriched in fatty acids with a chain length longer than 20. Membranes rich in sphingomyelin are less "fluid" than those with relatively larger amounts of lecithin ([58]). An increased ratio of sphingomyelin to lecithin is found in abetalipoproteinemia and probably accounts for the erythrocyte abnormalities associated with that disorder ([55]).

TABLE 8.2. Fatty Acids in Erythrocyte Phospholipids

Fatty Acid	Molecular Designation [a]	Percent
Saturated		
Palmitic	16:0	24.5
Stearic	18:0	19.0
Others	—	3.1
Total saturated	—	46.6
Unsaturated		
Oleic	18:1	16.4
Linoleic	18:2	11.2
Arachidonic	20:4	15.1
Others	—	10.3
Total unsaturated	—	53.0

[a] The first number indicates the number of carbons; the second, the number of double bonds.

From Ways P, Hanahan DJ. Characterization and quantification of red cell lipids in normal man. J Lipid Res 1964;5:318, with permission.

The neutral lipid of the erythrocyte consists almost entirely of free, nonesterified cholesterol ([58]). The distribution of cholesterol in the two membrane layers has been extremely difficult to study, at least in part because the translocation rate of cholesterol between the two layers is extremely rapid. Although findings in one report suggested that cholesterol is somewhat over-represented in the outer lipid layer ([53]), further data need to be gathered. Cholesterol has a pronounced effect on membrane fluidity ([59], [60]). It interacts with phospholipids to form what has been called an "intermediate gel state." Thus, as compared with pure phospholipid membranes, membranes containing cholesterol are less fluid, that is, more viscous. Relatively modest increases in membrane cholesterol content decrease membrane deformability ([61]). Abnormally high levels of cholesterol lead to distortions in red cell shape: Bizarre spicules form ("spur cells"), deformability of the cells is reduced, and they are destroyed in the spleen. Glycolipids (or glycosphingolipids) make up a small fraction of the total lipids of the erythrocyte membrane ([42]). These glycolipids resemble sphingomyelin in that the lipid base is a unit known as *ceramide*, consisting of sphingosine and a long-chain fatty acid. Attached to the base is a variable number of hexose molecules. The predominant erythrocyte glycolipid, globoside (GL-4), contains four hexose units: ceramide–glucose–galactose–galactose–N-acetylgalactosamine. Globoside appears to be a component only of plasma membranes and is not present in the membranes of intracellular organelles such as mitochondria. In this respect, it differs from cholesterol and the phospholipids, which are distributed widely. Globoside is particularly characteristic of the red cell membrane but has also been isolated from plasma membranes of several other cell types. Normal human red cells also contain ceramide glycolipids with one glucose (GL-1), one glucose and one galactose (GL-2), and one glucose and two galactose (GL-3) molecules attached. The relative proportions of the glycolipids are as follows: GL-4, 69%; GL-3, 12%; GL-2, 14%; and GL-1, 5% ([42]). In addition, fucose-containing ceramide glycolipids are present in trace amounts. These are of interest because they are surface structures that have antigenic activity corresponding to the A, B, H, and Lewis blood groups. They are not the exclusive bearers of these antigens, however, because glycoproteins with similar hexose arrangements have similar antigenic properties.

LIPID TURNOVER AND ACQUISITION The mature erythrocyte is unable to synthesize lipids *de novo*; therefore, any lipid loss must be compensated for by renewal

from pathways of interchange with the plasma (Fig. 8.7) ([57]). Quantitatively, the most important of these pathways is the transfer of cholesterol and phosphatidylcholine (lecithin) from plasma lipoproteins to red cells (pathways 1 and 3 in Fig. 8.7). The rates of transfer are functions of the relative plasma and red cell levels of these lipids and are indirectly affected by the activity of the cholesterol esterifying enzyme in plasma, lecithin-cholesterol acyltransferase (LCAT) ([62]). This enzyme catalyzes the reaction in which a fatty acid in the 2 position of lecithin is transferred to free cholesterol, forming cholesterol ester and lysolecithin (Fig. 8.7, reaction 1A). Neither of the LCAT reaction products can enter the membrane. In patients with congenital LCAT deficiency, membrane cholesterol and lecithin are increased, and the red cells are target shaped ([63]).

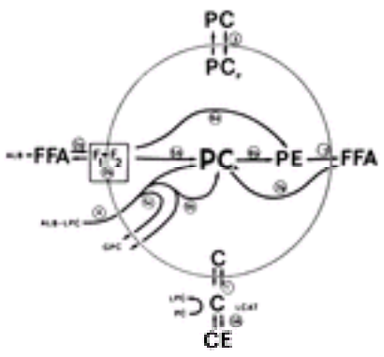

Figure 8.7. Pathways of lipid acquisition and turnover in the mature red cell membrane. Alb, albumin; C, cholesterol; CE, cholesterol ester; FFA, free fatty acid; GPC, glycerylphosphoryl choline; LCAT, lecithin-cholesterol acyltransferase; LPC, lysophosphatidyl choline; LPE, lysophosphatidyl ethanolamine; PC, phosphatidyl choline (lecithin); PE, phosphatidyl ethanolamine. Reactions and pathways are as follows: *1:* Exchange of C with plasma lipoprotein. *1A:* The LCAT reaction. *2a:* Transfer of FFA from Alb to membrane. *2b:* Penetration of FFA to a metabolically active site. *3:* Exchange of PC with plasma lipoprotein. *4:* Transfer of LPC from Alb to membrane. *5A:* LPC + FFA ? PC. *5b:* 2LPC ? FFA + GPC. *5c:* LPC ? FFA + GPC. *6a:* LPE + FFA ? PE. *6b:* PC + LPE ? LPC + PE. *7:* PE ? LPE + FFA. *7b:* PC ? LPC + FFA. (From Shohet SB. Hemolysis and changes in erythrocyte membrane lipids. N Engl J Med 1972;286:577, with permission.)

The exchange of cholesterol and lecithin between red cells and plasma is also affected by the plasma bile salt concentration ([64]). If erythrocytes are incubated in normal plasma to which bile salts have been added, the cells acquire cholesterol, and this change is accompanied by an increase in surface area and the formation of target cells. Although the mechanism of bile salt action is not fully understood, at least two properties appear important: Bile salts inhibit the LCAT reaction, and, in addition, they bring about a shift in the distribution of free cholesterol between plasma and cell. Phospholipids also may be added to the membrane by three other reactions. Albumin-bound lysophospholipid may be transferred to the membrane (Fig. 8.7, pathway 4) and acylated (Fig. 8.7, reactions 5a and 6a) to form a complete phospholipid ([57]). Of lesser quantitative importance is the transfer and conjugation of two lysophospholipid molecules to yield a phospholipid (Fig. 8.7, reaction 5b) and glycerylphosphorylcholine, which returns to the plasma ([65]). Finally, some PE is produced by transacylation of a fatty acid from lecithin to lyso-PE (Fig. 8.7, reaction 6b). A congenital defect in the last reaction results in the formation of cells that possess increased membrane lecithin and decreased membrane PE ([66]). These changes are associated with the clinical picture of nonspherocytic hemolytic anemia. The fatty acid composition, but not the major relative proportions of the phospholipid classes, may be altered by diet ([67], [68]). With low-fat diets, linoleic acid levels decrease. With diets high in linoleic acid, the amount of red cell linoleic acid increases. These changes occur relatively slowly, over approximately 4 to 6 weeks. The levels of myristic, arachidonic, and oleic acids in plasma membrane lipids are also affected by diet.

Membrane Proteins

Early in the history of membrane biochemistry, erythrocytes became the model system for the study of plasma membranes because they lacked organelle and nuclear membranes, making the plasma membranes easy to isolate. Solubilization of membrane proteins can be accomplished by the addition of detergent. Detergent usually is added to red cell ghosts, made relatively hemoglobin-free after hypotonic lysis of red cells ([41]). However, different erythrocyte membrane proteins are variably soluble in detergents. Nonionic detergents, which do not denature most proteins, efficiently solubilize some membrane proteins but leave several others, especially those with strong attachments to the cytoskeleton, unsolubilized. Use of an ionic detergent, most commonly sodium dodecyl sulfate (SDS), accomplishes solubilization of essentially all membrane proteins, although at the cost of denaturing the proteins, in some cases irreversibly.

Proteins extracted from membranes by detergent solubilization can be separated and analyzed with relatively high resolution by means of electrophoresis in polyacrylamide gels ([42], [69]). Such gels are stained by protein stains, usually Coomassie Brilliant Blue or silver stain, or by reagents that react with carbohydrate, such as periodic acid-Schiff (PAS). Alternatively, proteins are first labeled with a variety of radioactive reagents, and then the gels are exposed to x-ray film, a process known as *autoradiography*. One radiolabeling method is radioiodination of tyrosine residues performed using intact erythrocytes. This method radiolabels many of the membrane proteins that have extracellular domains but fails, naturally, to label cytoskeletal proteins. Failure to be radioiodine-labeled also occurs, however, among membrane proteins such as glycophorin C, because they lack available extracellular tyrosine residues. Each of these methods thus yields a different picture of membrane proteins, as different proteins are stained or radiolabeled by each of these methods, and no method identifies all proteins. Additional methods of identifying proteins in gels include coupling of surface structures to small molecules such as avidin (that can then be stained using a biotin-conjugate) or ^{3}H-containing sugars (a nontyrosine but carbohydrate-dependent method of radiolabeling). Finally, many important membrane proteins are not expressed in sufficient quantity to be distinguishable among the many proteins of the membrane, although immunologic methods of detecting them, such as Western blotting ([70]), can readily identify many of these.

On Coomassie-stained gels, seven major bands are usually identified, whereas PAS stains four major bands and several minor ones (Fig. 8.8). Some workers, however, have been able to differentiate as many as 40 proteins using the Coomassie technique ([71]). Originally, the seven major protein bands were referred to by their numeric designations (Table 8.3). As further refinements in SDS–polyacrylamide gel electrophoresis have produced greater resolution, other bands have been given decimal or alphanumeric designations, such as bands 2.1 and 4.2, sometimes with even further divisions such as 4.1a and 4.1b. At present, many of these proteins are no longer identified by this numeric nomenclature because they have been given specific names as their chemical structures have been defined and their complementary DNAs (cDNAs) and genes have been cloned.

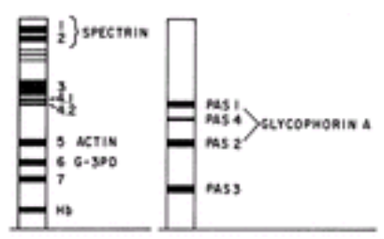

Figure 8.8. Polyacrylamide gel electrophoresis of erythrocyte membrane proteins. In this system, polypeptides migrate according to molecular size with the smaller molecules moving the farthest. Gels were stained with Coomassie Brilliant Blue (*left*) and periodic acid-Schiff (PAS) reaction (*right*). G-3PD, glyceraldehyde-3-phosphate dehydrogenase; Hb, hemoglobin. (From Steck TL. The organization of proteins in the human red blood cell membrane. J Cell Biol 1974;62:1, with permission.)

TABLE 8.3. Major Membrane Polypeptides

Likewise, the PAS-stainable proteins are now well characterized. The major PAS-stained bands contain three proteins, two of which form both hetero- and homomultimers. These three proteins have been termed *glycophorins*, or *sialoglycoproteins*, with letter designations that vary according to the investigator (Table 8.4) ([69] , [72] , [73] , [74] and [75]). Glycophorins A (GPA) and B are proteins that are derived from highly homologous genes and form both homo- and heterodimers. Glycophorins C and D are two proteins produced by a single gene and are structurally unrelated to GPA and glycophorin B.

TABLE 8.4. Nomenclature of Periodic Acid-Schiff (PAS)–Staining Erythrocyte Glycoproteins

Fairbanks et al. (69)	Furthmayr (75)	Dahr et al. (74)	Anstee et al. (72)
PAS-1	Glycophorin A homodimer	MN SGP	SGP-a
PAS-2	Glycophorin C [a]	Component D	SGP-ß
—	Glycophorin D	Component E	SGP-?
PAS-3	Glycophorin B	Ss SGP	SGP-d
PAS-4	Glycophorin AB heterodimer	MN/Ss heterodimer	SGP-a/d heterodimer

SGP, sialoglycoprotein.

[a] Depending on the resolution of the gel, the PAS-2 region may contain glycophorin A monomer, glycophorin C, and glycophorin B homodimer.

Historically, membrane proteins were characterized by whether they were stainable by protein-binding or carbohydrate-specific dyes. Now, however, they are classified on the basis of their functions or their relationship to the membrane. One common classification of membrane proteins comprises the categories of integral membrane proteins and peripheral membrane proteins ([32]). Integral membrane proteins are most often globular and amphipathic; in their folded, three-dimensional form, they have distinct hydrophobic and hydrophilic domains. Of the major Coomassie-stainable proteins, only bands 3, 4.5, and 7 are integral membrane proteins. These proteins have one or more membrane-spanning domain. Band 3 has several extracellular domains, of which some are highly glycosylated. Band 4.5 is the glucose transporter. Less is known about band 7, a protein that has a small extracellular and relatively larger cytoplasmic domain. All other Coomassie-stained bands are situated within the cell, either as part of the cytoskeleton or bound in a more or less loose fashion to the inner leaflet of the membrane. All the PAS-stainable proteins are integral membrane proteins. Integral membrane proteins require detergent for removal from the membrane, whereas peripheral membrane proteins can often be extracted from “ghosts” by manipulation of the pH and ion content of buffers and tend to be soluble in neutral aqueous buffers. Proteins attached by phosphatidylinositol anchors to the outer membrane layer also require detergents or other reagents capable of disrupting the lipid bilayer for solubilization ([35]).

TRANSMEMBRANE PROTEINS The two predominant erythrocyte transmembrane proteins are GPA and AE1 (formerly known as *Band 3*). However, although AE1 appears to play a number of crucial roles in red cell biology, the importance of GPA is less clear. GPA is the principal PAS-stainable glycoprotein of erythrocyte membranes. There are between 0.5 and 1.0 × 10^{6} copies of this protein per erythrocyte ([76]), accounting for approximately 85% of PAS-positive membrane protein. When analyzed by SDS–polyacrylamide gel electrophoresis, GPA forms homodimers, heterodimers with glycophorin B, and higher order multimers of up to several hundred kilodaltons. The monomeric form migrates anomalously, with an apparent molecular weight of 36,000 to 39,000, presumably because of its highly glycosylated state; approximately 60% of its weight is attributable to carbohydrate. Most of the carbohydrate is in the form of 15 O-glycosidically linked tetrasaccharides. The two sialic acid residues of each of these many O-glycosidically linked oligosaccharides account for 60% of the surface negative charge of the red cell. The other two components of these tetrasaccharides are one *N*-acetyl-galactosamine residue and one galactose residue. In addition, GPA bears one complex N-glycosidically linked oligosaccharide. GPA also bears blood group antigens. The N-terminus of GPA bears the M or N antigen, depending on whether serine and glycine or leucine and glutamic acid are in amino acid positions one and five, respectively. Although the antigenic polymorphism of the MN system thus depends on amino acid sequence differences, many human antibodies to these antigens do not recognize these antigens if sialic acid has been removed from the three O-linked oligosaccharides normally attached to amino acids two, three, and four. GPA has also been found to be a binding site for several pathogens, including *Plasmodium falciparum*. The complete amino acid sequence of GPA was determined in 1978 ([77]), and several investigators have since cloned the cDNA and explored the genomic structure of the glycophorin genes. GPA comprises 131 amino acids, of which 70 reside extracellularly, 22 within a single membrane-spanning domain, and the rest within the cytoplasm. The gene for GPA resides on chromosome 4 ([78]) and is organized into six exons that encode the leader peptide and mature protein, along with a seventh exon encoding 3' untranslated messenger RNA (mRNA) ([79] , [80]). Numerous variants of GPA have been described and may cause production of alloantibodies after transfusion. Rarely, some persons lack this protein totally. Although absence of GPA causes no clinically significant hematologic problems, persons with this deficiency may make antibodies that render blood transfusion difficult, given the general unavailability of blood from other GPA-deficient donors. In addition, some evidence suggests that the cytoplasmic *C*-terminal portion of GPA attaches loosely to the cytoskeleton via the cytoskeletal protein band 4.1 ([81] , [82]) and also is expressed as part of a macromolecular complex that includes a dimer of AE1 (see below) and as many as six GPA dimers. In experimental systems, GPA also acts as a chaperone to facilitate AE1 expression ([83]), and, in humans, absence of GPA is associated with altered glycosylation of AE1 ([84]). Glycophorin B, the second most abundant PAS-staining protein, is present on the erythrocyte in one-tenth to one-third the copy number of GPA ([76]). Also encoded by a gene on chromosome 4, glycophorin B is highly homologous to GPA. The N-terminus of glycophorin B carries the “N” amino acid sequence of GPA and continues to be largely homologous to GPA for the first 27 amino acids, so that glycophorin B always expresses the N antigen. At amino acid 29, within a region of glycophorin B less homologous to GPA, expression of methionine or threonine accounts for the S and s blood group antigens, respectively. The intramembranous portion of glycophorin B is likewise highly homologous to that of GPA, but glycophorin B lacks a large cytoplasmic domain corresponding to that of GPA. Like GPA, glycophorin B is encoded by a single-copy gene on chromosome 4; the GPA and B genes thus appear to have arisen from a single ancestral gene. A third related gene, encoding a protein that is expressed weakly or not at all, has also been described as belonging to this gene family. AE1, which is the erythrocyte anion channel or anion exchange protein, is expressed on erythrocytes in approximately the same copy number as GPA. Human erythroid AE1 cDNA has been cloned ([85] , [86]). Deduced cDNA sequence and confirmatory biochemical analyses have demonstrated that AE1 most likely traverses the membrane 12 times. Although it has several extracellular domains, the fourth is the major bearer of carbohydrate. This domain is heavily glycosylated and bears carbohydrate blood group antigens, including I and i and the antigens of the ABO major blood group system. Variations in the degree of glycosylation of this domain among individual protein molecules apparently account for the broad range of molecular weight (95,000 to 105,000) deduced for this protein from SDS gels. Gross changes in glycosylation of AE1 are also seen in certain inherited red cell abnormalities: AE1 bears increased sialic acid when GPA is absent, whereas glycosylation of AE1 is reduced in HEMPAS (hereditary erythroblastic multinuclearity with positive acidified serum test). Within the membrane, AE1 exists predominantly as a dimer, possibly in a macromolecular complex that includes GPA and the Rh proteins ([83] , [87] , [88]). Its primary function appears to be Cl^{-} HCO_3^{-} exchange. AE1 also interacts with the erythroid cytoskeleton by binding ankyrin and binds NO, possibly facilitating its transit across the erythrocyte plasma membrane ([89]). Complete absence of erythroid AE1 has been described in humans as resulting in a severe form of hereditary spherocytosis, as well as renal tubular acidosis with nephrocalcinosis. In addition, at least 24 different mutations of the membranous or cytoplasmic domain of AE1 have been described as leading to hereditary spherocytosis. In all, mutations of the AE1 gene account for approximately 30% of all cases of hereditary spherocytosis in whites ([90]). The Rh proteins are also important integral membrane proteins. Although present in only 100,000 copies per cell ([76]), these proteins are clearly important both to erythrocyte biology and to transfusion medicine. The RhD protein is the most immunodominant determinant of red cells outside the ABO antigens and is thus the only non-ABO determinant routinely taken into account when blood is selected for nonalloimmunized recipients. Absence of all Rh proteins, as in the Rh-null syndrome, is associated with multiple erythrocyte defects and mild hemolytic anemia ([91]). The proteins that carry the D, C (or c), and E (or e) Rh antigens are highly homologous to one another ([92]) and traverse the membrane multiple times ([92]). Two Rh genes situated very near each other on chromosome 1 encode the proteins that bear Rh antigens; in the normal situation, one gene encodes the D antigen, and the other encodes a protein that bears both the E/e and C/c antigens ([93]). However, in the membrane, the Rh proteins are part of a multimeric protein complex, including both structurally related and unrelated proteins ([94]). The function of this complex remains unknown, although it has been shown that the Rh-null syndrome occurs most frequently as a result of lack of expression of Rh50, one of the proteins in this complex, rather than a defect at the *RH* gene locus itself ([95]). Recombinant Rh50 expressed in yeast and in *Xenopus* oocytes has been shown to facilitate ammonium transport ([96] , [97]), although some evidence also suggests that Rh proteins play a role in CO_2 transport ([98]).

CYTOSKELETAL PROTEINS The most abundant of the peripheral proteins are those that make up the so-called spectrin–actin cytoskeletal complex. These proteins, which can be extracted in the presence of ethy-lenediaminetetraacetic acid and other chelating agents or by reducing ionic strength and raising pH, account for approximately 35% of the membrane protein. The complex includes large a- and ß-spectrin polypeptide chains (bands 1 and 2 on gel electrophoresis; molecular weight, approximately 240,000 and 225,000, respectively) and the smaller actin chain corresponding to band 5. The relationship between the integral and peripheral

proteins of the membrane is illustrated in Figure 8.9. Study of the erythrocyte cytoskeleton has led to the realization that similar spectrin-based skeletal structures are important not only in preserving erythrocyte integrity in the face of the shear stresses of the circulatory system and spleen, but also in the function of more complex nucleated cells ([99], [100]).

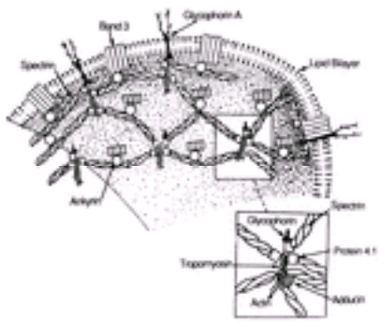

Figure 8.9. Model of the relationship between integral and cytoskeletal membrane proteins. Cytoplasmic domains of several integral membrane proteins interact with several cytoskeletal proteins. (From Gardner K, Bennett GV. Recently identified erythrocyte membrane-skeletal proteins and interactions. In: Agre P, Parker JC, eds. Red blood cell membranes—structure, function, clinical implications. New York: Marcel Dekker Inc, 1989, with permission.)

Spectrin proteins are long, rod-shaped molecules that self-associate into a two-dimensional network with the help of many other cytoskeletal proteins ([33]). The two forms of spectrin are homologous to each other, and both are composed primarily of 106–amino acid repeats (Fig. 8.10); however, they are encoded by genes on two different chromosomes, chromosome 1 (a-spectrin) and chromosome 14 (ß-spectrin) ([101], [102] and [103]). Each spectrin molecule appears to be folded over on itself an average of three times. The a- and ß-spectrin molecules form heterodimers by aligning in antiparallel pairs. These heterodimers then form tetramers by head-to-head association ([33]). Incorporation of these tetramers into the latticework of the cytoskeleton then occurs with the interaction of other peripheral membrane proteins (Fig. 8.9) ([33]).

Figure 8.10. The a and ß subunits of human erythrocyte spectrin. Each protein has numerous repeated segment domains, and the proteins combine to form antiparallel heterodimers. Most repeat domains (*rectangles*) are homologous and are exactly 106 amino acid residues in length; nonhomologous domains are represented by squares. Roman numerals represent domains identified historically as numbered from the spectrin self-association site (*at left*). Peptides produced by limited trypsin cleavage, often used to identify the many spectrin variants associated with abnormal erythrocyte shape, are indicated by "T" followed by the molecular weight (in thousands) of the fragment. (From Speicher DW. The present status of erythrocyte spectrin structure: the 106-residue repetitive structure is a basic feature of an entire class of proteins. J Cell Biochem 1986;30:245, with permission.)

Erythrocyte actin, or band 5 as identified in Coomassie-stained gels of erythrocyte membrane proteins (Fig. 8.8), is an abundant (approximately 500,000 copies) erythrocyte protein of approximately 45,000 daltons. Like actin in skeletal muscle cells, erythrocyte actin can polymerize into long filaments and can activate myosin ATPase activity. It seems more likely, however, that erythrocyte actin normally forms only short filaments ([104]). Actin filaments are known to associate with spectrin tetramers at the ends containing the carboxy-terminus of the a-chain and the amino terminus of the ß-chain. This association, however, is a low-affinity interaction in the absence of other accessory proteins. In addition to spectrin and actin, other cytoskeletal proteins appear to play a crucial role in membrane stability and maintenance of cell shape. Protein 4.1, of which approximately 200,000 copies are expressed per cell, is a 78,000-dalton protein that contains a spectrin-binding domain and also appears to bind to the transmembrane protein glycophorin C ([105]). Protein 4.1 is also known to promote spectrin–actin interaction, although protein 4.1 requires the presence of actin to interact directly with spectrin. Band 3 may also bind protein 4.1 to the membrane, because the two proteins can interact in solution. Protein 2.1, now known as *ankyrin*, also serves as a mode of attachment of the cytoskeleton to the membrane ([106]). Approximately 100,000 copies of ankyrin are expressed per cell; at least two forms of ankyrin, a 206,000-dalton form and a 190,000-dalton form, are present in membranes. The smaller form has also been designated *band 2.2*. Both forms contain an amino-terminal domain that binds the anion exchanger band 3 and a domain more toward the carboxy-terminal that binds spectrin. A peptide within the carboxy-terminal domain of protein 2.1 is absent from protein 2.2 because of differential processing of mRNA; this relatively small difference increases the affinity with which ankyrin binds both spectrin and band 3. Other proteins, although present in smaller quantities, nevertheless also play vital roles in formation and stability of the cytoskeleton. These proteins include protein (band) 4.9, tropomyosin, tropomodulin, and adducin. Deficiencies or abnormalities in some of these cytoskeletal proteins have been associated with abnormal erythrocyte shapes, abnormal membrane stability and rigidity, and hemolytic anemias. Thus, elliptocytosis, spherocytosis, and pyropoikilocytosis can result from a variety of defects of spectrin, ankyrin, protein 4.1, and glycophorin C ([107]). Acquired abnormalities of the membrane cytoskeleton can also occur. In sickle cell anemia and thalassemia, for example, oxidation of protein 4.1 appears to change the affinity of protein 4.1 for spectrin ([108], [109]). Also, in blood stored for transfusion, spectrin oxidation appears to occur with time, leading to loss of membrane surface area by formation of lipid vesicles comprising membrane unattached to the cytoskeleton. Other cytoskeletal proteins may also be affected by oxidative processes that alter their ability to interact with members of the spectrin–actin meshwork underpinning the erythroid membrane.

MEMBRANE TRANSPORT PROTEINS AND FUNCTIONS In general, the membrane acts as a partial barrier to penetration of all solutes. Nonpolar substances diffuse through the membrane at a rate proportional to their solubility in organic solvents. Polar solutes appear to cross the membrane at specialized sites. The erythrocyte membrane has a number of specialized transport proteins, including the anion transporter (AE1, band 3), several cation transporters, a glucose transporter, a urea transporter, and a water channel. Erythrocytes have an abundant and highly active water channel protein, aquaporin-1, which contributes as much as 85% of the osmotic water permeability pathway ([110]). Aquaporin-1, originally described as CHIP-28 (channel-forming integral protein-28 kd), occurs as a homotetrameric protein that expresses on its extracellular domain both ABH and Colton blood group antigens and is inhibitable by a variety of mercurial compounds ([111]). Red cells lacking aquaporin-1 have only slightly reduced lifespan *in vivo* ([110]). Anions appear to cross the membrane by one of two discrete pathways. The first represents an exchange reaction in which an internal anion is exchanged for an external anion. This rapid exchange is mediated by the band 3 anion exchange protein and plays an important role in the chloride–bicarbonate exchanges that occur as the red cell moves between the lungs and tissues (Fig. 8.11B) ([112]). The second anion pathway represents considerably slower ionic diffusion, accounting for net loss or gain of anions. This process is approximately 100 times as rapid as cation diffusion but 10,000 times slower than the cation exchange reaction.

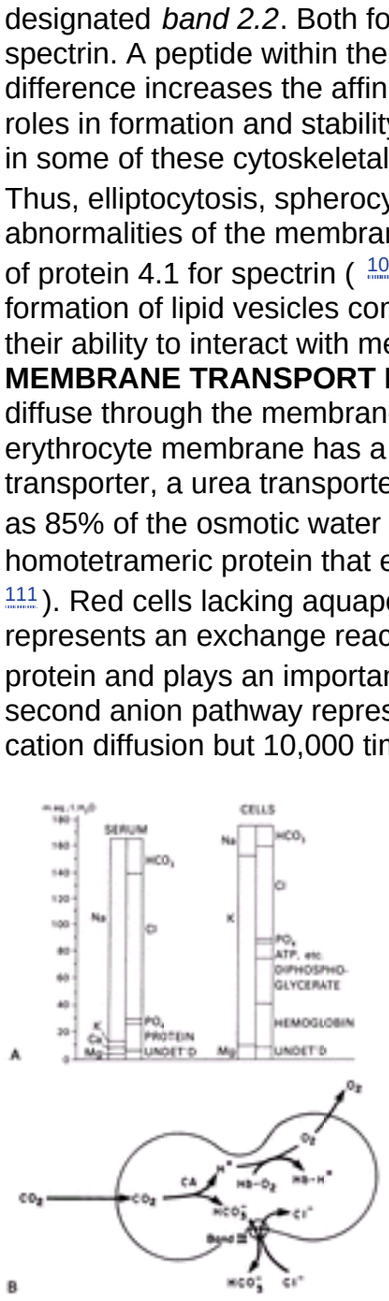

Figure 8.11. A: Intracellular electrolyte composition of the erythrocyte as compared with serum. **B:** Role of band 3 in anion and CO_2 transport. The ability of band 3 to accelerate anion transport across the membrane allows rapid equilibration of bicarbonate with the extracellular plasma and concomitant influx of chloride ion. ATP, adenosine triphosphate; CA, carbonic anhydrase; Hb, hemoglobin. (**A** is from Guest GM. Organic phosphates of the blood and mineral metabolism in diabetic acidosis. Glucose and other monosaccharides constitute an important exception to the generalization regarding nonpolar solutes, in that monosaccharides easily cross the membrane barrier, whereas the more lipid-soluble disaccharides do not. The speed of the process depends on molecular structure. Only D-isomers are transported; L-isomers are not. Of the common D-hexoses, glucose is transported most rapidly, followed by mannose, galactose, xylose, and arabinose. The concentration of solute at the half maximal transport rate (Km) is 6.2 mM for glucose and 18.5 mM for mannose. Fructose is not transported under physiologic conditions (Km >200

mM). Glucose enters the erythrocyte by facilitated diffusion, mediated by a transmembrane protein designated the *glucose transporter*, encoded by the gene *GLUT1* ([113]). This protein constitutes approximately 5% of erythrocyte membrane protein and accounts for a diffusely migrating band (band 4.5) in Coomassie-stained polyacrylamide gels of erythrocyte membrane proteins. (Although a single protein, the glucose transporter is heterogeneously glycosylated, causing its apparent molecular weight to range from 45,000 to 75,000.) The protein appears to occur in the membrane as a homotetramer. The glucose transporter has an asymmetric effect on glucose transit across the membrane: Glucose influx exhibits a higher Vmax and a lower Km than does glucose efflux. The transport of glucose into the erythrocyte provides the energy substrate for anaerobic glycolysis; however, the energy requirement of the erythrocyte appears relatively low, and the efficiency of glucose transport is relatively high. Therefore, glucose transport does not appear to be rate-limiting for glucose use ([114] , [115]). It is interesting that heterozygosity for a defective glucose transport protein has been reported to result in a heritable seizure disorder ([116]). The erythrocyte membrane is only slightly permeable to the major monovalent cations, sodium and potassium, and their movement depends greatly on an energy-requiring transport mechanism. Within the human erythrocyte, potassium is the predominant cation, and sodium is a relatively minor constituent, whereas the relationship is reversed in plasma (Fig. 8.11A). Cation concentrations within the erythrocyte are approximately 130 mM K^+ and 8 mM Na^+, whereas the plasma contains approximately 140 mM Na^+ and 4 mM K^+. The preservation of these gradients is the result of the cation transport process. The steady-state cation concentrations within the erythrocyte are the result of an equilibrium between passive diffusion (“leak”) and active transport (“pump”). With respect to sodium, the direction of leak is inward and the direction of pump is outward; in contrast, potassium leaks out and is pumped in. The major cation pump represents a process in which sodium inside the cell is exchanged for potassium on the outside and energy is supplied by ATP. For each molecule of ATP converted to adenosine diphosphate (ADP), three sodium ions are pumped out and two potassium ions enter ([117]). The overall reaction has been expressed as follows ([118]):

$$3Na_i^+ + 2K_o^+ + ATP_i \rightarrow 3Na_o^+ + 2K_i^+ + ADP_i + P_I$$

where subscript i indicates *intracellular* and subscript o indicates *extracellular* (outside). In this process, the erythrocyte experiences a net loss of one positive charge per cycle. Some of this loss may be compensated by outward movement of an anion (most likely Cl^-), but this cation pump also contributes to the low resting potential of human erythrocytes ([119]). Active Na^+ and K^+ transport depends on the activity of the membrane protein Na-K ATPase. This protein may exist in the membrane as part of a multienzyme complex, including glyceraldehyde-2-phosphate dehydrogenase and phosphoglycerate kinase ([120]). The pump protein itself comprises two noncovalently linked polypeptides. The a subunit has a molecular weight of approximately 112,500 daltons and contains the catalytically active domain; the ß subunit, which has a molecular weight of approximately 45,000 daltons, is likely to be important to regulation of the molecule's function ([121] , [122]). A small proteolipid ?-chain of approximately 10,000 daltons also copurifies with the protein but does not appear to be required for ATPase activity ([123]). The a subunit contains both ATP- and ouabain-binding, as well as ATPase activity. The complete amino acid structure for the a-chain of human Na-K ATPase has been determined ([124]). It is compatible with a protein structure that includes eight membrane-spanning domains, making the a subunit an integral membrane protein, as would be expected of an active membrane transport protein. The ß subunit is also an integral membrane protein, with at least one transmembrane domain ([125]). Most of the ß subunit protein appears to be extracellular, whereas the nonmembrane-spanning domains of the a subunit are primarily cytoplasmic. In the membrane, the Na-K ATPase may exist as oligomers of the a, ß, and ? units in a ratio of 1:1:1. The erythrocyte also has a urea transporter that transports urea rapidly across the membrane and helps preserve red cell osmotic stability and deformability ([126]). Although this transporter has similar characteristics to the renal urea transporter, they appear to arise from related but distinct genes ([127] , [128]).

MEMBRANE AND MEMBRANE-ASSOCIATED ENZYMES At least 50 enzymes are either membrane proteins or are bound to the erythrocyte membrane in some fashion; certain enzymes are both free in the cytoplasm and associated with the membrane. Their functions range from facilitating transport of a variety of molecules necessary to the erythrocyte to playing important roles in producing and using energy from glucose metabolism. Some erythrocyte enzymes are externally oriented and can therefore react with substrates in the red cell environment. Certain hydrolytic enzymes, including glycosidases and acid phosphatases, are among the externally oriented enzymes ([129]). A classic example of an externally oriented enzyme is acetylcholinesterase. Acetylcholinesterase was the first of several membrane proteins discovered to be missing from the affected erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (Chapter 37) ([130] , [131]). It belongs to a class of proteins that are attached to the membrane by a phosphatidylinositol-glycan anchor, so that the entire polypeptide portion of the molecule is extracellular ([35]). Although the role of acetylcholinesterase on the red cell remains obscure ([132]), some other proteins in this class are complement regulatory proteins; it is the absence of these proteins that causes the hemolysis typical of paroxysmal nocturnal hemoglobinuria ([131]). Among the enzymes required for the production and use of ATP are three enzymes that are believed to form a membrane-bound enzyme complex: aldolase, glyceraldehyde-3-phosphate dehydrogenase, and phosphoglycerate kinase. Together, these three enzymes convert fructose diphosphate to 3-phosphoglycerate with the production of ATP. Glyceraldehyde-3-phosphate dehydrogenase is the enzyme present in greatest amount in membrane preparations and is seen as band 6 in polyacrylamide gels. Glyceraldehyde-3-phosphate dehydrogenase is also found in the erythrocyte cytoplasm and can be demonstrated to bind to a cytoplasmic segment of band 3. Although the exact physiologic role of membrane binding for this enzyme remains unclear, its possible role in regulating metabolic responses to cell injury and stress is intriguing ([133]). ATP is not only generated by membrane-bound enzymes but also is used by membrane-bound molecules, among which are adenylyl cyclase, which catalyzes the conversion of ATP to cyclic adenosine monophosphate, protein kinases, and ATPases. The latter are involved in several transport functions, as was discussed previously. Protein kinases are enzymes that phosphorylate other proteins in the presence of ATP by forming phosphoserine, phosphothreonine, or phosphotyrosine bonds. Phosphorylation is a major step in the regulation of a variety of target molecules, including structural proteins and enzymes. Erythrocytes contain numerous protein kinases, including both cytosolic and membrane-bound cyclic adenosine monophosphate–dependent kinases, cytosolic and membrane-bound cyclic adenosine monophosphate–independent protein kinases, protein kinase C, and a calcium-regulated protein kinase. Both membrane-bound and cytosolic kinases may phosphorylate membrane proteins ([134]). In general, phosphorylated structural proteins demonstrate lower-affinity binding to their target proteins than do unphosphorylated proteins. For example, phosphorylation of protein 4.1 leads to a decreased affinity for spectrin and a decreased ability of 4.1 to promote spectrin–actin association ([33]). Phosphorylation of spectrin, however, leads to little if any change in spectrin self-association or in association of spectrin with other molecules such as ankyrin and actin ([33]). Exactly how such processes regulate cell shape and membrane integrity has not been well worked out as yet. In the case of protein 4.1, dephosphorylation because of ATP depletion, an event that might be associated with stress, would be predicted to lead to a more rigid spectrin–actin network and reduced membrane deformability ([135]). Phosphorylation of enzymes can likewise lead to activation of a variety of metabolic pathways; often, phosphorylation of one molecule leads to activation of both an enzyme system and the molecules that down-regulate activity of that system. Enzymes that use and degrade ATP are also found in the membrane, although they are not present in large enough quantity to account for bands seen in Coomassie-stained polyacrylamide gels of membrane proteins. Like protein kinases, ATPases phosphorylate membrane proteins, but instead of forming phosphoserine or phosphothreonine bonds, they form acyl bonds as transient intermediates in the catalytic cycle. Important and well-studied ATPases of the erythrocyte membrane include Na-K ATPase, Ca-Mg ATPase, and Mg ATPase. The Na-K ATPase is also known as the *sodium pump* or *sodium-potassium pump* ([124]). This enzyme is responsible for maintaining the high internal potassium and low internal sodium concentration of both erythrocytes and other mammalian cells. In the process of regulating the concentration of these cations, Na-K ATPase also effects regulation of cellular volume and maintains the potassium-dependent activation of some intracellular enzymes ([136]). Na-K ATPase is also known as the *ouabain-inhibitable ATPase*, because the enzyme is specifically sensitive to inhibition by ouabain. Finally, the mature erythrocyte is capable of responding to its environment through classical signaling mechanisms. It has a wide range of signaling molecules ([137]) and is affected by exogenous stimuli such as epinephrine ([138] , [139]). An adrenergic signaling mechanism has been implicated in the process producing abnormal adhesion of sickle red cells to endothelial components ([140]).

HEMOGLOBIN AND ERYTHROCYTE FUNCTION

Hemoproteins have been used by nature for processes as diverse as electron transfer down electrochemical gradients in the respiratory chain to the harvesting of light energy in photosynthesis. Hemoglobins are one of the most widespread and specialized hemoproteins existing in nature and have been found in prokaryotes, fungi, plants, and animals. These proteins permit the reversible binding of O_2 to heme while keeping the iron in the +2 state. They also facilitate the exchange of carbon dioxide between the lungs and the tissues. Recent studies have also demonstrated the importance of hemoglobin in control of vascular tone mediated by NO. In vertebrates, hemoglobin is the major constituent of the red cell cytoplasm, accounting for approximately 90% of the dry weight of the mature cell.

In most invertebrates, oxygen-carrying pigment is transported freely in the plasma rather than within cells. This is a relatively inefficient delivery system. Hemoglobin, as a protein free in the plasma, would exert an osmotic pressure approximately five times greater than that produced by the plasma proteins. By the inclusion of this pigment in corpuscles, the viscosity of the blood can be maintained at a low level, water is not drawn from the tissues by it, and the flow of blood containing such a large amount of protein is made possible. Furthermore, free hemoglobin is not maintained in the circulation and is subject to oxidative denaturation. Attempts to make hemoglobin substitutes have revealed that infusion of free hemoglobin or its derivatives causes a significant increase in blood pressure due to the scavenging of NO produced by vascular endothelium.

In a human at rest, approximately 250 ml of oxygen are consumed and 200 ml of carbon dioxide are produced per minute. During exercise, these quantities increase tenfold. If the respiratory gases were carried in physical solution in the plasma, human activity would be restricted to only one-fiftieth of that possible in the presence of hemoglobin-containing red cells. Hemoglobin permits the transportation of one hundred times more oxygen than could be carried by the plasma alone.

Evolution and Structure of Hemoglobin

Vertebrate hemoglobin is a conjugated protein with a molecular weight near 64,500 daltons. The hemoglobin molecule is roughly spherical with a maximum molecular diameter of approximately 6.4 nm. It is a tetramer, consisting of two pairs of similar polypeptide chains called *globins*, that exhibits a diad axis of symmetry. To each of the four chains is attached a prosthetic group, *heme*, a complex of iron and protoporphyrin (Fig. 8.12).

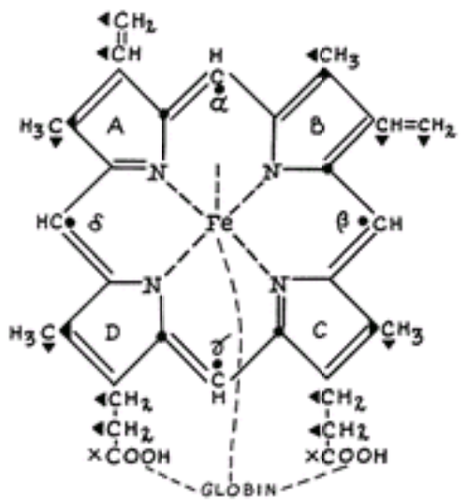

Figure 8.12. Chemical structure of heme and its manner of union with globin to form hemoglobin. The carbon atoms derived from the a carbon of glycine are represented by •, those supplied from the methyl carbon of acetate by s, and those derived from the carboxyl group of acetate by ×. The unmarked carbons are those derived from either the methyl carbon atom of acetate or from the carboxyl atom. (Prepared by Dr. G.E. Cartwright.)

Human hemoglobins share a common ancestry with a simpler, single-chain molecule that was similar to myoglobin. The divergence of the invertebrate and vertebrate globin genes occurred over 670 million years ago, and the divergence of the a and non-a globin genes probably descended from a common gene over 450 million years ago ([141]). Such an evolution would explain the high degree of homology between the a- and non–a- (ϵ, ?, ß, and d) chains, as well as the extraordinary similarities among the non-a globins. The non-a globin gene family is sometimes designated the ß *globin gene family*. The a and non-a peptide chains most likely arose because of gene duplication, after which time the genes for these individual proteins evolved independently ([142]). Likewise, the ß, d, ?, and ϵ globins probably also arose as a result of gene duplications ([143]). The occurrence of subunit cooperativity brought with it the advantage of increased physiologic effectiveness of the hemoglobin molecule and added a new pressure on further evolution of the hemoglobin chains ([144]). The a and non-a globins of vertebrates are approximately 50% identical with each other.

Ontogeny of Hemoglobins

Hemoglobin expression during ontogeny is characterized by three developmental periods: embryonic, fetal, and adult. In each developmental period, the oxygen delivery requirements are different, and erythroid development has evolved to meet these needs. The genes that encode the a globin gene family are on chromosome 16, whereas the genes encoding the members of the non-a globin gene family are on chromosome 11 ([145], [146]). These genes are developmentally and coordinately regulated, and, through the production of different pairs of globins, different hemoglobins are produced to permit their appropriate expression during different developmental periods. The a globin gene cluster is capable of producing two types of globins, ? and a. The ? is an embryonic globin chain produced during the first 8 weeks of fetal development, whereas a is produced during the remainder of fetal and adult developmental periods ([147]). The ß globin gene family members include the embryonic globin ϵ, the fetal globin ?, and two globins expressed primarily during the adult period, d and ß. A detailed description of the organization and structure of these genes is presented in Chapter 7 ([148]).

The transition from one developmental period to another is accompanied by the sequential and coordinate expression of the genes in each family. During early embryonic development, the expression of ? and ϵ globin genes leads to the production and assembly of these globins into the embryonic hemoglobin Gower-1 (? $_2$ϵ $_2$) ([149]). a and ? globins are also produced at low levels during this period, and this permits the production of two other embryonic hemoglobins, designated Gower-2 and Portland ([150]). Gower-2 is composed of a and ϵ globin chains (a $_2$ϵ $_2$), and Portland is assembled from ? and ? chains (? $_2$? $_2$). These embryonic hemoglobins display subunit cooperativity and serve as physiologic oxygen carriers in erythroid cells derived from yolk sac hematopoietic progenitors ([151]). Embryonic erythrocytes carrying these hemoglobins have an affinity for oxygen similar to fetal blood.

After the eighth week of development, erythropoiesis shifts from the yolk sac to the fetal liver, and the embryonic hemoglobins normally become detectable in fetal blood ([152]). Embryonic hemoglobins are replaced with hemoglobin F (a $_2$? $_2$), which remains as the predominant hemoglobin until after birth. The ?-chains are encoded by pairs of genes located near the normal ß globin gene on chromosome 11. The two ? genes encode nearly identical proteins: G? has a glycine at the codon position where A? has an alanine ([153], [154]). In addition, many A? genes also encode a threonine-for-isoleucine substitution at position 75 of the protein ([155], [156]). During fetal life, G? constitutes approximately 75% of ?-chains, whereas hemoglobin F in adults contains approximately 60% A? chains ([157], [158]). This has no known physiologic significance.

Red cells containing hemoglobin F have higher oxygen affinity than adult red cells. This permits the fetus to compete effectively for oxygen in the maternal blood. However, hemoglobin lysates from adult and fetal cells have nearly identical oxygen affinity when dialyzed against saline or a neutral buffer ([159]). This property of fetal hemoglobin is due to amino acid differences in the amino terminus of the ?-chains that impair binding of 2,3-diphosphoglycerate (2,3-DPG), an allosteric modifier of oxygen binding ([160]). Hemoglobin F also has an enhanced alkaline Bohr effect ([161]) whereby oxygen affinity is increased as hemoglobin passes through the pulmonary vasculature.

At approximately 20 weeks of fetal development, the site of erythropoiesis begins to switch from the liver and spleen to the bone marrow, where progenitors show increased expression of adult globins, a and ß. Hemoglobin A may constitute 5% of ß-family globin expression during this time. Beginning at the thirtieth week and proceeding to the time of birth, a significant switch from fetal to adult erythropoiesis takes place, such that at the time of birth, fetal hemoglobin constitutes approximately 80% of the total hemoglobin. Over the next 25 to 30 weeks after birth, fetal hemoglobin concentration decreases by approximately 10% every 2 weeks until it reaches its normal adult level of less than 2% by 30 weeks of age ([162]). Neonates with hemoglobinopathies or erythropoietic stress can have a greatly prolonged production of hemoglobin F, sometimes extending into adulthood ([163]). The proportion of hemoglobins produced during the different developmental periods is summarized in Table 8.5.

TABLE 8.5. Normal Human Hemoglobins

Name	Designation	Molecular Structure	Proportion	
			Adults (%)	Newborns (%)
Adult hemoglobin	A	a $_2$ß $_2$	97.0	20.0
Hemoglobin A $_2$	A $_2$	a $_2$d $_2$	2.5	0.5
Fetal hemoglobin	F	a $_2$? $_2$	<1.0	80.0
Portland	—	? $_2$? $_2$	0	0

Gower-1	—	? $_2$ϵ $_2$	0	0
Gower-2	—	a $_2$ϵ $_2$	0	0

Hemoglobin A, a $_2$ß $_2$, is the predominant adult hemoglobin and normally constitutes approximately 96% of the total adult hemoglobin. A minor adult hemoglobin, A $_2$, is produced beginning at 35 weeks of gestation but has little physiologic relevance. Hemoglobin A $_2$ is composed of a globins and the minor adult globin d. It normally constitutes less than 3.5% of total adult hemoglobin; however, it is typically increased in ß-thalassemias and may be increased in other conditions, to be described later. Clinically, its major importance is its value in diagnosing ß-thalassemias ([164]).

Modifications of Normal Hemoglobin

Analysis of human red cell hemolysates by cation-exchange chromatography reveals several negatively charged minor hemoglobins that are designated A $_{Ia}$, A $_{Ib}$, and A $_{Ic}$, corresponding to their order of elution. These hemoglobins are formed by the nonenzymatic interaction of glucose with the a-amino groups of valine residues at the N-termini of the ß-chains of hemoglobin ([165]). They account for the so-called hemoglobin A $_3$ fraction on starch-block electrophoresis (Fig. 8.13) ([166]).

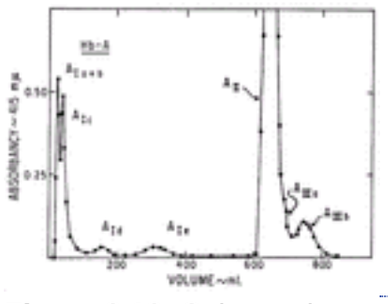

Figure 8.13. Column chromatograph of hemoglobin (Hb) A on IRC-50. The main component, A $_{If}$, corresponds to the HbA $_1$ demonstrated by starch-block electrophoresis, A $_{III}$ corresponds to HbA $_2$, and A $_I$ corresponds to A $_3$. (Courtesy of Dr. Robert L. Hill.)

The best characterized of the acquired variants is hemoglobin A $_{Ic}$, which constitutes approximately 3.5% of the hemoglobin in normal subjects and may be increased two- to threefold in individuals with diabetes mellitus. Its level is directly proportional to the time-integrated mean blood glucose concentration over the life of the red cell, typically the preceding 2 to 3 months ([167]). In the nonenzymatic glycosylation of hemoglobin A, a molecule of glucose forms a Schiff base with the *N*-terminus of the ß-chain, then undergoes an Amadori rearrangement to a stable ketamine, 1-amino, 1-deoxy fructose ([168] , [169]). With special techniques, two different derivatives can be detected in the A $_{Ia}$ fraction. In so-called hemoglobin A $_{Ia1}$, a fructose 1,6-diphosphate molecule is attached to the ß-chain, whereas in hemoglobin A $_{Ia2}$, glucose-6-phosphate occupies the same site ([167]). Hemoglobin A $_{Ib}$ has not yet been fully characterized, but it appears to be a glycosylated, nonphosphorylated derivative. Levels of hemoglobins A $_{Ia}$ and A $_{Ib}$, like hemoglobin A $_{Ic}$, are also increased in persons with hyperglycemia. Recently, hemoglobin A $_{Id3}$ has been identified and found to be due to the addition of glutathione (GSH) to the ß-chain of hemoglobin ([170]).

Because the glycosylated hemoglobins are synthesized throughout the lifespan of the red cell, older cells contain a higher proportion of these modified hemoglobins than younger ones ([171]). Preferential destruction of older cells explains the observation that the proportion of these hemoglobins is reduced in hemolytic anemia ([172]). Because the rate of synthesis of hemoglobin A $_{Ic}$ depends on the blood glucose level, the concentration of hemoglobin A $_{Ic}$ at any one time is proportional to the average blood sugar over the previous 2 to 3 months ([173]). For this reason, the level of glycosylated hemoglobins is now used widely as a measure of glucose control in diabetic patients, as well as a tool for diagnosis of diabetic states ([173] , [174] and [175]). In contrast, the hemoglobin A $_{Ia}$ components are not significantly increased in diabetes (Table 8.6), presumably reflecting the fact that their phosphorylated substituents are not increased in the red cells of patients with diabetes ([167]).

TABLE 8.6. Glycosylated Hemoglobins in Normal and Diabetic Individuals

Hemoglobin	ß-Terminal Group	Average Concentration (%)	
		Normal	Diabetes
A $_{Ia1}$	Fructose 1,6-diphosphate	0.19	0.20
A $_{Ia2}$	Glucose-6-phosphate	0.19	0.22
A $_{Ib}$ [a]	Unknown	0.48	0.67
A $_{Ic}$	Glucose	3.30	7.50
A $_{Ia}$ + A $_{Ib}$ + A $_{Ic}$	—	6.50 ± 1.50 [a]	11.0 ± 2.90 [a]

NOTE: Totals are greater than the sum of the components because of differences in technique in the two studies.

[a] Mean ± one standard deviation, 20 normal subjects and 75 adult diabetics. (Trivelli LA, Ranney HM, Lai HT. Hemoglobin components in patients with diabetes mellitus. N Engl J Med 1971;284:353.)

Clinical laboratories currently use a variety of assays to detect and quantify glycated hemoglobins, including cation-exchange chromatography, high-pressure liquid chromatography, immunoassays, and boronate affinity methods ([176]). Commonly encountered hemoglobin variants, such as hemoglobin S, hemoglobin C, hemoglobin E, and hemoglobin F, can interfere with these assays and may help explain discordant assay results ([176]).

Laboratory Analysis of Hemoglobins

Normal and variant hemoglobins can be detected and quantified by standard clinical laboratory techniques. The clinical utility in these measurements includes the identification of variants as well as determination of the levels of normal hemoglobins. Standard cellulose acetate electrophoresis performed at alkaline pH or isoelectric focusing can detect most of the common variants ([177]). Usually, confirmation can be achieved by citrate agar electrophoresis, isoelectric focusing, or high-performance liquid chromatography. The analysis of hemoglobin A $_2$ and fetal hemoglobin levels deserves special attention because the levels of these components are indicative of common conditions affecting hemoglobin synthesis. Hemoglobin A $_2$ normally constitutes less than 3.5% of the total hemoglobin in adults. In most cases of ß-thalassemia and some a-thalassemia, hemoglobin A $_2$ levels may be increased, ranging from 3.6 to 8.0% ([178] , [179]). The subtle increase in hemoglobin A $_2$ characteristic of these conditions cannot be quantified accurately by electrophoretic methods. Instead, most laboratories use ion-exchange resin microchromatography ([180]). It is a common error to use hemoglobin electrophoresis as the sole method to rule out ß-thalassemia, and most large laboratories add the chromatographic quantification of hemoglobin A $_2$ as part of their routine hemoglobin analysis.

Hereditary persistence of fetal hemoglobin and d-ß–thalassemia are types of ß-thalassemia caused by deletion of d and ß globin genes but distinguished from typical ß-thalassemia by more balanced a and non-a globin chain synthesis due to an increase in ? globin production. In both of these thalassemias, hemoglobin A $_2$ levels

are reduced due to deletion of d globin genes.

Elevated levels of hemoglobin F can be caused by thalassemias, disorders of hematopoiesis, or hereditary disorders of globin synthesis such as hereditary persistence of fetal hemoglobin and d-ß–thalassemia ([181]). Diagnosis requires the precise measurement of hemoglobin F levels, which can be achieved in clinical laboratories by taking advantage of the resistance of hemoglobin F to alkali denaturation ([182]). This resistance to alkali denaturation of fetal hemoglobin is due to the greater stability under these conditions of a-? globin dimers compared to a-ß globin dimers ([183]). In lysates exposed to alkali under controlled conditions, only fetal hemoglobin remains undenatured, and its concentration can be quantified after the other denatured hemoglobins are removed from solution ([184] , [185] and [186]). Routine electrophoretic procedures do not completely separate hemoglobin F from A, but a more adequate separation can be accomplished at pH 6.0 in agar gel ([187]).

In adults, fetal hemoglobin is unevenly distributed in erythrocytes, being restricted to between 0.1 and 7.0% of total cells ([188]). Cells containing fetal hemoglobin are designated F or A/F cells, wherein the hemoglobin F concentration is normally between 14 and 25% of the total hemoglobin ([189]). In certain thalassemias and in hereditary persistence of fetal hemoglobin, the number of F cells is increased. This condition can be detected by acid treatment of erythrocytes on a glass slide followed by elution of other unstable hemoglobins (Kleihauer-Betke technique). Counterstaining can identify hemoglobin F–containing cells ([190]).

Examination of normal blood by the Kleihauer-Betke method demonstrates both colorless cells and fetal hemoglobin–containing (light pink) cells that vary in intensity. By comparison, analysis of cord blood mixed with adult blood demonstrates that true fetal cells in cord blood stain intensely, reflecting the high level of fetal hemoglobin in fetal cells. This assay can be performed on maternal blood to detect feto-maternal hemorrhage or other contamination of the maternal circulation with fetal blood. This method is easily performed in small laboratories, but some larger laboratories are now using flow cytometry with a phycoerythrin-conjugated antiglycophorin antibody to detect feto-maternal hemorrhage ([191]).

Structure of Globin

Proteins have at least four levels of structural organization ([192]): (a) *primary structure*, or the linear sequence of amino acids; (b) *secondary structure*, which describes how the amino acids within segments of the protein are spatially organized (e.g., by folding into an a-helix or ß–pleated sheet); (c) *tertiary structure*, which refers to the steric relationships of sequence domains separate from each other when analyzed as part of the linear sequence of the protein; and (d) *quaternary structure*, or the way in which several polypeptide chains join to form a single molecule.

The exact primary structure of all normal globin chains has been determined based on the DNA sequence of the individual globin genes (Table 8.7) ([193]), and the polypeptide chains in hemoglobin differ from one another in amino acid sequence. The a-chain contains 141 amino acids and the non–a-chains, 146. The members of the non–a-chain family are more similar than any member of the non–a-chain and the a-chain family. The d-chain differs from the ß-chain in only 10 of its 146 amino acid residues, whereas the ?- and ß-chains differ by 39 amino acids.

TABLE 8.7. Primary and Secondary Structure of Hemoglobin Polypeptide Chains

[a] Amino acids are indicated by a three-letter code. Uncharged amino acids: Ala, alanine; Asn, asparagine; Cys, cystine; Gln, glutamine; Gly, glycine; Ile, isoleucine; Leu, leucine; Met, methionine; Phe, phenylalanine; Pro, proline; Ser, serine; Thr, threonine; Try, tryptophan; Tyr, tyrosine; Val, valine. Charged amino acids: Arg, arginine (+1); Asp, aspartic acid (–1); Glu, glutamic acid (–1); His, histidine (+1); Lys, lysine (+1).

[b] The two normal ?-chain genes differ from each other in that the ^{G}? gene encodes glycine at this position, whereas the ^{A}? gene encodes alanine.

Despite the differences in the primary structure of non–a globin chains, their secondary structures are remarkably similar. Each has eight helical segments designated by the letters A through H (Table 8.7) ([194]). The helixes of all the non–a-chain members are of identical length; however, a significant difference exists between the a and non–a globin chains in the region of the D helix, which contains seven amino acids in the ϵ-, ?-, d-, and ß-chains, but only two amino acids in the a-chain. Because of the size of the D helix in the a globin chains, many do not assign it a helix designation. The helixes make up approximately 75% of the molecule. Interspersed between them are seven nonhelical segments: NA, AB, CD, EF, FG, GH, and HC. This arrangement is important structurally, because the helixes are relatively rigid and linear, whereas the nonhelical segments allow bending.

A given amino acid in a hemoglobin polypeptide may be denoted either by its sequential number or by a helical number. In the sequential system, the *N*-terminal amino acid is assigned the number 1, and each succeeding amino acid receives the next higher number until the *C*-terminal is reached. With this system, amino acids are numbered from 1 to 141 in the a-chain and from 1 to 146 in the ß-, ?-, and d-chains. In the helical system, each amino acid is designated by a letter and a number that indicate the helix and the position in the helix, respectively. The helical system is gradually gaining favor, because it illustrates the homology between chains and has more structural significance. For example, the histidine to which heme attaches is amino acid 87 in the a-chain and 92 in the ß-, ?-, and d-chains; the helical designation for this histidine, F8, is the same in all the normal chains.

The tertiary and quaternary structures of hemoglobin have been studied by x-ray diffraction techniques, especially by Perutz and his co-workers ([194], [195]). In aqueous solutions and in crystals, the polypeptide chains assume a structure in which the polar amino acids face the molecular surface where they interact with water, rendering the molecule soluble. The groups directed toward the inner core of the molecule are all nonpolar, and the hydrophobic (van der Waals) bonding that occurs between them makes the structure stable. The resulting roughly spherical, tertiary structure is similar for all the normal hemoglobin polypeptides (Fig. 8.14) as well as for certain other heme proteins such as myoglobin.

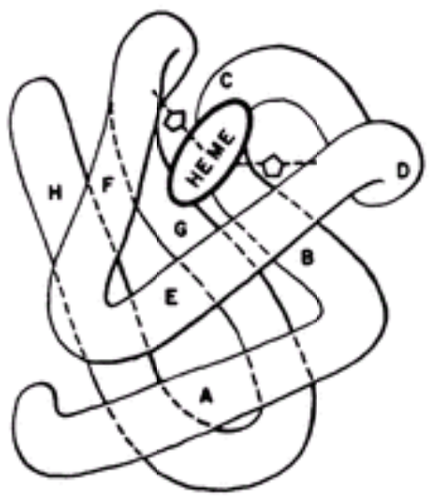

Figure 8.14. The tertiary structure of a single globin polypeptide chain. The helical segments, labeled A through H, are relatively linear; bending of the chains occurs between helices. Heme is suspended in a crevice between the E and F helices. (Courtesy of C.A. Finch.)

The heme pocket is the site of many dynamic interactions involving oxygen binding to hemoglobin. Heme is suspended in a nonpolar crevice between the E and F helixes (Fig. 8.14), and helixes B, G, and H constitute the floor of the pocket. Heme iron forms a covalent bond with the imidazole nitrogen of the “proximal” histidine at F8. In addition, heme forms van der Waals bonds with many other parts of the molecule and, in this way, makes an important contribution to tertiary structure. If heme is extracted, the central helical regions C, D, E, and F unfold with a consequent decrease in solubility ([196]). Not surprisingly, some unstable hemoglobins (Chapter 41) result from amino acid substitutions in the residues that line the heme pocket ([197]).

The binding of oxygen to the iron molecule causes the hemoglobin molecule to undergo conformational changes that affect the binding of oxygen to other heme sites. The mechanism for this property can be explained in part by the interactions in the heme pocket. The two histidines of globin (E7, F8) are located immediately above

and below iron, which is in the plane of the pyrrole ring in oxyhemoglobin ([198]). In deoxyhemoglobin, the bond between the imidazole nitrogen of the proximal histidine and iron undergoes considerable strain, displacing iron from the plane of the ring. This strain is conveyed to other parts of the molecule and is in part responsible for the tense state of deoxyhemoglobin ([199]). The addition of two molecules of oxygen, which are bound to the iron atom in the heme ring by end-on geometry, results in the formation of a hydrogen bond between the oxygen atom not bound directly to the iron and the imidazole nitrogen of the histidine at E7 (the "distal" histidine) ([199]). The binding of oxygen to iron changes the electron spin state of iron and relaxes the covalent bond with the proximal histidine, permitting the iron to move into the plane of the ring and relaxing the molecule, contributing to the relaxed state ([200]). The overall conformational changes to hemoglobin appear to be the greatest after three molecules of O_2 have been added. In general, proteins that undergo an allosteric change from the tense to a relaxed state are better able to interact with substrate in the relaxed state.

When four polypeptide chains combine to form the hemoglobin molecule, each chain lies approximately at the vertices of a regular tetrahedron. With high-resolution x-ray diffraction, the nature of the contacts between chains has been explored in detail for horse hemoglobin ([194]). Contacts between like chains (i.e., a $_1$a $_2$ and ß $_1$ß $_2$) are limited and of little importance. The two major contacts between unlike chains have been named a $_1$ß $_1$ and a $_1$ß $_2$, respectively (Fig. 8.15). (The a $_2$ß $_2$ contact is the same as a $_1$ß $_1$.) The a $_1$ß $_1$ contact point is extensive and moves relatively little (<0.1 nm) when hemoglobin is oxygenated. The a $_1$ß $_2$ contact is smaller and smoother, and movement on oxygenation is relatively great (as much as 0.7 nm). As a result, there are two quaternary structures for hemoglobin: one for the deoxygenated form and one for the liganded or oxygenated form. The main difference between the two is the nature of the a $_1$ß $_2$ contact (Fig. 8.16).

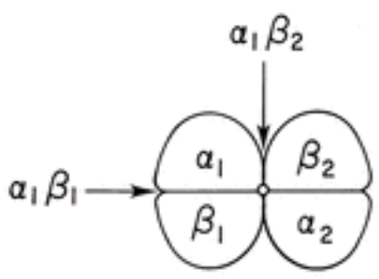

Figure 8.15. Diagram of hemoglobin tetramer illustrates two types of aß contact points: a relatively extensive one (a $_1$ß $_1$ or a $_2$ß $_2$) and one that is smaller (a $_1$ß $_2$ or a $_2$ß $_1$). The actual molecular contact points are detailed in Figure 8.16.

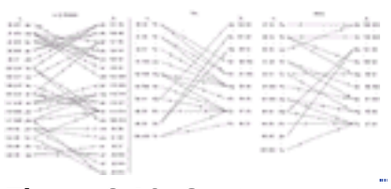

Figure 8.16. Quaternary structure of hemoglobin. At left is the most extensive contact, a $_1$ß $_1$, in which 16 amino acids in the a-chain form bonds with 18 amino acids in the ß-chain. The a $_1$ß $_1$ contact does not change significantly on oxygenation. The smaller a $_1$ß $_2$ contact, center and right, has two forms, depending on whether the hemoglobin is in the oxygenated (Oxy) or deoxygenated (Deoxy) form. At a $_1$ß $_2$, 10 or 11 amino acids in the a-chain form bonds with nine in the ß-chain. Plain lines indicate van der Waals bonds; broken lines indicate hydrogen bonds. Numbers on lines give the number of atoms in contact. (From Perutz MF, Miurhead H, Cox JM, et al. Stereochemistry of cooperative effects in haemoglobin. Nature 1968;219:29, with permission.)

Assembly of Hemoglobin

Much of our overall knowledge of the synthesis of proteins was learned from the study of globins, and many of the specific details of the synthesis of globins are described in Chapter 7. Assembly of the hemoglobin tetramer from the monomers, however, has received relatively little attention, although an understanding of the process can provide some insight into the laboratory evaluation of hemoglobins.

In general, there is little posttranscriptional regulation of the synthesis of globins, although factors such as the availability of heme can affect translation of globin mRNA ([201]). Aside from several variants, such as hemoglobin Lepore, that are synthesized at a slower rate, the synthesis rates of most normal or mutant globins are the same ([202]). Nevertheless, individuals with ß-chain variants often express less of the variant hemoglobin than hemoglobin A. This observation has been attributed to an increased rate of catabolism of newly synthesized globin chains due to decreased solubility, defective heme binding, or abnormal subunit assembly. The best data indicate that the variations seen in most stable hemoglobin variants result from differences in subunit assembly ([183] , [203]).

After translation of globin mRNA and globin chain synthesis, heme associates with globins, and a globin chains pair with members of the ß globin family. In large part, this binding is a consequence of the different charges on a globins, which are positively charged (pI = 8.1), and ß globins, which are negatively charged (pI = 6.6) ([204]). The greater the charge difference, the greater the electrostatic attraction. Positively charged variants, such as ß $_C$, and the uncharged ß $_S$ bind to a globin and assemble into a-ß dimers at approximately half the rate of ß $_A$ during *in vitro* mixing experiments ([203]). Conversely, more negatively charged variants, such as ß $_{N\text{-}Baltimore}$, bind with a greater association rate. This phenomenon has been suggested as an explanation for the ratio of 60:40 seen for hemoglobin A and hemoglobin S in heterozygotes for ß $_S$. Likewise, the percentage of N-Baltimore is increased over hemoglobin A.

In conditions of a globin deficiency, this competition is more pronounced, and the percentage of the more positively charged variant is further reduced. Patients heterozygous for ß $_S$ and a-thalassemia carry percentages of hemoglobin S of approximately 35%, 30%, and 25%, corresponding to one-, two-, or three-gene a-thalassemia ([205]).

Hemoglobin A $_2$ is reduced in certain a-thalassemias and in iron deficiency, which causes an acquired reduction in a globin synthesis as a result of decreased heme synthesis. Under these conditions, the more positively charged d globin would be expected to compete less well with the normal ß globin. In contrast, during ß globin deficiency associated with ß-thalassemia, d globin would be expected to compete more effectively for a globin chains, and the predicted increase in hemoglobin A $_2$ is observed ([206]).

Oxygen Transport

To function as the primary medium of exchange of oxygen and carbon dioxide, hemoglobin must fulfill the four requirements first delineated by Barcroft ([207]). It must be capable of transporting a large quantity of oxygen, it must be highly soluble, it must take up and release oxygen at "appropriate pressures," and it must also be a good buffer. Normal hemoglobin fulfills these requirements well, although many abnormal variants fail to meet one or more of these conditions.

When fully saturated, each gram of hemoglobin binds 1.39 ml of oxygen. The degree of saturation is related to the PO_2, which normally ranges from 100 mm Hg in arterial blood to approximately 35 mm Hg in veins. The relation between PO_2 and hemoglobin oxygen saturation is described by the oxygen dissociation curve of hemoglobin (Fig. 8.17). The characteristics of this curve are related in part to properties of hemoglobin itself and in part to the environment within the erythrocyte, with pH, temperature, and concentration of 2,3-DPG being the most important factors affecting oxygen affinity.

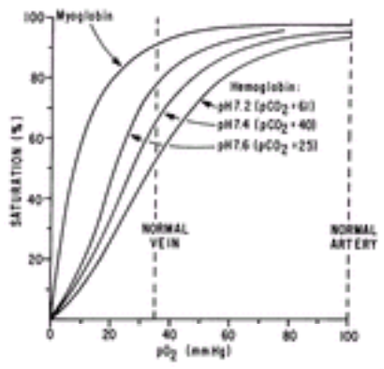

Figure 8.17. Oxygen dissociation curve of hemoglobin at three values for pH, compared with that of myoglobin. PO_2, partial pressure of oxygen; PCO_2, partial pressure of carbon dioxide.

Oxygen affinity of a particular hemoglobin is generally expressed in terms of the PO_2 at which 50% saturation occurs, the so-called P_{50}. When measured in whole erythrocytes, this value averages approximately 26 mm Hg in normal, nonsmoking males and slightly higher in normal, nonsmoking females (208). When oxygen affinity increases, the dissociation curve shifts leftward, and the value for P_{50} is reduced. Conversely, with decreased oxygen affinity, the curve shifts to the right, and P_{50} is increased.

The oxygen dissociation curve of single-subunit heme polypeptides (e.g., myoglobin) is hyperbolic, and oxygen affinity is considerably greater than that of hemoglobin (Fig. 8.17). Such a compound would function poorly in oxygen transport because little oxygen would be released until the tissue PO_2 was very low. For example, at the usual tissue PO_2 of 40 mm Hg, myoglobin would remain over 90% saturated. In contrast, the oxygen dissociation curve of hemoglobin is distinctly sigmoidal; the steepest part of its slope occurs at levels of PO_2 corresponding to those found in tissues. This difference between the hemoglobin and myoglobin curves is the result of interaction between the four heme-polypeptide units of hemoglobin. Although called *heme–heme interaction* in the past, *subunit cooperativity* better describes the process whereby the binding of oxygen by one subunit increases the oxygen affinity of other subunits; no direct interaction among heme moieties is involved. This allosteric property of hemoglobin permits rapid changes in oxygen affinity during the time the red blood cell passes through the capillary bed.

The change in oxygen affinity with pH is known as the *Bohr effect* (209 , 210). Hemoglobin oxygen affinity is reduced as the acidity increases (Fig. 8.17). Because the tissues are relatively rich in carbon dioxide and red cell carbonic anhydrase readily converts carbon dioxide to carbonic acid, the pH is lower there than in arterial blood; therefore, the Bohr effect facilitates transfer of oxygen to tissues. In the lungs, as oxygen is taken up and carbon dioxide is released, the pH rises and the oxygen affinity curve shifts to the left. This event, termed the *alkaline Bohr effect*, increases the oxygen affinity of hemoglobin, helping to maximize oxygen uptake. Thus, the Bohr effect links and enhances the transport of both oxygen and carbon dioxide.

Another important factor affecting the oxygen affinity of hemoglobin is the concentration of 2,3-DPG (211 , 212 , 213 and 214). The molecule can insert into the pocket between ß globin subunits in tetrameric hemoglobin and reduces oxygen affinity. 2,3-DPG is synthesized from glycolytic intermediates by means of a pathway known as the *Rapoport-Luebering shunt* (Fig. 8.18). In the erythrocyte, 2,3-DPG is the predominant phosphorylated compound, accounting for approximately two-thirds of the red cell phosphorus, whereas, in contrast, it is present in only trace amounts in other tissues.

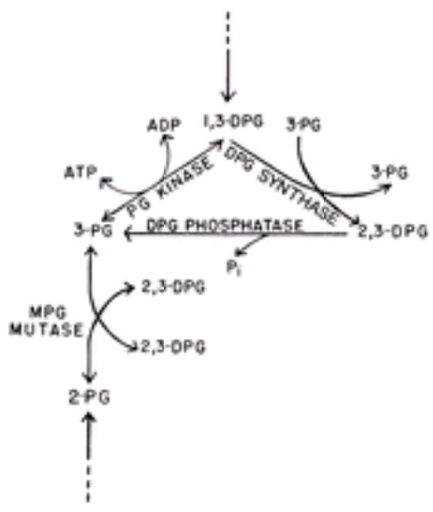

Figure 8.18. The synthesis of 2,3-diphosphoglycerate (2,3-DPG) or 3-phosphoglycerate (3-PG) and adenosine triphosphate (ATP) from 1,3-diphosphoglycerate (1,3-DPG) by the Rapoport-Luebering cycle. ADP, adenosine diphosphate; MPG, XX; $P_¡$, XX. (From Bunn HF, Forget BG. Hemoglobin: molecular, genetic and clinical aspects. Philadelphia: WB Saunders, 1986, with permission.)

The production of 2,3-DPG depends on the rate of formation of its precursor, 1,3-DPG, and the relative amounts of 1,3-DPG going into the Rapoport-Luebering shunt and into the ATP-forming glycolytic pathway. Actual 2,3-DPG concentration also depends on the rate of hydrolysis of 2,3-DPG. Although several steps in the glycolytic pathway may be sensitive to changing conditions, such as pH, ADP-ATP, and nicotinamide adenine dinucleotide (NAD-NADH) ratios, and the concentration of inorganic phosphorus, it is the relative concentrations of ATP and ADP that appear most directly linked to the rate of 2,3-DPG production. A relative increase in the amount of ADP is associated with an increase in the production of 3-phosphoglycerate and a decrease in 2,3-DPG. Oxidants such as methylene blue and pyruvate increase 2,3-DPG synthesis by affecting the NAD-NADH ratio.

Two multifunctional enzymes are important to the synthesis and degradation of 2,3-DPG. Both enzymes are capable of promoting three reactions: the synthesis of 2,3-DPG from 1,3-DPG; the breakdown of 2,3-DPG into 3-PG, water, and phosphorus; and the conversion of 3-PG to 2-PG. The structures of these enzymes and their relative activities have been described extensively (215 , 216 , 217 , 218 and 219).

The most important function of 2,3-DPG is its effect on the oxygen affinity of hemoglobin. In the deoxygenated state, hemoglobin A can bind 2,3-DPG in a molar ratio of 1:1, a reaction leading to reduced oxygen affinity and improved oxygen delivery to tissues. The increased oxygen affinity of fetal hemoglobin appears to be related to its lessened ability to bind 2,3-DPG. The cellular concentration of 2,3-DPG also affects intracellular pH, because 2,3-DPG is a highly charged, impermeant anion. Hemoglobin, also an impermeant anion, and 2,3-DPG together lower the intracellular concentration of chloride relative to the extracellular concentration. This effect, in turn, lowers intracellular pH relative to extracellular pH, which, by the Bohr effect, also lowers oxygen affinity and thus increases oxygen delivery to tissues (220).

The increased oxygen affinity of stored blood is accounted for by reduced levels of 2,3-DPG (221). Transfusion of such blood results in an *in vivo* increase in oxygen affinity that returns toward normal in 7 to 12 hours as the function of the glycolytic pathway is restored. The reduction in 2,3-DPG levels in stored blood can be mitigated by adding inosine or phosphate to the storage solutions (222). The actual clinical impairment in oxygen delivery due to low 2,3-DPG levels remains disputed, but it would be expected to have its greatest impact when large transfusions are required in critically ill individuals. In such situations, some centers administer fresh blood (223), although this practice remains uncommon.

Changes in 2,3-DPG levels play a significant role in adaptation to hypoxia. In some situations associated with hypoxemia, 2,3-DPG levels in red cells increase, oxygen affinity is reduced, and delivery of oxygen to tissues is facilitated. Such situations include abrupt exposure to high altitude, anoxia resulting from pulmonary or cardiac disease, blood loss, and anemia (224 , 225 and 226). Increased 2,3-DPG levels also play a role in adaptation to exercise (227). The compound is not essential to life, however; an individual who lacked the enzymes necessary for 2,3-DPG synthesis was perfectly well except for mild polycythemia. Heme–heme interaction, the Bohr effect, and the effect of 2,3-DPG have been explained on a molecular basis in a model proposed by Perutz (228). In the completely deoxygenated state, hemoglobin assumes a quaternary structure termed *T* (“taut” or “tense”). This structure is stabilized by salt bridges involving the carboxy terminals of the peptide

chains. The deoxy form is also stabilized by the presence of 2,3-DPG, which joins the ß-chains as shown in Figure 8.19.

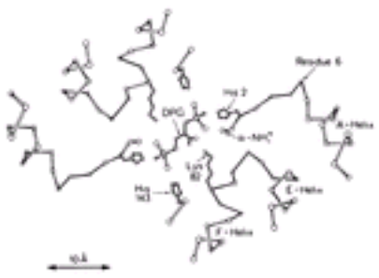

Figure 8.19. The 2,3-diphosphoglycerate (2,3-DPG) binding site. Part of one ß-chain is at upper left, the other at lower right. Salt bridges are found between the phosphates of 2,3-DPG and positively charged groups at 1 Val (a-NH_3^+), 2 His, and 143 His. The 82 Lys of one chain is also involved. (From Arnone A. X-ray diffraction study of binding of 2,3-diphosphoglycerate to human deoxyhemoglobin. Nature 1972;237:146, with permission.)

The tertiary structure of deoxygenated subunits also differs from that of the oxygenated form. In the deoxy form, heme iron is in a high-spin state and, in this form, is displaced slightly from the plane of the porphyrin ring. The penultimate tyrosine is wedged firmly between the F and H helixes. When oxygen is added, iron changes to a low-spin state and moves to a position in plane with the porphyrin ring, a distance of approximately 0.2 nm, pulling the attached F helix with it. This movement narrows the space between the F and H helixes, expelling the penultimate tyrosine from its pocket. The *C*-terminal amino acid moves with the tyrosine, thereby breaking the salt bridges with adjacent chains.

Fully oxygenated hemoglobin assumes the R or “relaxed” structure (Fig. 8.20). The exact series of events that bring about this change, along with the change in oxygen affinity that accompanies it, has been difficult to ascertain, in part because of the large number of variables that need to be controlled (e.g., temperature, pH, 2,3-DPG concentration, and hemoglobin concentration) and the extraordinarily large number of thermodynamic measurements that need to be made. Nevertheless, at least some of the molecular events that contribute to this shift in quaternary structure and oxygen affinity have been delineated ([229], [230]). Hemoglobin appears to exist in a third molecular form, intermediate between the T and R conformations. Achievement of the R conformation occurs when at least one oxygen molecule is bound on each side of the $a_1ß_2$ interaction; however, significant subunit cooperativity also exists within each $a_1ß_1$ dimer of the T-state tetramer. Conversion to the R form is also accompanied by expulsion of the 2,3-DPG and disruption of the salt bridges and hydrophobic interactions at the $a_1ß_2$ contact point (Fig. 8.20). Oxygen affinity then becomes much increased, and oxygen is added to the remaining ß-chain or chains. Because hemoglobin A has four subunits, it might be expected that the switch from the T to the R state would occur in four distinct steps. Experimentally, it appears to switch abruptly. This is best explained by the relationship of the four subunits. The a- and ß-chains in the dimers have many more contacts than the two dimers with each other, and the dimers can move onto each other. As oxygen is either loaded or unloaded onto the hemoglobin tetramer, tension is created, and the point where the two dimer subunits slide onto each other is determined by the concentration of the allosteric mediators in the cell, including pH, Cl^- concentration, and 2,3-DPG levels.

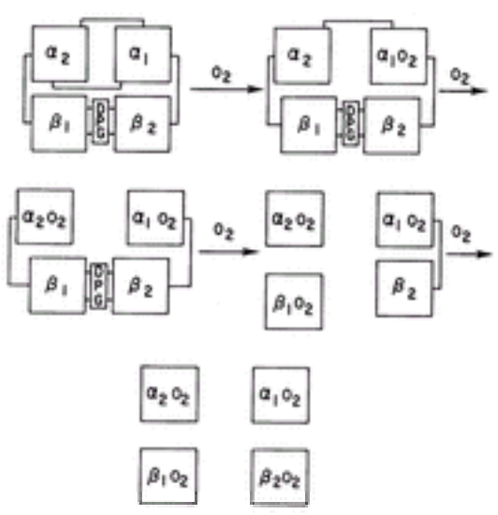

Figure 8.20. Diagrammatic representation of the subunit interaction in hemoglobin as oxygen is added. Deoxyhemoglobin (*upper left*), with low oxygen affinity, is in the T (taut) conformation, constrained by salt bridges (*interconnecting lines*) and the 2,3-diphosphoglycerate (2,3-DPG) molecule. As O_2 is added, salt bridges are broken, and, eventually, the DPG molecule is expelled, resulting in the R (relaxed) configuration with higher oxygen affinity.

The alkaline Bohr effect is explained by rupture of the salt bridges involving the ß-chain *C*-terminal histidine and the a- *N*-terminal valine. When these bridges are broken, the pK of the dissociation of hydrogen ion is reduced. It has also been suggested that approximately 25% of the alkaline Bohr effect may be accounted for by histidine at a122 ([231]).

Alterations in the oxygen dissociation curve occurring in various hemoglobinopathies are discussed later in this book in Chapter 41, Chapter 49, and Chapter 50.

Carbon Dioxide Transport

Transport of carbon dioxide by red cells, unlike that of oxygen, does not occur by direct binding to heme ([232]). In aqueous solutions, carbon dioxide undergoes a pair of reactions:

$$CO_2 + H_2O \rightarrow H_2CO_3$$

$$H_2CO_3 \rightarrow H^+ + HCO_3^-$$

Carbon dioxide diffuses freely and rapidly into the red cell, where the presence of the enzyme carbonic anhydrase facilitates the first of these two reactions. The H^+ liberated in the second reaction is accepted by deoxygenated hemoglobin, a process facilitated by the Bohr effect. The bicarbonate formed in this sequence of reactions diffuses freely across the red cell membrane, and a portion is exchanged with plasma Cl^-, a phenomenon called the *chloride shift*. The bicarbonate is carried in plasma to the lungs, where ventilation keeps the CO_2 tension (PCO_2) low, resulting in reversal of the above reactions and excretion of CO_2 in the expired air. Approximately 85% of tissue carbon dioxide is processed in this way, and 5% is carried in simple solution.

The remainder of the CO_2 is bound to the *N*-terminal amino group of each polypeptide chain by a carbamino complex, the result of an attack by the electron-poor carbon atom of CO_2 on the electron-rich terminal amino acids. This nonenzymatic process varies directly with pH. Approximately 10% of CO_2 is bound to deoxygenated hemoglobin, forming carbaminohemoglobin (Hb-NH-COO^-).

Earlier, the effect of CO_2 on oxygen affinity was noted and attributed to the Bohr effect. An additional, more direct effect results from CO_2 binding to hemoglobin. At a given pH, carbaminohemoglobin has a lower affinity for oxygen than has hemoglobin in the absence of CO_2. This is believed to be a result of the stabilization of the T state through additional bonds, especially involving arginine 141 ([233]).

The carbon dioxide dissociation curve is analogous to the oxygen dissociation curve in that it depicts the relationship between PCO_2 and CO_2 content (Fig. 8.21). It is somewhat more nearly linear than the oxygen curve, especially in the physiologic range (PCO_2, 40 to 60 mm Hg). Blood containing deoxyhemoglobin has greater

affinity for CO_2 than does oxygenated blood because of the Bohr effect. The shift in the CO_2 dissociation curve related to this phenomenon, known as the *Haldane effect*, facilitates CO_2 binding in the tissues and release in the lungs (Fig. 8.22).

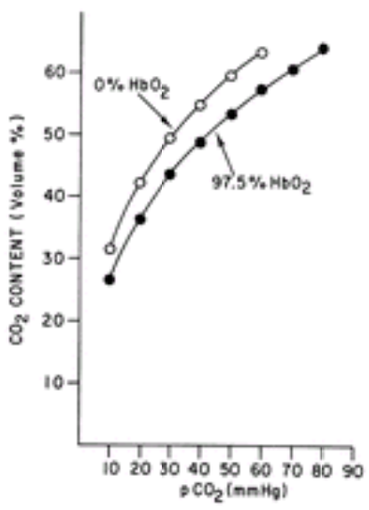

Figure 8.21. The carbon dioxide dissociation curve of whole blood. The curve is relatively linear between partial pressure of carbon dioxide (PCO_2) 40 and 60 mm Hg. The difference between the curves of oxygenated and deoxygenated blood is known as the *Haldane effect*. HbO_2, oxyhemoglobin.

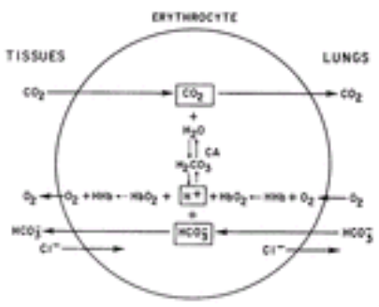

Figure 8.22. Interrelations of oxygen and carbon dioxide transport in the erythrocyte. Arrows to the left indicate direction of reactions taking place in the tissues; those to the right, in the lungs. In the tissue, CO_2 diffuses into the red cell, and its hydration is catalyzed by carbonic anhydrase (CA). Dissociation of the resulting carbonic acid produces bicarbonate and a proton (H^+). The bicarbonate is exchanged for chloride in the plasma. The proton is accepted by oxyhemoglobin (HbO_2), a reaction that, by means of the Bohr effect, facilitates the dissociation of oxygen. These reactions are reversed in the lungs because of the low partial pressure of carbon dioxide and high partial pressure of oxygen.

Carbonic anhydrase is the second most abundant cytoplasmic protein of the erythrocyte. It is a zinc-containing enzyme for which three separately encoded isoenzymes, CAI, CAII, and CAIII, are recognized. The predominant form in the human erythrocyte is CAI, although CAII is also found. Largely absent from fetal erythrocytes, erythrocyte CAI expression reaches adult levels during the first year of life, in a manner analogous to the expression of adult hemoglobin (hemoglobin A) (234, 235). All three isoenzymes of carbonic anhydrase have similar structures, and all appear encoded by genes on chromosome 8. CAI, however, contains within its active site a unique histidine that appears to stabilize the enzyme–HCO_3 complex, thus effecting the maximal rate of CO_2 hydration (236, 237, 238 and 239).

Although carbonic anhydrase clearly facilitates carbon dioxide metabolism, its presence in erythrocytes does not appear to be essential. Hereditary absence of CAI has been reported to occur without hematologic sequelae, and acquired deficiency is often seen with hyperthyroidism (240, 241). CAII deficiency is likewise without hematologic effect, although it is associated with the syndrome of renal tubular acidosis and cerebral calcifications (242, 243); enzyme activity with characteristics similar to those of CAIII is found to be increased in CAII-deficient erythrocytes (244). Also, complete inhibition of carbonic anhydrase by acetazolamide has little effect on carbon dioxide transport, at least under basal conditions (245). Nevertheless, carbonic anhydrase does appear to equalize the rate of hydration of carbon dioxide with the rate of protonation of hemoglobin, thus bringing into balance the rates of oxygen and carbon dioxide exchange. This equalization may be especially advantageous when the system is stressed, such as during exercise (246).

Nitric Oxide: Another Allosteric Effector of Hemoglobin

The discovery of NO as an important regulator of vascular and smooth muscle tone has provided many insights into our understanding of vascular physiology. NO is produced by the vascular endothelium and relaxes muscles surrounding vessels, thereby controlling blood pressure. Subsequently, it was determined that free hemoglobin could act as a scavenger of NO and inactivate it, explaining the observation that the infusion of free hemoglobin results in significant elevations of blood pressure. This reaction occurs because the oxygenated heme irons scavenge NO in a reaction yielding methemoglobin. More recent studies have revealed a new relationship between NO and hemoglobin (247).

Early studies of the interaction of hemoglobin with NO predicted that a function of hemoglobin was to eliminate or limit the biologic activity of NO and did not predict any functional impact on hemoglobin other than the oxidation of heme iron. This model did not explain how NO could be maintained at observed levels based on its known low levels of production. This was clarified with the discovery of S-nitrosohemoglobin (SNO-Hb) (248). When free hemoglobin is incubated with NO or S-nitrosothiols (SNOs), SNOs rapidly form on the two 93ß cysteines of hemoglobin rather than reacting with the oxygenated heme groups as might be expected. The infusion of this SNO-Hb results in no increase in blood pressure (247).

In the pulmonary circulation, coincident with oxygenation of hemoglobin, NO is added to hemoglobin, and, rather than oxidizing the heme iron, it binds to the iron or forms SNO-Hb through the reactive sulfhydryl groups of cysteine 93ß of hemoglobin (249, 250). This function for cysteine 93ß may explain why this amino acid is invariant in mammals and birds. Reactivity of NO with the SH groups of cysteine 93ß is controlled by the allosteric transition of hemoglobin and the spin state of heme iron. Thus, oxygen binding and conversion to the R state increase reactivity (248).

Likewise, loss of oxygen in the peripheral tissues results in transition of hemoglobin to the T state and release of NO. NO is either bound to small thiols or to the anion exchanger AE1. The latter is facilitated because hemoglobin can bind to the red blood cell membrane through specific, high-affinity binding to the amino-terminal cytoplasmic domain of the chloride/bicarbonate anion exchange protein AE1 (band 3 protein) (251). The amino terminus of AE1 inserts into the cleft usually occupied by 2,3-DPG (251). NO-mediated vasodilatory activity is released from AE1 by deoxygenation and binds to receptors on the vascular endothelium to induce vasodilation. SNO-Hb is therefore detected in arterial but not in venous blood.

Oxidative Denaturation of Hemoglobin: Its Reversibility and Prevention

Oxyhemoglobin in solution gradually undergoes autooxidation, becoming methemoglobin ($HbFe^{3+}$). The rate of oxidation is enhanced by conditions such as increased temperature, decreased pH, presence of organic phosphate and of metal ions, and partial oxygenation of hemoglobin. To bind oxygen reversibly, however, the iron in the heme moiety must be maintained in the reduced (ferrous, Fe^{2+}) state, despite exposure to a variety of endogenous and exogenous oxidizing agents. The red cell maintains several metabolic pathways to prevent the action of these oxidizing agents and to reduce the hemoglobin iron if it becomes oxidized. Under certain circumstances, these mechanisms fail, and hemoglobin becomes nonfunctional. At times, hemolytic anemia supervenes as well. These abnormalities are particularly likely to occur (a) if the red cell is exposed to certain oxidant drugs or toxins (see Chapter 38 and Chapter 49), (b) if the intrinsic protective mechanisms of

the cell are defective (see Chapter 33), or (c) if genetic abnormalities of the hemoglobin molecule affect globin stability or the heme crevice (see Chapter 41).

The oxidation of hemoglobin occurs in a stepwise fashion from fully reduced hemoglobin to fully oxidized hemoglobin. Intermediate forms are called *valence hybrids*. In deoxyhemoglobin, the heme iron is in the “high-spin” ferrous state, in which six electrons are in the outer shell, four of which are unpaired. When oxygen is added, one of these electrons is partially transferred to the bound oxygen. Usually, when oxygen is given up, oxyhemoglobin dissociates into partially deoxygenated hemoglobin and molecular oxygen:

$$Hb(O_2)_4 \rightarrow Hb(O_2)_3 + O_2$$

A superoxide anion rather than molecular oxygen may dissociate, however, thus oxidizing the Fe to the ferric state, producing methemoglobin:

$$HbFe^{2+} + O_2 \rightarrow HbFe^{3+}O_2^- \rightarrow HbFe^{3+} + O_2^-$$

This type of dissociation is particularly likely if water gains access to the heme crevice. Methemoglobin formation may also occur *in vivo* as the result of exposure to superoxide anions:

$$2HbFe^{2+} + O_2 + 2O_2^- + 4H^+ \rightarrow 2HbFe^{3+} + 3O_2 + 2H_2O$$

The formation of methemoglobin may also result from a direct reaction of reduced hemoglobin with the reduction product of the superoxide ion, peroxide:

$$2HbFe^{2+} + 2H_2O_2 \rightarrow 2HbFe^{3+} \cdot H_2O + O_2$$

As a result of these processes, methemoglobin is formed in normal cells at the rate of approximately 0.5 to 3.0% per day ([252]).

Methemoglobin is unable to bind oxygen. It has a distinctive, pH-dependent spectrum (Fig. 8.23; Table 8.8) and, in concentrations greater than 10% of the total hemoglobin, imparts to blood a distinctive brownish hue that does not disappear on vigorous shaking in air ([252]). When methemoglobin is present *in vivo* in concentrations greater than 1.5 to 2.0 g per dl, patients appear visibly cyanotic. Methemoglobin combines readily with cyanide to form cyanomethemoglobin, a pigment so stable that it is used in laboratory procedures for quantifying hemoglobin.

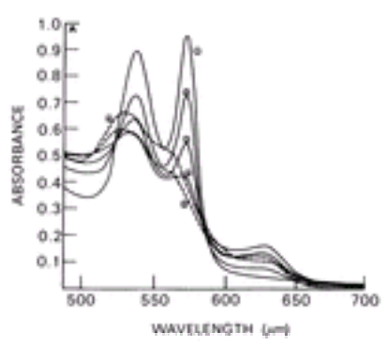

Figure 8.23. Change in hemoglobin spectrum as oxyhemoglobin changes to methemoglobin. The numbers 1 through 6 represent curves taken in sequence as oxidation proceeds. Note in particular the disappearance of the band at 575 μm and the appearance of the band at 631 μm.

TABLE 8.8. Spectral Characteristics of Hemoglobin (Hb) and Its Derivatives

Derivative	Formula	Spectral Bands					
		d	e	d	e	d	e
Deoxyhemoglobin	$Hb(d^6{}_2)$	430	133	555	12.5	—	—
Oxyhemoglobin	$Hb(d^5{}_{1/2})O_2^-$	415	125	541	13.8	577	14.6
Acid methemoglobin	$Hb(d^5{}_{5/2})H_2O$	405	179	500	10.0	631	4.4
Alkaline methemoglobin	$Hb(d^5{}_{1/2})OH^-$	410	120	540	11.0	575	9.2
Cyanomethemoglobin	$Hb(d^5{}_{1/2})CN$	419	124	540	12.5	—	—
Hemichromes	$Hb(d^5 1/2)X$	411	105	534	14.7	565	12.5
Carboxyhemoglobin	$Hb(d^6{}_0)CO$	419	191	—	—	569	13.4
Sulfhemoglobin	$Hb(d^6)S$	421	86	—	—	618	24.0

e, millimolar extinction coefficient; d, wavelength in nm.
From Antonini E, Buroni M. Hemoglobin and methemoglobin. In: Surgenor DM, ed. The red blood cells, vol. II. New York: Academic Press, 1975, with permission.

As oxidative denaturation continues, methemoglobin is converted to derivatives known as *hemichromes* (Fig. 8.24) ([253]). Hemichromes also may form directly from hemoglobin without methemoglobin as an intermediate. The hemichromes are low-spin, ferric compounds with a greenish hue and a characteristic spectrum (Table 8.8; Fig. 8.23). They are formed when the sixth coordination position of iron becomes covalently attached to a ligand within the globin molecule, a change that requires alteration of tertiary protein structure. Probably the most common internal ligand is the so-called distal histidine at E7 (Fig. 8.24). The compound so formed has been called a “reversible” hemichrome because relatively mild treatment with reducing agents and dialysis under anaerobic conditions converts it to deoxyhemoglobin. It may not be reversible *in vivo*, however, because it cannot be reduced by methemoglobin reductase.

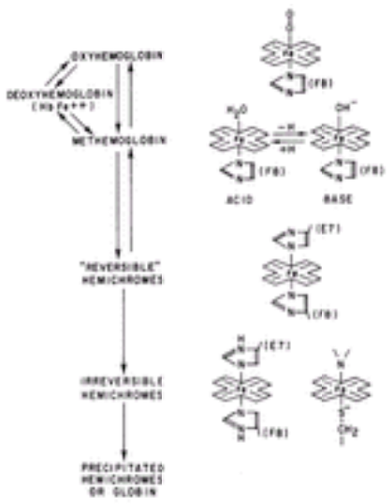

Figure 8.24. Stages in the oxidative denaturation of hemoglobin. Names of the stages are given on the left, proceeding from the most reduced form at the top to the most oxidized at the bottom. Partial structures are illustrated on the right. The heme group is denoted by a planar cross. For a more complete description, refer to the text.

In contrast, the “irreversible” hemichromes cannot be converted back to normal hemoglobin again *in vivo* or *in vitro*, implying that more severe distortions of tertiary protein structure have occurred. In one of the irreversible hemichromes, the histidine imidazole groups are protonated (i.e., they participate in hydrogen bonding). The other irreversible hemichrome is characterized by a mercaptide and nitrogenous linkage at the fifth and sixth positions (Fig. 8.24). Presumably, the mercaptide link is provided by a cysteine residue in the globin chain, perhaps at ß93.

As these changes occur in the vicinity of the heme group, oxidative changes also occur in other parts of the hemoglobin molecule. Once the cell's supply of GSH is exhausted, the titrable sulfhydryl groups at ß93(F9)Cys are oxidized, often forming a mixed disulfide with GSH ([254]). This change is reversible; however, as further alterations in globin conformation occur, normally protected or “buried” sulfhydryl groups at ß112(G14)Cys and a104(G11)Cys become exposed and are oxidized, changes that disrupt the $a_1ß_2$ contacts. These changes facilitate dissociation of polypeptide chains, first into aß dimers and finally into monomers ([253]). In some instances, heme may dissociate from globin, particularly in the case of certain unstable hemoglobins.

The end products of these changes are precipitated hemichromes and precipitated heme-free globin. In intact erythrocytes, these precipitates take the form of globular inclusions known as *Heinz bodies*, which are not visible with ordinary Wright stain but can be seen easily after supravital staining with crystal violet or brilliant cresyl blue. Heinz bodies may become attached to the cell membrane and shorten red cell survival.

Another nonfunctional hemoglobin derivative occasionally formed during the oxidative denaturation of hemoglobin is sulfhemoglobin. It is a relatively stable pigment and, once formed, cannot be converted to hemoglobin *in vivo*. Instead, it tends to remain within the cell throughout the cell's life. Sulfhemoglobin is bright green and has a distinctive spectrum characterized by an absorption band at approximately 618 nm (Table 8.8). It is a ferrous compound with one sulfur atom attached to each heme group. The sulfur is probably attached to a ß-carbon in the porphyrin ring, forming a thiochlorin (Fig. 8.25) ([254], [255]).

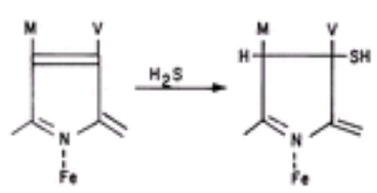

Figure 8.25. The probable structure of sulfhemoglobin. One of the four pyrrole rings in heme is illustrated at the left. Sulfur added at the ß carbon forms a thiochlorin, accounting for the spectral changes characteristic of sulfhemoglobin.

Although the exact mode of synthesis of sulfhemoglobin remains to be established, proposed models suggest that methemoglobin is first converted to ferrylhemoglobin in the presence of hydrogen peroxide ([255], [256]):

$$HbFe^{3+} + H_2O_2 \rightarrow HbFe^{4+}O + H_2O + e^-$$

With the addition of a sulfur-containing compound, such as hydrogen sulfide, the iron in ferrylhemoglobin is reduced, and sulfur is incorporated into the porphyrin ring:

$$HbFe^{4+}O + HS^- + 2e^- \rightarrow HbSFe^{2+} + OH^-$$

Although the iron in sulfhemoglobin is reduced, it binds oxygen with an affinity one-hundredth that of unmodified hemoglobin.

Known mechanisms for preventing or reversing oxidative denaturation of hemoglobin in the erythrocyte include (a) the methemoglobin reductases, (b) superoxide dismutase, (c) GSH peroxidase, and (d) catalase.

Methemoglobin Reduction

Most methemoglobin in erythrocytes is reduced through the action of an enzyme, cytochrome b_5 methemoglobin reductase, which acts in the presence of two electron carriers, cytochrome b_5 and NADH. Only a small amount of methemoglobin is reduced by all other pathways of methemoglobin reduction together (Table 8.9). These other pathways involve two compounds that cause the reduction of methemoglobin nonenzymatically, ascorbic acid and GSH, as well as a second enzyme, nicotinamide adenine dinucleotide phosphate (NADPH)–flavin reductase. Deficiency of cytochrome b_5 reductase, but not of NADPH-flavin reductase, is associated with methemoglobinemia, confirming that cytochrome b_5 reductase is the most important physiologic means of reducing methemoglobin ([257]). *In vitro* evidence also confirms that cytochrome b_5 reductase is the rate-limiting factor in methemoglobin reduction ([258]).

TABLE 8.9. Proportion of Methemoglobin Reduction by Various Erythrocyte Systems

Erythrocyte Component	Percentage of Methemoglobin Reduced (%)
Cytochrome b_5 reductase	67
Ascorbic acid	16
Glutathione	12
Nicotinamide adenine dinucleotide phosphate flavin reductase	5
Total	100

Modified from Scott EM. Congenital methemoglobinemia due to DPNH-diaphorase deficiency. In: Beutler E, ed. Hereditary disorders of erythrocyte metabolism. New York: Grune & Stratton, 1968.

Cytochrome b_5 reductase has been referred to by several other names, including *diaphorase I*, *DPNH dehydrogenase I*, *NADH dehydrogenase*, *NADH methemoglobin reductase*, and *NADH methemoglobin–ferrocyanide reductase*. Work in the 1940s established a relationship between the reduction of methemoglobin and the metabolism of lactate to pyruvate, thus implying an important role for NADH ([259]). Eventually, two methemoglobin-reducing enzymes were isolated. The NADH-dependent enzyme, which was absent from several patients with methemoglobinemia, has been shown to be a flavoprotein, with one mole of flavin adenine dinucleotide (FAD) per mole of apoenzyme. Its molecular weight is approximately 34,000 daltons. The corresponding cDNA has been identified, and the gene localized to chromosome 22 ([260] , [261]). Most likely, erythrocyte cytochrome b_5 reductase and hepatic cytochrome b_5 reductase are the products of a single gene.

The reduction of methemoglobin by highly purified cytochrome b_5 reductase in the presence of NADH is extremely slow, implying that another factor is most likely required as an electron carrier. *In vitro*, this role can be filled by dyes or by ferrocyanide. *In vivo*, cytochrome b_5 acts as the intermediate electron carrier ([262]). Erythrocyte cytochrome b_5 greatly accelerates reduction of methemoglobin by cytochrome b_5 reductase and can also serve as a substrate for hepatic microsomal cytochrome b_5 reductase. Congenital methemoglobinemia resulting from a deficiency in cytochrome b_5 has been described ([263]). cDNA for human liver cytochrome b_5 has been cloned; it encodes a protein of 134 amino acids ([264]). Erythrocyte cytochrome b_5 probably results from proteolytic cleavage of the membrane-attached protein present in erythroid precursor microsomes, an event that then yields a soluble cytochrome b_5 protein.

The process by which cytochrome b_5 reductase and cytochrome b_5 reduce hemoglobin in the presence of NADH probably involves three steps. In the first, NADH binds to the FAD–reductase complex, and, in the presence of hydrogen ion, the NAD is converted to NAD^+, and the FAD becomes $FADH_2$. In the second step, cytochrome b_5–Fe^{3+} is reduced to cytochrome b_5–Fe^{2+}, and the $FADH_2$ reverts to FAD. Finally, methemoglobin forms a bimolecular complex with reduced cytochrome b_5 through electrostatic interactions between negatively charged groups around the cytochrome heme and positively charged groups around the heme moieties of methemoglobin. The reduction of methemoglobin then takes place and can be represented as follows:

$$HbFe^{3+} + Cytb_5Fe^{2+} \rightarrow HbFe^{2+} + Cytb_5Fe^{3+}$$

Of lesser physiologic importance is the enzyme system that depends on NADPH for its activity. It probably accounts for only approximately 5% of the methemoglobin-reducing activity of normal red cells (Table 8.9), and its hereditary deficiency does not lead to methemoglobinemia ([265]). The lack of physiologic activity may result from the absence of an intermediate electron carrier analogous to cytochrome b_5. If methylene blue is supplied as the carrier, however, the NADPH-dependent enzyme becomes highly effective in methemoglobin reduction. This property is used in the therapy of methemoglobinemia from various causes.

Enzymes Reacting with Products of the Reduction of Oxygen

As molecular oxygen undergoes successive univalent reductions, a variety of reactive species are generated. These species constitute the oxidizing agents most likely to be responsible for the oxidative denaturation of hemoglobin, and they may damage other cellular components as well, especially lipid-containing elements such as the cell membrane ([266] , [267]). A variety of mechanisms have evolved in respiring organisms to deal with these potential toxins, and some are found within the erythrocyte.

Superoxide anions are produced in biologic tissues from several sources, including oxyhemoglobin itself, as well as oxidative reactions catalyzed by flavin enzymes, such as xanthine oxidase ([267] , [268]). In addition, many drugs and toxins have oxidant activity and appear to generate superoxide ([269]). Once superoxide has been generated in aqueous solution, additional toxic products of oxygen may form spontaneously (Fig. 8.26). Thus, superoxide can undergo spontaneous dismutation, yielding peroxide and oxygen:

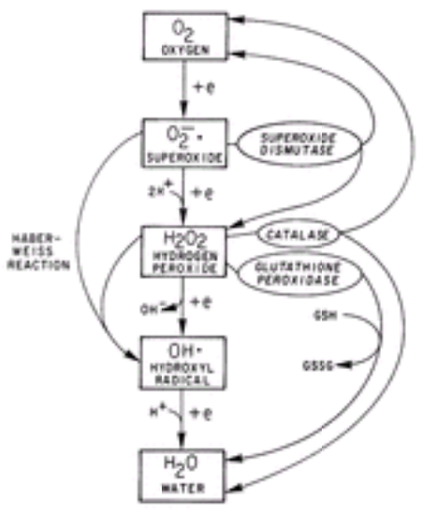

Figure 8.26. Steps in the univalent reduction of oxygen and enzymatic pathways affecting the intermediates. The enzymatic pathways, shown on the right, provide the means for processing these intermediates without formation of the highly reactive hydroxyl radical. This potent oxidant can be formed by the reaction shown on the left if superoxide and peroxide concentrations are sufficient and if catalytic quantities of transition metals are present. GSH, glutathione; GSSG, oxidized glutathione.

$$O_2 + O_2 + 2H^+ \rightarrow H_2O_2 + O_2$$

In addition, in the presence of catalytic quantities of transition metals, superoxide and peroxide may react to form the highly reactive hydroxyl radical (OH·):

$$O_2 + H_2O_2 \rightarrow OH\cdot + OH^- + O_2$$

Any of these oxygen derivatives may exert toxic effects on cellular components. As previously noted, superoxide appears to induce methemoglobin formation ([270] , [271]). It may also bring about cell lysis via its effect on membranes ([272]). Hydrogen peroxide is the most stable intermediate in the reduction of oxygen. Although hydrogen peroxide has often been shown to induce the oxidative denaturation of hemoglobin *in vitro*, whether it does so directly or by giving rise to other products, such as the hydroxyl radical, is not clear.

The hydroxyl radical is one of the most potent redox agents known ([267]). Because it is generated by the radiolysis of water, it is believed to account for many of the effects of radiation in biologic tissue. However, it may also be generated from superoxide and peroxide, as described previously, and from peroxide in the presence of certain metals:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH\cdot$$

Thus, enzymes that scavenge superoxide and peroxide may be viewed as mechanisms for preventing the accumulation of these intermediates in sufficient quantities to allow the hydroxyl radical to form ([268]).

The superoxide dismutases are enzymes that catalyze the dismutation of superoxide to oxygen and peroxide. Although this reaction occurs spontaneously, the presence of the enzyme speeds the reaction to a rate as much as 109 times faster than the spontaneous rate ([268]). In the erythrocyte, superoxide dismutase is a soluble, cuprozinc enzyme with a molecular weight of approximately 32,000 daltons. The enzyme accounts for most of the copper content of the red cell, and, before its enzymatic function was determined, it was called *erythrocuprein* or *hemocuprein*. The primary structure of human copper-zinc superoxide dismutase has been determined, and the gene has been mapped to chromosome 21 ([273]). Although superoxide dismutase prevents the formation of methemoglobin *in vitro* under conditions in which superoxide forms, the relative importance of this reaction *in vivo* remains to be established ([270] , [271]). Once hydrogen peroxide is formed, two enzymes catalyze the decomposition of hydrogen peroxide in erythrocytes. The most important of these enzymes is GSH peroxidase, which is a component of the following reaction ([274] , [275]):

$$H_2O_2 + 2GSH \xrightarrow{\text{GSH peroxidase}} 2H_2O + GSSG$$

where *GSSG* is oxidized glutathione.The enzyme is effective at very low concentrations of peroxide (Km = 1 × 10^{-6} M) ([267]).

GSH peroxidase is the major human selenoprotein, which probably accounts for the antioxidant properties of selenium as a micronutrient ([268] , [276]). Human cells grown in the absence of selenium express significantly reduced GSH peroxidase activity, despite normal GSH peroxidase mRNA and transcription levels. The gene for GSH peroxidase probably is on chromosome 3, although two homologous genes also appear to be present in the human genome ([277] , [278]). The importance of GSH peroxidase is exemplified by the fact that a genetic defect in the enzyme may lead to a drug-sensitive hemolytic anemia ([279]).

Catalase, a heme enzyme, decomposes hydrogen peroxide to water and molecular oxygen ([280]). It appears to be less important to the red cell than peroxidase, presumably because it is effective only when the peroxide concentration is relatively high ([281]). Individuals with hereditary acatalasemia do not develop methemoglobinemia or hemolytic disease; an increase in GSH peroxidase levels may compensate in part for the lack of catalase ([282]). Some evidence suggests, however, that erythrocyte catalase may be important in preventing oxidant damage to somatic tissues ([283]). Also, the level of catalase increases with physical conditioning, suggesting a physiologically significant role for erythrocyte catalase ([284]).

Catalase consists of a tetramer composed of 60,000-dalton subunits, with four heme groups per tetramer. It is encoded by a gene on chromosome 11 ([285]). Catalase is a major component of erythrocyte band 4.5 seen on Coomassie-stained gels of erythroid membrane proteins, as the enzyme interacts with the membrane in a calcium- and pH-dependent manner ([286]). Catalase also comprises a major reservoir of erythrocyte protein–bound NADPH. Each tetrameric molecule of erythrocyte catalase contains four molecules of tightly bound NADPH. Although not essential for enzymatic conversion of peroxide to oxygen, the NADPH appears to protect catalase from inactivation by peroxide ([287]).

Glutathione Metabolism

GSH is the principal reducing agent in erythrocytes and the essential cofactor in the GSH peroxidase reaction. Reduced GSH is a tripeptide (?-glutamyl–cysteinyl–glycine). Two ATP-dependent enzymatic reactions are required for the *de novo* synthesis of GSH:

$$\text{glutamic acid} + \text{cysteine} \rightarrow \gamma\text{-glutamyl–cysteine}$$

$$\gamma\text{-glutamyl–cysteine} + \text{glycine} \rightarrow \text{GSH}$$

The first reaction is catalyzed by glutamyl-cysteine synthetase, the second reaction by GSH synthetase. Both reactions can take place in normal erythrocytes ([288]). The capacity of red cells to synthesize GSH normally exceeds the rate of turnover by 150-fold.

In the course of reactions protecting hemoglobin from oxidation, GSH is oxidized, forming GSSG, which consists of two GSH molecules joined by a disulfide linkage, and mixed disulfides with hemoglobin. GSSG rapidly leaves the erythrocyte ([289]). Thus, maintaining a continuous supply of GSH requires a system to reduce the oxidized forms of GSH. Such a system is provided by GSH reductase, which catalyzes the reduction of GSSG by NADPH, a product of the pentose phosphate pathway (Fig. 8.27). GSH reductase also catalyzes the reduction of hemoglobin-GSH disulfides, yielding GSH and hemoglobin ([290]).

Figure 8.27. Glutathione metabolism in the erythrocyte. G-6-P, glucose-6-phosphate; GHS, glutathione; GSSG, oxidized glutathione; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate; 6-PG, 6-phosphogluconate.

The primary structure of GSH reductase is known because the protein has been isolated and sequenced, and the cDNA has been cloned and sequenced ([291] , [292] and [293]). The gene for GSH reductase maps to chromosome 8. GSH reductase is a flavoprotein consisting of two identical peptide chains of 478 amino acids. Because of its flavin component, the activity of GSH reductase depends on the dietary intake of riboflavin. Erythrocyte GSH reductase activity may be increased by administration of riboflavin, even in apparently normal subjects ([294] , [295]). The enzyme is inhibited by hexavalent chromium in concentrations as low as 5 to 25 µg/ml ([296]).

Abnormally high levels of GSH have been noted in patients with a variety of diseases and conditions ([297]). Neonatal erythrocytes have a higher level of GSH than do adult erythrocytes. Increased GSH has also been noted in inherited pyrimidine 5'-nucleotidase deficiency and in association with many dyserythropoietic anemias. The molecular bases of the increased levels of GSH in these conditions remain unclear.

Energy Metabolism

Although the mature red cell contains the enzymes required for glycogen metabolism, the balance between synthesis and utilization is such that no significant amount of glycogen accumulates within the cell under normal circumstances ([298]). Glycogen may accumulate, however, in glycogen storage diseases types III and VI.

Lacking a storage compound, the normal erythrocyte must have constant access to glucose if its energy metabolism is to be sustained. As previously discussed, glucose enters the cell by means of a facilitated, carrier-mediated transport mechanism. Insulin or other hormones are not required, and transport is not ordinarily the rate-limiting factor in glucose utilization. Without mitochondria, erythrocytes must depend on two less efficient pathways for production of high-energy compounds, the *anaerobic glycolytic* (Embden-Meyerhof) *pathway* and the *aerobic pentose phosphate pathway*, also known as the *hexose monophosphate shunt* or the *phosphogluconate pathway* (Fig. 8.28). Under normal circumstances, approximately 90% of glucose entering the red cell is metabolized by the anaerobic pathway and 10% by the aerobic pathway ([299]). Under conditions of oxidative stress, however, the oxidative pentose pathway may account for up to 90% of glucose consumption ([300]).

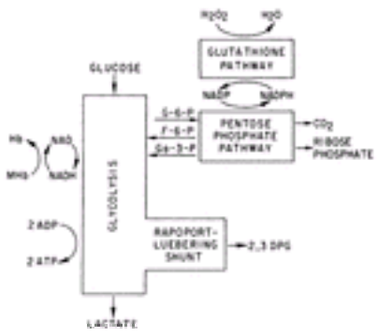

Figure 8.28. Energy metabolism in the erythrocyte. Main pathways are shown as boxes; major substrates and products of each are shown outside the boxes. More details of the pathways are given in Figure 8.27 and Figure 8.29. ADP, adenosine diphosphate; ATP, adenosine triphosphate; 2,3 DPG, 2,3-diphosphoglycerate; F-6-P, fructose-6-phosphate; G-6-P, glucose-6-phosphate; Ga-3-P, glyceraldehyde-3-phosphate; Hb, hemoglobin; MHb, met-hemoglobin; NAD, NADH, nicotinamide adenine dinucleotide; NADP, NADPH, nicotinamide adenine dinucleotide phosphate.

Figure 8.29. Energy metabolism in the erythrocyte. Circled numbers represent reactions referred to in the text. Enzymes are designated by abbreviations and shown in boldface to the right or above arrows representing reactions. Cofactors are shown in boldface to the left of the arrows or above the enzymes. ADP, adenosine diphosphate; Ald, aldolase; ATP, adenosine triphosphate; DPGM, diphosphoglyceratemutase; Ep, epimerase; G6PD, glucose-6-phosphate dehydrogenase; HK, hexokinase; LDH, lactate dehydrogenase; NAD-NADH, nicotinamide adenine dinucleotide; NADP-NADPH, nicotinamide adenine dinucleotide phosphate; PFK, phosphofructokinase; PGD, phosphoglyceraldehyde dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; PGI, phosphoglucose isomerase; PGK, phosphoglycerate kinase; PGM, phosphoglyceromutase; PK, pyruvate kinase; PRI, phosphoribose isomerase; TPI, triosephosphate isomerase; TRA, transaldolase; TRK, transketolase.

Three important products are formed by the anaerobic gly-colytic pathway: NADH, a cofactor in the methemoglobin reductase reaction; ATP, the major high-energy phosphate nucleotide that powers the cation pump; and 2,3-DPG, a regulator of hemoglobin function (Fig. 8.28). For each molecule of glucose that enters the pathway, two molecules of NADH are generated (Fig. 8.29, reaction 6). The yields of ATP and 2,3-DPG vary depending on the activity of the Rapoport-Luebering shunt (Fig. 8.29, reactions 7b and 7c), a side pathway unique to the red cell. Two molecules of ATP are used in the early steps of glycolysis (Fig. 8.29, reactions 1 and 3), and a maximum of four molecules is produced late in the pathway (two in reaction 7a and two in reaction 10). Thus, at maximum efficiency, a net yield of two molecules of ATP may be expected for each molecule of glucose catabolized. This net yield may be decreased, however, to the extent that 2,3-DPG is formed (Fig. 8.29, reactions 7b and 7c). For this reason, the DPG-forming step is sometimes referred to as an *energy clutch*.

Of the eleven enzymes in the glycolytic pathway, three appear to be particularly important in regulation of glycolytic rate. These are hexokinase, phosphofructokinase, and pyruvate kinase (Fig. 8.29, reactions 1, 3, and 10). Hexokinase is the least active enzyme in the series and is therefore often rate-limiting (Table 8.10). It is inhibited by its product, glucose-6-phosphate, and is stimulated by one of its substrates, Mg-ATP. The activity of phosphofructokinase is greatly affected by intracellular pH. Because the pH optimum of this enzyme is 8.0, the activity of the enzyme and the overall rate of glycolysis tend to increase with increased pH (alkalosis) and decrease with decreased pH (acidosis). Phosphofructokinase may also be activated by the product of the further phosphorylation of fructose-6-phosphate ([301]). Pyruvate kinase is strongly inhibited by its product, ATP, and pyruvate kinase activity may therefore be related to the rate at which ATP is used in the cell's metabolic processes.

TABLE 8.10. Activity of Glycolytic Enzymes in Erythrocytes of Normal Adults

Enzyme	Activity [a]
Hexokinase	1.3
Phosphoglucose isomerase	61.0
Phosphofructokinase	9.0
Aldolase	3.2
Triosephosphate isomerase	2111.0
Glyceraldehyde-3-phosphate dehydrogenase	226.0
Phosphoglycerate kinase	320.0
Diphosphoglyceromutase	4.8
Phosphoglyceromutase	25.0
Enolase	5.4
Pyruvate kinase	15.0
Lactate dehydrogenase	200.0

[a] Micromoles per minute per gram of hemoglobin at 37°C and at high substrate concentrations.
From Beutler E, Blume KG, Kaplan JC, et al. International Committee for Standardization in Hematology: recommended methods for red cell enzyme analysis. Br J Haematol 1977;35:331, with permission.

The importance of glycolysis to the red cell is illustrated by the manifestations of inherited disorders, in each of which the activities of one of the glycolytic enzymes is impaired (Chapter 33) ([302]). Under such circumstances, the viability of the red cell is reduced, and hemolytic anemia results.

The most important product of the pentose phosphate pathway in erythrocytes is reduced NADPH. The red cell lacks the reactions to use NADPH for energy; instead, NADPH, by serving as a cofactor in the reduction of GSSG, is a major reducing agent in the cell and the ultimate source of protection against oxidative attack. The utilization of NADPH is the main stimulus to the utilization of glucose-6-phosphate by the pathway. Redox agents, such as methylene blue, cysteine, ascorbate, and others, induce an up to 20-fold increase in pentose metabolism, presumably by bringing about oxidation of GSH ([303] , [304]). This metabolic flexibility allows the red cell to respond to unexpected oxidant challenge.

A second function of the pentose pathway is the conversion of hexoses to pentoses. For the most part, the latter are recycled into the glycolytic pathway; however, D-ribose-5-phosphate may be used for nucleotide synthesis.

Destruction of Erythrocytes

The mature erythrocyte lacks the organelles that make protein synthesis possible, and, thus, it is incapable of self-repair. Its lifespan is finite and is shortened further when the cell's environment becomes hostile or when the cell's ability to cope with damaging extracellular influences becomes impaired. Excessive destruction of red cells plays a major role in hemolytic diseases. This chapter focuses on the following issues: How long do normal red cells live? Why do red blood cells (RBCs) die? Where do RBCs die? What are the biochemical changes associated with red cell death?

METHODS FOR ESTIMATING ERYTHROCYTE LIFESPAN

Valid measurements of erythrocyte survival in the intact animal became possible in 1919 when Ashby devised the differential agglutination technique ([1]). Since then, other less cumbersome methods have been introduced. Studies with these techniques have demonstrated that, after a finite lifespan, the erythrocyte becomes nonviable and disappears from the circulation. In humans, this lifespan averages approximately 120 days. In other mammals, values range from 40 days in mice to 225 days in the llama ([2]). Still longer survivals, 600 to 1400 days, are observed in poikilotherms with low metabolic rates, such as toads and turtles ([3]).

There are a number of direct methods for measuring erythrocyte lifespan ([2], [4]). *Cohort methods* depend on the incorporation of an isotopically labeled substance into a group (“cohort”) of newly formed cells. If exposure to the label is brief and there is no reuse of label, the tagged cells will be of very nearly the same age. In contrast, *random-labeling methods* use tracers that bind with all cells in the circulation regardless of age. The patterns of time-dependent change in circulating red cell label produced by these two procedures are quite different (Fig. 9.1). Cohort labels result in a pattern characterized by a plateau, the length of which is a measure of erythrocyte lifespan. In contrast, random labels begin to disappear from the circulation immediately, and erythrocyte lifespan is related to the time when all label has vanished, the so-called extinction time. In the past, these procedures helped define normal and abnormal RBC survival in various anemias.

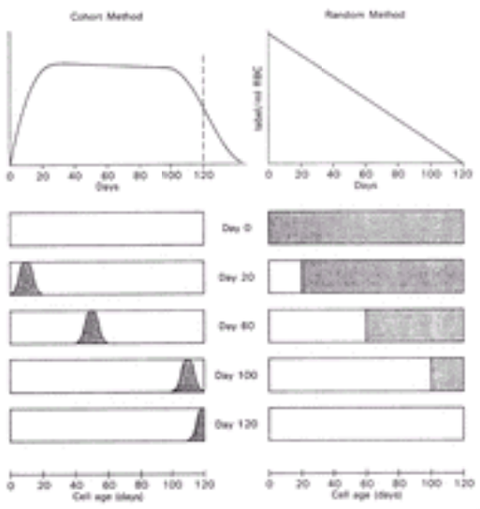

Figure 9.1. Comparison of idealized patterns produced by cohort and random methods of labeling circulating erythrocytes. These curves are constructed on the assumptions that no elution of label occurs and that all erythrocyte destruction is senescent. Bars below the main graphs indicate distribution of labeled cells (*shaded areas*) by cell age. These labeled cells can be thought of as being forced to the right by a piston made of newly produced, unlabeled cells. RBC, red blood cells. (Modified from Berlin NI, et al. Life span of the red blood cell. Physiol Rev 1959;39:577.)

Cohort Methods

The ideal cohort label would produce labeling in the shortest possible time, would label the erythrocyte and no other cells or proteins, would not injure the labeled cell or alter its survival, would remain with the cell throughout its life, would not be reused, would present no risks to the recipient, would be easily assayed, and would not be excessively expensive. Some of the isotopes used throughout the years include ^{59}Fe ([5]) and glycine tagged with ^{15}N, ^{14}C, or ^{3}H ([2]). These are incorporated into hemoglobin (Hb) when it is synthesized by the erythrocyte precursors and remain with the cell throughout its lifespan. To determine the erythrocyte lifespan with cohort labels, assays must be performed for over 120 days if the red cell lifespan is normal. Of the various cohort labels, ^{59}Fe is reasonably safe and relatively easy to assay.

Random-Labeling Methods

Random-labeling methods have proved to be much more useful than cohort methods for both clinical and research applications because accurate information is made available in a relatively short time. The time at which half of the label has disappeared from the circulation ($t_{1/2}$) is recorded. When there is neither a significant degree of random destruction nor elution of label, the shape of the disappearance curve is linear, and the mean erythrocyte lifespan is equal to twice the value for $t_{1/2}$. Random methods include those based on the Ashby differential agglutination technique as well as those in which cells are labeled with isotopes, the most

common of which is ^{51}Cr.

The Ashby method is of historical interest. This procedure uses the transfusion of compatible but immunologically identifiable blood (e.g., group O cells into a group A, B, or AB recipient) ([1], [6]). At appropriate intervals, the donor red cells are enumerated after agglutination or hemolysis ([7]) of the recipient's cells by appropriate antisera. When properly performed, the differential agglutination technique yields accurate results. The observed disappearance curves are linear in normal human subjects, and deviation from linearity indicates random destruction. Inability to measure the survival of a subject's cells in his or her own circulation, as well as the hazards of transfusion and the exacting requirements of technique, obviously limited the usefulness of this method.

Radioactive chromium was introduced as a red cell label in 1950 and was used in survival studies *in vivo* shortly thereafter ([8], [9]). Anionic (hexavalent) chromium in the form of the chromate ion ($^{51}CrO_4^{-2}$) can penetrate the red cell membrane. Once inside the cell, it is converted to the trivalent cation (Cr^{+3}) and, in this form, becomes firmly, but not irreversibly, bound to Hb. The chromium attaches to the ß-chains of Hb A and, to a lesser extent, to the ?-chains of Hb F ([10]). The principal disadvantage of the chromium label is that it is slowly eluted from the cell. The rate of elution in normal subjects was found to be 0.57 to 1.28%/day and averaged 0.93%/day ([8]). An assumed rate of 1%/day is often used for analysis of chromium survival curves. The disappearance of ^{51}Cr from the circulation thus reflects not only the red cell lifespan, but also the elution rate; as a consequence, the chromium disappearance curve is nonlinear. However, if the data are plotted on a semilogarithmic scale, or if appropriate correction factors ([11]) are applied, the pattern approximates a straight line (Fig. 9.2). From such a plot, the disappearance half-life ($t_{1/2}$ Cr) may be derived. The chromium elution rate depends in part on the techniques used in the labeling procedure ([12]). Consequently, reported average normal values for $t_{1/2}$ Cr have varied widely from 25 to 33 days.

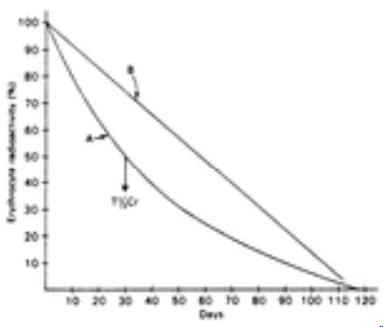

Figure 9.2. ^{51}Cr erythrocyte survival curve in a normal subject before (*A*) and after (*B*) correction for elution (see text). Half of the radioactivity is gone at 30 days ($T_{1/2}Cr$), but the radioactivity does not disappear completely until 115 days, the so-called extinction time.

Red cell survival studies are infrequently done nowadays, but, if performed, the chromium method is used more than any of the other available methods. Because it emits a high-energy ?-ray, radioassay is comparatively easy and requires little sample preparation. Also, radioactivity monitored over the body surface can be used to determine the principal sites of destruction ([13]). Because labeling usually is performed *ex vivo*, cross-transfusion studies also are possible; thus, survival of a patient's cells in a normal recipient or of normal cells in a patient can be evaluated by this method. Previously, these procedures yielded much information regarding cell survival in various hemolytic anemias, helping to define intrinsic versus extrinsic hemolytic disorders. Safety considerations nowadays do not allow for similar studies.

Diisopropylfluorophosphate labeled with ^{32}P (DF ^{32}P) reacts with esterases, especially cholinesterase, and becomes firmly bound to the cell ([14]). DF ^{32}P labels leukocytes and platelets as well as erythrocytes. In contrast to chromium, little DF ^{32}P is eluted after the first 24 to 48 hours, and none is eluted after 10 days. As a result, the normal disappearance curve is nearly linear, and many complexities of interpretation are avoided ([15], [16]). For these reasons, DF ^{32}P is a highly satisfactory label for determining lifespan. However, sample preparation is somewhat complicated, surface counting is not possible, and it is no longer commercially available ([17]).

The lifespan of the normal human erythrocyte as measured by the various procedures described above is essentially the same, namely, 117 (110 to 135) days by the Ashby method, 113 (108 to 120) days when the ^{51}Cr label is used, 118 (109 to 127) days with ^{15}N-glycine, and 124 days with DF ^{32}P. Thus, it appears that approximately 0.83% of the circulating red cells are replaced each day.

ERYTHROCYTE AGING

Once the erythrocyte has lost its nucleus and ribosomes, it can no longer synthesize protein. With the loss of its mitochondria, it is dependent on anaerobic glycolysis to provide energy. In humans, it must then survive 4 months and hundreds of miles of hazardous travel with very limited equipment with which to maintain itself. Nevertheless, it does retain significant repair capacity. In addition to its ability to sustain effective levels of adenosine triphosphate (ATP), the reduced form of nicotinamide adenine dinucleotide, and nicotinamide adenine dinucleotide phosphate (NADPH) and to maintain its ionic composition, it can also reduce methemoglobin and oxidized glutathione, synthesize glutathione, and reseal its membrane if a portion of it is lost. Despite these and other capabilities, the cell ultimately is unable to sustain its existence ([18], [19] and [20]).

In attempting to identify the changes that occur in the erythrocyte as it ages, the typical approach has been to separate young and old red cells, to measure a chemical or physical feature of the old cells, and to ascribe the observed difference to the effect of cell age. Further, it has been common to assume that the observed change believed to be due to age continues to worsen and ultimately causes the death of the erythrocyte. The most commonly used method for separating young and old cells makes use of the observation that erythrocyte density increases as a function of age ([21], [22], [23], [24] and [25]). Although this change occurs with considerable consistency ([22], [26]), some mixture of young and old cells has almost always been demonstrated in each density fraction ([27], [28], [29], [30] and [31]), and, thus, the different compartments represent mostly “young” or mostly “old” cells. Sensitivity to osmotic lysis is another property that increases with age; however, cell fractions separated on the basis of this property are also not uniform with respect to age ([32], [33]). Separation of red cells by age has also been proposed on the basis of surface charge ([34], [35]) or cell size ([36], [37]). Other approaches have been based on examining surviving RBCs in animals or patients with suppressed erythropoiesis ([38], [39] and [40]) or after a cohort of cells labeled with biotin ([41], [42]). These latter methods may avoid the problems inherent in the methods based on density separation.

Various hypotheses have been proposed to explain red cell death, and these include (a) changes in red cell enzymes with age, (b) alterations in calcium balance, (c) changes in membrane carbohydrates and surface charge, (d) oxidative injury, and (e) development of autologous antibodies to membrane antigens. The following sections summarize the data on which various hypotheses have been based. In addition to the abnormalities cited in these sections, many other changes have been observed in aging cells (Table 9.1). Whether any of these abnormalities is of physiologic significance is not known.

TABLE 9.1. Erythrocyte Changes Associated with Aging [a]

Changes in physical characteristics	Changes in glycolysis
Increased density (22, 289)	Decreased overall rate of glycolysis (298, 312)
Decreased deformability (290, 291)	Decreased ATP (76, 313)
Increased osmotic and mechanical fragility (116, 292)	Decreased 2,3-diphosphoglycerate (76, 294, 298)
Decreased cell size (36, 76, 292)	Decreased hexokinase (43, 44, 51, 313, 314, 315 and 316)
Changes in hemoglobin	Decreased glucose phosphate isomerase (44, 317)
Increased methemoglobin (293)	Decreased phosphofructokinase (44, 318, 319)
Increased hemoglobin-oxygen affinity (294, 295)	Decreased aldolase (44, 51, 313)
Increased glycosylated hemoglobin (296, 297)	Decreased triosephosphate isomerase (44)

- Changes in cellular constituents
  - Decreased K- (76, 298, 299)
  - Increased Na- (76, 298, 299)
  - Increased Ca^{2-} (70, 300)
- Changes in the membrane
  - Decreased lipid content (301, 302 and 303)
  - Decreased surface area (290, 301)
  - Decreased negative charge (75, 304, 305)
  - Decreased membrane glycoproteins (76, 306)
  - Decreased (Ca^{2-}-Mg^{2-})-ATPase activity (307)
  - Decreased protein 4.1b (308)
  - Decreased sialic acid residues (73, 74, 75 and 76)
  - Increased membrane-bound hemichromes (87)
  - Increased lipid peroxidation (90)
  - Increased membrane protein polymers (309)
  - Increased spectrin-hemoglobin aggregates (93)
  - Increased denatured hemoglobin–band 3 copolymers (310)
  - Increased protein 4.1a (308)
  - Decreased Na-K-ATPase (330)
  - Increased a-galactosyl residues (99)
  - Increased phosphatidylserine (108)
  - Altered blood group antigens (311)
  - Development of antigenic band 3 (72)
- Changes in the hexose monophosphate shunt pathway
  - Decreased glucose-6-phosphate dehydrogenase (43, 51, 116, 313, 321, 322)
  - Decreased 6-phosphogluconate dehydrogenase (116, 313, 322, 323)
  - Decreased transketolase (322)
  - Decreased glyceraldehyde-3-phosphate dehydrogenase (44)
  - Decreased phosphoglycerate kinase (44, 320)
  - Decreased 3-phosphoglycerate mutase (44)
  - Decreased enolase (44)
  - Decreased pyruvate kinase (44, 51, 312, 315, 318)
  - Decreased lactate dehydrogenase (44)
- Changes in glutathione metabolism
  - Decreased reduced glutathione (324, 325)
  - Decreased glutathione reductase (326)
  - Decreased glutathione peroxidase (86)
  - Decreased glutathione-S–transferase (325)
- Changes in purine and pyrimidine nucleotide metabolism
  - Decreased purine nucleoside phosphorylase (320)
  - Decreased adenylate kinase (320)
  - Decreased pyrimidine 5' nucleotidase (38, 51, 315)
- Miscellaneous enzyme changes
  - Decreased catalase (327, 328)
  - Decreased aminophospholipid translocase (329)
  - Decreased protein kinase C (53)
  - Decreased acetylcholinesterase (316, 331)
  - Deceased thiopurine methyltransferase (332)
  - Decreased S-adenosylhomocysteine hydrolase (333)
  - Decreased glyoxalase (288)

ATP, adenosine triphosphate.

[a] Many of these differences compare very young erythrocytes (reticulocytes; less dense cells) and older red cells (fewer reticulocytes; more dense cells). In some cases, particularly with enzyme changes, it is not clear whether the differences reflect changes between reticulocytes and most other red blood cells or whether the differences are a reflection of normal mature red blood cell aging *in vivo* (see text for details).

Erythrocyte Enzymes

The activities of erythrocyte enzymes have been measured in cells separated by age on the basis of cell density, osmotic lysis, or avidin-biotin affinity (41, 43, 44). The activities of a number of enzymes have been reported to decline with the age of the erythrocyte, including all of the glycolytic enzymes (Table 9.1). Red cell senescence and destruction may thus depend on this lost metabolic potential (45, 46, 47 and 48). However, the assumptions on which these studies are based have been criticized (49). It is recognized that the activities of certain age-dependent enzymes, such as glucose-6-phosphate dehydrogenase, hexokinase, aldolase, and pyruvate kinase, are greatly increased in red cells of individuals with hemolytic anemia. It also is agreed that the metabolic activity of reticulocytes decreases during their short maturation. However, it is less clear that the decrease continues during the erythrocytes' subsequent lifespan or that metabolic failure is the cause of red cell senescence and death. It has been pointed out that, if enzyme activity were lost rapidly during the first few days of the red cell's life but remained essentially stable thereafter, contamination of samples of old cells with progressively smaller numbers of reticulocytes would result in gradually decreasing enzyme activity in those samples (49). Studies using methods in which contamination of older cells with reticulocytes is less likely to occur have not consistently confirmed the loss of activities of these enzymes with age (38, 41, 50, 51 and 52). In one particularly interesting study in transient erythroblastopenia of childhood, a disorder characterized by an older population of red cells at diagnosis (Chapter 45), there was no difference in enzyme activity of affected patients or control erythrocytes, thus suggesting there is minimal loss of enzyme activity beyond the first days of red cell life (38). However, there are other studies to support the notion that the activity of some enzymes decline after reticulocyte maturation, in particular, the activity of several membrane protein kinases (53). Impaired phosphorylation of erythrocyte skeletal proteins or of a variety of substrates as a consequence of this lost kinase activity might render the red cell more susceptible to destruction.

Calcium Balance

Senescence of erythrocytes has been ascribed to a change in calcium balance resulting in an increasing concentration of calcium in older red cells, a change that might reduce erythrocyte deformability. It has been proposed that a major consequence of ATP depletion in aging cells is decreased activity of membrane-bound (Ca^{2+}-Mg^{2+})-ATPase and, therefore, calcium accumulation. This loss of calcium pump activity with age has been demonstrated in inside-out vesicles prepared from density-separated erythrocytes (54, 55). Alternatively, loss of pump activity might occur despite adequate ATP concentrations as a result of destruction of the enzyme by the calcium-activated protease calpain or by increased activity of an ATPase inhibitor (56). Increased cell calcium would, in turn, result in potassium loss, dehydration, increased cell density, increased viscosity, and diminished cell deformability (57). Others have proposed that calcium-activated transglutaminases can cross-link membrane or skeletal protein in senescent cells (58, 59). Data to support any of the above assumptions are not entirely convincing. ATP depletion may not occur during erythrocyte aging. A decrease in (Ca^{2+}-Mg^{2+})-ATPase activity in denser, and thus potentially older, red cells has been demonstrated (56, 60), but normal activity has also been reported (61), and, once again, the doubtful reliability of the density gradient separation method makes the significance of these observations uncertain. The presence of aggregates of polymerized polypeptides, as might arise from transglutaminase activity, has been disputed (62). Furthermore, the capacity of high-density red cells to extrude calcium after calcium loading was not different from that of low-density cells (63), and survival of transfused calcium-loaded cells was normal (64). More central to the hypothesis is the concentration of cell calcium. Measurements of the concentration of erythrocyte calcium have yielded inconsistent results (65, 66, 67, 68 and 69). Studies with fluorine nuclear magnetic resonance to measure calcium in cells separated using the density gradient system demonstrate a clearly greater concentration in the most dense, ostensibly the oldest cell fraction, than in the least dense fraction (70). The hypothesis that ATP depletion, calcium accumulation, and diminished cell deformability bring about red cell senescence and death is an attractive one but remains without reliable corroboration.

Membrane Carbohydrates and Surface Charge

It has been proposed that a diminished negative charge on the erythrocyte membrane would significantly reduce the repulsive interaction between red cells and tissue macrophages and thus facilitate red cell phagocytosis. Specifically, it has been shown that sialic acid, the principal source of membrane negative charge, is lost from membranes of high-density red cells, and the total surface negative charge is reduced. Desialylation of red cells decreases their lifespan *in vivo* (71) and increases phagocytosis by autologous macrophages *in vitro* (72, 73). It has been proposed that desialylation of membrane glycophorin occurs as the red cell ages and creates a “senescence factor glycopeptide” that is the signal for sequestration of moribund red cells (74). However, electrophoretic mobility of high- and low-density cells is not different (35, 75), and the difference in charge and sialic acid content is explainable by a loss of membrane surface area in the high-density cells (76, 77). Moreover, when red cells are desialylated and then reinfused, they do not behave as do high-density (and thus potentially aged) cells: Both are sequestered, but desialylated cells are sequestered in the liver rather than in the spleen (23); high-density cells are permanently removed from the circulation, but desialylated cells are only temporarily sequestered (78, 79). In addition, erythrocytes from individuals with recessively inherited deficiencies of red cell sialoglycoproteins survive normally (80). It

would seem that, if destruction of aging red cells is dependent on loss of sialic acid and of charge, the relationship is not a simple one.

Oxidative Injury

The role of the erythrocyte as an oxygen-carrying device repeatedly exposes it to the risk of oxidative injury ([81], [82]). In addition, intermediate products of oxidative denaturation of Hb, the hemichromes ([83]), interact with superoxide and hydrogen peroxide to generate hydroxyl radicals ([84]) and thus create another source of potential damage to the cell. Increased amounts of methemoglobin ([85]), hemichromes ([86]), and denatured Hb (Heinz bodies) ([86], [87]), decreased membrane-free sulfhydryl groups, and increased thiobarbituric acid–reactive substances ([88], [89]), an indicator of lipid peroxidation, all have been reported as evidence of oxidation damage in high-density red cells.

Further evidence is inferred from similarities between aged cells and those exposed to oxidants *in vitro*. In red cells incubated with H_2O_2 or with an end product of fatty acid peroxidation, malonyldialdehyde, polypeptide polymers are found that may result from cross-linking of the cytoskeletal protein, spectrin ([90]). Treatment of red cells with H_2O_2 or with the oxidant acetylphenylhydrazine induces the formation of membrane-bound, covalently cross-linked spectrin and a-globin chains of Hb that result from oxidative damage to Hb rather than to lipids ([91], [92], [93] and [94]). This oxidant-induced polymerization of spectrin results in decreased cellular deformability and increased adherence to and phagocytosis by monocytes ([92], [95]). Similar abnormalities have been found in high-density red cells ([92]), but not all investigators have observed a change in the oxidative state of membrane proteins with age using the density gradient method ([96]), and no abnormalities of spectrin could be found in old red cells separated by methods other than the density gradient method ([29], [62], [97]).

The cytoplasmic domain of cytoskeletal band 3, a transmembrane anion transport protein (see Chapter 8), provides a high-affinity site for hemichrome binding to the membrane in red cells exposed to oxidants ([98]). This interaction results in the formation of clusters of band 3 molecules in the membrane but apparently does not alter their molecular structure ([98]). The normally occurring distance between band 3 molecules is too great to be bridged by a single immunoglobulin (Ig) G molecule, but this aggregation of band 3 molecules provides a site to which an autologous anti–band 3 antibody might bind (see Autologous Antibodies to Membrane Antigens).

Autologous Antibodies to Membrane Antigens

Antibodies that bind to the membranes of some erythrocytes are present in the serum of normal humans. Two different IgG antibodies have been identified, one of which apparently binds to an altered form of band 3 protein ([72]) and the other to a Galal-3 galactosyl–containing glycolipid ([99]). It has been proposed that binding of one or both of these autologous antibodies provides a senescence signal that is responsible for directing the phagocytosis of aged cells, presumably by recognition of the Fc portion of the bound antibody by the Fc receptor of the macrophage.

The apparent anti–band 3 antibody has been demonstrated in a variety of mammals ([72], [100], [101] and [102]), but the amount is small. It is possible that during the aging process, modification of band 3 occurs, perhaps by clustering of band 3 molecules as a consequence of oxidative injury ([98]). The antibody binds to high-density but not to low-density red cells ([72], [102]). In dogs with biotin-labeled erythrocytes ([103]), it binds to old but not young erythrocytes. However, the number of IgG molecules per biotinylated red cell does not increase with increasing age of the cell ([104]). *In vitro*, the antibody promotes phagocytosis ([72]), but an effect on survival *in vivo* has not been shown.

Despite the large literature on the characteristics of the anti–band 3 antibody, there is little evidence of physiologic importance. *In vitro* sequestration of red cells is not inhibited by inhibitors of the Fc receptor, but it is by ß-galactosides, suggesting that erythrophagocytosis is mediated by a lectinlike receptor on macrophages ([73], [105], [106]). An increase in clearance of anti-band 3–treated guinea pig erythrocytes has been reported, but the increase is minimal ([107]). Erythrocyte lifespan in mice with severe combined immunodeficiency disease is normal, despite the absence of anti–band 3 antibody in the animals ([108]). In humans with mutations in band 3, none has been found in whom alterations in anti–band 3 binding sites resulted in prolonged erythrocyte survival ([109]).

The anti–a-galactosyl IgG is a polyclonal, monospecific antibody interacting specifically with oligosaccharides with the structure Galal-3ß1-4GlcNAc-R, a structure that is not normally expressed in humans, apes, or old world monkeys but is expressed in new world monkeys, nonprimate mammals, and in the bacterial lipopolysaccharides of *Escherichia coli* and *Klebsiella* ([99]). The antibody is present only in those species, like humans, that do not normally express the Galal-3 Gal epitope. Anti-Gal binds to high-density but not to low-density red cells. Galal-3 galactosyl is exposed on human red cells after their treatment with proteases, such as might occur after repeated exposure of cells to macrophages in the spleen ([99]). Anti-Gal is present in human plasma at 500 times the concentration of anti–band 3 ([99]). However, the physiologic significance of this antibody is unclear. Its absence from most mammals indicates that it is not a factor in the senescence of red cells in those species. If it plays a role in the destruction of aging red cells in humans, it is unlikely to be the exclusive mechanism.

The mechanism of red cell senescence is not clear. There is presently no marker by which aged red cells can be unequivocally identified. It may be that human erythrocyte senescence and destruction result from a combination of the many interesting abnormalities described in the preceding paragraphs or from some as yet unrecognized phenomenon.

MECHANISMS AND SITES OF RED CELL DESTRUCTION

When the erythrocyte reaches the end of its sojourn, it disappears from the circulation. However, as discussed above, the change in the cell that makes it no longer viable is not known. Much of what is believed to be true is based on inference or on observations made in individuals with hemolytic anemia. Under normal conditions, approximately 80 to 90% of normal erythrocyte destruction occurs without release of Hb into plasma ([110], [111]). Because of this fact, the major part of the destructive process is presumed to be *extravascular*, probably within macrophages of the spleen and, to a lesser extent, in the liver and bone marrow. Only 10 to 20% of normal destruction occurs *intravascularly*, and this mode of destruction has special characteristics.

Extravascular Hemolysis

It has long been assumed that erythrophagocytosis is the primary mode of extravascular destruction of senescent red cells in normal subjects ([112]). This is supported by two fundamental observations. First, the heme oxygenase system responsible for Hb degradation is located primarily in the phagocytic cells of the spleen, liver, and bone marrow and also in hepatocytes (see discussion below). Second, the iron derived from heme degradation is largely stored within the macrophage. Thus, it seems probable that Hb degradation and, hence, red cell destruction normally take place within these phagocytes. This clearly is true when red cell destruction is greater than normal, as in many types of hemolytic anemia. Likewise, when red cells are damaged *in vitro* and then reinfused, they are mostly removed from the circulation by the fixed macrophages of the spleen and liver ([113]). Also, as discussed above, old red cells bind autologous IgG antibodies, and, *in vitro*, these antibody-coated RBCs bind to macrophage Fc receptors, leading to erythrophagocytosis ([72], [99]).

The relative importance of the spleen and liver in erythrocyte destruction is influenced by the degree of cell damage ([113]). Severe degrees of damage lead to destruction in all macrophage-containing organs, but especially in the liver because of its relatively great blood flow. The spleen, in contrast, is apparently more sensitive to cell injury and cells only minimally damaged are preferentially removed by that organ ([114]). It is probable that effete red cells are destroyed primarily in the spleen; however, if this organ is removed from normal subjects, macrophages in other organs, especially the liver, rapidly assume this function, and there is no increase in cell survival ([115]).

Intravascular Hemolysis

Analysis of haptoglobin (Hp) kinetics in normal human subjects demonstrates that 10 to 20% of erythrocyte destruction occurs intravascularly ([110], [111]). The mechanisms by which intravascular red cell destruction can occur are osmotic lysis and red cell fragmentation. Susceptibility to osmotic lysis increases with increasing red cell age ([37], [116], [117]). However, it is unlikely that osmotic lysis has any significant role in normal red cell destruction because there is no site within the vascular compartment where the plasma is sufficiently hypotonic to bring lysis about. *Fragmentation* is defined as the loss of a portion of the erythrocyte membrane, often, but not always, accompanied by loss of cellular contents, including Hb. Fragmentation is the characteristic mode of cell destruction in the “microangiopathic” hemolytic anemias (Chapter 38). In these disorders, large red cell fragments are present in the circulating blood. They appear on blood smears as small, misshapen, often

triangular or helmet-shaped structures (*schistocytes* or *schizocytes*). Fragmentation of red cells usually is a result of erythrocyte interactions with altered endothelium, fibrin deposition, and increased shear stresses. Fragmented cells can be produced in a variety of ways *in vitro* ([118], [119], [120], [121], [122] and [123]). After a portion of the cell is lost, the membrane is capable of self-repair. Fragmentation also occurs within the spleen when the reticulocyte is pitted of red cell inclusions such as residual organelles and hemosiderin granules. To what extent this accounts for the small fraction of intravascular destruction seen in normal erythrocyte aging is not known.

FATE OF INTRAVASCULAR HEMOGLOBIN

Special features characterize those situations in which red cells are destroyed within the circulation rather than within macrophages. This occurs to a small extent with normal red cell aging, but it is increased significantly in certain hemolytic anemias. When intravascular breakdown of red cells happens, Hb is discharged directly into the circulation, from which it is removed by several mechanisms (Fig. 9.3).

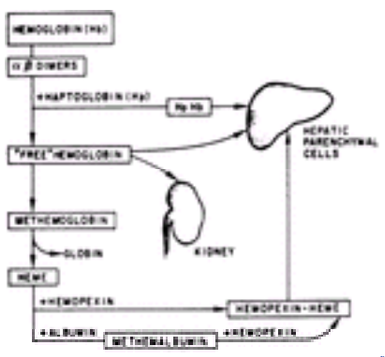

Figure 9.3. Pathways for the disposal of hemoglobin in plasma. Hemoglobin freely dissociates into aß dimers. These are bound by haptoglobin with subsequent removal of the hemoglobin-haptoglobin complex by hepatic parenchymal cells. Hemoglobin in excess of the haptoglobin-binding capacity circulates as the unbound (free) protein. In this form, it is partially removed by hepatic cells, but it may also follow two other pathways: It may be excreted by the kidney or oxidized to methemoglobin, from which heme is easily dissociated. Heme is initially bound to hemopexin, which transports it to the hepatic parenchymal cell. Heme may also be bound nonspecifically by albumin, forming methemalbumin. This complex probably transfers its heme to hemopexin as the latter becomes available.

Haptoglobin

At low rates of release of Hb into plasma, all of the Hb is found to be attached to Hp ([111], [124], [125], [126], [127], [128] and [129]). Because its concentration increases in a variety of inflammatory diseases, an increased Hp level is recognized as a nonspecific sign of disease with much the same significance as an accelerated sedimentation rate. The role of Hp as a Hb-binding protein and as the principal factor affecting the apparent “renal threshold” for Hb was described by Laurell ([130]).

Haptoglobins are a family of a $_2$-glycoproteins that bind Hb. The tetrameric molecule resembles that of certain Igs in that it has two light (a) chains and two heavy (ß) chains linked in humans by disulfide bonds ([131]). Hp is synthesized as a single polypeptide chain that is cleaved posttranslationally within the endoplasmic reticulum to generate its a and ß subunits ([132], [133]). Transcriptional activity of the Hp gene is promoted by interleukin-1, interleukin-6, and glucocorticoids as a part of the acute-phase response to systemic inflammation and related physiologic disturbances ([134], [135], [136], [137] and [138]), explaining why Hp levels are increased with inflammation. By electrophoresis of serum, several different Hp bands have been demonstrated. Most of the variations are due to differences in the a-chains. The observed pattern reflects the genetic constitution of the individual ([139]). The structural gene for Hp has been localized to the long arm of chromosome 16 (16q22) ([140], [141] and [142]). There are three common alleles in humans. Two of these, designated *Hp ^{1F}* and *Hp ^{1S}* , code for electrophoretically distinguishable fast (F) and slow (S) migrating classes of a-chains.

Early methods for the clinical determination of Hp concentration were based on the hemoglobin binding capacity of the plasma. Measured in this way, the normal range was 0.4 to 2.0 g Hb/L ([110]). Nowadays, most clinical laboratories measure Hp directly by radial immunodiffusion or immunonephelometric methods, and phenotyping can be performed using monoclonal antibodies and immunoblotting ([143], [144]). Normal concentrations differ substantially with technique; ranges such as 0.5 to 1.6 g/L ([145]) are representative, but each clinical laboratory should establish its own reference values. The concentration is also influenced by age. Hp levels are very low in newborns, but levels are measurable by approximately 3 months of age and increase gradually throughout childhood ([146]). Decreased Hp concentrations also may be observed in disorders associated with hemolytic anemia, ineffective erythropoiesis, liver disease and hereditary ahaptoglobinemia and with pregnancy and estrogen therapy. Increased concentrations may be present in any of those diseases in which concentrations of acute-phase reactants are increased, such as infections and malignancies.

Haptoglobin and Hb bind within the vascular compartment in an essentially irreversible, noncovalent complex. Hp binds aß Hb dimers. Thus, dissociation of tetrameric Hb is the necessary rate-limiting step in the reaction ([147]). Hp will complex with oxy-, met-, cyanmet- and carbon monoxyhemoglobin ([148]) but not with deoxyhemoglobin ([147]), Hb H (Hbß $_4$), Hb Bart's (Hb ? $_4$) ([149]), or myoglobin ([150]). Heme-free globin is bound, but heme is not ([151]).

Haptoglobin is synthesized in the parenchymal cells of the liver ([150], [152]). When not bound to Hb, it leaves the plasma with a half-disappearance time of 3.5 to 5.0 days ([111], [126], [153]). The Hp-Hb complex leaves much more rapidly, with a half-disappearance time of 9 to 30 minutes. Approximately 50 to 80% of the Hp turnover in the normal subject is accounted for by the rapid pathway ([111], [126]). From the kinetics of Hb turnover, it can be calculated that some 10 to 20% of normal erythrocyte destruction occurs intravascularly and uses the Hp system ([110], [111]). In hemolytic anemias characterized by intravascular hemolysis, catabolism of Hp is so rapid that it essentially disappears from the plasma, a change that is not accompanied by a compensatory increase in Hp synthesis. Hypohaptoglobinemia also occurs in hemolytic states associated with predominantly extravascular hemolysis ([154], [155]). The explanation for this observation is not established, but it has been suggested that some Hb may be regurgitated from macrophages when the rate of phagocytosis of erythrocytes or erythrocyte fragments reaches a maximum ([110]).

Catabolism of the Hp-Hb complex occurs in the hepatic parenchymal cell ([153], [156]). Internalization of the Hp-Hb complex by the hepatocyte is mediated by a receptor specific for the complex ([157]). The heme moiety is then detached from globin-Hp and apparently bound to another carrier protein before conversion to biliverdin. The globin-Hp complex is thereafter degraded. Hp is not returned to the plasma.

Hemoglobin and the Kidney

The Hb-Hp complex is too large (molecular weight, approximately 150 kd) to pass into the glomerular filtrate. Thus, the level of circulating haptoglobin is the most important determinant of the apparent renal threshold ([130]). When Hp is saturated, free (unbound) Hb circulates briefly in plasma. The hepatic parenchymal cell is responsible for the removal of some of the free Hb from plasma ([153]). In addition, Hb dissociates into aß dimers, which, having a molecular weight of approximately 32 kd, readily pass through the glomerulus ([158]). There is a low (less than 0.6 g/L) renal threshold for free Hb present after Hp saturation that is related to renal tubular reabsorption ([159]). If this tubular reabsorption capacity is exceeded, Hb appears in the urine. Thus, renal handling of Hb is similar to that of glucose, urate, and certain other substances ([158]).

Hemoglobinuria, when it is of considerable magnitude, can cause precipitation of heme pigment as casts in the distal tubules, proximal tubule cell necrosis, and acute renal failure. The mechanism is disputed, but several theories have been proposed: (a) that Hb or Hb products are directly toxic to proximal tubule cells; (b) that precipitation of Hb results in tubular obstruction and renal failure; and (c) that direct renal injury by Hb does not occur, but instead, products of intravascular hemolysis result in hypotension and other systemic and local vascular events, and these lead to renal failure ([160], [161], [162] and [163]).

Within the tubular epithelial cell, Hb iron is rapidly extracted and stored in the cell as ferritin and hemosiderin ([158]). Some of the tubular epithelial iron may be reused for Hb synthesis, but its mobilization for this purpose occurs only at a very slow rate. When iron-laden tubular cells are sloughed into the urine, the urine iron concentration increases, and both ferritin and hemosiderin may be detected ([163]). Clinically, hemosiderinuria is usually detected by the Prussian blue stain of the

urinary sediment ([164]). Detectable hemosiderin usually does not appear in the urine for 48 hours after a specific episode of hemoglobinuria ([163]) and may persist for more than a week ([160]). In chronic intravascular hemolysis, such as occurs in red cell fragmentation associated with abnormal prosthetic heart valves, hemosiderinuria is continuous ([165]) and can result in iron deficiency.

Plasma Heme, Hemopexin, and Methemalbumin

HEME Free Hb in plasma is readily oxidized to methemoglobin. The latter dissociates easily and nonenzymatically into heme and globin ([166]). Free heme is highly insoluble at physiologic pH. However, hemopexin and albumin are able to bind heme and maintain it in a soluble form. Heme is removed from these proteins by hepatocytes.
HEMOPEXIN Hemopexin is a ß1-glycoprotein, consisting of a single polypeptide chain and containing 20% carbohydrate, with a molecular weight of approximately 70 kd ([165]). It binds heme with the highest known affinity of any heme-binding protein and plays an important role in receptor-mediated hepatocyte heme uptake. The human gene encoding hemopexin has been localized to the region p15.4-p15.5 of chromosome 11 and is thus at the same site as the ß globin gene cluster, genes that also code for polypeptides that share the property of binding heme ([167] , [168] , [169] and [170]). Hemopexin is synthesized in the liver ([171]) and is found in the plasma in a concentration of 40 to 150 mg/dl. Each hemopexin molecule avidly binds one molecule of heme (Kd ~10^{-13} M). It also binds other porphyrins and bilirubin but with less avidity ([172] , [173]). Binding is through the heme iron to two histidine residues of hemopexin ([172] , [174] , [175] , [176] , [177] , [178] and [179]). The half-life of hemopexin in normal subjects is approximately 7 days ([180]), whereas the heme-hemopexin complex is removed from the circulation with a half-disappearance time of 7 to 8 hours ([165]). Hepatocyte uptake of the heme-hemopexin complex is presumably by receptor-mediated endocytosis ([181] , [182]). After endocytosis, the heme-hemopexin complex dissociates, and the released hemopexin is returned to the plasma as an intact protein ([176] , [181] , [183] , [184]). Transport of heme within the cytoplasm occurs by means of an intrinsic heme-binding membrane protein ([180] , [181]), and iron is rapidly released by heme oxygenase. Plasma hemopexin values may be reduced after intravascular hemolysis because of increased hemopexin catabolism ([180]). The depletion is less pronounced than is true of Hp, and low values imply a relatively severe degree of hemolysis. Hemopexin, like Hp, is an acute-phase reactant, and plasma levels rise with an inflammatory stimulus ([185]).
METHEMALBUMIN Each mole of human albumin can bind several moles of heme to form methemalbumin ([186]). The disappearance of methemalbumin from the circulation is kinetically complex ([187]). Heme added to human serum is initially associated primarily with albumin, presumably because the molar concentration of albumin is considerably greater than that of hemopexin ([172] , [188]).

EXTRAVASCULAR HEMOGLOBIN DEGRADATION

Formation of Bilirubin

Within 30 minutes of injection of either Hb or nonviable red cells, there is an increased concentration of bilirubin in both plasma and bile, as well as an increase in carbon monoxide (CO) production. The last component, derived from the a-methene carbon of heme ([188]), is exhaled from the lungs. These substances represent the products of heme degradation by a ternary enzyme complex that is composed of heme oxygenase, NADPH–cytochrome *c* (P-450) reductase, and biliverdin reductase ([189]). Almost all endogenously derived CO comes from this source ([188] , [190]). In most mammals, the heme oxygenase reaction is coupled with a second step in which biliverdin IXa is reduced to bilirubin IXa (Fig. 9.4).

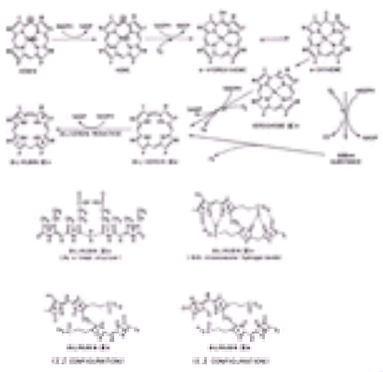

Figure 9.4. Formation of bilirubin IXa from heme. The initial reactions are catalyzed by microsomal heme oxygenase and require nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor. The reaction has a high specificity for the a-methene bridge, and a-oxyheme is a probable intermediate that is oxidized by molecular oxygen to biliverdin. In mammals, biliverdin is converted to bilirubin by biliverdin reductase. At bottom, alternative methods of representing the structure of bilirubin. The intramolecular hydrogen bonding that occurs with the Z,Z configuration is less extensive in the geometric isomers designated E,Z, and E,E (not shown); hence, the latter are more soluble in water. NADP, nicotinamide adenine dinucleotide phosphate.

Heme oxygenase activity is present in all tissues in which it has been measured ([191]). Heme is the preferred substrate, but methemoglobin, methemalbumin, and isolated a- and ß-Hb chains also serve as substrates; there is little or no activity against Hb, myoglobin, or intact Hb-Hp or heme-hemopexin complexes ([192]). The enzyme is inducible by its substrates ([190] , [193]), and increased heme oxygenase activity is observed in the spleen and liver during hemolytic anemia ([192] , [193] and [194]), in the liver after splenectomy ([192]), and in renal tubule cells in association with hemoglobinuria ([158] , [194]). The enzyme also is induced by metals, hormones, various drugs, organic compounds, fever, starvation, and stress ([195] , [196] , [197] , [198] , [199] and [200]). On the other hand, there also are agents that inhibit heme oxygenase activity ([201]); the most studied of these is tin-protoporphyrin ([202]). This substance acts as a competitive inhibitor of heme oxygenase; thus, its administration results in a marked decrease in the enzyme activity ([203]). The effect of tin-protoporphyrin is to inhibit the degradation of heme and, hence, the formation of bilirubin ([197] , [204] , [205] and [206]). Therefore, it may be useful in the treatment of hyperbilirubinemia states, such as those seen in newborn infants ([207] , [208] , [209] and [210]).

The process of heme degradation is a series of autocatalytic oxidations, catalyzed by heme oxygenase, with the reaction intermediates serving as cofactors ([211]) (Fig. 9.4). Overall, the oxidation of heme uses oxygen and NADPH, with the equimolar production of biliverdin, iron, and CO ([212]). In mammals, the heme oxygenase reaction is coupled with a second step in which biliverdin is converted to bilirubin. This reaction is brought about by an enzyme, biliverdin reductase, present in most tissues, that catalyzes the reduction of the central methene bridge of biliverdin. In birds, amphibians, and reptiles, biliverdin represents the principal end product of Hb degradation. Mammals have developed bilirubin as the end product, a change with important biologic consequences. Bilirubin is highly lipophilic and virtually insoluble in water, it is toxic to the developing brain, and it requires conjugation to make biliary excretion efficient ([213]). However, because of its lipophilicity, it can cross the placenta from fetus to mother with greater facility, and, thus, the fetus can use the mother's excretory mechanisms.

If isotopically labeled glycine is administered to a normal person, the label is incorporated into the porphyrin ring and ultimately makes its appearance in bilirubin ([214]) (Fig. 9.5). Most of the label appears approximately 120 days after administration of the isotope and, therefore, is presumed to be derived from the destruction of senescent red cells; however, a substantial fraction of the pigment is labeled within several days and, hence, is often referred to as the “early-labeled” bilirubin. The original studies estimated that approximately 10 to 20% of bilirubin was early-labeled ([214]). However, other studies suggest that an even greater fraction, approximately 25% ([214] , [215]), of bilirubin is derived from heme proteins that turn over much more rapidly than Hb. This fraction is made up of at least two components ([216]). The first, normally the larger one, is labeled maximally at 24 hours and is of hepatic origin, chiefly from the heme of cytochrome P-450 but also from other hemoproteins ([215]). The second is labeled maximally at approximately 3 to 4 days and is a by-product of erythropoiesis ([216]). An isotopic label from administered aminolevulinic acid, to which erythroid cells are relatively impermeable, appears primarily in the hepatic fraction, whereas that from glycine appears in both ([216]). The erythropoietic component is probably the product of “ineffective erythropoiesis” and results from the intramedullary destruction of defective red cells. In illnesses associated with exaggerated ineffective erythropoiesis, such as thalassemia or pernicious anemia, there is a marked increase in the early-labeled bilirubin fraction.

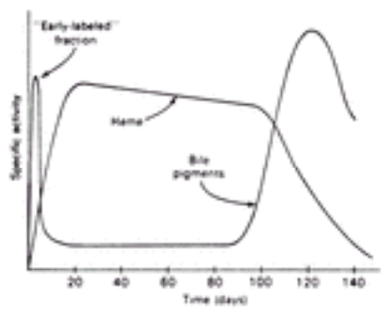

Figure 9.5. The incorporation of isotopically labeled glycine into heme and bile pigments. Most of the bilirubin labeling occurs at approximately 120 days, at the time of destruction of senescent red cells. Approximately 25% of bilirubin, however, is labeled within the first several days and is therefore called the “early-labeled” fraction.

Bilirubin Transport

After being released from the sites of heme catabolism, bilirubin appears in the plasma. The normal concentration of plasma bilirubin is less than 1.0 mg/dl. At equilibrium, the concentration is directly related to bilirubin production and inversely related to hepatic clearance ([217], [218]).

The structure of the bilirubin IXa molecule is asymmetrical, and several isomeric forms exist depending on the orientation of the outer pyrrole rings (rings A and D) in relation to the inner pyrrole rings (rings B and C) (Fig. 9.4) ([219]). In the naturally occurring configuration, all pyrrole rings are similarly rotated, representing the Z,Z or trans configuration. If either of the outer rings is rotated, the E,Z or Z,E geometric isomers are formed. Photoisomerization of the naturally occurring Z,Z configuration of bilirubin forms the photoisomers of the E,Z and E,E configurations in which intramolecular hydrogen bonding is less extensive. Thus, the E,Z and E,E isomers are more soluble and can be excreted without conjugation ([219], [220] and [221]); this is the basis for using phototherapy to prevent neurotoxicity in newborns with hyperbilirubinemia ([219], [220]).

Bilirubin is normally present in plasma in several forms ([222], [223]). Although unconjugated bilirubin is essentially insoluble in water, it combines reversibly with albumin in neutral or alkaline solution. At normal plasma albumin concentrations, the theoretical bilirubin-binding capacity is of the order of 70 mg/dl, of which half is tightly bound. These values are reduced by a decrease in plasma albumin concentration or by the presence of one of many organic, anionic substances that compete for albumin-binding sites, such as heme, fatty acids, sulfonamides, and salicylates ([224]). When the binding capacity is exceeded, bilirubin diffuses into the tissues. The tendency of bilirubin to bind to tissues, such as brain, may be due to complex formation with cell membrane polar groups, such as phosphatidylcholine ([221]).

In normal adults, less than 5% of measurable bilirubin is of the conjugated form ([225], [226]), but, under certain pathologic circumstances, the proportion of conjugated bilirubin is greater. This relatively soluble bilirubin derivative may also be bound to albumin. Most is less tightly bound than the unconjugated form, but a portion is covalently and irreversibly bound ([227]). That portion of esterified bilirubin that is reversibly bound to albumin is ultrafilterable. In contrast to the other forms of bilirubin present in the plasma, this complex enters the glomerular filtrate, is not reabsorbed in the tubules, and is excreted in the urine.

Hepatic Bilirubin Metabolism

The processing of bilirubin by the liver is one aspect of a general mechanism whereby plasma protein-bound, organic anions are metabolized and excreted. In addition to bilirubin, other anionic substances follow the same pathways, especially certain dyes (e.g., cholecystographic agents), drugs (e.g., salicylates), steroids, and thyroxine. The process of hepatic bilirubin metabolism may be divided into three distinct phases: uptake, conjugation, and excretion ([228]) (Fig. 9.6). All three phases must be operative if bilirubin is to be excreted at a normal rate; however, in the normal person, the excretion step is the slowest and is, therefore, the rate-limiting step.

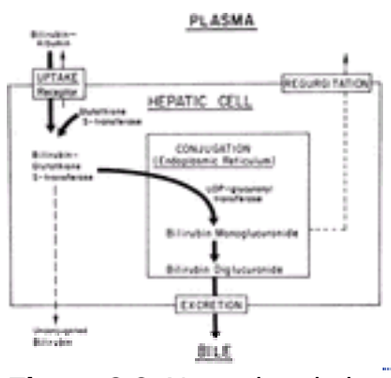

Figure 9.6. Normal and abnormal pathways of bilirubin excretion by the hepatic cell. The normal pathways (*solid arrows*) include uptake and conjugation of bilirubin and excretion of the conjugated derivative. Abnormal pathways (*dashed arrows*) include regurgitation of bilirubin glucuronide into plasma and excretion of unconjugated bilirubin into bile. UDP, uridine diphosphate.

Within the hepatic sinusoids, the albumin-bilirubin complex dissociates, and bilirubin, but not albumin, passes into the hepatocyte. The entry of bilirubin into the hepatocyte takes place via a bidirectional energy-dependent process ([229], [230], [231], [232], [233], [234], [235] and [236]). Conjugated bilirubin uses this mechanism as well ([233], [236], [237]). The bidirectional movement of bilirubin is extensive, with 40% of pigment extracted by hepatocytes in a single pass refluxing back into the plasma without change ([238]). In addition, a part of the bilirubin formed within the liver cell from degradation of hepatic heme, such as cytochrome P-450, refluxes into the plasma in the unconjugated form ([239]).

Within the hepatocyte, unconjugated bilirubin is bound by one or more of a group of cytosolic enzymes, the glutathione S-transferases, also referred to as *ligandin* or *Y protein* ([240], [241], [242] and [243]). Glutathione S-transferase probably has no direct role in the uptake of bilirubin ([244]) but may diminish its reflux back to the plasma ([240]). It is not known if glutathione S-transferase plays a role in the transport of bilirubin or bilirubin glucuronides within the cell or possibly may serve to regulate the delivery of bilirubin to sites of metabolism within the cell ([238]).

Within the liver cell, bilirubin is conjugated with glucuronic acid to form bilirubin diglucuronide (Fig. 9.7). In normal human bile, 80% of the bilirubin is present as the diglucuronide; the two monoglucuronide isomers comprise most of the remainder in approximately equal amounts ([245]). In humans, small amounts of conjugates of glucose and xylose are also present ([246]). Bilirubin diglucuronide and other conjugated bilirubins are considerably more water-soluble than unconjugated bilirubin, in part because the carbohydrate moieties prevent intramolecular hydrogen bonding. The increased solubility makes biliary excretion of the pigment possible. Little or no unconjugated bilirubin is found in bile, and, if conjugation is seriously impaired, bile bilirubin content is low.

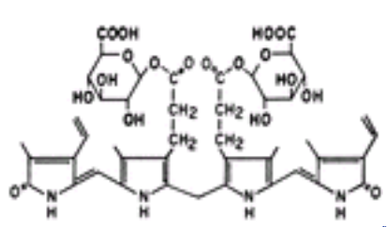

Figure 9.7. Bilirubin diglucuronide. The two glucuronic acid molecules are emphasized by bold type.

The conjugation reaction is catalyzed by uridine diphosphate–glucuronyl transferase (UGT). Glucuronic acid, a derivative of glucose, is transferred from uridine diphosphate–glucuronic acid to esterify one of the propionyl carboxyl groups of bilirubin, forming bilirubin monoglucuronide. The biologic advantage provided by forming the diglucuronide is not clear, because the monoglucuronide can be readily excreted into the bile and, in fact, is the major biliary pigment in many mammals ([246]).

Hepatocyte UGT exists in several isoforms, catalyzing the glucuronidation of a variety of substrates, such as steroid hormones, and a variety of carcinogens and drugs. Bilirubin serves as the substrate for two of these isoforms (B-UGT 1 and B-UGT 2) ([247]), but only B-UGT 1 is quantitatively significant in humans ([248]). This enzyme is capable of transferring glucose and xylose, as well as glucuronic acid ([249]). The availability of uridine diphosphate–glucuronic acid is an important factor regulating the activity of hepatocyte B-UGT 1 ([250] , [251]). B-UGT activity is also modulated by a variety of drugs, such as phenobarbital, and hormones, such as cortisol and thyroxine ([252]).

In hepatocellular disease or biliary obstruction, some conjugated bilirubin may be “regurgitated” into the plasma. In addition, a small portion of conjugated bilirubin within the hepatocyte is deconjugated, and the unconjugated bilirubin, in part, refluxes into the plasma ([239]). These pathways, in part, explain the increase of both fractions of bilirubin in patients with cholestatic liver disease. In other clinical situations, hyperbilirubinemia is mainly due to an increase in unconjugated bilirubin. The most common of these is hemolytic disease, in which Hb catabolism and, therefore, bilirubin production are increased. However, there also are several inherited disorders in which unconjugated hyperbilirubinemia occurs because of impaired capacity for bilirubin conjugation.

Decreased ability to conjugate bilirubin is the common feature of three hereditary disorders that differ from one another primarily in the severity of the conjugation impairment. In Crigler-Najjar syndrome, type I, severe unconjugated hyperbilirubinemia is present from birth, and kernicterus is common. In Crigler-Najjar syndrome, type II, less severe jaundice occurs, and, in Gilbert syndrome, the jaundice is quite mild, often not obvious clinically ([253] , [254]). These disorders are recessively transmitted, and most patients are therefore homozygous for the mutant gene, although, occasionally, heterozygotes are minimally jaundiced. Mutations in the gene for B-UGT 1 occur in all three diseases. In the two Crigler-Najjar syndromes, the mutation most often involves exon 1, the exon that confers substrate specificity to the enzyme, resulting in a structurally abnormal protein. In Crigler-Najjar syndrome, type I, and in the Gunn rat, an animal model of this disease, the gene product is entirely nonfunctional, whereas in type II, activity of the product is variably reduced ([248] , [255] , [256] , [257] , [258] and [259]). In Gilbert syndrome, the mutation in some patients has been shown to affect the promoter sequence of exon 1 ([257]). Gilbert syndrome is very common, occurring in as much as 10% of the general population, but both Crigler-Najjar syndromes are quite rare. In Crigler-Najjar syndrome, type I, tin-protoporphyrin may be effective in reducing the bilirubin concentration. Liver transplantation provides a more permanent benefit. No treatment is generally necessary for the other two disorders. However, it is now recognized that the magnitude of hyperbilirubinemia seen in children with different chronic hemolytic states is influenced by the simultaneous inheritance of the gene for Gilbert disease ([210] , [260]). In infants with hereditary spherocytosis who also are homozygous for the mutation responsible for Gilbert syndrome, hyperbilirubinemia almost always requires phototherapy ([260]). It also is believed that the variable degree of hyperbilirubinemia in glucose-6-phosphate dehydrogenase–deficient neonates reflects the presence or absence of the variant form of uridine-diphosphoglucuronosyl–transferase responsible for Gilbert syndrome ([210]). In infants known to be glucose-6-phosphate dehydrogenase–deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of tin-mesoporphyrin, an inhibitor of heme oxygenase, has been demonstrated to be highly effective and safe ([261]).

Excretion of conjugated bilirubin from the hepatic cell into the bile canaliculus proceeds against a 40:1 gradient when concentration in the bile is compared with that in plasma ([262]). From animal studies, it has been demonstrated that excretion of bilirubin from hepatocytes is mediated by an ATP-dependent transport system, a canalicular multispecific organic anion transporter in the apical or canalicular membrane of hepatocytes ([263]). The ATP-dependent carrier system is at least partially shared by a variety of organic anions ([264] , [265]). This is normally the rate-limiting step in overall hepatic bilirubin transport. The Dubin-Johnson syndrome ([266] , [267]) is a disorder transmitted by autosomal-recessive inheritance and characterized by mild conjugated hyperbilirubinemia and impaired biliary secretion of non–bile-acid organic anions. Bilirubin uptake and conjugation are normal. This defect is similar to that of the TR-rat in which the ATP-dependent transport system is absent ([265]). Dubin-Johnson syndrome is now believed to be due to mutations in the canalicular multispecific organic anion transporter gene ([268] , [269]).

Intestinal Bile Pigment Metabolism

Bilirubin diglucuronide is excreted into the duodenum with other constituents of bile ([270]). There is little or no intestinal absorption of the conjugated pigment, although unconjugated bilirubin is readily absorbed. Bilirubin diglucuronide probably remains in the conjugated form during its transit through the small intestine. However, during intestinal stasis and in newborns, increased deconjugation of bilirubin occurs and intestinal absorption takes place. This enterohepatic circulation of bilirubin may contribute to the severity of jaundice associated with the physiologic hyperbilirubinemia of the newborn ([271]).

When bilirubin diglucuronide reaches the terminal ileum and colon, it is hydrolyzed by bacterial ß-glucuronidases (Fig. 9.8). The two methene bridges and usually the two vinyl groups are then reduced by bacterial flora to form a series of colorless tetrapyrroles called *urobilinogens* ([272]). Because urobilinogen formation is accomplished by bacteria, it does not occur in newborns or in germ-free animals ([272]), and it may be markedly affected by administration of broad-spectrum antibiotics ([272]). The urobilinogens are easily dehydrogenated across the two middle rings to form the orange-yellow pigments, urobilins, that contribute to the color of feces.

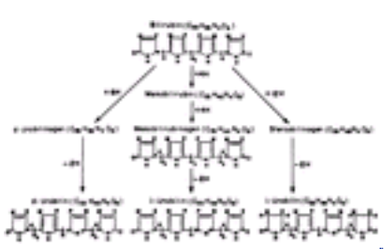

Figure 9.8. Bile pigment metabolism in the gut. These reactions are carried out by bacteria. d-Urobilinogen, mesobilirubinogen, and stercobilinogen are members of the urobilinogen group, which is characterized structurally by saturation of the carbon bridges connecting the pyrrole rings. The urobilins are derived from urobilinogens by oxidation and have one or more double bonds in the connecting carbon bridge. (From Lester R, Troxler RF. Recent advances in bile pigment metabolism. Gastroenterology 1969;56:143–169, with permission.)

Approximately 10 to 20% of the urobilinogen formed in the gut is reabsorbed, and the remainder is lost with the feces. The reabsorbed fraction is efficiently excreted by the normal liver without being conjugated ([270]). This sequence of events is referred to as the *enterohepatic recirculation of urobilinogen*. A portion of the reabsorbed pigment may also be excreted into the urine. Urobilinogen is filtered by the glomerulus, secreted by the renal tubule, and reabsorbed. If the liver's capacity to excrete urobilinogen is impaired, a disproportionate amount appears in the urine.

Also found in the colon is a group of poorly characterized dipyrroles known as *mesobilifuscins*. These brown pigments are partly responsible for the color of normal feces ([273]). Most of these dipyrroles do not appear to be derived from the degradation of bilirubin; instead, they probably are anabolic by-products of heme synthesis ([274]). However, in conditions associated with Heinz bodies, excessive amounts of such dipyrroles are excreted in the urine. These are believed to be derived from the heme freed from globin when the Heinz body forms. Furthermore, a dipyrrole is formed from the photodegradation of bilirubin ([275]), as discussed in the section Alternate Pathways of Heme and Bilirubin Catabolism.

Alternate Pathways of Heme and Bilirubin Catabolism

Several lines of evidence suggest that some heme may be degraded by pathways other than those previously described. On a stoichiometric basis, it can be calculated that 35 mg of bilirubin should be produced from degradation of 1 g of Hb. However, recovery of fecal urobilinogen is substantially less than expected, suggesting that as much as 20 to 40% of heme may be degraded by some other pathway ([275]). Only minimal amounts of unconjugated bilirubin are excreted in the urine. Excretion of conjugated bilirubin is substantial despite complete biliary obstruction. In rats with biliary fistulas, only 60 to 80% of administered radioactive Hb or

heme is recovered in bilirubin; a portion of the remainder is found in nonbilirubin fractions of bile ([276], [277]). Radioactive bilirubin in patients and rats with prolonged complete biliary obstruction gradually disappears via an unidentified route ([277]). Furthermore, in severe, inherited defects of bilirubin conjugation, such as those found in the Gunn rat and in human infants with Crigler-Najjar syndrome, the alternate pathways appear to be increased ([278]).

One explanation for these observations is that bilirubin is converted by a series of light-stimulated reactions to a variety of water-soluble derivatives, including hydroxyrubins, bilichrysins, and a dipyrrole ([275]). These light-induced products, which are colorless and do not react with diazo reagents, have been found in the bile of the Gunn rat. A microsomal P448-dependent monooxygenase may contribute to these alternate pathways because inducers of this enzyme increase the turnover of bilirubin in the Gunn rat and reduce the plasma bilirubin concentration ([279], [280]). In addition, a mitochondrial bilirubin oxygenase has been identified that *in vitro* degrades bilirubin to a variety of products ([279]).

Photodegradation of bilirubin, such as described above, has been applied to the treatment of unconjugated hyperbilirubinemia in infants (Chapter 36) ([219], [220], [275], [280]). Exposure to light brings about increased bilirubin excretion and a decrease in the serum bilirubin concentration to nontoxic levels. The photodegradation products are excreted promptly in the bile and may cause the stool to turn to a green or darker brown color. No toxicity of these products has been demonstrated.

Laboratory Evaluation of Hemoglobin Catabolism and Bile Pigments

The serum bilirubin concentration is an important marker of the rate of bilirubin production and of hepatobiliary function. Traditionally, it has been measured by the van den Bergh test described in 1916 ([281]). It is based on Ehrlich's observation that a mixture of sulfanilic acid, hydrochloric acid, and sodium nitrite (diazo reagent) yields a reddish-violet color with a maximum absorption at a wavelength of 450 nm when added to plasma or other solutions containing bilirubin. This reaction remains the basis for most automated clinical measurements of bilirubin ([282]). The color may appear and reach its maximum intensity at once (*direct reaction*). A direct reaction is obtained with bilirubin in bile and in the plasma and urine from patients with obstructive jaundice. The direct-reacting bilirubin approximately corresponds to conjugated bilirubin. The bilirubin in plasma of patients with hemolytic disease does not react directly with the diazo reagent but requires addition of an accelerator such as alcohol (*indirect reaction*). Indirect-reacting bilirubin corresponds to unconjugated bilirubin.

The measurement of fecal urobilinogen excretion over several days is a crude test previously used to quantify heme breakdown, but this is rarely used nowadays. More precise measurements of heme catabolism can be determined from measuring endogenous bilirubin production or generation of CO. As discussed previously, the principal catabolic products of heme are iron, CO, and bilirubin. There are no other significant endogenous sources of the last two compounds; thus, the breakdown of one mole of heme yields precisely one mole of CO and one mole of bilirubin.

The rate of bilirubin production can be calculated from the kinetics of plasma bilirubin disappearance ([238]). A tracer dose of ^{3}H- or ^{14}C-bilirubin is injected intravenously, the bilirubin pool size is measured, and serial determinations of plasma unconjugated radioactive bilirubin are made over a 24- to 48-hour period. The disappearance curve is complex and requires computer analysis ([238]). Generally higher rates of bilirubin production are observed in hemolytic states, and the data are expressed in terms of erythrocyte lifespan ([238]). However, the method is not suited for routine use in view of the difficulty in obtaining adequately labeled bilirubin.

It has been recognized for years that blood carboxyhemoglobin levels are increased in hemolytic disease ([283], [284] and [285]); but precise interpretation of such static measurements is complicated by exogenous exposure to CO and by variations in CO excretion. In contrast, the endogenous rate of CO production can be measured by a rebreathing method that circumvents these problems ([188]). The subject breathes into a closed system from which CO_2 is absorbed and to which O_2 is added. CO excretion is thereby prevented, and the blood level of carboxyhemoglobin increases. Endogenous CO production is calculated from the rate of increase over a 2-hour period and from the body CO dilution. With this method, the rate of CO production has been found to be increased several-fold from normal in patients with a variety of hemolytic anemias ([188]) and similarly elevated in conditions associated with ineffective erythropoiesis ([284]). For newborn infants with increased jaundice, it is important to know whether the hyperbilirubinemia is a consequence of accelerated red cell breakdown or due to some other cause. For this purpose, a noninvasive instrument to measure exhaled CO now is commercially available and appears to be a reliable marker of increased Hb breakdown ([286], [287]).

ACKNOWLEDGMENT

The author wishes to acknowledge Andrew Diess, MD, for the excellent previous chapter on Destruction of Erythrocytes, which served as a template for the current chapter in this eleventh edition of *Wintrobe's Clinical Hematology*.

Neutrophilic Leukocytes

Three types of granulocytes are readily identified in peripheral blood smears. Neutrophils are so named because of their neutral staining with Wright stain, whereas eosinophils avidly stain with the dye eosin, and basophils have readily identified large dark-staining granules with Wright stain. Neutrophils play a critical role in host defense by phagocytizing and digesting microorganisms, and inappropriate activation of neutrophils may result in damage to normal host tissues. In the resting uninfected host, the production and elimination of neutrophils are balanced, resulting in a fairly constant concentration of neutrophils in peripheral blood. When an infection occurs, chemotactic agents are generated that result in migration of neutrophils to the site of the infection and activation of neutrophil defensive functions. This effect is often associated with an increased production and release of neutrophils from the bone marrow. This chapter reviews the structure, morphology, production, distribution and kinetics, and functions of neutrophils. This chapter is written in several sections, and the first part of each section contains more general information for students, whereas the second part contains greater detail.

SUBCELLULAR STRUCTURE OF NEUTROPHILS

Mature neutrophils contain several types of granules and other subcellular organelles. To better understand the functions of neutrophils, many studies have been performed to identify and characterize the molecular composition of the various subcellular compartments of neutrophils. Two techniques are commonly used for this purpose: immunoelectron microscopy and subcellular fractionation. Most recent subcellular fractionation studies used the technique of nitrogen cavitation to disrupt the neutrophils. In this technique, cells are equilibrated with nitrogen at high pressure and then released into a pressure of one atmosphere. The rapid decrease in extracellular pressure results in disruption of the cells by the formation of nitrogen gas within the cell. The disrupted cells are then fractionated by density gradient centrifugation ([1]). Many types of subcellular organelles and structures are present in neutrophils, as seen by electron microscopy (EM). Four well-defined types of granules have been defined in neutrophils: primary granules, secondary granules, tertiary granules, and secretory vesicles. Some of the known constituents of these granules are indicated in Table 10.1.

TABLE 10.1. Contents of Human Neutrophil Granules

Azurophil (Primary) Granules	Specific (Secondary) Granules	Gelatinase (Tertiary) Granules [a]	Secretory Vesicles
Membrane	Membrane	Membrane	Membrane
CD63	CD15 antigens	Mac-1 (CD11b)	Alkaline phosphatase
CD66c	CD66a	FMLP receptor	Cytochrome *b* $_{558}$ [b]
CD68	CD66b	Diacylglycerol deacylating enzyme	Mac-1 (CD11b)
Matrix	Cytochrome *b* $_{558}$ [b]	Cytochrome *b* $_{558}$ [b]	u-PA receptor

Lysozyme	FMLP receptor	Laminin receptor	FMLP receptor
Defensins	Fibronectin receptor	Matrix	CD10, CD13, CD45
Elastase	G-protein a-subunit	Gelatinase [a]	CD16
Cathepsin G	Laminin receptor	Acetyltransferase	DAF
Proteinase 3	MAC-1 (CD11b)	Lysozyme	CR1 (CD35)
Esterase N	NB 1 antigen		Matrix
a $_1$-Antitrypsin	Rap 1, Rap 2		Plasma proteins (including tetranectin and albumin)
a-Mannosidase	Thrombospondin receptor		
Azurocidin	Tumor necrosis factor receptor		pro–u-PA/u-PA
Bactericidal permeability-increasing protein	Vitronectin receptor		
	u-PA receptor		
ß-Glycerophosphatase	Matrix		
ß-Glucuronidase	Apolactoferrin		
ß-Galactosidase	Lysozyme		
ß-Glucosaminidase	ß $_2$-microglobulin		
a-Fucosidase	Collagenase		
Cathepsin B	Gelatinase [a]		
Cathepsin D	Histaminase		
Acid mucopolysaccharide	Heparinase		
Heparin binding protein	pro–u-PA		
N-acetyl-ß-glucosaminidase	Vitamin B $_{12}$–binding protein		
Sialidase	Sialidase		
Ubiquitin protein	Protein kinase C inhibitor		
	hCAP-18		
	SGP28		
	Neutrophil gelatinase-associated lipocalin		

DAF, decay accelerating factor; FMLP, f-met-leu-phe; u-PA, urokinase-type plasminogen activator.

[a] Gelatinase is present in only a subset of specific granules; most is present in gelatinase granules.

[b] Cytochrome *b* ^{558} is also called *b* ^{245}.

Adapted from references 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 and 14.

Azurophilic Granules

The azurophilic, or primary, granules are formed during the promyelocytic stage and in general contain many antimicrobial compounds. These granules fuse with phagocytic vesicles, resulting in the delivery of their contents to the ingested organism. Among the azurophilic granule contents is myeloperoxidase (MPO), a protein that catalyzes the production of hypochlorite (OCl^-) from chloride and hydrogen peroxide produced by the oxidative burst. MPO constitutes approximately 5% of the dry weight of the neutrophil (15) and imparts the greenish coloration to pus. Defensins, a group of cationic proteins that kill a variety of bacteria, fungi, and viruses (16 , 17 and 18), also constitute approximately 5% of total neutrophil protein (19). Other components of azurophilic granules include lysozyme, which degrades bacterial peptidoglycans (20), bactericidal permeability-increasing protein, which has antibacterial activity against certain gram-negative bacteria (21 , 22 , 23 , 24 and 25), azurocidin, which has antibacterial as well as antifungal activity against *Candida albicans* (26 , 27), and the serine proteinases elastase, cathepsin G, proteinase 3, esterase N, and others (28 , 29 , 30 and 31). The granule membrane itself contains a large amount of CD66c (32 , 33) and CD63 antigens (34). Heterogeneity among azurophil granules is likely (2).

Specific Granules

Although some specific (also called *secondary*) granules, like azurophilic granules, fuse with phagocytic vesicles, it is believed that these granules are largely for release into the extracellular space. The known contents of these granules are also indicated in Table 10.1 and include apolactoferrin, the major specific granule protein, vitamin B $_{12}$-binding protein, plasminogen activator, and collagenase. Lysozyme and some gelatinase are also present in specific granules. Release of specific granule contents may modify the inflammatory process. For example, collagenase may degrade collagen, thus augmenting movement through collagen and participating in tissue remodeling. Apolactoferrin, by binding iron, may have an antibacterial effect by preventing bacteria from obtaining necessary iron for growth (35). Iron binding by apolactoferrin may also modify hydroxyl radical formation and cell adhesion (36 , 37 , 38 and 39). Specific granules also contain a number of membrane-bound molecules that are also expressed on the cell surface. This includes CD11, CD18, CD66a, CD66b, NB-1, f-met-leu-phe (FMLP) receptors, C5a receptors, and cytochrome *b* $_{558}$. When cells are stimulated, the surface expression of many of these membrane proteins is increased, and some of the up-regulated molecules may be derived from specific granules. The importance of the specific granules in neutrophil function is shown in patients who lack specific granules; these patients are susceptible to repeated skin and respiratory infections and have defective neutrophil chemotaxis and adhesion.

Tertiary Granules

Tertiary, or gelatinase, granules, which cosediment with specific granules in some subcellular fractionation techniques, were initially identified as gelatinase-containing granules (40). Like specific granules, tertiary granules also contain many membrane proteins that are up-regulated to the cell surface with stimulation (10). The relative contribution of tertiary granules and specific granules to up-regulation of membrane proteins is not clear.

Secretory Vesicles

Secretory vesicles, which largely distribute in the plasma membrane fraction using subcellular fractionation techniques, have also been described. Complement receptor (CR) 1, recognized by CD35 monoclonal antibodies, has been found exclusively in the light membrane fractions containing secretory vesicles and plasma membranes using subcellular fractionation techniques (12). The observation that CR1 can be readily up-regulated to the neutrophil surface with weak stimulation demonstrates that secretory vesicles provide an intracellular reservoir from which membrane proteins can be recruited to the cell surface. CR3 (HMac-1), recognized by CD11b antibodies and present in both secretory vesicles and specific granules, is also up-regulated to the cell surface with weak stimulation. In contrast to CR1, a more marked up-regulation of CR3 is observed with more potent stimulation, demonstrating that specific granules can also serve as an intracellular reservoir from which membrane proteins can be up-regulated to the cell surface (12). By EM, the secretory vesicles appear as smooth-surfaced vesicles. A defining feature of secretory vesicles is their rapid and complete translocation to the surface membrane with weak stimulation (12). These secretory vesicles also contain alkaline phosphatase, cytochrome *b* $_{558}$, and FMLP receptors. Secretory vesicles can be up-regulated to the cell surface in the absence of extracellular calcium, in contrast to specific and gelatinase granules, which require extracellular calcium for release (12). The secretory vesicles appear to be formed by a process of endocytosis and contain albumin.

Plasma Membrane

Many constituents of the neutrophil plasma membrane have been defined. These include membrane channels, adhesive proteins, receptors for various ligands, ion pumps, and ectoenzymes. In the last 15 years, there has been an explosion of information about membrane proteins, identified largely by monoclonal antibodies. Many of these cell-surface molecules probably play a role in regulating the neutrophil response. For example, aminopeptidase N (CD13) can inactivate interleukin (IL)-8, eliminating its chemotactic activity ([41]), and neutrophil endopeptidase (CD10) can inactivate the chemotactic peptide FMLP ([42]). Studies with CD66 monoclonal antibodies suggest a role for CD66a, b, c, and d in activating neutrophils ([43]), and some CD45 antibodies, which recognize a transmembrane protein with tyrosine phosphatase activity in its cytoplasmic domain, inhibit neutrophil chemotaxis ([44]). Some of the various clusters of differentiation (CD) expressed on neutrophils are shown in Table 10.2. The components of the membrane are not uniformly distributed. Studies have indicated the presence of differentiated domains in the membrane called *rafts*, which are described in the section Lipid Rafts.

TABLE 10.2. Some CD Antigens Expressed on Neutrophils

CD	CD Antigen
CD10	Common acute lymphoid leukemia antigen, neutral endopeptidase
CD11a	Leukocyte factor antigen-1
CD11b	Mac-1
CD11c	p150, 95
CD13	Aminopeptidase N
CD15	Le ^{x} (Ga1ß1?4G1cNAc(Fuca1?3)ß1?3Ga1ß1? 4G1cNAc?R)
CD15s	sLe ^{x}
CD16	FcRIII
CDw17	LacCer
CD18	ß $_{2}$ integrin
CD24	Glycosyl phosphatidylinositol–linked protein
CD31	Platelet endothelial cell adhesion molecule-1
CD32	FcRII
CD43	Leukosialin, sialophorin
CD44	Pgp-1
CD45	Leukocyte common antigen (a protein tyrosine phosphatase)
CD50	Intercellular adhesion molecule-3
CD53	Tetraspan molecule
CD55	Decay accelerating factor
CD62L	L-selectin
CD63	Tetraspan family member
CD64	FcRI
CD65	Ga1ß1?4G1cNAcß1?3Ga1ß1?G1cNAc(Fuca1?3)?R
CD65s	Sialylated CD65
CD66a	Biliary glycoprotein
CD66b	CGM6
CD66c	NCA
CD66d	CGM1
CD82	Tetraspan family member
CD88	C5a receptor
CD95	Fas, APO-1
CD114	Granulocyte colony-stimulating factor receptor
CD156	ADAM-8 (a disintegrin and metalloprotease domain)
CD157	Bifunctional ectoenzyme (adenosine diphosphate ribosylase)

NOTE: When used to describe the antigen, the term *CD antigen* should be used.

Cytoskeletal Matrix

Like many other cells, neutrophils contain a complex cytoskeleton. Alterations in the distribution of cytoskeletal elements may be important in chemotaxis, phagocytosis, and exocytosis. Many protein components of this cytoskeleton have been identified, including actin, actin-binding protein, a-actinin, gelsolin, profilin, myosin, tubulin, and tropomyosin. Actin accounts for approximately 10% of neutrophil protein ([45]). The reader is referred to other reviews for a more detailed description of the role of the cytoskeleton in neutrophil function ([46]).

Neutrophil Lipids

Although most studies of neutrophil structure have concentrated on proteins, lipids and carbohydrates also serve important functions. Lipids account for approximately 5% of neutrophils by weight ([47], [48]), of which approximately 35% is phospholipid ([49]). Phosphatidylcholine and phosphatidylethanolamine account for approximately 75% of the phospholipid in intact neutrophils ([49]). Subcellular distribution studies reveal that plasma membranes and secretory vesicles contain approximately 50% of the cellular phospholipid. Most of the phosphatidylinositol and phosphatidylcholine are present in plasma membrane and secretory granules, whereas a large part of the phosphatidylethanolamine is found in the specific granules ([49]). Among the phospholipids, the phosphoinositides are important as sources of inositol 1,4,5-triphosphate (IP $_{3}$) (a signal transduction molecule that results in calcium release) and diacylglycerol [which activates protein kinase C (PKC)]. The occurrence of arachidonic acid in phospholipids, especially phosphatidylcholine, is important as a precursor for the production of leukotrienes, prostaglandins, thromboxanes, and lipoxins ([50], [51]). Cholesterol and triglycerides constitute most of the nonphospholipid neutrophil lipid. Glycolipids, which include both neutral glycosphingolipids and gangliosides, constitute the remaining neutrophil lipids. The study of glycolipids is complex, and the glycolipid composition of neutrophils is not well understood. Glycolipids are important because their carbohydrate components contain many neutrophil differentiation antigens with a multitude of potential functions. The major neutrophil glycolipid is lactosylceramide (LacCer: Galß1 ? 4Glcß1 ? 1Cer) ([52], [53] and [54]) and is recognized by CDw17 monoclonal antibodies. Interestingly, the surface expression of LacCer decreases after neutrophil stimulation. More than 75% of neutrophil LacCer is found in intracellular granules ([53], [55]). It has been hypothesized that most LacCer in the granule membranes is found in the outer leaflet and may contribute to the ability of these membranes to form the highly convex surfaces necessary to form these submicron particles ([51]). Approximately 75% of the five major glycosphingolipids are located intracellularly ([55]). Studies of the subcellular distribution of glycosphingolipids in neutrophils have found no differences among the plasma membrane, primary granules, or secondary granules in the relative amounts of these five glycosphingolipids ([55]).

Lipid Rafts

Studies have demonstrated the existence of large noncovalent detergent-resistant complexes in cell extracts that contain important signaling molecules, including protein kinases and many glycosyl-phosphatidylinositol–linked membrane proteins capable of transmitting signals ([56], [57], [58] and [59]). These complexes have been termed *lipid rafts* or *large detergent-resistant complexes*. It is postulated that these complexes or rafts reflect the existence of specific membrane microdomains that

have a particular lipid composition, and that these clusters of molecules may be important in transmembrane signaling by proteins in the complex. Rafts or detergent-resistant complexes have been observed in neutrophils (60; Draber P, Draberova L, Skubitz K. *Personal communication*, 2001). There is evidence that in neutrophils proteins may enter these rafts when they are translocated to the cell surface. For example, it appears that CD63 and CD11b/CD18 are not present in detergent-resistant complexes when they are intracellular, but they enter such complexes after translocation to the cell surface ([60]).

Cytoplasmic Lipid Bodies

Cytoplasmic lipid bodies, non–membrane-bound cytoplasmic inclusions, have been described in neutrophils ([54]). In inflammation, the number of cytoplasmic lipid bodies in neutrophils increases ([62]). These lipid bodies may provide nonmembrane stores of esterified arachidonate. In addition, some signaling proteins, including phosphatidylinositide-3-kinase, are localized to these lipid bodies ([63]), although the exact role of these lipid bodies in cell function is unclear ([63], [64]).

Cytosol

Although neutrophil cytoplasm contains many components common to all cells, it is interesting to note that approximately 45% of neutrophil cytosolic protein appears to be attributable to migration inhibitory factor–related proteins (MRPs), MRP-8 and MRP-14 ([65]). MRP-8 and MRP-14 are members of the S100 family of calcium binding proteins and form homo- and heterodimers. MRP-14 has been variously called *p14*, *L1 heavy chain*, and *calgranulin b*, and MRP-8 is also known as *p8*, *L1 light chain, calgranulin a*, and *cystic fibrosis antigen* ([66], [67], [68], [69] and [70]). Although the role of these proteins in neutrophil function is unclear, the quantity of MRP-8 and MRP-14 associated with neutrophil plasma membranes has been reported to increase after stimulation ([65]). MRP-14 can inhibit macrophage activation ([71]). Annexin I or lipocortin I comprises approximately 3% of cytosolic protein ([72]). Annexin I is partially regulated by glucocorticoids and appears to be a mediator of the antiinflammatory effects of glucocorticoids ([72]).

One other notable cytoplasmic constituent is glycogen. Because neutrophils are sometimes required to function in hypoxic conditions, as in an abscess, they are very capable of obtaining energy by glycolysis. The presence of large intracellular glycogen stores gives them the additional ability to function in areas of low extracellular glucose.

Nucleus

In the past, it has been felt that neutrophils, as end-stage cells, undergo little RNA or protein synthesis. More recently, it has been demonstrated that mature neutrophils can synthesize both RNA and protein ([73], [74] and [75]).

MORPHOLOGY OF NEUTROPHILS AND PRECURSORS

Evidence for the replenishment of marrow and blood cells from a stem cell compartment is described in Chapter 8. Neither multipotent hematopoietic stem cells nor more committed progenitors are readily identified morphologically by traditional methods, and reliable EM criteria for distinguishing myeloblasts from monoblasts or lymphoblasts are also lacking ([76], [77], [78], [79] and [80]), although pronormoblasts often can be differentiated by the presence of ferritin on the cell surface or in coated vesicles ([76]). Only the more mature forms of each hematopoietic cell series can be reliably distinguished from one another. In the following pages, the cells identifiable as neutrophils and their precursors are described; other aspects of the eosinophil and basophil systems are considered in Chapter 14 and Chapter 15.

Neutrophilic, eosinophilic, and basophilic granulocytes are thought to follow similar patterns of proliferation, differentiation, maturation, and storage in the bone marrow and delivery to the blood. The details of these processes are best documented for neutrophils. In the first three morphologic stages, the myeloblast, promyelocyte, and myelocyte cells are capable of replication, as shown by their uptake of tritiated thymidine (^{3}H-TdR) and the presence of mitoses; in later stages, cells cannot divide but continue to differentiate. The morphologic boundaries of each cell compartment were defined many years ago and were based on criteria such as cell size, ratio of size of nucleus to cytoplasm, fineness of nuclear chromatin, nuclear shape, the presence or absence of nucleoli, the presence and type of cytoplasmic granules, and the cytoplasmic color of stained cells (Table 10.3).

TABLE 10.3. Morphologic Characteristics of Leukocytes (Wright Stain)

Type of Cell	Size (μm)	Nucleus			
		Position	Shape	Color	Chromatin
Granulocytes					
Myeloblast	10–18	Eccentric or central	Round or oval	Light reddish purple	Very fine meshwork
Promyelocyte	12–20	Eccentric or central	Round or oval	Light reddish purple	Very fine meshwork
Myelocyte	12–18	Eccentric	Oval or slightly indented	Reddish purple	Fine but becomes gradually coarser
Metamyelocyte	10–18	Central or eccentric	Thick horseshoe or indented	Light purplish blue	Basi- and oxychromatin clearly distinguished
Juvenile or band form	10–16	Central or eccentric	Band shape of uniform thickness	Light purplish blue	Basi- and oxychromatin clearly distinguished
Polymorphonuclear neutrophil	10–15	Central or eccentric	2–5 or more distinct lobes	Deep purplish blue	Rather coarse
Polymorphonuclear eosinophil	10–15	Central or eccentric	2–3 lobes	Purplish blue	Coarse
Polymorphonuclear basophil	10–15	Central	2–3 lobes	Purplish blue	Coarse, overlaid with granules
Lymphocytes					
Lymphoblasts	10–18	Eccentric or central	Round or oval	Light reddish purple	Moderately coarse particles, stippled
Mature lymphocyte	7–18	Eccentric	Round or slightly indented	Deep purplish blue	Large masses of moderate or large size, or pyknotic
Monocyte/macrophage					
Promonocyte	12–20	Eccentric or central	Round or oval, moderately indented	Pale bluish violet	Fine reticulated, skeinlike or lacy
Monocyte	12–20	Eccentric or central	Round, oval, notched, or horseshoe	Pale bluish violet	Fine reticulated, skeinlike or lacy
Macrophage	15–80	Central	Elongated, indented, or oval	Pale bluish violet	Spongy

Nucleus			Cytoplasm		
Nuclear Membrane	Nucleoli	Relative Amount	Color	Perinuclear Clear Zone	Granules
Very fine	2–5	Scanty	Blue	None	None
Fine	2–5	Moderate	Blue	None	Primary (azurophilic, eosinophilic, or basophilic)
Indistinct	Rare	Moderate	Bluish pink	None	Primary plus, in neutrophils, secondary or specific granules

Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
Present	None	Plentiful	Pink	None	Neutrophilic, eosinophilic, or basophilic
Present	None	Plentiful	Faint pink	None	Fine, pink, or violet pink
Present	None	Plentiful	Pink	None	Large, coarse, uniform in size, crimson red, numerous
Present	None	Plentiful	Faint pink	None	Large, coarse, uniform, bluish black
Fairly dense	1–2	Scanty	Clear blue	Present	None
Dense	None	Scanty or plentiful	Sky blue, deep blue, or even very pale pink	Present if cytoplasm is dark	None or few azurophilic
Present	1–2	Moderate	Grayish or cloudy blue	None	Few, fine, lilac, or reddish
Present	None	Abundant	Grayish or cloudy blue	None	Abundant, fine, lilac, or reddish blue
Distinct	None	Usually abundant	Opaque sky blue	None	Numerous, moderately coarse azure granules, and vacuoles

Because changes in nuclear chromatin and cell size occur during each cell replication cycle and the formation of granules and other cytoplasmic changes occur gradually during the stages of cell development, morphologic definitions are necessarily arbitrary and do not always conform to significant biochemical or physiologic changes. Classifying a cell in one category or another often is difficult because it is actually in transition between the two. Nevertheless, it is useful to separate the cell lines into morphologic compartments and to define normal limits of cell distribution therein because gross changes from these patterns indicate disease.

DEVELOPMENT OF NEUTROPHILS AND THEIR PRECURSORS

Neutrophil development is summarized in Figure 10.1.

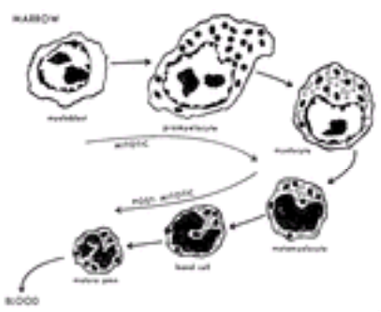

Figure 10.1. Appearance of granules during neutrophil maturation. Myeloblasts are undifferentiated cells with a large oval nucleus, large nucleoli, and cytoplasm lacking granules. They originate from a precursor pool of stem cells. Subsequently, there are two stages—the promyelocyte and the myelocyte—each of which produces a distinct type of secretory granule: azurophils (*dark granules*) are produced only during the promyelocyte stage; specific granules (*light granules*) are produced during the myelocyte stage. The metamyelocyte and band forms are nonproliferating stages that develop into the mature polymorphonuclear neutrophil characterized by a multilobulated nucleus and cytoplasm containing primarily glycogen and granules. Both nonspecific azurophilic granules and specific granules persist throughout these later stages. (Modified from Bainton DF, et al. The development of neutrophilic PMN leukocytes in human bone marrow: origin and content of azurophil and specific granules. J Exp Med 1971;134:907.)

Cell division is limited to myeloblasts, promyelocytes, and myelocytes, with later developmental stages undergoing differentiation but no further cell division. The myeloblast contains few granules and is derived from more primitive cells as described in Chapter 8. As the cell differentiates to the promyelocyte stage, development of primary or azurophil granule formation becomes evident. This granule contains MPO, an enzyme whose activity is a classic marker of myeloid differentiation. Azurophil granule production ceases at the end of the promyelocyte stage, coincident with the loss of peroxidase activity from the rough endoplasmic reticulum. Secondary granule, or specific granule, formation begins as the neutrophil enters the myelocyte stage. The peroxidase-negative specific granules are smaller (approximately 200-nm diameter) than the azurophil granules (approximately 500-nm diameter) and are near the limit of resolution by light microscopy. The specific granules impart a pinkish ground-glass background color to neutrophils in Wright-stained smears. Because azurophil granule formation ceases in the promyelocyte stage and the subsequent myelocyte form is still capable of cell division, the density of azurophil granules is lower in differentiation stages past the promyelocyte. The result is that mature neutrophils contain approximately two specific granules for every azurophil granule. With maturation, the azurophil granules, which generate reddish-purple staining in the promyelocytes, lose this metachromasia as they leave the myelocyte stage. This alteration in staining properties is thought to be caused by an increase in acid mucosubstances, which complex with basic proteins already present in the azurophil granules ([81]). Thus, in the mature neutrophil, the azurophil granules appear as light blue-violet granules on Wright-stained smears. The azurophil granules are readily demonstrated by peroxidase staining with light microscopy.

Data concerning antigenic differences between granulocytes and monocytes and their stages of maturation are developing rapidly. Much of this information has been developed using monoclonal antibodies. Such monoclonal antibodies have been analyzed in a series of international workshops in which antibodies are grouped into clusters of differentiation (CD). Although technically only antibodies are assigned CD specificity, in many publications the use of the CD terminology is often used to describe the antigen as well. It must be kept in mind that, because epitopes recognized by monoclonal antibodies are small, many epitopes may be present on an individual molecule, and antibodies may recognize several closely related epitopes, the use of CD nomenclature to characterize molecules recognized by antibodies of a particular CD may lead to confusion or incorrect conclusions. Some of the CD antigens expressed on neutrophils defined in the Fifth International Workshop and Conference on Human Leukocyte Differentiation Antigens are shown in Table 10.2. Immunogold and enzyme-linked immunologic methods ([82]) permit simultaneous morphologic and immunologic examination of individual cells.

Myeloblast

The word *myeloblast* describes an immature cell, typically found in the bone marrow and not in the blood. This cell can divide and give rise to promyelocytes, which in turn give rise to myelocytes. On the basis of the findings from marrow culture and transplant studies, the neutrophil and macrophage lines share a common stem cell, colony-forming unit granulocyte-monocyte (CFU-GM) ([83], [84], [85] and [86]).

The myeloblast (Fig. 10.2) has a large nucleus, is round or slightly oval, and has a small amount of cytoplasm. In preparations treated with Wright stain (Table 10.3), the nuclear membrane is smooth and even in outline and is exceedingly thin, with no condensation of chromatin near its inner surface, as noted in lymphoblasts. The chromatin shows an even, diffuse distribution with no aggregation into larger masses, although some condensation may be noted about the nucleoli. The chromatin may appear in the form of fine strands, thus giving the nucleus a sievelike appearance; alternatively, it may have the form of fine dustlike granules, producing a uniform stippled effect. Generally, the myeloblast contains two to five pale, sky-blue nucleoli. The cytoplasm is basophilic (blue), and usually, although not invariably, no clear zone is evident about the nucleus. Sometimes, the cytoplasm is reticular, spongy, or foamy. By definition, no granules are present in the cytoplasm. Leukemic myeloblasts that contain no perceptible granules often are identified by special stains that demonstrate the presence of MPO or esterase, thus providing early evidence of differentiation ([87]).

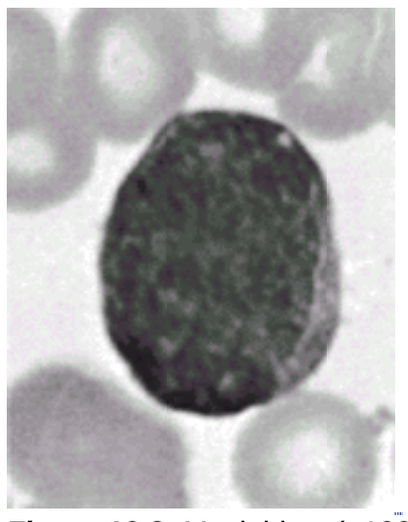

Figure 10.2. Myeloblast (×1000, Wright stain). See Color Plate.

EM reveals similar findings ([88], [89]). The nuclear membrane is thin and indistinct with minimal or no chromatin condensation. The numerous particles of ribonucleoprotein in the cytoplasm produce deep blue basophilia in stained preparations. Mitochondria are abundant but small, and the endoplasmic reticulum is flat and appears infrequently. The Golgi apparatus is indistinct, and no cytoplasmic granules are present. EM studies of myeloblasts show peroxidase activity in the rough endoplasmic reticulum and Golgi.

Some authors classify what may be slightly more mature cells with several rather large, angular, irregular, and dark-staining azurophilic cytoplasmic granules as myeloblasts. A simpler approach, however, is to include such forms in the promyelocyte stage, thus making the separation between the two cell types clear-cut. The EM classification of myeloid cells, which is based primarily on stages of granule formation, also places cells with beginning granule formation in the promyelocyte category ([80], [90]).

In wet films, myeloblasts appear immobile with thin, tenacious borders. The cytoplasm is hazy and usually contains no stainable substance other than mitochondria, which are diffusely scattered throughout the cytoplasm and stain brilliant blue-green with Janus green. The failure of myeloblasts to move in supravital preparations is probably related to the nature of the preparation itself rather than to the cells' immobility. In motion picture studies of hanging-drop preparations (Fig. 10.3), myeloblasts manifest a characteristic snaillike movement ([91], [92]).

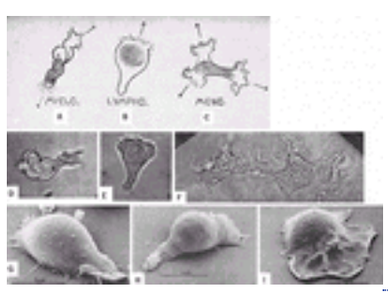

Figure 10.3. Diagrams **(A, B, C)**, photographs **(D, E, F)**, and scanning electron micrographs **(G, H, I)** of living, moving, unstained blasts. The photographs are of cells enlarged (×1000) from negatives of motion picture films of tissue cultures. **A:** Wormlike shape of myeloblast (myelo.) in motion. **B:** Hand-mirror shape of lymphoblast (lympho.) in motion. **C:** Shape of monocyte (mono.) (histiocyte) in motion. **D:** Myeloblast from the blood of a patient with acute myeloblastic leukemia. **E:** Lymphoblast from the blood of a patient with acute lymphoblastic leukemia. **F:** Two monocytes from normal blood. **G:** Human leukemic myeloblast. **H:** Human leukemic lymphoblast. **I:** Human leukemic monoblast. (Photographs used with permission from Rich AR, et al. The differentiation of myeloblasts from lymphoblasts by their manner of locomotion. Bull Johns Hopkins Hosp 1939;65:291; and electron micrographs used with permission from Senda N. The movement of leucocytes. J Clin Electron Microsc 1974;7:3.)

Because they are in the process of growth and division, myeloblasts vary considerably in size from 10 to 20 µm in diameter. Particularly in patients with acute leukemia, the nucleus may show several wide and deep indentations, suggesting lobulation. Such myeloblasts [see Rieder cells ([93])] suggest more rapid maturation on the part of the nucleus than of the cytoplasm (asynchronism of Di Guglielmo). Also in association with leukemia, Auer bodies are evident in the cytoplasm of cells that otherwise look like myeloblasts (Fig. 10.4A, Fig. 10.4B).

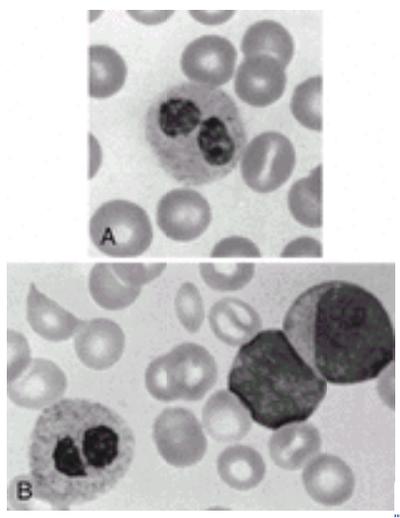

Figure 10.4. A, B: Pseudo–Pelger-Huët cells, the latter from the blood of a patient with acute myeloblastic leukemia (×1000, Wright stain). See Color Plate.

Rieder cells, in which the nucleus is polymorphous or highly differentiated yet the cytoplasm is immature, are not a specific cell type but probably represent asynchrony of nuclear and cytoplasmic differentiation in monocytes, lymphocytes, myeloblasts, leukoblasts, or reticuloendothelial monocytoid cells ([94]).

Differentiation from Lymphoblasts and Other Blasts

With the usual Romanowsky stains and light microscopy, distinguishing among the leukoblasts (myeloblasts, lymphoblasts, and monoblasts) and even pronormoblasts is extremely difficult if cells showing beginning maturational changes (granule formation or hemoglobin synthesis) are excluded from the blast category ([80], [88]). In the lymphoblast, the nuclear membrane is more dense than that of the myeloblast, and the chromatin is more coarse and may show some aggregation. Figure 10.5 shows representative acute lymphoblastic leukemia cells (Fig. 10.5A, Fig. 10.5B) and acute myeloid leukemia cells (Fig. 10.5C, Fig. 10.5D). Lymphoblasts generally have only one or two nucleoli, and their membrane usually is distinct. The mitochondria are short and plumper than those of myeloblasts and often assume a position close to the nucleus. The monoblast is described as showing characteristics similar to those of the mature monocyte, such as fine chromatin, pale nucleus, and ground-glass cytoplasm with a fine, irregular border. In many instances, the identification of blast cells is greatly aided by the company they keep (the more mature and more easily recognized cells about them in sections or in the same blood smear). With the myeloblast, the demonstration of associated promyelocytes, which show azure granulation in Wright or similar stains, is presumptive evidence for this cell's identification. Special stains to detect enzymes, such as peroxidase or esterase, in the blast cytoplasm before lysosomal granules appear may at times be useful in identification, especially in the classification of leukemia

([87], [95]).

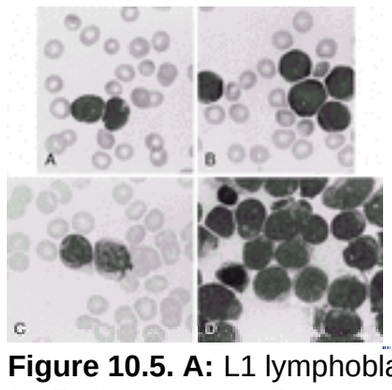

Figure 10.5. A: L1 lymphoblastic leukemia, blood. **B:** L2 lymphoblastic leukemia, blood. **C:** Acute leukemia, M1 blood (×1500). **D:** Acute leukemia, M1 marrow (×1500). See Color Plate.

Neutrophil Promyelocytes and Myelocytes

The developmental stages in the granulocyte series and some of their morphologic variations are shown in Figure 10.1. In the past, the several stages beyond the myeloblast were differentiated primarily on the basis of the number and type of granules. Now, EM histochemical and biochemical findings demonstrate that the azurophilic or primary granules first appear at the promyelocyte stage and can be identified on fine structural study as characteristic of the neutrophil, eosinophil, or basophil series ([80], [88], [90], [96], [97]). They do not transform into specific granules but persist throughout the remainder of the maturation sequence and are seen in all subsequent stages, including the polymorphonuclear forms (Fig. 10.1) ([90], [97], [98]).

The neutrophil promyelocyte is somewhat larger on average than the myeloblast. In both light and EM preparations, it has a round or oval nucleus in which the nuclear chromatin is diffusely distributed, as in the myeloblast; in later stages, slight chromatin condensation is discerned around the nuclear membrane. Nucleoli are present, but as the cell develops, they become less prominent. Compared with the myeloblast, the endoplasmic reticulum in EM preparations is more prominent and takes on a dilated, vesicular appearance. The azurophilic, primary granules appear and accumulate in increasing numbers during this stage, but the specific or secondary granules are not yet present (Fig. 10.6) ([80], [89], [90], [96], [98]). In early promyelocytes, the few granules present may be difficult to see by using light microscopy; they often lie over the nucleus and are evident only on examination at several focal planes.

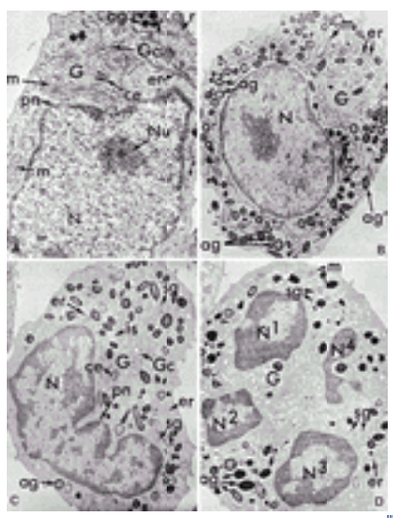

Figure 10.6. Early and late promyelocytes, a myelocyte, and a polymorphonuclear neutrophil (PMN) viewed by electron microscopy. (Courtesy of Bainton D, University of California, San Francisco.) **A:** Early neutrophilic promyelocyte (reacted for peroxidase, 10,500). The nucleus (*N*) with its prominent nucleolus (*Nu*) occupies the bulk of this immature cell. The surrounding cytoplasm contains a few azurophil granules (*ag*), a large Golgi complex (*G*), Golgi cisternae (*Gc*), several mitochondria (*m*), scanty rough endoplasmic reticulum (*er*), and many free polysomes (*r*). A centriole (*ce*) is present in the Golgi region. All of the azurophil granules (*ag*) appear dense because they are strongly reactive for peroxidase. The secretory apparatus [i.e., the perinuclear cisterna (*pn*), rough endoplasmic reticulum (*er*), and Golgi cisternae (*Gc*)] are also reactive although less so than the granules. Specimen was fixed in glutaraldehyde for 16 hours at 4°C, incubated in the peroxidase medium of Graham and Karnovsky for 1 hour at 22°C, postfixed in osmium tetroxide, treated in block with uranyl acetate, dehydrated in ethanol, infiltrated with propylene oxide, and embedded in Araldite. Section stained for 1 minute with lead citrate. **B:** Late neutrophilic promyelocyte (reacted for peroxidase, 7000). This cell is the largest (15 µm) of the neutrophilic series. It has a sizable, slightly indented nucleus (*N*), a prominent Golgi region (*G*), and cytoplasm packed with peroxidase-positive azurophil granules (*ag*). Note the two general shapes of the azurophil granules: spherical (*ag*) and ellipsoid (*ag'*). Most are spherical, with a homogeneous matrix, but a few ellipsoid forms containing crystalloids also are present. Many of the spherical forms (*ag*) have a dense periphery and a lighter core, presumably because of incomplete penetration of substrate into the compact centers of mature granules. Peroxidase reaction product is visible (under higher magnification) in less concentrated form within all compartments of the secretory apparatus (endoplasmic reticulum, perinuclear cisterna, and Golgi cisternae). No reaction product is seen in the cytoplasmic matrix, mitochondria, or nucleus. Specimen was fixed in glutaraldehyde for 10 minutes at 4°C and subsequently processed exactly as was the specimen in **A**. **C:** Neutrophilic myelocyte (reacted for peroxidase, 9000). At this stage, the cell is smaller (10 µm) than the promyelocyte, the nucleus is more indented, and the cytoplasm contains two different types of granules: large, peroxidase-positive azurophils (*ag*) and the generally smaller, specific granules (*sg*), which do not stain for peroxidase. A number of immature specific granules (*is*), which are larger, less compact, and more irregular in contour than mature granules, are seen in the Golgi region (*G*). Note that peroxidase reaction product is present only in azurophil granules and is not seen in the rough endoplasmic reticulum (*er*), perinuclear cisterna (*pn*), and Golgi cisternae (*Gc*), in keeping with the fact that azurophil production has ceased, and only peroxidase-negative specific granules are produced during the myelocyte stage. **D:** Mature PMN (reacted for peroxidase, 10,500). The cytoplasm is filled with granules; the smaller peroxidase-negative specific granules (*sg*) are more numerous, the azurophils (*ag*) having been reduced in number by cell divisions after the promyelocyte stage. Some small, irregularly shaped azurophil granule variants are also present (*unlabeled arrow*). The nucleus is condensed and lobulated (*N1–N4*), the Golgi region (*G*) is small and lacks forming granules, the endoplasmic reticulum (*er*) is scanty, and mitochondria (*m*) are few. Note that the cytoplasm of this cell has a rather ragged, moth-eaten appearance because the glycogen, which is normally present, has been extracted in this preparation by staining in block with uranyl acetate.

Like the myeloblast, the promyelocyte is immobile in flat slide and cover glass preparations; only in the last stage is slight locomotion evident. Even then, the streaming of granules so characteristic of mature granulocytes is lacking ([99]). For this reason, the cytoplasm has been thought to be in the form of a gel; the increased resistance of the cytoplasm of immature myeloid cells to changes in shape has been proposed as a factor in retention of these cells in the bone marrow ([100], [101]). In hanging-drop preparations, however, promyelocytes are actively mobile.

The *neutrophilic myelocyte* may be defined as the stage in which specific (secondary) granules appear in the cytoplasm and the cell consequently can be identified as belonging to the neutrophilic series when stained and observed to have a pinkish ground-glass background color with the light microscope. As mentioned above, earlier identification of a cell that will become neutrophilic can be made by EM examination of the azurophilic, or primary, granules ([88]). The nucleus of the neutrophilic myelocyte usually is eccentric and round or oval; one side may appear flattened. The nuclear chromatin is somewhat coarse, and nucleoli are small and often not visible, although they are seen clearly with the electron microscope ([96]). Primary granules persist in myelocytes, but formation of new primary granules is limited to the promyelocyte, and each succeeding cell division leads to a decrease in their number in the daughter population (Fig. 10.1) ([90], [98], [99]). The secondary granules of the neutrophil series are smaller than the primary granules; in the rabbit, cat, and human, they are formed in increasing numbers on the convex surface and lateral borders of the somewhat less prominent Golgi apparatus ([90], [96], [98]). The amount of granular endoplasmic reticulum is lower in the myelocyte than in

earlier forms, so the cytoplasmic basophilia decreases and disappears. The mitochondria remain small and are few.

Neutrophil Granule Development

Studies in the rabbit, cat, and human suggest that the primary granules are packaged and released from the inner, concave surface of the Golgi apparatus (Fig. 10.7A) —in contrast to the specific or secondary granules of the myelocyte and later granulocyte stages that appear to be formed and released from the outer, convex surface ([90], [96], [97] and [98]). Studies of membranes from rabbit azurophil and specific granules, although demonstrating similar ultrastructure, have shown them to be distinct and different in cholesterol-phospholipid ratios and protein components ([102]). This finding not only appears to confirm different sites of granule formation, but also may provide a basis for differences in interaction with endocytic vacuoles. In the mature neutrophil, a ratio of secondary to primary granules of approximately 9:1 is seen in the rabbit ([103]) and 2 or 3:1 in humans ([90], [104]).

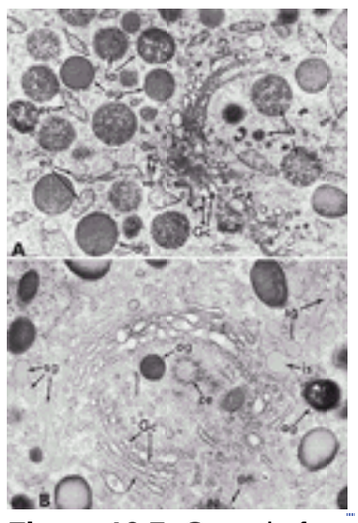

Figure 10.7. Granule formation in neutrophil precursors viewed by electron microscopy. (Courtesy of Bainton D, University of California, San Francisco.) **A:** Golgi region of a neutrophilic promyelocyte reacted for peroxidase (×40,000). At this stage, the peroxidase reaction product is present within the rough endoplasmic reticulum (*er*), the clusters of smooth vesicles (*ve*) at the periphery of the Golgi cisternae (*Gc*), in the Golgi cisternae, and in the immature (*ia*) and mature (*ag*) azurophilic granules. The immature granules are larger and less compact than the uniformly dense mature granules. **B:** Golgi region of a neutrophilic myelocyte reacted for peroxidase (×40,000). Peroxidase-reactive material is seen in the primary or azurophilic granules (*ag*) but not in the specific (secondary) granules (*sg*). At this stage (myelocyte), no peroxidase reaction product is seen in the endoplasmic reticulum, Golgi cisternae (*Gc*), or newly formed, immature specific granules (*is*). The stacked Golgi cisternae are oriented around the centriole (*ce*), and the outer cisternae (*unlabeled arrow*) contain material of intermediate density that is similar to the content of the specific granules, suggesting that the specific granules arise from the convex face of the Golgi complex as in the rabbit. pn, perinuclear cisternae.

The mature primary granules of human neutrophils usually contain central crystalloids when lightly stained ([97]). They apparently bind neutral red dye and thus are seen easily as neutral red bodies in supravital preparations ([105]). These membrane-bound lysosomes contain enzymes and other substances (Table 10.1) ([80], [90], [106], [107]). Acid phosphatase activity varies considerably, as reported in different studies and in different species ([96], [97], [108], [109]). This may be because of inadequacies of the histochemical assays or perhaps is related to species variations ([80]). Peroxidase has been associated with primary granules by histochemical, cytochemical, and biochemical methods and is considered a marker enzyme for primary granules in mammals ([80], [110]). Sulfated mucosubstance presumably accounts for the azurophilic staining of the primary granules; the uptake of radiosulfate by early-stage neutrophils may be the result of incorporation into this substance ([111], [112]).

The secondary granules of the neutrophil were thought in the past to be characterized by their content of alkaline phosphatase and lack of acid phosphatase ([80], [90], [113]); they lack peroxidase and sulfated mucosaccharide or contain a minimal amount ([80]). Alkaline phosphatase was found in blood and exudate neutrophils by many workers, but considerable variation exists between species ([80], [96], [106], [108]) and in certain pathologic states ([114]). Results of histochemical ([80], [90], [108], [115]) and biochemical ([113], [116]) studies suggested that this enzyme was located in the secondary granules of neutrophils in humans and rabbits, perhaps bound to the inner membrane ([104], [117]). However, subsequent studies demonstrated that alkaline phosphatase is localized in a previously unrecognized organelle, the secretory vesicle (Table 10.1) ([118]). Lysozyme is present in human neutrophil secondary granules ([119]), as well as in primary granules; approximately two-thirds of this antibacterial basic protein is in the secondary granule ([86], [116]). The standard marker enzymes for specific granules are lactoferrin ([110]) and B_{12}-binding protein ([120]).

A third type of granule, the tertiary granule, also known as the *gelatinase granule* (Table 10.1) ([97], [121]), is synthesized mainly during the band and segmented neutrophil stages ([97], [122], [123]).

Neutrophil Metamyelocytes

The metamyelocyte is characterized by a clearly indented or horseshoe-shaped nucleus without nucleoli (even by EM examination), and the nuclear chromatin is moderately dense, with considerable clumping evident along the nuclear membrane. The cytoplasm is filled with primary, secondary, and tertiary ([85], [111]) granules, but the secondary granules predominate. The endoplasmic reticulum is sparse, as are polysomes, thus signifying the virtual completion of protein synthesis.

The boundary between the myelocyte and metamyelocyte compartments is best defined physiologically by the fact that myelocytes synthesize DNA, take up ^{3}H-TdR into their nuclear chromatin, divide, and are actively involved in protein synthesis, as evidenced by the presence of nucleoli, abundant endoplasmic reticulum, and polysomes. Before such techniques became available, differentiation between myelocytes and metamyelocytes was defined mainly in terms of nuclear shape. This characteristic now is recognized as a poor criterion because it has been shown in time-lapse microcinematographic studies of human neutrophils that myelocyte nuclei may assume a markedly indented shape and may subsequently revert to an oval configuration and enter mitosis ([88]). Consequently, in classifying cells at this stage, the observer should pay particular attention to evidence in the nucleus and cytoplasm that protein synthesis has decreased or stopped. This determination is made on the basis of the fact that the nuclear chromatin is coarse and clumped and that the cytoplasm is faint pink and is essentially the color of the mature cell in stained preparations. These features also are helpful in differentiating metamyelocytes (Fig. 10.8A, Fig. 10.8B) from monocytes (Fig. 10.8C; see also Fig. 16.3) because in monocytes, nuclear chromatin remains fine, and evidence of protein synthesis persists. Ameboid movement is apparent in metamyelocytes, even in cover glass slide preparations, and it is at this stage that directional migration can regularly be demonstrated ([124]).

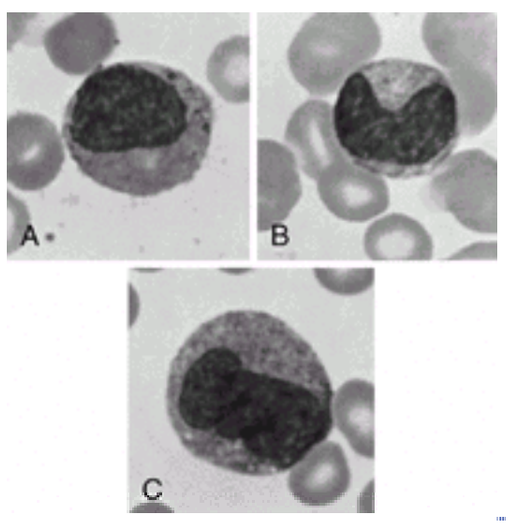

Figure 10.8. A: Late myelocyte or early metamyelocyte. **B:** Metamyelocyte. **C:** Monocyte (×1000, Wright stain). See Color Plate.

Band Neutrophils

The band stage is characterized by further condensation of nuclear chromatin and transformation of nuclear shapes into sausage or band configurations that have approximately uniform diameters throughout their length (Fig. 10.1). Subsequently, one or more constrictions begin to develop and progress until the nucleus is divided into two or more lobes connected by filamentous strands of heterochromatin, the polymorphonuclear stage. A difference of opinion exists concerning the differentiation of the juvenile (band) and polymorphonuclear stages. Some workers require a clearly visible filamentous strand between lobes (Fig. 10.9A, Fig. 10.9B) before classifying a cell as a polymorphonuclear form; anything less clear-cut, whether because of overlapping of nuclear lobes or incomplete constriction, is classified as a band form ([125], [126]). Other investigators regard a constriction greater than one-half or two-thirds of the nuclear breadth as adequate evidence of lobulation and classify such cells as polymorphonuclear ([127], [128]) or use slightly different criteria ([129]). Still others avoid the issue entirely. Because no clear difference has been shown between band and segmented stages other than nuclear shape and a slightly earlier appearance of ^{3}H-TdR in the band forms, the distinction becomes arbitrary. However, a clear and easily recognizable separation is needed if one wishes to count nuclear lobes for diagnostic purposes, as in the early detection of folic acid deficiency ([130]) or in assessing marrow release of young forms into the blood ([131]). For such purposes, we have chosen the clear separation of nuclear lobes as the criterion for inclusion in the polymorphonuclear category ([126]). Cells without this complete formation of distinct lobes (usually connected by a filamentous strand) are classified as band forms.

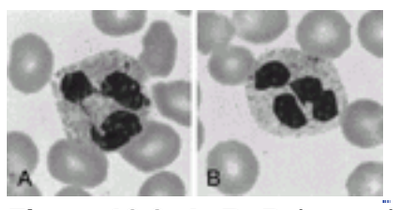

Figure 10.9. A, B: Polymorphonuclear neutrophils. See Color Plate.

Polymorphonuclear Neutrophils

In the polymorphonuclear stage, the nucleus in Wright-stained preparations is a deep, purplish color and contains course, condensed chromatin. The lobes are joined by thin filaments of chromatin, although the filaments may not be easily visible if the lobes are partially superimposed. Careful examination by focusing through several planes may facilitate identification. The cytoplasm is faint pink and contains fine, specific granules that sometimes give only a ground-glass appearance. The azurophilic or primary granules have usually lost their dark-staining characteristics by this stage but can be seen with EM. With this technique, the granules exhibit considerable variation in density, presumably a reflection of variation in enzyme content, and they maintain a minimum distance of 100 nm from the cell membrane ([132]). Large masses of glycogen become evident for the first time in mature neutrophils; this finding may contribute to their capacity for anaerobic metabolism.

The mechanism and purpose of nuclear lobulation are the subject of much speculation. Perhaps it enhances cell deformability and movement through vessel walls and into sites of inflammation, or perhaps nuclear segmentation results from nucleolar emptying and has no function ([133]). In studies of the nuclear protein matrix at different stages of neutrophil maturation, researchers found no significant changes other than collapse and an increased binding of DNA as the cell matures ([134]). Thus, the mechanism and purpose of nuclear segmentation remain unclear.

Arneth believed that nuclear lobulation continues as the cell ages and that granulocytes with three or four lobes are more mature than those with only two ([135]). This statement may be true in the sense that once nuclear constriction begins, the completion of lobulation may continue for some time; during this interval, the cell may be delivered to the blood and thus completion of lobulation may occur in the blood (or in cultures). However, the number of lobes a neutrophil develops appears to be determined in the band stage (or earlier), and the time of appearance of neutrophils in the blood after pulse labeling with ^{3}H-TdR is unrelated to the number of nuclear lobes ([136]).

In wet films, marked ameboid activity of polymorphonuclear neutrophils at physiologic temperatures is characteristic ([137]). In supravitally stained films, the (specific) granules appear yellowish pink and are refractile; in addition, occasional larger, nonrefractile, deep red vacuoles may be seen.

“Senile” polymorphonuclear leukocytes that are no longer motile and fail to take up the neutral red stain have been identified in *in vitro* preparations ([138]). They are seen in small numbers in the blood, in which their survival time is short ([139]).

Neutrophil Heterogeneity

In the past, polymorphonuclear neutrophils were thought to be a homogeneous population of end-stage cells incapable of protein synthesis and of essentially uniform size, granule content, and functional capability. Sabin first suggested potential heterogeneity among neutrophils when she reported that myelocytes were less motile than more mature neutrophils ([138]). A range of rates of motility among neutrophils from a single individual has been observed ([140], [141]), and Harvath and Leonard suggest the existence of two neutrophil populations based on chemotaxis ([142]). Subsequently, several monoclonal antibodies were described that recognize subpopulations of neutrophils, including one that appears to recognize the classic NB1 neutrophil antigen and one that recognizes an activation epitope on CD11/CD18 ([143], [144] and [145]). Another antibody, 31D8, appears to recognize a neutrophil subset that is more responsive to FMLP as determined by chemotaxis and respiratory burst activity ([143]). Neonates have a larger percentage of neutrophils that express low levels of 31D8 antigen ([146]). It has been reported that CR2 (CD21), the receptor for C3d, is present on immature neutrophils but not mature blood neutrophils ([147], [148]). One report found that neutrophils from patients with localized juvenile periodontitis express CD21 (CR2) on their surface, whereas normal neutrophils do not ([149]).

Some studies of these different populations of polymorphonuclear neutrophils have been interpreted as reflecting maturation or environmental influences ([150]), in some cases possibly reflecting intravascular exposure to stimuli ([151], [152]). The clinical significance of neutrophil subpopulations is unclear.

Neutrophil Antigens

Neutrophil antigens have been identified by the use of both monoclonal antibodies and patient sera using classic blood banking techniques. Some neutrophil antigens defined by monoclonal antibodies are shown in Table 10.2. Neutrophil antigens relevant to blood banking and immune neutropenia are discussed more fully in Chapter 26. The proteins bearing two clinically relevant neutrophil antigens (NA and NB) have been identified. The NA1 and NA2 alleles, originally described by Lalezari et al., are present on the glycosyl phosphatidylinositol-linked receptor Fc?RIIIB ([153], [154]). The NB1 antigen, also originally described by Lalezari et al. ([155]), is present on a glycosyl phosphatidylinositol-linked 58- to 64-kd protein of unknown function ([156], [157] and [158]).

EOSINOPHILS

Eosinophils (see Fig. 14.1) exhibit the same maturation phenomena as neutrophils, with the exception that only one type of granule is recognized ([80], [88]). In humans, these homogeneous granules appear to be formed throughout all the subsequent stages of maturation. Their contents are first seen as flocculent material in Golgi saccules, then in small vacuoles that condense to form the large homogeneous, dense granules. Subsequently, crystalloids develop, and the granules acquire an angular shape; the angular configuration predominates in the mature polynuclear forms ([121]). It is unusual to find more than two lobes in mature eosinophils, and the lobes are larger than those seen in neutrophils. The presence of eosinophils with more than two nuclear lobes suggests cell activation, as occurs in parasitic diseases. Eosinophilic granules are considerably larger than neutrophilic granules, appear somewhat refractile under the light microscope, and stain a bright

yellowish red with Wright stain ([99]).

Human eosinophil granules contain eosinophil peroxidase ([103]), a heme protein that is distinct from neutrophil MPO ([159], [160]); several cationic proteins, including eosinophil cationic protein ([161], [162]); and eosinophil major basic protein (MBP). MBP constitutes a major proportion of total granule protein and damages several parasites such as schistosomes, *Trich-inella spiralis* larvae, and trypanosomes as well as many types of mammalian cells, including respiratory epithelium ([162]). The granules also contain eosinophil-derived neurotoxin, the functions of which are less well understood ([162]). In some disease states, evidence for the involvement of eosinophils has been reported by the detection of MBP or erythropoietin at the site of pathology ([163], [164]). Of the mature granulocytes, eosinophils display the most intense staining with peroxidase; the intensity of staining appears to be related to their basic protein content. Eosinophils are discussed more fully in Chapter 14.

BASOPHILS AND MAST CELLS

Basophils play an important role in allergic reactions. They express a unique surface antigen profile ([165]) and contain a variety of vasoactive and immunomodulatory chemicals that are released on activation. Basophils are distinguished by their large, coarse, purplish-black granules (see Fig. 15.2A) that usually fill the cytoplasm and often obscure the nucleus. The granules are water soluble and thus may be dissolved in the process of staining and washing; the cells may then appear vacuolated with only a few or no basophilic granules remaining. On EM examination, a similar variation is noted in the appearance of the basophilic granules, possibly reflecting variable extraction of granule contents during preparative procedures ([80], [166], [167]).

The primary basophil granule is formed during the early cell stages and is bounded by a 75-d membrane that is identical to the cell membrane and to membranes bounding coated vesicles and multivesicular bodies ([168]). These primary granules are peroxidase positive ([102], [104]) and contain large amounts of heparin and histamine ([104], [132], [169]) (sulfated acid mucosubstance), features that are probably responsible for the affinity of the granules for basic dyes. These granules also contain the slow-reacting substance of anaphylaxis, kallikrein, an eosinophil chemotactic factor, and a platelet-activating factor ([170]). Charcot-Leyden crystals are also seen with both phase microscopy and EM; MBP is found in basophils as well as in eosinophils ([84], [168]). A second, smaller granule that is bounded by a 5-nm membrane identical to that in the endoplasmic reticulum, Golgi apparatus, and mitochondria has also been described ([168]). These granules are peroxidase negative ([102]).

Similar but somewhat larger cells found in the tissues are mast cells. Mast cells normally do not circulate in the blood, however, and probably mature locally in the tissues from mitotically active precursors ([171]). Although these cells resemble basophils in their metachromasia, acid nature, and content of histamine and heparin, they contain hydrolytic enzymes, 5-hydroxy-tryptamine ([169]), and serotonin ([104], [172]), which basophils do not. Also, the ultrastructure of their granules is different in humans and guinea pigs ([172]). Basophils are discussed more fully in Chapter 15.

MACROPOLYCYTES

Macropolycyte is the name applied to giant polymorphonuclear neutrophils with a diameter greater than 16 µm and with 6 to 14 nuclear lobes ([173]). Such cells are seen only occasionally in healthy subjects (1.3%), but they are found in approximately 5% of people with infections of various types or with intoxications, usually in association with a neutrophilic leukocytosis and myelocytes in the blood ([173]). Macropolycytes are commonly seen in association with folic acid or vitamin B_{12} deficiency, as well as in patients recovering from the pancytopenia that attends treatment with cytotoxic agents, especially hydroxyurea.

Some authors describe cells with hypersegmented nuclei but of a normal size and call them *polycytes* ([125]) or polylobocytes ([129]); similar cells with complex nuclei but without hypersegmentation are called *propolycytes* ([125]). The latter forms are seen in approximately 10% of patients recovering from leukocytosis with a marked shift to the left and appear in increasing numbers when anticoagulated blood is allowed to stand *in vitro* ([125], [174]).

The mechanism of macropolycyte formation is unknown, but one suggestion is that the skipping of one of the usual cell divisions that occurs during maturation results in a hypersegmented cell ([175]).

GENETIC SEX AS INDICATED BY LEUKOCYTES

Only one X chromosome is essential to the normal activity of a cell; the other in the normal XX female remains unextended and thus is visible as a chromatin body. Sex chromatin (Barr) bodies are present in 80 to 90% of the somatic cells of the normal female subject. The sex chromatin body of the neutrophil of females is a small mass, usually adjacent to the nuclear membrane, that stains deeply with hematoxylin, Feulgen reagent, and thionine and is approximately 0.7 to 1.2 µm in diameter. It takes the form of a drumstick projecting from one of the nuclear lobes of approximately 2 to 3% (extreme range, 1 to 17%) of the segmented neutrophils in the blood ([176]). They are well-defined, solid, round projections of chromatin connected to a lobe by a single, fine chromatin strand (Fig. 10.10). They must be distinguished from small-clubbed or racket-structured, nonspecific nodules that may be smaller or larger as well as irregular in shape or lacking in chromatin, as well as from small (minor) lobes attached to the rest of the nucleus by two strands. Confirmation of the X chromosome in the drumstick has been provided by *in situ hybridization* ([177]). Sessile nodules are equally gender specific but are more difficult to recognize ([166]). Drumsticks are not found in normal male subjects ([178]).

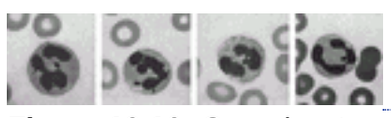

Figure 10.10. Granulocytes and sex chromatin patterns. Two cells on the left show the characteristic drumsticks found in the female subjects. The thin strand of chromatin joining the head to a nuclear lobe can be seen clearly. In the two cells on the right, small clubs, such as may be seen in male subjects, should not be confused with drumsticks (Wright stain, ×1300).

The number of chromatin bodies seen in a cell is one less than the number of X chromosomes present. With the increased numbers of X chromosomes found in certain disorders of human development, the number of Barr bodies and drumsticks increases, and isochromosomes formed by duplication of the long arms of the X chromosome give rise to larger drumsticks than are found in the normal female subject ([179]). Drumsticks or sessile nodules are seen in chromatin-positive male patients with Klinefelter syndrome and are absent in chromatin-negative female patients with Turner syndrome. Eosinophils and probably basophils also have drumsticks. Drumsticks may be difficult to find in the presence of a marked shift to the left. Drumstick counts are reportedly low in the leukocytes of patients with chronic myelocytic leukemia, paralleling the low leukocyte alkaline phosphatase and catalase concentrations ([180]). Double drumsticks ([178]) or a sessile nodule plus a drumstick in the same neutrophil are rare ([181]).

DIFFERENTIATION OF VARIOUS TYPES OF CELLS

Monocytes are described in detail in Chapter 16; lymphocytes and plasma cells are described in . The morphologic characteristics of the various leukocytes are summarized in Table 10.3 and Table 10.4 to facilitate comparison. Nucleated forms of the erythrocyte series are easily distinguished from most of the leukocytes by their lack of cytoplasmic granules. In Romanowsky-stained films, confusion arises only in the immature (blast) stage. Even then, the more granular and clumped nuclear chromatin may help to identify the pronormoblasts. Polychromatophilic normoblasts at times may be confused with plasma cells or lymphocytes. In the polychromatophilic normoblast, however, the nucleus is more centrally placed than that of the plasma cell or lymphocyte, the cytoplasm is blue-pink, and the cell border may be irregular. The mature lymphocyte is characterized by coarse, clumped chromatin in a nucleus that is eccentrically placed in sparse cytoplasm; a few granules also may be present. Deep blue cytoplasm in a cell with an eccentric nucleus containing coarse, clumped chromatin is the hallmark of the plasma cell.

TABLE 10.4. Morphologic Characteristics of Leukocytes (Supravital Stain)

The nucleated cells of the red cell series are nonmotile; in wet films, they have a rounded, distinct border with homogeneous, nongranular yellowish cytoplasm. The nucleus is round or oval and is centrally placed. The chromatin arrangement gives the nucleus a vesicular appearance; in early forms, one or two large nucleoli are present. In supravitally stained preparations, no neutral red bodies are seen, but many coarse, rod-shaped, and coccoid mitochondria are scattered diffusely in the cytoplasm.

Students will find it valuable, when learning to identify the various cells of the blood and bone marrow, to seek each of the morphologic criteria listed in Table 10.3 and Table 10.4 in systematic fashion. By doing so, they will acquire the habit of seeing all that they are viewing and, in time, learn to identify cells because of a number of characteristics perceived unconsciously. The actual identification of cells regarding which some doubt remains can be made only by weighing the evidence for and against each type being considered. One fact to keep in mind is that practically no characteristic of a cell is entirely specific. Thus, a perinuclear clear zone is sometimes seen in cells other than plasma cells, and a rosette of neutral red bodies has been observed in many types of blood and connective tissue cells other than monocytes.

DIFFERENTIAL CELL COUNTING AND NORMAL VALUES FOR LEUKOCYTES

Differential cell counting is the enumeration and classification of the leukocytes seen on the blood smear. The usual procedure is to count at least 100 consecutive leukocytes in an area of good cell distribution. A uniformly thin smear of blood on a cover glass is the best preparation for such examination.

Distributional errors are reduced as more cells are counted. Confidence tables or curves can be used to estimate the probable error of a differential count when various numbers of cells are counted. Table 10.5 shows 95% confidence limits. Clearly, as more cells of a given type are counted and as the total number of cells enumerated increases, the accuracy of the differential count is greater. Thus, if 200 cells are counted, and a frequency of 70% is found for a given cell type, the true value can be expected to lie between 63.5 and 76.5% for 95% of such counts. If a subsequent 200-cell differential count gives a figure of 80% for that cell type, the difference is probably real, whereas if only 100 cells have been counted, the difference would probably not be significant. Even so, when dealing with cells present only in small numbers (such as eosinophils or basophils in the usual smear), the values obtained from the differential count provide only a gross estimate of cell frequency. For more accurate enumeration of these cell types, absolute counting methods have been developed.

TABLE 10.5. 95% Confidence Limits for Differential Leukocyte Counts

Percentage (%) of Given Cell Type	100 Cells Counted	200 Cells Counted
0	0.0–3.0	0.0–1.5
1	0.5–4.7	0.2–3.1
2	0.4–6.3	0.7–4.6
3	0.8–7.7	1.3–5.9
4	1.4–9.1	2.0–7.2
5	2.0–10.5	2.7–8.5
10	4.0–16.0	5.8–14.2
20	12.0–28.0	14.3–25.7
30	20.8–39.2	23.5–36.5
40	30.2–49.8	33.1–46.9
50	40.0–60.0	42.9–57.1
60	50.2–69.8	53.1–66.9
70	60.8–79.2	63.5–76.5
80	72.0–88.0	74.3–85.7
90	84.0–96.0	85.8–94.2

NOTE: For percentages of 5 or less, the limits were derived by assuming a Poisson rather than a binomial distribution. (From Cartwright GE. Diagnostic laboratory hematology. New York: Grune & Stratton, 1968, with permission.)

From the total leukocyte count and the differential count, the absolute concentration of each leukocyte type can be calculated. The accuracy of the result depends on the validity of the total leukocyte count and the differential count. With automatic cell counters, the major component of error now lies in the differential count.

Normal values for absolute leukocyte concentrations obtained by using a Coulter counter and differential counts are shown in Table 10.6. Similar values have been reported with the use of other methods ([182]). Some variation is evident in values obtained in different population groups and appears to depend on age, sex, pregnancy, time of day, activity level, and other factors ([183]). Racial variation has been reported, especially in Ethiopian Jews ([184]) and black Africans, who have significantly lower neutrophil and monocyte counts ([185]). Lower counts are less evident in black Americans ([126]) and in Africans eating a Western diet ([183]).

TABLE 10.6. Normal Blood Leukocyte Concentrations (95% Confidence Limits)

Subjects (Age)	Sex	No.	Time of Day (h)	WBC	Neutrophils	Lymphocytes	Monocytes	Eosinophils	Basophils	WBCCounter	Differential(No. Cells)	Reference

WBC, white blood cell.

NOTE: Values obtained by using a Coulter counter and differential counts of at least 200 cells (except in one African study). Values are expressed in cells 10^9/L.

The absolute leukocyte concentration provides a more accurate picture than the differential count because each leukocyte type is a separate cell system with its own functions, control mechanisms, and responses to disease processes; for example, a patient with chronic lymphocytic leukemia whose total leukocyte count is 100×10^9 cells/L, 7% of which are neutrophils and 93% are lymphocytes, does not have granulocytopenia. With a blood neutrophil concentration of 7.0×10^9 cells/L, the problem is lymphocytosis.

Various systems for differential counting have been used (Fig. 10.11) ([186]). Arneth, for example, painstakingly recorded and tabulated from left to right the number of neutrophilic leukocytes with 1, 2, 3, etc. lobes and made other subdivisions ([135]). The term *shift to the left* is derived from this practice and indicates an increase in the proportion of cells with only one or few lobes, whereas *shift to the right* represents an increase in the proportion of multisegmented forms.

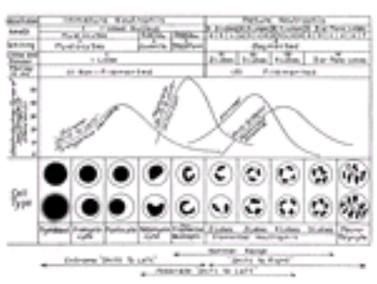

Figure 10.11. Several classifications of neutrophils. Note that all the classifications agree on a common dividing line between mature and immature cells. The Schilling classification further subdivides only the immature cells. The Cooke and Ponder and the Arneth classifications further subdivide only the more mature cells. (From Haden RL. Qualitative changes in neutrophilic leukocytes. Am J Clin Pathol 1935;5:354, with permission.)

From a clinical viewpoint, it is useful to determine whether young forms of neutrophils (band forms and younger) are increased and whether the proportion of multinucleated forms is increased. An increase of younger forms (band cells, metamyelocytes, and myelocytes) (shift to the left) suggests increased release of young neutrophils from the bone marrow, which is seen in association with acute infections ([131]) and inflammation. If a shift to the right is suspected, a neutrophil lobe count may be useful. This process involves counting the total number of nuclear lobes in 100 or 200 neutrophils, calculating the average lobe number/neutrophil, and comparing the results with normal values. The chief difficulty associated with this count is clear definition of what constitutes a separate lobe (see section Band Neutrophils earlier in chapter). If complete separation of nuclear lobes with or without a connecting filament is the definition used, the normal mean neutrophil lobe count is 2.04, with 95% of normal values falling between 1.66 and 2.42. An increase in mean neutrophil lobe count suggests vitamin B_{12} or folic acid deficiency, congenital hypersegmentation of neutrophils, or renal disease ([130]). A ratio of five-lobed to four-lobed polymorphonuclear cells that is greater than 0.17 is said to be associated more regularly with B_{12} deficiency than is an increase in mean nuclear lobe count ([128]).

Alterations in the total number of leukocytes and in their relative proportions are significant as measures of the reactions of the body to noxious agents. The reactions of leukocytes in association with certain diseases are discussed later in this book, as is the presence of abnormal inclusions, such as toxic granulation, Döhle bodies, and various inherited abnormalities in leukocyte morphology.

An additional type of differential cell count in common use is the histochemical, semiquantitative estimate of the leukocyte alkaline phosphatase content of neutrophils (see Chapter 2) ([114]).

NEUTROPHIL KINETICS

The importance of leukocytes in the defense of the organism is well known. Basic to their roles are cell multiplication, maturation, storage, and delivery to the tissues and sites of infection or cell damage. These processes are called *leukocyte kinetics* and are different for each leukocyte type. To simplify the discussion, each type of leukocyte is considered as a separate system, but these systems constantly interact and complement one another in the defense of the body.

Neutrophil Kinetics in the Adult

In Chapter 8, the process of mitotic cell division, the cell generation cycle, and the origin of neutrophils and other cell types from a multipotent hematopoietic stem cell were discussed. The multipotent hematopoietic stem cell is thought to produce a committed stem cell from which the myeloblast and monoblast are formed ([83]); from them, the neutrophilic and monocytic series are derived. The production, kinetics, and lifespan of the neutrophil have been the subject of a number of reviews ([187] , [188] , [189] , [190] , [191] , [192] , [193] , [194] , [195] , [196] , [197] , [198] , [199] , [200] and [201]). A model of these processes in adult humans is shown in Figure 10.12. The neutrophil system appears to be incompletely developed in premature babies and in early neonatal life; this topic is discussed in the section Neutrophil Kinetics in the Fetus and Newborn later in the chapter.

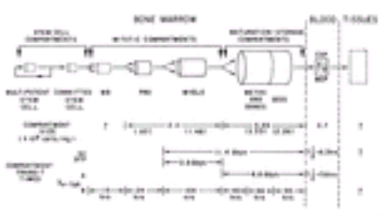

Figure 10.12. Model of the production and kinetics of neutrophils in humans. The marrow ([158]) and blood compartments ([145]) are drawn to show their relative sizes. In the lower one-third of the figure, the compartment transit times as derived from diisopropylfluorophosphate (DF ^{32}P) studies ([136] , [145]) and from tritiated thymidine (^{3}H-TdR) studies ([149] , [158]) are compared. CGP, circulating granulocyte pool; MB, myeloblast; MGP, marginal granulocyte pool; myelo, myelocyte; pro, promyelocyte.

Cytoplasm					
			Mitochondria		
Relative Amount	Color	Neutral Red Vacuoles	Shape or Size	Distribution	Evidence of Phagocytosis
Scanty	Slightly yellow	None	Spherical	Numerous, diffuse	None
Moderate	Gray	Refractile, bright red: A = 3–10; B = 30–100; C = full amount	Spherical	Diffuse	None
Plentiful	Gray	Beginning streaming	Spherical	Few	Slight to moderate for bacteria, debris, etc.
Plentiful		Yellowish-pink, tiny, refractile	Spherical	Few	Slight
Clear ecto- and endoplasm except in basophil	Homogeneous and clear	Bright yellow, large, oval, refractile Deep maroon, nonrefractile, all streaming			Slight
Scanty	Yellow	None	Short plump rods	Numerous, especially close to nucleus	None
More	Grayish yellow	None or many Any distribution	Short plump rods	Numerous, especially at one side	None
Usually plentiful	Gray	None or many Any distribution	Short plump rods	10–20	None
Usually scanty	Colorless	None or many Any distribution	Smaller	0–10	None
Scanty	Slightly yellow and muddy	None, or very fine in centrosphere	Fine spheres or slender rods	Numerous	None
Moderate	Colorless and muddy	Numerous, small	Fine, dustlike	Moderate number	Uncommon
Abundant	Colorless and muddy	Very numerous, vary in size, occasionally rosette	Fine, dustlike	Few	Moderate
Usually abundant	Colorless	Often many, but vary in number, size, and color	Delicate filaments	Few or none	Usually for particles or whole cells

MITOTIC AND MATURATION COMPARTMENTS Neutrophil production in normal adult humans appears to take place only in the bone marrow. The life cycle of the neutrophil can be divided conveniently into bone marrow, blood, and tissue phases. The assumption is that cells move through the system in an orderly manner as if in a pipeline; this view is supported by the progressive movement of isotopic tracers ([112], [198], [202], [203]) and azurophilic granules ([80], [90], [98]) through the system. The myeloblast, promyelocyte, and myelocyte are capable of cell division, as judged by direct observation in cultures ([88]) and by their ability to incorporate ^{3}H-TdR into their nuclear DNA ([204]). These forms, therefore, constitute the mitotic compartment (Fig. 10.12). Simultaneously, they undergo differentiation, as evidenced by the appearance of azurophilic and specific granules in their cytoplasm. The more mature forms of the neutrophil series (metamyelocyte, band, and polymorphonuclear neutrophil) are usually considered incapable of cell division (except perhaps in unusual circumstances) ([205]) and do not incorporate ^{3}H-TdR into their nuclei, but they do exhibit continuing maturational changes and thus constitute the maturation compartment. From the maturation compartment, cells flow into the blood and are distributed in two sites: the circulating blood granulocyte pool (CGP) and the marginal granulocyte pool (MGP). Cells in these two pools are in constant equilibrium. Eventually, the cells move through vessel walls to enter the tissues. The exact nature of the MGP is not clear. In the past, it was felt to represent transient adhesion to and rolling along the surface of endothelial cells, primarily in postcapillary venules. However, subsequent studies of a patient with leukocyte adhesion deficiency-2 (LAD-2) demonstrated the presence of a marginating pool ([206]), although the MGP in this patient with LAD-2 was reduced. Patients with LAD-2 lack the ligands for the selectins CD62P and CD62E and have a marked decrease in neutrophil rolling in postcapillary venules. Normally, the MGP is approximately equal in size to the CGP. Studies of this patient suggested that approximately 20% of neutrophils are in a selectin-independent MGP and approximately 30% are in a selectin-dependent MGP ([206]). Surprisingly, this patient's neutrophils had a shorter than normal half-life in the circulation with an increased turnover rate. The inability of CD18 or CD62L antibodies to shift neutrophils from the MGP to the CGP also suggests that the transient adhesion to endothelial cells manifest as rolling does not account for the MGP ([207], [208]). In this model, cell production can be estimated either by assessing the production rate in the mitotic compartment or by measuring cell flow through subsequent stages, such as the blood. Accuracy of these measurements is facilitated if the system is studied in the steady state when compartment sizes are constant and cell flow reflects net production and destruction ([194]). If one assumes a steady state in a scheme such as that shown in Figure 10.7, the flow of cells out of any pool (K_{out}) is equal to the flow of cells into that pool (K_{in}) plus any cells produced in the pool (K_b); thus,

$$K_{out} = K_{in} + K_b \quad (1)$$

Clearly, in pools other than those in the mitotic compartment, K_b is 0, and measurements of cell flow (K_{in} or K_{out}) equal effective cell production, provided no cell death occurs within the pool.

Production in the Mitotic Compartment Because myeloblasts, promyelocytes, and myelocytes constitute approximately 0.9%, 3.3%, and 12.7% of the marrow cells, respectively, it has been assumed that the system has four or five divisions ([200]). From a review of blood neutrophil radioactivity curves obtained after diisopropylfluorophosphate (DF ^{32}P) injection into humans, investigators raised the possibility of at least three divisions at the myelocyte stage ([200]). Another suggestion generated from marrow differential counts was that only four or five divisions occur in the entire neutrophil proliferation scheme ([200]). This supposition agreed with results from experiments in dogs ([209]) and with data from model studies ([210]). In contrast, studies of myeloid islands in the rat thymus provided evidence for seven divisions during granulocytopoiesis: one in the myeloblast stage, two in the promyelocyte stage, three in the myelocyte stage, and a final one in the metamyelocyte stage ([133], [211]). Calculations made from mitotic index (MI) data ([192], [212], [213] and [214]) provide estimates of cell generation time (t_g) and pool turnover time. *MI* ([212], [215], [216]) is defined as

$$\mathrm{MI} = N_m/N \quad (2)$$

in which MI is the mitotic index for any morphologic cell pool, N_m is the number of mitoses in that pool, and N is the total number of cells in the pool. MI can also be expressed as the ratio of the time spent in mitosis (t_m) to the cell generation time (t_g):

$$\mathrm{MI} = t_m/t_g \quad (3)$$

By combining both definitions,

$$\mathrm{MI} = N_m/N = t_m/t_g \quad (4)$$

By providing determined values for MI and mitotic time (t_m) in the last equation, the generation time (t_g) for a particular cell pool can be approximated. From t_g and the pool size (N), the birth rate, K_b, can be obtained if all cells in the pool are in cycle because each mitosis gives rise to one new cell:

$$K_b = N/t_g \quad (5)$$

In effect, the cell birth rate is equal to the number of mitoses occurring/unit time (t), or

$$K_b = N_m/t \quad (6)$$

Although the concept is simple, several problems arise ([214], [217]). A major problem is that the morphologic boundaries of most cell pools are not clearly delineated in terms of the cell cycle ([217]). For example, to calculate cell production in the myelocyte pool, it must be assumed that all myelocytes are destined to divide; that is, no cells are recognized as myelocytes that are not going to divide again. Because the daughter cells of the last myelocyte mitosis almost certainly do not suddenly become metamyelocytes on completion of division, N in the preceding equation will be erroneously large, and thus estimates of t_g will be erroneously long. If the

fraction of nonmitotic cells in the myelocyte population were known, the calculations could be corrected for this error, as has been attempted ([190]). A second major problem is the fact that values for the MI have varied considerably ([212], [214], [215], [218], [219], [220] and [221]). In addition, a considerable diurnal variation exists in the MI in humans, as well as in animals ([214], [221], [222] and [223]). Finally, to calculate the absolute neutrophil production rate (in cells/unit of time), the size of the marrow mitotic compartment must be known. Methods for measuring the sizes of marrow myeloid pools have been developed ([224], [225], [226] and [227]) (see section Size of Marrow Compartments and Their Morphologic Subdivisions later in chapter), but to date no one has measured these sizes and MI in the same animal at the same time and then calculated neutrophil production rate. Nevertheless, values for the MI for each of the neutrophil precursors capable of mitosis have been determined ([214], [215]), and within the assumptions inherent in such calculations ([217]), neutrophil production has been estimated ([196], [213]). Similar calculations of neutrophil production can be made from ^{3}H-TdR–labeling index data. After flash labeling with ^{3}H-TdR, autoradiographs of the bone marrow are obtained, and the proportion of nucleated cells that have incorporated the label into their nuclei is determined ([191], [197]). This labeling index (LI) represents the ratio of labeled cells, * N, or cells in DNA synthesis (N_s) to total cells (N) of a defined morphologic type:

$$\mathrm{LI} = {}^{*}N/N = N_s/N \quad (7)$$

The LI can also be defined in terms of DNA synthesis time (t_s) and the cell generation time (t_g), because ^{3}H-TdR is taken into the cell only during the period of DNA synthesis; thus,

$$\mathrm{LI} = t_s/t_g \quad (8)$$

By combining both definitions,

$$\mathrm{LI} = N_s/N = t_s/t_g \quad (9)$$

and from determined values for LI and t_g , the generation time and turnover of a given cell population can be estimated. As with MI data, birth rate is a function of the population turnover time, which can be approximated from the generation time or time spent in various phases of the cell cycle:

$$K_b = N/t_g = N_s/t_s \quad (10)$$

Some of the same problems arise with the ^{3}H-TdR LI that are encountered in the use of the MI ([217], [228]). In addition, the use of labeled compounds raises questions of label reuse ([229], [230]) or elution ([228]) and perturbation of the cell population by the compound ([188], [209], [231], [232] and [233]) or by its radioactivity ([228], [234], [235]). The LI reported for humans is myeloblast, 0.85; promyelocyte, 0.65; and myelocyte, 0.33 ([191]). Somewhat different values have been reported in dogs ([197]) and rats ([215]). By using the LI for humans and a value for t_s of 5 hours (based on studies in dogs) and by determining relative compartment sizes for each cell type from the bone marrow differential count, the relative birth rates (K_b) of cells have been calculated ([190], [215]). Some authors have found good agreement between neutrophil production as calculated from the MI and the LI ([215]), but considerable discrepancy has been reported by other authors ([190]). This difference may result from the fact that the MI values obtained were low, the studies were done in different subjects at different times, and too small a value for t_s was used in the calculations. The turnover time of a labeled compartment and neutrophil production rate also may be estimated by measuring the grain count halving time ([202]). The generation time is derived only if each cell in a given class divides and if no label feeds into the compartment from a labeled precursor class or as a result of label reuse ([236]). If any of these criteria are not met, the half-time for grain count decrease is longer than the true value, and the estimate of generation time is only a maximal value. Additional disadvantages of this method are that at least several bone marrow samples distributed throughout several half-times are needed and that grain counting is extraordinarily tedious and subject to considerable error. Nevertheless, estimates of compartment turnover time have been made with this method by using ^{3}H-TdR ([202]) and radiosulfate ([121]). After flash labeling with ^{3}H-TdR, the cohort of cells labeled during DNA synthesis may be followed as it subsequently enters mitosis, and the time course of labeled mitoses can be recorded ([236], [237]). Theoretically, such curves should permit measurement of the post-DNA synthesis gap (G2), mitotic time (t_m), DNA synthesis time (t_s), cell generation time (t_g), and pre-DNA synthesis gap (G1) (see Chapter 8 and Fig. 10.13). In actual practice, biologic variation rounds off the percentage of labeled mitosis curves, and rapid damping of the waves of cells passing through mitosis (Fig. 10.13) renders such measurements less precise than ideal. However, estimates of myeloid DNA synthesis time obtained with this method are approximately 11 to 13 hours in humans ([236], [237]) and are in good agreement with estimates made in gastrointestinal mucosal cells. From the level of the damped plateau reached after a few hours, the ratio of t_s to t_g can be obtained (Fig. 10.8), and the generation time can then be calculated. If the generation time and compartment transit time are presumed to be the same or if the proportion of cells in a compartment that is actively proliferating is known, the neutrophil production rate can be calculated.

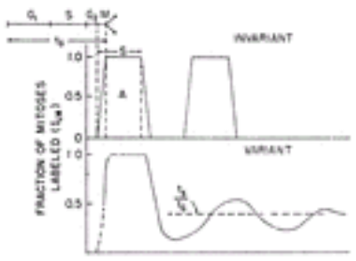

Figure 10.13. The percentage of labeled mitoses in the course of cell generation. At top of the diagram is the theoretical configuration that would be seen if cells flowed through the proliferation cycle with no variation. The effects of moderate variation in time spent in the several cycle phases on the percent labeled mitosis curve are shown at the bottom. G_1 is the pre-DNA synthesis resting phase (*gap*), *S* is the DNA synthetic period, G_2 is the post-DNA synthesis gap, and *M* is mitosis. t_S is the time spent in *S*, and t_G is the duration of the entire generative cycle. Natl Cancer Inst Monogr 30, Human Tumor Cell Kinetics 1969;51, with permission.)

Neutrophil Production as Measured by Cell Flow in Other Compartments Another method for approximating neutrophil production involves following the appearance of ^{3}H-TdR–labeled cells in the metamyelocyte compartment. Because metamyelocytes do not divide or take up ^{3}H-TdR, the appearance of labeled cells in this compartment should reflect the flow of cells into it from the myelocyte compartment; in the steady state, this influx of cells should also reflect the turnover of the metamyelocyte compartment and thus cell production. Approximately 3 hours pass after the injection of ^{3}H-TdR before label appears in metamyelocytes both in dogs ([197]) and in humans ([236]); this time interval is the minimum time for myelocytes taking up the label to pass through G2 and mitosis and become metamyelocytes. After this lag, the rate of labeled cell inflow into the metamyelocyte compartment is approximately 3 to 5%/hour in both species. In the dog, cell inflow into the metamyelocyte compartment measured in this fashion is less than 50% of that calculated from LI data ([197]), suggesting the existence of a major component of ineffective granulocytopoiesis, a myelocyte sink, in the normal animal. However, similar calculations in humans do not confirm the findings of such studies ([190]). The resolution of this enigma requires the simultaneous measurement of cell production by using several methods in the same animal at the same time. In a similar manner, the marrow production of neutrophils has been estimated from the size of the postmitotic maturation–storage compartment and the compartment turnover time ([224], [225], [238]). The compartment size is calculated from the marrow neutrophil to erythroid (NE) ratio (determined in marrow sections) and the mean normal marrow normoblast pool size (calculated by multiplying the ratio of subjects' erythroid iron turnover value over the mean normal value for this determination by the mean normal erythroblast population) ([225]). The compartment transit time is estimated by injecting ^{3}H-TdR and noting the time required for labeled neutrophils to appear in the blood. By this method, marrow neutrophil production in humans has been calculated to be 0.85 × 10^{9} cells/kg/day in the normal steady state. Neutrophil production also can be approximated by measuring the flow of cells through the blood, the blood granulocyte turnover rate (GTR). DF ^{32}P binds irreversibly with a number of esterase enzymes and has been shown to label neutrophils primarily ([239], [240]). By means of this agent, a subject's own cells can be labeled, and the total blood granulocyte pool (TBGP) and the rate of disappearance of labeled neutrophils from the blood can be determined ([195]). Similar measurements can be made by transfusing ^{3}H-TdR–labeled cells from a suitable donor ([225]). Because neutrophils leave the blood in a random manner (exponential disappearance curve), the GTR is calculated as follows from the TBGP and the $t_{1/2}$:

$$\mathrm{GTR} = 0.693/t_{1/2}\ \mathrm{TBGP} \quad (11)$$

in which 0.693 is the natural logarithm of 2 and *t*1/2 is the blood neutrophil half-disappearance time. An important point to keep in mind is that all of these methods assume that the system is in a steady state during the entire course of the measurements. If neutrophil death in the marrow is not significant, the blood GTR equals total neutrophil production. If neutrophil death in the bone marrow is significant, the blood GTR measures effective neutrophil production, and the difference between this determination and total neutrophil production is ineffective granulocytopoiesis. Measurements of neutrophil production by compartment turnover methods have given values ranging from 62 to 400 × 10^{7} neutrophils/kg/day in humans (Table 10.7) ([225], [241]) and 150 to 560 × 10^{7} neutrophils/kg/day in dogs ([225], [238], [242]).

TABLE 10.7. Blood Neutrophil Kinetic Parameters in Normal Humans

Parameter [a]	Diisopropylfluoro- phosphate (Autologous) [a]		Tritiated Thymidine (Isologous) [b]	
	Mean	95% Limits	Mean	Range
Total blood granulocyte pool (cells × 10^7/kg)	61	27–128	40	30–48
Circulating blood granulocyte pool (cells × 10^7/kg)	31	13–49	22	15–29
Marginated granulocyte pool (cells × 10^7/kg)	29	8–115	17	12–26
Half-life (hr)	6.3	4–10	7.6	5.4–9.6
Granulocyte turnover rate (cells × 10^7/kg/day)	160	62–400	87	69–100

[a] Based on data from 71 normal subjects whose own blood was labeled *in vitro* and reinfused; see reference 241.

[b] Based on five subjects transfused with cells labeled in compatible donors; see Dancey JT, et al. Neutrophil kinetics in man. J Clin Invest 1976;58:705 .

Of the methods for assessing neutrophil production just described, only the measurement of blood neutrophil turnover rate with DF ^{32}P or ^{3}H-TdR can be performed easily enough to be of use in studying groups of patients in a clinical setting, and even this is possible in only a few research centers.

Size of Marrow Compartments and Their Morphologic Subdivisions In all of the procedures described, with the exception of DF ^{32}P and ^{3}H-TdR blood kinetic measurements, the number of marrow myeloid cells under study must be known to calculate neutrophil production. In the absence of such data, only calculations of relative cell production are possible (190). Direct measurements of the volume and cellularity of the marrow (isolation of skeleton and cell counting or bone biopsy and radioactivity measurement) have been made in dogs (225), rats (243), mice (244), and guinea pigs (245, 246). Several methods for estimating marrow myeloid mass have been devised, but probably the best data are those derived by using marrow NE ratios and measurement of marrow erythroblast mass by the iron dilution technique as originally suggested by Suit (247). In early studies by Donohue et al. (226, 227), marrow erythroblast radioactivity and NE ratios were counted in marrow suspension smears. Corrections were made for incomplete iron localization in the erythron and for an estimated 30% cell destruction that occurred in preparing the marrow suspensions. In later studies by Harker (248), the NE ratios and radioactivity measurements were made on marrow sections in the hope of avoiding the problem of possible cell destruction. Values for marrow erythroid mass were somewhat lower than those reported by Donohue et al. (226, 227), but they agreed with results obtained when no correction for cell destruction was made. By using marrow sections and the ^{59}Fe isotope dilution technique, investigators have directly determined the marrow myeloid mass in the dog (225). In humans, however, direct measurement of the marrow normoblast mass has not been feasible in normal subjects, so marrow normoblast mass was estimated from erythron iron turnover values (225, 249). The mean values obtained in 13 normal subjects are presented in Figure 10.12.

Transit Time through the Nondividing Maturation Pool After injection of a pulse label of ^{3}H-TdR or radiophosphate, a delay of several days occurs before labeled segmented neutrophils appear in the blood. This interval represents the minimum time from DNA synthesis in the last myelocyte generative cycle until the cell has matured into a segmented neutrophil (or band form) and is released into the blood. In patients in a normal steady state, this minimum transit time or emergence time was between 96 and 144 hours (250, 251); in patients with infection, it was as short as 48 hours. Emergence time in dogs is 2 to 3 days (252); in the rat, it is 36 to 42 hours (136). The mean value for myelocyte-to-blood transit time after DNA labeling (defined as the time from ^{3}H-TdR or radiophosphate injection to the peak of the blood granulocyte radioactivity curve) was 6 to 9 days in hematologically normal convalescent patients and 7.2 days in eight normal subjects (224). In contrast, studies in which DF ^{32}P was injected intravenously into normal volunteers (prisoners) led to the conclusion that the mean promyelocyte to blood transit time was 11.4 days, with a myelocyte compartment transit time of 2.9 days (189, 200)—in other words, an 8.5-day myelocyte-to-blood transit time. Results of studies involving the simultaneous use of ^{3}H-TdR and DF ^{32}P in the same subjects suggest that the discrepancies reflect differences between normal ambulatory subjects and hematologically normal convalescent patients (253). In dogs, the average myelocyte-to-blood transit time was 5 days, as measured with both ^{3}H-TdR and DF ^{32}P (253).

Neutrophil Release from Marrow into Blood After ^{3}H-TdR injection and at the time of first seeing label in band and segmented neutrophils in the bone marrow, some labeled cells are also seen in the blood (190). Authors have suggested that the release of band or segmented neutrophils from the marrow does not follow a strict pipeline or first-in-first-out sequence (190, 250). However, it is not clear whether these observations reflected variance around a mean transit time (200, 252, 254) or random release of mature neutrophils from the marrow (250). Findings in dogs strongly favor the mean transit time concept rather than random release (252). In fact, because the ratio of band to segmented cells is much higher in marrow than in blood, selective release of segmented cells must occur. The mechanisms controlling the release of marrow cells into the blood are only partially understood. Endotoxin disturbs the relationship between marrow sinus endothelial cells and the adventitial (reticular) cells (255, 256), which usually cover approximately 60% of the extraluminal sinusoid surface (257). Endotoxin induces a reticular cell movement away from the endothelium, thus facilitating hematopoietic cell contact with and migration between the endothelial cells (255, 257). Findings of *in vitro* studies of factors influencing marrow granulocyte migration through membranes demonstrate that pore diameter, morphologic age of cells, and the presence of a chemical attractant may be important in marrow cell release (258). Thus, immature granulocytes (myeloblasts and promyelocytes) could not penetrate membranes with pores smaller than 8 µm and were not responsive to chemoattractants. Mature granulocytes (band and segmented) could penetrate membranes with pores as small as 1 µm, and egress was accelerated by increasing pore size and by use of a chemoattractant. Myelocytes and metamyelocytes exhibited intermediate activity. Integrins and immunoglobulin (Ig) superfamily members appear to play an important role in the organization of the bone marrow microenvironment, and stem cell factor alters the avidity of a $_4$ß $_1$ and a $_5$ß $_1$ integrins on hematopoietic cell lines for their ligands (259). A number of mediators of neutrophil release from the bone marrow have been identified, including tumor necrosis factor (TNF)-a, TNF-ß, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-8, and C5a (206, 260, 261).

KINETICS IN THE BLOOD

Diisopropylfluorophosphate Studies With the development of the DF ^{32}P labeling technique, in which neutrophils are labeled *in vitro* with DF ^{32}P and returned to the donor, two pools of neutrophils in the blood have been demonstrated: a CGP and an MGP (195, 262, 263). In normal humans, neutrophils in these two pools are in constant equilibrium, and the pools are of approximately equal size (Table 10.7). The CGP is calculated from the blood leukocyte count and the blood volume. The TBGP is measured by the dilution of DF ^{32}P-labeled neutrophils after their reinjection (262). MGP is the difference between the TBGP and the CGP. Brief exercise or epinephrine injection increases the size of the CGP by approximately 50%, but the TBGP is unchanged; the neutrophilia produced reflects a demargination of cells that lasts only a few minutes (262). The location of at least some of the marginated cells is thought to be along the walls of small blood vessels, primarily postcapillary venules, in many body tissues where neutrophils roll along the vessel wall in loose contact with the endothelial cell surface (264). The distribution of cells in the CGP and MGP can be altered by other means. For example, transient neutropenia was noted 90 minutes after endotoxin injection, but the TBGP was not significantly increased; thus, essentially a shift from CGP to MGP occurred. At the end of 5 hours, the TBGP increased significantly as a result of an outpouring of cells from the bone marrow, and the CGP and MGP were of approximately equal size (263). The administration of steroids also produced an increase in the size of the TBGP, in part for the same reason but also because of decreased outflow into the tissues (265). A rapid transient increase in the marginating pool has been observed during hemodialysis when cuprophane membranes are used (266, 267). Activation of the complement system by contact with the dialyzer membrane was found to produce inflammatory mediators (C5a being a major contributor) that stimulated an increase in neutrophil margination manifest both by an increase in rolling along small vessel endothelium and by the formation of homotypic aggregates of neutrophils with sludging in small vessels (268, 269, 270, 271 and 272). This neutrophil margination was transient, being maximal by approximately 15 minutes and resolving by 1 hour of dialysis. After the return of DF ^{32}P-labeled neutrophils to their donor, the disappearance of labeled cells from the blood follows a single exponential curve with a half-disappearance time (t_2) of approximately 7 hours in most normal subjects (189, 195, 224, 273, 274, 275 and 276). This finding implies that neutrophils are destroyed or leave the blood randomly rather than according to their age (senescence), as is the case for erythrocytes and platelets (195). Support for this theory is found in the fact that ^{3}H-TdR–labeled neutrophils appear in the blood and in saliva almost simultaneously (139). Studies involving leukapheresis (277) and other experiments (278) reveal that neutrophils that have crossed the endothelial barrier between blood and tissues probably do not reenter the circulation, at least not in significant numbers. The number of neutrophils that pass through the blood each day has been estimated at 62 to 400 × 10^7 cells/kg/day (Table 10.7) —that is, the GTR. In 1964, it was proposed that neutrophils became senescent and developed pyknotic nuclear lobes over time, this process truncating the exponential curve of disappearance of DF ^{32}P-labeled neutrophils (139). Although this concept seemed plausible, no truncation of DF ^{32}P curves has been noted. Similar blood kinetic results have been obtained with the use of ^{3}H-TdR and autora-diographic techniques (279). More recent studies describe the occurrence of apoptosis in neutrophils, and this may be an important mechanism of senescence in some circumstances. Neutrophils undergo apoptosis in tissue culture (approximately 50% of cells in 24 hours); this process is accompanied by a fall in intracellular pH (280, 281 and 282). The addition of G-CSF, GM-CSF, or IL-1 delays but does not prevent this process (280, 283). Macrophages phagocytose senescent (apoptotic) neutrophils (as observed more than a

century ago), and this is probably one fate of the short-lived blood neutrophil ([281], [282], [284], [285], [286] and [287]). Interestingly, glucocorticoids inhibit neutrophil apoptosis ([288]), but they induce it in susceptible lymphocytes. Fas (CD95) is expressed on neutrophils and is capable of inducing apoptosis as it does in other susceptible cells ([288], [289]).

^{51}Cr Studies Leukocytes can also be labeled *in vitro* with radiochromate ($^{51}CrO_4$) and then returned to the body ([290], [291] and [292]). Unlike DF ^{32}P, which labels primarily granulocytes ([238], [240], [279]), leukocyte types other than neutrophils are heavily labeled by the ^{51}Cr technique ([251], [290], [292], [293], [294] and [295]). Under some circumstances (such as chronic lymphocytic leukemia), this capacity is advantageous because the distribution and turnover of leukocytes other than neutrophils can be followed ([290], [293], [295], [296]). In addition, ^{51}Cr is a ?-emitting isotope, so external counting techniques may detect sites of sequestration or destruction. Results of studies of the infusion of autologous, radiochromate-labeled leukocytes into hematologically normal subjects are more variable than those using the DF ^{32}P method. The proportion of cells recovered in the blood is sometimes less than that associated with DF ^{32}P-labeled neutrophils ([292]), and complex curves are often noted ([296]). Furthermore, there is no general agreement on $t_{1/2}$ values; most investigators report values similar to those obtained with DF ^{32}P ([251], [290], [292], [293], [297]), but values two to three times longer have been described ([298], [299]). Several factors may explain these differences, but a major one is probably ^{51}Cr labels of multiple cell populations. No significant organ sequestration of labeled leukocytes has been detected in normal subjects ([292]).

^{111}In Studies After the evaluation of a variety of other radioactive agents for labeling leukocytes *in vitro* ([300]), ^{111}In chelated with 8-hydroxyquinoline (oxine) was thought to be promising for evaluating the *in vivo* localization of abscesses. The ^{111}In-oxine complex labels blood cells effectively (95% uptake in 15 minutes) and exhibits minimal elution (<1% released in 2 hours) ([301]). This label is nonspecific, however, in that it binds to all cell types; thus, cell separation and purification are necessary before labeling occurs ([302]). Nevertheless, the labeling of autologous neutrophils (or leukocyte suspensions containing mostly neutrophils) and their reinjection is sometimes useful in localizing abscesses in humans although much of the radioactivity initially localizes in the lungs and subsequently appears in the spleen and liver ([301]).

MIGRATION INTO TISSUES AND SITES OF DESTRUCTION At a local site of tissue damage or infection, adherence of neutrophils to the endothelial cells of the vessel wall and their subsequent migration into the tissues can be seen within minutes. After initial adherence, neutrophils project microscopically visible pseudopods between the endothelial cells and force a passage between them ([303], [304]). This directed movement, chemotaxis, is induced by the binding of a variety of chemoattractant molecules, such as n-formyl peptides (e.g., FMLP), a cleavage product of the fifth component of complement (C5a), leukotriene B_4, and platelet-activating factor, to specific membrane receptors. Further migration is then delayed by the basement membrane and periendothelial cells, and the neutrophils may move parallel to, but beneath, the endothelium until a passage into the surrounding connective tissue is found. Once neutrophils leave the blood, they do not return in significant numbers ([278], [305]). The sites into which neutrophils normally disappear are poorly understood. Labeled blood neutrophils are found in saliva ([136]), but loss into saliva may reflect subclinical infections, because few if any cells are found in the salivary ducts ([306]); the rate at which granulocytes enter the oral cavity has been correlated with the degree of gingivitis ([307]). Some cells do penetrate the oral mucosa in healthy subjects, presumably as a result of diapedesis ([306]). Loss of leukocytes in the urine also has been demonstrated in normal subjects ([308]). Leukocyte loss increases significantly in association with pyelonephritis ([309]). In addition, arteriovenous catheterization studies in dogs ([310]) and in humans ([311]) provide evidence that suggests leukocytes also are removed in the lungs, liver, and spleen. Significant numbers may be lost into the gastrointestinal tract. No quantitative data concerning the rate of loss through these various organs are available. Interestingly, bone marrow and blood leukocyte counts were essentially the same in germ-free and normal mice, suggesting that loss via subclinical infections at the various body surfaces is not a major factor in neutrophil turnover ([312], [313]). Neutrophil function can also be regulated by the neuroendocrine axis. For example, glucocorticoids can regulate neutrophil function, at least partly through annexin I or lipocortin I ([72]). Opiates have been reported to alter many immune functions, including neutrophil functions such as the respiratory burst, in many species ([314]). MRP-14, a prominent component of neutrophils, can inhibit the function of activated macrophages and, possibly by this mechanism, can decrease inflammatory pain ([71]).

Neutrophil Kinetics in the Fetus and Newborn

The fetus exists in a sterile environment and, unlike the adult, does not require antibacterial defenses. However, if the systems ensuring adequate neutrophil production, storage, delivery to tissues, phagocytosis, and bacterial killing are not intact at birth, extrauterine existence is seriously compromised. Maturation of the neutrophil system is not complete in the midgestation fetus, and even the neonate delivered at term has a neutrophil system that in several respects is quantitatively and qualitatively immature. Therefore, one might anticipate that newborns, particularly those delivered prematurely, would be at significant risk for serious bacterial infection, and many studies reveal a strong correlation between prematurity and serious bacterial infection ([315], [316], [317], [318], [319] and [320]). Of all the risk factors for bacterial infection analyzed by the national collaborative study on neonatal infection, premature birth showed the strongest correlation ([321]). In addition, babies delivered at term experience a higher incidence of bacterial infection than do older children or adults ([321], [322]) and, when infected, often display poor resolution of infection despite antibiotic therapy.

Newborn infants, particularly if premature, display many other deficiencies in antibacterial defense, such as low levels of IgG antibody, complement components, fibronectin, and lymphokine production ([323]), but only maturational differences in neutrophil kinetics are discussed here. Realizing that the neutrophil system of a fetus is underdeveloped and in a state of maturation, a difference in neutrophil pool sizes and kinetics in this group from those in adults can be expected. In addition, rapid somatic growth in the fetus and newborn places added demands, unique to the neonate, on neutrophil production ([324]); cells are needed not only for ongoing antibacterial defense, but also for a rapidly increasing body mass.

The investigation of neutrophil kinetics during fetal and neonatal life in humans has been hampered by lack of applicability of the techniques used for such studies in adults. For instance, DF ^{32}P and ^{3}H-TdR blood kinetic measurements have not been used in babies because of the radiation exposure and the large volumes of blood required. Nevertheless, the results of clinical studies, coupled with extensive investigation in developing animals, illustrate several developmental differences.

GRANULOCYTE-MACROPHAGE PROGENITOR CELLS CFU-GM has been isolated from the livers of aborted 5- to 6-week human fetuses ([325]). Although early fetal CFU-GM produced colonies of mature neutrophils *in vitro*, no mature neutrophils could be located in the liver, marrow, or blood of the 5- to 6-week fetuses from which this CFU-GM was obtained ([325]). In separate studies, mature neutrophils were not detected in the human fetus until approximately 15 to 16 weeks' gestation ([326], [327], [328] and [329]), at least 10 weeks after the first appearance of CFU-GM. The concentration of CFU-GM in blood is higher in the fetus and newborn than in adults: 20 to 300 CFU-GM/ml of venous blood in adults and approximately 2000 CFU-GM/ml in term neonates ([330], [331], [332], [333], [334], [335], [336] and [337]). Even higher venous blood concentrations are found in prematurely delivered infants ([331], [336]), with the highest values noted in the most premature subjects ([331]). The total body pool of CFU-GM has not been measured in human neonates; in rats, the number of CFU-GM/g body weight is small in the fetus ($0.5 \pm 0.1 \times 10^3$ CFU-GM/g) and increases to adult levels ($10.5 \pm 0.2 \times 10^3$/g) at 4 weeks of age ([338]). The proliferative rate of CFU-GM during human gestation, assessed by thymidine suicide, is rapid in the second trimester ([331]). Whereas CFU-GM in venous blood of adults displays a thymidine suicide rate ranging from 0 to 7% ([331], [339], [340] and [341]), rates of 45% have been observed in term neonates, and rates of 75% were noted in prematurely born neonates ([331]). Similarly, in fetal and neonatal rats ([246]) and mice ([340]), the CFU-GM proliferative rate is high and appears to be near maximal at birth, even in the noninfected state ([342], [343]). Unlike in adult animals, no further increase in CFU-GM number ([344]) or CFU-GM proliferative rate ([342]) has been detected during either sublethal or lethal bacterial infection, suggesting that the system operates at capacity. It has been suggested that the inability to accelerate neutrophil production above baseline might handicap neonates by limiting their neutrophil supply during a bacterial infection.

NEUTROPHIL STORAGE POOL In the fetus, as in the adult, mature neutrophils are stored within the skeletal marrow but also are found in the liver and spleen ([344]). Techniques that measure the size of the neutrophil storage pool, such as radioisotopic iron labeling, with subsequent liver, spleen, and bone marrow biopsy, have not been applied to normal human neonates. In fetal and neonatal animals, however, the liver and spleen, as well as the long bones, can be removed, and the neutrophils within them can be quantified. Such studies in rats show that the neutrophil storage pool is considerably smaller in prematurely delivered animals (1.0 to 1.3×10^6 cells/g body weight) than in term (1.3 to 2.5×10^6 cells/g) and adult animals (4.5 to 7.5×10^6/g) ([345]). During experimental bacterial sepsis in neonatal dogs and rats, the size of the neutrophil storage pool has been serially quantified. Experiments performed with a variety of organisms ([344], [346], [347], [348], [349], [350], [351] and [352]) demonstrate depletion of the storage pool and neutropenia before death. Similarly, in human neonates with lethal bacterial sepsis, neutropenia and depletion of the neutrophil storage pool, as assessed by bone marrow aspiration, are nearly universal findings ([328], [350], [353], [354]).

RELEASE FROM STORAGE POOL INTO BLOOD Within 1 hour of inoculating adult animals with as few as 10^4 type III group B streptococci/g body weight, an accelerated rate of egress of neutrophils from the storage pool into the blood can be detected ([353]). In contrast, when newborn animals were given the same or a larger inoculum of 10^6 organisms/g, a 4-hour delay occurred before this acceleration in neutrophil storage pool release was observed ([353]). This delay between bacterial inoculation and accelerated release of marrow neutrophils may be a significant physiologic disadvantage, which permits prolific initial bacterial multiplication. In other studies, this delay in release of marrow neutrophils was completely corrected by prior administration of type-specific antibody directed toward the organism

with which the animal was inoculated ([347], [353]). Some cytokines (e.g., IL-8) readily induce neutrophil release from the marrow ([261]).

ALTERATIONS IN MIGRATION INTO TISSUES AND SITES OF DESTRUCTION IN NEONATES In many studies, investigators have demonstrated defective neutrophil chemotaxis in neonates. In early investigations, Eitzman and Smith, using the Rebuck skin window technique, demonstrated that a preponderance of eosinophils, not neutrophils, were attracted to the abraded dermis of neonates ([355]). Using the same technique, Bullock et al. demonstrated that neutrophils in neonates remained at the site of abrasion longer than they did in adults ([356]). Using the Boyden chamber method, neutrophils from newborns were found to be less responsive than adult neutrophils in chemotaxis ([357]). In addition, factors generated from neonatal serum attracted neutrophils less well than did factors from adult serum. Diminished chemotaxis of cord blood neutrophils was also demonstrated, with reduction to approximately 80% of levels observed with adult neutrophils ([358], [359] and [360]). Using a different *in vitro* technique for quantification of neutrophil movement (agarose gel), newborn neutrophil chemotaxis was found to be reduced to approximately 20 to 27% of that seen with adult neutrophils ([361]). In prematurely delivered neonates, neutrophil chemotaxis was even more defective ([362]), and the defect persists for a considerable time after birth. A further reduction in chemotaxis of neutrophils from ill neonates compared to healthy neonates ([363]) and decreased chemotaxis in preterm neonates with bacterial sepsis followed by a return to normal neonatal values (approximately 20% of adult values) with resolution of the infection ([364]) have been reported. Neutrophil migration has also been investigated *in vivo* in neonatal and adult animals. One technique involved surgical implantation of a sterile polyvinyl sponge disc, standardized for body weight, into rats. At various intervals, the sponges were removed, and neutrophils that had migrated into them were chemically quantified. Concurrent with sponge removal, the long bones (and the liver and spleen in neonates) were also removed, and the size of the total body neutrophil storage pool was determined ([349]). By comparison with control animals, only approximately 9% of the neutrophils released from the storage pool in neonates could be accounted for in the sponge. In contrast, approximately 60% of the neutrophils released from the marrow in adults migrated to the sponge, indicating more efficient neutrophil migration in the adult. Another study found that the accumulation of neutrophils in the peritoneal cavity of rats after intraperitoneal inoculation with various chemical attractants was impaired in neonates ([365]). The mechanism responsible for deficient neutrophil chemotaxis in neonates is only partly known. By measuring the pressure needed to aspirate neutrophils into a glass pipette, Miller determined that the neonatal neutrophil was more rigid and less deformable than the adult neutrophil, a characteristic that may be detrimental to movement of neutrophils through tissues ([366]). In addition, neutrophils from human neonates irreversibly aggregated after activation by C5a, whereas after exposure to the same stimulus, adult neutrophils aggregated and then deaggregated ([268], [269], [270] and [271], [367]). Irreversible aggregation of neonatal neutrophils has also been seen in response to activation by FMLP ([368]). If irreversible neutrophil aggregation occurs *in vivo* in neonates, then independent neutrophil mobility would probably be impaired. A deficiency in the redistribution of cell-surface adhesion sites, factors related to impaired migration, and impairment of neutrophil adhesiveness has also been reported ([369], [370]) and would impair neutrophil function *in vivo*. Response to complement-derived peptides was also impaired, as shown in the response of cord blood neutrophils to endotoxin-activated serum ([371]). Concanavalin A capping ([372]), phytohemagglutinin-induced aggregation ([373]), and C5a-induced chemotaxis ([358]), as well as FMLP-induced membrane potential change ([374]), are reduced in the neonatal neutrophil. No difference in calcium uptake in FMLP-stimulated neutrophils was noted between human neonates and adults, but reduction in calcium uptake by resting neonatal neutrophils was significant ([375]). Diminished orientation of neonatal neutrophils after exposure to a chemotactic gradient was noted, and a significant decrease both in the number of microtubules/cell and in the assembly of microtubules was observed ([376]).

PHYSIOLOGIC VARIATION IN LEUKOCYTES

The changes in blood leukocyte concentration that occur with growth and development are shown in Appendix A. By the age of 4 to 8 years, the blood differential cell count approaches that seen in the adult. Normal values are presented in Table 10.6. Metamyelocytes or myelocytes are not often seen on routine examination of the blood smear, but a few such cells can be found in normal blood after a careful search or, more readily, by examination of buffy coat smears (3.6/3000 granulocytes) ([377]); atypical mononuclear forms and megakaryocyte fragments containing nuclei are also seen in such smears. Whether a significant difference exists in leukocyte concentration between the sexes or with advancing years has been debated ([183], [378], [379], [380] and [381]). Racial variations were reported in black Africans, with lower neutrophil and monocyte counts and higher eosinophil counts; however, these differences were not as evident in Africans eating a Western diet ([382]) or in black Americans ([126], [183]).

Although leukocyte concentration is maintained within definite limits in normal humans, fluctuations occur during a single day and from day to day. The suggestion that a characteristic hourly rhythm occurs has not been confirmed ([383], [384]), nor has the occurrence of a digestive leukocytosis been established ([385]). Light influences the diurnal variation of neutrophils ([223], [386]). Under conditions of complete physical and mental relaxation, a basal level of 5.0 to 7.0 × 10^9 cells/L is usual ([387]). Ordinary activity may be associated with a moderate increase, and a somewhat higher level is common in the afternoon. Under all these conditions, however, the leukocyte count tends to remain within the normal range (Table 10.6).

Conclusive demonstration of the effects of climate or season on the leukocyte count is lacking. Some authors claim that meteorologically conditioned fluctuations occur ([388]). Heat and intense solar radiation are said to cause leukocytosis ([389]). Prolonged residence in Antarctica has been reported to cause leukopenia ([390]). Artificially induced heat, sunlight, and ultraviolet light have been reported to cause lymphocytosis ([391]). Acute anoxia, both anoxic and anemic, causes neutrophilic leukocytosis ([392]) that does not develop in adrenodemedullated rats. In the first few days after a subject has arrived at a high altitude, some leukocytosis, accompanied by lymphopenia and eosinopenia, has been observed, followed quickly by slight lymphocytosis and eosinophilia ([393]).

Marked leukocytosis regularly occurs with strenuous exercise. Counts as high as 22.0 × 10^9/L have been recorded for a runner after an 11-second 100-yard dash, and 35.0 × 10^9/L has been recorded after completing a quarter-mile run in less than 1 minute ([387]). The increment of cells usually consists of segmented neutrophils, but lymphocytosis may be prominent as well. Such leukocytosis recedes to normal in less than 1 hour and, in the neutrophil series, is related to a shift of cells from marginal sites (MGP) to the circulation (CGP) (shift leukocytosis) ([261], [262]). This leukocytosis occurs in the absence of the spleen, suggesting that the spleen is not a major site of cell margination. Leukocyte counts higher than 20.0 × 10^9/L, mainly neutrophils, are regularly recorded for runners who complete a 26-mile marathon in 2.5 to 3.0 hours; whether a shift to the left, suggesting mobilization of marrow neutrophils, occurs in this circumstance is debatable ([387]). Postmarathon leukocytosis subsides slowly over a number of hours and probably reflects a redistribution of granulocytes in the blood, combined with mobilization of cells from the marrow with an increase in TBGP size. The magnitude of the leukocytosis associated with exercise appears to depend primarily on the intensity of the activity rather than on its duration ([394]).

Convulsive seizures, from whatever cause, are associated with an increase in leukocyte count similar to that noted after violent exercise. Electrically induced convulsions are followed by a reduction in eosinophil and lymphocyte number and an increase in neutrophil number, findings consistent with the effects of adrenal hormone secretion ([395]). Epinephrine injection produces leukocytosis, the nature and duration of which appear to vary with the mode of administration. Intramuscular injection causes leukocytosis in two phases ([396], [397]). In the first phase, maximal at 17 minutes, the number of neutrophils, lymphocytes, and eosinophils increases and then returns toward normal over several hours. This pattern almost certainly represents a shift leukocytosis. In the second phase, the number of neutrophils rises again at approximately 4 hours, although the number of lymphocytes and eosinophils remains at or below preinjection levels ([397]); this phase may reflect an adrenal steroid effect and consists of an absolute neutrophilia. After intravenous injection, leukocytosis peaking at 5 to 10 minutes and of total duration of less than 20 minutes occurs and has been shown to be purely shift neutrophilia ([262], [263]). The leukocytosis that follows subcutaneous injection is more variable.

During attacks of paroxysmal tachycardia, leukocytosis with cell counts of 13.0 to 22.0 × 10^9 cells/L has been reported ([398]). Pain, nausea and vomiting, and anxiety may cause leukocytosis in the absence of infection ([399]). The paucity of band forms and metamyelocytes indicates that the neutrophilia results from the redistribution of the cells between the marginal and circulating pools.

Ether anesthesia produces leukocytosis, probably because of emotional and reflex reactions, as well as struggling during the stage of excitement. Narcosis with barbital compounds usually reduces the leukocyte count.

During the ovulatory period, eosinopenia and a slight rise in the number of leukocytes, as well as increased 17-hydroxycorticosteroid levels, have been reported ([400], [401]). Slight leukocytosis occurs during pregnancy, and neutrophilia increases as term approaches ([183], [400]). The onset of labor is accompanied by neutrophilic leukocytosis, which sometimes is pronounced (34.0 × 10^9/L). This state continues for 1 day after delivery, receding to normal only after 4 or 5 days. These changes are accompanied by a reduction in the number of circulating eosinophils ([400]).

Many of the physiologic variations in leukocytes that have been described can be explained as manifestations of stimulation of the adrenal cortex. The administration of cortisone or hydrocortisone results in increased blood levels of 17-hydroxycortico-steroids that peak at 1 hour ([402]) and are associated with neutrophilia ([403]).

Eosinopenia and lymphopenia follow, become maximal at 4 to 8 hours, and are proportional to the quantity of hormone administered. Neutrophilia was less constant than the depression in eosinophil and lymphocyte numbers but is probably caused by a steroid hormone–mediated decreased efflux of neutrophils from the blood and increased cell release from the bone marrow ([263], [265]). Just as exercise can raise the circulating neutrophil count, intense exercise has also been reported to induce neutrophil activation as determined by studies of cell-surface antigen expression ([404]). In contrast, ultraviolet B radiation, at doses similar to those naturally received, inhibits neutrophil phagocytosis and adhesion, although the practical significance of these observations is unknown ([405]).

CONTROL MECHANISMS REGULATING NEUTROPHIL PRODUCTION

It is evident that a true steady state of neutrophil kinetics exists only for brief periods. Shifts of cells between marginal and circulating sites may occur without changes in blood neutrophil turnover ([263]), but any change in TBGP size must result from changes in cell inflow or egress. Studies involving leukapheresis have shown that a normal animal replenishes a depleted TBGP by mobilizing cells from the marrow granulocyte reserves ([277]). This increase in neutrophil concentration and TBGP size, like that seen with most bacterial infections or after endotoxin or steroid administration, must be triggered by some signal, and some means of stimulating cell production must be available to replenish depleted marrow reserves, whatever the etiology.

The nature of these control mechanisms is not well understood, but several control points exist: recruitment of pluripotent stem cells and their induction into committed stem cells, stimulation (and perhaps inhibition) of stem cell and myeloid proliferative cell growth, and selective release of cells from the marrow.

Blood cell development is discussed in Chapter 3 and is only briefly discussed here. Pluripotent stem cells are mostly in the G_0 state and must be induced into actively proliferating committed stem cells. Hematopoietic cell growth and development are usually restricted to certain tissues (e.g., bone marrow in adult humans and bone marrow and spleen in mice). Because cell differentiation is influenced by organ microenvironment (e.g., erythropoiesis is favored in mouse spleen, but granulocytopoiesis is favored in the bone marrow), the concept of local control of pluripotent stem cell induction was developed (the hematopoietic microenvironment) ([406]). The importance of the hematopoietic microenvironment is exemplified by the anemia of Steel mice, which results from a defective hematopoietic microenvironment ([406]). The defect in Steel mice involves the granulocyte system as well as erythropoiesis ([407]) and results from a diminished ability of organ stroma in the bone marrow and spleen to induce committed stem cells from pluripotent stem cells ([408]). The demonstration that the Steel (Sl) gene product, deficient in Steel mice, is a growth factor (stem cell factor or stem cell colony-stimulating factor) that binds to a receptor coded by the c-kit protooncogene (or white-spotting locus, W) has provided a molecular basis for understanding the hematopoietic abnormalities in mice with genetic defects in the Steel or W genes ([259], [409]).

As judged from suspension cultures, at least three cell types (giant fat cells, epithelial cells, and phagocytic mononuclear cells) provide the microenvironment needed for multipotent stem cell proliferation ([410]). Presumably, these stromal cells produce sufficient concentrations of hematopoietic cell growth factors locally to promote multipotent stem cell proliferation and renewal when required ([411]).

Growth Factors

A large number of growth factors or colony-stimulating factors have been identified that regulate neutrophil production in the bone marrow, as described in Chapter 8. Two of these, G-CSF and GM-CSF, are in clinical use. Exogenous administration of G-CSF expands the granulocyte mitotic pool and also decreases the bone marrow transit time of the postmitotic cells without changing the blood neutrophil half-life ([412]). These factors not only speed the recovery of neutrophil counts after chemotherapy and may decrease associated infectious complications ([413], [414], [415], [416] and [417]), but also have effects on mature neutrophils. For example, G-CSF transiently increases CD11b expression ([414], [418], [419]) and the affinity of CD62L (L-selectin) for its ligand and then causes CD62L surface expression to decrease ([420]). G-CSF also primes neutrophils for subsequent superoxide production in response to FMLP ([421], [422], [423] and [424]). Intravenous administration of G-CSF can result in an immediate transient neutropenia ([425], [426]) similar to the transient increase in the MGP seen with hemodialysis. Evidence of neutrophil degranulation *in vivo* after administration of G-CSF has also been observed ([427]). A number of other cytokines among this rapidly expanding class can also activate or prime neutrophils, including TNF-a, IL-6, IL-1, and IL-8 ([428], [429], [430] and [431]).

In addition to locally produced stimulators of colony-forming unit stem cell proliferation ([432]), inhibitors of proliferation have also been described ([433], [434]). Lactoferrin (present in the secondary or specific neutrophil granule) binds to specific receptors on some monocyte-macrophages and suppresses release of GM-CSF (and other cytokines), thus inhibiting colony formation. Transferrin also exhibits colony suppression activity, possibly through inhibition of GM-CSF production by T lymphocytes ([435]). Soluble forms of receptors for cytokines may also regulate the response of bone marrow progenitors to growth factors ([436]). Neural mechanisms controlling hematopoietic cell proliferation and release have also been suggested ([437]).

Another control point in the system is the selective release of granulocytes from the marrow. In studies of perfused rat hind limbs, the release of neutrophils from the marrow into the blood ([438]) increased with an increase in perfusion flow rate or with a low leukocyte content of the perfusate ([439]). Serum or plasma from animals or humans made neutropenic by endotoxin, vinblastine, or nitrogen mustard also induced neutrophilia ([440], [441], [442] and [443]). The activity was present during the period of neutropenia and rising neutrophil concentration—but not before or after this period. This neutrophilia-inducing activity was qualitatively dissimilar from that noted after endotoxin, epinephrine, or cortisone administration and acted by causing release of marrow cells. The results of these studies suggest that an endogenously produced humoral factor causes neutrophil release from the marrow ([440]). Several factors that stimulate neutrophil release from the bone marrow have been identified, including G-CSF, GM-CSF, C5a, TNF-a, TNF-ß, IL-8, and, possibly, a cleavage product of the third component of complement ([206], [260], [261]). Studies in rabbits have found that IL-8 induces neutrophil release from the bone marrow without altering the transit time through the mitotic and postmitotic marrow pools ([261]).

Thus, evidence exists that several factors, including cell nuclear and cytoplasmic deformability, cell motility, affinity of cell adhesion molecules for ligands, blood flow, and others are important in the control of marrow cell release ([100], [101], [259], [444]).

NEUTROPHIL FUNCTION

The major role of neutrophils is to protect the host against infectious agents. To accomplish this task, the neutrophil must first sense infection, migrate to the site of the infecting organism, and then destroy the infectious agents. Although neutrophils can sense a stimulus in suspension, they can migrate only when in contact with a surface. Thus, although in some cases neutrophils in blood may respond to a stimulus by adhering to other blood cells or foreign bodies, such as bacteria or biomaterials, the usual first step of the neutrophil after sensing an inflammatory stimulus is to adhere more strongly to the blood vessel wall. Usually, this occurs in a postcapillary venule. After adhesion to the endothelial surface, the neutrophil follows a gradient of chemotactic factors to the site of infection and interacts with the organisms. Finally, when the neutrophil reaches the infecting organism, it must destroy it. This destruction is generally accomplished by phagocytosis of the agent followed by release of granules into the phagocytic vesicle, followed by killing of the organism. The mechanisms by which these phenomena occur are very complex and not completely understood.

History

Antibacterial properties of blood were described by British surgeon John Hunter at the time of the Revolutionary War. He observed that the cellular (buffy coat) component of blood could retard the “spoilage” of blood ([445]); we now would recognize these effects as reflecting the antibacterial properties of leukocytes.

The response to infection by neutrophils in the microvasculature was elegantly described in *An American Text-Book of Surgery* in 1892 ([287]). This description remains instructive and is summarized here. At one time, the inflammatory cells at sites of infection were thought to be caused by proliferation of connective tissue cells. After the observations of von Recklinghausen that many of these cells were capable of locomotion (and called “ameboid cells from their resemblance to the amoeba”), Cohnheim identified the cells in the inflamed tissue as leukocytes ([287]). Microscopic examination of a frog's mesentery or tongue reveals “an arteriole with its rapid pulsating current of blood, and near by a small vein in which the blood flows with a more steady movement. The red blood-corpuscles occupy the axis of the blood vessel, and the few white corpuscles which are seen float in the more sluggish stream of plasma which occupies the borders of the lumen and appears as a transparent layer” (Fig. 10.14). Induction of inflammation by the application of a caustic agent leads to hyperemia. “The rapidity of the flow of blood is greatly increased and a greater amount of blood is observed in the part. The lumen of the artery is greater than before, and the column of red corpuscles is much broader, and fills a comparatively greater portion of the lumen of the vessel. The capillaries are now quite distinctly seen, and are crowded with blood-corpuscles” (Fig. 10.15).

This is followed by

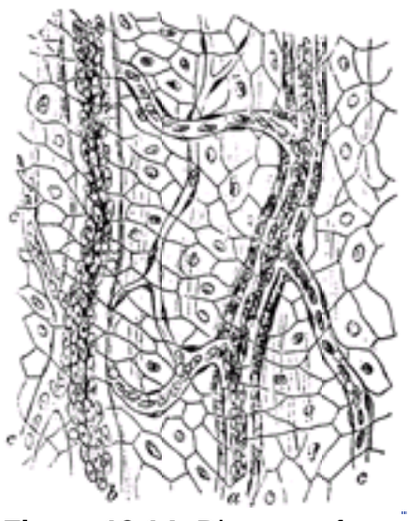

Figure 10.14. Diagram of normal vessels and bloodstream: *a*, artery; *b*, vein; *c*, capillary. (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;11, with permission.)

Figure 10.15. Diagram of dilation of the vessels in inflammation: *a*, artery; *b*, vein; *c*, capillary. (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;11, with permission.)

> a slowing of the current which soon becomes much more sluggish than in the normal state. This is first noticed in the capillaries, and soon after in the veins. The pulsation, however, continues in the arteries. As a result of this diminution of speed the column of blood-corpuscles becomes broader and almost completely fills the interior of the vessels. In the veins a great accumulation of white corpuscles takes place on the interior of the walls…. Finally, they are so greatly increased in numbers that the entire wall of the vessel appears to be lined with leukocytes. The white corpuscles also accumulate in the capillaries, but not to the same extent [Fig. 10.16].

Figure 10.16. Diagram of stasis of blood and diapedesis of white corpuscles in inflammation: *a*, artery; *b*, vein; *c*, capillary. (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;12, with permission.)

The margination of the neutrophils is shown schematically in Figure 10.17 (platelets or “blood-plaques” are also shown).

Figure 10.17. Blood plaques or third corpuscles (*a*). Red corpuscles (*b*). White corpuscles (*c*). (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;14, with permission.)

> Beginning concurrently with the slowing of the blood-stream, is the emigration of the leukocytes from the interior of the veins. Many leukocytes, by a change of shape, send out little prolongations of protoplasm into the substance of the wall, and slight protuberances are soon seen projecting from its outer surface. These enlarge, and we now see the corpuscles presenting an hour-glass appearance. The portions within the vessel soon follow those without, and the leukocytes escape from all contact with the vessel. Many corpuscles appear to follow one another through the same point in the wall [Fig. 10.18].

Figure 10.18. Diagram of stages of the migration of a single white blood corpuscle through the wall of a vein in 1 hour and 50 minutes (mesentery of the frog). (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;13, with permission.)

Migration takes place to a limited extent also from the capillary vessels, but no such process is observed in the walls of the arteries. These same actions of neutrophils, as well as the formation of neutrophil-neutrophil aggregates with infections in rabbit ear veins, were videotaped by W.B. Wood in the 1960s. Using fluorescein-labeled neutrophils, Hammerschmidt et al. later demonstrated that injection of C5a reproduced the increase in neutrophil margination and aggregation in rat mesentery ([446]).

Early views of neutrophil function at the site of inflammation included a role in the repair process. Later, their ability to phagocytose was recognized. Metchnikoff advanced the theory known as

> phagocytosis, according to which the cells of the inflamed part, in virtue of their ability to consume foreign substances, attack and destroy the invading bacteria [Fig. 10.19]. These cells are called phagocytes (from the Greek, “to eat,” and, “a cell”). If they are able to destroy the bacteria, the system is protected from the invading organisms. The leukocytes are called micro-phagocytes (or microphages), and the larger cells developed from the fixed connective-tissue cells are called the macro-phagocytes (or macrophages) ([287]).

Figure 10.19. Diagram of a phagocyte destroying a bacillus. The cell is shown at three different times (**a**, **b**, and **c**). (From Keen WW, White JW, eds. An American textbook of surgery. Philadelphia: WB Saunders, 1892;16, with permission.)

Chemotactic Factor Receptors

The initial step of the neutrophil response to infection is the detection of an appropriate signal. The interaction of bacteria with blood components, especially antibodies and the complement system, results in the formation of various chemotactic factors. In some instances, the bacteria directly release factors that are chemotactic for neutrophils. The interaction of bacteria or their products with other host cells may also result in the formation of chemotactic factors. Neutrophils express specific receptors on their cell surface for a variety of chemotactic factors. These receptors include those for n-formylated peptides such as n-formyl-met-leu-phe (FMLP), C5a, leukotriene B_4, and platelet-activating factor. The initial activation of the neutrophil occurs when soluble chemotactic factors bind their receptors on the neutrophil surface. As with the interaction of antibodies and haptens, the association kinetics for these receptor–ligand interactions are very rapid. Typically, sufficient receptor–ligand interaction to initiate neutrophil activation occurs within seconds.

Signaling

Many chemotactic factor receptors appear to be coupled to guanine nucleotide binding proteins (G proteins) ([447]). The role of G proteins in neutrophil signal transduction is supported by a variety of studies, including classic studies using pertussis toxin. Pertussis toxin adenosine diphosphate–ribosylates certain G proteins and inhibits neutrophil responses to a number of stimuli, including FMLP. In contrast, some neutrophil responses, such as phorbol ester–induced secretion, are not inhibited by pertussis toxin. Although the details of signal transduction in neutrophils are not fully elucidated, it appears that the G proteins associated with chemotactic factor receptors are important in receptor activation of phospholipase C, which then hydrolyzes phosphatidylinositol bisphosphate (PIP_2), resulting in the generation of two second messengers, IP_3 and 1,2-diacylglycerol (DAG). Experiments suggest that IP_3 binds to specific receptors on intracellular membranes, resulting in the release of calcium from intracellular stores, which is rapidly augmented by an influx of extracellular calcium. Thus, shortly after receptor-ligand binding, the intracellular calcium rapidly rises from a resting level of approximately 0.1 mmol/L to approximately 1 mmol/L ([448] , [449] and [450]). This rise in free intracellular calcium is transient and returns to baseline in approximately 1 to 3 minutes.

It appears that the initial rise in intracellular calcium caused by the release of intracellular calcium stores plays a critical part in the alteration of membrane permeability to allow the influx of extracellular calcium. To some extent, variations in intracellular calcium transients may direct specific cellular functions in that specific granule release occurs at very low (submicromolar) free calcium concentrations, whereas in studies using permeabilized cells, higher (micromolar) levels of free calcium result in release of both specific and azurophil granules ([451] , [452] and [453]). Although the extracellular calcium influx is critical for many neutrophil responses, it is not critical for all, as degranulation is not blocked by ethyleneglycol-bis (2 aminoethyl) tetraacetic acid ([454]). Similarly, phagocytosis of particles opsonized with C3bi can occur without apparent intracellular calcium transients ([455]).

Protein phosphorylation is an important mechanism of the regulation of protein function, and a number of studies suggest its role in neutrophil activation. phorbol myristate acetate, which activates a number of neutrophil functions, binds to PKC and results in its activation. Although Phorbol myristate acetate is not present in neutrophils, DAG, released when phospholipase C hydrolyses PIP_2, also binds and activates PKC. Because calcium is also important in PKC activation and IP_3 increases intracellular calcium, the hydrolysis of PIP_2 to IP_3 and DAG may contribute to PKC activation via both DAG and IP_3. Interestingly, the specific granules have been reported to contain a PKC inhibitor, thus providing a possible mechanism to down-regulate PKC-mediated responses ([456]).

Although this model explains many observations, it has become clear that signal transduction in neutrophils is far more complex, with both Ca^{2+} and PKC-independent pathways. Tyrosine phosphorylation has been found to play a critical role in signal transduction from various chemotactic factor receptors. Multiple neutrophil proteins are rapidly phosphorylated after activation, including Src family kinases; the Lyn kinase is activated by chemotaxins, increasing its ability to phosphorylate substrates. Serine and threonine kinases also appear to be involved in signaling, and some are activated by FMLP. In addition, phosphatidylinositol 3-kinase is also activated by chemotaxins. Phosphatidylinositol 3-kinase catalyzes the phosphorylation of PIP_2 to PIP_3. Phosphatidylinositol 3-kinase binds some phosphotyrosine residues via the SH2 domain on one of its subunits. Protein tyrosine phosphatases probably also play a role, as the transmembrane protein phosphatase CD45 has been implicated as a regulator of neutrophil function ([44] , [457]). Chemotactic factors have also been found to activate phospholipase A_2 and phospholipase D. Finally, the importance of low-molecular-weight guanosine triphosphatases (LMWG) is also being recognized. Knowledge of signal transduction is rapidly advancing, and the reader is referred to a review ([461] , [462]) and the current literature.

Physiologic soluble inhibitors of neutrophil function have also been identified. For example, adenosine inhibits neutrophil aggregation, adhesion, chemotaxis, and superoxide production ([463] , [464] and [465]). These inhibitory effects appear to act via A_2 receptors without preventing the transient rise in intracellular Ca^{2+} ([463] , [464] and [465]).

NEUTROPHIL PRIMING “Priming” is an important concept in neutrophil signaling. Signaling in neutrophils is complex and can be initiated by many different stimuli that may share downstream signaling pathways. When neutrophils are exposed to an appropriate low level of a stimulus, they can be primed to a condition such that they display a much more prominent response to a second stimulus than they would if they had not been primed ([466]). This phenomenon may be involved in many physiologic neutrophil responses *in vivo*.

Neutrophil-Endothelial Adhesion

Both neutrophils and endothelial cells express a variety of adhesive molecules on their cell surface, and the expression and activity of these molecules in many cases can be regulated by stimuli. Some of the known adhesion molecules of neutrophils and endothelial cells are indicated in Table 10.8. Approximately one-half of the circulating neutrophils exist in the so-called marginating pool, some of which can be seen microscopically to be rolling along the endothelial surface, maintaining a loose intermittent contact with endothelial cells. The importance of hemodynamic forces, especially of red cells, in directing leukocytes outward from the flowing blood toward the endothelium was described many years ago and subsequently confirmed ([287], [467], [468] and [469]). An attractive model of neutrophil-endothelial cell adhesion has been proposed by Springer, which accounts well for the known data ([470]). In this model, selectin molecules on the cell surface are responsible for neutrophil rolling along the vessel wall. This loose adhesion brings the neutrophil in close proximity to the endothelial cell, where chemoattractants can be released or displayed on the cell surface. The interaction of these chemoattractants with neutrophil receptors results in signal transmission and the activation of integrin molecules. These integrins can then bind their ligands on the endothelial cell surface, resulting in a marked increase in adhesion to the endothelial cell and cessation of rolling. After this, the cells sense further chemoattractant gradients and migrate into the tissue.

TABLE 10.8. Neutrophil-Endothelial Cell Adhesion Proteins

Neutrophil Integrin		Ligand
$a_1ß_1$	Leukocyte factor antigen-1, CD11a/CD18	ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)
$a_Mß_2$	HMac-1, CD11b/CD18	ICAM-1, iC3b, fibrinogen, factor X
$a_Xß_2$	p150, 95, CD11c/CD18	iC3b, fibrinogen
Neutrophil Selectins		**Ligand**
L-selectin	CD62L, leukocyte adhesion molecule-1, Mel-14	Sialylated carbohydrates related to sLe^x (CD15s) and sLe^a
Endothelial Selectins		**Ligand**
E-selectin	CD62E, ELAM-1	Sialylated carbohydrates
P-selectin	CD62P, granule membrane protein-140, platelet activation–dependent granule-external membrane protein	Sialylated carbohydrates including PSGL-1 on neutrophils
Endothelial Ig Family		**Ligand**
CD54	ICAM-1	CD11a/CD18 CD11b/CD18
CD102	ICAM-2	CD11a/CD18
CD31	PECAM-1	CD31/$a_vß_3$?
Neutrophil Ig Family		Ligand
CD31	PECAM-1	CD31/$a_vß_3$?
CD50	ICAM-3	CD11a/CD18
CD66a	(Biliary glycoprotein)	CD66a, CD66c, CD66e
CD66b	(CGM6)	CD66c
CD66c	(NCA 50/90)	CD66a, CD66b, CD66c, CD66e

ELAM, endothelial leukocyte adhesion molecule; Ig, immunoglobulin; ICAM, intercellular adhesion molecule; PECAM, platelet endothelial cell adhesion molecule; PSGL, P-selectin glycoprotein ligand.

SELECTINS Three selectins have been identified that each have an *N*-terminal domain that is homologous to Ca^{2+}-dependent lectins (Fig. 10.20). L-selectin (CD62L, LAM-1, LECAM-1) is expressed on the neutrophil surface. The ligand for L-selectin is the glycoprotein known as *Gly-CAM-1* (glycosylation-dependent cell adhesion molecule-1). Endothelial cells express both E-selectin (CD62E, endothelial-leukocyte adhesion molecule-1) and P-selectin (CD62P, granule membrane protein-140, platelet activation–dependent granule-external membrane protein). E-selectin and P-selectin both recognize $Lewis^x$-related sialylated carbohydrates. Expression of E-selectin on the endothelial cell surface can be induced with stimuli such as IL-1 and TNF but requires protein synthesis. In contrast, P-selectin (CD62P) is found in both the Weibel-Palade granules of endothelial cells and the platelet a-granule. Thus, stimulation of endothelial cells with the appropriate stimulus, such as thrombin or histamine, can result in a rapid mobilization of CD62P (P-selectin) to the endothelial cell surface.

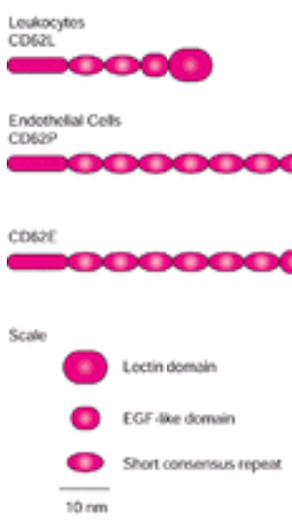

Figure 10.20. Schematic representation of selectins. The selectins are shown to scale, based on electron micrographs of P-selectin, and estimates of the sizes of the short consensus repeats, the epidermal growth factor (EGF) repeat, and the lectinlike *N*-terminal domain are given. (From Springer T. Traffic signals for lymphocyte recirculation and leukocyte emigration: the multistep paradigm. Cell 1994;76:301–314, with permission.)

INTEGRINS Integrins are noncovalently associated heterodimers of a and ß subunits, each of which has characteristic structural motifs (Fig. 10.21 and Fig. 10.22). The major integrins of neutrophils are the $ß_2$ integrins made up of a $_Lß_2$ (leukocyte factor antigen-1, CD11a/CD18), a $_mß_2$ (HMac-1, CD11b/CD18), and a $_xß_2$ (p150,95, CD11c/CD18). Intercellular adhesion molecule (ICAM)-1 (CD54) expressed on the endothelial cell surface is a ligand for both CD11a/CD18 and CD11b/CD18. Other Ig superfamily members are probably also involved in neutrophil-endothelial cell adhesion, including platelet endothelial cell adhesion molecule-1 (CD31), ICAM-3 (CD50) (expressed on the neutrophil but not the endothelial cell), and the CD66 family of neutrophil activation antigens.

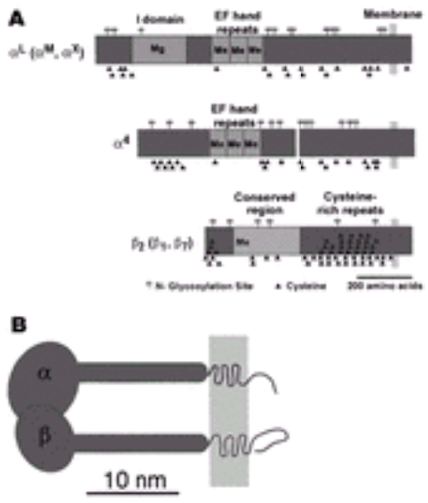

Figure 10.21. Integrins that bind endothelial ligands. **A:** Schematics of representative integrin a and ß subunits. The structures of a $_{L}$ and ß $_{2}$ integrin subunits are shown as representative of a $_{M}$ and a $_{X}$ or ß $_{1}$ and ß $_{7}$, respectively; cysteines are identical, whereas glycosylation sites vary but are sparse in the I domain and E hand repeats. The EF hand repeats are divalent metal-binding motifs that may bind Ca $^{2+}$ or Mg $^{2+}$ (labeled *Me*). A binding site for Mg $^{2+}$ and Mn ^{2} but not Ca $^{2+}$ has been identified in the I domain. The a $_{4}$ integrin subunit has a posttranslational proteolytic cleavage site. A putative divalent cation-binding site has been defined in the conserved domain of the integrin ß $_{3}$ subunit and is shown for ß $_{2}$. **B:** Scale model of an integrin, based on electron micrographs of the integrins gpIIbIIIa and very late antigen-5 (a $_{5}$ß $_{1}$). (From Springer T. Traffic signals for lymphocyte recirculation and leukocyte emigration: the multistep paradigm. Cell 1994;76:301–314, with permission.)

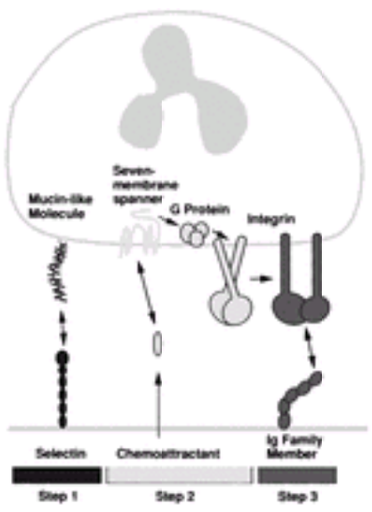

Figure 10.22. Three sequential steps provide the traffic signals that regulate leukocyte localization in the vasculature. Selectin molecules that bind carbohydrate ligands, often displayed on mucinlike molecules, are responsible for the initial tethering of a flowing leukocyte to the vessel wall and for labile, rolling adhesions. Tethering brings leukocytes into proximity with chemoattractants that are displayed on or released from the endothelial lining of the vessel wall. Chemoattractants bind to receptors that span the membrane seven times on the surface of leukocytes. These couple to G proteins, which transduce signals that activate integrin adhesiveness. The integrins can then bind to immunoglobulin (Ig) superfamily members on the endothelium, increasing adhesiveness and resulting in arrest of the rolling leukocyte. Following directional cues from chemoattractants and using integrins for traction, leukocytes then cross the endothelial lining of the blood vessel and enter the tissue. (From Springer T. Traffic signals for lymphocyte recirculation and leukocyte emigration: the multistep paradigm. Cell 1994;76:301–314, with permission.)

SEQUENCE OF NEUTROPHIL–ENDOTHELIAL CELL ADHESION In the Springer model, selectins are responsible for the initial rolling of the neutrophil along the endothelial cell. The association and disassociation constants of selectins for their ligands are very rapid, and stimulation of neutrophils can result in a rapid increase in L-selectin affinity for its ligand, resulting in tethering of a flowing cell and rolling within a millisecond ([470], [471]). This increase in affinity is transient, and, in fact, by 5 minutes after stimulation, much of the CD62L is shed from the neutrophil surface. The close interaction of the neutrophil with the endothelial cell surface, mediated by the selectins, allows the neutrophils to sense chemoattractants released from or displayed on the endothelial surface. These chemoattractants bind to specific receptors on the neutrophil surface, many of which span the membrane seven times, are coupled with G proteins, and result in transduction of signals that activate integrin adhesive activity (Fig. 10.22). Some of the known chemoattractants for neutrophils are listed in Table 10.9. Many tissue-derived chemotactic factors form a protein family termed *chemokines*. These proteins have four conserved cysteines that form two disulfide bonds. The chemokine family is composed of CXC and CC chemokines. The CXC chemokines have their first two cysteines separated by a single amino acid and stimulate neutrophils, whereas the CC chemokines do not. Among the classically described chemoattractants are the n-formyl peptides. These chemoattractants were initially identified by studies of the observation that supernatants of bacterial cultures were chemotactic for neutrophils. Subsequent studies identified a number of n-formyl peptides with chemotactic activity, and it was hypothesized that the presence of such a receptor would provide a preimmune receptor for the neutrophil to sense bacterial infections because bacterial protein synthesis begins with n-formyl methionine, whereas mammalian protein synthesis does not. Interestingly, mammalian mitochondria do synthesize n-formyl methionyl peptides, and these may in some cases also result in neutrophil activation. Another classic chemoattractant is C5a, a cleavage fragment of the fifth component of complement.

TABLE 10.9. Neutrophil Chemoattractants

Chemoattractant	Source
Classic chemoattractants	
N-formyl peptides	Bacterial (? mitochondrial) protein synthesis
C5a	Complement activation
Leukotriene B $_{4}$	Arachidonic acid metabolism
Platelet-activating factor	Phosphatidylcholine metabolism
C-X-C chemokines	
Interleukin-8 (NAP-1)	Multiple cells including T cells, monocytes, endothelial cells
ß-Thromboglobulin (NAP-2/CTAP)	Degradation of platelet a-granule protein
gro-a (MGSA)	Multiple cells including endothelial cells, monocytes
ENA-78	Epithelial cells

Modified from Springer T. Traffic signals for lymphocyte recirculation and leukocyte emigration: the multistep paradigm. Cell 1994;76:301–314, with permission.
NAP, neutrophil-activating protein.

Integrins form a family of adhesive molecules whose affinity for ligand can be rapidly regulated. Stimulation of neutrophils with n-formyl peptides or C5a results in rapid up-regulation of CD11b/CD18 expression on the neutrophil surface. This increase in expression is caused by fusion of secretory vesicles with the cell membrane. With strong stimulation, it is possible that secondary granule fusion contributes as well. However, mere translocation to the cell surface with an increase in cell-surface expression of CD11/CD18 is not sufficient for an increase in adhesiveness. Similarly, studies of cytoplasts have demonstrated that alterations in ß $_{2}$ integrin–mediated cell adhesion can be manifest without a change in surface expression of CD11b/CD18. Data suggest that alterations in CD11b/CD18-mediated cell adhesiveness are the result of a conformational change of the integrin, causing an alteration in ligand binding. Studies show that, after activation of neutrophils by chemoattractants, approximately 10% of the surface CD11b/CD18 molecules express an activation epitope recognized by a monoclonal antibody ([145]). As shown in Table 10.8, several Ig superfamily members are expressed on endothelial cells and are ligands for leukocyte integrins. Mac-1 (CD11b/CD18) binds to a specific site in the third Ig domain of ICAM-1. Leukocyte factor antigen-1 (CD11a/CD18) binds to the *N*-terminal domains of both ICAM-1 and ICAM-2. Thus, the model for neutrophil

adhesion and transmigration through vessel walls can be depicted as in Figure 10.22 and Figure 10.23. The initial rolling of neutrophils along the vessel wall is mediated by selectins (L-selectin, E-selectin, and P-selectin), and their expression and affinity for ligand can be regulated by inflammatory stimuli. At sites of inflammation, leukocyte rolling along the vessel wall is increased, and cells may become more closely apposed to the vessel wall, allowing better interaction with chemoattractants released from or presented on the surface of the endothelial cells. Interactions of these chemoattractants with the neutrophil then result in activation of integrin affinity for its ligand, with a resultant firm adhesion of the neutrophil to the endothelial cell surface. Subsequent migration of the neutrophil through the endothelial cell proceeds along the gradient of chemotactic agent. The presence of multiple adhesion molecules and ligands on both the neutrophil and the endothelial cell, which may vary among endothelial cells in different environments, coupled with the array of chemoattractant agents that may be released locally, provides potentially high specificity for localizing the interaction of a particular type of cell within a particular endothelial environment, based on the large number of combinatorial adhesive molecule–ligand pair combinations available ([470]).

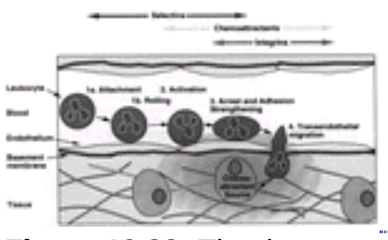

Figure 10.23. The three-step area code model. Selectins, chemoattractants, and integrins act in sequence with some overlap. (From Springer T. Traffic signals for lymphocyte recirculation and leukocyte emigration: the multistep paradigm. Cell 1994;76:301–314, with permission.)

This model is supported by elegant studies demonstrating that at physiologic shear stress, neutrophils form rolling adhesions on phospholipid bilayers containing P-selectin but not on those containing ICAM-1. Chemoattractants result in integrin-mediated adhesion to bilayers containing ICAM-1 under static conditions but not under shear conditions. In contrast, neutrophils rolling on bilayers containing both P-selectin and ICAM-1 respond to chemoattractants by spreading and becoming firmly adherent via an integrin–ICAM-1 interaction. Chemoattractants do not increase adhesion or rolling on bilayers containing P-selectin alone ([470]).

Neutrophil Aggregation

The increase in polymorphonuclear neutrophil adhesion after stimulation is manifest not only by increased adhesion to endothelial cells, but also by neutrophil–neutrophil and neutrophil–platelet adhesion. Although the *in vivo* formation of neutrophil aggregates was clearly visualized by W.B. Wood in a rabbit ear model of inflammation in the 1960s, the possibility of neutrophil homotypic aggregation was considered novel when formally demonstrated by Craddock et al. ([268] , [269]). Craddock's observations stemmed from earlier descriptions of the phenomenon of hemodialysis neutropenia ([266] , [267]). The initiation of hemodialysis, using cuprophane membranes, is followed by a rapid fall in the circulating neutrophil count caused by a transient sequestration of neutrophils in the lung, with a return to the circulation by 1 hour ([266] , [267]). Craddock demonstrated that neutrophils undergo homotypic aggregation in response to plasma that had been exposed to cuprophane, largely because of generation of C5a by complement activation ([268] , [269] , [271] , [272]). Aggregation was also induced by other neutrophil stimuli. Further studies demonstrated that the transient nature of hemodialysis neutropenia was caused by desensitization of neutrophils to the continued infusion of stimulus from the hemodialysis machine, thus demonstrating *in vivo* the phenomenon of desensitization ([270]). This phenomenon, in some clinical situations (e.g., viral infections), may result in neutrophil dysfunction as described later in this book. Subsequent studies have suggested that neutrophil aggregation and sludging, with resultant organ damage or dysfunction, may play a role in a variety of pathologic processes including adult respiratory distress syndrome and reperfusion injury.

Chemotaxis

The work of von Recklinghausen and Conheim described amoebalike movement of leukocytes more than a century ago ([287]). The neutrophil moves on a surface through a gradient of chemotactic agent by advancing a projection called a *lamellipodium* or *pseudopodium*. Chemotaxis begins with the protrusion of a pseudopodium or lamellipodium at the front of the cell. This occurs where the submembranous actin filament network (the cortex) becomes less filamentous. As the cell moves, the pseudopodium ruffles rapidly. Part of the pseudopodium adheres to the underlying surface, and the contents of the cell move forward into the pseudopodium, making the pseudopodium less prominent. This cycle is then repeated with the protrusion of another pseudopodium. Chemotaxis occurs by repetitions of this process, although often the process is so well coordinated as to appear as a continuous gliding motion. The mechanism of these cell movements has been reviewed ([46]) and appears to involve alterations in the polymerization state of actin, regulated by several proteins, including actin binding protein, gelsolin, and others, as well as adenosine triphosphate–dependent contraction of the actin network mediated by myosin. Local contraction of the cytoskeleton could move intracellular components forward into an area where the cortical gel has weakened because of shortening of actin filaments beneath the surface of the advancing pseudopodium. Characteristic contraction waves have been observed in human leukocytes and likened to those seen in amoebae and earthworms (Fig. 10.24) ([472]). In leukocytes, the contraction wave appears to originate in the superficial layer of the submembranous organelle-excluding region called the *cortex*, producing a concave area, and the anterior part of the cell stretches or is propelled forward as a pseudopodium ([472]).

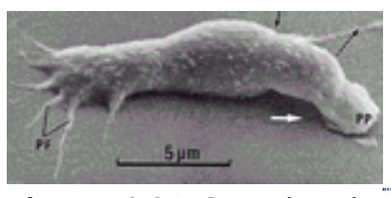

Figure 10.24. Scanning electron micrograph of a moving neutrophil. The contraction wave is observed as a concave (black solid arrow) and a convex (*black dashed arrow*) area. The advancing pseudopodium (PP) is seen being pushed out in the direction of movement (*white arrow*). Pseudoflagellae (PF) are seen in the rear of the cell. (From Senda N, et al. The mechanism of the movement of leucocytes. Exp Cell Res 1975;91:393, with permission.)

Interestingly, mice that express no gelsolin can breed in captivity and have a prolonged bleeding time and abnormal neutrophil chemotaxis ([46]). Thus, gelsolin is important in neutrophil chemotaxis, but other proteins can compensate to some extent in its absence. The increase in free calcium that alters the cytoskeleton by activating gelsolin, and thereby decreasing filamentous actin with a resultant decrease in viscosity, may play a role in locomotion; in addition, the transient dissolution of the submembranous cytoskeletal network may allow closer contact of intracellular granules with the plasma membrane, facilitating granule fusion and release. Some granule release occurs with chemotaxis.

Although the mobility of neutrophils and their concentration in inflammatory lesions were appreciated in early experiments, the development of a two-compartment chamber separated by a leukocyte-permeable membrane has permitted quantitation of chemotaxis *in vitro* and facilitated the investigation of chemotactic factors ([473] , [474]). Such studies revealed that neutrophils show directional migration under the influence of chemotactic agents, but a concentration gradient is needed for migration to occur. Even in the absence of a gradient, however, in the presence of a chemotactic factor, random migration is enhanced, and localization, or trapping, of the phagocytes occurs.

Phagocytosis

Metchnikoff played an important role in describing the phenomenon of phagocytosis (Fig. 10.25). When a neutrophil meets a particle, it envelops it with pseudopodia, which fuse around it, forming a phagosome that rapidly fuses with azurophilic and specific granules. *Endocytosis* is the process by which material is taken into a cell enclosed within pieces of plasma membrane and, therefore, never occurring free within the cytoplasm of the cell ([475]). Endocytosis is further divided into pinocytosis (drinking by cells) and phagocytosis (eating by cells). Phagocytosis is usually visible by light microscopy, whereas pinocytosis is not, involving ingestion of small particles, such as macromolecules. Both processes proceed through invagination of the cell membrane and the formation of vesicles or vacuoles (phagosomes).

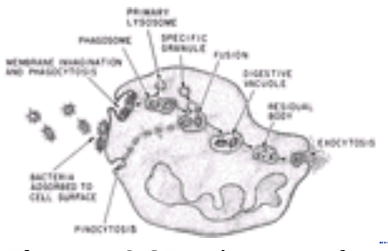

Figure 10.25. Diagram of endocytosis; both phagocytosis of immunoglobulin-coated bacteria and pinocytosis are shown. The fusion of a primary lysosome and a specific granule with the phagosome to form the digestive vacuole, the subsequent degradation of the bacteria leading to the formation of a residual body, and the expulsion of indigestible components are also depicted.

Neutrophils and macrophages are motile and thus are free to migrate into sites of inflammation. Once in the area of inflammation, they come in contact with the foreign material, engulf it, and subject it to the microbicidal and digestive enzymes they contain. This sequence was appreciated by Metchnikoff in the 1880s ([476]) when he observed the migration of phagocytes into areas of tissue damage in sponges and lower animals. How phagocytes distinguish foreign particles and damaged autologous cells from normal self-components remains unclear, but this capacity is critical to effective phagocytic function.

Granule Release

Neutrophils contain four well-defined types of intracellular granules: azurophilic, specific, and gelatinase granules and secretory vesicles. The azurophilic granules contain many antibacterial compounds, and it appears that the fusion of these granules with phagocytic vesicles is important in bacterial killing. Azurophilic granules also contain compounds, such as elastase, that may alter locomotion by hydrolyzing certain extracellular matrix components. The specific granules are more readily released from the cell, suggesting an important function in the extracellular milieu. For example, specific granules contain products that activate the complement cascade ([477]). Collagenase may be important in hydrolyzing extracellular matrix proteins and facilitating locomotion. Apolactoferrin, which binds iron, may exert an antibacterial effect by depriving bacteria of iron, altering hydroxyl radical formation, and altering cell adhesion ([36] , [37]). The tertiary granules contain gelatinase in addition to other components, and, like collagenase, this enzyme may play a role in extracellular matrix remodeling during locomotion. Finally, both tertiary granules and the secretory vesicles contain membrane proteins that can be rapidly up-regulated to the cell surface and may play a role in alterations of the functional use of these surface proteins after stimulation. Membrane components of secondary granules are also up-regulated during granule release and may play a role in regulating the expression of these membrane proteins on the cell surface. The specific granules are more readily released than the azurophilic granules, and their secretion, therefore, must be regulated somewhat differently.

Bacterial Killing and Digestion

Bacterial killing by neutrophils can be ascribed to two general and often synergistic mechanisms: oxidative and nonoxidative. Bacterial killing in the phagosome is augmented by the generation of superoxide. Activated neutrophils produce superoxide via a multicomponent nicotinamide adenine dinucleotide phosphate (NADPH)–dependent oxidase that is activated by neutrophil stimulation. In resting cells, the oxidase components are found in both the plasma membrane and intracellular stores. After stimulation, intracellular components are translocated to the plasma membrane and activated, producing O_2. Subsequent reactions result in the formation of H_2O_2 and hypochlorous acid (HOCl), which increase bacterial killing. Small amounts of other species (such as singlet oxygen and hydroxyl radical) may also form but are probably of little import in bacterial killing.

Bacterial killing decreases under anaerobic conditions, whereas phagocytosis does not, so the respiratory burst is important to bactericidal activity. Furthermore, because chronic granulomatous disease is one of the most severe clinical disorders characterized by a defect in bacterial killing, and the defect in this disorder is an inability to develop all of the reactions associated with the respiratory burst, the oxygen-dependent mechanisms appear to be of major importance in bacterial killing ([478] , [479]). However, other bactericidal mechanisms not requiring oxygen also operate within phagocytes (Table 10.10).

TABLE 10.10. Antimicrobial Systems of the Neutrophil

Oxygen dependent

Oxygen-Dependent Antimicrobial Systems

Neutrophil activation is accompanied by a prominent increase in O_2 use called the *oxidative burst*. The respiratory burst or oxidative burst is a series of metabolic events that take place when phagocytes are appropriately stimulated, resulting in an increase in oxygen consumption, the production of superoxide (O_2), the production of H_2O_2, and an increase in glucose oxidation via the hexose monophosphate shunt ([478] , [480] , [481]). Most of the oxidative burst is caused by activation of an NADPH oxidase that catalyzes the one electron reduction of oxygen to superoxide, using the electron donor NADPH ([478] , [482]):

$$2O_2 + NADPH \rightarrow Oxidase \rightarrow 2O_2^- + NADP^+ + H^+ \quad (12)$$

Activation of the hexose monophosphate shunt occurs because of the increased $NADP^+$ produced.

The NADPH oxidase exists in a latent state consisting of both membrane and cytosolic components. Activation involves multiple steps, including assembly and translocation to the resting membrane-bound oxidase complex (consisting of at least three proteins including gp91 ^{phox}, p22 ^{phox}, and Rap 1) of at least two cytosolic components (p47 ^{phox} and p67 ^{phox}) (the term *phox* indicates that the protein is a component of the phagocyte oxidase), phosphorylation of p47 ^{phox}, and translocation of a cytosolic G protein (Rac 1/2) to the membrane-bound oxidase complex ([481]) (Fig. 10.26). The activated oxidase is readily detected by nitroblue tetrazolium or cytochrome reduction or the production of chemiluminescence; several mechanisms by which this series of oxygen-dependent reactions may kill bacteria have been postulated (Table 10.10).

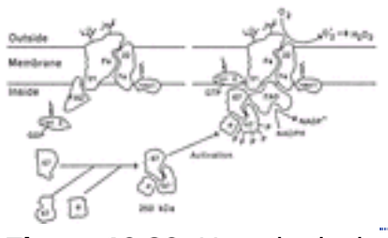

Figure 10.26. Hypothetical model of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activation. Current knowledge of the oxidase suggests that, in its dormant state (left side of figure), it is composed of both membrane-bound and cytosolic components. The former include the gp91- *phox* and p22- *phox* subunits of cytochrome *b* $_{558}$ (and, possibly, rap 1). Evidence suggests that the flavin adenine dinucleotide (FAD) redox center is bound to gp91- *phox*, but because this has not been conclusively established, the FAD is shown bound to a distinct oxidase subunit in the membrane. The cytosolic components include p47- *phox* and p67- *phox*, which appear to exist in a preformed complex of 260 kd. This complex probably contains at least one other additional component (as yet undetermined) labeled in this model as *a*. The low-molecular-mass guanosine triphosphate (GTP)–binding protein, rac 2, is also present in the cytosol in its inactive state [with (guanosine diphosphate) GDP bound], presumably complexed with a GDP dissociation inhibitor (not shown) that serves to keep rac 2 in its inactive state. On stimulation, the p47-/p67- *phox* complex translocates to the membrane. This process may be under the control of the active (GTP-bound) form of rac 2 and further regulated by phosphorylation of p47- *phox*. In its active state, the FAD redox center accepts electrons from NADPH and passes them to molecular oxygen via the heme groups in cytochromes b $_{558}$. Two heme groups are believed to be present in each cytochrome b $_{558}$ heterodimer. (From Curnutte JT. Chronic granulomatous disease: the solving of a clinic riddle at the molecular level. Clin Immunol Immunopathol 1993;67:S2–S15, with permission.)

Although O2 has some antibacterial activity, most O $_2$ is rapidly converted to H $_2$O $_2$ by dismutation, either spontaneously or catalytically by superoxide dismutase:

$$2O_2^- + 2H^+ \rightarrow O_2 + H_2O_2 \quad (13)$$

Of the microbicidal oxidants generated by the respiratory burst, O $_2$ and H $_2$O $_2$ are not potent microbicides; rather, they function as starting materials to generate more potent oxidizing radicals, such as oxidized halogens and oxidizing radicals ([478]).

MYELOPEROXIDASE-MEDIATED OXYGEN-DEPENDENT BACTERIAL KILLING WITH OXIDIZED HALOGENSMPO is present in high concentration in the azurophilic or primary granules of neutrophils and is released into the phagosome during granule-phagosome fusion. MPO, together with H $_2$O $_2$ generated during phagocytosis ([483] , [484]) and an oxidizable cofactor such as halide (e.g., Cl or Br), forms oxidized halogens that are potent antimicrobials effective against bacteria, fungi, viruses, mycoplasma, and tumor cells ([479]):

$$Cl^- + H_2O_2 \rightarrow MPO \rightarrow H_2O + OCl^- \quad (14)$$

The combination of MPO, halide, and H $_2$O $_2$ is efficient in killing bacteria at H $_2$O $_2$ concentrations as low as 10 µm, whereas H $_2$O $_2$ in the absence of MPO requires 0.5 mmol/L or greater levels to produce similar killing ([478]). Thus, H $_2$O $_2$ alone is a weak antimicrobial. Several mechanisms that have been proposed to explain bacterial killing by this system include halogenation of the bacterial cell wall, oxidation of various bacterial components, the decarboxylation of bacterial wall amino acids ([478] , [479]), and the generation of long-lived chloramines that have antimicrobial activity ([478] , [485]):

$$OCl^- + RNH_3 \rightarrow OH^- + RNH_2Cl \quad (15)$$

There is some evidence that reactive nitrogen intermediates may also be produced ([486] , [487]). Regardless of the mechanisms of killing, the fact that azide inhibition of MPO greatly decreases the microbicidal activity of normal leukocytes provides strong evidence for the importance of this system ([483]). In patients with MPO deficiency (which is often quantitative rather than qualitative), the activity of other antimicrobial systems is increased, thus partially compensating for the MPO deficiency ([483]). This finding may explain the increased susceptibility to infection in only approximately 20% of MPO-deficient patients ([488]).

MYELOPEROXIDASE-INDEPENDENT (BUT OXYGEN RADICAL–DEPENDENT) BACTERIAL KILLING This antimicrobial system is important because cells with no detectable MPO activity retain antibacterial actions that require oxygen; in fact, bacterial killing in MPO-deficient cells is associated with greater oxygen consumption than in normal cells ([479]).

HYDROGEN PEROXIDE As mentioned, H $_2$O $_2$ at high concentrations (>0.5 mmol/L) has antimicrobial activity in the absence of MPO ([489]). Some organisms are more sensitive than others to H $_2$O $_2$, and this sensitivity may depend in part on their ability to degrade it (i.e., catalase or peroxidase content). Certain substances such as iodide or ascorbic acid may enhance the bactericidal action of H $_2$O $_2$ or render organisms more sensitive to still other killing mechanisms, such as lysozyme ([479]).

SUPEROXIDE ANION After the discovery that O $_2$ $^-$ was generated in phagocytes, some authors postulated that O $_2$ $^-$ itself might be microbicidal. The microbicidal activity of O $_2$ $^-$ appears to be weak, however, when compared to that of the H $_2$O $_2$ formed from it, especially if MPO is present. Superoxide by itself has minimal bactericidal activity ([478] , [479]).

HYDROXYL RADICALS Human neutrophils and monocytes generate OH· radicals, but the role of this highly reactive compound in microbial killing is unclear ([478] , [479]). OH $^-$ production from H $_2$O $_2$ and superoxide is catalyzed by iron in the Haber-Weiss reaction:

$$H_2O_2 + O_2^- \rightarrow Fe^{3+} \rightarrow OH\cdot + OH^- + O_2^- \quad (16)$$

SINGLET OXYGEN Singlet oxygen (^{1}O $_2$) is a highly reactive form of oxygen that is capable of attacking compounds containing double bonds. However, significant amounts of singlet oxygen are unlikely to form, so its role in bacterial killing is probably not significant ([488]).

NITRIC OXIDE Nitric oxide may interact with neutrophil-derived oxidants to yield other relevant oxidant species. Nitric oxide (NO·) reacts with superoxide (O $_2$ $^-$·) to form the potent oxidant peroxynitrate (ONOO $^-$). Nitrite (NO $_2$ $^-$), a major end product of nitric oxide metabolism, has been found to interact with hypochlorous acid (HOCl) or MPO, or both, to form nitrylchloride (NO $_2$Cl) and thus promotes tyrosine nitration ([490] , [491]). Activated neutrophils can convert NO $_2$ $^-$ to NO $_2$Cl and NO2· through an MPO-dependent pathway and inactivate endothelial angiotensin-converting enzyme ([490]). Thus, neutrophil conversion of NO $_2$ $^-$ to nitrating and chlorinating species may play important physiologic roles. In this regard, nitric oxide synthase has been found in neutrophil primary granules ([492]), and NO· production by neutrophils has been observed ([491]).

Oxygen-Independent Antimicrobial Systems

Because an anaerobic environment does not abolish antimicrobial activity, other mechanisms must be operative, and several have been identified, including the effects of acid, lysozyme, lactoferrin, defensins, cationic proteins, and neutral proteases. The delivery of the wide array of antibacterial compounds to the phagosome by fusion with azurophilic and specific granules generally results in bacterial killing caused by the direct actions of the granule contents. In addition, these effects are potentiated by the acidification of the phagosome, caused partly by the granule contents themselves, as well as active translocation of H $^+$ ions into the phagosome by ion pumps. The effectiveness of these mechanisms in the absence of superoxide production is demonstrated by both bacterial killing in anaerobic environments and killing by cells from patients with chronic granulomatous disease, in which catalase-positive organisms have an advantage over catalase-negative species. Nonoxidative killing is of obvious importance in hypoxic environments such as an abscess.

ACID After particle ingestion, the intraphagosomal pH has been reported to decrease to between 3.0 and 6.5 ([493] , [494] and [495]). Some organisms, such as pneumococci, are sensitive to an acid pH, whereas others tolerate acid environments without damage. In addition, the acid environment may enhance the effect of lysosomal hydrolytic enzymes, most of which have optimal activity at acid pH.

LYSOZYME This low-molecular-weight (14,500-d) basic protein is present in both primary and secondary neutrophil granules and is capable of hydrolyzing the cell wall of certain bacteria. Most organisms are resistant to the direct action of lysozyme ([479]), although they may become sensitive to its action after exposure to antibody and complement or to H $_2$O $_2$ and ascorbic acid ([479]). Usually, bacterial death appears to precede the action of lysozyme, so its action may be mostly digestive. The leukocytes of Guernsey and Hereford cattle contain no lysozyme but kill organisms normally ([496]).

LACTOFERRIN This microbiostatic protein (molecular weight of 77,000 d) is found in the specific granules of rabbit heterophils ([497]) and in human neutrophils ([498]) as well as in many secretions (e.g., milk and mucus) and exudates ([499]). It inhibits bacterial growth by binding the essential nutrient iron (two atoms/molecule), and, in contrast to transferrin, this property is maintained at the low pH values encountered in exudates. A synergistic relationship between lactoferrin and other antimicrobial

systems may exist, and lactoferrin may be bactericidal for some organisms ([500]).

DEFENSINS Prominent among the cationic neutrophil granule proteins are the defensins. These small microbicidal peptides kill a variety of bacteria, fungi, and viruses ([16] , [17] and [18] , [501]). Defensins appear to exert their effects by forming voltage-dependent ion channels. They are present in a very high concentration compared to other stored antibacterial peptides (approximately 5% of total neutrophil weight).

BACTERICIDAL PERMEABILITY-INCREASING PROTEIN Bactericidal permeability-increasing protein has antibacterial activity against certain gram-negative bacteria ([21] , [22] , [23] , [24] and [25]). It also has the property of neutralizing the toxic effects of endotoxin.

OTHER GRANULE PROTEINS Leukocyte granules from humans, rabbits, guinea pigs, and chickens contain several other basic proteins that migrate toward the cathode on electrophoresis in agarose and exhibit antimicrobial activity ([21] , [498]). These proteins differ from species to species ([21] , [498]), and their relative importance as antimicrobial agents probably also varies. For example, because chicken leukocytes lack MPO, the cationic proteins presumably are of greatest importance in that species. In rabbit heterophils ([502]) and chicken ([503]) and human ([16] , [17] and [18]) polymorphs, the cationic proteins are located in the primary granules and are delivered into the phagosome, where they coat the bacteria and are presumed to kill them ([21] , [498]). Other antibacterial granule components include azurocidin ([26] , [27]) and the serine proteinases elastase, cathepsin G, and proteinase 3 ([28] , [29] , [30] and [31] , [504]).

Digestion

Digestion of bacteria is demonstrated both by changes in the morphologic appearance of organisms after phagocytosis and by the release of labeled fragments of bacteria into the surrounding medium ([504] , [505]). Digestion is thought to result from the action of the acid hydrolytic enzymes released into the phagosome from the primary lysosome. Metabolic blocking agents, such as iodoacetate, cyanide, and arsenite, which inhibit glycolysis and respiration, have no effect on digestion once the bacteria are within the cell ([507]). Some bacteria ingested by neutrophils (e.g., certain pneumococci) may be killed and digested slowly, the undigested material remaining as myelin or residual bodies.

UNSUCCESSFUL INGESTION, KILLING, OR DIGESTION Phagocytosis and bacterial killing are not always completed successfully. Some organisms (e.g., certain virulent staphylococci) may survive and multiply within neutrophils and appear to kill them, thus overcoming the defense mechanism ([508]). Still other materials ingested by neutrophils, such as the uric acid crystals of gout or the hydroxyapatite crystals of pseudogout, may cause breakdown of the phagosome wall and release the hydrolytic enzymes into the cell sap ([509]). This action may be fatal to the cell, which then lyses and releases its enzymes into the surrounding tissues, where they cause tissue damage and secondary inflammation. In certain streptococcal and other infections, bacterial exotoxins (e.g., streptolysin) are released and damage the phagosomal membrane, thus killing the cell in a similar manner ([510]); the infecting organism is freed in the process. Also, certain vitamins (vitamin A) and drugs, when incorporated into phagosomal membranes, render the membranes fragile and readily susceptible to rupture, thereby leading to inflammation ([509]).

Infections That Exhibit Tropism for Neutrophils

Granulocytic ehrlichiosis is a human pathogen ([511] , [512] , [513] and [514]). The *Ehrlichia* are obligate intracellular bacteria related to rickettsia. Human granulocytic ehrlichiosis is an acute febrile illness accompanied by severe myalgias and headaches, usually occurring within 2 weeks of contact with ixodid ticks. Common laboratory findings include leukopenia, thrombocytopenia, and increased transaminases. Although most patients respond promptly to doxycycline, death occurs in approximately 5% of reported cases, and complications such as pneumonia, renal failure, and central nervous system damage have been reported. Characteristic intracytoplasmic inclusions in neutrophils (morulae) are not always seen or recognized. Human granulocytic ehrlichiosis is closely related to two veterinary pathogens infecting granulocytes, *Ehrlichia equi* and *Ehrlichia phagocytophila*, which affect horses and ruminants, respectively.

Secretory Functions of the Neutrophil

In addition to the fact that the contents of the neutrophil are released passively as a result of cell lysis, a variety of substances probably are actively secreted by leukocytes *in vitro*. Most of these substances have been shown to originate from the granule (including secretory vesicle) fraction. Specific granule contents (lactoferrin, B_{12}-binding protein, or both) are released before primary granule contents, and tertiary granules and secretory vesicles are secreted even more rapidly and completely, providing evidence for a differential secretion of granule contents ([515]). Because some of these substances are present in plasma normally and the concentration increases in patients with diseases involving the neutrophil system ([516] , [517] and [518]), some authors suggest that neutrophils may serve a secretory function as well as a phagocytic role *in vivo* ([519] , [520]).

Two modes of enzyme release or exocytosis are released into phagocytic vacuoles (including release outside the cell during phagocytosis but before the phagosome is sealed off from the exterior of the cell or release during attempted phagocytosis that cannot be completed because of particle size) ([515]), and granule content release also occurs that is not associated with phagocytosis—that is, true secretion ([515]).

Two well-studied released granule proteins are the B_{12}-binding proteins or transcobalamins. Granulocytes contain and actively release B_{12}-binding protein ([519] , [521]). This protein was thought to be a storage protein and is a poor source of metabolically available vitamin ([522]). It appears that transcobalamin III is derived from granulocytes; it is unsaturated with B_{12} ([523]). Markedly elevated transcobalamin I levels are seen in cases of chronic myelocytic leukemia and myeloid metaplasia; low values occur in patients with chronic leukopenia and aplastic anemia ([522]), and good correlation with blood granulocyte pool size has been reported ([516]).

Lysozyme is present in primary, secondary, and tertiary granules and is also present in monocytes, serum, and tears and other secretions ([518] , [524]). Increased concentrations in serum and urine are found in association with monocytic and myeloblastic leukemias ([517] , [524]). Although it was proposed that serum lysozyme may provide a measure of GTR ([525]), lysozyme is present in several cell types, and the GTR does not correlate with serum lysozyme levels in neutropenic patients. In addition, the plasma kinetics of lysozyme do not mirror the kinetics of other neutrophil granule proteins or short-term alterations in the number of circulating neutrophils (in contrast to the kinetics of lactoferrin and gelatinase) ([518]).

Stimulated neutrophils also synthesize and release a variety of cytokines that may regulate the inflammatory response. For example, neutrophils stimulated with lipopolysaccharides synthesize IL-1, TNF-a, and IL-1 receptor antagonist ([526]), whereas GM-CSF induces synthesis of TNF-a and IL-6 ([527] , [528]).

Activation of Proteases by Oxygen Metabolites

Reactive oxygen metabolites may also contribute to the physiologic effects of activated neutrophils by activating latent enzyme activities of granule proteases such as collagenase ([529]). The significance of this process for bacterial killing is unclear but is relevant to other pathophysiologic processes.

The Human Eosinophil

The eosinophil was first described for its characteristic intracytoplasmic granules that exhibit a high affinity for eosin, a negatively charged dye. Although rare in healthy individuals, the eosinophil is prominent in peripheral blood and tissue in association with various disease conditions including allergy ([1], [2] and [3]), inflammatory responses against metazoan helminthic parasites ([4], [5]), and certain skin and malignant conditions. The eosinophil has received special attention for its potential pathophysiologic role in the manifestation of allergic diseases such as asthma, rhinitis, eczema, and Crohn's disease. Disorders of the respiratory tract, particularly allergic asthma and rhinitis, exhibit a strong correlation with the number as well as activation status of infiltrating tissue eosinophils. Similarly, many disorders of the gastrointestinal system exhibit prominent eosinophilic inflammation in the mucosa. The presence of eosinophils in the airway and gut mucosa has been associated with both allergic [immunoglobulin (Ig) E–dependent] and nonallergic (IgE-independent) manifestations of disease. Although clinically these conditions have been characterized as either allergic or nonallergic, it appears that the mechanisms underlying recruitment and activation of eosinophils in both types of disease are similar. In spite of extensive efforts to characterize this enigmatic leukocyte, the immunologic role of the eosinophil in disease and its importance in the pathogenesis of asthma remain unclear. However, there is increasing evidence that the eosinophil is a major effector cell in many types of allergic and nonallergic inflammation, as well as in parasitic disease.

Eosinophils are mobile, terminally differentiated granulocytes that arise principally from the bone marrow ([6]). They are approximately 8 μm in diameter, and their nuclei are usually bilobed, although three or more lobes are also often observed. The eosinophil is characterized by its large crystalloid granules, also known as *secondary* or *specific granules*, as shown in light microscopy by their bright red staining properties with acidic dyes such as eosin (Fig. 11.1). As apparent in electron micrographs, the crystalloid granules contain electron-dense crystalline cores surrounded by an electron-lucent granule matrix (Fig. 11.2). Eosinophils contain up to four other granule types: primary granules, small granules, lipid bodies, and small secretory vesicles. *Crystalloid granules* are membrane-bound and contain a number of highly cationic basic proteins (see section Granule-Derived Proteins). The latter have been implicated in the tissue damage observed in asthma and other similar allergic conditions. Allergen and parasite-induced eosinophilia have been shown to be T-cell–dependent and are mediated by soluble factors (cytokines) released from sensitized lymphocytes ([7]). Recent advances in human eosinophil research have also indicated that eosinophil infiltration into the tissue in allergic-type responses and asthma is regulated by a series of biologic events, which includes a complex interplay between immunologic and inflammatory mechanisms including cytokines and chemokines ([8], [9]).

EOSINOPHIL DIFFERENTIATION

Peripheral blood and tissue eosinophils are derived by hemopoiesis from CD34 $^{+}$ myelocytic progenitors found in the bone marrow and in inflamed tissues. Eosinophils make up approximately 3% of the bone marrow from healthy individuals, of which 37% are fully differentiated, and the remainder are promyelocytes/myelocytes and metamyelocytes ([6], [10]). The appearance of newly matured cells in the blood occurs approximately 2.5 days from the time of the last mitotic division ([6]). The turnover of eosinophils is approximately 2.2 × 10 ^{8} cells per kg per day, and the bone marrow possesses the largest end-differentiated eosinophil reservoir in the healthy body (9 to 14 × 10 ^{8} cells per kg) ([11]). Progenitors differentiate on exposure to a network of cytokines and chemokines to become committed to the eosinophil/basophil (Eo/B) lineage ([12]). Eosinophils are more closely related to basophils than neutrophils and monocytes due to lineage differentiation at this stage ([13]). In addition, eosinophils retain elements of expression of basophil/mast cell–specific high-affinity Fce receptor (a subunit) ([14]), whereas basophils continue expression of low concentrations of eosinophil major basic protein (MBP) ([15]). Cytokines and chemokines are soluble immunoregulatory factors generated under appropriate stimulation from T cells in the bone marrow. The three key cytokines that are critical for stimulation of bone marrow production of eosinophils are interleukin (IL)-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) ([16], [17]). These three cytokines are also produced by CD4 $^{+}$ and CD8 $^{+}$ T lymphocytes from peripheral blood as well as inflamed tissues ([18]). In bone marrow samples, committed eosinophil precursors can be recognized by their expression of the IL-5 receptor (IL-5R) and the C-C chemokine receptor, CCR3, in addition to CD34 ([19]). It is now well recognized that IL-5 is a key cytokine in terminal differentiation of eosinophils ([20]), and expression of IL-5R on the progenitor cell is one of the first signs of commitment to the eosinophil lineage. The expression of IL-5R is almost exclusively limited to eosinophil progenitors and mature peripheral blood eosinophils, with some expression on basophils but not neutrophils or monocytes. This selectivity in receptor distribution indicates that IL-5 acts primarily as an eosinophilopoietic cytokine.

Interleukin-5 Receptor Signaling

The IL-5R consists of two subunits: an a subunit of 60 to 80 kd and a common ß $_{c}$ subunit of between 120 and 140 kd, which is shared with IL-3R and GM-CSF receptor. IL-5 interacts with its a subunit specifically but at a lower affinity than the ß $_{c}$ subunit ([40]). IL-5 stimulation through the ß $_{c}$ subunit leads to phos-phorylation of the tyrosine kinases Jak (Janus kinase) 2, Lyn, and Syk. Whereas Jak2 signals through the nuclear translocation factor STAT (*s*ignal *t*ransducer and *a*ctivator of *t*ranscription)-1, Lyn and Syk signal through the mitogenic Ras-Raf1–mitogen activated protein kinase kinase–extracellular signal regulated kinase pathway (Fig. 11.3). Tyrosine phosphorylation enhances the expression of the antiapoptotic protein Bcl-x $_{L}$ in eosinophils and decreases translocation of the proapoptotic signaling molecule Bax, resulting in decreased activation of apoptotic signaling through the caspase family ([41], [42]). GM-CSF prolongs the survival of eosinophils bound to tissue sites via a $_{4}$ integrin for up to 2 weeks ([34]) and has also been shown to inhibit eosinophil apoptosis similarly to IL-5. This has resulted in several groups proposing that inhibition of IL-5 with anti–IL-5 antibody therapy results in the complete loss of eosinophils from the body, thus preventing the manifestation of allergic symptoms (see section The Eosinophil Controversy). The obligatory role of IL-5 in the differentiation of the eosinophil has been confirmed by numerous studies on transgenic mice in which the expression of the gene for IL-5 caused marked eosinophilia and increased numbers of eosinophil precursors in their bone marrow ([21], [22]). Interestingly, eosinophil differentiation in this transgenic model appeared to be completely independent of IL-3 and GM-CSF, suggesting that IL-5 alone may be sufficient to generate an eosinophilia from stem cell precursors. However, although IL-5 gene-deficient mice exhibit almost no eosinophils in their blood, a small pool of apparently IL-5–independent eosinophils persists in the mucosal tissues of these animals. Additional eosinophilopoietic factors may assist in inducing the differentiation of Eo/B progenitors in the bone marrow, including IL-4, IL-6, IL-11, IL-12, stem cell factor, and others ([23]). C-C chemokines, named for their adjacent cysteine residues in the C-terminus amino acid sequence as distinct from the CXC chemokines, include eotaxin and RANTES (*r*egulated on *a*ctivation, *n*ormal *T*-cell *e*xpressed and *s*ecreted), which have also been shown to be important in the development of eosinophils ([24]). Overall, at the level of the bone marrow, the early development of Eo/B progenitors is driven by IL-3 and GM-CSF, among other factors, whereas at later stages, IL-5 regulates the terminal differentiation of eosinophils. Eotaxin may facilitate the efflux of fully mature eosinophils into the peripheral circulation.

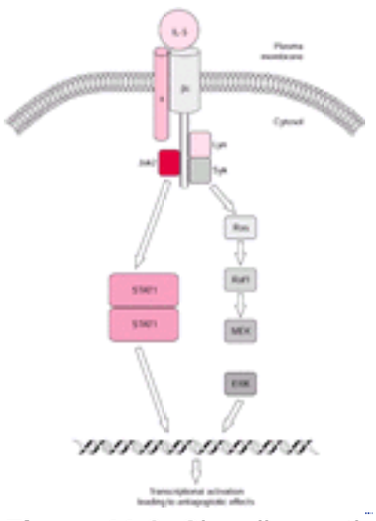

Figure 11.3. Signaling pathway leading from binding of interleukin-5 (IL-5) to its receptor in the membrane to transcriptional activation in the cell nucleus via the Ras-Raf1-MEK-ERK pathway. The ß subunit of the receptor is also able to activate the Jak2–STAT-1 (Janus kinase 2– *s*ignal *t*ransducer and *a*ctivator of *t*ranscription pathway-1). Transcriptional activation is proposed to generate antiapoptotic effects in eosinophils.

The half-life of eosinophils in the circulation is approximately 18 hours with a mean blood transit time of 26 hours ([25]), although this is extended in eosinophilic conditions, possibly due to the elevation of systemic eosinophil-activating cytokines that promote eosinophil survival. Based on a study of 740 medical students, the normal range of blood eosinophils was shown to average between 0.0 to 0.5 × 10 ^{9}/L, with counts ranging from 0.015 to 0.65 × 10 ^{9}/L ([26]). Circulating eosinophil counts exhibit diurnal variation in humans, in which the lowest and highest levels are seen in the morning and evening, respectively, often exhibiting more than 40% variation within a day ([27], [28]). Mild eosinophilia is generally considered to be 0.5 to 1.5 × 10 ^{9}/L, moderate eosinophilia is 1.5 to 5.0 × 10 ^{9}/L, and marked eosinophilia is greater than 5.0 × 10 ^{9}/L. Allergy is commonly associated with eosinophilia in the mild range, whereas parasitic infestation is often characterized by a marked eosinophilia.

Eosinophils are predominantly tissue cells, and their major target organs for homing include the gastrointestinal tract, the lungs, and the skin. Once they enter target tissues, eosinophils do not return to the blood circulation. Tissue eosinophil numbers can remain high in tissues even when peripheral numbers are low, suggesting that their survival is enhanced on extravasation. Curiously, pathogen-free laboratory animals have no eosinophils in their blood, whereas tissue eosinophils are difficult to find, suggesting that the appearance of eosinophils may be disease related ([10]).

Eosinophil Production and Survival in Peripheral Tissue

Eosinophil development and maturation may also occur *in situ* in peripheral (extramedullary) sites outside of the bone marrow. In this case, Eo/B precursors are released into the bloodstream directly from the bone marrow to circulate to sites where they specifically transmigrate in response to locally produced cytokines and chemokines. This may provide an alternative mechanism for the persistence or accumulation of tissue eosinophils. Like neutrophils, eosinophils are end-stage cells, which, in culture, rapidly undergo cell death by either apoptosis or necrosis. However, eosinophil-active cytokines, such as IL-3, IL-5, and GM-CSF, as well as interferon (IFN)-?, prolong eosinophil survival in culture for up to 2 weeks ([29], [30] and [31]). They also enhance receptor expression as well as cell function including cytotoxicity against metazoan targets and mediator release. Activated eosinophils can generate a number of cytokines themselves *in vitro*. This may lead to autocrine prolongation of eosinophil maturation and survival in tissues ([32]). Local tissue types such as endothelial cells, fibroblasts, and epithelial cells may also contribute to the production of IL-5 and GM-CSF for *in situ* eosinophil maturation and differentiation in airway or gut mucosa.

Extracellular matrix proteins have been shown to modulate eosinophil response to physiologic soluble stimuli ([33]). Eosinophils adhere specifically to fibronectin ([34]), an abundant extracellular matrix protein; very late antigen (VLA)-4, a known receptor for fibronectin ([35]), was involved in mediating eosinophil–fibronectin interactions ([34]). Similarly, VLA-6 expressed on eosinophils was shown to interact with the connective tissue protein laminin.

IL-5 delays eosinophil apoptosis and promotes eosinophil priming and activation ([36]). IL-5 production by airway CD4 $^{+}$ T cells may be directly stimulated by eosinophils in a paracrine manner to enhance survival of tissue eosinophils ([37]). Eosinophil progenitors in nasal explants from atopic patients have been shown to survive and develop into fully mature eosinophils *ex vivo* using similar mechanisms ([38]). Allergen challenge of these explants, as well as lung explants of Brown-Norway rats, was shown to evoke a rapid (6-hour) accumulation of MBP-positive cells after allergen challenge ([39]). This was shown to be dependent on IL-5 production within the explant—a key cytokine in eosinophil survival. Thus, the growth, maturation, and prolongation of survival of eosinophils in extramedullary tissues may occur in sites other than the bone marrow.

EOSINOPHIL HETEROGENEITY

Human peripheral blood eosinophils exhibit marked heterogeneity based on their physical, morphologic, and functional properties. There are three different populations of eosinophils that can be characterized based on their intrinsic buoyant density and responsiveness to stimuli. These are the normodense, hypodense, and primed eosinophils, which can be described in both normal and eosinophilic subjects. Each of these populations responds differently to stimuli, which may be related to their stage of maturation. In addition, they may derive from distinct pools of eosinophils that are genetically regulated. The majority of blood eosinophils (>90%) from normal individuals are normodense, which separate out from other leukocytes in the lower interfaces of Percoll or metrizamide discontinuous density gradients. Hypodense eosinophils can be seen in a proportion of eosinophils from individuals with a raised eosinophil count that exhibit lower density than eosinophils from normal subjects, resulting in a spread of eosinophil populations in the gradient, with contaminating mononuclear cell bands ([43]). Morphologically, hypodense eosinophils appear vacuolated, contain more lipid bodies, express less MBP, and possess smaller crystalloid granules that appear to be slightly more lucent and take up less cell volume, although these are of equal numbers to normodense eosinophils ([44]). They also exhibit a greater cell volume than normodense eosinophils ([45]). The mechanism for this heterogeneity is not clear. The presence of low-density (or hypodense) eosinophils appears to be a nonspecific phenomenon that occurs in any eosinophilic condition including parasitosis, asthma, allergic rhinitis, idiopathic hypereosinophilic syndrome, and certain malignancies. It was originally thought that the numbers of hypodense cells correlated with the degree of eosinophilia, although this has not been consistently observed ([43] , [46] , [47] , [48] and [49]). Thus, the mechanisms governing the production of hypodense eosinophils are likely to be distinct from those that control eosinopoiesis.

Functionally, hypodense eosinophils appear to be more activated because they exhibit elevated oxygen consumption ([43]) and increased cytotoxicity toward helminthic targets ([46]) and release more leukotriene C $_4$ (LTC $_4$) after physiologic stimulation ([50]). Activation of eosinophils *in vitro* with inflammatory mediators such as platelet-activating factor (PAF), as well as long-term culture with cytokines (e.g., IL-3, IL-5, and GM-CSF), has been associated with a decrease in eosinophil density ([29] , [51]). Two possible explanations may account for the enhanced responsiveness of hypodense eosinophils. The first is that hypodense eosinophils frequently comigrate to the same density as neutrophils in metrizamide or Percoll gradients, thus making it difficult to separate these two cell types. Neutrophils could, therefore, enhance the responsiveness of eosinophils through cell–cell interaction. For example, total LTC $_4$ produced by a mixture of eosinophils and neutrophils was found to be greater than the amount produced by either cell type alone ([52]). However, other studies assessing the possibility of neutrophils enhancing eosinophil responsiveness have been negative ([53] , [54] and [55]). Second, hypodense eosinophils have been shown to express a greater number of receptors for IgG, IgE, CD44, complement, and the p55 subunit of the IL-2 receptor when compared with normodense cells ([43] , [56] , [57] and [58]), which may explain their enhanced responsiveness to stimuli. However, the surface expression of numerous other receptors does not differ between normodense and hypodense eosinophils, with some populations (e.g., CD18) even showing decreased expression in hypodense cells ([59]). Furthermore, normodense eosinophils from patients with an eosinophilia have enhanced effector function compared with eosinophils from normal individuals. It is possible, therefore, that the formation of low-density eosinophils results from the migration of normodense eosinophils from the bone marrow to the circulation, whereupon they become activated by elevated systemic factors. Another scenario may be that the association between hypodensity and activation is coincidental, with the less dense cells being immature.

EOSINOPHIL TISSUE ACCUMULATION

Eosinophils migrate to the lungs and the gastrointestinal tract during their normal development ([60] , [61]) and, possibly, in response to environmental factors as part of a role in innate defense against parasites. The mechanisms involved in the selective tissue recruitment of eosinophils across the vascular endothelium and into tissues in allergic reactions occur sequentially in four well-defined steps. These include (a) the *tethering* of the eosinophil to the luminal surface of the vascular endothelium during normal transport through the blood vessel, (b) the *rolling* of the eosinophil along the luminal surface of the activated endothelium in a reversible manner, (c) firm *adhesion* of the eosinophil to endothelial cells, and (d) *transmigration* of the eosinophil through the endothelium into target tissues (Fig. 11.4). A further, less understood step in eosinophil trafficking in the tissues is the *in situ* differentiation of circulating committed Eo/B precursors. Most migration through endothelium occurs at postcapillary venules. Each of these steps is controlled by a complex network of chemotactic factors and adhesion molecules that collectively direct the movement of the eosinophil into the tissues. For eosinophils, selectins and a $_4$ integrins are thought to be important in tethering and rolling, whereas a $_4$ and ß $_2$ (CD18) integrins mediate firm adhesion. The transmigration step is believed to be primarily regulated by ß $_2$ integrins as well as C-C chemokines such as eotaxin. Cytokines and chemokines are elaborated by surrounding tissues to modulate the transmigration of eosinophils into tissues. Many of these mechanisms appear to be controlled at the level of the T-cell response to antigen (allergen)-presenting cells and the subsequent release of cytokines and chemokines, which, in turn, regulate the activity of eosinophils.

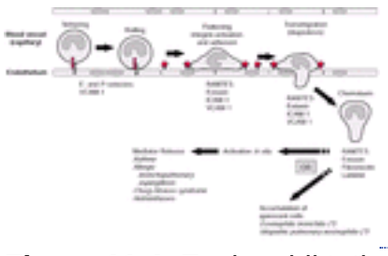

Figure 11.4. Eosinophil tethering, rolling, adhesion, transmigration, and chemotaxis in response to inflammatory signals in tissues. During chemotaxis, eosinophils may either become activated in response to local inflammation and release mediators, as in asthma and other related conditions, or accumulate in tissues in the apparent absence of mediator release. ICAM-1, intercellular adhesion molecule; RANTES, regulated on activation, normal T-cell expressed and secreted; VCAM-1, vascular cell adhesion molecule-1.

Tethering and Rolling

Our knowledge of the mechanisms involved in eosinophil interactions with the endothelium extends primarily from *in vitro* assays of leukocyte adhesion to cultured human umbilical vein endothelial cells (HUVECs) both in stable and under flow conditions. Antibodies specific for adhesion molecules have been applied in this system and have identified critical regulatory molecules required for adhesion and transmigration of eosinophils. Tethering and rolling of eosinophils on HUVECs under flow conditions are regulated by selectins [L-selectin (CD62L)] expressed on the eosinophil surface interacting with E- and P-selectins (CD62E and CD62P, respectively) on endothelial cells ([62]). Selectins are characterized by a lectin-binding domain that is involved in the initial anchoring of inflammatory cells to the venular endothelium. This interaction is enhanced after the release of inflammatory mediators from these cells as well as neighboring tissues. Once tethered, eosinophils roll until they become stimulated by a chemoattractant stimulus (indicating local inflammation), which induces activation of a $_4$ integrin receptors on the leukocyte. In addition, rolling appears to facilitate the subsequent adherence and transmigration of eosinophils into tissues. Eosinophils also express P-selectin glycoprotein ligand-1 and the integrins a $_4$ß $_1$ (VLA-4) and a $_4$ß $_7$, which are involved in cell rolling ([62]). Eosinophil integrins bind to target sites in the endothelium, primarily intercellular adhesion molecule (ICAM)-1 (CD54) and vascular cell adhesion molecule (VCAM)-1 (CD106) through their Mac-1 (a ß $_2$ integrin, also known as *CR3* or *CD11b*/ *CD18*) and VLA-4 (a $_4$ß $_1$ integrin) receptors, respectively. The constitutive expression of VLA-4 (a $_4$ß $_1$ integrin) is limited to a small number of leukocytes, including eosinophils, monocytes, basophils, and T cells, suggesting that regulated expression of its ligand, VCAM-1, on endothelial cells may be important in selective recruitment of these cells ([63]).

Adhesion

The firm adhesion of eosinophils involves the interaction of a $_4$ and ß $_2$ integrins with the endothelial layer. Specifically, eosinophils adhere to tumor necrosis factor

(TNF)-a–, IL-1ß–, and lipopolysaccharide-activated HUVECs through CR3/ICAM-1 and VLA-4/VCAM-1 interactions ([63], [64], [65], [66] and [67]). Other adhesion molecules that may contribute to this process are leukocyte function-associated antigen-1, VLA-6 (a $_4$ß $_1$), a $_4$ß $_7$ integrin, p150,95, and CD11d. Eosinophils exhibit differential binding properties through VCAM-1 and ICAM-1, which are dependent on their activation status. Freshly prepared unstimulated eosinophils preferentially bind to endothelial VCAM-1 via VLA-4 (a $_4$ß $_1$) rather than ß $_2$ to ICAM-1 ([24], [24], [68]). Once activated, eosinophil preference for VCAM-1 shifts to that of endothelial ICAM-1 via ß $_2$ integrins ([24], [69], [70] and [71]). During extravasation (diapedesis) into tissues, the eosinophil becomes progressively more activated on contact with extracellular matrix proteins and other stimulated cells. Tissue eosinophils from an antigen challenge model express increased CD11, CD69, and ICAM-1 ([72]). Eosinophil binding in tissues switches to ICAM-1 and the connecting segment-1 region of tissue fibronectin ([62], [69], [73]). The change in the activation status is also confirmed by the changes in the expression of cell-surface molecules seen as the eosinophil goes through tissue. Eosinophils recovered from bronchoalveolar lavage (BAL) express increased ICAM-1, Mac-1, CD69, and decreased L-selectin, suggesting an activated state ([42]).

Cytokines such as IL-4 and IL-13 have been shown to up-regulate eosinophil adhesion, primarily through up-regulation of VCAM-1 on endothelial cells ([74], [75]). The effects of IL-4 and IL-13 are mediated through Jak3 and the nuclear transcription factor STAT-6 ([76], [77]). Interestingly, a decrease in tissue eosinophilia has been observed in allergen-challenged STAT-6 $^{-/-}$ mice, in spite of high levels of VCAM-1 expression ([77]). This difference was thought to be due to decreased expression of CCR3 in eosinophils, which is directly controlled by STAT-6 ([78]). Results from STAT-6 $^{-/-}$ mice would suggest that IL-4 and IL-13 also have a role in the induction of CCR3 on eosinophils and T cells. These findings underline the importance of cytokine and chemokine cross-talk in the generation of blood eosinophilia and tissue diapedesis.

The switch to ICAM-1–mediated adhesion and transmigration may be associated with facilitation of eosinophil entrance into the tissue. Increased ß $_1$ expression (VCAM associated) has been shown to slow eosinophil migration compared with ICAM-1/ß $_2$ ([79]). It is important to note that anti–VLA-4 antibodies may not prevent eosinophil migration into tissue if ICAM-1 or P-selectin sites are the first targets for activated eosinophils ([62]).

IL-5 also up-regulates eosinophil, but not neutrophil, adhesion to unstimulated endothelium, offering a selective pathway of eosinophil adhesion ([64]). IL-5 has been shown to activate transendothelial migration of eosinophils through ICAM-1 via decreased ß $_1$ and increased ß $_2$ integrin expression ([80]). Similarly, stimulation of eosinophil CCR3 with a chemo-kine such as eotaxin, which can be released from endothelial cells, also increases ß $_2$ integrin expression, resulting in preferential binding to ICAM-1 ([81]). Thus, numerous cytokines and chemokines have been shown to enhance eosinophil adhesion to endothelium.

Complement proteins are also important in eosinophilic trafficking in tissues. Complement-mediated inflammation, as seen with parasite infection, is associated with the release of C3a and C5a. Whereas C3a increases binding of eosinophil to endothelium but does not increase migration, C5a increases both adhesion and migration ([82]). VCAM-1 and ICAM-1 are involved in complement-mediated binding and migration of eosinophils, as this process is blocked by the application of anti-a $_4$ and -ß $_2$ antibodies. These findings illustrate the importance of adhesion molecules VCAM-1 and ICAM-1 in the complement-mediated pathway of anaphylaxis and host defense.

Other more general inflammatory cytokines, such as IL-1 and TNF, are also released by inflamed tissues and have significant effects on eosinophil migration ([62]). Messages encoding both IL-1 and TNF are increased in the airways of symptomatic as opposed to nonsymptomatic asthmatics ([83]), and IL-1 is increased in tissues from sites of cutaneous allergy ([84]). Antibodies to IL-1 have been shown to decrease the expression of VCAM-1 and ICAM-1 in endothelial cells ([85]). Mice deficient in IL-1 expression (IL-1 $^{-/-}$) have decreased eosinophil rolling, adhesion, and transmigration ([86]). TNF has also been shown to increase expression of endothelial ICAM-1, VCAM-1, P-selectin, and E-selectin, causing increased eosinophil rolling and adhesion ([87], [88] and [89]). In addition, TNF $^{-/-}$ mice show decreased eosinophil adhesion and migration into tissue, similar to IL-1 $^{-/-}$ mice ([90]). These factors may have important roles in allergic asthma in which preferential accumulation of eosinophils is a feature of atopic (IgE-dependent) inflammatory conditions.

Eosinophils move through the endothelium by extending lamellipodia, thus leading to lamellar motion ([62]). Changes in the binding affinity for adhesion molecules and extracellular matrix proteins are thought to contribute to cell movement on a substratum. A gradient in binding affinity of eosinophil VLA-4 to fibronectin has been demonstrated ([91]), in which increased adherence at the leading edge of the cell is followed by deadherence at the rear of the cell, allowing the cell to move on. Cytokines and chemokines also influence the binding of eosinophils to tissue surfaces, such as GM-CSF, which increases the binding affinity of VLA-4 to VCAM-1 or connecting segment-1 ([92]), and eotaxin, which stimulates the reverse reaction ([81]). In addition, eotaxin may induce cytoskeletal changes via mitogen-activated protein kinases ([62]). Other chemokines or chemotactic factors, such as RANTES, monocyte chemoattractant protein (MCP)-3, and C5a, may also alter ß $_1$ integrin affinity ([69], [93]). The balance of these factors determines the rate of eosinophil migration.

Transmigration and Chemotaxis

Once eosinophils adhere to vascular endothelium, they commence diapedesis, whereby they emerge out of the capillaries and traverse the adjacent connective tissue en route to the focus of the inflammatory response. Although cytokines (e.g., IL-3, IL-5, and GM-CSF) are essential for the development and proliferation of eosinophils, they are likely to play an immunomodulatory role in priming eosinophils for better chemotactic responses to target tissue sites. The most potent eosinophil chemoattractants include PAF, leukotriene D $_4$, C5a, IL-2, and C-C chemokines such as eotaxin and RANTES ([94], [95]). C-C chemokines appear to be essential for inducing the specific migration of eosinophils to inflamed sites. Several distinct families of chemokines have been identified, and the CCR3-binding family in particular plays a crucial role in generating tissue eosinophilia due to the nearly exclusive expression of CCR3 in eosinophils ([24]). This family of chemokines consists of eotaxin ([1], [2] and [3]); RANTES; MCP-2, -3, and -5; and macrophage inhibitory protein (MIP)-1a. Chemokines binding CCR3 may be selective for granulocytes such as eosinophils and basophils, as neutrophils do not express this receptor. Eotaxin is the only chemokine specific to eosinophils, making it a key member of the CCR3 family ([94], [96]). CCR3 chemokines are produced by endothelial cells, epithelial cells, T cells, macrophages, fibroblasts, and eosinophils, among other tissue sources ([32], [97]).

Basal expression of eotaxin in the gut is elevated compared with other tissues in the normal animal ([98]). During allergen-induced eosinophilia, eotaxin expression is further increased within tissues ([99]). Some synergism exists between IL-5 and eotaxin, as IL-5 stimulation enhances the eosinophil response to eotaxin both *in vitro* and *in vivo* ([100], [101]). To define the specific role of eotaxin in inflammation, eotaxin gene knock-out (Eo $^{-/-}$) mice have been deployed ([60], [102]). These mice produce IL-5 normally and, thus, continue to develop blood eosinophilia similar to their wild-type heterozygotes. However, Eo $^{-/-}$ mice do not develop tissue eosinophilia. Thus, the primary role of CCR3 appears to be involved in the homing of circulating eosinophils to target tissues expressing eotaxin.

Additional chemokines of the CCR3 family have been shown to exert important effects in situations in which eotaxin may not be necessarily essential to the response ([62], [103]). Each chemokine appears to have a unique role in the timing and location of tissue eosinophilia. Peripheral blood levels and cultured mononuclear cells from patients with allergic dermatitis produce increased levels of RANTES, MCP-1, and MIP-1a compared with nonallergic controls ([104]). Similar to eotaxin, IL-5–stimulated eosinophils have an increased affinity for RANTES. However, unlike eotaxin, RANTES was specifically associated with exacerbations of eosinophilic bronchitis, thought to be provoked by viral infection. Infections with respiratory syncytial virus leading to eosinophilia have been correlated with increased RANTES, MCP-1, and MIP-1a expression ([105], [106]). Children with asthma have large increases in eosinophil-associated MBP, RANTES, and MIP-1a in their nasal secretions during naturally acquired viral infections ([107]). Therefore, the apparently broader range of effects of RANTES, MIP-1a, and MCP-1 may also increase the range of eosinophil activity in disease, even though all of these bind specifically to CCR3 on eosinophils.

Other factors are also produced in mucosal tissues that are moderately or strongly chemotactic for eosinophils. These include bacterial products [e.g., endotoxin and the tripeptide f-Met-Leu-Phe (fMLP)], the anaphylatoxin complement factor, C5a, opsonized particles [which exert their effect via complement (CR1, CR3) and Fc?RII receptors], and other cytokines (IL-4, IL-8, and, possibly, IL-13). In addition, the lipid-derived mediators leukotriene B $_4$ (LTB $_4$) and PAF, which are elevated in allergic responses and induce eosinophil respiratory burst and degranulation at higher doses ([23], [33], [108], [109]), are also eosinophilotactic. Eosinophil cytokines IL-3, IL-5, and GM-CSF are able to enhance the chemotactic ability of each of these factors. Although PAF antagonists are not sufficient at preventing eosinophilic inflammation in allergy, treatment of allergic individuals with leukotriene modifiers has been effective at reducing eosinophil numbers and inhibiting eosinophil activation ([110]).

Eosinophils also express a range of receptors for Igs that may contribute to chemotactic and activation responses in tissues. These include receptors for IgA, IgD, IgE, IgG, and IgM, which may possess up to three chains (a, ß, and ?). Some controversy has surrounded the existence of the high-affinity receptor for IgE (FceRI) on eosinophils. Recent studies have shown that the a subunit of FceRI in eosinophils is expressed intracellularly rather than on the cell surface in resting cells, which may be mobilized to the surface and released during activation ([111], [112]). Interestingly, although murine FceRI contains a, ß, and ? subunits, the human homolog lacks the ß subunit, suggesting that this subunit is redundant in signaling in cells expressing FceRI. Eosinophils express an IgE-binding protein, galectin-3 (Mac-2/e–binding protein), as well as the low-affinity FceRII (CD23), which may have contributed to apparent high-affinity binding for IgE in earlier studies. Cross-linking of Ig receptors on eosinophils has been shown to be highly effective at inducing respiratory burst and eosinophil-derived neurotoxin (EDN) degranulation in eosinophils, with a hierarchy of effectiveness in degranulation demonstrated to be in the order of secretory IgA = IgA > IgG ≫ IgE ([113]). Eosinophil cytokines such as IL-3, IL-5, and GM-CSF were demonstrated to enhance this process ([114]). IgA, particularly the secretory isoform, is an important mucosal antibody involved in supporting the body's first line of defense. Thus, the sensitivity of the eosinophil to IgA is in agreement with its proposed role in protection against invasive organisms in mucosal tissues.

EOSINOPHIL MEDIATORS

The eosinophil is considered to be both a factory and a store for a large array of mediators that are released on activation and are thought to be important in various inflammatory reactions associated with this cell (Fig. 11.5).

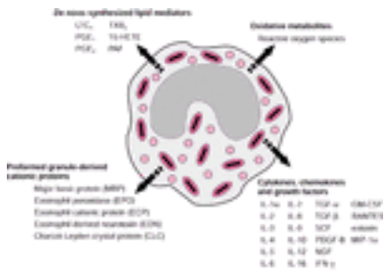

Figure 11.5. Mediators released by activated eosinophils. *De novo*–synthesized lipid mediators and oxidative metabolites are elaborated directly from cell membrane or lipid bodies after enzyme activation, whereas granule-derived cationic proteins and cytokines, chemokines, and growth factors are released after granule-plasma membrane fusion during degranulation. GM-CSF, granulocyte-macrophage colony-stimulating factor; 15-HETE, 15-hydroxyeicosatetraenoic acid; IFN, interferon; IL, interleukin; LTC $_4$, leukotriene C $_4$; MIP, macrophage inhibitory protein; NGF, nerve growth factor; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PG, prostaglandin; RANTES, regulated on activation, normal T-cell expressed and secreted; SCF, stem cell factor; TGF, transforming growth factor; TXB, thromboxane B.

Membrane-Derived Mediators

Eosinophils produce a wide variety of lipid-derived mediators that have profound biologic activity. The more important products are eicosanoids, which include leukotrienes (especially LTC $_4$), prostaglandins (PGs) (especially PGE $_2$), thromboxane, and lipoxins (especially lipoxin A $_4$), as well as PAF. The main substrate for these mediators is arachidonic acid (AA), which is specifically liberated from membrane phospholipids possessing this fatty acid at the *sn*-2 position by phospholipase A $_2$ (PLA $_2$) during receptor stimulation. Of the nine known families of PLA $_2$, two families are expressed in eosinophils: the type IIA and type IV enzymes, commonly known as *secretory* (s) and *cytosolic* (c) *PLA* $_2$, respectively ([115], [116]). These enzymes are distinguished by their distribution, size, and sensitivity to Ca $^{2+}$. Thus, granule-stored sPLA $_2$ (13 to 15 kd) requires millimolar amounts of Ca $^{2+}$ for activity, whereas cytosolically localized cPLA $_2$ (85 kd) is catalytically active in the presence of micromolar amounts of Ca $^{2+}$. Interestingly, eosinophils express 20- to 100-fold higher levels of sPLA $_2$ in their granules than other circulating leukocytes, suggesting a functional role in inflammatory processes involving eosinophil degranulation.

Eosinophils are a rich source of LTC $_4$ (5S-hydroxy-6R, S-glutathionyl-7,9,- *trans*-11,14- *cis*-eicosatetraenoic acid) ([117], [118]). Stimulation with the calcium ionophore A23187 generates up to 40 ng per 10 ^{6} cells of LTC $_4$ from normal-density eosinophils, whereas light-density eosinophils elaborate 70 ng per 10 ^{6} cells. Eosinophils produce negligible amounts (6 ng per 10 ^{6} cells) of LTB $_4$ (5S-12R-dihydroxy-6,14- *cis*-8,10- *trans*-eicosatetraenoic acid) compared with up to 200 ng per 10 ^{6} cells from neutrophils. LTC $_4$ generation by human eosinophils was also observed after stimulation with both opsonized zymosan and via an Fc?RII-dependent mechanism using Sepharose beads coated with IgG ([50]). Release was maximal at 45 minutes, greater in hypodense eosinophils than in normal-density eosinophils, and enhanced by fMLP. The production of LTC $_4$ is critically dependent on the activation of 5-lipoxygenase, an enzyme that resides in the euchromatin region of the nucleus that translocates to the nuclear membrane on cell activation, where it activates an 18-kd protein called *FLAP* (5-lipoxygenase-activating protein) ([119]). The substrate for 5-lipoxygenase is AA, which may be released from membrane phospholipids by PLA $_2$. The first product of this enzyme is the intermediary compound 5-HPETE (5-hydroperoxyeicosatetraenoic acid), which is transformed into the unstable epoxide LTA $_4$. At this point, human eosinophils predominantly generate LTC $_4$ through the action of LTC $_4$ synthetase ([117], [118]). Eosinophils are particularly rich in LTC $_4$ synthetase and account for 70% of all LTC $_4$ synthetase–positive cells in the airway mucosa of normal and asthmatic individuals ([120]). LTC $_4$ is generated intracellularly in human eosinophils stimulated with the calcium ionophore A23187. LTC $_4$ is later exported from the cell in a regulated manner ([121]).

The production of 15-HETE (15-hydroxyeicosatetraenoic acid) via the 15-lipoxygenase pathway occurs in activated eosinophils. 15-Lipoxygenase may be distinguished from 5-lipoxygenase in that it can modify a larger pool of fatty acid substrates than the latter enzyme and oxygenates fatty acids that are esterified in phospholipids. Substrates include AA, linoleic acid, polyenoic acids, and more complex lipids, such as lipoproteins. Eosinophils are capable of generating 100 to 300 times more 15-HETE than neutrophils, endothelial cells, and fibroblasts ([122]), and eosinophils also account for 85% of cells positive for 15-lipoxygenase in the airway submucosa of normal and asthmatic subjects, which was elevated in asthmatic airways ([123]).

Eosinophils generate large amounts of PAF after stimulation with calcium ionophore, opsonized zymosan, or IgG-coated Sepharose beads ([124], [125], [126] and [127]). PAF (1- *O*-alkyl-2-acetyl- *sn*-glycerol-3-phosphocholine) is a potent phospholipid mediator that causes leukocyte activation. For instance, eosinophils elaborated 25 ng per 10 ^{6} cells of PAF after stimulation with calcium ionophore and up to 2 ng per 10 ^{6} cells after IgG stimulation. Much of the PAF remained cell associated, possibly acting as an intracellular messenger or alternatively binding to PAF receptors on eosinophils (thus acting as an autocrine agent). Interestingly, stimulation of eosinophils with fMLP did not augment PAF release, and hypodense eosinophils from patients with a marked eosinophilia released less PAF than normal eosinophils. [^{3}H]PAF added to hypodense eosinophils was more rapidly incorporated into the phospholipid pool than [^{3}H]PAF with normal-density cells ([126]). This suggested that hypodense eosinophils were metabolizing the exogenous PAF at a greater rate than normodense cells and may explain why stimulation with fMLP did not result in an increased amount of PAF generation. As with leukotriene synthesis, eosinophil-derived release of PAF was maximal at 45 minutes. Regulated PAF production is controlled by the release of biologically inactive lyso-PAF from membrane phospholipids by PLA $_2$, which is later acetylated to form PAF by an acetyltransferase ([125]).

The cyclooxygenase pathway is prominent in eosinophils as well, and eosinophils are capable of producing PGE $_1$ and PGE $_2$, as well as thromboxane B $_2$ from cyclooxygenase acting on free AA. In studies with guinea pig eosinophils, thromboxane B $_2$ and PGE $_2$ were shown to be generated after PAF or A23187 stimulation ([128], [129]).

Many of the enzymes associated with membrane-derived mediator release from eosinophils, including cyclooxygenase and 5-lipoxygenase, are found stored in association with lipid bodies (Table 11.1) ([130], [131] and [132]).

TABLE 11.1. Content of Human Eosinophil Granules and Secretory Vesicles

Crystalloid Granules	Primary Granules	Small Granules	Lipid Bodies	Secretory Vesicles
Core				
Catalase				
Cathepsin D				
Enoyl-CoA-hydrolase				
ß-Glucuronidase				
Major basic protein				
Matrix				
Acid ß-glycerophosphatase		Elastase	Esterase	
Acid phosphatase	Charcot-Leyden crystal protein (galectin-10)	Acid phosphatase	Arachidonic acid	Plasma proteins [albumin]
Acyl-CoA oxidase		Arylsulfatase B (active)	Cyclooxygenase	
Arylsulfatase B (inactive)		Catalase	Eosinophil peroxidase	
Bactericidal/permeability-increasing protein		Eosinophil cationic protein	5-Lipoxygenase	
Catalase			15-Lipoxygenase	
Cathepsin D			Leukotriene C_4 synthase	
Collagenase				
Elastase				
Enoyl-CoA-hydrolase (also in core)				
Eosinophil cationic protein				
Eosinophil-derived neurotoxin				
Eosinophil peroxidase				
Flavin adenine dinucleotide				
ß-Glucuronidase				
ß-Hexosaminidase				
3-Ketoacyl-CoA thiolase				
Lysozyme				
Major basic protein				
Nonspecific esterases				
Phospholipase A_2 (type II)				
Membrane				
CD63				Cytochrome b_{558} [p22 *phox*]
V-type H^+-adenosine triphosphatase				Vesicle-associated membrane protein-2

CoA, coenzyme A.

Granule-Derived Proteins

Eosinophils contain at least five different populations of phospholipid bilayer membrane-bound granules.

Crystalloid granules These specialized and unique granules measure between 0.5 and 0.8 µm in diameter, contain crystalline electron-dense cores (internum) surrounded by an electron-lucent matrix, and can take up acidic dyes avidly due to their cationic nature ([2], [133]). They are mainly present in mature eosinophils, although coreless granules have been observed in immature eosinophils. These granules contain the bulk of highly charged cationic proteins present in eosinophils, including MBP, eosinophil peroxidase (EPO), eosinophil cationic protein (ECP), and EDN. There are approximately 200 crystalloid granules in each cell. The core is predominantly comprised of crystallized MBP (Fig. 11.6).

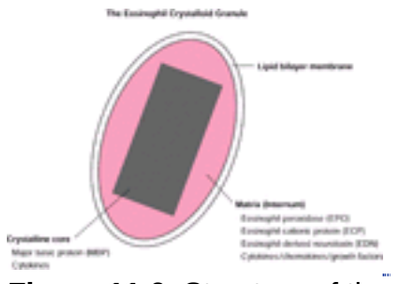

Figure 11.6. Structure of the eosinophil crystalloid granule. This membrane-bound organelle is a major site of storage of eosinophil cationic granule proteins as well as a number of cytokines, chemokines, and growth factors.

Primary granules These coreless granules are enriched with Charcot-Leyden crystal (CLC) protein and are present in immature as well as mature eosinophils. Some authors refer to immature crystalloid granules as *primary granules in eosinophil promyelocytes*. These measure between 0.1 and 0.5 µm in diameter and are less abundant than crystalloid granules.
Small granules These granules are also free of cores and contain acid phosphatase, arylsulfatase B, catalase, and cytochrome b_{558}.
Lipid bodies There are approximately five lipid bodies per mature eosinophil, the number of which increases in certain eosinophilic disorders, especially in idiopathic hypereosinophilia. Lipid bodies are enriched in AA esterified into glycerophospholipids.
Secretory vesicles Eosinophils are densely packed with small secretory vesicles in their cytoplasm. These vesicles appear as dumbbell-shaped structures in cross sections and contain albumin, suggesting an endocytotic origin. These structures are also known as *microgranules* or *tubulovesicular structures*. Eosinophil MBP (13.8 kd) is an arginine-rich 117-amino acid protein that constitutes a significant proportion of total cell protein in human eosinophils (5 to 10 pg per cell). MBP was originally named for its abundance in guinea pig eosinophils, which contain as much as 250 pg per cell, making up 50% of the total cellular protein ([134]). The high isoelectric point of MBP (10.9) cannot be measured accurately due to the extremely basic nature of the protein ([135]). MBP has been shown to be cytotoxic to airway tissues, including bronchial epithelial cells and pneumocytes. Thus, MBP may be at least partly responsible for tissue damage associated with eosinophil infiltration into the bronchial mucosa in asthma ([2]). Indeed, airway sections from patients with status asthmaticus exhibit intense MBP-specific immunofluorescence, suggesting that infiltrated eosinophils were fully activated, undergoing extracellular secretion of their contents of MBP ([136]). The effects of MBP, in the absence of opsonization, on target cells such as parasites is thought to result from increased membrane permeability through surface charge interactions leading to perturbation of the lipid bilayer ([137]). MBP is synthesized during the promyelocytic stage of eosinophil development, characterized by the presence of message encoding this protein, in a neutral prepro-form that is later processed to form pro-MBP, which is subsequently transported to the immature crystalloid granule and cleaved to form MBP ([138], [139]). Mature MBP undergoes condensation from the periphery of immature crystalloid granules to the internum, where it develops a crystalline core as its concentration is increased ([139], [140]). Once eosinophils have reached full maturity, MBP is no longer synthesized, and messenger RNA encoding MBP disappears from the cell ([139], [141]). MBP acts on other inflammatory cells, including neutrophils and eosinophils, to induce degranulation and lipid mediator release ([142], [143]). Other eosinophil basic proteins include EPO, ECP, and EDN, which reside in the matrix compartment of the crystalloid granule. EPO is a highly basic [isoelectric point (pI) of 10.9] heme-containing protein composed of two subunits: a heavy chain of 50 to 57 kd and a light chain of 11 to 15 kd. EPO is a haloperoxidase with 68% sequence identity to neutrophil myeloperoxidase, suggesting that a peroxidase multigene family may have developed through gene duplication ([135], [144]). Eosinophils store

approximately 15 pg per cell of EPO, which is important in catalyzing the peroxidative oxidation of halides and pseudohal-ides, leading to the formation of bactericidal hypohalous acids, particularly hypobromous acid, in reaction with superoxide generated during respiratory burst ([145], [146] and [147]). The molecular mass of ECP is between 16 and 21 kd, with approximately 15 pg per cell expressed in human eosinophils. The pI of ECP (10.8) is identical to that of MBP due to a similar arginine-rich sequence. Early studies have demonstrated that ECP, a member of a subfamily of RNase (ribonuclease) A multigenes that possesses intrinsic RNase activity, is bactericidal, promotes degranulation of mast cells, and is toxic to helminthic parasites on its own ([148], [149]). The mechanism of action of ECP is thought to involve the formation of pores or channels in the target membrane, which is apparently not dependent on its reversible RNase activity ([150]). ECP is perhaps most well known for its ability to elicit the Gordon phenomenon when it was injected into the cranial ventricles of rabbits, causing the destruction of Purkinje cells and leading to spongiform changes in the cerebellum, pons, and spinal cord ([151], [152]). EDN, another member of the RNase A multigene family, of 18.5 kd with approximately 100-fold higher RNase activity than ECP, is less basic than MBP or ECP with a pI of 8.9 due to a relatively smaller number of arginine residues in its sequence. ECP and EDN share a remarkable sequence homology of 70% at the amino acid level for the pre-form of both proteins, suggesting that evolutionarily, these proteins are derived from the same gene ([153], [154]). Eosinophils express approximately 10 pg per cell of EDN, but there is marked variation between individuals. EDN similarly induces the Gordon phenomenon when injected intracranially in laboratory animals ([151], [152]). Messenger RNA encoding EPO, ECP, and EDN has been detected in mature eosinophils, suggesting that eosinophils have the capacity to continue to synthesize these proteins in their end-differentiated state ([141]). Recent findings have suggested that the gene family expressing ECP and EDN has one of the highest rates of mutation in the primate genome, ranking with those of Igs, T-cell receptors, and major histocompatibility complex classes ([154]). These genes effectively comprise a superfamily of RNases expressed in the mammalian genome. Such an extreme rate of mutation suggests that the evolutionary constraints acting on the ECP/EDN superfamily have promoted the acquisition of a specialized antiviral activity. This may be inferred from the high mutation rates of other genes commonly associated with host protection against viral infection. Whether ECP or EDN possess any antiviral activity has yet to be demonstrated, although some studies have indicated that EDN and EPO may be potent antiviral factors in respiratory infections ([155]). The CLC protein (17.4 kd) is produced in eosinophils at very high levels (accounting for 10% of the total cellular protein), although its functional role is still obscure. CLC is a hydrophobic protein with strong sequence homology to the carbohydrate-binding galectin family of proteins and has been designated *galectin-10* ([156]). CLC is released in large quantities in the tissues in eosinophilic disorders, resulting in the formation of distinct, needle-shaped structures that are colorless and measure 20 to 40 µm in length and 2 to 4 µm across. CLCs are abundant in the sputum and feces of patients with severe respiratory and gastrointestinal eosinophilia, which were first observed by Charcot and Robin in 1853. A list of these and other granule proteins synthesized and stored in eosinophils is presented in Table 11.1 and published elsewhere ([23], [157], [158]).

Eosinophil-Derived Cytokines

Human eosinophils have been shown to produce up to 29 different cytokines, chemokines, and growth factors (Table 11.2) with the potential to regulate various immune responses. These cytokines have been identified in eosinophils by detecting mRNA or protein (or both) using reverse transcriptase-polymerase chain reaction, *in situ* hybridization, and immunocytochemical staining ([159], [160] and [161]). In addition, picogram amounts of cytokines, chemokines, and growth factors were measured in supernatants of stimulated eosinophils ([160], [162]). These cytokines are likely to act in an autocrine, paracrine, or juxtacrine manner, thereby regulating local inflammatory events. Studies have demonstrated that the production of eosinophil-activating cytokines (e.g., IL-3 and GM-CSF) by eosinophils may be important in prolonging the survival of these cells by a putative autocrine loop ([34], [160]). For instance, the adherence of highly purified eosinophils to the extracellular matrix protein fibronectin resulted in prolonging the survival of these cells in the absence of exogenous cytokines ([34]). Fibronectin-induced eosinophil was inhibitable by antibodies against fibronectin and VLA-4 and up-regulated by picogram amounts of IL-3 and GM-CSF derived from eosinophils ([34]). Observations on eosinophil cytokine release have been mainly studied *in vitro*, but a few have been confirmed *in vivo* ([163], [164], [165] and [166]).

TABLE 11.2. Cytokines, Chemokines, and Growth Factors Produced by Human Eosinophils

Cytokine	Product	Stored Protein in Resting Cells (per 10^6 cells)	Intracellular Site of Storage
Interleukins			
Interleukin-1a	mRNA protein	—	—
Interleukin-2	mRNA protein	6 ± 2 pg	Crystalloid granules (core)
Interleukin-3	mRNA protein	—	—
Interleukin-4	mRNA protein	~75 ± 20 pg	Crystalloid granules (core)
Interleukin-5	mRNA protein	—	Crystalloid granules (core/matrix?)
Interleukin-6	mRNA protein	25 ± 6 pg	Crystalloid granules (matrix)
Interleukin-9	mRNA protein	—	—
Interleukin-10	mRNA protein	~25 pg	—
Interleukin-11	mRNA protein	—	—
Interleukin-12	mRNA protein	—	—
Interleukin-13	mRNA protein	—	—
Interleukin-16	mRNA protein	1.6 ± 0.8 ng	—
Leukemia inhibitory factor	mRNA protein	—	—
Interferons and others			
Interferon-?	mRNA protein	—	—
Tumor necrosis factor	mRNA protein	—	Crystalloid granules (matrix)
Granulocyte-macrophage colony-stimulating factor	mRNA protein	15.1 ± 0.3 pg	Crystalloid granules (core)
Chemokines	mRNA protein		
Eotaxin	mRNA protein	19 ± 4 pg	Crystalloid granules
Interleukin-8	mRNA protein	<3 pg	Cytoplasmic
Macrophage inflammatory protein-1a	mRNA protein	—	—
MCP-1	Protein	—	—
MCP-3	mRNA	—	—

MCP-4	mRNA	—	—
RANTES	mRNA protein	72 ± 15 pg	Crystalloid granules (matrix) and small secretory vesicles
Growth factors			
Heparin-binding epidermal growth factor–like binding protein	mRNA	—	—
Nerve growth factor	mRNA protein	4 ± 2 pg	—
Platelet-derived growth factor B-chain	mRNA	—	—
Stem cell factor	mRNA protein	—	Membrane, cytoplasm
TGF-a	mRNA protein	22 ± 6 pg	Crystalloid granules (matrix) and small secretory vesicles
TGF-ß1	mRNA protein	—	—

MCP, monocyte chemoattractant protein; mRNA, messenger RNA; RANTES, regulated on activation, normal T-cell expressed and secreted; TGF, transforming growth factor.

A major distinction in cytokine production between eosinophils and T cells is that the former store their cytokines intracellularly as preformed mediators. Although many eosinophil-derived cytokines are elaborated at lower concentrations than other leukocytes, eosinophils possess the ability to release these cytokines immediately (within minutes) after stimulation. Stored cytokines include IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, IL-16, GM-CSF, TNF, eotaxin, IL-8, RANTES, nerve growth factor, and TGF-a. Studies using immunogold electron microscopic analysis or confocal laser-scanning microscopy coupled with double immunofluorescence labeling have indicated that several of these cytokines are found in close association with either the crystalline core or matrix of the crystalloid-specific granules of the cell (Table 11.2) ([161] , [167] , [168] , [169] , [170] , [171] and [172]). For example, RANTES was found to be associated predominantly with the matrix compartment of the crystalloid granule in eosinophils (Fig. 11.7).

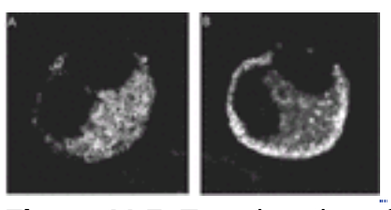

Figure 11.7. Translocation of the chemokine RANTES (regulated on activation, normal T-cell expressed and secreted) in human eosinophils activated by interferon-? *in vitro*. Immunoreactivities for RANTES (green fluorescence) and eosinophil major basic protein (MBP) (red fluorescence) are shown in control **(A)** and IFN-?–stimulated (10 minutes, 500 U/ml) **(B)** cells. The yellow color **(B)** resulted from co-localization of green and red immunofluorescence stains. Note that immunoreactivity for MBP remained associated with the cores of the crystalloid granules in both cells, whereas the green label for RANTES translocated toward the cell membrane. RANTES was proposed to be released from eosinophils by piecemeal degranulation. See Color Plate. (Experimental conditions described in Lacy P, Mahmudi-Azer S, Bablitz B, et al. Rapid mobilization of intracellularly stored RANTES in response to interferon-gamma in human eosinophils. Blood 1999;94:23–32.)

Developing eosinophils possess the ability to express cytokine message and protein at early stages of maturation. Eosinophils generated from semisolid culture of cord blood–derived $CD34^+$ cells in the presence of IL-3 and IL-5 were shown to express IL-5 and GM-CSF mRNA after 10 days of culture ([173]). Freshly purified $CD34^+$ cells expressed IL-4 and RANTES mRNA but not IL-4 and RANTES protein. On day 23 of culture, IL-4 and RANTES immunofluorescence were found localized to the matrix of MBP^+ crystalloid granules ([174]). In addition, IL-6 protein expression was found in cells after day 16 of culture ([140]).

Another site of storage of cytokines and chemokines is within the small secretory vesicle. At least two such proteins were shown to be associated with these vesicles—namely, RANTES and TGF-a immunolabeling ([161]). These organelles ([175]) belong to the same group of secretory vesicles identified by electron microscopy analysis as tubulovesicular structures. RANTES-positive vesicles are highly sensitive to stimulation by IFN-? and are rapidly mobilized (within 10 minutes of stimulation) to secrete RANTES extracellularly ([161] , [176]). Crystalloid granules, which also contain RANTES within their matrix compartment, were found to release this chemokine more slowly in response to IFN-? (1 hour), whereas the majority of MBP remained associated with the core of these granules. These observations suggest that eosinophils have the ability to "shuttle" RANTES from the crystalloid granules to the cell exterior and may provide an important *in vitro* model for eosinophil piecemeal degranulation (PMD) (see section Degranulation Mechanisms).

The bioactivity of cytokines from eosinophils has also been explored to determine the potential physiologic effects of these factors. Studies have shown that IL-2, IL-4, IL-12, IL-16, GM-CSF, RANTES, and TGF-ß derived from eosinophils are capable of exerting bioactive effects on bystander cells using *in vitro* assays ([32] , [158]). For example, the release of IL-4 from eosinophils was thought to be important in driving the initiation of a T helper cell 2 (Th2)–type response in *Schistosoma mansoni* infection in mice. IL-2 and IFN-? from CD28-stimulated eosinophils were shown to stimulate proliferation in an IL-2–dependent cell line and major histocompatibility complex class II expression on Colo 205 cells, respectively ([177]). These studies have demonstrated that eosinophil-derived cytokines and chemokines have the ability to regulate responses, at least at the level of local inflammatory responses.

Generally speaking, eosinophils produce significantly smaller amounts of cytokines than T cells, B cells, and other cells in the immune system. However, in eosinophilic inflammation, eosinophils outnumber T cells in the tissues by as much as 100-fold. As such, the magnitude of the presence of eosinophils may be a determining factor in regulating immune responses at a local level. The release of eosinophil cytokines often takes place within a much shorter period than T-cell–released cytokines (which may be several hours), as eosinophil-derived cytokines are stored as preformed mediators in crystalloid granules that may be secreted in response to stimuli in a matter of minutes. The implications of eosinophil cytokine production are extensive, such as in the case of IL-4, which may be released from eosinophils to direct Th2 cell differentiation in local lymph nodes. In support of this possibility, eosinophils have been shown to traffic to paratracheal draining lymph nodes (in a mouse model of asthma), where they were demonstrated to function as antigen-presenting cells expressing major histocompatibility complex class II and costimulatory CD80 and CD86 to stimulate $CD4^+$ T cells ([178]). During intimate cell–cell contact, the production of IL-4 and IL-13 is not required in abundance to effect important immunomodulatory events, such as enhanced switching of T cells to the Th2 phenotype and increased IgE synthesis, both of which are hallmarks of allergic disorders ([179] , [180]).

The recognition of the capacity of the eosinophil to synthesize and release these cytokines has introduced a new paradigm shift toward understanding the potential of the eosinophil as an effector cell in allergic inflammation. However, the full capacity of the eosinophil to elaborate cytokines, the precise microenvironment requirements for such synthesis, and the intracellular pattern of production and storage remain to be the subject of intensive investigation.

Respiratory Burst

Eosinophils undergo respiratory burst concurrently with the release of other mediators during cell activation. *Respiratory burst* is defined as the increase in cell metabolism (measured by the elevated activity of the hexose monophosphate shunt) and oxygen consumption, coupled with the release of reactive oxygen species (ROS). Many stimuli are capable of inducing respiratory burst in eosinophils, including LTB_4, PAF, fMLP, C5a, opsonized particles, and RANTES ([23]). The principal product of respiratory burst is superoxide (O_2^-), a potent oxidant with a highly reactive electron in its outer valence, possessing relatively weak intrinsic microbicidal activity. The function of O_2^- is thought to reside in its ability to dismutate into more reactive ROS, including hydrogen peroxide (H_2O_2) and the hydroxyl radical (OH^-). The reaction of ROS with granule EPO also leads to the formation of hypohalous acids (hypobromous acid) on reaction with EPO produced after eosinophil degranulation. The formation of ROS subsequent to O_2^- generation is dependent on the presence of a number of catalysts, such as superoxide dismutase, which

accelerates the formation of H_2O_2, and the ferrous ion, which induces OH^- production from H_2O_2. O_2^- is also able to react with nitric oxide (NO) produced from nitric oxide synthase (NOS) enzymes (e.g., iNOS, eNOS) to form the highly reactive peroxynitrite ($ONOO^-$), which has been shown to modify tyrosine residues and alter cell function.

The regulated burst of O_2^- production is largely mediated through the activation of a membrane-associated enzyme complex: the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (Fig. 11.8). This enzyme complex is crucial for maintenance of host defense as it mediates the destruction of ROS-sensitive organisms. In addition, overactivation of the NADPH oxidase is likely to be cytotoxic to tissues and has been implicated in the pathogenesis of many eosinophil-related disorders including allergic asthma ([181]). Interestingly, eosinophils possess the ability to generate up to tenfold more superoxide than other phagocytes, including neutrophils, in which the mechanisms associated with NADPH oxidase activation have been studied in greater detail ([182]). The ability of eosinophils to release more O_2^- is thought to be the result of higher levels of expression of the protein components that make up the NADPH oxidase complex ([183] , [184] , [185] , [186] and [187]).

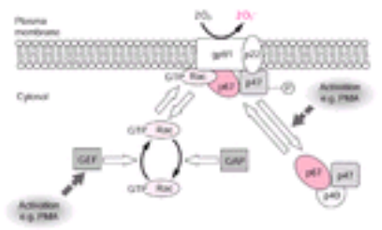

Figure 11.8. Assembly and activation of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex during respiratory burst. This complex is essential for the inducible release of superoxide for microbicidal reactions and is also present in neutrophils. During cell activation, the guanosine triphosphatase (GTPase) Rac, normally bound to guanosine diphosphate (GDP) in the resting cell, is activated by a guanine exchange factor (GEF) to bind to GTP. This results in translocation of Rac-GTP to the cell membrane, where other cytosolic proteins (p67 *phox* and p47 *phox*) have also translocated, to bind to the two subunits of cytochrome b_{558} (gp91 *phox* and p22 *phox*). After the assembly of the oxidase, electrons are transferred from NADPH in the cytosol via flavin adenine dinucleotide (a cofactor) to oxygen molecules to form the highly reactive oxygen intermediate superoxide. Assembly of this complex is reversed by GTPase-activating protein (GAP), which hydrolyzes GTP on Rac to GDP, and by dissociation of the *phox* subunits. PMA, phorbol myristate acetate (a phorbol ester commonly used to activate respiratory burst in granulocytes).

NADPH oxidase is a complex of at least five subunits: two (p22 *phox* and gp91 *phox*) reside in the membrane as part of the cytochrome b_{558} protein. The other three (p67 *phox*, p47 *phox*, and p40 *phox*) remain in the cytosol in resting states ([182]) but assemble to form a complex and to be translocated to the membrane after a phagocytic stimulus. Rac1 or Rac2 is complexed with the guanine dissociation inhibitor RhoGDI. Rac1 and Rac2 are monomeric guanine triphosphatases (GTPases), which exhibit 92% homology in their amino acid sequence, and are functionally interchangeable in their ability to activate NADPH oxidase, although they differ in their tissue distribution. Another potential modulator of the oxidase is the monomeric GTPase Rap1a, although its precise role is unknown. Thus, whereas Rac1 is ubiquitously expressed throughout the body, neutrophils, eosinophils, and other blood cells predominantly express Rac2, which is mainly expressed in hemopoietic tissues ([188] , [189] and [190]). The five minimal components of the NADPH oxidase complex were determined using cell-free assays ([191]), although several other proteins, such as p40 *phox* and Rap1a, may be involved in fine-tuning the activity of the oxidase ([192]).

The pathway leading from receptor stimulation to activation of the oxidase is still poorly understood and appears to exhibit species differences. For example, phorbol esters, such as phorbol myristate acetate, are commonly used as highly potent artificial stimuli to activate respiratory burst in eosinophils in experimental conditions. Phorbol esters are classically known for their ability to directly activate protein kinase C (PKC) ([193] , [194] and [195]). However, the use of pharmacologic inhibitors of PKC has generated paradoxic results in that PKC inhibitors only partially inhibit agonist-induced H_2O_2 release in guinea pig eosinophils ([194] , [196]). In human eosinophils, PKC inhibitors actually augment the rate of oxygen consumption in response to opsonized particles ([197]). These findings suggest that PKC is not critical for agonist-induced respiratory burst in eosinophils, although stimulation of PKC appears to be able to induce superoxide release on its own.

Taken together, eosinophils generate substantial amounts of O_2^- as part of their role in host defense, and the mechanisms associated with the release of this toxic mediator are under investigation. The release of O_2^- from eosinophils is likely to be a crucial component of the pathophysiologic processes underlying eosinophilic inflammation in mucosal tissues.

Degranulation Mechanisms

Degranulation is defined as the exocytotic fusion of granules with the plasma membrane during receptor-mediated secretion. During exocytosis, the outer leaflet of the lipid bilayer membrane surrounding the granule encounters the inner leaflet of the plasma membrane, a process known as *docking*. The docking step is hypothesized to be regulated by intracellular membrane-associated proteins that act as receptors directing the specificity of granule targeting. After docking, the granule and plasma membrane fuse together and form a reversible structure called the *fusion pore*, which is also thought to be regulated by similar, or the same, membrane-associated proteins regulating granule docking. Depending on the intensity of the stimulus, the fusion pore may either retreat, leading to reseparation of the granule from the plasma membrane, or expand and allow complete integration of the granule membrane into the plasma membrane as a continuous sheet. The inner leaflet of the granule membrane becomes outwardly exposed, and the granule contents are subsequently expelled to the exterior of the cell ([198]).

There are four main forms of eosinophil granule release that have been observed *in vitro* and *in vivo* (Fig. 11.9). The first is the classic sequential release of single crystalloid granules, which was the original hypothesis suggested for a predominant route of degranulation in eosinophils. This type of release is typically seen *in vitro* and can be elegantly demonstrated electrophysiologically using patch-clamp procedures that measure changes in membrane capacitance, which are directly proportional to increases in the surface area of the cell membrane. During the sequential release of individual crystalloid granules, a stepwise increment in capacitance may be observed as their membranes fuse with that of the cell membrane ([199] , [200] and [201]). The second mode of granule release is compound exocytosis, also demonstrated by patch-clamp analysis in which sudden, very large increments in cell membrane capacitance were measured that can be divided into discrete numbers of granules ([202]). Ultrastructural studies of guinea pig eosinophils have also demonstrated evidence for compound exocytosis ([203]) similar to that observed in rat eosinophils adhering to the outer surface of opsonized parasitic larvae ([202] , [204]). Additional evidence for compound exocytosis was suggested in eosinophils stimulated with a cocktail of IL-3, IL-5, and GM-CSF, which were observed to fuse their granules after activation as determined by immunofluorescence for CD63, a marker for crystalloid granules ([205]). The third manner in which eosinophils degranulate is by PMD. PMD was first characterized by Dvorak and colleagues for the appearance of numerous small vesicles in the cytoplasm coupled with the apparent loss of crystalloid granule core and matrix components, creating a “mottled” appearance in electron microscopy analysis ([206]). This was thought to be due to small vesicles budding off from the larger secondary granules and moving to the plasma membrane for fusion, thereby causing gradual emptying of the crystalloid granules to the outside of the cell. PMD was the most commonly observed pattern of degranulation seen *in situ* in biopsy samples from the upper airways of allergic individuals ([207]) and is likely to be physiologically the most important mechanism for eosinophil mediator release in allergic disease. An *in vitro* model for PMD has been established using IFN-?–stimulated eosinophils, in which a piecemeal manner of RANTES release was detected by a combination of confocal laser-scanning microscopy, immunogold labeling, and subcellular fractionation ([161]). Airway tissue eosinophils not undergoing PMD appeared necrotic, which is a fourth pattern of granule release termed *cytolysis* ([208]). This type of release has been previously observed to occur after prolonged *in vitro* stimulation of human eosinophils with the calcium ionophore A23187 ([209]) and appears to be a physiologically relevant granule release event.

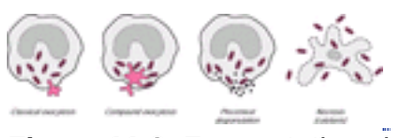

Figure 11.9. Four putative physiologic modes of eosinophil degranulation. The most common observed forms of degranulation in allergic disease are piecemeal degranulation and necrosis (cytolysis). Parasitic and fungal diseases typically exhibit eosinophils undergoing compound exocytosis.

The mechanisms associated with classic exocytosis, compound exocytosis, and PMD, but not cytolysis, are thought to require specific intracellular membrane-associated proteins acting as receptors for granule docking and fusion. These proteins include a family of molecules known as *SNAREs* [an acronym for *SNA*P (soluble NSF attachment protein) *re*ceptors]. The paradigm associated with SNARE molecule function predicts that these proteins are essential for exocytosis. SNAREs were originally described in neuronal tissues and were found to group themselves into two distinct locations: the granule-associated SNAREs (the so-called vesicular SNAREs, or v-SNAREs) and the plasma membrane–associated SNAREs (target SNAREs, or t-SNAREs) ([210]). For a functional SNARE complex to form, allowing the granule to dock with the plasma membrane, one v-SNARE binds to two t-SNARE molecules. In neuronal cells, a commonly observed v-SNARE is vesicle-associated membrane protein (VAMP)-1 or its isoform VAMP-2. In these cells, the t-SNAREs associating with VAMP-2 that were originally described were synaptosome-associated protein of 25 kd (SNAP-25) and syntaxin-1A. These three molecules form a stable detergent-resistant four-helix coiled-coil bundle, which may be regulated by protein phosphorylation. The precise mechanisms regulating SNARE binding and activation are not yet known.

Nonneuronal cells also express SNAREs, although some isoforms have been identified with high sequence homology to the neuronal SNAREs. Up to three SNAP-25 isoforms and approximately 16 syntaxin-1 isoforms have been characterized based on detection of homologous SNARE motif messenger RNA sequences. Interestingly, most nonneuronal secretory cells appear to require SNAP-23 and syntaxin-3, syntaxin-4, or syntaxin-6 ([211], [212] and [213]) for control of exocytosis. Eosinophils have been shown to express the v-SNARE VAMP-2 in their small secretory vesicles containing RANTES but not their crystalloid granules ([214]). The t-SNARE isoforms syntaxin-4 and SNAP-23 are expressed in the cell membrane of eosinophils, and these have the potential to act as cognate membrane-binding partners for VAMP-2 during PMD ([215]). The SNARE molecules identified in eosinophils are proposed to regulate docking of RANTES-containing small secretory vesicles during PMD (Fig. 11.10).

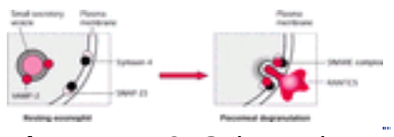

Figure 11.10. Schematic model for molecular regeneration of granule–plasma membrane fusion proposed to occur in piecemeal degranulation in eosinophils. In this model, the v-SNARE (SNAP receptor) vesicle-associated membrane protein (VAMP)-2 is expressed on small secretory vesicles that store RANTES (regulated on activation, normal T-cell expressed and secreted) as a preformed mediator; t-SNAREs, SNAP-23, and syntaxin-4 reside on the inside of the plasma membrane. After cell activation, v- and t-SNAREs bind together to form a SNARE complex, resulting in fusion and release of vesicular contents, including RANTES. (See Lacy P, Logan MR, Bablitz B, et al. Fusion protein vesicle-associated membrane protein 2 is implicated in IFN-gamma-induced piecemeal degranulation in human eosinophils from atopic individuals. J Allergy Clin Immunol 2001;107:671–678; and Logan MR, Lacy P, Bablitz B, et al. Expression of eosinophil target SNAREs as potential cognate receptors for vesicle-associated membrane protein-2 in exocytosis. J Allergy Clin Immunol 2002;109:299–306.)

Mechanisms associated with granule release in eosinophils are critical for effector function of eosinophils. Without degranulation and mediator secretion, the eosinophil is a relatively inert cell and does not affect the surrounding tissues, as seen in cases of idiopathic pulmonary eosinophilia and eosinophilic pneumonia. In these conditions, eosinophil numbers are increased in the capillaries and tissues of the lung, but no cellular or structural damage is evident, probably because of the lack of eosinophil degranulation. In contrast, asthmatic patients show profound eosinophilia in the airways combined with significant tissue destruction, suggesting that, in addition to eosinophilic infiltration, their undergoing degranulation may contribute to mucosal damage in the airways and related symptoms of asthma.

Eosinophils and Allergic Disease

The association between eosinophils and allergic disease has been known for many years. Eosinophils are a feature of allergic and nonallergic asthma, and large numbers of eosinophils ([216]) and eosinophil granule products are commonly found in and around the bronchi in patients who have died of asthma ([136]).

Eosinophils and Asthma

A correlation between the degree of bronchial hyperresponsiveness (a cardinal clinical feature of asthma) and peripheral blood eosinophilia has been observed in subjects who exhibited a dual response after allergen challenge ([27], [217]). Eosinophils in the airways may be assessed using bronchial biopsy or BAL or, more recently, by the use of sputum, a noninvasive technique that may be of clinical value ([218], [219]). The use of fiberoptic bronchoscopy in obtaining bronchial samples in the past decade has helped in acquiring a better appreciation of eosinophil involvement in asthma ([220]). A consistent finding in asthmatic airways was the presence of increased numbers of activated eosinophils, which correlated broadly with the severity of disease as reflected in symptoms, bronchial hyperreactivity, and lung function ([221]).

Even in mild disease, there is a significant increase in number of eosinophils in the airways of patients, and these eosinophils are activated, as evidenced by the presence of the early activation marker CD69 in tissue eosinophils ([222]). This marker was also present in eosinophils from BAL fluid in patients with mild asthma ([222]). Challenge with allergen ([223], [224]) or low-molecular-weight occupational compounds such as toluene diisocyanate ([225]) has been associated with eosinophilia. In *intrinsic asthma*, defined as nonatopic asthma lacking a dependency on IgE-mediated immune responses, similar increases in airway eosinophils have been noted when there is no clear involvement of allergy ([221], [225]).

Challenge of the airways with allergen induces local airway inflammation characterized by influx of both neutrophils and eosinophils. In the late phase of the response, eosinophils are the predominant feature ([217], [224]). A transient peripheral blood eosinophilia may also occur after these challenges ([217]). Increases in ECP-positive eosinophils were observed in both intrinsic and extrinsic asthma and correlated with the degree of airway responsiveness and asthma symptom scores ([221]). Data from this study also demonstrated up-regulation of $CD4^+$ T-cell activation in both intrinsic and extrinsic asthma.

Although eosinophils are closely associated with the pathogenesis of allergic diseases, the evidence that this reflects a cause-and-effect relationship is still largely circumstantial. Inhibition of the migration of eosinophils into the airways of allergen-challenged nonhuman primates has been achieved by the use of monoclonal antibodies against the adhesion molecule ICAM-1, which also inhibited the development of airway hyperresponsiveness ([226]). A number of studies showed that although there was an increased number of eosinophils in the peripheral blood, BAL and bronchial biopsies in asthmatics, as well as a significant increase in the level of eosinophilia with increasing clinical severity, there did not appear to be a direct linear correlation between the degree of bronchial hyperresponsiveness and that of eosinophilic inflammation in asthmatics ([227], [228]). This suggests that other factors, independent of airway inflammation, may control the degree of airway hyperresponsiveness.

The Eosinophil Controversy

Early studies on eosinophil function in the immune response suggested that eosinophils played an immunoprotective role in allergy. For example, eosinophils produce histaminase, which was thought to act by down-regulating mast cell–mediated early phase responses to allergen ([229]). However, reports emerging in the latter part of the twentieth century suggested that eosinophils may have a destructive role in allergy and asthma, based on the discovery of intensely stained deposits of eosinophil MBP in the airways of individuals who died from fatal asthma ([136]). Nevertheless, significant correlations between numbers of activated airway eosinophils (and their released products) and disease severity have been provided in a large body of literature ([2], [3]). More recent studies have thrown this concept into doubt, including animal models of asthma (IL-5 gene knock-outs and anti–IL-5–treated mice) and clinical trials using anti–IL-5, IL-12, and IFN-?. In particular, a small clinical trial using a humanized mouse monoclonal anti–IL-5 in patients with mild atopic asthma was reported ([230]). This treatment has significant therapeutic potential and was predicted to reduce eosinophil numbers in the blood and, consequently, reverse asthmatic symptoms in these patients, based on the hypothesis that eosinophils are principal effector cells in asthma. Anti–IL-5 treatment in animal models of airway hyperresponsiveness was shown to reduce eosinophil numbers and reverse airway hyperresponsiveness ([231]). As expected, a single intravenous injection of anti–IL-5 induced a profound reduction in peripheral blood eosinophils in patients for up to 16 weeks. However, in spite of the loss of eosinophils from the circulation, bronchial hyperresponsiveness to histamine persisted in these patients for up to 6 weeks after treatment. Based on these findings, the authors questioned the role of the eosinophil in the late-phase asthmatic response and bronchial hyperresponsiveness. This proposal was reinforced by findings from mouse models of asthma, some of which indicated that the eosinophil may be redundant in mechanisms associated with

the development of airway hyperresponsiveness. However, these studies have been contradicted by the findings of other laboratories. It appears that the design of the study is crucial in influencing the outcomes, as discussed below for animal models.

MOUSE MODELS OF AIRWAY HYPERRESPONSIVENESS Animal models of asthma have used IL-5 $^{-/-}$ mice to determine the contribution of eosinophils to the pathogenesis of airway inflammation induced by allergens. One such report showed that airway hyperresponsiveness was not affected in allergen-sensitized and -challenged IL-5 $^{-/-}$ mice, although blood eosinophil numbers were significantly diminished ([232]). Studies using anti–IL-5 injections in mice generated similar observations ([233] , [234]). In another allergen challenge model, increased blood and tissue IL-5 levels were evident in wild-type mice ([235]). These levels correlated with both blood and tissue eosinophilia and airway hyperresponsiveness. In the same study, IL-5 $^{-/-}$ mice neither mounted a blood or tissue eosinophil response after allergen challenge nor developed airway hyperresponsiveness ([235]). Restoring IL-5 expression in these animals via vaccinia virus encoding IL-5 reconstituted blood and tissue eosinophilia with an associated development of airway hyperresponsiveness. In an inducible model of T-cell–specific transgenic expression of IL-5, mice produced severe skin lesions, gastrointestinal dysfunction, splenic enlargement, and airway hyperresponsiveness similar to symptoms associated with human eosinophilic disorders ([236]), supporting a crucial role for the eosinophil in tissue damage associated with allergy. The roles of IL-5 and eosinophilia in these mouse models are still in question. Airway hyperresponsiveness may still persist in animals despite treatment with an antibody to IL-5 and depletion of blood eosinophils, depending on the protocol used for sensitization and challenge. Thus, airway hyperresponsiveness may persist during allergen challenge even though blood eosinophilia is lost. The answer to this dilemma may be in the persistence of tissue eosinophils even during IL-5 depletion. Although IL-5 is important in the differentiation and proliferation of eosinophils in the bone marrow, once they arrive in peripheral mucosal tissues, they may switch to an IL-5–independent mechanism of activation and, possibly, recruitment, due to the strong down-regulatory effects of IL-5 on eosinophil IL-5R expression. The possibility of persistence of IL-5–dependent tissue eosinophils has been implicated in results from eotaxin gene-deficient (Eo $^{-/-}$) mice. Despite developing blood eosinophilia, Eo $^{-/-}$ mice do not generate tissue eosinophilia ([37]) with its associated eosinophil-mediated tissue damage after allergen challenge ([237]). However, in double–knock-out mice, in which IL-5 and eotaxin expression is deficient (IL-5 $^{-/-}$/Eo $^{-/-}$), both blood and tissue eosinophilia were eradicated, and airway hyperresponsiveness was significantly decreased during allergen challenge ([237a]). These studies indicate that there are distinct roles for eotaxin and IL-5 in eosinophil maturation, proliferation, and homing to target tissues. Thus, although IL-5 is critical for the maturation and proliferation of eosinophils in the bone marrow, eotaxin may be equally essential for movement and maintenance of eosinophilia in the tissues. Therefore, a key event in eosinophil-mediated inflammation leading to airway hyperresponsiveness may lie in the persistence of activated eosinophils in the tissue. However, the appropriateness of the mouse as an animal model for investigating airway hyperresponsiveness has been brought into question. A major limitation of mouse models is that murine eosinophils seem to lack the ability to degranulate *in vivo* or *in vitro* in response to any known eosinophil-specific agonists. As mentioned earlier, eosinophil degranulation appears to be a vital component of the symptoms associated with allergic airway disease, and the use of mice may be counterproductive in providing clues relating to a better understanding of the role of the eosinophil in airway hyperresponsiveness. In support of this suggestion, knocking out eosinophil MBP or EPO was shown to have little effect on the development of airway hyperresponsiveness after allergen challenge in murine studies ([238]). In conclusion, these findings have important implications for the treatment of asthmatic patients with anti–IL-5, such that IL-5 depletion may not be sufficient to clear the airways of a persistent population of IL-5–independent, activated tissue eosinophils. Further studies are essential for determining the precise role of the eosinophil in contributing to mucosal inflammatory events in allergy.

Eosinophils and Atopic Dermatitis

Increased numbers of activated eosinophils are also observed in studies of allergen-challenged nasal and cutaneous tissue in atopic subjects ([220]). Atopic dermatitis is classically associated with peripheral eosinophilia. Local cutaneous infiltrate with eosinophils is common, and, typically, activated EG2 $^{+}$ eosinophils are apparent ([239]). Atopic dermatitis and other cutaneous lesions, such as urticaria, are often associated with deposition of eosinophil products such as the eosinophil granule MBP ([240] , [241]). Cytokines associated with the Th2 lymphocyte, including IL-5, are present at the site of allergen-induced, late-phase cutaneous reactions in allergic individuals ([242]). Treatment with IFN-? improves atopic dermatitis, but discontinuation of treatment allows for recurrence of the disease. Recent data provide supportive evidence for the importance of eosinophils in atopic dermatitis. Tissue eosinophilia and superficial deposition of eosinophilic granule proteins including EG1, EG2, MBP, and EPO are universally found in skin biopsies of atopic dermatitis. The activated eosinophil appears to be critical to the development and maintenance of chronic atopic dermatitis ([243]).

Eosinophils and Gastrointestinal Disease

Eosinophils have been associated with inflammation of the gastrointestinal tract including eosinophilic esophagitis, eosinophilic gastroenteritis, and eosinophilic colitis (reviewed in reference 244). Etiopathic eosinophilic esophagitis is a selective inflammatory esophageal disorder in which T cells, IL-5, eosinophils, and, possibly, IgE-mediated mechanisms may be involved ([245]). Allergy may play a role in this process, and, in some patients, potentially causative foods may be defined with the use of skin prick testing and patch testing ([246]). However, treatment with dietary restriction has not been overly successful for the management of eosinophilic esophagitis in children, whereas treatment with orally inhaled fluticasone has been shown to relieve mucosal inflammation and symptoms ([247]).

Eosinophilic gastroenteritis is also associated with peripheral blood eosinophilia. Infants with bloody diarrhea may have a form of allergic proctocolitis associated with cow's milk allergy, although this may also occur in infants fed soy formula or even those receiving breast milk ([248] , [249]). Either a change in the infant's diet to casein hydrolysate or a change in the maternal diet with avoidance of dairy products usually results in resolution of symptoms ([249]).

Pulmonary Infiltrates with Eosinophilia

The complex of *p*ulmonary *i*nfiltrates and peripheral blood *e*osinophilia (PIE syndrome) is found in a number of illnesses, including such syndromes as the classic transient pulmonary eosinophilic infiltrate (Löffler's) syndrome, allergic angiitis and granulomatosis (Churg-Strauss syndrome), hypersensitivity vasculitis, and allergic bronchopulmonary aspergillosis (ABPA) (reviewed in reference 250). Schatz and co-workers ([251]) classified PIE syndromes based primarily on pulmonary infiltrates with the presence of peripheral blood eosinophilia. The above syndromes are classically associated with both pulmonary infiltrates and peripheral blood eosinophilia. In addition, drug reactions, hypereosinophilic syndrome (see section Eosinophilia Associated with Neoplastic and Myeloproliferative Disease), and parasitic infestation may be associated with a PIE syndrome.

The term *Löffler's syndrome* is seldom used at present because most of these patients are found to have some evidence of parasitic infestation, drug reaction, or even ABPA ([252]). ABPA is also often seen in patients previously diagnosed with asthma, which has become resistant to treatment. This is usually associated with marked eosinophilia. ABPA is characterized by a picture of asthma, positive skin test to aspergillus, and aspergillus-precipitating antibodies. Proximal bronchiectasis may also be seen ([252]). Churg-Strauss syndrome is a vasculitic disorder associated with eosinophilia, systemic vasculitis, and an asthmalike picture in which the appearance of asthma may precede the vasculitis by some years ([250]). Both ABPA and Churg-Strauss syndrome may be diagnosed as severe poorly controlled asthma; unfortunately, both have the potential for fatal outcome. The presence of marked eosinophilia in a patient with poorly controlled asthma must be considered an indicator of underlying vasculitic disease. On rare occasions, parasitic infestation of the lungs can occur (tropical eosinophilia). This also is associated with marked eosinophilia and pulmonary infiltrates. Often, infiltrates are nodular, and consolidation may also be observed, particularly with a subsegmental distribution ([251]). Appropriate treatment for the underlying parasitic infiltration is associated with a good prognosis.

Eosinophilia and Toxic Responses

A toxic oil syndrome, characterized by eosinophilia, pneumonitis, and loss of muscle bulk and strength, occurred in Spain in 1981. This epidemic resulted in the death of 277 people and the hospitalization of 12,656 and affected more than 20,000 people ([253]). Studies revealed a relationship between the illness and illegally sold cooking oil. The toxic response appeared to be the result of a contaminant (possibly aniline and anilide-oil complexes) in the mixture of vegetable and animal fats.

In 1989, an epidemic of eosinophilia-myalgia syndrome occurred in the United States secondary to the ingestion of L-tryptophan ([254] , [255]). This syndrome was subsequently shown to be due to ingestion of a novel form of tryptophan present in one specific manufacturer's product ([255]). Recent studies have demonstrated that L-tryptophan–supplemented guinea pigs have altered eotaxin regulation ([256]). The authors hypothesize that tryptophan metabolism could affect chemokine levels by several mechanisms leading to hypereosinophilic disorders in susceptible individuals.

Both syndromes were associated with marked eosinophilia. Whereas the acute phase of the toxic oil syndrome was associated with respiratory distress, the chronic phase resembled the eosinophilia-myalgia syndrome with moderate to marked eosinophilia, severe myalgia, fatigue, cough, rash, headache, and continued shortness

of breath.

Eosinophilia Associated with Neoplastic and Myeloproliferative Disease

Idiopathic hypereosinophilic syndrome is a rare condition characterized by extremely high peripheral blood eosinophil counts and is more commonly seen in males (9:1) ([257]). The etiology is unknown. Patients have eosinophilia that may progress to extremely high levels (often >50 × 10^9 per L). This is differentiated from eosinophilic leukemia by the absence of blast cells. There is multiple organ involvement with a progressive and, almost always, fatal course, with death often occurring as a result of cardiac dysfunction. Central nervous system damage is also common. In the past, treatment with high doses of corticosteroids and cytotoxic agents has not usually been successful. Treatment with cytokines, such as IFN-a and anti–IL-5, may hold more hope for these patients ([257], [258]).

Eosinophilia with Other Neoplastic Disease

Eosinophilia is present in patients with eosinophilic leukemia and may also be associated with lymphoid malignancies and bronchogenic carcinoma. Eosinophilia associated with these malignancies is thought to be related to excess production of IL-5 and, possibly, other cytokines by the tumor cells. Studies in Hodgkin's disease have shown presence of mRNA coding for IL expressed in Reed-Sternberg cells ([259]). Eosinophilia associated with neoplasia may actually predate the diagnosis of the malignancy ([260]).

Iatrogenic Eosinophilia

Treatment for a variety of diseases may be associated with eosinophilia. For example, treatment of malignancies with IL-2 induces eosinophilia in most patients during the course of treatment ([261]). Similarly, infusion of GM-CSF may induce eosinophilia. For example, eosinophilia occurs frequently with reactions to trimethoprim-sulfamethoxazole ([262], [263]) but may occur with reactions to a wide variety of drugs including other antibiotics (e.g., penicillin, tetracycline, nitrofurantoin).

After transplantation, allograft rejection induces eosinophilia in most patients ([264]). There is substantial evidence for the role of eosinophil granule MBP as an effector for tissue damage during acute allograft reaction ([265]).

Eosinophils and the Human Immunodeficiency Virus

Eosinophilia is commonly seen in patients with acquired immunodeficiency syndrome. Eosinophilia in human immunodeficiency virus–infected individuals may relate to intercurrent parasitic infestation or to a characteristic reaction to trimethoprim-sulfamethoxazole treatment for *Pneumocystis carinii* infection ([263]). However, there are some data to suggest that human immunodeficiency virus may actually use the eosinophil as an important reservoir *in vivo* ([266]).

Effector Role of the Eosinophil in Worm Infections

There is a strong apparent relationship between parasitic infection and eosinophilia. Infection with helminths is the most common cause of moderate to marked eosinophilia. The relationship between peripheral blood eosinophilia and tissue-invading helminths has been recognized for many years. In particular, studies in the late 1970s demonstrated that eosinophils had the capacity to kill parasitic targets and led to the concept that eosinophils were immunoprotective ([181]).
