Foreword

Nephrology, Dialysis and Transplantation

Is there a need for another nephrology text? Certainly a number of excellent textbooks are available for nephrologists to look up in-depth information on the various topics in the field. The current treatise pursues a different purpose and incorporates a novel approach pioneered by Dustri-Verlag. The ring binder format allows removal of chapters to be carried to rounds or conferences, and replacement of individual chapters as the field progresses in one, but not necessarily all other topics covered by the book. This obviates the need to purchase every two to three years an entire new set of textbooks and allows ongoing and timely updating of individual topics as required. It was the goal of the editors to create a clinically oriented text providing the reader with concise, up-to-date information without lengthy historical perspectives and background information. The development of a CD should later complement this treatise by allowing more in-depth listings of detailed references, presentation of charts, graphs, photomicrographs, x-rays, etc. The current two volumes represent a well rounded first edition, which was made possible by the diligent and devoted input from the co-editors, Drs. B. Peter Sawaya, Mohamed H. Sayegh, and Raymond M. Hakim, with enormous help from Dr. Nuhad Ismail. The overall quality of this treatise was accomplished through excellent contributions of the authors of the individual chapters. The authors were recruited from around the world and the editors would like to extend their deepest gratitude to these fine academicians for their great work. We are looking forward to an ongoing collaboration in the continued updating process of the text. This lively process of continuous updating will hopefully be enhanced by input from the readers, which is solicited and welcomed by all section editors and the chief editor. Finally, we would be remiss if we did not express our thanks to Jörg Feistle of Dustri-Verlag, who has been a consistent and pleasant force essential to the creation of this work. Looking forward to an enjoyable and successful ongoing documentation of the clinical knowledge base and progress in the field of nephrology, dialysis and transplantation.

Diagnostic Evaluations of the Kidney and the Urinary Tract

Francis Dumler, Leslie L. Rocher and Beatrice L. Madrazo

Urinalysis

The urinalysis is the single most useful and cost effective method of screening for renal and urological disease. It is simple, inexpensive, widely available, and noninvasive. Although not specific as to cause, urinalysis provides valuable information regarding the type and severity of renal involvement. Until recently, it was common practice to perform a urinalysis on all patients upon hospital admission or for preoperative clearance regardless of clinical presentation. This is not cost effective, and routine urinalysis is no longer recommended as a screening test in the general population. However, it is indicated in all patients at risk or suspected of having renal or urological disease. In addition, pregnant women, diabetics, and the elderly should be routinely screened. In patients with proteinuria, urinary sediment findings are a general predictor of histology on renal biopsy.

Early morning concentrated urinary specimens are preferred for urinalysis. Optimal samples are obtained after 14 hours of no fluid intake. Specimens can be obtained by spontaneous voiding, catheterization, or suprapubic aspiration. Clean-catch/midstream-voided samples are first choice. In males, specimens should be obtained after retraction of the foreskin. Females should manually separate the labia and gently clean the periurethral area using cotton balls prepacked in a soap solution. Suprapubic aspiration is most suitable for infants and has almost no use in adult practice. Urinalysis is best performed within 2 hours of collection. If needed, samples may be maintained at 4°C for up to 24 hours. When delays are expected, adding a few drops of acetic acid facilitates the preservation of formed cast elements.

A sample of urine is placed in a clear tube for dipstick testing. A similar aliquot, usually 10 – 12 mL, is centrifuged at 3000 rpm for 3 – 5 minutes, the supernatant poured, and the sediment resuspended in the residual volume, usually 0.1 mL, for microscopic analysis. A complete urinalysis consists of 3 major evaluations: physical examination, overall chemical composition, and analysis of formed elements in the sediment. In many laboratories the latter is performed only if dipstick testing is abnormal or when specifically requested regardless of dipstick results.

Physical examination of the urine is done by visual inspection of the sample, placed in a clear transparent container, under proper lighting, and against a white background. The color of the urine is determined by its chemical composition, concentration of solutes, and pH. Hematuria is the most common cause of abnormal color, ranging from red to black depending on amount, pH, and time. Red-tinged urine may also be seen with hemoglo-

Table 1. Routine Urinalysis Testing by Dipstick

Parameter	Seconds	Comment
Glucose	30	No false positives
Bilirubin	30	Noncharted colors are positive*
Ketone	40	Detects acetoacetic acid only
Specific Gravity	45	Not affected by glucose or dye
Blood	60	Hemoglobin and myoglobin*
pH	60	
Protein	60	Albumin > globulin > light chains
Urobilinogen	60	
Nitrite	60	Positive test suggests >10^5 CFU/mL
Leukocytes	120	Fairly specific

*False negative results may occur due to high ascorbic acid content

binuria and myoglobinuria, after eating beets, and during rifampin therapy. Yellow to brown urine is due to bile pigments in jaundiced patients. Urine of normal color upon voiding that darkens with time suggests porphyria (porphobilinogen), melanoma (melanogen), or alkaptonuria (homogentisic acid) in the appropriate clinical setting. Many drugs also influence the color of urine. The urine sample may be immediately cloudy due to the presence of formed elements, or it may get cloudy later because of precipitation of phosphates (alkaline or neutral pH) or urates (acid pH). Refrigeration accelerates precipitation. Profuse white foam may suggest proteinuria. A pungent smell suggests bacteria, while a sweet fruity odor may be due to ketones. In addition, inborn errors of metabolism may lead to a particular smell in the urine: maple syrup (maple syrup urine disease), mousy (phenylketonuria), sweaty (isovaleric acidemia), or fishy (hypermethionemia) odor.

Overall chemical composition is most commonly evaluated using the dipstick method. Parameters usually tested are listed below and in Table 1 by the time required to complete the reaction.

Glucose: Measured using a specific glucose oxidase and peroxidase method. Glucose is metabolized with glucose oxidase into gluconic acid and hydrogen peroxide. The peroxidase catalyzes the oxidation of a potassium iodide chromogen by hydrogen peroxide resulting in a shade of colors ranging from green to brown. False negatives may occur in the presence of large amounts of ascorbic acid.

Bilirubin: Under normal circumstances only conjugated bilirubin is excreted into the urine. In patients with jaundice due to obstruction or hepatocellular disease, bile pigments overflow into the urine. Bilirubin binds to diazotized dichloroaniline in a strong acid medium and produces various shades of tan.

Ketone: The nitroprusside reaction, which detects acetoacetate, is most commonly used. Beta hydroxybutyric acid (which accounts for 80% of ketones in blood) and acetone are not detected by this method. With prolonged fasting or starvation, ketonuria may be detected in the absence of ketonemia.

Specific gravity: Assesses the ability to concentrate or dilute the urine. It correlates closely with osmolality except when a high concentration of glucose or other substances

present in the urine (i.e. contrast agents, proteins) contribute more mass (an increase in specific gravity) than osmols. The usual range is 1.001 – 1.035. It can be measured using a hygrometer, a refractometer, or a dipstick; the latter is most commonly used. The dipstick detection method uses a polyionic polymer reagent that releases hydrogen ion (H^+) as it is saturated with cations present in the urine. The resultant change in acidity of the indicator dye causes a color change from blue to yellow. Although not influenced by glucose or contrast agents, this method is useful only as a screening tool. It tends to overestimate specific gravity at pH < 6.0 and underestimate at pH > 7.0. When clinically relevant, it is essential to measure urine osmolality. Osmolality provides the true measure of solute concentration in the urine. It is usually quantitated by the freezing point technique. Normal values range from 50 to 1,200 mosm/kg.

Blood: Detection is based on the pseudoperoxidase capacity of hemoglobin or myoglobin to catalyze a reaction between diisopropylbenzene dihydroperioxide and 3,3',5,5'-tetramethylbenzidine. A spotted pattern indicates intact red blood cells, and a uniform pattern suggests free hemoglobin, myoglobinuria, or methemoglobinuria. This method is very sensitive and can detect as little as 3 red blood cells (RBC) per high power field (HPF). A positive test in the absence of RBCs in the urinary sediment usually implies lysis of RBCs with release of hemoglobin but may be due to the presence of free pigmenturia. Specific testing for hemoglobinuria or myoglobinuria should be ordered for definitive identification when clinically indicated.

pH: Although the normal range is from 4.5 to 7.9, the usual urinary pH is between 5.0 and 6.5. During waking hours urinary pH is lower as the acid load contained in the diet is excreted.

The most common detection method uses methyl red and bromothymol blue, to provide a wide range of colors for measuring pH. A consistently alkaline pH may be associated with a substantial vegetarian diet, the presence of urea-splitting bacteria, or metabolic alkalosis. An acid pH is common during large meat consumption but may be indicative of a metabolic acidosis. The dipstick technique is adequate for screening only. When acid-base disorders are clinically suspected and knowledge of the urine pH is essential for diagnosis and treatment, accurate measurement requires use of an electrode pH meter and a urine sample collected under oil.

Protein: Urine dipstick techniques for protein primarily detect albumin and do not react with immunoglobulin light chains. Sulfosalicylic acid detects both albumin and immunoglobulins. These techniques provide only a qualitative assessment. As proteinuria is the major abnormality observed in patients with renal disease, a positive dipstick test should be followed by quantitation of protein in a 24-hour urine sample, or at least by a protein to creatinine ratio in a random sample. Dipstick methods use a pH-sensitive colorimetric indicator, tetrabromophenol blue buffered at pH 3.0, that changes from yellow to dark green and turquoise as protein concentration increases. The color shift is caused by the binding of negatively charged proteins. Neutral or positively charged proteins will not cause color change. As little as 20 mg/dL of albumin can be detected. It may be difficult to differentiate normal from trace. A high urine pH may give a false negative result. Detection of proteinuria is the most important reason for ordering a urinalysis when screening the general population for the presence of renal disease.

Urobilinogen: Based on the reaction between p-diethylaminobenzaldehyde and a color enhancer that reacts with urobilinogen in a strong acid medium to produce a pink-red color. A value > 2.0 mg/dL marks the transi-

Table 2. Urinary Sediment: Normal Values and Clinical Significance

RBC: < 5/mm^3 or < 3/HPF (0.3 mm diameter)*	
WBC: < 10/mm^3 or < 5/HPF (0.3 mm diameter)**	
Tubular epithelial cells: usually distal tubular cells (< 1/HPF)	
Squamous epithelial cells: lower urinary tract	
Casts: distal tubular lumen molds of Tamm Horsfall matrix:	
hyaline:	no clinical significance
RBCs:	glomerular hematuria
white blood cells:	inflammation of renal parenchyma
epithelial cells:	desquamation of tubular epithelium
granular:	denatured cells, precipitated plasma proteins

*If >80% of RBCs are dysmorphic (with blebs or fragmented), the likelihood of glomerular hematuria is high
**Eosinophiluria (Hansel staining technique) is highly suggestive of allergic interstitial nephritis, particularly when infection or other causes of acute tubular necrosis are excluded

tion from normal to abnormal. A high urobilinogen concentration suggests the presence of a hemolytic process. As the base value is equivalent to 0.2 mg/dL, this test cannot determine the absence of urobilinogen.

Nitrate: Many urinary tract pathogens are capable of converting nitrates to nitrites. Dipstick methods allow nitrites to react with p-arsanilic acid to form a diazonium compound, which, after further reaction with 1,2,3,4-tetrahydrobenzo(h)-quinolin-3-ol, results in a pink end point. False negatives occur when low dietary protein intake results in a low nitrate content in the urine, when prolonged storage in the bladder leads to nitrite breakdown, or when high concentrations of ascorbic acid ($\geq$ 25 mg/dL) are present. In addition, gram-positive organisms do not break down nitrate. This test may be negative in up to 50% of patients with bacteriuria.

Leukocytes: Lysed white blood cells (WBC) will release esterases. Dipstick methods provide a substrate that liberates 3-hydroxy-5-phenyl pyrrole after hydrolysis. The pyrroles then react with a diazonium salt causing a change in color from pink to purple.

Microscopic examination of the urinary sediment is a very useful and semiquantitative procedure. A drop of resuspended urine is placed on a glass slide, shielded with a cover slip, and examined at low (100x – 160x) and high (400x) magnification under a bright-field microscope. Although not essential, some recommend use of a counting (Fuchs-Rosenthal) chamber. Timed collections (Addis counts) are rarely used because they are cumbersome, formed elements deteriorate, and other diagnostic methods, such as renal biopsy, are more likely to provide a definitive diagnosis. Phase-contrast microscopy enhances cell morphology and allows the best definition of all formed urinary sediment elements. Polarized light may be used to look for anisotropic crystals (as is done with synovial fluid in the assessment of crystal-induced arthropathy). In general, the sample should be examined as soon as possible to avoid bacterial contamination and lysis of formed elements. Normal values for the urinary sediment are shown in Table 2.

Red blood cells (Figure 1a): The normal amount in a spun urinary sediment is < 3

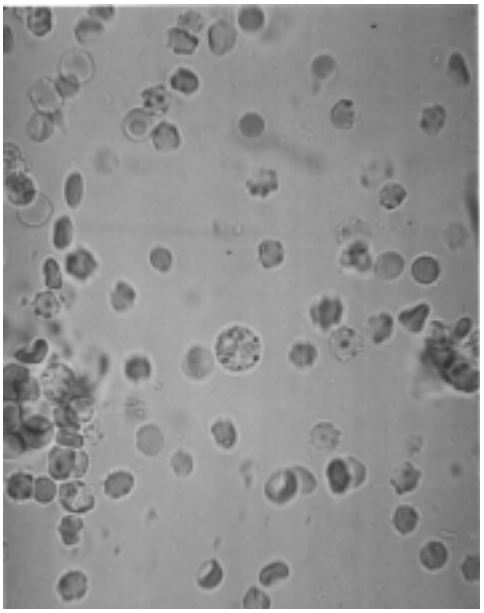

Figure 1a.

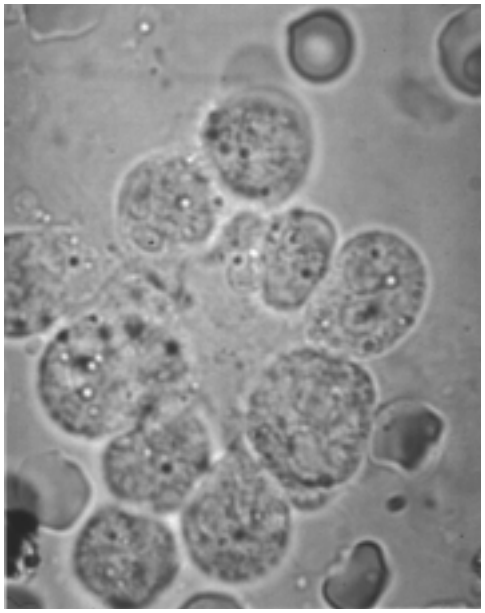

Figure 1b.

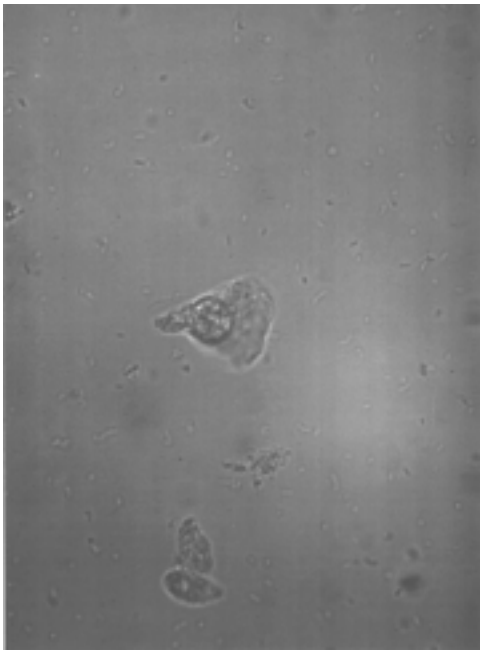

Figure 1c.

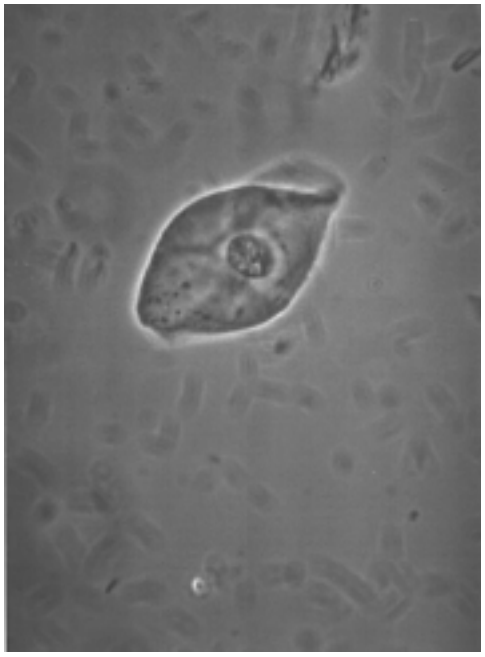

Figure 1d.

Figure 1. Urinary sediment cells. a: numerous RBCs and occasional white (granular) cells; b: numerous white cells in cluster and occasional RBCs; c: tubular epithelial cells; d: transitional cells (with permission of Hoffmann-La Roche Inc., copyright 1973)

RBCs/HPF. Because of varying amounts of RBC sediment on centrifugation, some prefer to use a counting chamber and an aliquot of unspun urine. With this method the upper range of normal is 13,000 RBCs/mL. However, there are no data to substantiate a significant advantage relative to semiquantitative techniques. On occasion, yeast and air bubbles may be confused with erythrocytes. Adding a drop of 25% acetic acid will dissolve RBCs but not yeast or bubbles.

It may be clinically relevant to ascertain whether hematuria is glomerular, tubular, or distal to the renal papillae in origin. RBCs acquired distal to the renal papillae tend to be homogenous, while those originating from the glomerulus or tubuli are quite dysmorphic with various abnormalities in size, shape, and membrane appearance due to pH and osmolality changes in the distal segments of the nephron. The latter may appear as crenated forms, ghost cells, or biconcave disks, or may simulate budding yeast. Phase-contrast microscopy allows for the best discrimination between dysmorphic and homogenous (isomorphic) RBCs. All RBCs in normal urine are dysmorphic. Nondysmorphic hematuria is always abnormal. Hematuria associated with > 80% dysmorphic cells is very suggestive of glomerular disease. Furthermore, the presence of RBC casts or renal tubular epithelial cells containing phagocytized RBCs is almost always indicative of glomerulonephritis.

Although the above technique has potential for discriminating between glomerular (need for renal biopsy) and nonglomerular (need for urological workup) hematuria, patients with IgA nephropathy or postinfectious glomerulonephritis may have a predominance of nondysmorphic erythrocytes. In addition, aggressive diuresis with furosemide may convert hematuria from isomorphic to dysmorphic. Overall sensitivity and specificity values are 88% and 95%, respectively. Unfortunately, the negative predictive value is high enough that nonglomerular bleeding cannot be excluded by dysmorphic hematuria alone.

Perhaps the most important reason in testing for hematuria is the detection of urological malignancies. The US Preventive Services Task Force recommends screening all patients over age 60 for hematuria. In nonselected populations, the prevalence of hematuria is about 2 – 4%. Of those with a positive test, 1% are bound to have urological malignancies, the most common being bladder carcinoma.

White blood cells (Figure 1b): The normal amount in a spun urinary sediment is < 5 WBCs/HPF. Leukocytes are slightly larger than erythrocytes and have a granular cytoplasm. With the use of a counting chamber, the upper limit of normal is 2,000 WBCs/mL. Leukocytes may be differentiated from renal tubular cells by specific staining techniques or by addition of glacial acetic acid that enhances the nuclei of white blood cells. Leukocytes can enter the urine at any point in the urinary tract. The presence of white blood cell casts and proteinuria suggests nephron involvement. The most common causes of leukocyturia are infection, inflammation, hemorrhage, and contamination. Pyuria most commonly represents infection; its absence is helpful in excluding it. Polymorphonuclear cells (PMNs) are the rule. However, in acute allergic tubulointerstitial nephritis, a large number of urinary leukocytes are eosinophils; these are best identified using Hansel's stain (methylene blue and eosin Y in methanol). A positive value is defined by >5% of white cells. In addition to acute interstitial nephritis, eosinophiluria can occur in rapid (crescentic) acute glomerulonephritis (GN), acute prostatitis, and atheroembolic renovascular disease.

Renal tubular cells (Figure 1c): They are rarely detected in normal urine (normal ≤ 1 cell/HPF). They derive from the distal tubule, are slightly larger than leukocytes, and have a

single large round nucleus and granular cytoplasm. An increased number, when present, is indicative of tubular damage. They are better differentiated from WBCs by staining. When containing phagocytized lipid droplets, they are called oval-fat bodies. The identification of renal tubular cells containing phagocytized RBCs has the same clinical significance as an RBC cast.

Squamous epithelial cells: They are the most common cell types after white and red blood cells and appear as large flat cells which are derived from bladder, urethra, or vagina.

Transitional epithelial cells (Figure 1d): They line the urinary epithelium from the renal calyx to the proximal urethra. They are rarely present in normal urine but may be seen with infections and neoplasias of the urinary tract. When numerous, they are particularly suggestive of malignancy and require further cytologic examination.

Urinary casts are cylindrical elements formed in the distal tubule by aggregates of Tamm-Horsfall glycoprotein gel. This process is more likely to occur in acid urine at high solute concentration. Acellular casts may be hyaline, granular, waxy, or fatty. Cellular casts contain erythrocytes, leukocytes, or renal tubular cells. Pigmented casts may be observed in hemoglobinuria and in hyperbilirubinemic states. Casts should be screened for at low (10x) and identified at high (45x) power magnification. Large bizarre casts in males are likely of prostatic origin. Triamterene can form casts from trapped crystals at an acid pH.

Hyaline casts (Figure 2a): These are composed of Tamm-Horsfall glycoprotein and have a homogenous, clear, colorless appearance. They may be seen in normal individuals during high volume diuresis, in the course of febrile illnesses, or in concentrated urine. Their presence in the urine has no pathologic meaning.

Granular casts: Finely granular casts, like hyaline casts, may be seen in normal individuals and provide little useful information. Coarse granular casts were thought to be the result of lysis of constituent granular cells. However, recent studies indicate that the granules are composed of plasma proteins incorporated into the Tamm-Horsfall glycoprotein matrix. Coarse granular casts are seen in a variety of glomerular and tubular disorders and are therefore not specific.

Waxy casts: They are highly refractile and, unlike hyaline casts, resistant to alkaline pH. They are broad and convoluted, not disease specific, and suggestive of tubular hypertrophy and chronic renal disease. They are believed to be the consequence of cellular cast degeneration and are usually seen with severe renal insufficiency.

Fatty casts: Usually seen in nephrotic patients. Oval fat bodies are tubular epithelial cells with lipid-laden drops commonly associated with fatty casts.

RBC casts (Figure 2b): They are characteristic of glomerular bleeding (glomerulonephritis), but on rare occasions may be due to severe acute interstitial nephritis. If the erythrocytes degrade, the structure takes the appearance of a pigmented cast. True hemoglobin casts are amorphous cylinders of an orange to reddish color. In acid urine, erythrocytes lose their hemoglobin, and the cast may look granular, but under phase-contrast the double contours of the cell membrane are clearly delineated. Disintegration of erythrocytes may eventually result in brick-red granular cast. Strings of RBCs are not truly casts but have the same clinical significance as a RBC cast.

WBC casts (Figure 2c): Indicative of infection (acute pyelonephritis), particularly when associated with bacterial casts. However, they may also be seen in acute and chronic intersti-

tial nephritis, postinfectious GN, and lupus nephritis.

Renal tubular epithelial cell casts (Figure 2d): They are formed of tightly packed nucleated cells and are indicative of tubular injury. They are usually seen in acute tubular necrosis (ATN) and acute GN.

A variety of crystals may be found in the urine (Figure 3a-d). Crystals of uric acid, calcium, phosphate, or urates are commonly found, in addition to amorphous phosphates and urates. In patients with active stone disease, larger quantities of crystals may be seen. None has specific clinical relevance, as their formation is pH, temperature, and food dependent. However, they may provide diagnostic clues in patients with microhematuria, nephrolithiasis, or toxin ingestion.

Urate: They may appear as an amorphous background in acid urine or have diamond, needle, or rhombus shapes, usually clustered like flowers. They are commonly observed and are not diagnostic. However, in the presence of acute renal failure (ARF), sheets of uric acid crystals are highly suggestive of acute urate nephropathy.

Amorphous phosphates: Common in alkaline urine, and can be cleared by addition of glacial acetic acid.

Calcium oxalate (Figure 3a): Octahedral envelope shapes are the best recognized. The presence of large amounts in a patient with ARF is strongly suggestive of ethylene glycol poisoning.

Triple phosphate (Figure 3b): Coffin lids or quartz crystals are the usual forms.

Cystine: Perfect hexagons ("benzene ring") are diagnostic of cystinuria.

In the absence of contamination, urinary lipids are almost always pathological. Lipiduria usually implies the presence of a nephrotic syndrome. However, it may occur in the absence of proteinuria in bone marrow and fat embolization syndromes. Numerous fat particles in urine may also be seen in preeclampsia and in rapidly progressive glomerulonephritis. Nonpolarizing fat particles seen within casts are called oval fat bodies. Maltese Cross spherulites are composed of cholesterol esters and are identified using polarized light. On bright microscopy they may be confused with RBCs.

Table 3. Urinalysis Findings in Various Renal Syndromes

Syndrome	Findings
– Glomerulonephritis	– hematuria with red blood cell casts – phagocytized red blood cells – dysmorphic red blood cells – proteinuria – lipiduria
– Acute tubular necrosis	– granular and epithelial cell casts – many epithelial cells
– Acute tubulo-interstitial nephritis	– pyuria with white and granular cell casts
– Acute pyelonephritis	– bacterial casts
– Urinary tract infection	– pyuria alone
– Prerenal azotemia – Obstructive uropathy – Renal ischemia	– near normal urine

The presence of microorganisms is most commonly due to contamination. The presence of leukocytes suggests infection. *Trichomonas vaginalis* is the most common protozoan in urine. *Enterobius vermicularis* is usually an anal contaminant. Parasites are not common except in specific endemic areas (*Schistosoma haematobium* in Africa and the Middle East).

Finally, automated urinalysis devices are being tested that can read dipstick strips and

examine the sediment using thin layers of uncentrifuged urine, a stroboscopic lamp, and a video camera. To recapitulate, from a clinical perspective a variety of renal syndromes can be associated with urine abnormalities that, although not specific, provide useful diagnostic clues (Table 3).

Clinical Evaluation of Renal Function

Glomerular Filtration Rate (GFR)

Glomerular filtration is a key function of the kidney. About 1.2 – 1.3 million glomeruli provide 1.0 m^2 of filtration surface and generate 180 L of tubular fluid per day. Glomerular filtration is the result of high hydraulic pressure across the glomerular capillaries and increased glomerular capillary hydraulic permeability. The glomerular filtration barrier is size and charge selective, with substances up to 10 kilodaltons (kD) being freely filtered. Approximately one-fifth of the cardiac output flows through the kidneys (500 mL/min per kidney). The rate of glomerular filtration is a function of renal plasma flow, hydrostatic pressure, oncotic pressure, surface area, and hydraulic permeability. In the absence of experimental data, filtration disequilibrium in humans is presumed from network thermodynamic and mathematical modeling. GFR and renal plasma flow remain constant when renal arterial pressure is varied between 80 and 180 mm Hg. This autoregulation phenomenon is achieved by corresponding changes in renal resistance vessels (afferent at normal pressures and afferent/efferent at low pressures) that ensure maintenance of adequate filtration pressure.

The concept of renal clearance is based on the premise that the excretion rate of any inert solute in the urine equals its simultaneous rate of removal from plasma. Therefore, the renal clearance (C) of a given substance is defined by the relationship between the excretion per unit time (U) and the concentration in plasma (P) as expressed by the relationship

$$C = U/P$$

True GFR is measured with a marker that is completely filtered and not reabsorbed, secreted, or metabolized. Inulin, a polymer of fructose (5.2 kD), is such a marker and has been long considered the gold standard. However, it is scarce, and the required technique is cumbersome and time consuming. Patients are typically studied in the morning after an overnight fast. An oral water load of 10 – 15 mL/kg is given followed by additional fluid intake to achieve urine flow rates of 4 mL/min. A loading dose of inulin is administered followed by a continuous infusion. Once a steady state has been reached (30 min), urine collections are obtained. Clearance is calculated using the time average inulin plasma concentration and the urinary excretion rate. The average of 3 – 4 clearance periods is used as the final calculation. Because glucose is detected in most inulin assays, it must be removed or measured and subtracted from the total plasma value. In a given individual, GFR measured by this technique is very constant, with a coefficient of variation < 10%.

Methods using noninulin labeled agents are discussed in the radionuclide section. Unlabeled radiocontrast agents such as iothalamate and diatrizoate meglumine have been used in lieu of inulin. As little as 1 mL injected subcutaneously is all that is required. However, assays require high performance liquid chromatography (HPLC), which is less easily available and more costly. An alternative method based on detection of low concentra-

tions of iodine can be used with the low-osmolality, nonionic radiocontrast agent iohexol.

There is a diurnal variation in GFR related to feeding. Values are highest in the afternoon and lowest at past midnight. Similar increases have been noted in patients receiving parenteral hyperalimentation, in patients with extensive burns, and during pregnancy when GFR may increase by as much as 50%. On the other hand, exercise induces transient decreases with up to 40% reductions after strenuous physical activity. During the first weeks of life, GFR is about 50% of normal but gradually rises to peak values by 12 months of age and remains constant up to age 40. A gradual decline is then observed, so that by the eighth decade GFR may be only at 30% of its peak value.

GFR measurements are best suited for monitoring disease progression in a given individual. Normal values have too wide a range to be useful in the detection or diagnosis of specific disease processes. Because renal size (and presumed filtration surface) is proportional to surface area, attempts have been made to normalize glomerular filtration values to this parameter. Although this approach tightens the distribution of normal values, the range is still substantial. Some of this normal variability could be minimized by measuring GFR at a fixed dietary protein intake.

Creatinine Clearance (C_{cr})

C_{cr} is the most widely used clinical estimate of GFR. Creatine is derived from the metabolism of creatine in skeletal muscle and from dietary meat intake, with about 1.6% of the creatine pool converted to creatinine. It is freely filtered at the glomerulus and not reabsorbed or metabolized. However, approximately 15% of the urinary creatinine is derived from tubular secretion. Its overall excretion rate is 15 – 20 mg/kg/day in females and 20 – 25 mg/kg/day in males.

Although creatinine generation is fairly constant at a given protein intake, several factors influence the apparent generation rate. Ingestion of cooked stewed meats increases the dietary creatinine load and the apparent generation rate. A change in muscle mass results in unstable creatinine generation rates that can take up to 3 weeks to stabilize. Similarly, a change in dietary protein intake induces changes in creatinine generation rate that do not reach steady state for up to 4 weeks. In addition, creatinine excretion is not constant over time. Short-term variations in a single individual range from 6 – 20%. As renal failure progresses, creatinine secretion into the gut and bacteria breakdown account for an approximate C_{cr} of 2 mL/min. Furthermore, tubular secretion of creatinine increases proportionally to the decline in GFR and may reach values 25% greater than at normal renal function. In severe renal failure, C_{cr} rates may be double those obtained with inulin. Incomplete urine collections are also an important source of error. It is best to use 24-hour collections to minimize the impact of bladder emptying and inaccurate timing.

Serum creatinine is usually measured using the Jaffé reaction (creatinine reacting with alkaline picrate) to form an orange-red complex. Unfortunately, this reaction also detects noncreatinine chromogens and therefore overestimates creatinine concentration. This is particularly true at low creatinine concentrations. Enzymatic methods are more precise, and HPLC provides direct measurements without any interference. The latter methods are more expensive and involved and are not frequently used in routine clinical testing.

Interestingly, measurements of C_{cr} using the Jaffé method in normal subjects yield results very close to the inulin clearance. The

Table 4. Empiric Estimation of Creatinine Clearance

Method	Formulae

1 Cockcroft DW, Gault MH 1976 Nephron 16: 31-41, 2 Siersbaek-Nielsen K, Molholm HJ, Kampan J et al. 1971 Lancet 1: 1133-1134, 3 Jelliffe RW, Jelliffe SM 1972 Mathematical Biosciences 14: 17-24, 4 Gates GF 1985 Am J Kidney Dis 5: 199-205

reason is that the overestimation of serum creatinine concentration due to detection of nonchromogens mathematically offsets the tubular secretion of creatinine. However, in renal failure the nonchromogen effect decreases as the serum creatinine concentration rises, and tubular secretion increases so that overestimation of GFR becomes the norm. Under these circumstances, inhibition of tubular secretion of creatinine with cimetidine results in values closer to those obtained with inulin clearance. Other drugs capable of inhibiting tubular secretion of creatinine include potassium-sparing diuretics, probenecid, and trimethoprim. In advanced renal failure (< 15 mL/min) the increased tubular reabsorption of filtered urea and the increased tubular secretion of creatinine balance each other, so that the average of the urea and creatinine clearances is very close to true GFR measured by inulin clearance.

In spite of the above limitations, C_{cr} measurements are very helpful in defining whether GFR is normal or abnormal and in determining whether it is stable or unstable over time. When urine collections are not available or are unreliable, indirect calculations of C_{cr} can be made using empiric formulae that estimate creatinine generation. A summary of these empiric equations is shown in Table 4.

Serum Creatinine and Blood Urea Nitrogen Concentration

Serum creatinine and blood urea nitrogen (BUN) concentrations are most commonly used as estimates of GFR because of ease of use, wide availability, and considerable practical value in patient care. Serum creatinine concentration is the recommended test for screening asymptomatic adults for overt renal dysfunction. However, the sensitivity for detecting mild decreases in true (inulin) GFR (50 – 90 mL/min) is not very high. Among patients with decreased renal function documented by inulin clearance, 25% have a normal creatinine clearance and 40% have serum creatinine measurements within the normal range. This is particularly true in patients with low muscle mass and reduced creatinine generation who maintain serum creatinine concentrations within the normal range despite a 25 – 30% loss of renal function. In addition, progressive renal injury may be associated with an increase in the tubular secretion of creatinine, so that the expected rise in serum creatinine concentration may be substantially blunted.

In most clinical circumstances, defining whether GFR is changing is more important than obtaining an accurate measure of the actual value. Serial assessment of serum creatinine concentration is very useful in this regard. Serum creatinine concentration varies inversely with GFR. In general, a rising serum creatinine concentration implies decreasing GFR, a falling serum creatinine concentration an increasing GFR, and a stable value no change. Nevertheless, there are certain limitations in using serum creatinine concentration alone as an index of change in GFR. In early renal disease GFR may fall substantially (by as much as 20 – 30%) without an obvious increase in serum creatinine. In addition, because the relationship between GFR and serum creatinine concentration is logarithmic, the absolute difference between creatinine measurements does not accurately portray the degree of renal deterioration. While a serum creatinine concentration increase from 1 – 2 mg/dL represents a 50% loss of function, the same increase in serum creatinine concentration at lower levels of renal function (i.e. from 4 – 5 mg/dL) implies a functional decline of a much smaller magnitude (20%).

Progressive renal failure can be monitored by a variety of methods, the most practical of which employs the reciprocal of serum creatinine concentration. In most patients with glomerular injury, reciprocal serum creatinine concentration values decline linearly with time as renal function worsens. This linear relationship may suggest that glomerular filtration changes at a constant rate throughout the course of disease. More likely, glomerular filtration decreases at a slower rate early on, only to accelerate late in the disease process. Although useful in patient management, this method is too insensitive for use in clinical research studies.

BUN concentration also varies inversely with the GFR. Urea (60 daltons) is the primary end point of protein metabolism. It is synthesized in the liver and distributed in all body fluids. It is freely filtered but reabsorbed in the proximal and distal tubules. However, it is not a very useful marker because its production and excretion rates are very dependent on dietary protein intake and proximal tubular reabsorption, respectively. Volume depletion from any cause enhances proximal tubular reabsorption of urea resulting in a disproportionate increase in BUN relative to the fall in GFR. This observation is used clinically to substantiate a diagnosis of prerenal azotemia. In addition, a high protein diet, increased tissue breakdown, and gastrointestinal bleeding will increase BUN concentration without a corresponding change in GFR. On the other

hand, alcoholism, liver disease, or a low dietary protein intake will lower BUN concentrations in the absence of changes in glomerular filtration. The usual BUN/Cr ratio is 10:1. Higher values indicate volume depletion, and lower values suggest volume expansion, liver dysfunction, or malnutrition. Urea clearance usually underestimates GFR and may be one half or less than that measured by creatinine or inulin techniques. However, in advanced renal failure (< 15 mL/min) the lower urea clearance (due to increased reabsorption) and the higher creatinine clearance (due to increased secretion) cancel each other so that the average of both is very close to the GFR measured with inulin.

Proteinuria

Proteinuria is the hallmark of many renal diseases. Substantial amounts of large molecular weight plasma proteins normally flow into the glomerular capillaries without crossing into the urinary space. The glomerular barrier with its charge and size selectivity prevents all but a small fraction of albumin, globulins, and other large proteins from entering the urinary space. Low molecular weight proteins (< 20 kD) are filtered freely but are then reabsorbed in the proximal tubule. Under usual circumstances, urinary protein excretion ranges between 30 – 130 mg/day, with the upper range of normal being 150 – 200 mg/day.

Approximately 60% of the total urinary protein excreted is derived from filtered plasma proteins. Of these, serum albumin is the single largest component (40%), followed by serum immunoglobulins (15%), and miscellaneous proteins including kappa and lambda chains (5%). The remaining 40% consists mostly of tubular proteins (Tamm-Horsfall protein or uromodulin) secreted into the urine. Uromodulin is a negatively-charged glycoprotein formed on the epithelial side of the thick ascending segment of the loop of Henle and the early distal convoluted tubule. Although small (80 dalton), it forms aggregates of $7 – 23 \times 10^6$ dalton. Its major physiological role is to bind and inactivate interleukin-1 and tumor necrosis factor. IgA and urokinase are also secreted by tubular cells and may appear in the urine in small amounts. Filtration of plasma proteins may increase with exercise, upright posture, or fever and may result in mild transient proteinuria.

Urinary protein content may be measured in random samples, in timed or untimed samples, and in 24-hour collections. The latter is the standard for assessing and quantitating proteinuria. The subject is instructed to discard the first voided morning urine, record the time, and collect all subsequent urine voided for 24 hours up to the time noted. When the urine is being evaluated for orthostatic proteinuria, the collection must be done in two separate containers, one for urine produced during waking hours (~16 hours) and the second for the overnight (~8 hours) sample. Urinary creatinine excretion rates may be used to gauge the completeness of the collection (20 – 25 mg/kg/day in males and 15 – 20 mg/kg/day in females). Because of the great variability of creatinine excretion, this approach is best used for longitudinal follow-up of proteinuria in a given patient. There are no specific recommended assays for measuring protein content in timed samples. The sulfosalycylic acid method relies on precipitation and measurement of turbidity with a photometer or nephelometer and has a 20% coefficient of variation. Trichloroacetic acid can be added to increase detection of gamma globulins. The Coomassie blue method is very reliable and is favored by many.

Urinary protein/creatinine ratios have been used as a surrogate of the 24-hour urinary protein method. Ratios >3.0 – 3.5 are seen with nephrotic range proteinuria, and ratios < 0.20 indicate values < 200 mg/day. Timing is important, as early morning samples tend to have less protein than afternoon samples. In addition, having to perform 2 measurements instead of one significantly increases the coefficient of variation for the test.

The normal urinary albumin excretion rate (microalbuminuria) is 12 μg/min or 20 mg/day. Its detection requires sensitive methods such as electrophoresis, immunoelectrophoresis, radioimmunoassay (RIA), immunoturbidimetry, laser nephelometry, or enzyme-linked immunosorbent assay (ELISA). The performance profile for these methods is similar, and selection usually depends on availability and local experience. Dipsticks for detection of microalbuminuria are now commercially available, but there is not enough experience with them to recommend routine clinical application. A timed 24-hour collection is the ideal method for sample collection. If not feasible, the second choice is a timed 30- to 45-minute collection after a 300mL water load. First morning sample testing should be used only by default.

The most important clinical use of urinary protein excretion measurements is the detection and monitoring of renal disease and its progression. In general, the use of standard protein determinations is sufficient for this purpose, and 24-hour collections are preferred over random sampling and protein/creatinine ratios. In patients suspected of having monoclonal gammopathies, specific tests are required for identification of light or heavy chains. In diabetic patients, testing for microalbuminuria is the method of choice for early detection of risk for nephropathy. In nondiabetic patients the relationship between proteinuria and progressive renal disease is significantly more variable than in diabetics. The number of false positive dipstick tests for protein in the population at large is relatively high, particularly when the expected prevalence of renal disease is low. For this reason, a positive test should be repeated and followed by stricter testing if positive. For instance, proteinuria detected by routine urinalysis in patients with lower urinary tract infections (UTI), fever, or congestive heart failure (CHF) may revert to negative upon improvement or correction of the underlying condition. In young, otherwise healthy individuals, proteinuria that is intermittent and postural (≤ 1,000 mg/day) has no pathologic significance. Renal survival of college students with intermittent proteinuria is the same as in normals.

Determining whether proteinuria is glomerular or tubular may have clinical relevance. An increase in both albumin and high molecular weight proteins indicates glomerular disease, whereas low molecular weight proteinuria suggests a tubular process. β_2-microglobulin is a small molecular weight (11.8 kD) protein that is freely filtered at the glomerulus and almost completely removed by proximal tubular cells, so that < 0.1% of the filtered load appears in the urine (370 μg/day). Many tubulointerstitial diseases are associated with a substantial increase in β_2-microglobulinuria, particularly acute pyelonephritis and acute interstitial nephritis. Defining whether glomerular proteinuria is selective or nonselective has been used in the past to differentiate minimal change disease from other causes of glomerular proteinuria. The amount of immunoglobulin G (IgG) (160 kD) is compared to that of albumin (69 kD) or transferrin (88 kD). A ratio < 0.10 is indicative of highly selective proteinuria (minimal change disease). A ratio > 0.50 is indicative of nonselectivity and suggests a diagnosis of glomerulonephritis.

Urinary Electrolytes

Measurement of urinary electrolytes may provide useful adjuvant clinical information. Under conditions of neutral balance, the 24-hour urinary sodium excretion is in equilibrium with intake and is a measure of dietary sodium. When balance is not neutral, it reflects either increased sodium reabsorption (decreased effective intravascular volume) or increased renal excretion (diuretics, salt-wasting). Urinary chloride measurements have a similar clinical implication. Urinary potassium excretion is a function of dietary intake, gastrointestinal losses, and renal excretion. In conditions associated with hypokalemia, a low potassium excretion is indicative of nonrenal losses (i.e. gastrointestinal tract), and a high excretion is characteristic of concomitant hyperaldosteronism (usually associated with a decreased effective intravascular volume) or renal potassium wasting (tubulointerstitial disease). In the presence of hyperkalemia, a low urinary potassium excretion denotes an inadequate renal response (decreased GFR, primary or secondary hypoaldosteronism), while a high value signifies an appropriate response and is suggestive of nonrenal causes of hyperkalemia. Quantitation of the urinary anion gap may provide an estimate of ammonia production and thus be useful in assessing the renal response in systemic hyperchloremic acidosis. Metabolic acidosis due to diarrhea is associated with increased ammonia production and a negative anion gap, while a positive anion gap indicates renal tubular acidosis (RTA). In most clinical circumstances urinary electrolytes are measured in random urine samples, so that concentrations rather than excretion rates are used for interpretation. These results are summarized in Table 5.

Other Tests of Tubular Function

Tests of concentrating ability: The most common cause of a decreased urinary concentration ability (hyposthenuria) is chronic renal failure (CRF), as a fall in concentration capacity parallels the loss in GFR. In tubulointerstitial or medullary diseases, the loss of concentrating ability may be greater than expected for the degree of renal failure. Central and nephrogenic diabetes insipidus are also causes of hyposthenuria. Urine osmolality (U_{osm}) is the standard assessment of concentrating ability. The early morning U_{osm} is > 800 mOsm/kg. A more rigorous evaluation requires induction of dehydration. An 18 – 26 hour water deprivation period (with a body weight loss of 3 – 5%) increases U_{osm} to about 1,100 mOsm/kg (range: 800 – 1400). When the test identifies a decreased urinary concentration, desmopressin acetate (DDAVP) may be used in a second phase to distinguish central from nephrogenic diabetes insipidus. Plasma arginine vasopressin levels may be measured concomitantly. The osmolal and free water clearance can be calculated using general renal clearance formulae as shown below:

$$\text{Osmolal Clearance } (C_{osm}) = \frac{\text{Urinary Osmolality } (U_{osm}) \times \text{Urine Volume } (V)}{\text{Plasma Osmolality } (P_{osm})} \quad (1)$$

$$\text{Water Clearance } (TcH_2O) = C_{osm} - V \quad (2)$$

(a negative value indicates net water loss or free water clearance).

Diluting capacity: This test is usually used for research purposes only. After a 1 – 2 L water load, while on a normal solute intake, healthy individuals dilute the urine to 40 – 80 mOsm/kg.

Hydrogen ion excretion: All measurements must be made using a pH meter in urine

Table 5. Clinical Interpretation of Urinary Electrolytes

Clinical syndrome	Urinary electrolytes
Hypokalemia	*Urinary K ≤ 30 mEq/L (extrarenal losses)*
– with associated metabolic acidosis:	Small bowel diarrhea, gastrointestinal fistulae, laxative abuse
– with normal acid-base parameters:	Low potassium intake, increased skin fluid losses, laxative abuse
– with associated metabolic alkalosis:	Colonic diarrhea, upper gastrointestinal losses. laxative abuse
	Urinary K > 30 mEq/L (renal losses)
– with associated metabolic acidosis:	Renal tubular acidosis, anion gap acidosis, ureteroneosigmoid-ostomy
– with normal acid-base parameters:	Recovering acute tubular necrosis, post obstructive diuresis, leukemia, magnesium depletion
– with associated metabolic alkalosis and low urinary chloride (< 20 mEq/L):	Vomiting, nasogastric drainage, chloride loosing diarrhea, prior diuretic use
– with associated metabolic alkalosis and high urinary chloride (> 20 mEq/L):	Diuretic use, Bartter syndrome, magnesium depletion if normo-tensive Hyperaldosteronism (primary or secondary), congenital adrenal hyperplasia, exogenous mineralocorticoid use, Liddle syndrome if hypertensive
Decreased total body water: (hypovolemia)	*Urinary Na ≤ 20 mEq/L (extrarenal losses)* *Urinary Na > 20 meq/L (renal losses)*
Increased total body water (hypervolemia/edema)	*Urinary Na ≤ 20 mEq/L*
	Decreased effective vascular volume due to congestive heart failure, liver disease, nephrotic syndrome
	Urinary Na > 20 meq/L Advanced renal failure
Metabolic alkalosis	*Urinary Cl ≤ 20 mEq/L* chloride responsive alkalosis Gastric fluid loss, non-reabsorbable anion delivery, post diu-resis therapy, post hypercapnea, villous adenoma, congenital chloridorrhea
	Urinary Cl > 20 mEq/L Chloride unresponsive alkalosis
Urinary potassium ≤ 30 mEq/L	Laxative abuse or severe potassium depletion
Urinary potassium > 30 mEq/L	Bartter syndrome or diuretic abuse if normotensive Primary hyperaldosteronism or licorice abuse if hypertensive and with low plasma renin Secondary hyperaldosteronism if hypertensive and with high plasma renin, Cushing syndrome with high plasma cortisol

Table 6. Serologic Tests Used in the Diagnosis of Renal Disease

Diagnostic test	Clinical Condition
ANCA-c	Wegener's, vasculitis, rapidly progressive glomerulonephritis
ANCA-p	Pauci-immune rapidly progressive glomerulonephritis
Anti GBM antibody	Goodpasture syndrome, renal allograft in Alport syndrome
C4 normal/C3 decreased	Postinfectious glomerulonephritis
C4 and C3 decreased	Membranoproliferative glomerulonephritis types 1 and 2
C3 nephritogenic factor	Membranoproliferative glomerulonephritis type2 > type 1
Anti nuclear antibody > 160	Systemic lupus erythematosus
Anti double stranded DNA	Systemic lupus erythematosus
Anti single stranded DNA	Drug-induced systemic lupus erythematosus
Anti-Scl-70	Scleroderma, CREST syndrome
Cryoglobulins	Primary and secondary cryoglobulinemia
Serum proteins by immunodiffusion	Monoclonal gammopathies
Hepatitis B/C screen	Glomerulonephritides associated with hepatitis B/C infection

collected under oil. A pH < 5.3 in an early morning specimen excludes a defect in hydrogen ion secretion (type 1 or distal RTA). An acid load test with $CaCl_2$ may be used to identify milder defects. Type 2 (or proximal RTA) patients have resting acidosis and an alkaline urine, but generate an acid urine in response to an acid load when serum bicarbonate concentration falls below 16 – 20 mEq/L. In CRF, the most common cause of decreased hydrogen ion excretion is a decrease in ammonia production. Although urinary ammonia production is not routinely measured, it can be estimated by the urinary anion gap.

Serological Evaluation of Patients with Renal Disease

Serologic tests are useful in evaluating patients with systemic or primary renal diseases in which glomerular involvement is highly probable. Tests include a wide range of assays aimed at detecting etiologic agents with pathophysiological roles or surrogate markers of diseases that define renal involvement. Many of these assays do not have established international standards, so results must be referred to normal values specifically defined for a particular procedure used. Commonly used tests are shown in Table 6.

Antineutrophilic Cytoplasmic Antibody (ANCA)

Recognition of these antibodies has had a major impact in clinical practice. Their detection is associated with syndromes characterized by systemic or renal-limited segmental vasculitis and fibrinoid necrosis, and titers correlate reasonably well with severity of illness. Most of these autoantibodies are IgG, although some patients may have a predominant IgM or IgA type. They produce a diffuse cytoplasmic appearance when using formalin-fixed neutrophils. However, with etha-

nol fixation 2 distinct patterns are observed: cytoplasmic (C) and perinuclear (P). Over 95% of C-ANCA is directed to a 29 kD serine proteinase known as proteinase 3 (PR3), which appears to be identical to myeloblastin, azurophil granule protein (AGP7), and P29. P-ANCA is mostly directed against myeloperoxidase (MPO) but binds with other intracellular components including elastase, lactoferrin, and cathepsin G.

C-ANCA is most often associated with Wegener's granulomatosis, while P-ANCA is mostly associated with pauci-immune renal disease. In the presence of a clinical picture consistent with rapidly progressive GN, a renal biopsy is still recommended because there are some false positive ANCA results in patients with acute interstitial nephritis, lymphoma, *Mycobacterium bovis* infection, and human immunodeficiency virus (HIV) disease. About 95% of patients with rapidly progressive GN and pauci-immune findings will have a positive ANCA. Of these, about 60% have a peripheral pattern. Only 5% of patients with immune-complex glomerulonephritis will be positive. In addition, 10 – 30% of patients with antiglomerular basement membrane (anti-GBM) disease will also have a positive ANCA test. ANCA does not react with the noncollagenous domain of type 4 collagen, indicating true double disease rather than antibody cross reactivity.

Some laboratories still use standard immunofluorescence microscopy. In this case all serum with a P-ANCA pattern should also be tested for antinuclear antibodies (ANA) to exclude an ANA peripheral pattern. More recent methods employ radioimmunoassay (RIA) or ELISA techniques using purified proteins as substrate. Assays using granule extracts have a higher false positive rate. Patients with high IgA levels, particularly in association with Henoch-Schönlein purpura, may have false positive results. ANCA may also be positive, in the absence of renal involvement, in patients with ulcerative colitis, sclerosing cholangitis, Crohn's disease, and retrobulbar fibrosis.

Antiglomerular Basement Membrane (Anti-GBM) Antibody

Anti-GBM antibodies are directed against an epitope in the noncollagenous domain (NC1) of the alpha3 chain of type IV collagen. The most specific assays use purified intact type IV collagen as substrate. Most laboratories employ solid phase assays (RIA, ELISA, immunoblotting), which usually detect only IgG antibodies; on rare occasions antibodies are IgA. Indications for testing include the presence of rapidly progressive GN, pulmonary-renal syndrome, or unexplained hemoptysis. Approximately 60% of patients with anti-GBM disease have lung involvement. A kidney biopsy still plays a major role in the diagnosis of anti-GBM disease. A positive linear staining in the absence of anti-GBM antibodies occurs in diabetes mellitus (DM), focal segmental glomerulosclerosis (FSGS), and acute postinfectious GN. There is no correlation between anti-GBM titers and severity of clinical illness. However, serial titers may be used to monitor therapy. Plasma exchange is continued until titers are less than twice background. Patients awaiting transplantation should not undergo surgery until antibody levels are low or undetectable.

In patients with Alport's syndrome the reactive epitope may be absent in the GBM. After renal transplantation about 10 – 30% develop a positive linear immunofluorescence on biopsy. However, very few have detectable circulating anti-GBM antibodies. The allograft disease is usually benign, with only a very small subset actually developing rapidly progressive GN and renal failure.

Serum Complement Levels

The serum complement battery routinely includes assessment of CH50, C3, and C4 levels. CH50 is assayed by incubating serum samples with sheep RBCs sensitized with rabbit anti-red-blood-cell antibodies. One CH50 unit is defined as the amount required to lyse 50% of RBCs in the assay. A normal CH50 indicates that complements 1 – 9 are present, but is less sensitive in screening for C4 deficiency. A low CH50 identifies patients with hereditary or acquired deficiencies. C3 and C4 are measured by nephelometry or immunodiffusion. A normal value does not exclude complement activation as a pathogenetic mechanism, because hypocomplementemia occurs only when consumption exceeds production. A low complement may be associated with immune complex disease, chronic antigenemia, stabilization of C3 or C4 convertase by autoantibodies such as nephritic factors, decreased production of complement components, and isolated genetic deficiencies.

Complement levels should be measured when acute GN is suspected because the complement profile may aid in the differential diagnosis. For instance, acute postinfectious GN is characterized by a normal C4 and a low C3 that rapidly returns to normal. Membranoproliferative glomerulonephritis (MPGN) type 1 is associated with a persistent fall in both C3 and C4, while type 2 has a normal C4 and a persistently low C3. The C3 nephritogenic factor (C3NeF) is an IgG autoantibody directed against a neoantigen in the C3 convertase C3bBb (alternate pathway). It is found in patients with MPGN types 1 and 2 but is much more common in the latter. It is also detectable in individuals with partial lipodystrophy, regardless of the presence of GN. C4NeF is an autoantibody that stabilizes C4b2a convertase (classical pathway). It has been described in patients with systemic lupus erythematosus (SLE), MPGN type 1, acute postinfectious GN, and in various other forms of chronic GN. Atheromatous embolic renal failure is commonly associated with significant hypocomplementemia.

Antinuclear Antibodies

Many autoimmune disorders are associated with the presence of antinuclear antibodies (ANA). Some are fairly disease specific, but many are not. However, the prevalence of ANA types varies enough between disease processes so that pattern identification becomes useful in differential diagnosis.

The most common screening method is indirect immunofluorescence. There are 4 general patterns described: diffuse, speckled, nucleolar, and peripheral. The diffuse pattern is the most commonly observed (60%), followed by the speckled (30%). Approximately 3 – 4% of Caucasians develop a positive titer with increasing age. In addition, low titers (< 1 : 60) are common in many acute or chronic inflammatory conditions. A positive result should be followed by further testing when clinically indicated. Assays using molecularly cloned antigens give the most specific test results.

Perhaps the most common use for ANA testing in clinical nephrology is detection of renal involvement due to systemic lupus erythematodes (SLE). Screening testing usually identifies a homogenous pattern at titers >1 : 60. In general, absolute levels of ANA do not correlate well with clinical disease activity. The presence of anti-double-stranded DNA (anti-ds DNA) antibodies, which bind to epitopes in the double helical structure of DNA, are highly specific for SLE but are seen in only 60% of patients. The presence of anti Smith (Sm), anti ribonucleoprotein particles

(RNP) or anti-SSA/Ro antibodies also suggest SLE but are less sensitive. Anti-ssDNA antibodies are very characteristic of drug-induced SLE. Anti-Scl-70 antibodies are highly specific for scleroderma and the CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasias) syndrome. Anti-SSB/La/Ha antibodies are characteristic of Sjögren's syndrome.

Antiphospholipid Antibodies

Antiphospholipid antibodies are a heterogenous family of acquired circulating IgG antibodies that react with various anionic phospholipids including cardiolipin, phosphatidic acid, and phosphatidylcholine. They have the common property of inhibition phospholipid-dependent coagulation reactions in vitro and are often detected as a prolonged PTT. Clinically, their presence is highly associated with a thrombotic diathesis. Some clinicians consider them a risk factor for recurrent clotting of hemodialysis vascular accesses. The lupus anticoagulant testing is most specific for these antibodies. It is important to recognize that IgG and/or IgM anticardiolipin antibody titers do not necessarily parallel the anticoagulant activity in vitro. Of related interest, a primary antiphospholipid syndrome characterized by otherwise unexplained thrombosis in large arteries and veins has been associated with the presence of these antibodies.

Cryoglobulins

Cryoglobulins are abnormal immunoglobulins that precipitate in the cold and redissolve on rewarming to 37° C. They are very nonspecific and occur in a variety of disease processes, including autoimmune disorders, infections, lymphoproliferative disorders, vasculitis, and primary GN. Small amounts of cryoglobulins (< 80 ng/mL) may be detected in up to 38% of normal subjects. The sampling method is critical, and the syringe and needle must be warmed up for the blood draw. A high titer (> 1g/dL) is considered diagnostic. Three major types have been described. Type I has a single monoclonal component (IgG, IgM, IgA, light chain); type II is a monoclonal IgM directed against IgG; type III is a polyclonal IgM against IgG.

Cryoglobulinemia of any type or etiology may cause renal involvement; however, it is most common with type II. About 50% of patients have isolated hematuria/proteinuria, 20% develop a nephrotic syndrome, and another 20% present as an acute GN. Other systemic symptoms suggestive of cryoglobulinemia include recurrent palpable purpura, skin ulceration and necrosis, arthritis, Raynaud's phenomenon, liver abnormalities, and neurologic symptoms.

Streptococcal Serologies

Streptococcal serologies (ASO, anti-DNAase B, antihyalurodinase, antistreptokinase, anti-DNAase) are most commonly used in the evaluation of patients with acute GN in whom an infectious etiology is sought. However, a positive test for group A β-hemolytic streptococcus is only indicative of previous infection and does not confirm a diagnosis of postinfectious GN. These tests are positive in > 95% of patients with throat infection and 80% of patients with skin infections. Titers become positive within 1 – 5 weeks of infection and last for about 3 – 6 months. When patients are promptly treated with antibiotics, the antibody response can be abrogated.

Serum Protein Electrophoresis

Serum protein electrophoresis is most commonly used to assess monoclonal gammopathies. Standard serum protein electrophoresis does not identify light chains. Immunoelectrophoresis identifies both heavy (G, A, M, D, E) and light (kappa and lambda) chains. Immunofixation is a more reliable method. It is important to perform immunoelectrophoresis in both urine and plasma samples, as detection in urine but not serum is not uncommon.

Multiple myeloma and amyloidosis are the major renal diagnoses sought with these techniques. DM and SLE are associated with increased polyclonal urinary light chains. Monogammopathies may be seen in a variety of disorders, including hematologic, connective tissue, autoimmune, and dermatologic conditions. Actually, up to 3% of normal individuals over 70 may have an identifiable monoclonal component, usually < 3 g/dL. Of note, about 25% of patients with idiopathic monoclonal gammopathy eventually develop multiple myeloma.

Miscellaneous

Hepatitis B and C virus serology may be used for screening patients with glomerular disease that may be attributable to these agents. Periarteritis nodosa may also be associated with hepatitis B. HIV serology is indicated in patients suspected of having acquired immunodeficiency syndrome (AIDS) nephropathy. IgA levels are high in 30 – 40% of patients with IgA nephropathy.

Rheumatoid factor is an antibody with specificity for Fc fragments of IgG. The latex test is positive in 80% of patients with rheumatoid arthritis, and may also be positive in patients with subacute bacterial endocarditis, syphilis, tuberculosis, shunt nephritis, acute postinfectious GN, collagen vascular diseases, autoimmune diseases, and systemic vasculitis. An IgM rheumatoid factor is particularly common in Wegener's granulomatosis. An IgA rheumatoid factor is very suggestive of Henoch-Schönlein purpura.

Circulating immune complexes are measured using a C1q binding assay. They are positive in autoimmune, vasculitic, neoplastic, and infectious diseases. They have little practical application in clinical nephrology.

High serum IgE titers may be seen in Churg-Strauss vasculitis, allergic drug reactions, and in patients with latex allergy.

Renal Radiology

Intravenous Pyelography (IVP)

Radiologic techniques are based on the differential attenuation of X-rays by tissues. Dense structures such as bones greatly attenuate the beam and appear light on film. Low-density tissues like fat cause little attenuation and appear dark. High-osmolality contrast media (diatrizoic or iothalamic acid) are composed of a negatively-charged anion containing a benzene ring with 3 iodine molecules and a positively-charged cation (sodium or methylglucamine). Newer low-osmolality agents, anionic (ioxaglate-dimer) or nonanionic (iopamidol, iohexol, ioversol), provide twice the concentration of iodine for a given osmolality than conventional agents. Use of low-osmolality agents reduces the prevalence of side effects from 5 – 1%. Severe reactions including cardiac arrhythmias, cardiac arrest, pulmonary edema, loss of consciousness, and

seizures occur in < 0.01 of patients and are 5 – 10 times less common with the use of low-osmolality agents. Fluid restriction in preparation for an IVP is no longer warranted except to minimize emesis. Patients are asked to abstain from food after midnight and limit fluid intake to < 500 mL in the 4 hours preceding the study. A laxative such as bisacodyl may be used daily for 1 – 2 days prior to IVP.

The major clinical advantage of the IVP is its ability to provide an overall survey of the anatomy of the kidney and urinary tract as well as an estimate of renal function. A drip technique allows delivery of higher doses with less discomfort and may improve the nephrographic phase. The nephrogram defines renal size and contour and identifies changes in substance. The blush of contrast in the renal capillaries allows definition of the parenchyma, and, as it concentrates in the proximal collecting tubules (PCT), the image is enhanced. A normal nephrogram is synchronous and symmetrical; if not, the presence of nonfunctioning parenchyma should be considered. The left kidney is usually 2 cm longer than the right; a renal size < 11 cm is abnormal. Renal size by IVP is greater than by ultrasonography because of a greater magnification artifact and contrast-induced osmotic diuresis. Although resolution is 1.5 – 2.0 cm, a 1 cm cyst is easily observed whereas a 1.0 cm mass may not be apparent.

The pyelographic phase permits identification of abnormalities in the contour of the pyelocalyceal collecting system and recognition of intrapelvic filling defects. The ureters are not visualized symmetrically nor at the same time. Filling defects may also be noted. Persistent total filling of a ureter suggests an obstructive component. Retrograde and/or antegrade visualization may be required if there is concern about significant pathology. The bladder is well seen, but polyps or other lesions may be missed. Masses may appear as filling defects or as abnormalities in the contour itself. However, defects may be misinterpreted as superimposed bowel. Observed abnormalities may warrant further evaluation by cystoscopy. Small residual bladder volumes (< 50 mL) are not well seen. The urethra can be visualized by emptying the bladder post IVP. It should be specifically assessed with a voiding cystourethrogram or retrograde urethrography under special circumstances including bladder and/or perineal trauma, voiding abnormalities, and vesicoureteral reflux.

Major indications for IVP include acute renal colic and nonglomerular hematuria. In these conditions, IVP is more sensitive than ultrasonography because it provides anatomic definition of the entire urinary tract as well as functional information. Other clinical indications for IVP include renal stone disease, voiding difficulties, neurogenic bladder, recurrent urinary tract infections (UTIs), sterile pyuria, congenital abnormalities (Figure 4), unexplained abdominal pain, and postoperative complications (Table 7). With the advent of ultrasonography, computed tomography (CT), and nuclear imaging, IVP is no longer the first-line diagnostic study in patients suspected of having renal neoplasias, obstructive uropathy, or renovascular hypertension or in the follow-up of renal allograft recipients.

Renal tuberculosis is an important diagnosis to keep in mind. Pulmonary tuberculosis has decreased markedly but extrapulmonary disease has not changed in prevalence. Tuberculosis is more common in immigrant populations. A history of pulmonary tuberculosis is almost always present, but is usually inactive at the time of presentation. Renal lesions are indolent until very late in the course of disease. About 25% of patients have gross hematuria. Sterile pyuria is seen in about 10%. IVP is the test of choice and is positive in 90% of patients. Major findings include moth-eaten papilla, parenchymal calcification and

scarring, and multiple irregular infundibular stenosis or strictures with subsequent hydrocalicosis. If renal function is decreased (which happens about 50% of the time) then retrograde pyelography is indicated. If the ureteral orifice is scarred, cannulation may be very difficult. As the bladder is commonly affected, cystoscopy provides additional diagnostic benefit. Advanced disease may present as a nonfunctioning kidney (autonephrectomy).

Vesicoureteral reflux results from a dysfunctional vesicoureteral junction. If the intramural segment of the ureter is too short, the junction behaves as a leaky valve. As a child with this abnormality grows, the intraluminal segment lengthens and becomes fully operational. However, in some children this abnormality persists into adulthood. A diuretic intravenous pyelogram is very helpful in assessing this condition. Grade I reflux involves up to the lower third of the ureter. Grade II reaches the renal pelvis without causing dilation. Grade III results in mild pelvic dilatation. Grade IV produces marked dilatation and tortuosity of the ureter. At times, grade III may need to be differentiated from obstruction. Intrarenal reflux is more common in the upper and lower poles because these papillary orifices are round and more open. Patients with neurogenic bladder also have a higher incidence of reflux. When duplicate ureters are present, the lower one tends to reflux.

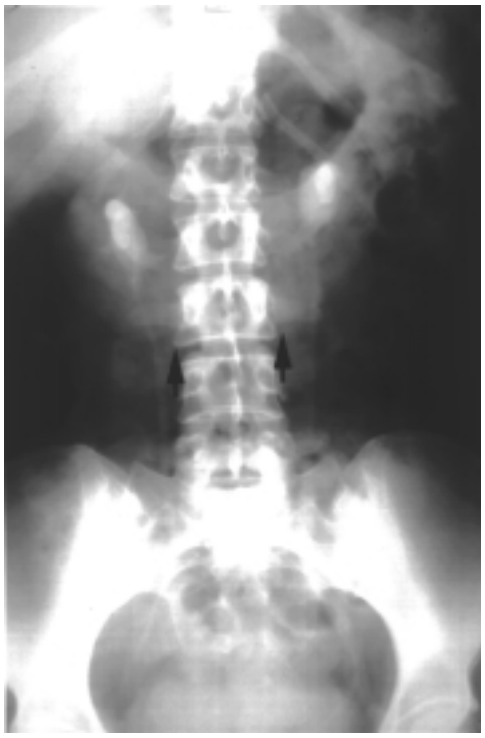

Figure 4. Horseshoe kidney. Excretory urogram demonstrates a medial orientation to the lower pole of both kidneys. The lower poles may be bridged by fibrous or nephrogenic tissue, such as in this case (arrows).

Ultrasonography

Ultrasonography is based on the differential acoustic impedance of tissues. Ultrasonic pulses are generated from short electric energizing pulses by a piezoelectric transducer. Bounced energy is reflected back to the transducer and reconverted to an electrical impulse. Transmission is optimal at water-like density; air and adipose tissue dampen the echo. Because the velocity of sound in tissues is constant, depth can be calculated from the time difference between sending and receiving an impulse. Real time digital images are generated by transforming reflected energy into a gray scale equivalent. Rapid sweeping with the transducer provides cross-sectional capabilities, and multiple planes can be sequentially generated by altering the positioning of the transducer. High-frequency probes provide better resolution but have less penetration. Patency of arteries and veins, as well as direction, magnitude, and velocity can be assessed with Doppler techniques. Renal ultrasonography is most often the first-line mo-

Table 7. Radiologic Studies Used in Diagnosis of Renal and Urological Disease

Suspected Condition	Radiographic Procedure	Comments
Nonglomerular hematuria Acute renal colic/nephrolithiasis Congenital malformations Recurrent urinary tract infections	IVP IVP IVP IVP	Anatomic definition of the entire urinary tract and estimation of individual function
Acute renal failure	US	Does not require contrast and is the best method to exclude obstruction
Chronic renal failure	US	Does not require contrast and increased echogenicity correlates with degree of sclerosis/fibrosis
Renal stone disease	US	Identifies stone only in the pelvis, may detect obstruction
Renal cysts	US	95% accuracy in differentiating cysts from solid masses US and CT are preferred for diagnosis of polycystic kidney disease
Renal masses	CT	Best method for assessing solid masses MRI is best for evaluating tumor extension into the renal vein and inferior vena cava and for identifying lesions < 2cm in diameter
Renal transplantation	US	Excludes obstruction, identifies perirenal fluid collections, provides supportive evidence of acute rejection
Perirenal hematoma	US	CT if recent hemorrhage is suspected
Atherosclerotic renal vascular disease & renal hypertension	DSA	Best resolution and the gold standard Spiral CT and MR angiography are promising Captopril renography is useful for screening
Renal vein thrombosis	MRA	Best resolution, US is a good alternative
Acute (complicated) pyelonephritis	CT	Can identify wedge lesions, abscess, and perirenal-fluid collection,US is a good alternative
Renal trauma	IVP	A normal IVP is highly accurate in excluding renal damage An abnormal IVP must be followed by dynamic CT with imaging of entire abdomen/pelvis

Figure 5. Normal kidney. Sagittal sonogram of the right kidney demonstrates the central hyperechoic sinus echo CT (S) surrounded by the hypoechoic renal parenchyma (P). The medullary pyramids are hypoechoic and located peripheral to the sinus (arrows).

dality for visualization of the kidneys. It is harmless, portable, free of ionizing radiation, and provides morphologic analysis totally independent of renal function.

The right kidney is best imaged with the patient in a supine position and with the liver as an acoustic window. The left kidney is best visualized in the right lateral decubitus position with the spleen as an acoustic window whenever possible. The echogenicity of the spleen is greater than that of the liver, which in turn is more echogenic than the kidney. If the ultrasonographic appearance of the liver is abnormal, comparisons may be distorted. Each kidney measures 10 – 12 cm in length. The renal sinus is hyperechoic. The renal pyramids are seen as hypoechoic triangles abutting the sinus and surrounded by the more echogenic parenchyma (Figure 5). The renal cortical area is homogenous. Minimal dilatation of the pelvis may be observed with a full bladder. Color Doppler technology allows sampling of the main renal vessels and its branches, including interlobar, arcuate, and capsular arteries.

Major strengths of ultrasonography include detection of pelvic and calyceal dilatation, identification of intrarenal fluid collections, separation of cystic and solid masses, and assessment of the perirenal space (Table 7). Disadvantages include poor resolution of the pelvicalyceal system and the retroperitoneum and poor visualization of the ureter. In addition, ultrasonography is very operator dependent.

Acute renal failure (ARF): Ultrasonography is the first diagnostic test of choice because it is the best method for excluding obstructive uropathy and does not require contrast administration. In hydronephrosis (Figure 6), branching, nonechoic, fluid-filled calyces, infundibulae, and pelvis distort the normal appearance of the compact sinus complex. Mild obstruction shows no distortion, and moderate obstruction is characterized by rounding of the collecting structures. In severe forms the sinus fat is replaced with rounded dilated infundibulae and calyces. Unilateral obstruction has multiple causes. Identification of bilateral hydronephrosis mandates assessment of the bladder and pelvis to exclude bladder outlet obstruction and retroperitoneal disease as etiologic factors. False negatives are unusual, but may be due to severe dehydration, acute obstruction with not enough time for distension, intermittent or partial obstruction, a ruptured calyx, staghorn calculi that obscure the underlying hydronephrosis, retroperitoneal fibrosis, tumor encasement, or near-absent renal function.

Figure 6. Hydronephrosis. The sinus echoes are separated by the hypoechoic urine-filled and dilated collecting system (arrows).

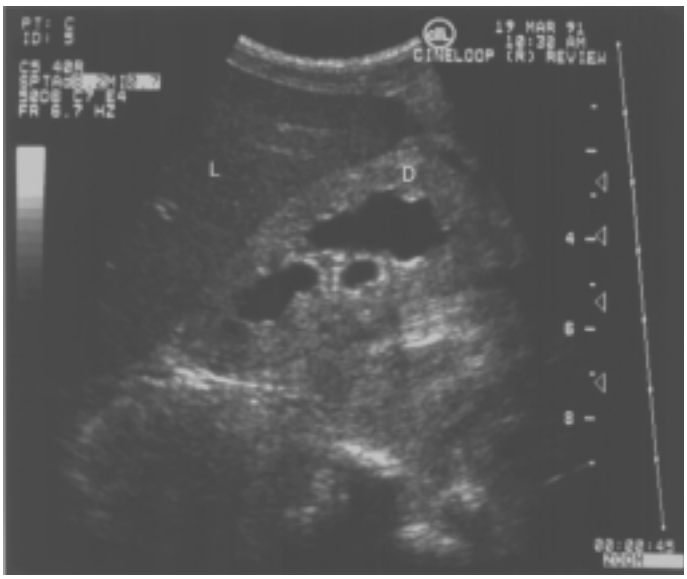

Figure 7. Medical renal disease. Sagittal sonogram reveals an echogenic renal parenchyma (D) with loss of normal central sinus echoes. The kidney is more echogenic than the liver (L).

Medical renal disease (Figure 7): Renal size, cortical thickness, and degree of echogenicity provide nonspecific information. Increased echogenicity is the most common characteristic associated with medical renal disease. There is a high degree of correlation between increased echogenicity and global glomerular sclerosis, tubular atrophy, and the presence of an infiltrative or inflammatory process.

Renal masses: The most common renal masses are cysts. Ultrasonography has a 94% accuracy in separating solid from cystic masses. About 90% of cysts are cortical and tubular in origin. It is not uncommon to find 1 – 5 cysts per kidney in patients over 50 years of age. Polycystic kidney disease (PKD) can be excluded if there are < 10 cysts per kidney set between normal-looking parenchyma. In PKD, other organs such as liver, pancreas, and

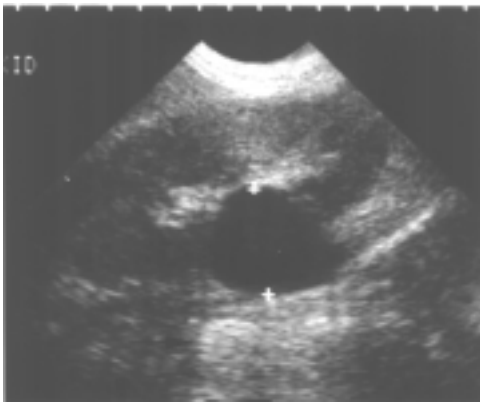

Figure 8. Renal cysts. A sharply circumscribed anechoic area consistent with a cyst is noted at the renal hilum. Acoustic enhancement beyond the cyst is present (arrow).

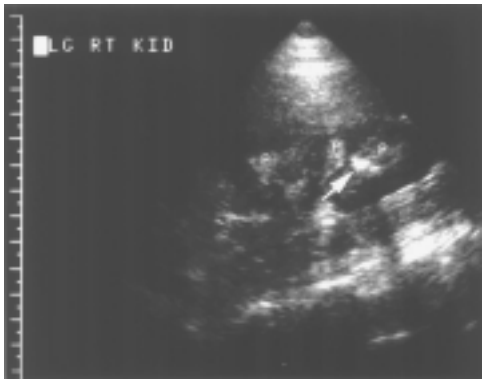

Figure 10. Medullary sponge kidney. The echogenic medullary pyramids create a pattern of triangular areas bordering the renal hilum (P). Note a large calculus in lower pole (arrow).

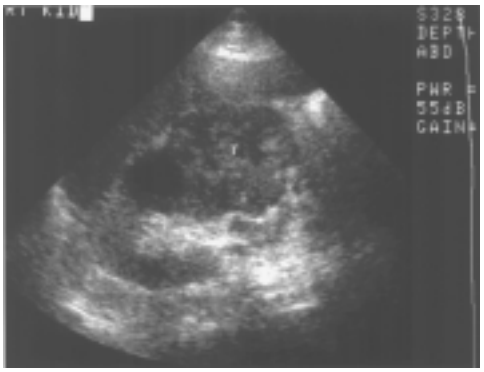

Figure 9. Renal cell carcinoma. Transverse sonogram demonstrates a large tumor (T) with small adjacent cyst. Obstruction of collecting system and/or infiltration of tubules by tumor gives rise to adjacent cysts (sentinel cyst).

spleen may show cystic lesions. Criteria for benign cysts include smooth and sharply defined walls, absence of internal echoes, posterior wall enhancement proportional to fluid content, and a narrow band of acoustic shadowing beyond the outer margin (Figure 8). If all these criteria are not met, CT is indicated. Bleeding into a cyst may give the appearance of a solid mass. Multiple thick septae are highly suggestive of malignancy. The best method for assessing solid renal masses is CT. Angiomyolipomas are benign tumors that are characteristically well circumscribed and very echogenic.

Malignant lesions are typically ≥ 3 cm in diameter before they are well detected by ultrasonography (Figure 9). About 85% of tumors are renal cell carcinomas. They are quite varied in appearance, with low, normal, or increased echogenicity. Posterior wall attenuation may be noted. Infiltrative tumors can appear as multiple hyperechoic masses in lymphomas and focal masses, as diffuse enlargement in leukemia, or as bizarre distortions. Renal cell carcinomas are best evaluated by CT and magnetic resonance (MRI).

Renal stone disease: When renal calculi is suspected, a kidney, ureter and bladder radiograph (KUB) should always be obtained first. Ultrasonography may detect actual calculi (> 5 mm in diameter) or identify hydronephrosis (Figure 10). Practically all stones regardless of composition are highly echogenic and accompanied by shadowing. Most stones cause obstruction at the level of the ureteropelvic or ureterovesical junction; neither area is well visualized by ultrasonography. IVP and/or CT may be required for definitive diagnosis.

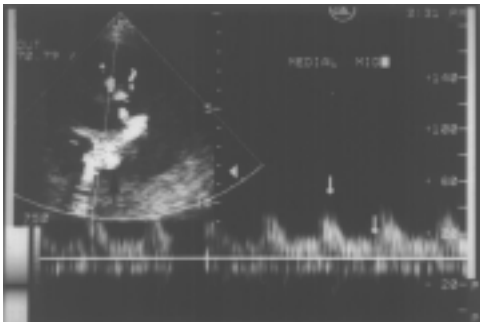

Figure 11. Normal renal transplant. Transverse sonogram demonstrates flow at the renal hilum (arrows). Spectral waveform on interlobar artery demonstrates normal low-resistance arterial waveform.

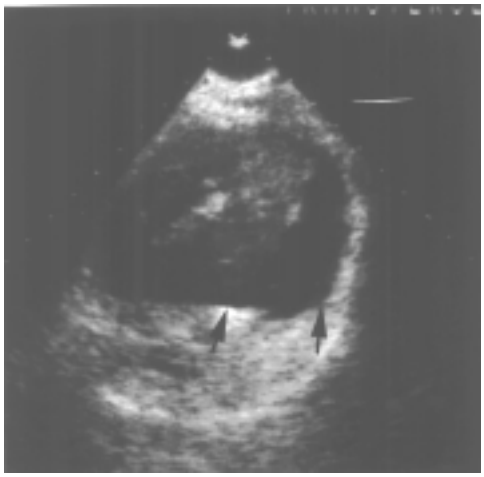

Figure 12. Renal transplant with infected lymphocele. Transverse sonogram of a left-sided allograft demonstrates a complex collection due to an infected lymphocele (arrows).

Infections: Ultrasonography is usually normal in about 75% of patients but may identify an underlying hydronephrosis. Acute pyelonephritis may result in renomegaly, heterogenous echogenicity, and perirenal fluid collections. A localized phlegmon presents as a focal, hypoechoic mass of ill-defined margins that may simulate a malignant lesion. A classic abscess has thick walls, well-defined borders, and a hypoechoic fluid level. Xanthogranulomatous pyelonephritis usually presents as enlarged hypoechoic areas surrounded by a hyperechogenic sinus.

Renal hypertension: Color Doppler ultrasonography is of limited value as a screening test. Intra-arterial digital subtraction angiography is the gold standard. Spiral CT angiography and magnetic resonance angiography show great promise. Captopril renography may be a useful screening tool.

Renal vein thrombosis: Magnetic resonance techniques are the best diagnostic tools. Ultrasonography with Doppler studies is a good alternate because it is noninvasive and requires no contrast administration. Findings include a dilated renal vein with a thrombus in the lumen, thrombus extension into the inferior vena cava, renal enlargement, thickening of Gerota fascia, and formation of pericapsular venous collaterals.

Renal transplantation (Figure 11): Ultrasonography is the method of choice for evaluation of renal allografts. Mild degrees of pyelocaliectasis are not uncommon. Urinomas, lymphoceles, hematomas, and abscesses are easily detected but have a similar appearance (Figure 12). Peripheral arterial resistance is usually quantitated as the resistivity index (RI).

$$RI = \frac{\text{peak systolic velocity} - \text{lowest diastolic velocitiy}}{\text{peak systolic velocity}}$$

A value > 0.70 indicates increased intrarenal resistance. This is a nonspecific finding commonly observed in acute rejection and cyclosporine nephrotoxicity but less frequently in delayed graft function. Acute rejection may also be associated with renal enlargement, prominent hypoechoic pyramids, and effacement of the central sinus. Acute allograft pyelonephritis is indistinguishable from acute rejection by ultrasonography.

Hematomas: Quite echogenic in the acute phase, hematomas become hypoechoic and septated as they liquefy. If recent hemorrhage is suspected, CT is indicated because ultrasonography cannot detect fresh blood.

Computed Tomography

CT is a digital cross-sectional imaging technique capable of detecting subtle variations in X-ray attenuation by different tissues. Data samples are obtained by moving the source around the patient at a given cross section of the body while measuring attenuation values along the X-ray beam. A computer calculates the average X-ray attenuation of all tissues within a specific volume element or voxel and represents it by a resulting number (CT number or pixel value). All CT numbers are referenced to water, which has a value of zero. Tissues less dense than water (fat) have a negative number; denser structures have positive numbers. Images are created by converting pixel values to light intensity on a cathode ray tube from which a hard copy (film) is obtained. Current scanners are capable of detecting a 0.3% difference in attenuation and achieving a spatial resolution of 0.5 – 1 mm. The system operator defines a window width (500 Hounsfield units [HU]) and an attenuation range (15 – 30 HU).

The attenuation coefficients within the retroperitoneum are different enough to allow visualization of the kidney, vascular structures, and the renal fascia. The renal parenchyma is uniformly homogeneous at 30 – 50 HU. The collecting system is differentiated from the parenchyma because of its water content (0 – 20 HU). Fat fills the perirenal space and sharply defines the renal border. Renal imaging by CT uses an initial digital/computer-generated radiograph to define the location of the kidneys. A nonenhanced study is then done using contiguous 1 cm thick sections. Thin sections (0.5 cm or less) are used occasionally to better delineate abnormalities or to identify small calculi. Contiguous bowel loops are identified by an oral barium swallow. Best definition is obtained with intravenous (IV) contrast media, except when calcification, hemorrhage, or urine extravasation is suspected, in which case a nonenhanced study is preferred. Images are usually displayed in the transverse plain, but sagittal and coronal images may also be constructed (Table 7).

The renal vascular anatomy is best seen with a bolus dye injection and rapid acquisition of images (dynamic CT). Within seconds the aorta, arteries, and veins are visualized. The nephrographic phase, characterized by enhancement of the cortex and the corticomedullary junction, is apparent within 1 min. The tubular phase, identified by increasing enhancement of the medulla, is noted at 2 min. Finally, the collecting system is apparent at 2 – 3 min. In patients with significant renal failure, enhancement is proportional to the amount of dye filtered, and usually only the vascular phase is reliably observed.

Obstructive uropathy: Ultrasonography is the technique of choice for initial evaluation of suspected obstructive uropathy. In addition to detection of hydronephrosis in a nonenhanced study, CT can define the anatomic site, degree, and cause of obstruction with nonenhancing imaging. Retroperitoneal fibrosis is suspected by increased attenuation within fat tissue that suggests encasement of the ureters. A dilated ureter is identified as a column of water surrounded by a thin tube. Extrinsic masses compressing the ureters, intraluminal masses, or stones may also be visualized. Regardless of composition, calculi have high attenuation rates (600 HU for calcium and 180 – 500 for uric acid) when compared to tissue (30 – 60 HU). Therefore, all uric acid and

cystine stones are radiopaque with CT. Blood clots have a wide range of HU ranging from soft tissue to near calculi. Serial examinations are required for better definition because clots lose attenuation with age.

Congenital anomalies: Usually found incidentally or by intravenous pyelography (IVP). CT does not provide any imaging advantage unless the kidney cannot be located or an identified mass needs further investigation.

Polycystic kidney disease: The kidneys are bilaterally enlarged with multiple cysts of various sizes distorting the collecting system. Hepatic, pancreatic, splenic, and pulmonary cysts may also be identified. Hemorrhagic cysts are seen as high-density lesions. Calculi within cysts and cyst wall calcifications may also be noted.

Acquired cystic disease: Multiple small cysts in hypotrophic kidneys may be seen in long-term dialysis patients. Perirenal hemorrhage and renal cell carcinoma are increased in this group.

Renal masses: Simple benign cysts are the most commonly detected renal masses, occurring in more than 50% of patients after age 50. They are characterized by a homogenous low attenuation value (0 – 20 HU) and nearly indiscernible thin walls, are very sharply delineated from the surrounding parenchyma, and are not enhanced by contrast. Diagnostic accuracy for simple cysts is virtually 100%. Parapelvic cysts are hilar renal masses with all the characteristics of simple cysts. They may mimic hydronephrosis or an extrarenal pelvis in nonenhanced scans.

Complicated cysts have a higher density, an irregular shape, and thickened or calcified walls. At times they may simulate solid tumors. Hyperdense lesions (50 – 90 HU) may be benign or malignant. The former include simple cysts complicated by hemorrhage, infection, dye leakage, and a high protein content. Lesions less than 3 cm in diameter and with simple cyst characteristics except for density are considered benign. Calcification always raises suspicion of malignancy. Occasionally, a benign cyst may show a small, fine, linear plaque. Septations in simple cysts are few in number and always less than 1 mm thick. When indicated, percutaneous cyst aspiration and biopsy may be performed under CT guidance.

Renal carcinoma accounts for 85% of primary renal malignancies. Approximately 1% are bilateral and 4.5% multifocal. Although most carcinomas are large at the time of diagnosis (7 – 8 cm), size alone should not be used as the major criterion for differential diagnosis. Renal cell carcinomas characteristically are > 3 cm in diameter, have a density greater than 30 HU but are less dense than the surrounding parenchyma, distort the renal contour, and are usually poorly differentiated from the rest of the parenchyma. They tend to be homogenous, but hemorrhage and necrosis may cause heterogeneity. Calcification may be present. CT is very useful for staging renal cell carcinomas: I – lesion limited to the parenchyma; II – extension to the perirenal space; III – extension to the renal vein, lymph nodes, or inferior vena cava; IV – extension outside Gerota fascia. Stages III and IV are better identified with CT than with angiography. Retroperitoneal lymph node involvement is well seen by CT. MRI is the technique of choice for evaluating tumor extension into the renal vein. Angiography is reserved for rare situations in which detailed vascular anatomy is needed. CT scanning is also an excellent method for detecting local recurrence after nephrectomy. A baseline study should be performed in the immediate postoperative period.

Metastatic renal disease is twice as common as renal cell carcinoma. Lung cancer is the most common type. Lesions look like renal cell carcinoma but are typically multifocal,

bilateral, small, and cortical in location. Renal vein and inferior vena cava involvement is rare in metastatic disease.

Lymphomas, particularly non-Hodgkins types, frequently involve the kidneys and are seen in 30 – 50% of autopsies. They usually appear as multiple bilateral nodules. A diffuse enlargement is due to progressive enlargement and coalescence of single lesions.

Angiomyolipomas are the most common benign renal tumors of the kidney. They are hamartomas in nature and usually present as a large solitary renal mass. Identification of adipose tissue within the mass virtually excludes malignancy. Hemorrhagic areas within the tumor are common. Tuberous sclerosis is associated with a high frequency of small, multiple, bilateral angiomyolipomas. Dynamic CT will usually demonstrate the hypervascular nature of the tumor.

Oncocytomas are benign tumors, usually 6 – 7 cm in diameter, that arise from the proximal tubular epithelium. They are solid homogenous masses of smooth contour, distinct interface, and, at times, a central stellate scar. Although these characteristics suggest a benign lesion, the diagnosis can only be confirmed histologically.

Transitional cell carcinomas account for 90% of renal pelvis neoplasms and are associated with exposure to organic chemicals used in aniline dye production. Papillary forms are most common (85%), tend to be low-grade, and are slow to infiltrate and metastasize. Nonpapillary lesions are more aggressive. Squamous cell carcinomas are the second most common type. They may be associated with infection and calculi in about 50% of patients. They usually present as an intraluminal mass of soft tissue attenuation (35 – 45 HU) with nodular borders, and they show enhancement with contrast. Large lesions may cause hydronephrosis. Calcification may occur, but it is less frequent than frank calculi. Loss of the peripelvic fat stripe indicates parenchymal invasion and overt malignancy. Because 40% of patients have concomitant pathology in the ureter or bladder, images including these areas are essential.

Pyelonephritis: CT is superior to ultrasonography for delineating renal and perirenal inflammatory masses. Findings range from a slight increase in overall renal size to radially oriented wedge-shaped areas of diminished attenuation oriented from the collecting system to the capsule. Focal renal enlargement with distortion of the renal contour may also be noted. A frank abscess will be delineated by a well-defined wall. The presence of gas within the renal parenchyma is highly suggestive of emphysematous pyelonephritis. Infected hydronephrosis (pyonephrosis) may show a debris-fluid level, gas, or both.

Xanthogranulomatous pyelonephritis may present as a focal tumefactive or a diffuse lesion. The parenchyma is replaced by masses that represent dilated calyces as well as abscesses filled with debris and pus. The thick walls noted are a result of granulation tissue and compressed normal parenchyma. Calculi are often lodged within the pelvis and calyces. Involvement of the perirenal and pararenal compartments is not uncommon.

Renal tuberculosis is second only to pulmonary disease. Most kidneys are small, with areas of focal fibrosis and distortion. Thickening of the pelvis and ureteric wall is very suggestive of tuberculosis. Calyces are usually filled with caseating material and putty-like calcifications or frank calculi.

Renal vascular disease: Infarcts are identified as wedge-shaped areas of diminished attenuation, with the cortical rim showing increased density due to perfusion from collaterals (Figures 13a and 13b). These lesions may also be seen in acute cortical necrosis, ATN, and renal vein thrombosis. Global in-

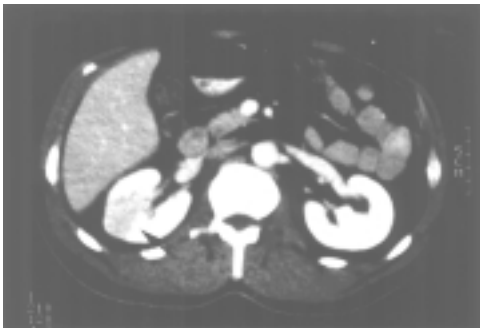

Figure 13a.

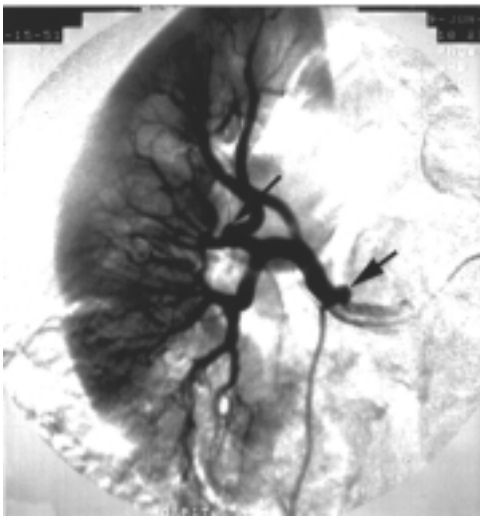

Figure 13b.

Figure 13. Renal infarction. a: Wedge-shape, low-density area is present in right kidney (arrow) in a 42-year-old male who presented with right flank pain and no evidence of bacteriuria. b: Renal arteriography shows 2 small renal aneurysms (arrows).

farcts produce a homogenous lesion involving at least 50% of the surface area. Acute renal cortical necrosis shows a thin rim of low attenuation between the capsule and the medulla. In renal vein thrombosis the kidney is enlarged and the renal vein full of low density material. Renal artery stenosis results in diffuse uniform atrophy of the parenchyma.

More recently, spiral CT has been used for noninvasive imaging of the vascular system. The kidneys are localized with standard nonenhanced CT. A dose of nonionic contrast medium is then injected manually and a short sequence of dynamic scans done for estimation of contrast transit time from the point of injection to the abdominal aorta. The spiral CT is then started at the level of the superior mesenteric artery after bolus injection administration and scans obtained at 2 – 3 mm section thickness with a table feed of 2 – 3 mm per second for a scanning time of up to 32 seconds. Multiplanar reformatting and 3-dimensional surface reconstructions are created by use of a threshold level dependent on the degree of vascular enhancement (130 – 220 HU). Maximum-intensity-projection images are reconstructed by eliminating bone structures from axial sections and subsequent display of the maximum pixel values along each path. Spiral CT can accurately identify multiple renal arteries and renal arterial stenosis in vessel segments between the origin and the hilum. More complicated anatomy requires use of active cine display of axial sections and multiplanar image reformatting at narrow intervals (1 – 2 mm) for evaluation of the entire vessel length. Spiral CT can detect mural calcification of blood vessels and acquires perfusion images (nephrographic phase) not available with magnetic resonance angiography. Potential difficulties with this technique include a relatively large dye load and difficulty in assessing peripheral stenoses and differentiating high-grade stenosis from total occlusion with collateral circulation. The overall specificity and sensitivity of this technique compared to angiography are 92% and 83%, respectively. The major clinical use of spiral CT is in the diagnosis of renal artery stenosis and in the anatomical assessment of living renal allograft donors.

Renal trauma: Best assessed initially by IVP. A normal IVP is highly accurate in excluding renal damage. However, an abnormal

IVP is nonspecific so that further examination by dynamic CT is indicated. Imaging of the entire abdomen and retroperitoneum is needed because about 20% of patients have other organs affected. CT scanning differentiates between minor (contusion, incomplete laceration, intrarenal hematoma) and major (complete laceration, renal fracture, shattered kidney) injuries. CT also identifies areas of focal renal infarction and subcapsular, perirenal, and pararenal hematomas as well as minimal amounts of bleeding (Figure 14). Accumulation of contrast-laden urine within the interstitial space of the kidney is characteristic of renal contusion. Parenchymal tears are seen as hypodense areas. If functional, they will be enhanced during dynamic CT. Focal infarctions are wedge shaped. Hematomas in the space medial to the kidney should raise suspicion of vascular damage. Arteriography is the procedure of choice for evaluation of potential vascular lesions.

Renal allograft evaluation: The major disadvantage when compared to ultrasonography is the need for a contrast agent. When hydronephrosis is present, CT may provide an etiologic diagnosis. Urinomas can be identified by assessing tissue density before and after dye injection. Acute rejection is characterized by loss of corticomedullary junction during dynamic CT.

Figure 14. Renal trauma. Precontrast CT reveals a hyperdense perinephric collection secondary to hemorrhage (H)

Magnetic Resonance Imaging

MRI is based on the spontaneous alignment of magnetic moments of the nuclei contained in tissues when an external electromagnetic field is applied. Because H^+ is abundant in the human body and has a high gyromagnetic ratio, MRI is almost exclusively carried out with protons. Images are produced by applying multiple radiofrequency signals (256 – 512 pulses) over several minutes. Fat saturation spin echo techniques improve image resolution by reducing the respiratory artifact caused by moving subcutaneous fat.

Although CT is superior for defining calcified and fatty structures, MRI provides better tissue contrast resolution, does not require dye, directly measures multiplanar images, and has no biological side effects. Major drawbacks include availability, cost, and the relatively long time needed for imaging. MRI is most commonly used as a problem-solving technique when ultrasonography and CT provide equivocal results. The renal venous circulation is particularly well defined, and MRI is the technique of choice for detection of renal vein thrombus or tumor invasion (Table 7). Gadolinium is approved for use as a paramagnetic contrast agent. Minor side effects occur in 2.4% of patients (nausea, vomiting, urticaria). Only 5% of the usual iodinated dosage is delivered. Estimated incidence for anaphylaxis is 0.001%. No renal, hepatic, or cardiovascular toxicity has been reported.

Magnetic resonance angiography (MRA) is based on the phase differences between moving and stationary objects and on the bulk spin flow in the area of interest. Renal arteries are best studied with phase contrast and the renal

veins and inferior vena cava with time of flight techniques (TOF). Proximal lesions are better seen than distal or intrarenal ones, particularly limiting the study of fibromuscular dysplasia.

Magnetic resonance spectroscopy (MRS) requires use of a magnet capable of delivering at least 1.5T with a field homogeneity 100 times greater than for MRI. Nuclei used for spectroscopy include ^{31}P, ^{13}C, ^{1}H and ^{19}F. The most common element used is ^{31}P (energy transfer, ATP hydrolysis, and intracellular pH). An increase in inorganic phosphate (Pi) from ATP hydrolysis during hypoxia leads to a decreasing ATP/Pi ratio. The phosphomonoester (MP)/Pi ratio is a good predictor of renal parenchymal viability. Acute renal failure is characterized by rapid loss of ATP, increased Pi, and decreased pH. In renal allografts, a decrease in MP/Pi is suggestive of rejection.

Obstructive uropathy: Anatomy is well preserved in acute and subacute cases, while in chronic obstruction the corticomedullary interface disappears. A diuretic MRI may be useful in differentiating anatomical obstruction from its functional counterpart.

Congenital anomalies: MRI provides excellent anatomical definition of congenital anomalies including agenesis, duplication, congenital obstruction, and horseshoe or pancake kidney. Ultrasonography, more readily available and less expensive, is the procedure of choice. However, MRI is warranted with inconclusive ultrasonographic studies.

Renal masses: Ultrasonography and CT are the methods of choice. However, MRI is specifically indicated for evaluation of the renal vein and inferior vena cava. With fat saturation techniques, cysts< 1 cm can be identified. This resolution is similar to that of CT. Cysts have sharp borders and thin walls and lack contrast enhancement. A complicated cyst (bleeding or infection) will have similar changes to those described with CT. MRI offers no advantage in the study of polycystic kidney disease. Calcifications are not detected by MRI. Angiomyolipomas are best studied by CT.

Renal cell carcinoma presents with a spectrum of findings. MRI is very helpful in identifying lesions < 2 cm and is preferred over CT. Additional advantages for staging include multiplanar imaging and better vessel visualization. MRI is the method of choice for detecting thrombus and tumor extension into the renal vessels. Gadolimium enhances tumor signals but does not affect blood signals.

Renal functional assessment: Glomerular filtration can be evaluated with injection of contrast and fast breath-hold gradient echo techniques. MRI provides better spatial and multiplanar resolution than isotopic renography and allows visualization of the kidney even in the absence of function.

Pyelonephritis: The collecting system is seen well with T1 imaging because urine has a low signal. Infected urine has a higher T1 signal than normal and can thus be identified. The kidney may appear swollen and lobar areas of high density may be noted, with abscesses identified as low-density images.

Medical renal disease: Loss of the corticomedullary junction is a very sensitive finding indicating significant renal disease; however, it is quite nonspecific. Exceptions to this rule are sickle cell disease and paroxysmal nocturnal hemoglobinuria. In both, the cortex has a very low signal intensity when compared to the medulla, because cortical iron deposition shortens T2. MRI changes are observed in 30% of patients after extracorporeal shock wave lithotripsy. Findings include parenchymal hemorrhage contusions and subcapsular or perinephric hematomas. Bleeding increases the signal, while contusion and edema produce focal or diffuse loss of corticomedullary differentiation. In ATN, the kidney appears normal, but after contrast

the signal intensity in the renal medulla increases because of proximal tubule edema.

Renovascular disease: The oblique course and small size of the renal arteries limit the usefulness of MRI. However, MRA is a promising tool in the evaluation of renovascular disease, particularly in renal allografts.

Renal allograft evaluation: MRI has no advantage over ultrasonography.

Angiography

Renal Arteriography

The most common use of renal angiography is the detection of renovascular disease manifesting itself as hypertension and/or progressive loss of renal function. In cases of renal trauma, angiography is indicated when vessel damage is strongly suspected. Angiography is necessary at times for differentiating avascular benign cystic lesions from neoplasms that are usually highly vascularized. Of note, about 10% of renal cell carcinomas are avascular.

The femoral artery is the preferred entry area; if unavailable, the axillary approach is a reasonable alternative. Before angiography, platelet counts, prothrombin, partial thromboplastin, and bleeding times should be checked and corrected when abnormal. Solid food is restricted from midnight and fluid intake is encouraged, as adequate hydration and fluid expansion can substantially lessen contrast nephrotoxicity. Modern computer technology allows real time recording of images, digital subtraction arteriography (DSA), postprocedure processing for enhancement, less use of film, and lower contrast loads. The major disadvantage of digital techniques is motion artifact. Use of smaller diameter catheters (≤ 5 French) and computer assistance have made angiography a routine outpatient procedure (Table 7). The complication rate of the procedure itself is < 1%, including hematomas, thrombosis, arteriovenous fistulae, pseudonaneurysms, and infections.

A pigtail catheter is placed at the presumed level of the renal arteries (first lumbar vertebral body). A bolus dye injection (≤ 4 mL/kg) is made, and films are taken at a rate of at least 2/sec. After identifying the origin of the renal artery, a curved catheter is positioned and selective renal arteriograms obtained. A single renal artery is found in about 70% of patients. As it reaches the hilum, the main renal artery branches into several segmental vessels, which subsequently divide into interlobar arteries that traverse between the renal pyramids. The interlobar arteries give rise to arcuate arteries that curve around the medulla and run parallel to the cortex. The intralobular arteries branch out at right angles from the interlobar segment. Initial images are taken in the anteroposterior view. Lateral views are then obtained to better evaluate the renal ostia. Upon completion the catheter is removed and compression applied for 10 minutes. The patient usually remains in bed rest for 4 – 6 hours. When appropriate, venous renin samples are obtained from the renal veins and the inferior vena cava.

Renal artery stenosis: The most common cause is atherosclerosis. Most frequent location is the main renal artery and its proximal branches. Plaques may be smooth or irregular and at times accompanied by poststenotic dilatation. Ostial stenosis is usually aortic in origin. Fibromuscular dysplasia is most common in white females younger than 40. There are 4 major types: I. medial fibroplasia with aneurysm formation (70%) presenting as the classic string of beads; II. perimedial fibroplasia (15%) with a string of beads smaller than the unaffected segments of the vessel; III. intimal fibroplasia; IV. periarterial fibroplasia. The latter 2 are associated with

decreased renal mass and small circumferential stenoses. Angiography can also be used for detection of renal allograft arterial stenosis.

A renal vein to inferior vena cava renin ratio ≥ 1.5 with contralateral renin suppression is very specific for renovascular hypertension. However, because of a 50% false negative rate, many centers perform angioplasty without waiting for renal vein renin results. Percutaneous transluminal angioplasty is extensively used for the treatment of renal artery stenosis. Results are best in medial fibroplasia. Atheromatous disease that is short, segmental, and not ostial is reasonably well treated by angioplasty (70 – 90% patency at 12 – 18 months with good blood pressure control in 60 – 70% of patients). Restenosis occurs in 10 – 20% of patients within the first year and is most common in patients with ≥ 30% residual stenosis after angioplasty. Ostium lesions respond poorly to angioplasty and may be best managed by stenting. Complications include ARF (2%), worsening of renal function (2%), and development of arterial rupture, perforation, dissection, segmental occlusion, symptomatic embolization, false aneurysm, fistula formation, or puncture site trauma (10%). Less than 4% of these require surgical correction. It is important to remember that atherosclerotic stenosis may not cause hypertension.

Renal artery aneurysms: These tend to be focal and saccular and are usually located near the hilum. About 30 – 50% have a calcified wall. They are seen in 1% of renal arteriograms and are most commonly associated with stenosis. The risk of rupture is 6%.

Embolic renal disease: May result from left atrial or ventricular thrombus, atrial myxoma, cardiac valvular vegetations, or mural thrombus within an aneurysm in the aorta or renal artery, and may be precipitated by angiography. Cholesterol embolic disease may be identified by pruning of vessels in the appropriate clinical setting.

Vasculitis: The distal vessels are most affected. In periarteritis nodosa, multiple 1 – 3 mm punctate aneurysms may be noted in the distal renal artery branches.

Other vascular lesions: In renal infarction, an occluded vessel may be identified in association with a wedge-shaped radiolucent defect. Arteriovenous fistulae usually result from trauma and are characterized by rapid shunting to the venous system. Arteriovenous malformations have the appearance of serpentine arteries that opacify quite early.

CO_2 Angiography

Currently limited to a few centers but receiving increasing attention for its ability to provide adequate definition of vascular anatomy without use of iodinated contrast agents. Because this technique allows multiple studies without risk of nephrotoxicity, it has great potential for screening patients with suspected occlusive renal arterial disease. Studies comparing CO_2 angiography and flush aortography (without selective catheterization) indicate an 83% sensitivity and a 99% specificity with this technique. Peripheral vessels of the lower extremity are well seen and may provide a particular advantage for evaluation of renal allograft arterial stenosis. The most significant side effect of CO_2 angiography is neurotoxicity (multifocal ischemic infarction due to gas embolization). It is also contraindicated in patients with significant pulmonary disease, as they may be unable to excrete a large CO_2 load. Concomitant congestive heart failure is also of concern because it may be associated with livedo reticularis, rhabdomyolysis, and intestinal infarction from gas embolization following aortography. Lack of commercially available CO_2 injectors and the

need for tilting tables also limit the widespread use of this technique.

Intravenous Digital Subtraction Angiography

It is rarely used at present. On the other hand, dye injection into the right atrium makes DSA suitable for follow-up assessment of percutaneous interventional procedures.

Renal Venography

There are very few indications for venography because it has been replaced by MRI. A renal vein thrombus may be seen angiographically as a radiolucent filling defect or as a venous occlusion.

Transcatheter Embolization

Used in the treatment of neoplasms and arteriovenous fistulae or to control bleeding. Embolization can be done with autologous clot, Gelfoam, polyvinyl alcohol coils, detachable balloons, or absolute alcohol. Many patients develop a postembolectomy syndrome characterized by malaise, fever, local pain, and leukocytosis lasting 3 – 5 days.

Radionuclide Studies

Glomerular Filtration Rate

Available radionuclide agents excreted only by glomerular filtration include iothalamate, diethylenetriamine pentaacetic acid (DTPA) and ethylenediamine tetraacetic acid (EDTA). Most accurate clearance values are obtained using standard clearance techniques (as described previously for inulin) including timed blood and urine samples. ^{125}I-iothalamate (614 dalton) may also be administered as a subcutaneous bolus injection obviating the need for a constant infusion. It provides GFR values identical to those obtained with inulin. Because of the prolonged half life of the isotope (60 days), concomitant Lugol administration is required to protect the thyroid. Values obtained with ^{51}Cr-EDTA (292 dalton) are 10% lower than inulin, perhaps because of in vivo protein binding, tubular reabsorption, or in vivo dissociation. The disadvantage in using ^{99M}Tc-DTPA (393 dalton) is that its short half-life of 6 hours requires preparation immediately before administration and prompt counting of samples. Protein binding also results in lower clearance values when compared to inulin. Radiation is always an issue. Although less than with a standard radiologic procedure, there is transient accumulation in the urinary tract during excretion. It is recommended that patients ingest large amounts of fluid the day of the study. These methods are most commonly used as a replacement for inulin clearance measurements.

Radionuclide agents can be used to assess GFR without collection of timed urine specimens. A single injection or a continuous infusion technique may be used. GFR is measured as the amount of injected radiolabel cleared from plasma divided by the integrated area of its plasma concentration over time curve. Mathematical modeling must be used because it is not possible to obtain enough samples to directly measure the area under the curve. The method presumes that arterial and venous compartments are in prompt equilibrium. Both single and double compartment models have been used. Because the latter requires multiple sampling, the one-compartment model is most commonly used in the clinical setting. Clearance is described by the equation

$C = V_O (\ln (2)/t^{1/2})$

where C = clearance, V_O = initial volume, ln = natural logarithm, and $t^{1/2}$ = radiolabel half-life.

This technique is quite accurate and as few as 2 samples are enough. Second sampling time should be adjusted to the probable level of GFR as follows: 1 hour for near normal function, 4 – 5 hours for moderate renal failure, up to 24 hours for severe chronic renal failure or, regardless of renal function, when significant ascites is present. A shorter single plasma method assumes that the volume of distribution (*Vd*) is given by the dilution of the administered dose (D) at the time of sampling (t). At about 3 hours when the tracer concentration has reached equilibrium, *Vd* can be calculated as D/Pt. Because the radiolabel disappearance rate is proportional to GFR and *Vd*, the former can be mathematically derived. This technique loses accuracy at GFR < 30 mL/min.

In the absence of plasma samples, total GFR can be calculated by gamma camera capture of the activity time curves (renogram) generated over the kidneys. The renogram consists of an initial spike related to the immediate uptake of the arterial bolus (aortorenal transit time), a renal parenchymal transit time segment, and a final pelvic transit time. Absolute estimates of GFR using this approach have a 20% variation and are less accurate than plasma sampling. However, an important advantage of this technique is the ability to measure the relative contribution of each kidney to total function as determined by the individual activity time curves generated. A normal peak occurs at about 150 – 180 seconds. As the first 90 seconds are unstable due to mixing, measurements are made from 90 – 180 seconds. The normal range of relative uptake function is 42.5 – 57.5 %. Estimation of relative renal function is the most important measurement obtained with radionuclide techniques. Results are accurate and reproducible (6% variation). Errors increase when overall GFR is < 20 mL/min.

Renal Plasma Flow

Radiopharmaceuticals, which are primarily secreted by the tubules, provide a reasonable index of renal blood flow. Agents include para-aminohippurate (PAH), orthohippurate (OIH), and mercaptoacetyltriglycine (MAG3), labeled with ^{131}I or ^{99m}Tc. In general, ^{99m}Tc-MAG3 is considered the agent of choice. After injection, samples are taken at defined intervals (7, 17, 30, 44, 60, and 120 min). Calculations using two (7, 17 min) and one (44 min) samples are also available but have a greater coefficient of variation.

Dynamic Diagnostic Imaging

Renovascular hypertension: Stenosis of the renal artery will decrease uptake, increase transit time, and delay tracer excretion on the affected side. The sensitivity of renography in the diagnosis of renovascular hypertension is similar to that of rapid sequence IVP (70% sensitivity and 79% specificity). Diagnostic accuracy is improved by performing renography before and after captopril administration. Captopril induces a further acute decrease in renal blood flow and GFR on the affected side, thereby magnifying the asymmetry of the renogram curves and cortical retention (90 – 95 % sensitivity and specificity). Prior furosemide administration may further enhance differences. Normally, uptake is maximal at 1.5 – 2.5 min, and the difference be-

tween kidneys is no more than 60:40%. Findings suggestive of renal artery stenosis include the following: I. less than 42% accumulation of tracer, II. a delay of >1 min in peak time, and III. increased residual activity at 15 – 20 min. In mild stenosis the latter may be the only positive finding. Lateralizing findings are less likely to be apparent when GFR is significantly decreased.

Vesicoureteral reflux: This abnormality may be assessed directly or indirectly. The direct method is identical to a micturating cystogram but has the disadvantage of offering no anatomical detail. On the other hand, it uses less radiation exposure and is more easily quantifiable. The indirect technique employs a standard dynamic ^{99m}Tc-DTPA renal scan. Upon completion of the test, the patient drinks until the bladder feels full and there is an urge to void. Baseline renal and bladder counts are taken at this point. The patient then voids while the gamma camera updates data for several minutes after voiding. The presence of reflux into the kidney is detected in the time-activity curves as a peak. Lesser degrees of reflux are more prone to error and not easily identified by this method.

Obstructive uropathy: Ultrasonography is the best modality for detecting obstruction (90 – 95% sensitivity and 70% specificity) but provides no functional data. This may be of particular importance in neonates, in patients with previous urological surgery, and in those who have recently passed a kidneys stone. An atonic collecting system appears like hydronephrosis in the absence of obstruction. A furosemide renogram can separate true obstruction from functional dilatation. A standard renogram identifies obstruction as a prolonged transit time. After a standard renogram, a single IV dose of furosemide is given (0.5 mg/kg) and data collected over 15 min. A normal response is a steeping of the rate of fall with a concave washout curve. The absence of washout indicates obstruction. In retroperitoneal fibrosis, ultrasonography may show no hydronephrosis, but the renogram will demonstrate progressive accumulation of tracer without excretion.

Acute renal failure: Isotopic renography is not particularly helpful in the evaluation of patients with ARF. It identifies blood flow to the kidney and the presence or absence of functional tissue. ATN has a normal perfusion phase followed by moderately good visualization at 90 – 180 seconds. Tracer density then gradually decreases with little accumulation in the collecting system. Acute GN and acute interstitial nephritis are characterized by delayed perfusion, very slow accumulation, and virtually no excretion.

Chronic renal failure: Nuclear studies are of very little help. Scans may identify small scarred kidneys or the presence of polycystic kidney disease.

Renal transplantation: The most commonly used agent is ^{99m}Tc-MAG3. Delayed graft function is characterized by good perfusion and decreased function, while in acute allograft rejection both are decreased. Cyclosporine toxicity is indistinguishable from delayed graft function. Isotopic renography may assist in the detection of a suspected urinary leak. In many centers, routine early postoperative isotopic renography is being replaced by color Doppler ultrasonography.

Static renal imaging: Increased gallium uptake is a nonspecific indicator of inflammation. This test will be positive in the presence of acute pyelonephritis, acute interstitial nephritis, and neoplastic infiltration.

Urological Procedures

Major indications for urological interventions encompass abnormal bladder function, suspected lesions (benign or malignant), presumed lower tract bleeding, intra/extraluminal ureteric lesions, the need for precise definition of the collecting system, and evaluation of vesicoureteric reflux. Urological procedures of interest to the nephrologist include cystoscopy, retrograde and antegrade pyelography, cystourethrogaphy, and upper tract endoscopy and lithotripsy.

Retrograde pyelography: Contrast is injected directly into the ureter or ureteral orifice for direct visualization of the collecting system and ureter. The degree of distention and opacification is controlled by the amount of dye and the injection pressure. The ureter can be cannulated cystoscopically and the catheter advanced to the desired level for dye injection (direct), or a bulb-shaped catheter may be wedged to the orifice for injection (bulb pyelogram). If a suspected lesion is found, brush cytology should be performed at the same time. Overdistention may cause pyelosinus extravasation due to fornix rupture and extravasation into the renal sinus, pyelolymphatic extravasation, and/or pyelotubular back flow to the papillary distal collecting ducts.

Renal pelvis tumors are best screened for with retrograde pyelography. Hematuria is the most common clinical presentation, with obstruction noted on occasions. Flank pain, dysuria, or palpable mass are distinctly unusual. Exposure to metabolites of aminophenols is associated with a higher risk. Individuals who consume large amounts of phenacetin are also at greater risk. Renal pelvis tumors account for < 10% of renal tumors. Most common are transitional cell carcinomas, which are twice as frequent in males as females and peak in the 7th decade of life. They may occur anywhere in the urothelium but are 15 times more common in the bladder than in the ureter or pelvis. Lesions may be flat or papillary, with 20% containing metaplastic squamous changes. The papillary types are easier to detect and are usually less malignant. Flat lesions are harder to find, are more malignant, and include squamous cell carcinomas. Multicentric lesions are very common in the bladder and in about 30% of pelvis tumors.

Antegrade pyelography: Contrast is directly injected into the collecting system. It is usually performed when IVP fails and retrograde studies are considered risky or not possible. In children this is the preferred method because cystoscopy is problematic. It is usually done under ultrasonographic or CT guidance.

Cystography: Mainly used for assessment of low-pressure vesicoureteral reflux or bladder rupture. Voiding cystography can be done using a drip method or a direct injection via a urethral catheter. The study may demonstrate low-pressure vesicoureteral reflux, radiolucent filling defects (tumor or radiolucent stone), bladder diverticuli, or vesicocolic fistulae. The bladder is usually filled until the patient feels the urge to void. The catheter is then removed and the patient voids. A cine or video is obtained during voiding and recorded in spot films, 100 mm cut film, or continuous 105 mm film. High-pressure reflux, bladder extravasation, and small neck diverticuli may not be apparent until the voiding study is obtained. For air contrast cystography, the bladder is first coated with barium, drained, and then insufflated with air, CO_2, or nitrous oxide. This technique has better resolution and allows visualization of lesions located within diverticuli or those too small to be detected by standard cystography.

Retrograde urethrography and voiding cystourethrography (VCUG): These are indicated in male patients with neuromuscular bladder dysfunction. A Foley catheter is inserted into the fossa navicularis and the balloon inflated with 1 mL of saline. Contrast is injected via the Foley and the bladder filled. The catheter remains in place during the voiding study. If low pressure reflux is noted, abdominal compression is applied to prevent reflux into the kidneys.

Dynamic retrograde urethrography: This procedure is done using a Foley catheter (preferred method as above) or a Brodny clamp. The latter is a device that has an external meatal plug that is fitted over the glans penis by a traction clamp. The study should be followed by VCUG.

Urodynamic studies: Cystometry measures changes in intravesical pressure with progressive increases in bladder volume. The cystometrogram (CMG) evaluates the filling and/or storage phases of detrusor contraction and consists of four phases:

- I. the initial rise to achieve bladder resting pressure,
- II. the tonus phase where filling causes little change in pressure (400 – 750 mL at < 15 cm H_2O),
- III. the peak capacity at which additional volume causes a rise in pressure while the patient is still able to suppress involuntary voiding, and
- IV. the last phase is voluntary voiding. This evaluation detects bladder compliance abnormalities, involuntary detrusor contraction, and decreased bladder volume.

Uroflowmetry allows the recording of flow volumes and patterns. Flow rate is a function of the combined activity of detrusor and urethra. Urethral obstruction may be overcome by a more forceful detrusor contraction. The normal flow pattern reaches a maximum rate within one third of the total voiding time, with ≥ 45% of the total void volume evacuated within the same period. Mean flow rate should equal 50% of the maximum rate achieved. An interrupted stream is suggestive of striated sphincter contraction, detrusor sphincter dyssynergia, or artifact. Outlet obstruction is characterized by a flat, elongated curve with a low maximum flow rate.

Residual urine volume also gives an index of poor detrusor function and/or bladder outlet obstruction. The larger the volume, the more likely the detrusor hypocontractility. Neurogenic bladder is a term used to describe neuromuscular dysfunction of the detrusor muscle and the urethral sphincter. In this condition, the normal reciprocal parasympathetic and sympathetic activity is inhibited and results in voiding difficulties. Urological evaluation for this condition includes urodynamic studies, electromyography, and radiology. Dual-microtipped pressure transducer catheters allow simultaneous measurement of bladder and urethral pressures. Within the bladder, readings are obtained at the bladder neck, distal sphincter, and bulbous urethra. Sphincter dyssynergy can be easily detected at the internal and distal sphincter sites. Urinary flow measurements are also helpful in evaluating bladder emptying. Normal values for males under age 40 are 22 mL/sec; these drop to 13 mL/sec by age 60. In females normal values for age < 50 are 25 mL/sec and decrease to 18 mL/sec thereafter. Striated muscle activity is assessed by inserting an electromyographic needle into the external sphincter. Normal activity is present at rest, increases with rising intraabdominal pressure, and ceases upon voiding. In upper motor neuron lesions, no increase in electrical activity during rising abdominal pressure is noted because of discontinuity of the neural pathway. Continuous activity during voiding indicates

dyssynergia. An areflexic bladder shows no activity at any time.

Endoscopy of the upper urinary tract: This technique is helpful in evaluating patients with a radiolucent filling defect in the upper urinary tract. Patients with unilateral hematuria identified by cystoscopy require a comprehensive evaluation. If retrograde ureterography and upper tract cytology are negative, a CT study is indicated. If this is negative, an arteriogram is indicated. A negative angiogram is an indication for ureteroscopy.

Instrumentation and endoscopy: Cystourethroscopy allows direct visualization of the anterior and posterior urethra, bladder neck, and bladder. Hematuria is the most common indication. In patients with initial hematuria, bleeding is usually urethral or prostatic. In total hematuria, the source is likely the bladder or the upper tract. Terminal hematuria usually arises from the bladder neck. Next in frequency is the presence of voiding symptoms (obstructive and/or irritative). Visualization of the upper urinary tract can also be accomplished by flexible ureteroscopy. A case of essential hematuria localized to the right or left supravesical collecting system is an indication for ureteroscopy. Anatomical sites of hematuria, when found, can be treated by direct fulguration.

Local bladder pathology commonly identified by cystoscopy includes filling defects, foreign bodies, cystitis (infectious or inflammatory), diverticuli, herniation, tumors (leiomyoma, hamartoma, nephrogenic adenoma, fibrous polyp, papilloma, transitional cell carcinoma, squamous cell carcinoma, adenocarcinoma), and bladder calculi.

Extracorporeal shock wave lithotripsy: Shock waves can be reliably reproduced by the underwater discharge of a capacitor. These waves propagate to the stone without energy loss or tissue damage. They can be precisely focused by integrating the energy source into a suitable reflecting system. Shock waves give rise to mechanical stresses in brittle materials such as kidney stones and cause disintegration. Except for cystine stones, human calculi can be dealt with at low levels of pressure (700 – 900 bar). Side effects include hematuria, perirenal hematoma, parenchymal hemorrhage, edema, tubular necrosis, and fibrosis. The hemorrhage and edema are similar to blunt renal trauma and are short lived.

Renal Biopsy

Examination of renal tissue obtained by biopsy is a crucial component of disease management in clinical nephrology. While correlations between clinical disease and histologic change had long been derived from autopsy material, the introduction of percutaneous biopsy methods dramatically expanded the understanding of glomerular disease in particular.

Current practice incorporates use of a renal biopsy to establish a specific diagnosis when other clinical assessment of renal disease by history, physical examination, urinalysis, and serology is inconclusive. A precise diagnosis has the potential to influence selection of medical therapy. The biopsy may also be helpful in defining prognosis of certain disease states, and in limited circumstances may assess the evolution of renal disease by serial examination of tissue samples over time.

Indications for Renal Biopsy

The most common settings for considering renal biopsy are the evaluation of the neph-

rotic syndrome or nephrotic range proteinuria, acute nephritis, and acute renal failure of obscure origin. Biopsies are also commonly done to evaluate renal dysfunction in transplanted kidneys. Less commonly, a biopsy may be undertaken in the evaluation on non-nephrotic range proteinuria and isolated hematuria. It is important to emphasize that the decision to pursue an invasive diagnostic study such as a biopsy always be individualized, and that the clinical utility of biopsies varies markedly depending on clinical circumstances.

Nephrotic range proteinuria (≥ 3.0 g/24 hours) is classified as secondary if due to systemic disease and primary or idiopathic if an underlying nonrenal disease is not identified. Most clinicians consider a renal biopsy in adult patients with nephrotic proteinuria when diabetes mellitus , amyloidosis, multiple myeloma, hereditary nephropathies, and certain infections have been excluded. The best clinical judgment before biopsy can differ from the biopsy diagnosis in 45% of patients, with modification of planned therapy in 35% of these same patients. Because treatment alternatives for idiopathic nephrotic syndrome remain somewhat limited, other clinicians have advocated use of a decision analysis model advocating use of empiric therapy with corticosteroids. This approach assumes that diagnoses other than the common forms of idiopathic nephrotic syndrome (membranous nephropathy, focal and segmental glomerulosclerosis, minimal change disease, and membranoproliferative glomerulonephritis) occur in only 2% of cases. Some clinicians have found that patients clinically judged to have idiopathic nephrotic syndrome have other diagnoses established by biopsy more frequently. Moreover, treatments with cytotoxic and immunosuppressive agents are currently considered in the treatment idiopathic nephrotic syndrome. It is important to discuss the relative utility of renal biopsy with patients before recommending a renal biopsy for evaluation and treatment of idiopathic nephrotic syndrome. A wide array of issues such as age, co-morbidities, and level of renal function should be addressed.

The renal biopsy may also be useful in evaluating proteinuric conditions in patients with systemic disease. The best example is lupus nephritis. In this setting, even though diagnosis is rarely the issue, the specific morphology of renal involvement guides the choice of therapy. A standardized set of criteria (World Health Organization classification of lupus nephritis) has been developed to assist the clinician in deciding on appropriate treatment regimens. Additionally, an NIH-modified semiquantitative histologic scoring system for lupus nephritis with scales grading the inflammatory activity and chronicity of biopsy lesions has been described and correlated with clinical outcomes.

Investigation by renal biopsy of patients with less than nephrotic range proteinuria (0.5 – 2.5 g/day) is not routinely undertaken in clinical practice. The etiology of such proteinuria is frequently nonspecific. This in no way lessens the importance of a prudent search to explain the proteinuria by other, less invasive clinical methods. On the other hand, biopsies have occasionally been undertaken in such situations and have even led to the description of new forms of uncommon renal disease. Clinical judgment is key in deciding which patients may benefit from this procedure.

Renal biopsy in patients with an acute nephritic syndrome is commonplace. It is particularly useful when abnormal renal function is only of short duration, and clinical evaluation does not identify an immediate specific diagnosis. Patients with rapidly progressing glomerulonephritis (RPGN) are a distinctive subset. In this clinical setting an active urinary

sediment, often with dysmorphic erythrocytes and occasionally red cell casts, is noted in association with variable degrees of proteinuria and hematuria. The differential diagnosis of an acute nephritic syndrome is broad and includes several forms of glomerulonephritis, thrombotic microangiopathies such as hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP), and (rarely) unsuspected hypersensitivity interstitial nephritis or atheroembolization. The importance of distinguishing these processes cannot be overstated, as therapies range from supportive in the case of poststreptococcal glomerulonephritis (PSGN) to immunosuppression with plasmapheresis and cytotoxic drugs in the case of antiglomerular basement antibody-mediated renal disease.

Investigation of ARF by biopsy is generally limited to special clinical situations. In most circumstances, the clinician can reasonably assess the cause of the renal dysfunction without the aid of the biopsy. Prerenal states such as volume contraction and congestive heart failure are usually clinically apparent. Postrenal causes of renal dysfunction are generally best elucidated with imaging techniques, particularly renal ultrasound. Persistent renal failure due to intrarenal processes is most commonly related to acute tubular necrosis due to hypotension or drug toxicity. However, when ARF is associated with a persistent and very active urinary sediment, a biopsy may be invaluable. A renal biopsy may occasionally be utilized in the absence of an active urinary sediment when the clinical cause of prolonged acute renal failure is of obscure etiology. In this situation, common biopsy findings include ATN, interstitial nephritis, atheroembolization, or cortical necrosis. These conditions may require different treatment strategies and have varying degrees of possible recovery of renal function, thereby justifying the use of this invasive procedure. In this setting about 20% of patients will have a change in treatment plan based on the renal biopsy findings.

In the setting of renal transplantation, a biopsy is most commonly undertaken to evaluate renal dysfunction. Acute allograft rejection is often difficult to distinguish from more benign causes of allograft dysfunction, such as nephrotoxicity due to cyclosporine or tacrolimus. Biopsies are also very useful in characterizing the severity and nature of rejection (cellular vs. vascular) and are of help in selecting appropriate antirejection therapy. A standardized classification system, the Banff classification, is very useful in clinical practice and also allows comparisons between patients treated at separate centers. When performing routine biopsies in renal transplant recipients as part of an established protocol, some centers have reported many patients with histologic evidence of rejection in the absence of clinical findings, including renal dysfunction.

The evaluation of hematuria may result in the use of a renal biopsy, although in most circumstances this is not routinely recommended. Patients with hematuria come to the attention of the nephrologist when other investigations, usually including structural studies such as IVP, ultrasound, or CT with contrast agents, and cystoscopy with retrograde studies have not yielded a diagnosis. In this setting microscopic hematuria and/or recurrent macroscopic hematuria may reflect an abnormality of the renal parenchyma. Typically patients with this presentation have normal renal function as assessed by serum creatinine. The principal clinical diagnoses to consider include IgA nephropathy, hereditary nephritis (Alport syndrome), thin glomerular basement membrane syndrome, and the loin pain hematuria syndrome. The prognosis for long-term stable renal function is excellent when there is no concomitant proteinuria. Bi-

opsy is then undertaken primarily to establish a definite etiology of the hematuria and avoid repeated structural imaging studies. However, it should be noted that while frequently abnormal, the renal biopsy is entirely normal in as many as 30% of patients. As more specific treatments are described and validated, such as fish oil in the treatment of IgA nephropathy or angiotensin-converting enzyme (ACE) inhibitors to diminish the frequency of episodes of macroscopic hematuria in thin glomerular basement disease or loin pain hematuria syndrome, the renal biopsy may become more commonplace in patients with isolated recurrent or persistent hematuria.

Specific Considerations Prior to Performance of Renal Biopsy

In counseling an individual patient with one of the above indications for biopsy, the clinician must weigh the likelihood of obtaining information that will change treatment against the risk of the procedure itself. Factors to consider are the presence or absence of coagulopathy, increased renal echogenicity, chronic renal dysfunction, uncontrolled hypertension, a solitary kidney, the inability to comply with verbal instruction, hydronephrosis, active pyelonephritis, or a mass that may be neoplastic. Each of these conditions increases the risk of percutaneous biopsy. The presence of small and echodense kidneys by ultrasound and/or chronic renal dysfunction substantially diminish the diagnostic value of the procedure.

Before percutaneous renal biopsy, patients need to understand that the procedure is a diagnostic study and not a treatment. A platelet count and prothrombin (PT) and partial prothrombin times (PPT) should be obtained. Antiplatelet drugs such as aspirin or other nonsteroidal anti-inflammatory drugs should be omitted for a period of at least one week if the biopsy is elective. Systemic anticoagulants should also be stopped before the procedure. Patients receiving heparin should have the drug discontinued at least 6 hours and preferably 12 hours before the procedure. A PPT should be in the normal range before the biopsy. Warfarin should be stopped long enough for the PT to normalize. In certain high-risk patients who must minimize the period off warfarin, it may be prudent to administer heparin as a short-acting agent after warfarin is stopped and reinstate heparin and warfarin 12 – 24 hours after the biopsy, continuing the heparin until the PT is in a therapeutic range. The use of a bleeding time as a prebiopsy screening study is common but not universally accepted. There are no data indicating that use of this test decreases the risk of hemorrhagic complication after biopsy. Nonetheless, many clinicians continue to use this study. It is probably most relevant in patients with renal dysfunction who may have associated secondary platelet dysfunction. Arginine desmopressin (DDAVP) can be useful in normalizing a prolonged bleeding time in such patients. The clinician should also determine if the patient has 2 functioning kidneys before percutaneous biopsy. An IVP or radionuclide study were previously used for this purpose. A reasonable alternative is an ultrasound evaluation demonstrating 2 kidneys of similar size, and if available, a concomitant Doppler study demonstrating normal perfusion to each kidney.

Biopsy Techniques, Patient Selection, and Tissue Handling

The most widely used biopsy method is the percutaneous renal biopsy. Most clinicians now favor localization of the kidney with

ultrasound techniques because it provides more accurate localization than IVP and obviates the need for radiocontrast material. Additionally it is now possible, and some would argue desirable, to perform the procedure with real time ultrasound monitoring. Smaller bore needles (18-gauge spring-loaded devices instead of 14-gauge needles) are increasingly popular because of the simplicity of their use and the perceived safety of the smaller caliber of the instrument. If there are no anatomic considerations (for example, a large renal cyst at the inferior pole), either kidney may be biopsied, right-handed operators usually sampling the left kidney. The procedure may take place in either a radiology suite or any suitably equipped hospital room. While nephrologists have traditionally performed percutaneous biopsies, radiologists now also frequently perform this procedure.

Sedation is commonplace when children undergo this procedure but is not necessary in adults. After informed consent, the patient is placed in a prone position with a pillow or wedge under the upper abdomen. This has the effect of pushing the kidney toward the back and stabilizing the kidney so that the biopsy needle does not push the kidney away. The inferior pole of the kidney is localized by ultrasound at the time of a held breath in inspiration. The distance from the skin to the capsule of the kidney is noted and a mark is made on the skin where the biopsy needle will enter the skin. The skin is cleansed with an antiseptic solution and the patient is draped to maintain sterile technique throughout the procedure. Local anesthetic, typically 1% lidocaine, is administered superficially to raise a weal in the skin and then carried down to the renal capsule using a 22-gauge needle. A small (0.5 cm) incision is made in the skin to accommodate the biopsy instrument. At this point further localization of the kidney may be undertaken by passing a needle towards the kidney in small increments. When the needle enters the renal parenchyma, a large respiratory excursion of the needle is observed. Additional anesthetic may then be given as the needle is withdrawn. Care is taken to remove the needle in such a fashion as to be able to measure the depth. Some operators now omit this step when the procedure is performed using real time ultrasound guidance. In this circumstance, the biopsy needle may be placed in a guide and the needle brought down under direct visualization to the renal capsule, at which point the biopsy is taken while the patient holds his or her breath in inspiration. In the absence of real time ultrasound guidance, the operator advances the biopsy needle in short increments (0.5 cm) while the patient maintains a held inspiration, and then the operator observes needle swing with respiration. When the needle is anchored in the kidney, the biopsy is performed with the patient maintaining a held inspiration to minimize the risk of renal laceration. Sufficient renal tissue is obtained to submit for the desired studies, including light microscopy and usually immunofluorescence and electron microscopy. A pathologist or technician at the bedside can be helpful in examining the tissue for adequacy with a low power microscope.

After the procedure the patient is placed at bed rest for a minimum of 8 hours, and vital signs are monitored frequently. Serial urines are examined for the presence of macroscopic hematuria. A hemoglobin or hematocrit measurement is sometimes taken several hours after the procedure, although many nephrologists now omit this if obvious clinical complications are not manifested. The patient may be discharged home on the same day, although some physicians still prefer overnight monitoring. Full activity may be resumed 24 – 48 hours after the procedure in most instances. The patient should again be counseled to avoid aspirin or nonsteroidal anti-inflamma-

tory drugs for several days and to immediately report any gross hematuria or unusual flank pain.

In special circumstances, an alternative approach to percutaneous biopsy should be considered. If the need to obtain biopsy material is great and the risk of percutaneous biopsy excessive, the standard alternative is an open procedure using general anesthesia and direct visualization of the biopsied area. This procedure is considered in patients with solitary native kidneys, those with coagulopathies not amenable to complete correction, or those who cannot cooperate by holding respirations. Any factor that might increase the risk of biopsy as listed above is also considered. Several modifications of open procedures have been described and include an approach using local anesthesia through a limited flank incision and a novel transjugular approach in cirrhotic patients with coagulopathies and renal abnormalities. At this time, there are no absolute indications for the use of such alternatives to percutaneous biopsy. For example, it had long been taught that the presence of a solitary native kidney was an absolute contraindication to percutaneous biopsy. A careful analysis of the risks of open biopsy including death related to anesthesia has resulted in a reappraisal of this admonition. Percutaneous renal biopsy has been successfully reported in 9 such patients without serious complication in any and with adequate tissue in 8.

The clinician must also consider other special situations that influence the risk/benefit analysis of a renal biopsy. The role of renal biopsy during pregnancy deserves special mention. Because of the combined risk to the mother and the fetus, most clinicians avoid use of this procedure throughout pregnancy but will undertake the procedure when renal abnormalities persist beyond a reasonable postpartum period. However, biopsies have been performed in women during the first or second trimester of pregnancy for proteinuria with or without hematuria, hypertension, renal insufficiency, and nephrotic syndrome. Adequate tissue was obtained with a percutaneous method in all but 3 cases on initial biopsy attempts. One patient developed hemorrhage 4 days after biopsy while receiving therapy with plasma exchange. Otherwise there were no serious complications. Patients in the ICU receiving mechanical ventilatory assistance with pulmonary-renal syndromes pose a special technical challenge. Seven such patients underwent percutaneous biopsy using ultrasound guidance. Adequate tissue was obtained in all. None had gross hematuria, although 2 patients did receive blood transfusions; however, both had been previously transfusion dependent. Some authors have advocated the use of CT guidance in particularly obese patients in whom ultrasound localization is difficult because of poor resolution of the kidneys. Percutaneous biopsy has been shown to be safe and effective in series of geriatric patients. These patients have a greater likelihood of amyloidosis, membranous nephropathy, vasculitis, and diabetes. Almost one-third of geriatric patients have tubulointerstitial disease as the primary finding. Infants and children can usually be safely subjected to percutaneous renal biopsy if adequate sedation is provided. Real time visualization of the kidney is preferred in these patients. One group has reported on the feasibility of fetal renal biopsy.

Once obtained, the renal tissue must be appropriately handled to yield maximal information. It is imperative that the tissue be treated gently and if the samples are divided, that forceps not be used to avoid crush injury. The sample is placed in a fixative such as Duboscq-Brazil or alcoholic Bouin's solution in preparation for light microscopy. The sample is then transferred into an embedding medium such as paraffin and cut in sections of 1

Table 8. Complications of Renal Biopsy

Complications	Frequency
Major	
Clinically important macroscopic hematuria > 12 hours	0 – 5%
Ureteral obstruction secondary to clot	< 0.5%
Bleeding sufficient to require blood transfusion	0 – 5%
Bleeding sufficient to require surgical exploration	< 1%
Bleeding leading to nephrectomy	0 – 0.3%
Symptomatic perinephric hematoma	0 – 1%
Puncture of viscera (liver, spleen or bowel)	0 – 1%
Sepsis	<0.5%
Death from any cause related to biopsy	0.05 – 0.12%
Minor	
Microscopic hematuria	25% – 100%
Macroscopic hematuria self limited, persisting < 12 hours	0 – 10%
Asymptomatic perinephric hematoma (any size)	
Detectable by CT	Up to 85%
Detectable by routine US	Up to 30%
Traumatic A-V fistula	4 – 18%

to 2 μm in thickness for staining with hematoxylin and eosin, periodic acid Schiff (highlights basement membrane, mesangial matrix, and brush border of proximal tubular epithelial cells), Masson's trichrome (demonstrates areas of fibrosis), Congo Red (a thick section is used to stain for amyloid), and methenamine silver (to search for epimembranous spikes). Samples submitted for immunofluorescence microscopy are promptly snap frozen and then cut on a cryostat at temperatures about –25° C. After a brief period of fixation in acetone, the slides are covered with fluorescein-tagged antiserum in a chamber shielded from light. After several washes to remove unbound antibody, the slides are examined with a fluorescence microscope and photographs taken. Antisera routinely used include anti-IgG, anti-IgA, anti-IgM, anti-C1q, anti-C3, anti-GBM, anti-fibrin, and anti-kappa and anti-lambda light chains. It is also possible in some circumstances to take tissue embedded in paraffin and process it for immunofluorescence microscopy. Samples submitted for electron microscopy are commonly fixed in 3% phosphate buffered glutaraldehyde. The tissue is then post fixed in 1% osmium tetroxide, dehydrated and embedded.

Complications of Renal Biopsy

It is useful to divide complications of percutaneous renal biopsy into major and minor, as detailed in Table 8. Complication rates must be interpreted both in the context of the series size as well as the method of percutaneous biopsy. The largest reported series in the literature did not use real time ultrasound monitoring or smaller (15- or 18-gauge)

spring-loaded needles. More recent series using these approaches report significantly fewer complications.

The most common major complication of renal biopsy is hemorrhage. Gross hematuria is described in most large series as occurring between 2 – 10% of cases. It is generally manifest within the first 12 hours after biopsy but can be delayed up to several days after the procedure in a small minority. In most cases it is self limited. In a series of 127 patients using ultrasound and an automated spring-loaded biopsy needle, 3.1% of patients required transfusions after biopsy. One of these patients required exploratory laparotomy for definitive care. The risk of serious complication was independent of the number of passes to obtain tissue. Patients with poorly controlled hypertension had a higher rate of any complication (7/15 patients; 41 %) compared to 21 complications among the remaining 116 patients (18%). Perinephric hematoma is another serious complication if blood loss is sufficient to cause hypotension or the need for transfusion. Perinephric hematomas are actually quite common if sought by imaging techniques on a routine basis. They are easily detectable by CT in as many as 85% of patients. Clinically significant hematomas with pain, palpable flank mass, or a dropping hemoglobin with or without gross hematuria are far less frequent, occurring in 2 – 6.5% of patients. Perinephric hematoma formation may also be associated with transient renal insufficiency, presumably by compression of renal parenchyma and secondary decrease in blood flow. Inadvertent puncture of intra-abdominal organs such as liver, spleen, and large or small bowel have been reported and may result in serious bleeding, hemoperitoneum, or peritonitis. Fortunately, this is quite infrequent (< 1%) when appropriate measures to localize the kidney are taken. The risk of fatal outcome from any complications due to percutaneous renal biopsy varies between 0.08 – 0.12%. Most modern series do not report any fatalities, but none includes > 1,000 patients in their reports to date.

Lesser complications of renal biopsy not necessitating blood transfusion or an invasive intervention occur in up to 25% of patients. Most exhibit some degree of microscopic hematuria, which most clinicians do not consider a complication. Self-limited gross hematuria not requiring any intervention occurs in 2 – 10% of patients. Traumatic arteriovenous fistulae complicate percutaneous renal biopsies in 4 – 12% of patients and are usually clinically silent and resolve spontaneously. However, they may occasionally be associated with gross hematuria soon after the biopsy and, rarely, high output congestive heart failure, hypertension, or renal insufficiency.

The management of patients with clinically recognized hemorrhagic complications is generally one of close observation. An IV catheter should be placed and blood sent for type and screen if not already done. Frequent monitoring of vital signs is continued. If gross hematuria develops, samples of serial urine voids are saved to assess its resolution. In patients with gross hematuria, the post biopsy observation period should be extended overnight. At a minimum, the patient must remain in the recovery unit until repeated voided urine samples are clear and until stability of hemodynamic parameters and hemoglobin concentration are demonstrated. Normal saline should be administered to maintain a brisk diuresis so as to minimize the risk of clot development in the urinary tract. A urinary bladder catheter need be placed only if patients develop bladder outlet obstruction due to clot retention or if the bleeding is sustained and copious. Bleeding that does not spontaneously resolve requires appropriate use of blood products and further investigation by

CT or ultrasonography looking for a perinephric hematoma or an arteriovenous fistula. Embolization of the bleeding site with selective angiography may be needed. Surgical intervention to control bleeding is the other major alternative. Among all patients undergoing percutaneous renal biopsy, surgical intervention is rare, < 0.3% of cases in modern series.

The observation period after elective renal biopsy is a matter of protocol. Many experienced nephrologists and radiologists monitor patients for 8 – 12 hours post biopsy and then discharge home if no complications are evident. Major complications are usually apparent within 12 hours of the procedure.

Interpretation of the Renal Biopsy

The proper interpretation of the renal biopsy by pathologist and clinician requires that several questions be answered:

- What is the diagnosis?
- How much of the kidney is involved with the pathologic process that is observed in the biopsy sample?
- How reproducible is the biopsy interpretation between different pathologists?
- Can the biopsy material help in defining the prognosis of the patient?

Even one glomerulus can establish a diagnosis of membranous nephropathy or amyloidosis. On the other hand, if a disease state is patchy in its renal distribution, a large sample is required for accuracy. The most common clinical example is making the distinction between minimal change nephropathy and focal segmental glomerulosclerosis (FSGS) in children with nephrotic syndrome. Patients with FSGS may have biopsy findings identical to those of patients with minimal change nephropathy except for a fraction of glomeruli with diagnostic focal sclerosis lesions. If a patient with FSGS has 10% of glomeruli affected with focal lesions and 10 glomeruli are available for examination, there is a 35% chance that the sample will not contain an abnormal glomerulus, leading to an incorrect diagnosis of minimal change disease. If 20 glomeruli are available, there is a 12% chance that a glomerulus with the characteristic changes of FSGS will not be in the biopsy sample. Therefore, the number of glomeruli needed to establish a correct diagnosis is in large measure related to the nature of the diagnosis being considered. Most pathologists view 5 or 6 glomeruli as a minimum for suitable interpretation of a biopsy. When focal lesions are a consideration, 20 glomeruli are a better standard. Similar considerations are applicable when the clinician must decide how truly representative of the whole kidney the biopsy sample is. For example, if a biopsy sample of 10 glomeruli shows 3 with crescents, the likelihood that 30% of all glomeruli have such involvement is only 25%. The chance that the actual involvement is as high as 50% is 1 in 10, and the probability that only 10% of glomeruli are so affected is about 5%. This broad confidence range increases uncertainty in clinical decision making and underlines the difficulties in stratification of patients by biopsy results in clinical trials.

The reproducibility of the pathologist's interpretation has been assessed during evaluation of standardized classification schemes such as the NIH modified semiquantitative histologic scoring system for lupus nephritis and the Banff classification system for interpretation of renal transplant biopsies. In one study 5 pathologists each assessed multiple samples in a blinded fashion; findings were only moderately reproducible. It seems that the more detailed the classification system, the greater the likelihood of inter-and intra-pathologist differences in interpretation.

It is unclear if a renal biopsy can independently predict the patient's renal prognosis any better than other clinical parameters such as creatinine clearance, measured renal size, or degree of proteinuria. It is known that tubulointerstitial damage and fibrosis are more powerful predictors of declining renal function than the percentage of sclerotic glomeruli in a biopsy sample. Some researchers have performed serial renal biopsies to better evaluate renal prognosis. The clinical role of serial biopsies is unclear. However, large amounts of parenchymal damage may be evident independent of observable changes in measured creatinine clearance. Precise quantitative morphometry and assessment of turnover rates of key proteins responsible for renal injury using sensitive polymerase chain reaction (PCR) techniques to evaluate gene activation in biopsy samples may provide new insights of clinical relevance in the not too distant future.

Hypokalemia, Hyperkalemia, and Metabolic Alkalosis

Kamel S. Kamel and Mitchell L. Halperin

The dyskalemias are common electrolyte disorders that may have serious sequelae, notably cardiac arrhythmias. This chapter will begin with a brief synopsis of the physiology of potassium (K^+), as this information will provide the backbone for our clinical approach to the diagnosis and treatment of patients with hypokalemia or hyperkalemia. The clinical approach to patients with dyskalemias and the tools that can be used to determine "where is the lesion" in the renal handling of K^+ will then be outlined. The approach to therapy of the patient with hypokalemia and hyperkalemia will emphasize circumstances in which these disorders represent a life-threatening condition that requires emergency treatment. Attention will also be given to certain disorders in which new insights into their pathophysiology have been revealed by molecular studies.

Physiology of K^+ Homeostasis

K^+ are the most abundant cations in the body. Close to 98% of K^+ (4000 mmol in a typical adult) exist in the intracellular fluid (ICF) compartment and close to 60 mmol are in the extracellular fluid (ECF) compartment. The ratio of the concentration, $[K^+]$, in the ICF compartment to that in the ECF compartment reflects the resting membrane potential (RMP). The RMP must remain relatively constant in the face of a daily intake of K^+ that is roughly equal to the total content of K^+ in the ECF. Regulation of K^+ homeostasis has 2 important aspects. While the control of the transcellular distribution of K^+ is vital for survival as it acts to limit acute changes in the $[K^+]$ in plasma, it is the long-term regulation of K^+ excretion by the kidney that maintains overall K^+ balance.

Short-term Regulation of K^+ Homeostasis

K^+ are held within cells by an electrical force (inside negative) created by the net exit of positive charges as sodium ions (Na^+) via the Na-K-ATPase and the passive diffusion of K^+ through K^+ ion-specific channels in the plasma membrane.

For K^+ to enter the ICF compartment, the RMP must have a more negative interior voltage. This will occur when Na^+ are pumped out of cells by the Na-K-ATPase, which is an electrogenic ion pump. It exports 3 Na^+ while allowing only 2 K^+ to enter the cell [1]. There-

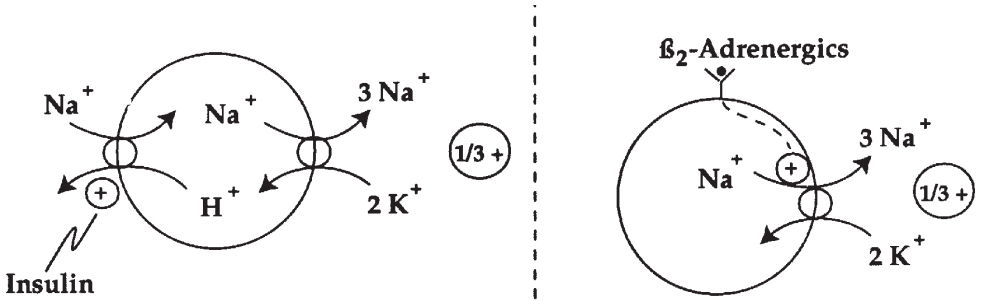

Figure 1. Hormones causing K^+ to shift into cells. For details, see text. The major hormones involved are insulin and β_2-adrenergics.

fore, there is the net export of one-third of a positive charge per Na^+ ion transported (Figure 1). Furthermore, most of the K^+ that enters cells will exit by diffusion through K^+ ion channels in the cell membrane [2, 3]. For every K^+ that exit cells via K^+ channels, there is the net export of one positive charge, creating the majority of the RMP. Some K^+ channels in cell membranes are regulated by voltage, others by calcium (Ca^{2+}), and yet others by adenosine triphosphate (ATP) [2, 3]. Aside from rare conditions such as barium poisoning, specific causes of dyskalemia related to changes in K^+ channel activity are very uncommon.

To increase the absolute magnitude of the RMP and allow more K^+ to shift into cells, there must be a net export of positive charges out of these cells. This occurs only when the Na^+ exported by the electrogenic Na-K-ATPase are Na^+ that already existed inside cells or are Na^+ that entered the cells in an electroneutral fashion, e.g., in exchange for H^+ via the Na^+/H^+ exchanger (NHE-1) [4] (Figure 1). These considerations provide the background for understanding the mechanism of action of the 2 major hormones that affect the transcellular distribution of K^+.

Hormones

– *Catecholamines cause the export of intracellular Na^+*. The effect of β_2 agonists to lower the plasma [K^+] by shifting K^+ into cells is probably the result of stimulation of the Na-K-ATPase via a cyclic AMP-dependent mechanism (Figure 1), which leads to the export of pre-existing intracellular Na^+ [5]. Clinically, hypokalemia due to an acute shift of K^+ may be seen in conditions associated with a surge of catecholamines (e.g. a patient with a subarachnoid hemorrhage, myocardial ischemia, or an extreme degree of anxiety) [6]. β_2 agonists have been used to cause a shift of K^+ into cells in the treatment of patients with hyperkalemia [7].

– *Insulin leads to the electroneutral entry of Na^+*. The effect of insulin to shift K^+ into cells is through its action to promote the electroneutral entry of Na^+ into cells via NHE-1 [4, 8, 9] (Figure 1). This increased entry of Na^+ into cells then stimulates the electrogenic Na-K-ATPase. For this reason, insulin is given to enhance a shift of K^+ into cells in the treatment of patients with severe hyperkalemia by rendering the RMP more electronegative.

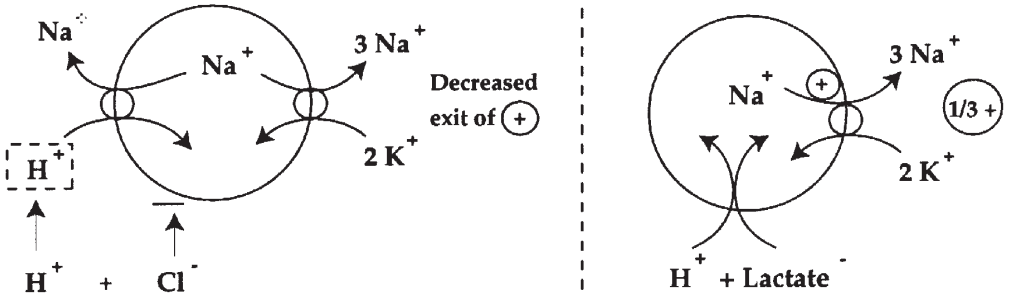

Figure 2. Buffering of H^+ and the consequent K^+ shift. The circles represent the cell membrane. In the left-hand figure, because the acid added is HCl, H^+ enter cells by the NHE-1 and Cl^- remain largely in the ECF. Hence there is a loss of Na^+ from the ICF in this setting. As a result, there is less Na^+ to pump out by the Na^+-K^+- ATPase and the RMP becomes less electronegative. Therefore there is a tendency for K^+ to enter the ECF compartment. In contrast, in the right-hand figure, the acid added is lactic acid, so H^+ enter cells on a cotransporter with lactate anions. As a result, there is no change in the amount of Na^+ to pump out by the Na^+-K^+-ATPase and the RMP does not change. Therefore, there is no tendency for K^+ to enter the ECF compartment.

Acid-base Disorders

When an acid is added to the body, most of the H^+ are buffered in the ICF compartment [10]. A shift of K^+ out of cells may occur if the anions that accompany these H^+ are distributed primarily in the ECF compartment. This is seen experimentally with the infusion of hydrochloric acid in dogs [10]. The extracellular H^+ exchange for intracellular Na^+ via NHE-1 results in less Na^+ in the ICF to be exported by the electrogenic Na-K-ATPase (Figure 2). In contrast, when H^+ enter the ICF compartment accompanied by their conjugate base, there will be no shift of K^+ out of cells (no modification of the electrogenic exit of Na^+). For example, the infusion of L-lactic acid or ketoacids into nephrectomized dogs did not cause a shift of K^+ out of cells because the accompanying organic anions entered the ICF along with their H^+ [11, 12].

Several clinical implications follow from these observations. First, if hyperkalemia is present in a patient with an organic acidosis, a cause for the hyperkalemia other than the acidosis should be sought, e.g. lack of insulin in patients with diabetic ketoacidosis (DKA), tissue injury, or a decrease in the RMP in patients with lactic acidosis [13]. Second, although inorganic acidosis causes the shift of K^+ from the ICF, patients with chronic hyperchloremic metabolic acidosis, e.g. patients with diarrhea or renal tubular acidosis (RTA), usually have a normal or even low plasma [K^+] because of the loss of K^+ in the diarrheal fluid or the urine (reviewed in reference [14]). Therefore, a defect in K^+ excretion is to be suspected if hyperkalemia persists in these patients.

Two other points are worth mentioning. First, although hypokalemia is a common finding in patients with metabolic alkalosis [15 – 17], this reflects renal K^+ wasting for the most part due to the underlying disorder (e.g. vomiting, diuretic use, hyperaldosteronism) rather than the small effect of alkalemia to shift K^+ into cells when H^+ exit. Second, respiratory acid-base disorders cause only small changes in the plasma [K^+], as there is little movement of Na^+ across cell membranes in these disorders [18, 19].

Tissue Anabolism/Catabolism

Intracellular anions do not cross cell membranes for the most part because they are large molecular organic phosphates. Thus, they help retain K^+ in cells.

When anabolism occurs, K^+ along with macromolecular organic phosphates redistribute into cells. Nevertheless, the $[K^+]$ does not rise appreciably in the ICF compartment because the ICF volume also increases (more osmoles but the same osmolality) [20]. Accordingly hypokalemia may be seen in conditions associated with rapid cell growth with the accumulation of intracellular organic phosphates if not enough K^+ is given. Examples include patients with a catabolic state who are treated with total parenteral nutrition (TPN), patients with rapidly growing leukemias and lymphomas, and during the course of treatment in patients with DKA or pernicious anemia. On the other hand, catabolic states are associated with a loss of K^+ and phosphate anions from the ICF compartment. For example, severe hyperkalemia may be seen in patients with crush injury or tumorlysis syndrome [21]. In these patients, factors that compromise the kidney's ability to excrete K^+ are usually present as well. In patients with DKA, tissue catabolism with the loss of organic phosphates from the ICF compartment leads to a parallel loss of K^+ and total body K^+ depletion [22]. There is a large loss of K^+ in the urine because of the high urine flow rate (osmotic diuresis) and high levels of aldosterone (low ECF volume) [23]. These patients usually present with hyperkalemia because there is a shift of K^+ from the ICF compartment to the ECF compartment owing to the lack of insulin [4]. The corollary is that complete replacement of the K^+ deficit in these patients must await the provision of cellular constituents (e.g. phosphates, amino acids, Mg^{2+}),and the presence of anabolic signals.

Long-Term Regulation of K^+ Homeostasis

The rate of urinary excretion of K^+ is a function of 2 factors, the urine flow rate and the $[K^+]$ in the urine. Each must be analyzed independently.

$$K^+ \text{ excretion} = \text{Urine volume} \times [K^+]_{urine} \quad (1)$$

The major site of regulation of K^+ excretion is the cortical collecting duct (CCD) [23]. One must analyze the 2 factors in equation 1 in terms of events in the CCD to understand how the excretion of K^+ might have been altered.

Flow rate in the CCD

The CCD flow rate is directly proportional to the rate of osmole excretion when arginine vasopressin (ADH) acts (ADH acts throughout most of the 24-hour cycle).

$$\text{Flow rate}_{CCD} = (U_{osm} \times \text{Urine flow rate})/P_{osm} \quad (2)$$

where U_{osm} and P_{osm} represent the osmolality of the urine and plasma, respectively. When ADH acts, the major determinant of the CCD flow rate is the number of osmoles to be excreted (equation 2) [24]. Because ADH acts throughout most of the 24-hour cycle [24], a minimum estimate of the flow rate in terminal CCD is obtained by dividing the rate of excretion of osmoles by the osmolality at the end of the CCD (P_{osm} when ADH acts, Figure 3). The major osmole in the urine is urea. Na^+ and chloride (Cl^-) are the other quantitatively important osmoles in the urine. This information is useful clinically. For example, a low rate of osmole excretion can lead to an even lower rate of K^+ excretion and can worsen the degree of hyperkalemia in some patients [25]. Con-

versely, increasing the rate of Na^+ and Cl^- excretion with a loop diuretic can help augment K^+ excretion by enhancing the flow rate in the CCD [26].

$[K^+]$ in the CCD Lumen

Net K^+ secretion is augmented by an electrical driving force (lumen-negative) created by reabsorbing Na^+ faster than Cl^- – the electrogenic reabsorption of Na^+ in the CCD.

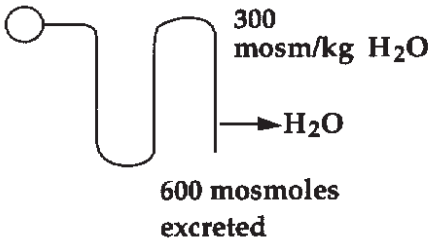

Figure 3. Non-invasive estimate of the flow rate in the CCD. The stylized structure is a nephron. When ADH acts, the osmolality in the plasma and the luminal fluid of the CCD are equal (represented as 300 mosm/kg H_2O for easy math). If 600 mosm are excreted in a given time, the flow rate to the CCD is 2 L under these conditions.

For K^+ secretion, one must also have K^+ channels in an open-configuration in the luminal membrane of the CCD.

Long-term K^+ homeostasis is primarily due to regulation of K^+ secretion by principal cells in the late distal convoluted tubule and the CCD [23]. The generation of a lumen-negative voltage in the CCD requires that Na^+ be reabsorbed at a faster rate than the accompanying anion, usually Cl^-, i.e. electrogenic reabsorption of Na^+ (Figure 4). K^+ channels in the lumen of the CCD are abundant and have a high open probability [2, 3] so they might not be rate-limiting for net secretion of K^+ in most instances.

Sodium: Reabsorption of Na^+ occurs via its specific epithelial Na^+ channel (ENaC) in the apical membrane of principal cells (Figure 5) [27]. Under most circumstances, variations in the luminal $[Na^+]$ in the CCD do not play a role in the regulation of K^+ secretion [28]. Aldosterone causes this ENaC to be in a more open configuration and also increases the number of these channels in the luminal membrane [27]. The steps involved in this action of aldosterone include entry of the hormone across the basolateral membrane and its bind-

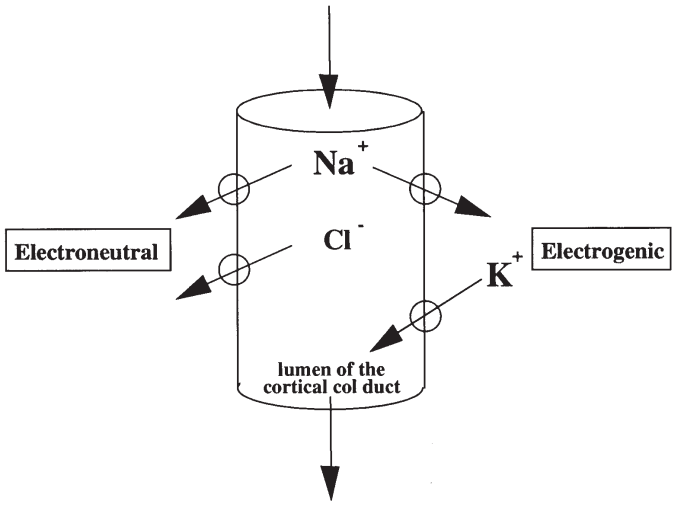

Figure 4. "Electrogenic" and "electroneutral" reabsorption of Na^+. The barrel-shaped structure is the CCD. When Na^+ and Cl^- are reabsorbed in equimolar amounts, there is no transepithelial potential difference (TEPD) created to favor net secretion of K^+; this is termed electroneutral on the left side. In contrast, as depicted on the right side of the figure, reabsorption of Na^+ without Cl^- is electrogenic and generates a TEPD (lumen negative) which drives the net secretion of K^+.

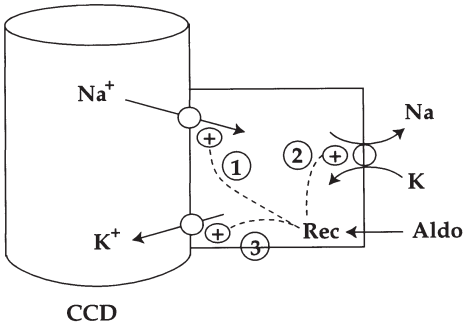

Figure 5. Mechanism of action of aldosterone in the CCD. The barrel-shaped structure is the lumen of the CCD and the rectangle on its right border is a principal cell. Aldosterone (Aldo) enters these cells through their basolateral membrane, binds with its cytoplasmic receptor (Rec), and the hormone-receptor complex enters the nucleus to drive the synthesis of new proteins. In the early phase, this leads to activation of the ENaC (point 1); late phase changes include the synthesis of Na^+-K^+- ATPase pump units (point 2), and luminal K^+ ion channels (point 3).

ing to a cytoplasmic receptor in principal cells. This is followed by entry of this hormone-receptor complex into the nucleus, which leads to the synthesis of new proteins (Figure 5).

Even though the concentration of glucocorticoids is much higher than aldosterone in blood and both have an equal affinity for the mineralocorticoid receptor, glucocorticoids do not usually stimulate K^+ secretion in the CCD. The reason for this lack of effect of glucocorticoids is that principal cells have a pair of enzymes called 11 β-hydroxysteroid dehydrogenase (11 β-HSDH) that converts cortisol to an inactive metabolite (cortisone) that does not bind the mineralocorticoid receptor (Figure 6) [29]. This pair of enzymes acts in concert. First, a low-affinity, high-capacity enzyme destroys most of the cortisol. Second, a high-affinity, low-capacity enzyme removes the remaining cortisol so that there is now an insufficient amount of this hormone

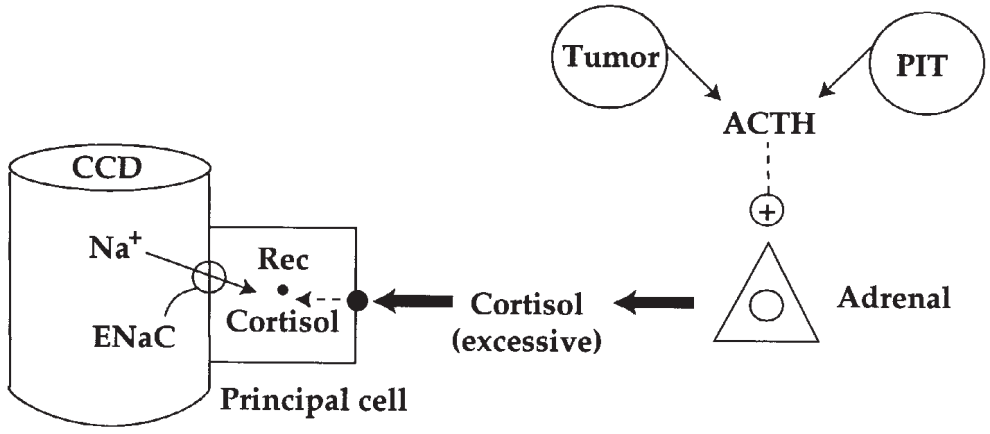

Figure 6. Influence of 11β-hydroxysteroid dehydrogenase on "aldosterone-like" actions in the CCD. Cortisol has a very high affinity to the aldosterone receptor. As cortisol enters principal cells of the CCD, the pair of enzymes 11β-HSDH (shown by the larger solid dot in the membrane), inactivates it before it can bind to the aldosterone receptor (rec, the smaller dot in the cell). There are 3 circumstances in which cortisol will successfully bind to the aldosterone receptor: when there is a deficiency of 11β-HSDH (apparent mineralocorticoid excess syndrome), when an inhibitor 11β-HSDH is present (e.g. licorice), and possibly when there is an excess supply of cortisol relative to the normal activity of 11β-HSDH (perhaps ectopic production of ACTH by a tumor). Abbreviation: PIT = Pituitary gland.

in these cells to bind to the mineralocorticoid receptor. Glucocorticoids, however, can exert a mineralocorticoid effect if the activity of this enzyme is

- decreased, e.g. patients with apparent mineralocorticoid excess syndrome (AME);
- inhibited, e.g. by licorice, carbenoxolone, or a product from swallowed chewing tobacco; or
- overwhelmed by an extreme abundance of cortisol, e.g. patients with ACTH-producing tumors or severe Cushing syndrome (Figure 6).

The K^+-sparing diuretic amiloride [30] and the antibiotic trimethoprim in its cationic form [31, 32] block the ENaC and thereby decrease net secretion of K^+ in the CCD.

Chloride: The pathway(s) for the reabsorption of Cl^- in the CCD is (are) not well defined [33]. Nevertheless, changes in the apparent permeability for Cl^- in the CCD have been postulated to be responsible for the abnormal rate of K^+ excretion in some patients with dyskalemia [34]. For example, a relative increase in Cl^- reabsorption in the CCD is thought to diminish the electrogenic, lumen-negative, driving force for K^+ secretion (the so-called Cl^- shunt disorder). As a result, the rate of K^+ excretion is low, and this could explain the hyperkalemia in patients with Gordon's syndrome [35] and in patients treated with cyclosporin [36] (Figure 7).

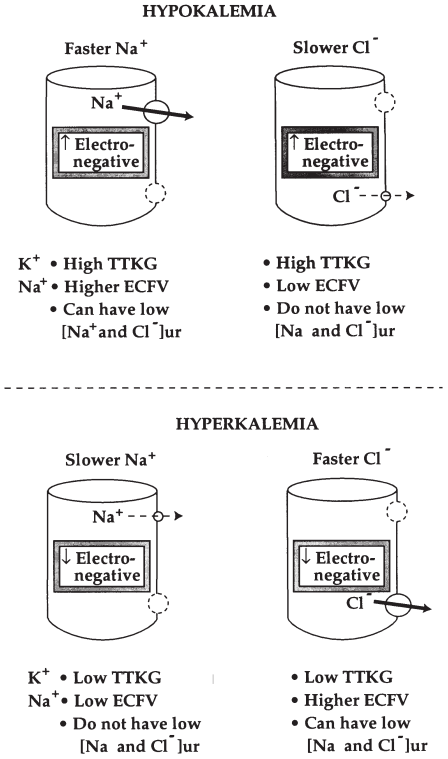

Figure 7. Components of K^+ excretion in the CCD. The barrel-shaped structures represent the CCD. The normal pathway for Na^+ and Cl^- reabsorption are shown in the hatched circles in the luminal membrane. Slower pathways are indicated by smaller open circles with dashed lines and faster ones by larger open circles with bold arrows. Reproduced with permission [104].

Regulation of the apparent permeability for Cl^- in the CCD is important in determining whether aldosterone will be an NaCl-retaining or a K^+-excreting hormone when the ENaC is open (Figure 4) [37]. The presence of bicarbonate ions (HCO_3^-) in the lumen of the CCD seems to be important in this regard. HCO_3^- and/or an alkaline pH in luminal fluid seems to augment net secretion of K^+ in the CCD even when luminal [Cl^-] is high, possibly by decreasing the apparent permeability for Cl^- in the CCD [34]. Thus, aldosterone is allowed to exert its kaliuretic action. On the other hand, a diminished delivery of HCO_3^- to the CCD allows aldosterone to function as an NaCl-retaining rather than as a kaliuretic hormone [37].

Two other points are worthy of mention. First, anions like sulfate that are not reabsorbed in the CCD augment K^+ secretion only in the presence of a very low luminal [Cl^-]. Second, in states where there is a magnesium (Mg^{2+}) deficit, the net K^+ secretion is often

Table 1. Urine electrolytes in the differential diagnosis of hypokalemia. Reproduced with permission [104].

Condition	Urine Electrolyte Na^+	Urine Electrolyte Cl^-

Recent	High	High
Remote	Low	Low
– Diarrhea or laxative abuse	Low	High
– Bartter's or Gitelman's syndrome	High	High

Values not valid for polyuric states.
*High = urine concentration > 15 mM,
**Low = urine concentration < 15 mM.

augmented, but the mechanisms responsible for this effect are not clear [38].

Clinical implications: To evaluate why the $[K^+]$ is not the expected one for a given abnormality in plasma $[K^+]$, one should try to determine the basis of this abnormality at the ion channel level. In this analysis, one attempts to derive information about the relative rates of reabsorption of Na^+ and Cl^- in the CCD. For example, in a patient with hypokalemia, a higher-than-expected $[K^+]$ in the lumen of the CCD implies that an unusually high lumen-negative voltage is present. This voltage is the result of a relatively faster reabsorption of Na^+ and/or relatively slower reabsorption of Cl^- in the CCD. The converse is true for hyperkalemia. Further analysis requires an assessment of the ECF volume and the expected urine $[Na^+]$ and $[Cl^-]$ when the ECF volume is contracted (Table 1) [26]. Determining this underlying pathophysiology has implications for therapy.

Reabsorption of K^+ in the Distal Nephron

Stimulation of the K^+ reabsorption is usually important when its excretion rate should be low. The transport system involved (H-K-ATPase) can only reabsorb a small quantity of K^+ because an acceptor for H^+ in the lumen is needed.

Reabsorption of K^+ may occur by α-intercalated cells in the CCD and medullary collecting duct (MCD) via a H-K-ATPase [39]. For the H-K-ATPase to operate, there must be luminal acceptors for H^+. Since there is usually little NH_3 and HPO_4^{2-} available in the lumen of the MCD [40], this transport system can only reabsorb a small quantity of K^+.

Clinical Approach to Assessing a Patient with Hypokalemia or Hyperkalemia

Emergency Therapy for the Dyskalemia

Because hypokalemia and hyperkalemia can be life threatening, one should recognize those situations in which a dyskalemia represents an emergency, as priority should be given to therapy rather than diagnosis at this point.

The major danger is a cardiac arrhythmia. This is more likely to occur with acute and/or large changes in the plasma $[K^+]$, especially if there is underlying cardiac pathology or the use of digitalis in a patient who has hypokalemia. Other situations that may represent an

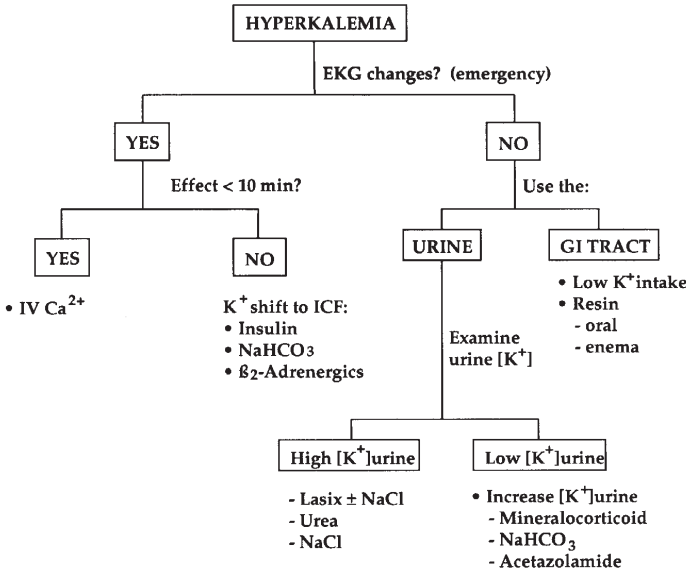

Figure 8. Treatment of the patient with hyperkalemia. If an emergency is present (usually cardiac), IV Ca^{2+} must be given. This treatment should act promptly. Once the emergency is dealt with, or if there is just a severe degree of hyperkalemia, efforts are now to shift K^+ into cells with insulin ± $NaHCO_3$. Longer term strategies are to limit intake of K^+, prevent its absorption in the GI tract, and promote its excretion. In this latter context, examine the urine $[K^+]$ and flow rate to decide leverage for therapy. Reproduced with permission [104].

emergency are if hypokalemia causes respiratory muscle weakness in a patient with respiratory or metabolic acidosis, and hypokalemia in a patient with hepatic encephalopathy.

– *Emergency therapy for hypokalemia*: Enough K^+ should be given to eliminate the cardiac arrhythmia. Replacement of the remainder of the K^+ deficit should be done later and at a much slower pace. If a large dose and hence a high $[K^+]$ need to be given initially, this K^+ should be administered via a large central vein [41]. Electrocardiographic (ECG) monitoring is mandatory. The following example illustrates how much K^+ to give. With a patient who has a severe degree of hypokalemia (plasma $[K^+]$ of 1.5 mM) that led to ventricular tachycardia, the aim of therapy is to raise the plasma $[K^+]$ by 2 mM in 1 min. A typical adult has a blood volume of 5 L, and if the hematocrit is 40% the plasma volume is 3 L. Assuming a cardiac output of 5 L/min, then 6 mmol of K^+ needs to be given in 1 min to achieve the goal. Note, however, that the rise in plasma $[K^+]$ in venous blood will be much < 2 mM because the infused K^+ will be distributed in the larger interstitial volume. Of greater importance, $[K^+]$ will not be high in the interstitial fluid bathing cardiac myocytes with this initial therapy. If the arrhythmia persists, the procedure should be repeated. After this initial bolus, K^+ should be infused at 1 mmol/min, and the plasma $[K^+]$ should be measured in 5 min. With such a high rate of K^+ infusion, vigilant monitoring of the ECG and the plasma $[K^+]$ is an absolute requirement. Administration of glucose or HCO_{3-} should be avoided because either might lead to the shift of K^+ into cells and thus aggravate an already severe degree of hypokalemia.

– *Emergency therapy for hyperkalemia*: Because mild ECG changes may progress rapidly to a dangerous arrhythmia, any patient with an ECG abnormality related to hyperkalemia other than simply peaked T waves should be considered as a potential medical emergency. Patients with a severe degree of hyperkale-

mia (> 6.5 mM) should also be treated aggressively, even in the absence of ECG changes (Figure 8). A note of caution, however, is needed. A severe degree of hyperkalemia is well tolerated in certain settings such as extremes in exercise (the super-marathon [42]) and in infants, so not all hyperkalemia requires the measures described below.

The first step in therapy is to antagonize the cardiac toxicity of hyperkalemia. Ca^{2+} is the best agent, and its effects should be evident within minutes. It is usually given as 10 mL of a 10% calcium gluconate solution. This dose can be repeated in 5 min if ECG changes persist. The effect may last 30 – 60 min. Extreme caution should be exerted using Ca^{2+} in patients treated with digitalis because hypercalcemia may precipitate digitalis toxicity.

The next step is to induce a shift of K^+ into the ICF. The effect of insulin to shift K^+ into cells is rapid [43]. Approximately a 0.6 – 1.0 mM fall in the plasma [K^+] is expected within 30 min, usually lasting for 1 – 2 hours. Usually 6 – 10 units of regular insulin are given. Glucose (50 g) is also given to avoid hypoglycemia, but careful monitoring of the blood sugar is required. Obviously, glucose should not be given if the patient is hyperglycemic.

A second strategy to shift K^+ into cells is to infuse $NaHCO_3$. Recent studies have questioned the efficacy of $NaHCO_3$ to lower the plasma [K^+] in patients with end-stage renal disease (ESRD) on dialysis [44]. Notwithstanding, these patients had only a mild degree of acidosis. The K^+-lowering effect of $NaHCO_3$ may be more prominent in patients with a more severe degree of acidosis. Some studies showed that when combined with glucose/insulin therapy, $NaHCO_3$ did cause a further fall in [K^+] [45]. Excessive administration of $NaHCO_3$ should be avoided because hypernatremia, ECF volume expansion, CO_2 retention, and a fall in ionized Ca^{2+} may occur. In a severely hyperkalemic, acidemic patient with heart failure, phlebotomy may be needed to permit use of $NaHCO_3$.

A third strategy to shift K^+ into cells is to administer β_2-adrenergic agonists. Albuterol or salbutamol (10 –20 mg in 4 mL of saline by nasal inhalation over 10 min or 0.5 mg intravenously (IV)) may lower the plasma [K^+] by 0.6 – 1.5 mM. The peak effect is usually seen within 30 min when these drugs are given intravenously, but it may be delayed for up to 90 min when the nebulized form is used [43, 46]. A significant number of patients with ESRD did not respond to these agents with the expected fall in [K^+]. In a number of studies only a modest increase in heart rate was observed when these drugs were used; however, there is still the potential risk of tachyarrhythmias and myocardial ischemia in patients with coronary artery disease. Considering the inconsistent K^+-lowering effect and the potential for side effects in a population with a high prevalence of heart disease, we do not recommend the routine use of these agents.

In some patients, the rapid removal of K^+ from the body by dialysis may be required. Hemodialysis (HD) is more effective than peritoneal dialysis (PD) for removing K^+. Removal rates of K^+ can be close to 35 mmol/hour with a dialysate bath [K^+] of 1 – 2 mM. A glucose-free dialysate is preferable to avoid the glucose-induced release of insulin and the subsequent shift of K^+ into cells, which limits the removal of K^+. For the same reason, one should also consider discontinuing the insulin/glucose infusion once HD is initiated.

Ensure that there is no Laboratory or Technical Problem

Pseudohyperkalemia may occur because of prolonged fist clenching during blood sampling [47]. Muscular contraction leads to depolarization of cell membranes and the release of K^+ from cells. The local architecture in muscle is important because most K^+ is released locally into T-tubules that minimize their escape into the circulation. If this architecture is disturbed (e.g. in patients who are cachectic), more K^+ is released into venous blood during blood sampling.

K^+ may be released from lysed red blood cells (RBC), but hemolysis is readily detected. K^+ may be released from platelets that have lysed during coagulation, or if they are in contact with glass. For this to cause a significant degree of hyperkalemia, platelets must have a large cytoplasmic volume (megakaryocytes) [48]. In rare circumstances, K^+ may be released from "fragile" white blood cells (WBC) in a patient with leukemia during blood sampling.

Assess the Role of the Kidney as a Cause of the Dyskalemia.

Rate of Excretion of K^+

There is no normal rate of K^+ excretion. In normal subjects K^+ excretion reflects K^+ intake [49]. To assess the renal response to a disorder of K^+ homeostasis, we use the expected rate of K^+ excretion when hypokalemia or hyperkalemia is due to nonrenal causes (Table 2). In subjects who were rendered hypokalemic with dietary K^+ deprivation, K^+ excretion fell to 10 – 15 mmol/day [50]. On the other hand, with chronic K^+ loading, the rate of K^+ excretion can exceed 200 mmol/day [51]. If these expected responses are not observed in patients with hypokalemia or hyperkalemia, respectively, then a renal component to the pathophysiology of their disorder must be present.

Components of K^+ Excretion

Inappropriate flow rate in the CCD: On its own, this will not be a significant problem to cause a dyskalemia (unless it is unduly low, thereby limiting K^+ excretion); nevertheless, it may be a contributing factor. Simply counting the osmoles excreted in a given time period permits this aspect to be assessed (Figure 3) [24].

Inappropriate [K^+] in the CCD: We use the following noninvasive test to help with the assessment of the net secretion of K^+ in the CCD.

– *The transtubular [K^+] gradient (TTKG):* In the first step to calculate the TTKG, the aim is to obtain a reasonable approximation of the [K^+] in the lumen of the terminal CCD [52]. This is done by correcting the [K^+] in the urine for the amount of water reabsorbed in the MCD (Figure 9). To correct for water reabsorption in the MCD, the [K^+] in the urine is divided by the ratio of urine osmolality to plasma osmolality ($(U/P)_{osm}$) because the latter is the same as the osmolality in the terminal CCD when ADH acts. For this calculation to be valid, the osmolality of the urine must be equal to or greater than that of plasma because one must deduce the osmolality of the fluid entering the MCD. In the second step of TTKG calculation, the [K^+] in the terminal CCD is divided by the plasma [K^+] to obtain a semiquantitative index of the driving force to raise the [K^+] in the terminal CCD (equation 3).

$$TTKG = [K^+]_{urine}/[K^+]_{plasma}/(Uosm/Posm) \quad (3)$$

Table 2. Tests to examine K^+ excretion in patients with hypokalemia or hyperkalemia. Reproduced with permission [104]

Test	Advantages	Disadvantages	Expected values
24-hour K^+ excretion rate or K^+ : creatinine ratio	– Indicates overall renal response in patients with hypokalemia or hyperkalemia	– Does not indicate the mechanism responsible for the defect. – Takes 24 h or measurement of creatinine in urine. – Collections are not always accurate.	– Normal: 60 – 80 mmol/day or 6 – 8 mmol/mmol creatinine. – Hypokalemia: < 10 mmol/day or 1 – 1.5 mmol/mmol creatinine. – Hyperkalemia: > 150 mmol/day or 10 – 15 mmol/mmol creatinine.
Fractional excretion of K^+		– Results must be compared with GFR, so it is impractical, and the GFR must be measured.	– Cannot express a normal value without knowing the GFR.
Spot urine [K^+]	Convenience	– Influenced by 2 independent factors: K^+ secretion and water reabsorption in the medulla; thus a wide gray zone	– Hypokalemia: < 20 mmol/day if due to a non-renal cause and > 20 mmol/day if due to a renal cause. – Hyperkalemia: no expected value reported.
TTKG	– Physiological relevance – Separation of $[K]_{CCD}$ and flow rate – Little overlap	Indirect test Must have Uosm > Posm Reabsorption of solutes in MCD an uncertainty	– Hypokalemia < 2 – Hyperkalemia > 10

Several assumptions are made in calculating the TTKG. First, in using the $(U/P)_{osm}$ to correct for water reabsorption in the MCD, one assumes that the majority of osmoles delivered to the MCD are not absorbed during transit. If a significant number of particles are absorbed in the MCD, for the same urine osmolality, one will underestimate the volume of water reabsorbed there, and hence the calculated $[K^+]_{CCD}$ will be higher than what it is in vivo. The major particles delivered to the MCD are urea and the electrolytes. In the absence of a marked degree of ECF volume contraction, the amount of urea and electrolytes reabsorbed in the MCD should not pose a problem [53].

Another assumption in the TTKG calculation is that an appreciable amount of K^+ is not secreted or reabsorbed in the MCD. Studies in normal rats showed that when samples of fluid were obtained from the beginning and the end of the MCD, there was little net change in the content of K^+ [54]. Although K^+ reabsorption has been observed in the MCD in K^+-deprived

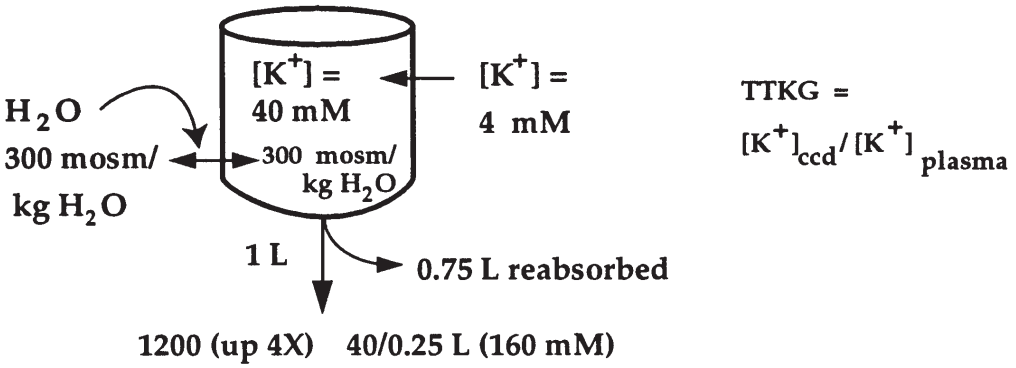

Figure 9. Effect of medullary water reabsorption on the urine [K^+]. The barrel-shaped structures represent the CCD, and the arrows below them represent the MCD. In the example, there is a high TTKG; i.e. the luminal [K^+] is 40 mM or 10 × the peritubular [K^+] of 4 mM. Consider what happens when 1 L of fluid traverses the MCD. In the example, 75% of the water is reabsorbed, but no K^+ is reabsorbed or secreted in the MCD. Therefore, the urine [K^+] is 4-fold higher (160 mM) as is the urine osmolality (1200 mOsm/kg H_2O). To correct for the rise in the urine [K^+] due to the reabsorption of water, we divide the urine [K^+] by 4, the ratio of the rise in urine osmolality between the terminal CCD and the final urine.

rats [55], these observations were made under conditions of profound K^+ depletion and may not apply in clinical conditions where the degree of K^+ depletion may be less severe. Similarly, K^+ secretion was demonstrated in the MCD in rats, but again under extreme conditions [56].

Keeping the above assumptions and pitfalls in mind, the TTKG can be used clinically to provide useful information about the role of the activity of the K^+ secretory process in the CCD in the pathogenesis of the disorders of K^+ homeostasis. The expected values for the TTKG under different stimuli are summarized in Table 2.

Possible Lesions to Explain a Higher than Expected [K^+] in the Lumen of the CCD

An unduly high [K^+] in the lumen of the CCD requires that the electrogenic reabsorption of Na^+ be augmented to generate a higher lumen-negative voltage in the CCD. From an ion channel analysis, this means that either there was faster reabsorption of Na^+ or slower reabsorption of Cl^- (Figure 7).

– *Relatively faster reabsorption of Na^+ in the CCD:* The clinical characteristics of a patient with a more open Na^+ channel are, on the Na^+ side, ECF volume expansion, low renin levels, and a tendency to hypertension in those individuals whose blood pressure is more sensitive to changes in volume than to vasoconstrictors (Figure 7). With ECF volume contraction, the urine could be free of Na^+ and Cl^-.

– *Relatively slower reabsorption of Cl^- in the CCD:* This may occur for 2 major reasons. For some patients, the following are required: a large delivery of Na^+ and Cl^- to the CCD and a stimulus to reabsorb these ions (ECF volume contraction) together with a capacity to reabsorb Na^+ faster than Cl^- in the CCD. For other patients, there is a decrease in the apparent permeability of the luminal membrane for Cl^-. Both of these groups of patients will have ECF volume contraction and hyperreninemia. They will not conserve Na^+ and Cl^- appropriately despite ECF volume contraction. Blood pressure

is not usually high despite a high level of the vasoconstrictor, angiotensin II (Ang II), because of the associated hypovolemia.

Possible Lesions to Explain a Lower than Expected [K^+] in the Lumen of the CCD

An unduly low [K^+] in the lumen of the CCD may indicate an inability to generate a favorable electrochemical gradient to promote secretion of K^+. From an ion channel analysis, this means a less electrogenic reabsorption of Na^+, either due to a more closed than usual ENaC, or a higher than usual permeability for Cl^- (or other anions) in the CCD. It is also conceivable that the defect may be one of a low open probability of the apical K^+ channels.

- *Relatively slower reabsorption of Na^+ in the CCD:* A low delivery of Na^+ to the CCD could possibly limit the secretion of K^+ (e.g. in a patient with a very marked degree of contraction of ECF volume and high rate of urea excretion). A relatively closed ENaC could diminish the ability to generate a favorable electrochemical gradient for the secretion of K^+ in the CCD and lead to hyperkalemia with a low [K^+] in the CCD. If the patient is particularly sensitive to vasoconstrictors, hypertension may develop [57]. Otherwise, a tendency to hypotension could be present, especially with a low salt diet. The other characteristics of this syndrome are a low ECF volume and renal Na^+ wasting. Renin levels will be high and there should be an inability to achieve an Na^+- and Cl^-- free urine when on a low salt diet (Table 1).
- *Relatively faster reabsorption of Cl^- in the CCD:* If this lesion were present, there would be an enhanced electroneutral rather than electrogenic absorption of Na^+ (Figure 4). Therefore, the cardinal features should be hyperkalemia, lower-than-expected TTKG that does not rise with the administration of exogenous mineralocorticoids, a tendency to an expanded ECF volume with low levels of renin, and possibly hypertension in those subjects whose blood pressure is particularly sensitive to an expanded ECF volume. These subjects should be able to have Na^+-and Cl^--poor urines and high plasma renin levels in response to ECF volume contraction. The induction of bicarbonaturia, however, can lead to a marked increase in the TTKG (if aldosterone is present) in these patients and we use this observation to support the speculation that there is a Cl^- shunt in the CCD [14, 26].
- *A low open probability of the luminal K^+ channel:* Other than in inherited diseases with a low ROM-K channel activity, there are no reports that specifically characterize this hypothetical lesion.

Molecular Studies

Recently the molecular basis of a number of the genetic disorders of hypokalemia and hyperkalemia has been identified. Therefore, characterization of the molecular defect can be carried out in the appropriate patients (Table 3, Figure 10).

Assess if Factors that Could Cause a Shift of K^+ Across Cell Membranes are Present

One should always ask whether a shift of K^+ across cell membranes is making the degree of hypokalemia or hyperkalemia more severe. If present, its basis should be explored.

Table 3. Hereditary Diseases and Hypokalemia.
All the disease categories present with hypokalemia and excessive excretion of K^+ associated with higher than expected urine [K^+]. Reproduced with permission [104].

	Gitelman's	Bartter's	Liddle's	GRA*	AME
Molecular lesion	Inhibited NaCl cotrans-porter in DCT	Inhibited NKCC, ROM-K channel, or basolateral Cl^- channel	Activated Na^+ channel in the CCD	Chimeric gene: ACTH driven mineralocorticoid synthesis	Defect in 11 β-HSDH in principal cells
Presenting feature	Tetany, unexpected lab finding	Failure to thrive, lab finding	Hypertension, hypokalemia, family history	Severe hypertension	Hypertension
Age of 1st symptoms	Teenage	Children	Young if severe	Young adult	Children
Mimicked by drugs	Thiazides	Loop diuretics	Amphotericin B	Mineralocorticoids	Licorice, carbenoxolone
Plasma Mg^{2+}	Low	Low	Normal	Normal	Normal
ECF volume	Low	May be low	High	High	High
Hypertension	No	No	Yes	Yes	Yes
Key diagnostic feature	Hypo-calciuria	Lower than expected maximum Uosm	Hypertension	Suppression of aldosterone by dexamethasone, excess cortisol and C-18 oxidation metabolites	Urine cortisone to cortisol ratio

*Some patients with this disorder do not have hypokalemia.

Assess the Contribution of K^+ Intake

The plasma [K^+] can be maintained in the normal range despite wide fluctuations in K^+ intake. Nevertheless, variations in K^+ intake can contribute to the degree of hypokalemia or hyperkalemia if there is an underlying abnormality in the rate of excretion of K^+.

Specific Causes of Hypokalemia

A summary of the causes of hypokalemia is provided in Table 4 and Figure 11. We shall comment only briefly on some of these disorders, either because they are common or because new strides have been made in understanding their pathophysiology.

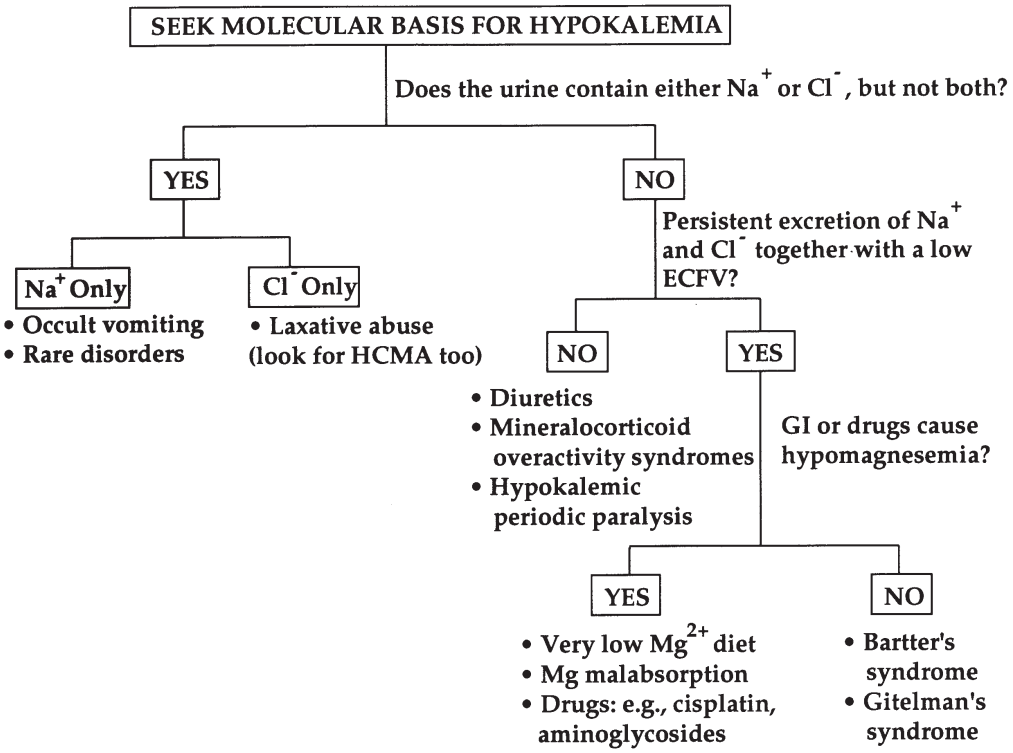

Figure 10. Differential diagnosis of hereditary causes of hypokalemia. The initial step is to rule out common causes of hypokalemia which may be denied by the patient. Here the urine electrolytes become very important (Table 1). A finding of persistent excretion of Na^+ and Cl^- despite a contracted ECF volume narrows the differential diagnosis to causes where there is obvious basis for hypomagnesemia or not. Finding Mg^{2+}-poor urine will suggest a low intake or poor GI absorption of Mg^{2+}. Failure to find an obvious cause for renal Mg^{2+} wasting suggests that Bartter's or Gitelman's syndrome may be present. Reproduced with permission [104].

Disorders with Hypokalemia and a Low ECF Volume

Diuretic-induced Hypokalemia

– *Underlying pathophysiology:* Two factors contribute to the development of hypokalemia in patients receiving diuretics: a high rate of flow in CCD and an increased net secretion of K^+ due to the effect of aldosterone (released in response to a low ECF volume).

– *Clinical features:* Hypokalemia is usually modest in degree. A fall in plasma $[K^+]$ to < 3 mM is observed in < 10% of patients, usually within the first 2 weeks of therapy [58].

– *Diagnosis requirement:* One must ask if the patient has been taking diuretics. At times, abuse of diuretics may be denied, so screening the urine for diuretics may be needed (choose a urine when diuretics are acting, i.e. one which contains appreciable Na^+ and Cl^-).

– *Differential diagnosis:* If diuretic abuse is firmly denied by the patient, a diagnosis of Bartter's or Gitelman's syndrome may be suspected because the urine will

Table 4. Causes of Hypokalemia

I. Decreased intake of K^+

II. Shift of K^+ into cells
- Hormones: Insulin, sympathomimetics
- Gain of anions in the intracellular fluid (recovery phase of ketoacidosis, refeeding after cachexia, treatment of pernicious anemia)
- Metabolic alkalosis
- Others: Hypokalemic periodic paralysis.

III. Intestinal loss of K^+
- Diarrhea, ileus

IV. Excessive loss of K^+ in urine
1. **High flow CCD**, e.g. diuretics, genetic disorders with inhibition of Na^+-transport (Bartter's syndrome or Gitelman's syndrome).
2. **High $[K^+]_{CCD}$**

A) Disorders leading to a relatively "faster Na^+" in the CCD
- High aldosterone, high renin: Low effective circulating volume (diuretics, vomiting, diarrhea), malignant hypertension, renal artery stenosis, renin-secreting tumor
- High aldosterone, low renin: Adrenal adenoma or bilateral adrenal hyperplasia, glucocorticoid remediable aldosteronism
- Low aldosterone, low renin: Decreased 11-βHSDH activity (apparent mineralocorticoid excess syndrome), inhibition of 11-βHSDH (e.g. licorice, carbenoxolone, swallowed chewing tobacco), very high levels of glucocorticoids (e.g. ACTH-producing tumor), increased activity of ENaC (Liddle's syndrome, drugs: amphotericin B)

B) Disorders leading to a relatively "slower Cl^-" in the CCD
- Bicarbonaturia: Vomiting, use of acetazolamide, distal RTA, patients with proximal RTA treated with alkali.
- Hypomagnesemia.

often contain abundant Na^+ and Cl^- in both settings. Diuretic abuse should be suspected if even one spot urine has little Na^+ and Cl^- reflecting the normal renal response to low ECF volume (Table 1). This diagnosis can be confirmed by screening a urine sample with abundant Na^+ and Cl^- for diuretics. The urine electrolytes also provide clues to the differential diagnosis in patients with hypokalemia due to diuretic abuse from those with hypokalemia due to occult vomiting or the abuse of laxatives. In the occult vomiter, the key finding is a very low urine $[Cl^-]$ (Table 1). In the laxative abuser with a contracted ECF volume, the urine $[Na^+]$ will be low, but the urine $[Cl^-]$ may be high if there is a high rate of excretion of NH_4^+ in response to the hyperchloremic metabolic acidosis (Table 1).

– *Molecular basis:* None.

– *Therapy:* Some of the issues discussed here under treatment of diuretic-induced hypokalemia will apply to the treatment of other settings with hypokalemia. Specific issues related to therapy of diuretic-induced hypokalemia will also be addressed.

Whether a mild degree of hypokalemia should be treated is debatable. Since patients with ischemic heart disease, those with left ventricular hypertrophy, and those treated with digitalis may be at increased risk for arrhythmias, even a mild degree of hypokalemia should be avoided in these patients. While it is generally stated that a fall in plasma $[K^+]$ from 4 to 3 mM indicates a total body deficit of 200 – 400 mmol of K^+ and may be as much as 800 mmol if plasma $[K^+]$ falls to 2 mM [59]; this is not a useful quantitation in any individual patient. Factors that may induce a shift of K^+ into the ICF compartment may also be present, and it is not possible to determine the magnitude of the total body deficit of K^+ based on the value of plasma $[K^+]$. The bottom line is that careful monitoring of plasma $[K^+]$ is required as the K^+ deficit is being repleted. Two other issues bear mentioning. First, with chronic hy-

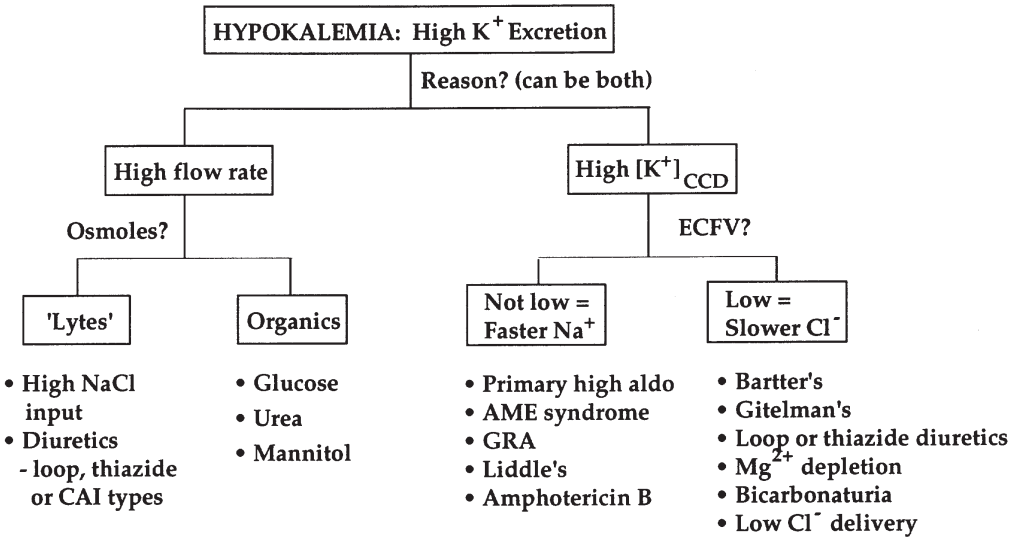

Figure 11. Approach to the patient with hypokalemia. The causes for excessive excretion of K^+ (> 15 – 20 mmol/day) despite hypokalemia are too high a flow rate in the CCD (left limb) and/or too high a $[K^+]$ in the lumen of the CCD (right limb). Both flow rate and $[K^+]_{CCD}$ should be evaluated in each patient. Final considerations are shown by the bullet symbols. A slower Cl^- reabsorption in the CCD is suggested by high plasma renin activity and NaCl wasting despite low ECF volume; the converse applies for faster Na^+ reabsorption. Reproduced with permission [104]. Abbreviations: CAI = Carbonic anhydrase inhibitor type of diuretic, AME = Apparent mineralocorticoid excess, GRA = Glucocorticoid-remedial aldosteronism.

pokalemia, the CCD may become hyporesponsive to the kaliuretic effect of aldosterone and thus there is a risk for the development of hyperkalemia during K^+ replacement [60, 61]. Second, patients who have disorders, or are taking drugs that may impair their ability to shift K^+ into cells or to excrete K^+ in the urine, may be particularly at risk of developing hyperkalemia with therapy.

In the absence of conditions that may limit the oral intake of K^+ or its absorption by the gut (e.g. vomiting, ileus or the absence of bowel sounds), the oral route is usually preferred. At times, however, the urgency of treatment may necessitate using the IV route. When using a peripheral vein, the $[K^+]$ in the infusate should not exceed 40 mM, as higher $[K^+]$ may irritate small veins and cause painful phlebitis. In general, the rate of K^+ administration should not exceed 60 mmol/hour.

Since patients with diuretic-induced hypokalemia have both K^+ and Cl^- deficits, K^+ should be given as its Cl^- salt. In general, tablets are better tolerated than the liquid form. Most tablets are slow-release preparations, either microencapsulated or in wax matrix, which have occasionally caused ulcerative or stenotic gastrointestinal lesions. A salt substitute may be an inexpensive and generally well-tolerated form of K^+ supplementation (Co-salt provides 14 mmol of K^+ per gram). Contrary to customary belief, increasing intake of K^+-rich food (e.g. bananas) is not an effective way to replace a K^+ deficit. Bananas provide little K^+, only about 1 mmol per inch.

Some particular issues about hypokalemia

and diuretic use are worth highlighting. First, because the risk of development of hypokalemia is dose-dependent and because increasing the dose of hydrochlorothiazide beyond 12.5 – 25 mg does not usually result in further benefit in terms of blood pressure control, the lowest effective dose of this drug should be used. Second, the degree of renal wasting of K^+ can be minimized by restricting NaCl intake to 100 mmol/day. Third, the use of K^+-sparing diuretics provides an effective way of reducing the renal loss of K^+. The ENaC blockers (amiloride and triametrene) are generally better tolerated and lack the gastrointestinal and hormonal side effects (impotence, decreased libido, amenorrhea, gynecomastia) that may occur with the aldosterone competitive inhibitor spironolactone. The availability of combination tablets of hydrochlorothiazide with amiloride or triametrene also makes compliance less of an issue. These drugs, however, blunt the renal response to an increase in the plasma $[K^+]$ and also have a long half-life. Therefore they should be used cautiously in patients on β-blockers, angoitensin-converting enzyme (ACE) inhibitors, or nonsteroidal anti-inflammatory drugs (NSAID) and those with an underlying renal disease.

Vomiting-induced Hypokalemia

– *Underlying pathophysiology:* Because the $[K^+]$ in gastric fluid is usually < 15 mM, hypokalemia in patients with vomiting or nasogastric suction results primarily from the loss of K^+ in the urine. Aldosterone is released in response to Ang II that is formed because of ECF volume contraction. Aldosterone leads to a more open ENaC in the CCD (Figure 5). Delivery of HCO_3^- to the lumen of CCD is the result of a transient rise in its concentration in plasma due to vomiting (Figure 12). A higher distal delivery of HCO_3^- causes a higher net secretion of K^+ (Figure 13 and [34, 37]). To a lesser extent, hypokalemia may be the result of a shift of K^+ into the ICF compartment due to the alkalemia. Once the degree of hypokalemia becomes more severe, the rate of K^+ excretion declines, but not to the very low rates in otherwise normal subjects consuming a low-K^+ diet [50].

– *Clinical features:* Hallmarks are a significant degree of hypokalemia, metabolic alkalosis, and a very low $[Cl^-]$ in the urine (Table 1). In a patient with recent vomiting, the urine may contain an abundant Na^+ despite ECF volume contraction because the excretion of HCO_3^- obligates the excretion of Na^+.

– *Diagnosis requirement:* Key elements are a history of vomiting, a significant degree of hypokalemia, metabolic alkalosis, and a very low $[Cl^-]$ in the urine (Table 1). The use of urine electrolytes may help reveal the basis for hypokalemia in a patient with occult vomiting.

– *Differential diagnosis*: If the patient denies vomiting, other causes of hypokalemia with a low ECF volume must be considered (Table 4).

– *Molecular basis:* None.

– *Therapy:* Therapy is directed towards the underlying cause of vomiting and the administration of K^+. Again, these patients also have a deficit of Cl^-. K^+ should be administered as its Cl^- salt along with NaCl as needed.

Hypokalemia in Patients with Hyperchloremic Metabolic Acidosis

– *Pathophysiology:* The 2 major entities to consider in these patients are distal RTA due to a low rate of H^+ secretion in the

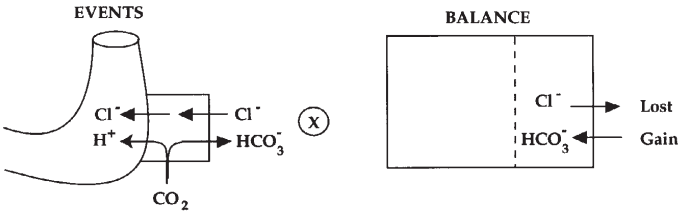

Figure 12. H^+ Secretion in stomach and mass balance for H^+. The structure on the left represents a parietal cell in the stomach. There is an net gain of HCO_3^- and a loss of Cl^- from the ECF compartment when HCl is secreted. Reproduced with permission [104] of the authors.

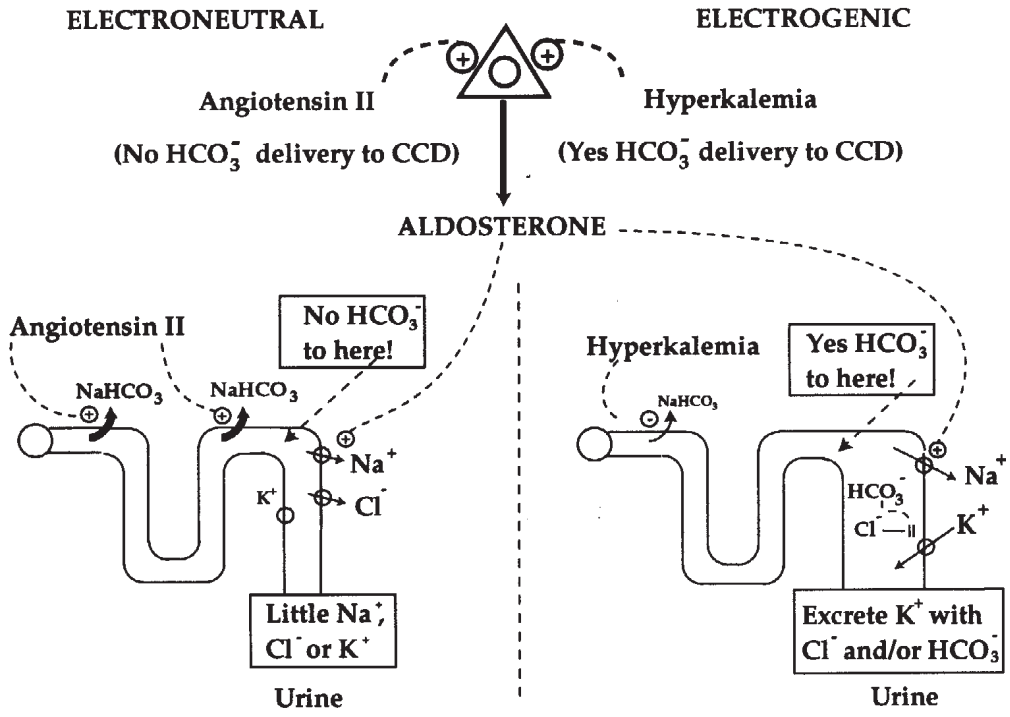

Figure 13. Aldosterone and the augmented reabsorption of NaCl. The adrenal gland is depicted by the triangular structure. The secretagogue on the left for the release of aldosterone is angiotensin II. Angiotensin II, by stimulating the reabsorption of HCO_3^- in the proximal and distal convoluted tubules, diminishes the delivery of HCO_3^- to the CCD and thereby a kaliuresis is not promoted. The secretagogue on the right for the release of aldosterone is K^+. Hyperkalemia, by inhibiting the reabsorption of HCO_3^- in the proximal convoluted tubule, increases the delivery of HCO_3^- to the CCD and thereby a kaliuresis is promoted. Reproduced with permission [104].

distal nephron and loss of $NaHCO_3$ via the gastrointestinal (GI) tract. For the former, the key element in the pathophysiology of their hypokalemia is the retention of HCO_3^- in the lumen of the CCD. In the latter, loss of K^+-rich colonic fluids (especially from distal colon) can lead directly to hypokalemia. In some cases of diarrhea, however, the degree of hypokalemia is modest. The reason is that al-

though the presence of aldosterone (due to ECF volume contraction) causes the ENaC in the CCD to be open, limited delivery of HCO_3^- to the CCD (low filtered HCO_3^- due to metabolic acidosis plus the effects of Ang II, metabolic acidosis, and hypokalemia to enhance proximal reabsorption of HCO_3^- [37]) leads to electroneutral reabsorption of Na^+ in the CCD. Therefore, aldosterone acts as an NaCl-retaining rather than a kaliuretic hormone (Figure 13).

– *Clinical picture:* Hypokalemia with hyperchloremic metabolic acidosis.
– *Diagnosis requirement:* In patients with distal RTA due to a low rate of H^+ secretion in the distal nephron, there is a low rate of NH_4^+ excretion and a relatively high urine pH (about 6.5) (see chapter I-3 on *Acid-base Balance* for more details). In patients with a GI problem, a history of a diarrheal illness may be obtained. Abuse of laxatives, however, may be firmly denied. If suspected, measurement of the urine electrolytes may provide helpful clues. The urine $[Na^+]$ will be low if the ECF volume is contracted, but the $[Cl^-]$ in the urine is characteristically high reflecting the high rate of NH_4^+ excretion in response to metabolic acidosis (Table 1). At times, one might have to rely on measurements of stool electrolytes and other evidence for laxatives in the stool to confirm the diagnosis.
– *Differential diagnosis:* Other causes of hypokalemia with a low ECF volume are illustrated in Table 4.
– *Molecular basis:* Usually this is not an issue.
– *Therapy:* Because these patients have hypokalemia and metabolic acidosis, K^+ can be given with HCO_3^- or other anions that can be metabolized to HCO_3^- (e.g. citrate). Nevertheless, because the administration of HCO_3^- may cause the shift of K^+ into the ICF compartment, K^+ should be replaced for the most part as its Cl^- salt early in therapy.

Bartter's and Gitelman's Syndromes

– *Pathophysiology: The pathophysiology of Bartter's syndrome can be thought of as having a loop diuretic acting 24 hours a day. The pathophysiology of Gitelman's syndrome can be thought of as having a thiazide diuretic acting 24 hours a day.*

  The high rate of K^+ excretion in both disorders has 2 components: a high flow rate in CCD and a high $[K^+]$ in the lumen of the CCD. The high flow rate in the CCD is due to the very large delivery of Na^+ and Cl^-, the result of their inhibited reabsorption in upstream nephron segments (Figure 3). The high $[K^+]$ in the lumen of the CCD is due to a relatively faster rate of reabsorption of Na^+ relative to that of Cl^-. The rate of Na^+ reabsorption is stimulated because of the contraction of the ECF volume, one of the hallmarks of the clinical picture. Hypomagnesemia may contribute to the pathophysiology of renal K^+ wasting, especially in patients with Gitelman's syndrome [62].
– *Clinical picture:* These uncommon disorders are characterized by ECF volume contraction due to renal salt wasting, hypokalemia, and metabolic alkalosis (Table 4). Hypomagnesemia is more consistently seen in patients with Gitelman's syndrome. While hypercalciuria is found in many patients with Bartter's syndrome, an extreme degree of hypocalciuria

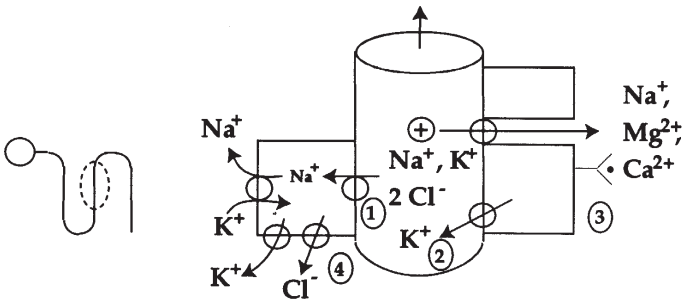

Figure 14. Possible lesions for Bartter's syndromes. A stylized nephron is shown on the left with the thick ascending limb of the loop of Henle (LOH) shown by the dashed oval. The structure to the right represents an enlargement of the thick ascending limb of the LOH. The possible lesions are the Na^+-K^+-2 Cl^- cotransporter (site 1), the luminal K^+ channel (site 2), occupation of the basolateral Ca^{2+} receptor by a cationic ligand (site 3), or the Cl^- channel in the basolateral membrane (site 4).

is a characteristic finding in almost all patients with Gitelman's syndrome [62]. In contrast to patients with Bartter's syndrome, patients with Gitelman's syndrome should have the ability to elaborate a maximally concentrated urine when ADH acts, unless there is another lesion that caused renal medullary damage as chronic hypokalemia or the chronic use of drugs that might damage this area of the kidney such as NSAIDs.

– *Diagnosis requirement:* The presence of hypokalemia with renal salt wasting and persistently elevated [Na^+] and [Cl^-] in the urine is the hallmark of the diagnosis (Table 1).
– *Differential diagnosis:* The major differential diagnosis is with patients with diuretic abuse, laxative abuse, or occult vomiting. The use of urine electrolytes in this differential diagnosis is a critical step (Table 1).
– *Molecular basis:* Patients with Bartter's syndrome seem to represent a heterogeneous group with regard to the molecular lesions (Table 3, Figure 14). Mutations that cause a loss of function have been identified in the genes encoding for the bumetonide-sensitive Na^+-K^+-2 Cl^- co-transporter [63], the luminal K^+ channel (ROM-K) [64], and the Cl^- channel in the basolateral membrane of the thick ascending limb of the loop of Henle [65]. Those patients with a ROM-K channel defect may have their initial presentation as hyperkalemia and NaCl wasting because ROM-K is the major K^+ channel in principal cells of the CCD. The biochemical findings evolve to the more typical ones of hypokalemia and metabolic alkalosis with time.

  The vast majority of patients with Gitelman's syndrome have mutations in the gene encoding the NaCl co-transporter in the early distal convoluted tubule [66]. Nevertheless, some patients have all the clinical characteristics of Gitelman's syndrome without a recognized mutation in this transporter [67].
– *Therapy:* Correction of hypokalemia is extremely difficult in these patients, even with large supplements of K^+. Hypomagnesemia seems to be an important factor in the enhanced kaliuresis in some, but not all patients with Gitelman's syndrome. Correction of hypomagnesemia with

oral magnesium is usually limited by gastrointestinal side effects. K^+-sparing diuretics may help conserve K^+ but they may also exacerbate renal salt wasting. ACE inhibitors have been tried in some patients with variable success, but hypotension is a major concern with this therapy. We are concerned about the prolonged use of NSAIDs because of the potential for chronic renal dysfunction.

Hypokalemia Due to Cationic Drugs Like Gentamicin

- *Pathophysiology:* Gentamicin is an antibiotic that has the capacity to bind to a receptor for Ca^{2+} on the basolateral aspect of cells of the thick ascending limb of the loop of Henle (Figure 14) [68]. This binding of gentamicin leads to inhibition of the luminal K^+ channel (ROMK), and thereby to furosemide-like effects. Therefore, the pathophysiology of gentamicin-induced hypokalemia can be thought of as having a loop diuretic acting 24 hours a day. The high rate of excretion of K^+ has 2 components: a high flow rate in the CCD and a high [K^+] in the lumen of the CCD. The high [K^+] in the lumen of the CCD is due to a faster rate of Na^+ reabsorption relative to that of Cl^-. Hypomagnesemia may contribute to the pathophysiology of renal K^+ wasting in these patients. A similar story might apply for other drugs that bind to the Ca^{2+} receptor in the loop of Henle such as cisplatin.
- *Clinical picture:* This disorder is characterized by ECF volume contraction due to renal salt wasting, polyuria, a fall in the glomerular filtration rate (GFR), hypokalemia, hypomagnesemia, hypercalciuria, and metabolic alkalosis.
- *Diagnosis requirement:* The presence of the features outlined above in a patient receiving gentamicin or drugs with a similar effect.
- *Differential diagnosis:* All the conditions described above must be considered.
- *Molecular basis:* None.
- *Therapy:* Discontinue the drug. Wait for its side effects to wear off, but this may take a considerable amount of time. Supportive therapy with Na^+, K^+, and Mg^{2+} should be given if the patient is symptomatic and in danger from these deficits.

Disorders with Hypokalemia and a Normal or High ECF Volume

Primary Hyperaldosteronism

- *Pathophysiology:* Hypersecretion of aldosterone due to an adrenal adenoma or bilateral adrenal hyperplasia.
- *Clinical Picture:* This diagnosis should be suspected in patients with hypertension and unexplained hypokalemia with renal K^+ wasting. Nevertheless, hypokalemia is not a universal finding in these patients [69].
- *Diagnosis requirement:* The diagnosis hinges on the finding of an elevated plasma aldosterone level and a very low plasma renin activity. A random plasma aldosterone to plasma renin activity ratio is a sufficient screening test [70]. The next step is to differentiate patients with adrenal adenoma from those with bilateral adrenal hyperplasia. This can be usually achieved with computed tomography (CT) or magnetic resonance imaging (MRI). If an adrenal adenoma is not detected, adrenal vein sampling or an iodocholesterol scan can be used to distinguish between these 2 possibilities [71].

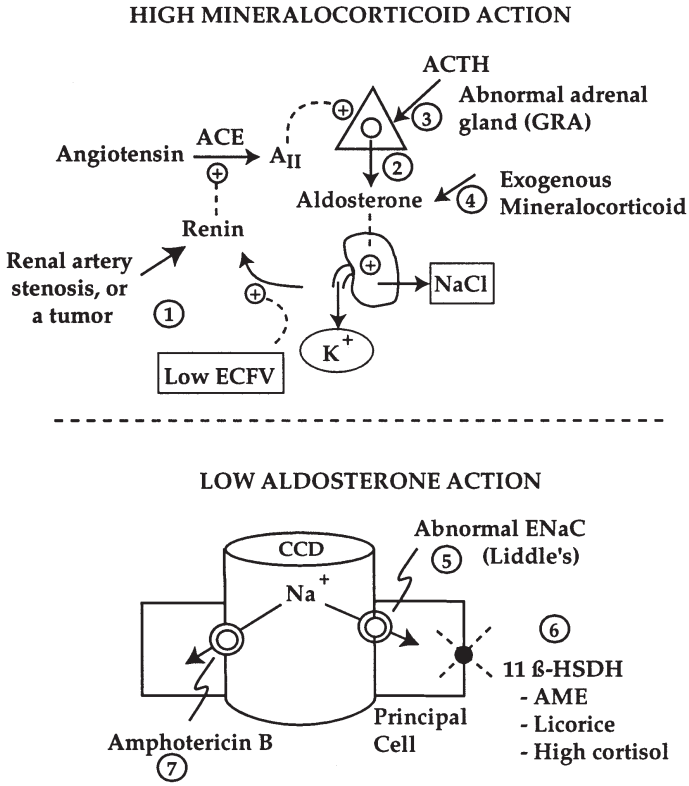

Figure 15. Differential diagnosis of the patient with hypokalemia. There are 7 causes for high mineralocorticoid action identified in this figure with the following numbers. Reproduced with permission [104].
A) Those with high mineralocorticoid action: 1. High renin (e.g. renal artery stenosis, renin producing tumors). 2. Cells (e.g. adenoma) in the adrenal cortex produce aldosterone or a compound with mineralocorticoid bioactivity. 3. ACTH stimulates aldosterone production because there is a genetic lesion in the adrenal gland in which the ACTH promoter drives the synthesis of a compound with mineralocorticoid bioactivity. Suppressing ACTH with glucocorticoids decreases their production (GRA, a genetic chimera). 4. Exogenous compounds mimicking the actions of aldosterone such as fludrocortisone.
B) Those with low mineralocorticoid action: 5. An epithelial ENaC in the luminal membrane which is permanently in an open conformation due to a mutation (Liddle's syndrome). 6. Blocking the destruction of cortisol in principal cells by creating a relatively low activity of 11 β-HSDH (e.g. licorice). 7. Insertion of an artificial Na^+ channel in the luminal membrane of the CCD (e.g. amphotericin B).

– *Differential Diagnosis:* The finding of very low plasma renin activity (PRA) with high plasma aldosterone levels separate patients with primary hyperaldosteronism from those with other causes of hypertension and hypokalemia (Figure 15, Tables 3 and 4). Patients with glucocorticoid remediable aldosteronism (GRA), however, also have elevated plasma aldosterone levels with suppressed PRA. These patients typically have the onset of hypertension in early adulthood and a strong family history of hypertension, cardiovascular, and cerebrovascular events. The hypersecretion of aldosterone in these patients is suppressed with the

administration of dexamethasone. Patients with GRA also have marked hypersecretion of 18-hydroxycortisol and 18-oxocortisol in their urine.

– *Therapy:* In patients with an adrenal adenoma, unilateral adrenalectomy is usually the preferred treatment. In patients with bilateral adrenal hyperplasia and those with adrenal adenomas who are not candidates for surgery, medical therapy with K^+-sparing diuretics is recommended. Amiloride is generally better tolerated than spironolactone.

Glucocorticoid Remediable Aldosteronism (GRA)

– *Pathophysiology:* GRA is a rare form of adrenal hyperplasia in which aldosterone secretion is regulated exclusively by ACTH [72]. There is also marked overproduction of C-18 oxidation products of cortisol, 18-hydroxycortisol, and 18-oxocortisol.

– *Clinical picture:* The onset of severe hypertension may occur in early adulthood. There is often a strong family history of hypertension and early onset of cardiovascular and cerebrovascular diseases. Interestingly, hypokalemia is not present in a significant number of these patients.

– *Diagnosis requirement:* The diagnosis hinges on demonstrating suppression of aldosterone with the administration of glucocorticoids (dexamethasone or prednisone), detection of very high levels of C-18 oxidation products of cortisol in the urine [73], and ultimately, genetic testing to detect the chimeric gene.

– *Differential diagnosis:* One must rule out other causes of hypertension and unexplained hypokalemia (Figure 15). The characteristic features for the diagnosis of GRA were discussed previously.

– *Molecular basis:* This disorder is due to a chimeric gene in which the regulatory region of the gene encoding for the enzyme P-450 (the zona fasciculata enzyme required for the synthesis of cortisol) is linked to the coding sequence of the gene for the enzyme P-450, 18-C (the zona glomerulosa enzyme required for the synthesis of aldosterone) [72]. Therefore, secretion of aldosterone is exclusively regulated by ACTH. Also, because of an apparent expression of this enzyme in the zona fasciculata, cortisol (a C-17 hydroxylated steroid) also becomes hydroxylated at the C-18 position, leading to the production of cortisol-aldosterone hybrid compounds.

– *Therapy:* Administration of glucocorticoids (dexamethasone or prednisone) corrects the hypersecretion of aldosterone by suppressing ACTH.

ACTH-Producing Tumor or Severe Cushing Syndrome

– *Pathophysiology:* The clinical picture is similar to hyperaldosteronism, but the level of aldosterone in plasma is low. Because of an overabundance of cortisol, the activity of the two 11 β-HSDH enzymes probably fail to inactivate all the cortisol that enters principal cells (Figure 6). As a result, cortisol binds to the mineralocorticoid receptor and exerts mineralocorticoid activity.

– *Clinical picture:* ACTH overproduction is commonly seen in patients who have oat cell carcinoma of the lung. In patients with ACTH-producing tumors, overt signs of glucocorticoid excess may not be evident at the time of diagnosis. The plasma $[K^+]$ is often very low.

– *Diagnosis hinges on:* One must demonstrate very elevated plasma cortisol levels. Plasma ACTH levels will be high if there is an ACTH-producing tumor and markedly suppressed in patients with Cushing syndrome.
– *Differential diagnosis:* A similar clinical picture can be induced with primary aldosteronism, GRA, Liddle's syndrome and chronic ingestion of licorice or licorice-like compounds (such as carbenoxolone or chewing tobacco) [74].
– *Molecular basis:* None.
– *Therapy:* Therapy is directed at the primary disorder. For treatment of hypokalemia, large supplements of KCl and drugs that inhibit ENaC are often necessary.

Syndrome of Apparent Mineral Corticoid Excess (AME)

– *Pathophysiology:* The clinical picture is of hyperaldosteronism, but the level of aldosterone in plasma is low. Because of decreased activity of the enzyme 11 β-HSDH, cortisol binds to the mineralocorticoid receptors and exerts mineralocorticoid activity [75].
– *Clinical picture:* One finds an autosomal recessive disorder of juvenile hypertension and hypokalemia.
– *Diagnosis requirement:* The demonstration of suppressed plasma aldosterone and PRA without excess cortisol secretion (Figure 15). The diagnosis is confirmed by finding of an elevated urinary cortisol: cortisone ratio.
– *Differential diagnosis:* A similar clinical picture can be induced with chronic ingestion of licorice or licorice-like compounds (such as carbenoxolone or chewing tobacco). The active moiety in these compounds is glycyrrhetinic acid, which inhibits the 11 β-HSDH.
– *Molecular basis:* Several mutations in the gene that encodes for the kidney isoform of the enzyme 11 β-HSDH have been identified [76]. These mutations result in decreased enzyme activity and thus impaired inactivation of cortisol.
– *Therapy:* The administration of dexamethasone, which does not bind the mineralocorticoid receptor, helps to correct the hypertension and hypokalemia by suppressing endogenous cortisol production.

Liddle's Syndrome

– *Pathophysiology:* The clinical picture is of hyperaldosteronism, but the level of aldosterone is low. The pathophysiology of this disorder is one of a constitutively active ENaC in the CCD [77].
– *Clinical picture:* One finds an autosomal dominant inherited disorder of early onset of severe hypertension and hypokalemia.
– *Diagnosis requirement:* A positive family history of early onset hypertension and hypokalemia, very low plasma aldosterone levels and PRA are key elements in the diagnosis (Figure 15). There is no excess secretion of cortisol, and the urine cortisol to cortisone ratio is not elevated. Control of hypertension and correction of hypokalemia are more likely achieved with the administration of ENaC blockers (amiloride) rather than with mineralocorticoids antagonist (spironolactone).
– *Differential diagnosis:* Other causes of hypertension and hypokalemia, the distinguishing features of Liddle's syndrome were mentioned above.

– *Molecular basis:* Several mutations in the gene encoding for ENaC have been described in patients with this syndrome [78]. Some of these mutations resulted in truncation of the cytoplasmic regions of the β- or α-subunits of the ENaC complex. Other mutations involved a missense mutation in the proline-rich region of these subunits; hence these regions seem to be critical in the interaction between ENaC and cytoskeletal elements such as Nedd 4 protein [79]. As a result of these mutations, there seems to be decreased retrieval of the ENaC from the luminal membrane.
– *Therapy:* The administration of amiloride or triametrene, drugs that directly block the ENaC, is the best medical therapy.

Hypokalemia Due to Drugs Like Amphotericin B

– *Pathophysiology:* The pathophysiology of amphotericin B-induced hypokalemia can be thought of as having an ENaC-like channel which is permanently in an open configuration in the CCD. The high rate of K^+ excretion is due to a relatively high [K^+] in the lumen of the CCD, the result of a faster rate of Na^+ reabsorption relative to that of Cl^-.
– *Clinical picture:* The clinical picture is predominantly due to the underlying illness that necessitates the administration of amphotericin B. Hypokalemia is usually associated with a normal or expanded ECF volume (Figure 15).
– *Diagnosis requirement:* The presence of the features outlined above in a patient receiving amphotericin B.
– *Differential diagnosis*: All the conditions described above must be considered.
– *Molecular basis:* The lesion is due to the insertion of an artificial, unregulated ENaC.
– *Therapy:* Treat the underlying illness, discontinue the drug if the side-effects are life threatening, and wait for its side effects to wear off. Take measures to decrease the flow rate in the CCD when amphotericin B is acting.

Hypokalemic Periodic Paralysis

– *Pathophysiology:* Episodes of transient shift of K^+ from the ECF to the ICF.
– *Clinical Picture:* The dominant finding is recurrent, transient episodes of muscle weakness that may progress to paralysis in association with hypokalemia. Hypokalemia may be severe at times (< 2.0 mM). Characteristically, the attacks occur after a large carbohydrate meal, strenuous exercise, or the administration of insulin. A variant of this disorder occurs in Asians and is associated with thyrotoxicosis. The idiopathic variety is inherited as an autosomal dominant disorder and usually manifests in the teenage years.
– *Diagnosis requirement:* The diagnosis hinges on finding the characteristic clinical picture and is confirmed by molecular studies.
– *Molecular basis:* In patients with this disorder, the RMP is 10 – 15 mvolts less negative than in normal muscle fibers even if the plasma [K^+] is normal. The basis of this does not seem to be a problem with the voltage-gated Na^+ channel as in patients with hyperkalemic periodic paralysis [80, 81]. Genetic analysis has suggested that the abnormality in patients with hypokalemic periodic paralysis is linked to the gene that encodes for the

Table 5. Causes of Hyperkalemia

I. Pseudohyperkalemia:
- – Tight tourniquet, fist clenching
- – Thrombocytosis with megakaryocytes
- – High WBC count

II. Excess intake of K^+ (in patients with impaired renal excretion of K^+).

III. Shift of K^+ from the ICF to the ECF:
- – Catabolism (rhabdomyolysis, tumor lysis syndrome)
- – Metabolic acidosis (acute phase of inorganic acidosis)
- – Drugs (digitalis, depolarizing agents)
- – Fasting hyperkalemia (dialysis patients)
- – Hyperkalemic periodic paralysis

IV. Decreased K^+ excretion (renal failure):

A. Decreased flow in the CCD:
- – Low rate of excretion of osmoles (malnutrition)

B) Decreased luminal negativity in the CCD:

i) Disorders leading to relatively "slow Na" in the CCD:
- – Chronic renal failure
- – Low renin: Damage to, or synthetic defect in, JG apparatus
- – Low aldosterone: Hyporeninemia, damage to adrenal glands (autoimmune disorder, granulomatous disease), defect in aldosterone biosynthesis; congenital or acquired (heparin, ketoconozole), decreased aldosterone binding to its receptor (competitive inhibition by spironolactone)

ENaC defect: Type I pseudohypoaldosteronism, drugs that block the ENaC (amiloride, triamterene, trimethoprim, pentamidine).

ii) Disorders leading to a relatively "fast Cl" in the CCD:
- – Gordon's syndrome
- – A subgroup of the patients with hyporeninemic hypoaldosteronism
- – Cyclosporin A.

dihydropyridine-sensitive Ca^{2+} channel in skeletal muscles [82]. It is not clear how this leads to the effects on RMP and plasma $[K^+]$.

– *Therapy:* Therapy for this disorder is largely symptomatic or empirical. Hyperthyroidism, if present, is treated in the usual fashion. Patients are advised to avoid carbohydrate-rich meals and vigorous exercise. Nonselective β-blockers may reduce the number of the attacks and the severity of fall in plasma $[K^+]$ during an attack. Acetazolamide 250 – 750 mg/day has been used successfully in some patients, although the basis of its beneficial effect is unclear. An acute attack is treated with the administration of KCl. There is, however, the risk of post-treatment hyperkalemia as K^+ move back into the ECF.

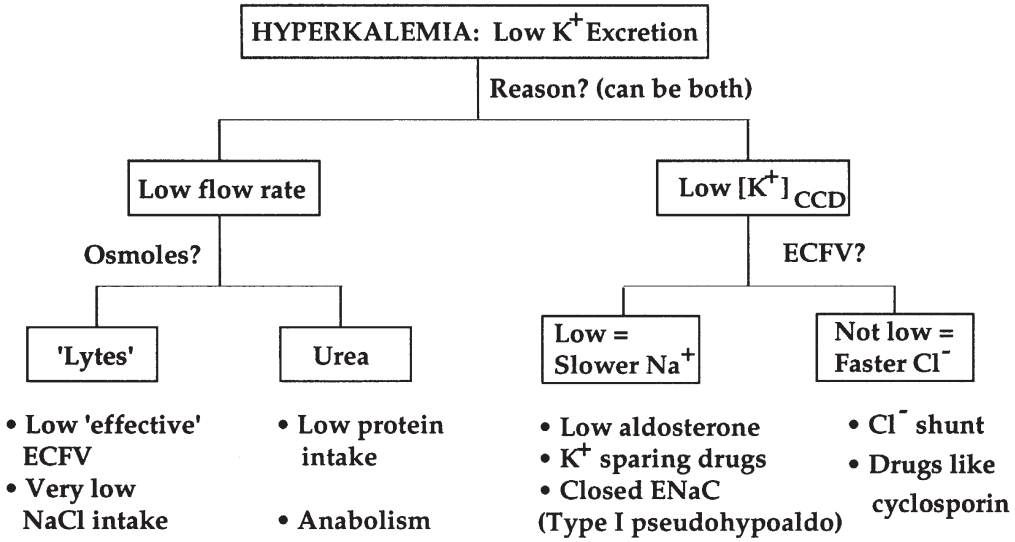

Figure 16. Approach to the patient with hyperkalemia. The causes for a low rate of excretion of K^+ (< 200 mmol/day) despite hyperkalemia are too low a flow rate in the CCD (left limb) and too low a $[K^+]$ in the lumen of the CCD (right limb). Both flow rate and $[K^+]_{CCD}$ should be evaluated in each patient. Final considerations are shown by the bullet symbols. A slower Na^+ reabsorption is suggested by high renin and NaCl wasting despite low ECF volume; the converse applies for faster Cl^- reabsorption. In some cases of renal failure, the excessive flow rate per nephron limits electrogenic reabsorption of Na^+ and thereby behaves as if there is relatively slower reabsorption of Na. Reproduced with permission [104].

Specific Causes of Hyperkalemia

A list of the causes of hyperkalemia based on their possible underlying pathophysiology is provided in Table 5. An algorithm of the clinical approach to these patients is in Figure 16.

Addison Disease

– *Pathophysiology:* The lack of aldosterone leads to "closed" ENaC in CCD.
– *Clinical picture:* The most common cause of this disorder used to be bilateral adrenal destruction with tuberculosis, but now autoimmune adrenalitis accounts for the majority of cases. Other causes include other infectious diseases (disseminated fungal infection), adrenal replacement by metastatic cancer or lymphoma, adrenal hemorrhage or infarction, or drugs that impair the synthesis of aldosterone (e.g. ketoconazole) [83].

Patients with chronic primary adrenal insufficiency may present with chronic malaise, fatigue, generalized weakness, anorexia, and weight loss. In most patients, the blood pressure is low and postural symptoms of dizziness and syncope are common. Salt craving is a distinctive feature in certain patients. Some patients may present with acute adrenal crisis and shock. Hyperpigmentation is evident in nearly all patients. Hyperkalemia is usually of moderate degree unless a si-

gnificant degree of intravascular volume depletion that diminishes the flow rate in CCD is also present. Other abnormal laboratory findings include hyponatremia, hyperchloremic metabolic acidosis, hypoglycemia, and eosinophilia.

– *Diagnosis requirement:* Once Addison's disease is suspected, the diagnosis is established by findings of low plasma aldosterone and cortisol levels, high PRA, and a blunted cortisol response to the administration of ACTH.
– *Molecular basis:* None
– *Therapy:* Adrenal crisis is a life-threatening emergency that requires immediate treatment to restore intravascular volume with the administration of saline and to correct the cortisol deficiency with the immediate administration of dexamethasone or hydrocortisone.

Patients with chronic adrenal insufficiency should receive replacement with both a glucocorticoid and a mineralocorticoid. For the former, 25 mg of hydrocortisone (15 mg in the morning and 10 in the afternoon) is usually given. For mineralocorticoid replacement, fludrocortisone in a single dose of 50 – 200μg is usually used. Dose adjustments are made based on patients' symptoms, ECF volume status, blood pressure measurements, and plasma $[K^+]$.

Pseudohypoaldosteronism Type I

– *Pathophysiology:* The underlying pathophysiology of this disorder is a "closed" ENaC in the CCD.
– *Clinical picture:* Patients with this rare inherited disorder usually present in the neonatal period with severe ECF volume contraction and renal salt wasting, hyperkalemia, metabolic acidosis, failure to thrive, and weight loss.
– *Diagnosis requirement:* Despite the clinical evidence of low actions of aldosterone, these patients fail to respond to exogenous mineralocorticoids. Furthermore, their plasma aldosterone levels and PRA are markedly elevated.
– *Molecular basis:* Mutations in the α or β subunits of ENaC that result in diminished ENaC activity have been identified [84]. This results in an autosomal recessive form of the disease with manifestations persisting into adult life. Other forms of the disease are autosomal dominant or sporadic ones and these may remit with age. They are believed to result from mutations in the mineralocorticoid receptor gene [85].
– *Therapy:* Treatment includes supplementation with NaCl and the use of cation-exchange resin to control the hyperkalemia. Dialysis may be required for treatment of life-threatening hyperkalemia. An interesting feature is that some of the affected children may grow out of the disease.

Syndrome of Hyporeninemic Hypoaldosteronism

– *Pathophysiology:* Patients with this syndrome represent a heterogeneous group with regard to the pathophysiology of their disorder. One group may have destruction of, or a biosynthetic defect in, the juxtaglomerular apparatus that leads to hyporeninemia, hypoaldosteronism, and hyperkalemia due to less luminal negative voltage in the CCD because of a relatively slower reabsorption of Na^+ in the CCD. In another group of patients, however, the pathophysiology seems to

be compatible with a Cl^--shunt disorder in the CCD [86]. This leads to expansion of the ECF volume and hence the hyporeninemia and hypoaldosteronism [26, 35, 87]. This relatively faster reabsorption of Cl^- in CCD causes the voltage across the CCD to be less electronegative and hence the low $[K^+]$ in the lumen of the CCD.

– *Clinical picture:* This syndrome is most commonly seen in patients with diabetic nephropathy but also has been associated with many other renal diseases. The clinical findings differ, based on the pathophysiology of the disorder. In the first group of patients one would expect to find renal salt wasting with a low ECF volume and inability to conserve Na^+ and Cl^- maximally in response to the stimulus of a contracted ECF volume. On the other hand, in the group of patients with a Cl^--shunt disorder, the ECF volume should be normal or expanded. Hypertension is commonly seen, and these patients should be able to produce a urine that is virtually free of Na^+ and Cl^- in response to contraction of their ECF volume.
– *Diagnosis requirement:* Both groups of patients have hyperkalemia with low PRA and plasma aldosterone levels that are low relative to the stimulus of hyperkalemia. The group with hyporeninemic hypoaldosteronism and a relatively slower reabsorption of Na^+ should respond to the administration of exogenous mineralocorticoids with a significant rise in their TTKG. On the other hand, patients with hyporeninemic hypoaldosteronism due to a Cl^--shunt disorder do not have an appreciable rise in their TTKG with the administration of exogenous mineralocorticoids, but their TTKG may rise significantly with the induction of bicarbonaturia (e.g. the administration of acetazolamide) [34].
– *Molecular Basis:* None.
– *Therapy:* Obviously the use of exogenous mineralocorticoids is of no benefit to the group of patients with a Cl^--shunt type of disorder. It may even aggravate their hypertension. In this group of patients, the administration of a loop or thiazide diuretic should enhance the kaliuresis by increasing the rate of flow in the CCD. This may also cause the loss of the excess Na^+ and may thereby help control hypertension. Diuretic therapy poses a threat to patients with hyporeninemic hypoaldosteronism with a low ECF volume. The administration of 9 α-fludrocortisone to these patients results in both a kaliuresis and retention of Na^+.

Hypertension and Hyperkalemia

– *Pathophysiology:* These patients represent a heterogeneous group. In some, the pathophysiology seems to be of a Cl^--shunt disorder in CCD [87]; in others the defect may be one of closed ENaC in CCD [57]. In this latter group, the renal salt wasting and the resultant ECF volume contraction lead to activation of the renin-angiotensin-system and possibly the release of other vasoactive mediators that could lead to the development of hypertension in patients who may be unduly sensitive to the action of these vasoconstrictors.
– *Clinical picture:* In both groups of patients there is the association of hypertension and hyperkalemia. In the group with a possible Cl^--shunt, the ECF volume is expected to be normal or expanded. On the other hand, patients with a possible closed ENaC are expected to have a low ECF volume.

– *Diagnosis requirement:* In patients with hypertension and hyperkalemia due to a Cl^--shunt, the PRA is suppressed, and the plasma aldosterone level is inappropriately low for the presence of hyperkalemia. These patients are expected to be able to excrete virtually Na^+- and Cl^--free urine in response to the induction of ECF volume contraction. The group of patients with hypertension and hyperkalemia due possibly to a relatively closed ENaC in the CCD are expected to have high PRA and high plasma aldosterone levels. Despite the presence of contracted ECF volume, these patients have renal salt wasting.
– *Molecular basis:* Genetic and molecular studies are needed in patients with hypertension, hyperkalemia, and possible closed ENaC to determine if these patients do indeed have inactivating mutations in ENaC.
– *Therapy:* Loop or thiazide diuretics are helpful in patients with hypertension and hyperkalemia due to a Cl^--shunt disorder. These agents, however, are likely to worsen the renal salt wasting and hypertension in patients with a relatively slower ENaC. Control of hypertension in these patients may be helped with salt supplementation.

Cyclosporin-induced Hyperkalemia

– *Pathophysiology:* Hyperkalemia develops in some patients receiving cyclosporin, as for instance, following organ transplantation. The pathophysiology of hyperkalemia in these patients resembles a Cl^--shunt disorder in the CCD [36].
– *Clinical picture:* These patients usually have hypertension in association with hyperkalemia. The PRA is suppressed, and the plasma aldosterone level is low relative to the stimulus of hyperkalemia.
– *Diagnosis requirement:* The administration of exogenous mineralocorticoids does not cause a rise in TTKG in these patients. A significant increase in the TTKG is observed following the induction of bicarbonaturia.
– *Molecular basis:* None.
– *Therapy:* Kaliuresis could be enhanced with the administration of a loop or thiazide diuretic to increase flow in CCD in these patients. Inducing bicarbonaturia with the use of acetazolamide could also be considered, but supplementation with bicarbonate may be required.

Trimethoprim-induced Hyperkalemia

– *Pathophysiology:* The cationic form of trimethoprim and pentamidine can cause hyperkalemia by blocking the ENaC in the CCD [31, 89, 90, 91].
– *Clinical picture:* Although first reported in patients with AIDS who received high doses of trimethoprim for the treatment of *Pneumocystis carinii* pneumonia [91], a rise in plasma [K^+] may occur in patients even when these agents are used in conventional doses [92]. Patients with AIDS may also have other conditions that make them prone to the development of a more severe degree of hyperkalemia: shift of K^+ from cells, decreased K^+ excretion because of a low flow in the CCD due to a low rate of osmoles (urea) excretion [25, 31].
– *Diagnosis requirement:* There is a history of intake of these drugs. Because these agents induce hyperkalemia by blocking the ENaC in the CCD, these patients also

have renal salt wasting with elevated PRA and plasma aldosterone levels.

– *Therapy:* Because only the protonated form of these drugs block ENaC, increasing the urine pH should cause less of the trimethoprim to be in its cationic form, and its antikaliuretic effect should be minimized [31]. Inducing bicarbonaturia with acetazolamide is a rational therapeutic option in patients with hyperkalemia in whom continuation of these drugs is necessary. However, enough alkali would need to be given to avoid the development of metabolic acidosis. The use of a loop diuretic may also help by lowering the concentration of these drugs in the urine. Enough NaCl administration will be required to maintain the ECF volume.

Hyperkalemic Periodic Paralysis (HYPP)

– *Pathophysiology:* The defect in this disorder seems to be in the regulation of a specific population of Na^+ channels (tetrodotoxin-sensitive) in the cell membrane in skeletal muscle. When the muscle is stimulated to contract, Na^+ influx depolarizes the cell. As the RMP approaches –50 mV, normal Na^+ channels close. In patients with HYPP, these defective Na^+ channels fail to close, causing the cells to have less negative RMP. Depending on the absolute voltage, lesser changes may result in myotonic seizures, while larger changes can cause paralysis.

– *Clinical picture:* This syndrome has an autosomal dominant inheritance. Symptoms of weakness and ultimately paralysis in association with hyperkalemia usually follow bouts of exercise.

– *Diagnosis requirement:* The diagnosis hinges on finding a characteristic clinical picture and is confirmed later by molecular studies.

– *Molecular basis:* This disorder is the result of a mutation in the alpha subunit of the skeletal muscle Na^+ channel gene [80, 81]. This leads to failure to completely close these voltage-gated Na^+ channels in skeletal muscle cells when the $[K^+]$ in the ECF is raised, and hence the electrical inexcitability of the skeletal muscle.

– *Therapy:* Treatment is directed at measures to avoid hyperkalemia. Acetozolamide seems to be effective, though its mechanism of action is not clear.

Therapy of Hyperkalemia When There is No Medical Emergency

It is important to recognize that lowering the plasma $[K^+]$ from 7 to 6 mM requires much less K^+ loss than what is needed to lower the plasma $[K^+]$ from 6 to 5 mM. Therefore, creating a small K^+ loss can be very important in severe hyperkalemia.

– *Diuretics and/or mineralocorticoids:* If K^+ excretion is low because of a low urine volume with a high $[K^+]$, a loop diuretic may induce kaliuresis by increasing the flow rate in the CCD (Figure 3). Unwanted ECF volume contraction can be avoided by replacing the NaCl lost in the urine. NaCl should be given at the same tonicity as the urine to avoid a dysnatremia. If the urine $[K^+]$ is unduly low, giving a mineralocorticoid (100 μg 9α-fludrocortisone) and inducing bicarbonaturia with the carbonic anhydrase inhibitor, acetazolamide may cause substantial kaliuresis (HCO_3^- lost in the urine may need to be replaced).

– *Cation-exchange resins:* The cation exchange resin that is most often used is Na^+ polystyrene sulfonate (Kayexalate). The resin can be given either orally or as a retention enema. It has the capacity to bind 3.5 mmol K^+/g of resin, but the actual amount bound in vivo is closer to 1 mmol K^+/g [92]. When used orally, 20 g of the resin is usually given with 100 mL of 20% sorbitol solution to avoid constipation. This can be repeated every 4 – 6 hours as needed. When given as an enema, 50 g of the resin is usually mixed with 50 mL of a 70% sorbitol solution and 100 mL of tap water. This solution is retained in the colon for at least 30 – 60 min, preferably longer. With this, the negative balance for K^+ that is usually achieved is 25 – 50 mmol). Sorbitol-induced colonic necrosis is a reported complication of this therapy in postoperative patients, perhaps reflecting decreased colonic motility that may increase the duration of contact of hypertonic sorbitol with the colonic mucosa. A cleansing enema may be needed to prevent the colonic retention of the resin-sorbitol mixture.

Metabolic Alkalosis

The hallmarks of metabolic alkalosis are an elevated [HCO_3^-] and decreased [H^+] in plasma [16, 94, 95]. As such, it is customary to discuss the topic of metabolic alkalosis in the section on acid-base disorders in most textbooks. We have chosen to break away from this tradition and include the discussion of metabolic alkalosis in the section on K^+. The reason for that decision is to emphasize that in conceptual terms, metabolic alkalosis due to vomiting is not primarily an acid-base disorder, but rather a disorder resulting for the most part from a deficit of KCl. Although metabolic alkalosis is defined clinically by changes in the composition of the ECF, presence of a high [HCO_3^-] in plasma, however, it is a disorder in which there is usually intracellular acidosis and a deficit of K^+ [15, 17].

Pathophysiology of Metabolic Alkalosis

To understand the pathophysiology of metabolic alkalosis, one must examine the total body balance for critical ions, analyzing events in 3 major areas: the ECF, the ICF, and the urine.

Mass Balance Data

The simplest model of metabolic alkalosis in humans is that produced when the only initial change in mass balance is to remove HCl from the stomach. In the most often-quoted study of this type of metabolic alkalosis [16], normal human volunteers underwent this process for 4 – 5 days. All ions and water losses other than HCl were replaced during that period. After this, subjects were allowed to stabilize in a post-drainage period of 5 – 7 days, during which their deficits of Cl^- were not replaced (Figure 17). Examining the mass balance data reveals that during the HCl drainage period, there was a deficit of Cl^- but not of Na^+ or K^+, and only a very modest decline in ECF volume. During the post-drainage period, however, all subjects developed a prominent degree of K^+ depletion due to renal K^+ loss. While it is not clear from the data what anion was excreted with K^+ in the urine, it is obvious that the source of K^+ was the ICF, as

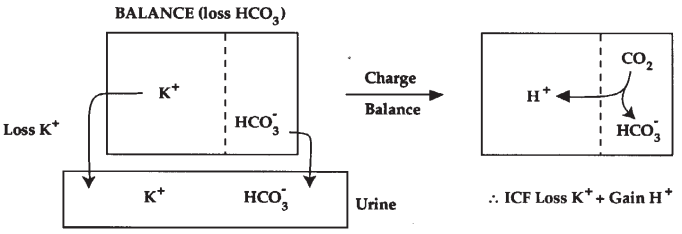

Figure 17. Stoichiometry when K^+ are excreted. When K^+ are excreted, there is a need to have a cation enter the ICF compartment (H^+ in this example) and an anion enter the urine with the K^+ for electroneutrality. The anions excreted are not Cl^-; they are HCO_3^- or their acid-base equivalents.

Table 6. Mass Balance for Na^+, K^+ and Cl^- in "Selective Depletion of HCl"'.
Data were selected from studies in the literature where there was selective loss of HCl (or swap of HCO_3- for Cl^-) together with a post-drainage period in humans [16], dog [105] or rat [17].

	Species		
Parameter	Human (mmol)	Dog (mmol)	Rat (μmol)
Na^+	-22	- 9	-535
K^+	-213	-118	-2931
Cl^-	-199	-110	-2533
ECF volume	-0.5 liters	—	-10 mL
–% change	-3	—	-12

there is not enough K^+ in the ECF to account for the magnitude of its negative balance. The striking feature is that on mass balance, there was near-equimolar losses of Cl^- and K^+ with little change in the mass balance for Na^+. Similar observations were made in experiments in animals. Mass balance data from human and animal experiments are summarized in Table 6.

H^+ Balance During KCl Depletion

Having established that the mass balance during this selective HCl loss (or so-called selective Cl^--depletion alkalosis, which is, of course, a misnomer because one must maintain charge balance) is one of equimolar loss of K^+ and Cl^-, then what is the mass balance for H^+ (Figure 17)? It is important to recognize that while there is equimolar loss of K^+ and Cl^-, the loss of these 2 ions did not occur in the same time frame or even by the same route. During the HCl drainage period, there was the loss of Cl^- with H^+, which resulted in a gain of HCO_3^- in the ECF (Figure 12). During the post-drainage period, K^+ were lost with anions other than Cl^-. If these anions were produced endogenously with H^+, their excretion in the urine with K^+ can be equated with a gain of H^+ in the body (Figure 17). Because the HCO_3^- content in the ECF did not decline when these H^+ were added to the body, they must have been retained in another compartment, the ICF. Because on mass balance data, there was an equimolar loss of K^+ and Cl^-, the HCO_3^- gain in the ECF was equiva-

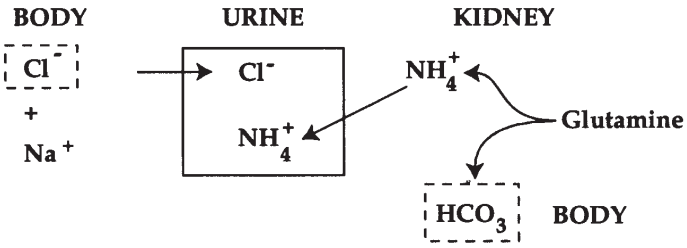

Figure 18. Stoichiometry when NH_4Cl is excreted. When NH_4Cl is excreted (solid box in center), there is a net loss of Cl^- together with the net gain of HCO_3^- in the ECF compartment (dashed boxes).

lent to the H^+ gain in the ICF, and the mass balance for H^+ was virtually nil.

To summarize, analysis of mass balance data during the simplest form of metabolic alkalosis, selective HCl loss, reveals a large KCl deficit. The mass balance for H^+ is largely nil with a HCO_3^- gain in the ECF and an equivalent gain of H^+ in the ICF. However, to recognize how the pathophysiology of metabolic alkalosis evolves, an analysis of events in 3 major areas, the ECF, the ICF and urine, is required.

Analysis of Events in Metabolic Alkalosis

Events in the ECF

With the constraints of electroneutrality, there are only 2 ways to add a specific anion to a compartment, either with a cation or an exchange for the loss of another anion.

In clinical disorders of metabolic alkalosis, the major way to add HCO_3^- to the ECF is to swap HCO_3^- for another anion in the ECF. The only anion present in sufficient quantities in the ECF is Cl^-. Because a loss of H^+ or NH_4^+ is equivalent to a gain of HCO_3^-, 2 organs are capable of inducing the swap of Cl^- for HCO_3^-: the stomach (HCl loss during vomiting or gastric drainage, Figure 12) and the kidney (excretion of NH_4Cl) (Figure 18).

Another way to add HCO_3^- to the ECF and yet maintain electroneutrality is the administration of HCO_3^- (or an anion that could be metabolized into HCO_3^-, e.g. citrate or acetate) along with a cation (Na^+). The normal diet supplies a load of alkali that is normally removed by excreting a family of organic anions [96]. With hypokalemia, the excretion of anions like citrate declines [97], and this will yield a net load of alkali to the body.

Renal Events

The early work of Pitts and coworkers has demonstrated a maximal tubular excretion (Tm) for HCO_3^- reabsorption by the kidney [98]. However, these experiments were done with the infusion of $NaHCO_3^-$ that also caused expansion of the ECF volume. In fact, in the absence of ECF volume expansion, the capacity of the proximal tubule for reabsorption of HCO_3^- is large, with no threshold for HCO_3^- reabsorption even at plasma [HCO_3^-] of close to 50 mM [99, 100, 101] (see chapter I-3 on *Acid-base Balance* for more discussion).

Two major factors seem to enhance the activity of the Na^+/H^+ exchanger (NHE-3) in the proximal tubule: Ang II [102] and intracellular acidosis. Ang II is released in response to low effective circulating volume. As the plasma [HCO_3^-] rises initially not all filtered HCO_3^- is reabsorbed. To the extent that some HCO_3^- is lost with Na^+ in the urine, a degree of contraction of the ECF volume occurs. With regard to the fall in intracellular pH, both hypokalemia and a rise in pCO_2 raise the [H^+]

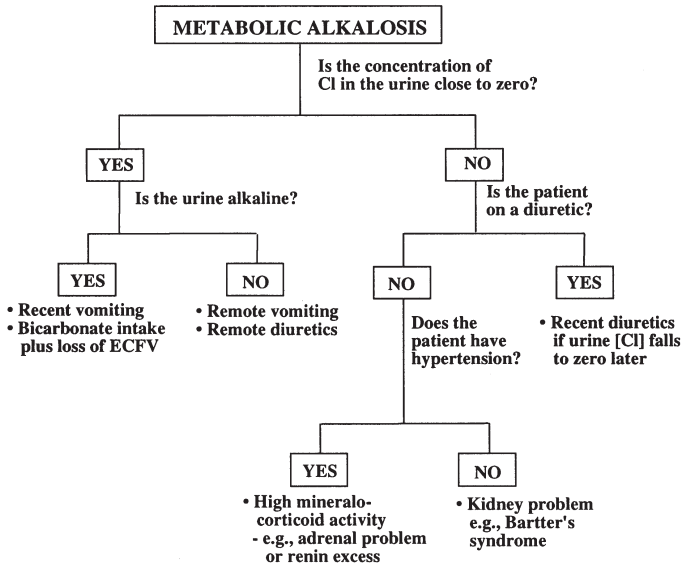

Figure 19. Diagnostic flow chart for metabolic alkalosis. For details, see text. Final diagnoses are shown in the boxes at the bottom of each limb of the flow chart. Reproduced with permission [104].

in the ICF and hence the activity of NHE-3 in the PCT. These renal mechanisms lead to HCO_3^- retention and protect against bicarbonaturia with the associated loss of Na^+ (loss of ECF volume) and K^+ (worsening hypokalemia). Moreover, the loss of HCO_3^- must be prevented as the body does not have a total HCO_3^- surplus.

Events in the ICF

As discussed previously, mass balance data reveal a large deficit of K^+. The source of this K^+ is from the ICF, and its loss in the urine occurs with an anion other than Cl^-. The loss of K^+ with an endogenous anion is equivalent to the gain of H^+ (see Figure 17). To provide mass balance and electroneutrality for the ECF and ICF, H^+ and Na^+ enter the ICF as K^+ exit. Therefore, there is both depletion of K^+ and intracellular acidosis.

To summarize, the pathophysiology of the so-called Cl^- depletion metabolic alkalosis has the following features: a higher content and concentration of HCO_3^- in ECF, an enhanced reabsorption of HCO_3^- by the kidney, and K^+ depletion with intracellular acidosis.

Clinical Aspects of Metabolic Alkalosis

A list of the common causes of metabolic alkalosis is provided in Figure 19. Metabolic alkalosis is seen most often in patients who vomit on a chronic basis or those who are taking diuretics. Less commonly, causes include patients with disorders of primary excess of mineralocorticoid actions. The most helpful aspects in the differential diagnosis on presentation are the history, an assessment of the ECF volume, the measurements of the plasma creatinine concentration, and an analysis of electrolyte excretion in a random urine.

History

Often, the diagnosis of metabolic alkalosis is straightforward. However, a number of patients are not willing to admit to self-induced vomiting or the abuse of diuretics. Therefore, the history cannot be relied upon entirely, and one must often resort to a series of laboratory tests to establish the diagnosis (Table 1).

Assessment of the ECF Volume

The major causes of metabolic alkalosis, vomiting or diuretic abuse, are usually accompanied by a significant degree of ECF volume contraction. On the one hand, patients with metabolic alkalosis due to primary excess of mineralocorticoid actions have a normal or somewhat expanded ECF volume. Hypertension is also a common finding in these patients.

Urine Electrolytes

A single spot urine, or perhaps several spot urine samples, can unravel the pathophysiology of metabolic alkalosis (Table 1). It must be stressed at the outset that there are no normal values for urine electrolytes, just expected values in a given clinical setting.

In patients with metabolic alkalosis, ECF volume contraction, and similar low excretions of Na^+, K^+ and Cl^- could represent the presence of remote vomiting or 'yesterday's diuretics', or the prior intake of nonreabsorbable anions. Some patients with metabolic alkalosis have a low rate of Cl^- excretion, yet the urine contains an abundant quantity of Na^+. The reason for the Na^+ excretion is the presence of an anion that was not reabsorbed. If the urine contains a large quantity of HCO_3^- (pH > 7), vomiting or nasogastric suction are the most likely diagnoses. A low urine pH suggests the intake of anions that are poorly reabsorbed by the kidneys.

Excretion of an abundant amount of Na^+ and Cl^- in the urine is expected in a patient with a normal ECF volume. In a patient with metabolic alkalosis and a contracted ECF volume, this pattern of electrolyte diuresis suggests a diagnosis of Bartter's or Gitelman's syndrome(s) or the recent use of diuretics.

Plasma Creatinine

Some patients with ECF volume contraction will have elevated values for plasma creatinine corrected for their body mass, especially if the degree of ECF volume contraction is marked. Previous values and the clinical setting make this interpretation relatively simple.

Patients with chronic renal failure (CFR) usually have a normal or expanded ECF volume and a markedly elevated level of creatinine in plasma. If a patient with renal failure ingests or is given alkali or organic anions, little HCO_3^- will be filtered and HCO_3^- will be retained.

Clinical Approach

An outline to a clinical approach to a patient with metabolic alkalosis is provided in Figure 19. The first step in the resolution of the basis of metabolic alkalosis is to rule out the presence of significant renal function impairment (GFR < 25% of normal). If renal failure exists, the specific cause of the metabolic alkalosis should be evident from the history.

If a very low GFR plus alkali input is not the cause of metabolic alkalosis, the ECF volume status is the next critical parameter to assess. The majority of patients have a contracted ECF volume and their urine [Cl^-] is very low (< 20 mM). The differential diagnosis in this group of patients with a contracted ECF volume is indicated in Figure 19.

Effect of Metabolic Alkalosis on Ventilation

The [H^+] is a major determinant of ventilation, and therefore one would expect metabolic alkalosis to have a depressant effect on ventilation. In fact, there is a linear relationship between the increasing plasma [HCO_3^-] and progressive increase in the partial pressure of carbon dioxide (pCO_2), with a slope of approximately 0.7, indicating that for every mM increase in plasma [HCO_3^-], a 0.7 mmHg increase in pCO_2 would be expected. Thus, when patients present with CO_2 retention and metabolic alkalosis, the metabolic alkalosis should be corrected before attributing the CO_2 retention to lung disease.

As hypoventilation develops, it is accompanied by hypoxia, which offsets the degree of respiratory suppression achieved. The reduction of tissue oxygen (O_2) delivery in metabolic alkalosis is further aggravated by the fact that the O_2 hemoglobin dissociation curve is shifted to the left by alkalemia, increasing the affinity of hemoglobin for O_2.

Patients with chronic lung diseases often take diuretics to cope with their Na^+ retention and may develop metabolic alkalosis. The mixed acid-base disturbance may return their plasma [H^+] to the normal range. This removes the acidemic drive to ventilate and may worsen the clinical condition [103].

Treatment of Patients with Metabolic Alkalosis

Group with a Low ECF or Effective Circulating Volume

It goes without saying that patients with ECF volume contraction require Na^+ and Cl^- replacement. When their ECF volume is restored, the [HCO_3^-] will fall, owing to dilution. Eventually there will be some bicarbonaturia. Moreover, the [HCO_3^-] in the ECF can fall to the normal range when a large excess of NaCl is given (the ECF volume is expanded by 4 – 5 L), even if the K^+ deficits are not completely restored [94]. Up to this point the large K^+ deficit in cells and the intracellular acidosis have been ignored. Therefore, NaCl administration is only partial therapy in patients with metabolic alkalosis who have ECF volume contraction, as it does not address the accompanying intracellular acidosis and K^+-deficit. In fact, some patients with metabolic alkalosis have only a marginal depletion in their ECF volume. Clearly in this case, NaCl should not be the linchpin of therapy. To treat the ICF acidosis and K^+ depletion, obviously K^+ must be given with an anion that permits retention of this cation in the ICF. This means KCl in most cases because as K^+ enters the ICF, Na^+ and H^+ exit for the most part. The H^+ titrates the excess HCO_3^- in the ECF and the extra NaCl is excreted.

In patients in whom the metabolic alkalosis is due to a reduction in effective circulating volume with ECF volume expansion (e.g. congestive heart failure (CHF) on diuretics), the metabolic alkalosis requires therapy with KCl, and additional Na^+ should *not* be given (as K^+ enters the ICF, Na^+ leaves, adding some Na^+ to the ECF). A loop diuretic will be needed to excrete the net gain of NaCl in the ECF compartment.

If the patient has been abusing diuretics or inducing vomiting, therapy of the underlying psychopathology proves to be the greater problem.

If the patient is ventilated and has a fixed alveolar ventilation, the pCO_2 may rise with H^+ administration. Therefore, in these patients, treatment must be very slow.

High or Normal ECF Volume Group

Therapy is generally more difficult in patients with ECF volume expansion. If they have renal failure and are very alkalemic ($[H^+]$ < 20 nM, pH > 7.70), they should receive some H^+ in the form of HCl or NH_4Cl. If these patients are dialyzed, the bath should have the $[HCO_3^-]$ reduced so as to ameliorate rather than contribute to the alkalemia.

If the patient has hyperadrenalism, agents blocking the reabsorption of Na^+ by the ENaC in the CCD (amiloride) or mineralocorticoid antagonists have an important role in the therapy. Aggressive K^+ replacement in conjunction with amiloride or spironolactone must be used with caution, so as to avoid the development of a serious degree of hyperkalemia [60, 61]. In the acute setting, it is safest to order only one day of K^+ therapy at a time, checking the serum $[K^+]$ each day before ordering that day's therapy.

Patients with Mg^{2+} deficiency should have their deficiency corrected, but it is important to follow up on the effectiveness of the therapy, since patients with hyperaldosteronism also have Mg^{2+} deficiency.

At times, one would like to alleviate the alkalemia quickly (e.g. weaning from a ventilator). Acetazolamide is sometimes used in such a setting, but the large load of $NaHCO_3$ delivered to the collecting duct can promote a substantial additional urinary K^+ loss. For this reason, we prefer an IV HCl preparation in such patients. With IV HCl, one also has better control over the degree of fall in $[HCO_3^-]$ than with acetazolamide.

Disorders of Acid-base Balance

Mitchell L. Halperin, Shih-Hua Lin, Manjula Gowrishankar and Kamel S. Kamel

Overview of Hydrogen Ions

Hydrogen ions (H^+) play a central role in cellular physiology [1, 2]. Their most important function is in the regeneration of adenosine triphosphate (ATP) that permits cells to perform biological work. To regenerate ATP, H^+ are first actively pumped out of mitochondria using energy derived from a redox pump; this creates an electrochemical driving force for H^+ to enter mitochondria. This proton motive force across the inner mitochondrial membrane is largely due to voltage (inside negative) and also to a pH difference (inside alkaline). When H^+ diffuse into the mitochondrial compartment, the entry system has two components, a special H^+-ATP synthetase that is linked to a system to convert ADP plus inorganic phosphate to ATP. This system of linking H^+ transport and ATP turnover is a fundamental one in acid-base homeostasis. For example, the reverse of this reaction causes H^+ to be transported out of cells of the collecting duct with the driving force being the hydrolysis of ATP – the H^+ pump is now an H^+-ATPase using energy trapped in ATP to move H^+ against its electrochemical gradient [3].

The H^+ concentration in all body compartments is maintained at a very low level because H^+ bind very avidly to histidine residues in proteins. Binding of H^+ to proteins changes their charge (more positive) – this might alter their configuration, and possibly their function [4]. Since most proteins are enzymes, transporters, contractile elements, and structural compounds, a change in their function could pose a major threat to survival. Notwithstanding, not all H^+ binding to proteins results in a diminished function; for example, H^+ binding to hemoglobin promotes the release of O_2 at the tissue level and the converse applies in the alveoli of the lung [5].

Two quantitative aspects illustrate this delicate homeostasis for H^+. First, the concentration of H^+ in plasma is exceedingly tiny as compared to the concentrations of ions like bicarbonate (HCO_3^-) (P_{HCO3}), sodium (Na^+) (P_{Na}), potassium (K^+) (P_K), or chloride (Cl^-) (P_{Cl}). Moreover, the concentration of H^+ is maintained within a very narrow range in the extracellular fluid (ECF) (40 2 nM) or in cells (close to 80 nM in many cell types) [6]. This is even more impressive because an enormous number of H^+ are produced and removed by metabolism each day [7]. In more detail, acids are obligatory intermediates of carbohydrate, fat, and protein metabolism. For example, since adults typically consume (and oxidize) 1,500 mmol of glucose per day, at least 3,000 mmol or 3,000,000,000 nmol of H^+ are produced (as pyruvic and/or L-lactic acids) and removed daily. In an adult eating a typical Western diet, 70 mmol or 70,000,000 nmol of these H^+ are added to the body. This implies that there are very effective control mechanisms that minimize fluctuations in the concentration of H^+, thereby avoiding large changes in the net valence on body proteins.

Table 1. Major concepts in acid-base balance. For details, see text. Reproduced with permission [187].

Concept	Comment
1. Net H^+ production is revealed by finding new anions.	The rate of turnover of ATP sets an upper limit on the rate of ketoacid and L-lactic acid production and removal. Diminished metabolic removal of ketoacids is critical for ketoacid accumulation.
2. Buffering of H^+ is good if H^+ are removed by HCO_3^- and not proteins.	A low tissue PCO_2 is needed for the BBS. Tissue PCO_2 depends on the arterial PCO_2, CO_2 production and blood flow rates.
3. Kidneys add new HCO_3^- to the body by excreting NH_4^+.	NH_4^+ production is stimulated by a low PCT cell pH, and is limited by PCT ATP turnover and the presence of an alternate fuel.
4. Eliminate dietary alkali with endogenous H^+ production.	Alkali is eliminated by organic acid production and the excretion of organic anions in the urine as their Na^+ and K^+ salts.
5. Excrete urine at a pH of 6.0.	Arguably, this is the most important renal function in acid-base balance because a urine pH of 6 minimizes the risk of uric acid and $CaHPO_4$ stone formation.

BBS = Bicarbonate Buffer System.

Overview of Acid-base Balance

An analysis of acid-base balance must consider not only acid balance but also the balance for bases or alkali.

Acid-balance

There are 3 major components to consider in the physiology of acid balance (Figure 1). First, during the metabolism of certain dietary constituents, H^+ are produced. This production of H^+ is recognized by finding of the appearance of new anions (Table 1) [2, 7]. Second, H^+ are ultimately removed from the body largely because they react with HCO_3^-, forming CO_2 + water; the CO_2 so-formed is eliminated via the lungs. The net result of these reactions is a deficit of HCO_3^- in the body that is equal to the net H^+ load. Third, generate new HCO_3^- (without H^+) to replace that lost in titrating these H^+ [8]. This is accomplished by excreting ammonium ions (NH_4^+) in the urine.

Base-balance

The diet also provides alkaline salts [9]; the best example is the ingestion of fruits that contain K^+ citrate salts. Metabolism of these citrate anions occurs rapidly in the liver and

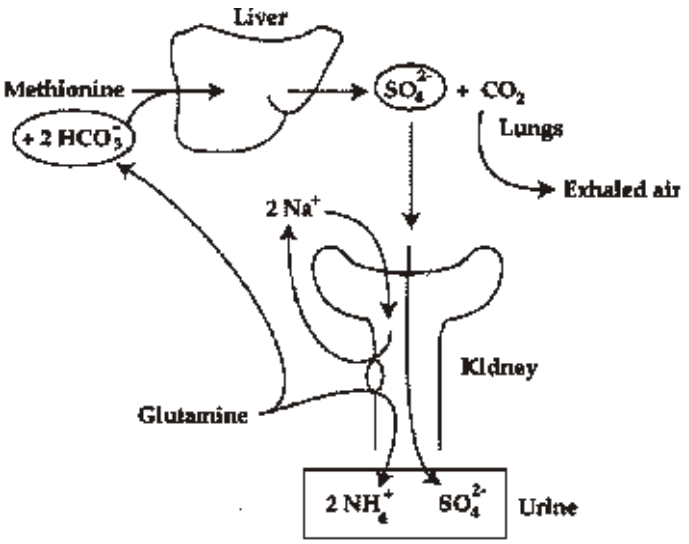

Figure 1. Acid balance. The portion of new H^+ produced in metabolism that requires renal actions for its elimination come from the oxidation of sulfur-containing amino acids depicted as methionine oxidation in the liver. This process removes HCO_3^- from the body and adds SO_4^{2-} anions. The kidney excretes these extra SO_4^{2-} anions while adding an equal quantity of HCO_3^- to the body. This is achieved as equivalent amounts of $NH_4^+ + SO_4^{2-}$ are excreted in the urine. Reproduced with permission [187].

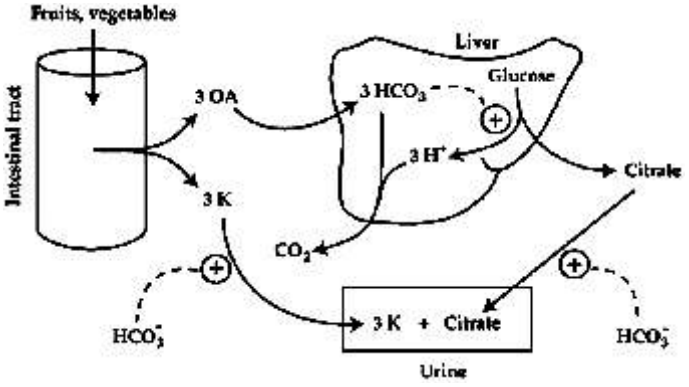

Figure 2. Disposal of an alkali load. The alkali load of the diet is derived from ingested K^+ salts of organic anions for the most part. This spectrum of organic anions is converted to HCO_3^- in the liver. Organic acids (citric acid in this example) are then produced by hepatocytes and its conjugate base (citrate anion) will be excreted in the urine as a K^+ salt. Reproduced with permission [187].

the net result in acid-base terms is the production of HCO_3^- [7]. Removal of this HCO_3^- load is achieved via production of new endogenous organic acids including citric acid [9]. The H^+ of these acids titrate HCO_3^- and base balance is maintained by excreting the conjugate base of these acids (e.g., $citrate^{3-}$) in the urine as their Na^+, K^+, and/or calcium (Ca^{2+}) salts [2, 9 – 12] (Figure 2). This disposal of alkali with the excretion of organic anions minimizes the risk for kidney stone formation. It avoids the excretion of HCO_3^- which, by alkalinizing the urine, could lead to calcium phosphate precipitation [13]. Further, in response to a load of alkali, renal reabsorption of citrate declines [14], citrate chelates Ca^{2+} in the urine and therapy reduces the risk of stone formation.

H^+ Production

CONCEPT 1: H^+ production is revealed by finding of new anions.

Metabolic analysis of net production of acids: A metabolic process can span more than one organ (Figure 3). In general, the starting

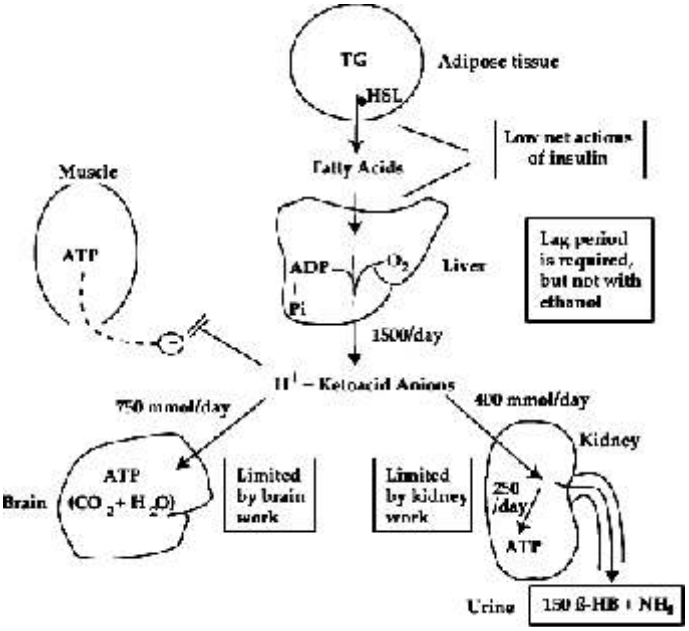

Figure 3. The metabolic process involved in ketoacid metabolism. The metabolic process of ketoacid metabolism begins with activation of hormone sensitive lipase (HSL) in adipose tissue. After a lack of insulin for several days, the production of ketoacids in the liver rises to about 1500 mmol/day. The main sites of removal of ketoacids are the brain (750 mmol/day) and the kidneys (400 mmol/day). Reproduced with permission [187].

points are dietary or stored fuels (glycogen or triglycerides) and the final products are ATP or storage forms of fuels [2]. From an acid-base perspective, one can determine if H^+ are produced or consumed in a metabolic process by a quantitative examination of the net charge or valence of its substrates and end products [7]. H^+ are formed if the net charge of the compounds produced is more anionic than that of substrates; the converse is also true. In this analysis, the net charge on adenine nucleotides (ADP, AMP, ATP) or NAD(P) does not need to be considered as the conversion of ATP to ADP to do biological work initiates the regeneration of ATP and NAD(P).

Acid balance is maintained if the new anions are metabolized to neutral end products, or if they are excreted in the urine along with H^+ or NH_4^+. On the other hand, there is a net gain of H^+ in the body if these anions are retained in the body or are excreted as their Na^+ or K^+ salts. Therefore every new anionic valence retained in the body or excreted with Na^+ or K^+, one new H^+ was added (Figure 4). Using the above analysis, the net addition of H^+ to the body can be classified into 2 categories:

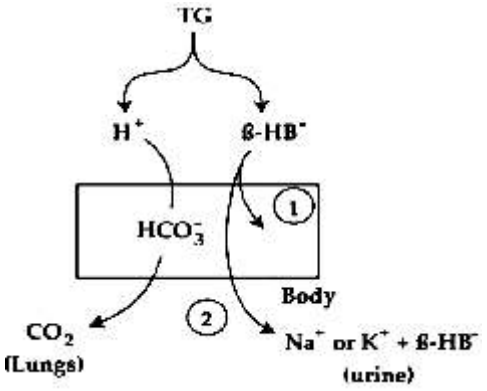

Figure 4. Metabolic analysis of net production of acids. The partial oxidation of storage triglyceride (TG) yields H^+ plus -hydroxybutyrate anions (--HB^-). The H^+ are titrated in the body by HCO_3^-, generating water and CO_2 – the latter is exhaled and the body has a deficit of HCO_3^- and a gain of -HB^-. If the -HB^- are retained in the body (point 1) or are excreted as Na^+ (or K^+) salts (point 2), there is a deficit of HCO_3^- that is equivalent to a net gain of H^+. Reproduced with permission [187].

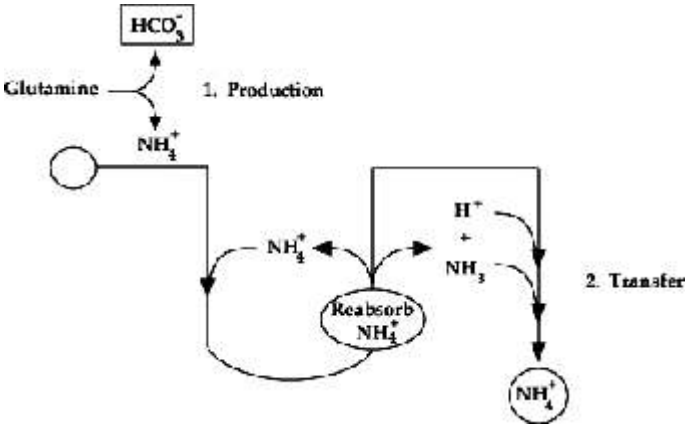

Figure 5. Physiology of NH_4^+ excretion. There are 2 major steps. First, NH_4^+ and HCO_3^- are produced when glutamine is metabolized in cells of the PCT. Second, NH_4^+ is transferred via the medullary interstitial compartment to the lumen of the MCD because of a high medullary interstitial concentration of NH_3 and NH_4^+.

– *H^+ production during normal metabolism:* In effect, this means the production of sulfuric acid (SO_4^{2-} anion + 2 H^+) from the oxidation of sulfur-containing amino acids and the production of phosphoric acid from the oxidation of monovalent phosphate diesters. These latter H^+ are removed when they are excreted bound to phosphate in the urine as $H_2PO_4^-$ (titratable acid excretion). On the other hand, H^+ that are produced with sulfate (SO_4^{2-}) anions during metabolism of sulfur-containing amino acids cannot be removed via metabolism or by excreting SO_4^{2-} in the urine because the affinity of SO_4^{2-} for H^+ is too low at typical urine pH values. In this case, maintenance of acid balance requires a mechanism for the generation of new HCO_3^- *without* adding H^+ to the body. This is accomplished by metabolizing a neutral amino acid, glutamine, to a cation (NH_4^+) and an organic anion (-ketoglutarate). This anion is metabolized in the kidney to a neutral end product (CO_2 and/or glucose), yielding new HCO_3^- that are added to the body. For a net gain of HCO_3^-, NH_4^+ must be made into an end product of metabolism by being excreted in the urine (Figure 5) [15].

– *H^+ production during incomplete or abnormal metabolism:* We cite 3 major examples here. First, the fastest rate of production of H^+ is from carbohydrate metabolism when the supply of oxygen is inadequate to meet demands. Now L-lactic acid is generated by anaerobic glycolysis (Table 2). Although metabolism of the L-lactate$^-$ anion to a neutral end product (e.g., glucose, glycogen or CO_2) removes H^+, this occurs at a much slower rate. Second, H^+ production occurs during fat metabolism if there is a relative lack of insulin. In this case, ketoacids (-hydroxybutyric acid and acetoacetic acid) are formed [16]. The degree of ketoacidosis depends on how quickly the brain and the kidneys remove these acids. Third, at times, compounds are ingested (usually alcohols or precursors of alcohols) that can be metabolized to anions at a much faster rate than these anions can be converted to neutral end products to remove these H^+.

Endogenous net production of acids, a physiological analysis: We can identify 2 major categories of endogenous acid production. One type of H^+ production requires renal net acid excretion to eliminate these H^+ (e.g.,

Table 2. Rates of production of H^+ and its removal. The rate of L-lactic acid production listed in this table is that occur during anaerobic metabolism, assuming an O_2 consumption rate of 12 mmol/min and that the rate of turnover of ATP is unchanged. This rate is much greater than in all other causes of net H^+ addition. H^+ removal by metabolism of L-lactate anions is depicted for gluconeogenesis and oxidation in the liver and kidneys.

	Rate (mmol/min)
Production of H^+	
– L-lactic acid during anoxia	72
– ketoacids during a lack of insulin	(up to) 1.5
– methanol/ethylene glycol	(up to) 1.0
Removal of H^+	
– *renal generation of new HCO_3^-*	
– normal	0.03
– chronic acidosis	0.15
– *metabolism (maximum in vivo rates in mmol/min)*	
– L-lactic acid	4 – 8
– ketoacids in brain and kidneys	1.0

monovalent diester phosphates and sulfur-containing amino acids described above). H^+ produced in metabolism of sulfur-containing amino acids are eliminated by the excretion of an equivalent amount of NH_4^+ in the urine. The second type of dietary-driven H^+ production is part of the physiological response to eliminate the dietary alkali (part of base balance, Figure 2, [9, 11]). This process yields H^+ plus organic anions – H^+ titrate HCO_3^-, while the organic anions are made into end products of metabolism by being excreted in the urine as their Na^+ and/or K^+ salts. Hence although both types represent endogenous H^+ production, they have very different functions.

Basis for metabolic acidosis: There are 3 ways to raise the concentration of H^+ in the body – the addition of acids that yield H^+ (one form of metabolic acidosis), failure to eliminate CO_2 normally (called respiratory acidosis), and failure to add new HCO_3^- to the body by excreting enough NH_4^+ (another form of metabolic acidosis). In yet another condition, H^+ may redistribute from the ECF to the intracellular fluid (ICF) compartments without requiring an overall change in the total number of H^+ in the body. An example of such a shift of H^+ into cells occurs in patients with a large deficit of K^+. In this case one develops an intracellular gain of H^+ together with a gain of HCO_3^- in the ECF compartment [17, 18]; from the perspective of the ECF, this is called metabolic alkalosis, but from the perspective of the ICF compartment, it would be called metabolic acidosis and a deficit of K^+ (see Chapter on K^+ where metabolic alkalosis is considered in more detail).

Tools to HelpIdentify Net Production of Acids

Metabolic acidosis that is due to an overproduction of acids can be recognized by finding the "footprints" of the added acids,

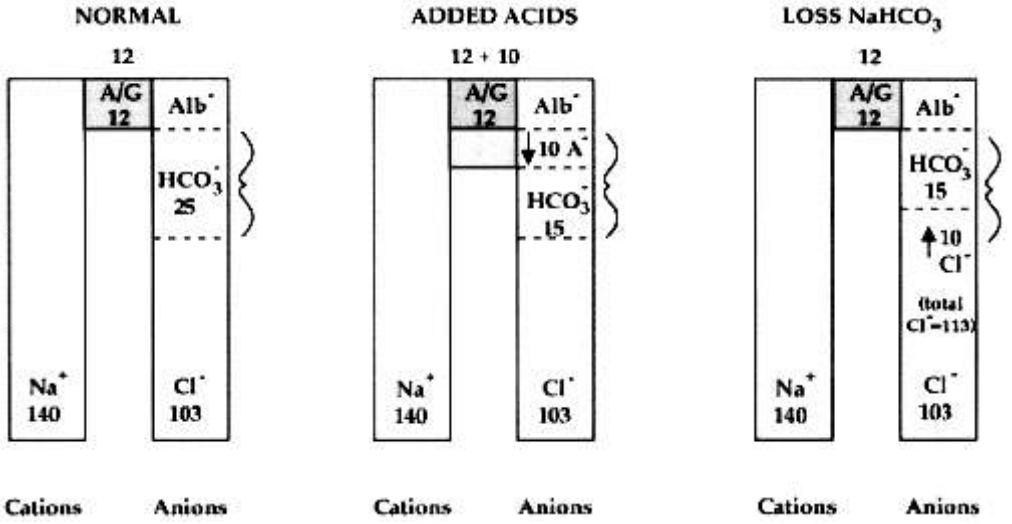

Figure 6. Plasma anion gap. The anion gap is a calculation for "diagnostic convenience"; it reveals the "footprints" of added acids. One measures only the major cation Na^+ and subtracts the major anions Cl^- and HCO_3^-. The usual value is 12 mEq/l (140 – 103 – 25); the anion that is not measured as such is primarily albumin. When acids are added and their anions are retained in the ECF compartment, the P_{HCO3} falls and the extra anions are revealed by the larger value for the plasma anion gap. When $NaHCO_3$ is lost, the P_{HCO3} falls and there are no extra anions; rather, the P_{Cl} rises.

their conjugate bases (or new anions) in the body (Figure 6) or in excreted fluids (usually the urine). At times one can gain a helpful hint about the nature of the added acids from examining the renal handling of their anions.

New anions in the body: New anions in the body are detected by calculating the anion gap in plasma (Figure 6). The concentration of unmeasured anions in plasma (the plasma anion gap) is the difference between the concentrations of the measured cation (Na^+) and the measured anions (Cl^- and HCO_3^-) in plasma (Equation 1). K^+ is not commonly included in this anion gap calculation because its concentration is low relative to that of Na^+. The usual normal range for the plasma anion gap is 12 2 mEq/l and this reflects for the most part, the net anionic valence of albumin in plasma. In some laboratories, this value may be closer to 6 or 8 mEq/l due to higher reported values for Cl^- because of different analytical techniques for measurement of Cl^-.

$$\text{Plasma anion gap} = P_{Na} - (P_{Cl} + P_{HCO3}) = 12 \quad 2\,\text{mEq/l} \qquad (1)$$

If the value for the plasma anion gap is higher than expected for the anionic valence on albumin, this suggests that acids have accumulated (Figure 6, middle panel). There are, however, some potential pitfalls to consider when evaluating the plasma anion gap. The net anionic charge on albumin accounts for most of this "gap". At a plasma pH of 7.4 and a concentration of albumin is 40 g/l or 4 g/dl, its valence is close to 12 mEq/l (when the valence on K^+ is ignored) [19]. Therefore a low concentration of albumin in plasma will cause the "baseline" value for the anion gap in plasma to be lower; as a clinical short cut, for

every 10 g/l decline in albumin concentration, one should anticipate a 3 – 4 mEq/l fall in the "baseline" value for the plasma anion gap.

Another cause for a low anion gap in plasma is the presence of unusual cations in plasma such as myeloma proteins. Although hypercalcemia or hypermagnesemia will in theory lower the value for the plasma anion gap, the change in their concentrations is rarely high enough to make a significant change in the plasma anion gap; the same is true for other cations such as lithium. A low plasma anion gap can be due to overestimation of Cl^- (e.g., bromism).

Renal handling of new anions: The renal handling of anions produced in association with H^+ has an important effect on the magnitude of the rise in the plasma anion gap as compared to the decrease in the P_{HCO3} [20]. One can utilize the renal handling of these anions to help recognize which acid was produced. For example, if the new anions are retained in plasma, this implies that there was little excretion of these anions in the urine. For the most part, this means either a low rate of filtration (low GFR), protein binding, and/or avid reabsorption of these new anions by the kidney (L-lactate anions, ketoacid anions, and to a lesser extent, D-lactate anions). On the other hand, metabolic acidosis due to a high rate of production of acids can be associated with a near-normal anion gap in plasma if the accompanying anion is largely excreted in the urine; an example is the production of hippuric acid and excretion of the anion, hippurate as its Na^+ or K^+ salt (e.g., in glue sniffers [21]).

Plasma osmolal gap: This tool is used primarily to detect uncharged, low molecular weight precursors of acids. In practice, the calculation of the plasma osmolal gap is used to detect toxic alcohols (methanol and ethylene glycol). The plasma osmolal gap is defined as the difference between the measured and the calculated plasma osmolality (P_{Osm}). The calculated P_{Osm} is the sum of twice the plasma P_{Na} plus the concentration of glucose (P_{Glu}) and of urea (P_{Urea}) in plasma, all in mM terms (Equation 2). To convert to mM terms, divide the BUN in mg/dl by 2.8 and the P_{Glu} in mg/dl by 18.

$$\text{Plasma osmolal gap} = \text{Measured } P_{Osm} - ((2 \times P_{Na}) + P_{Urea} + P_{Glu}) \quad (2)$$

To use this calculation, one must presume that there is no error in measurement of P_{Na} (e.g., due to hyperlipidemia). Ethanol will also be detected by the calculation of the plasma osmolal gap. Therefore one should not think that methanol or ethylene glycol is absent simply because there is a history of consumption of ethanol. At times, compounds such as mannitol, or very high concentrations of ions such as Mg^{2+} may cause a high value for the plasma osmolal gap. When there is methanol or ethylene glycol toxicity, the value for the plasma osmolal gap is usually considerably greater than 25 mOsm/kg H_2O.

Buffering of H^+

CONCEPT 2: In physiological buffering, H^+ are to be removed by the bicarbonate buffer system and not by proteins.

In the traditional view, the role of buffering is to minimize the change in the concentration of H^+ when an acid or alkali is added to a solution. From a physiological perspective, however, the main role of buffering is to force H^+ to bind to HCO_3^- rather than to proteins [4]. Binding of H^+ to intracellular proteins could be detrimental to cellular function because this changes the charge on these proteins which could alter their tertiary structure and may thereby affect their function. Therefore, while it is customary to rely on measurements

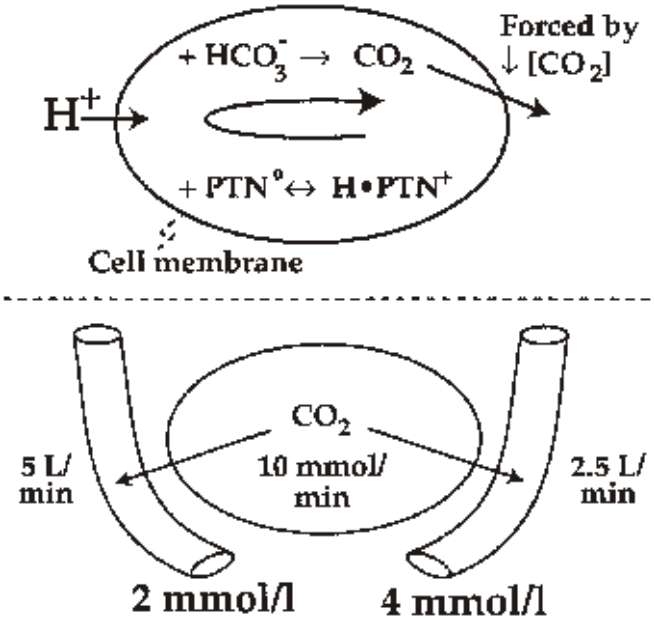

Figure 7. Role of the tissue PCO_2 in the selection of ICF buffers. As shown in the top portion of the figure, when the tissue PCO_2 falls, the H^+ concentration in cells will decrease and these H^+ will be removed by HCO_3^-. This will reduce the quantity of H^+ bound to intracellular proteins ($H\bullet PTN^+$). As shown in the bottom portion of the figure, there will be a rise in the cell and venous PCO_2 when the blood flow rate is slower (2.5 vs 5 l/min), as may be the case in a patient with a contracted ECF volume. This higher cell PCO_2 forces H^+ to bind to proteins. The converse occurs when the ECF volume is re-expanded.

in plasma (pH, PCO_2, P_{HCO3}^-) to assess the acid-base disturbance, it is also important to recognize that events in the ECF, and especially in arterial blood, may not reflect the acid-base status in the ICF compartment.

Several factors determine the degree of binding of H^+ to intracellular proteins (Figure 7). The first step for buffering of H^+ in cells is that they must cross cell membranes. Buffering by intracellular HCO_3^- can only occur if the tissue PCO_2 falls (Equation 3).

$$H^+ + HCO_3^- \quad H_2CO_3 \quad H_2O + CO_2 \qquad (3)$$

Distribution of H^+ Between the ECF and ICF

This issue will be considered in some detail because it also provides the basis to understand why hyperkalemia develops in patients with certain types of metabolic acidosis [22]. To shift K^+ out of cells, the mechanism of entry of H^+ into cells should cause a less negative voltage in cells. H^+ move across cell membranes by passive entry of electroneutral free acids or by carrier-mediated transporters for monocarboxylate acids. With regard to the former, diffusion must be very slow because the concentration of free acids with pK values in the 2 – 4 range are very low at the pH of body fluids. Hence specific transport systems that permit H^+ to cross cell membranes are the most important pathways to understand (Figure 8).

H^+ do not appear to enter cells by ion channels because if H^+ or HCO_3^- ion channels were present and open in cell membranes, the ratio of the concentration of H^+ in the ICF and ECF compartments would be similar to that of K^+. Therefore the concentration of H^+ in the ICF compartment would be 30 – 40 times higher than that in the ECF compartment – i.e., the pH of the ICF compartment would be close to 1.5 pH units lower than the ECF while measured values are close to 0.3 pH unit [6]. Three pathways are available for electroneutral H^+ movement.

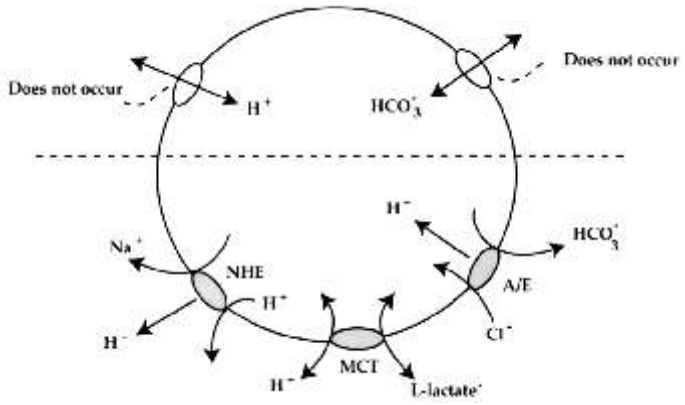

Figure 8. Pathways for net H^+ transport across cell membranes. The circle represents a cell. Given the large net ICF negative voltage across cell membranes and the 2-fold H^+ concentration difference, H^+ or HCO_3^- ion channels could not be in an open configuration (open ovals above the dashed line). Rather, there are 3 possible transport systems, as shown by the shaded ovals, which could lead to the net transport of H^+. Abbreviations: NHE = Na^+/H^+ exchanger; MCT = monocarboxylic acid transporter; AE = Cl^-/HCO_3^- anion exchanger.

(i) The monocarboxylic acid transporter (MCT): The MCT catalyzes, for example, the cotransport of L-lactate$^-$ or -HB$^-$ anions plus H^+ across cell membranes [23]. Because flux through this cotransporter is electroneutral, it does not cause a change in the resting membrane potential. Therefore this form of transport of H^+ does not lead directly to a shift of K^+ across cell membranes.

(ii) The Na^+/H^+ exchanger (NHE): A simple examination of existing concentrations of Na^+ and H^+ in the ECF and ICF compartments indicates that the NHE must be largely inactive in vivo because it is appreciably displaced from its electrochemical equilibrium (Na^+ concentration in the ECF compartment is higher (140 vs ~ 14 mM) and lower H^+ concentration is lower (40 vs 80 nM) in the ECF compartment). When NHE does become active, the only direction for net movement of H^+ is from the ICF to the ECF compartment [24]. Hence NHE is *not* directly involved in buffering of an ECF H^+ load.

(iii) The chloride (Cl^-)/HCO_3^- anion exchanger (AE): This AE catalyzes an electroneutral exchange of anions [25]. Exit of HCO_3^- leads to the accumulation of Cl^- in the ICF compartment. Since all cells have Cl^- channels in their membrane [26], the rise in the ICF Cl^- concentration in conjunction with the usual negative voltage forces Cl^- to exit from cells (Figure 9). This export of negative voltage when Cl^- ions exit causes a less negative voltage in cells. As a result, K^+ will exit from cells if K^+ channels are open. The net effect of this flux through the AE is the export of K^+ and HCO_3^- from cells. Thus a shift of K^+ out of cells would occur in response to an inorganic acid load or a non-monocarboxylic organic acid load such as citric acid [27].

Buffering of H^+ by Intracellular Proteins

P_{HCO3}: When the P_{HCO3} is very low, there is little HCO_3^- in the ECF compartment to buffer newly added H^+ so most of these H^+ will now be bound to intracellular proteins. Hence when the P_{HCO3} is *very* low and if there is a possibility that it may decline even further, this may be an indication to administer $NaHCO_3$. In this regard, it is also important to note the impact of very small absolute changes in the P_{HCO3} when this concentration is very low to begin with. For instance, if the fall in the P_{HCO3} is only 2 mM, but it fell from 4 mM to 2 mM, there is a doubling (100% rise) of the plasma H^+ concentration and a fall

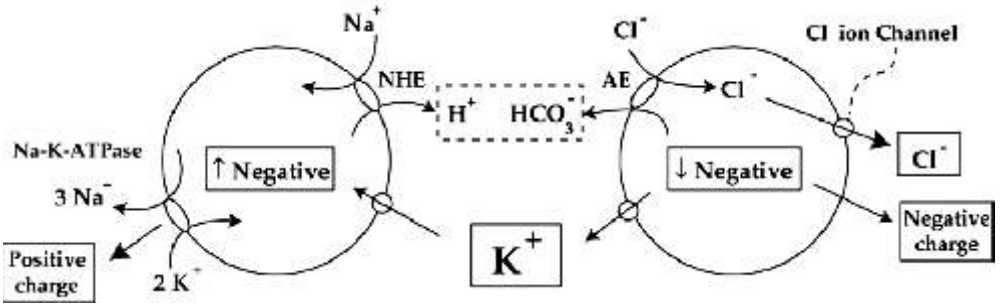

Figure 9. NHE and NE adjust the cell voltage and the P_K. The circles represent cells with their usual net negative ICF voltage. Because of the higher Na^+ concentration outside cells and the higher H^+ concentration in cells, the NHE catalyzes H^+ exit and Na^+ ion entry into cells in an electroneutral fashion (left portion). This transport requires activation by insulin or intracellular acidosis. When Na^+ ions are exported by the Na-K-ATPase, the voltage in cells becomes more negative. The net effect is to shift K^+ ions into cells. As shown on the right, because of the much higher Cl^- ion concentration outside cells, the AE catalyzes HCO_3^- exit and Cl^- ion entry into cells in an electroneutral fashion. The combination of flux through the AE and the Cl^- ion channel tends to decrease the negative ICF voltage and cause intracellular acidification and ECF alkalinization. This transporter required activation but the mechanism is not clear. The net effect is to shift K^+ ions into cells.

in plasma pH of 0.3 units if the arterial PCO_2 remains unchanged (which is likely to be the case as hyperventilation is probably already maximal). In contrast, a fall in the P_{HCO3} of 2 mM from 25 mM to 23 mM will cause only a 10% rise in the plasma H^+ concentration.

Arterial PCO_2: A high value for the arterial PCO_2 can have profound effects on the ICF pH in a patient with metabolic acidosis. For CO_2 to diffuse out of cells, intracellular PCO_2 will have to be somewhat higher than in the capillaries. The arterial PCO_2 depends on the balance between CO_2 production and its removal from the body by ventilation (Figure 7). Thus the arterial PCO_2 will be higher in a patient who cannot increase ventilation appropriately. In this case, mechanical ventilation is the most effective means to lower the intracellular pH and thereby minimize the binding of H^+ to intracellular proteins. There are several ways to assess this ventilatory response to the presence of metabolic acidosis (Table 4). Use the approximately 1 : 1 ratio between the fall in P_{HCO3} from the normal value of 25 mM and the fall in arterial PCO_2 from 40 mmHg [28]. We emphasize that these are not meant to be exact values.

CO_2 production: As an isolated event, a rise in CO_2 production rate will increase the capillary PCO_2. Similarly, a low arterial PCO_2 may also reflect a lower rate of production of CO_2 in patients who have a fixed degree of ventilation [29].

Venous PCO_2: The impact of a higher venous PCO_2 on the degree of buffering of H^+ by intracellular proteins is illustrated in Figure 7. If the venous PCO_2 is high, the intracellular PCO_2 will be even higher, which shifts the equilibrium of Equation 3 to the left, raising the H^+ concentration in the ICF so that more H^+ will bind to proteins. Three factors could lead to an elevated venous PCO_2; first, a high PCO_2 of arterial blood; second, a higher rate of metabolic production of CO_2; third, the quantity and the concentration of CO_2 that each liter of blood must carry will rise if there is a reduced rate of blood flow to an organ. It follows that in the setting of metabolic acidosis associated with reduction in ECF volume (Table 3), a very important mea-

Table 3. Metabolic acidosis classified according to extracellular fluid volume status.

Metabolic acidosis with a reduced "effective" circulating volume
– type A L-lactic acidosis (*venous* volume may not be reduced)
– diabetic or alcoholic ketoacidosis
– gastrointestinal loss of $NaHCO_3$
– metabolic acidosis and excessive loss of Na^+ in the urine
  – e.g. overproduction of hippuric acid in glue-sniffers

Metabolic acidosis with a near-normal or expanded ECF volume
Increased anion gap
– ketoacidosis of fasting or due to hypoglycemia
– toxic alcohol ingestions (methanol, ethylene glycol)
– overproduction of D-lactic acid
– renal failure

Normal anion gap
– low NH_4^+ excretion (e.g. distal RTA)
– proximal RTA

Table 4. Expected responses to primary acid-base disorders.

Disorder	Response
Metabolic acidosis	For every mM fall in P_{HCO3} from 25 mM, the arterial PCO_2 should fall by 1 mmHg from 40 mmHg.
Metabolic alkalosis	For every mM rise in P_{HCO3} from 25 mM, the arterial PCO_2 should rise by 0.7 mmHg from 40 mmHg.
Respiratory acidosis	
Acute	For every mmHg rise in arterial PCO_2 from 40 mmHg, the plasma H^+ concentration should rise by 0.77 nM from 40 nM. Alternatively, for every 2-fold increase in arterial PCO_2, the P_{HCO3} should increase by 2.5 mM.
Chronic	For every mmHg rise in arterial PCO_2 from 40 mmHg, the plasma H^+ concentration should rise by 0.32 nM, or the P_{HCO3} should rise by 0.3 mM from 25 mM.
Respiratory alkalosis	
Acute	For every mmHg fall in the arterial PCO_2 from 40 mmHg, the plasma H^+ concentration should fall by 0.74 nM from 40 nM.
Chronic	For every mmHg fall in arterial PCO_2 from 40 mmHg, the plasma H^+ concentration should fall by 0.17 mM, or the P_{HCO3} should fall by 0.4 mM from 25 mM.

sure to correct the intracellular acidosis may in fact be the aggressive restoration of the effective circulating volume.

Hypokalemia: Hypokalemia may be present in some patients with metabolic acidosis (e.g., patients with distal renal tubular acidosis (RTA) or those with diarrhea or glue sniffing). As K^+ shift from the ICF into the ECF compartment, electroneutrality must be maintained. This could be achieved if the K^+ are lost from the ICF along with intracellular anions (phosphate), or if K^+ enter and extracellular cations (Na^+ and/or H^+) exit. To the extent that there is a net exit of K^+ and entry of H^+, the degree of intracellular acidosis will become more severe and now more H^+ should be titrated by intracellular proteins. Hypokalemia may also affect the intracellular H^+ concentration by causing respiratory muscle weakness; the hypoventilation could cause a rise in arterial and thereby the tissue PCO_2.

Excretion of NH_4^+

CONCEPT 3: Generation of new HCO_3^- without H^+ occurs when NH_4^+ is excreted.

To generate new HCO_3^-, glutamine, must be metabolized in the cells of the proximal convoluted tubule (PCT) to yield NH_4^+ and the -ketoglutarate (-KG) anion [15]. Metabolism of -KG to neutral end products (CO_2 or glucose) yields HCO_3^- that are added to the body. Nevertheless, for a net gain of HCO_3^-, NH_4^+ must be made into an end product of metabolism by being excreted in the urine (Figure 5). The rate of excretion of NH_4^+ can be influenced by 2 major factors, its rate of production in the PCT and its rate of transfer to the final urine.

Production of NH_4^+: Several factors influence the rate of production of NH_4^+. It is important to recognize that there is a 1- to 2-day lag period before acidosis augments renal ammoniagenesis. In response to chronic metabolic acidosis, the rate of excretion of NH_4^+ can increase to more than 200 mmol/day [30, 31]. Hypokalemia also stimulates ammoniagenesis as it causes intracellular acidosis [32]. The converse is true for hyperkalemia. There is an upper limit on the rate of NH_4^+ production in cells of the PCT set by the rate of regeneration of ATP in these cells [33]. ATP is utilized in PCT cells primarily to provide the energy for the reabsorption of filtered Na^+ [34]. Hence patients with a low GFR filter less Na^+ and they have a lower rate of reabsorption of Na^+ in the PCT. This lessens the need to regenerate as much ATP so the rate of production of NH_4^+ is lower in these patients. Rarer causes of a low rate of production of NH_4^+ are low levels of glutamine in plasma (malnutrition) [35] or if another fuel is oxidized by the cells of the PCT for regeneration of ATP (e.g., an excessive supply of ketoacids or fatty acids as in patients receiving total parenteral nutrition) [36]. Patients with isolated proximal RTA may have a lower rate of NH_4^+ production due to an alkalinized PCT cell pH, the underlying pathophysiology in this condition [37].

Transfer of NH_3 into the urine: NH_4^+ produced in cells of the PCT is secreted into its lumen, at least in part, by replacing H^+ on the Na^+/H^+ exchanger (NHE-3), making it a Na^+/NH_4^+ exchanger [38]. Reabsorption of NH_4^+ in the medullary thick ascending limb (mTAL) of the loop of Henle (LOH) occurs when NH_4^+ replaces K^+ on the Na^+, K^+, 2 Cl^-cotransporter [39]. This provides the "single effect" for the medullary recycling of NH_4^+ required for the establishment of a high concentration of NH_4^+ and NH_3 in the medullary interstitium (Figure 5). The function of this medullary interstitial NH_4^+/NH_3 system in our opinion is to prevent the excretion of urine with too low a pH [40]. An important factor that influences the transfer of

NH_4 from the medullary interstitial compartment to the urine is the secretion of H^+ in the distal nephron. This H^+ secretion provides the luminal substrate for an NH_4^+/H^+ ion exchanger [41]. This NH_4^+/H^+ exchanger results in the net addition of NH_3 into the lumen.

H^+ secretion in the distal nephron is mediated primarily by an H^+-ATPase, but it may also occur by an H^+/K^+-ATPase. Distal H^+ secretion by the H^+-ATPase is an electrogenic process that tends to create a lumen positive voltage [42]. Because the lumen of the MCD can only maintain a small positive voltage [43], for H^+ secretion to continue, either an anion (like Cl^-) must be secreted along with H^+ or a cation like Na^+ or K^+ must be reabsorbed.

H^+ secretion also occurs by an H^+/K^+-ATPase, but only if H^+ acceptors are available in the lumen of the distal nephron. These luminal H^+ acceptors are HCO_3^- and NH_3. Luminal HCO_3^- can be high if its reabsorption by upstream nephron segments was diminished or if HCO_3^- was secreted into the lumen of the MCD by a Cl^-/HCO_3^- anion exchanger [25]. In this latter circumstance, there is a net reabsorption of K^+ and Cl^-; hence this combination of ion exchangers may be important for K^+ homeostasis under conditions of K^+ depletion [44]. If both the H^+/K^+-ATPase and the Cl^-/HCO_3^- anion exchanger were active simultaneously, the urine PCO_2 should be very high. When NH_3 is available to accept H^+ secreted by the H^+/K^+-ATPase, its overall function could be to reabsorb K^+ and/or excrete NH_4^+.

Importance of the Urine pH to Avoid Kidney Stone Formation

All the water-soluble waste products and all the ions and water ingested in excess of needs must be excreted in the urine without forming precipitates. One of the most important renal physiological functions is to excrete urine with a composition that makes ions and organic materials sufficiently soluble to avoid kidney stone formation. Key to this aim is to have independent regulation of the urine pH – select a value that is close to 6.0 to achieve this aim [45] (Figure 10). Excreting urine at

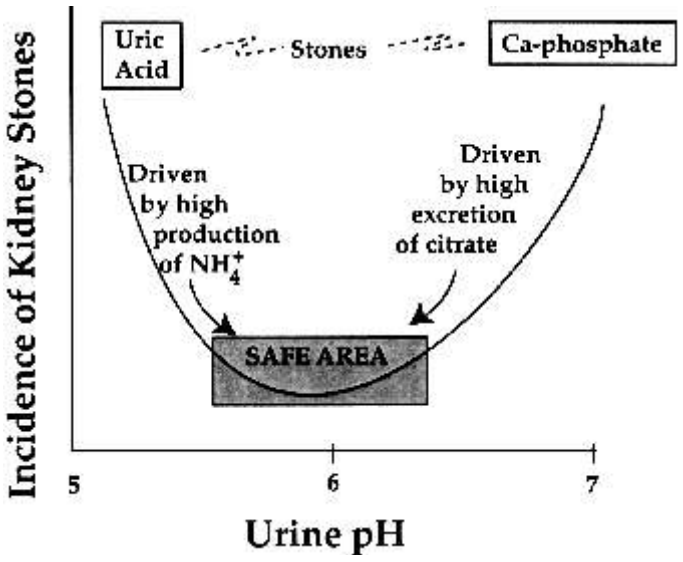

Figure 10. Urine pH and kidney stones. The safest urine pH to avoid kidney stones is close to 6. Below this value, uric acid stones are most likely to form. Ca-phosphate stones precipitate in alkaline urine. By driving NH_4^+ excretion with a high distal H^+ secretion, a considerable quantity of H^+ can be eliminated at a urine pH close to 6.0. By excreting organic anions rather than HCO_3^-, a considerable quantity of HCO_3^- can also be eliminated at a urine pH close to 6.0 (see Figure 2).

this pH must not sacrifice acid-base balance. This in turn means that with a large, chronic acid load, the excretion of NH_4^+ should be maximally high at a urine pH of close to 6 (see reference Kamel et al. 1998 [46] for more discussion). Similarly, when an alkali load is ingested, it must be excreted without obligating a large excretion of HCO_3^- and thereby a high urine pH [9, 11] – this latter topic will be discussed in more detail when $CaHPO_4$ stones are considered below.

Avoiding uric acid kidney stones: Uric acid is the waste product of purine metabolism [47]. The free acid form, uric acid, rather than total urates is the critical component for kidney stone formation because uric acid is sparingly soluble in water (Equation 4). Because the pK of uric acid in the urine at 37ºC is close to 5.3 [47], precipitation of uric acid can be avoided without increasing the urine volume by raising the urine pH to 6 at the same total urate excretion rate [48].

$$Urate^- + H^+ \quad \text{Uric acid (pK 5.3)} \qquad (4)$$

Avoiding $CaHPO_4$ kidney stones: All the ionized Ca^{2+} absorbed from the GI tract of an adult is excreted in the urine in steady state [49]. The chemistry of Ca^{2+} and HPO_4^{2-} in the urine is the same as in the body [50], but with one exception. A metabolic equivalent of HCO_3^- in acid-base terms, citrate [14], can chelate ionized Ca^{2+} in the urine, forming a soluble ion complex and thereby minimize the risk of $CaHPO_4$ kidney stone formation. This excretion of citrate rises with an alkali load [14], a time when urine $H_2PO_4^-$ is converted to HPO_4^{2-} – i.e., when the urine pH rises towards the pK of the phosphate buffer system (pH 6.8). In this context, the body disposes of the usual alkali load of the diet by forming an organic acid such as citric acid [9, 11]. The H^+ of citric acid titrate HCO_3^-. The citrate anions rather than an appreciable amount of HCO_3^- are excreted in the urine so that the urine pH remains close to 6.0 without sacrificing acid-base balance [48] (Figure 10). Excreting citrate rather than HCO_3^- when there is a dietary alkali load chelates Ca^{2+} in the urine, lessening the risk of Ca-containing kidney stones in alkaline urine [51].

Tests Used at the Bedside to Estimate NH_4^+ in the Urine

The first step to evaluate the renal response to chronic metabolic acidosis in a patient is to examine the rate of excretion of NH_4^+. Since most routine biochemical laboratories do not provide a direct assay for the concentration of NH_4^+ in the urine (U_{NH4}), clinicians usually employ the following indirect tests to *estimate* U_{NH4}. To convert the U_{NH4} to an excretion rate, one needs to know the urine flow rate or divide the U_{NH4} by the urine creatinine concentration. Normal adults excrete close to 20 mg of 200 mol of creatinine per kg body weight [52].

The urine net charge: The sum of the concentrations of urinary cations and anions must be equal. The major urine cations are Na^+, K^+, and NH_4^+, and the major urine anion is Cl^- (although there are also modest concentrations of SO_4^{2-}, phosphate, HCO_3^- and organic anions). The urine net charge provides a qualitative *estimate* of the U_{NH4} providing that the major anion excreted with NH_4^+ is Cl^- (Equation 5, Figure 11). Hence if the U_{NH4} is appropriately high, the U_{Cl} should be appreciably greater than the sum of the $U_{Na} + U_K$, and the urine net charge is said to be *negative*. On the other hand, with a low U_{NH4}, the U_{Cl} is less than the sum of the $U_{Na} + U_K$. In this case, the urine net charge is said to be *positive*, suggesting that a defect in NH_4^+ excretion is at least contributing to the pathogenesis of metabolic acidosis. Be careful. This will not be true if an

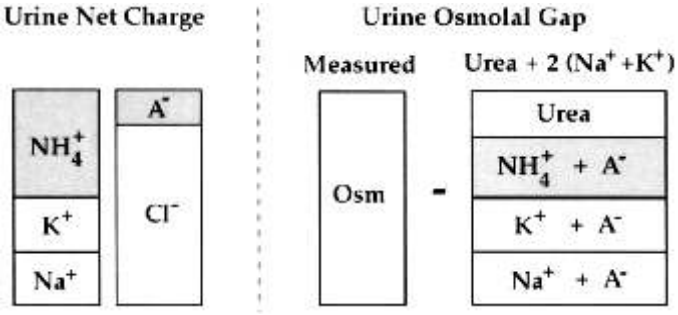

Figure 11. Use of the urine net charge and urine osmolal gap to reflect the concentration of NH_4^+ in the urine. The urine net charge is shown in the left portion of the figure and the urine osmolal gap is shown in the right portion of the figure. The components needed to calculate the U_{NH4} are depicted by the clear areas. Reproduced with permission [187].

anion other than Cl^- accompanied U_{NH4}. Some examples of these non-Cl^- urine anions are hippurate, -HB, salicylate, organic anions, and anions of drugs such as penicillin-type antibiotics given in high dosage. In such cases, one must use the urine osmolal gap to estimate U_{NH4}.

$$\text{Urine net charge} = U_{Na} + U_K - U_{Cl} \quad (5)$$

The urine osmolal gap: The urine osmolal gap is the best indirect test to estimate the U_{NH4}. The rationale for the urine osmolal gap is also depicted in Figure 11. The major osmoles in the urine are urea and electrolytes; occasionally, glucose may be present in the urine in high concentrations. The contribution of electrolytes is approximately equal to twice the sum of the concentrations of the major cations, Na^+, K^+ (since each cation is accompanied by an anion). Therefore, the total urine osmolality (U_{osm}) can be approximated as shown in Equation 6 in which the concentration of all the substances in the urine is given in mM terms as described earlier. A significant difference between the measured and calculated U_{osm} indicates the presence of an NH_4^+ salt in the urine. The U_{NH4} is half the urine osmolal gap. The rate of excretion of NH_4^+ is then obtained by multiplying this approximate concentration by the urine flow rate or estimated from the urine creatinine concentration and its excretion rate [52]. If this is substantially less than 3 mmol NH_4^+/kg/day, then the kidneys are at least a contributing factor to the degree of metabolic acidosis because there is a lower than expected rate of excretion of NH_4^+.

$$\text{Calculated } U_{osm} = U_{Urea} + U_{Glu} + 2\,U_{Na} + 2\,U_K$$
$$U_{NH4} = 0.5 \times$$
$$(\text{measured } U_{osm} - \text{calculated } U_{osm}) \quad (6)$$

Tests to Detect the Basis for the Low Rate of Excretion of NH_4^+

Use of the urine pH: In patients with chronic metabolic acidosis, a low rate of excretion of NH_4^+ could be due to decreased availability of NH_3 in the medullary interstitium or decreased H^+ secretion in the distal nephron (Figure 12). The basis for low NH_4^+ excretion can be deduced from the urine pH (Figure 13). A low value for the urine pH (< 5.3) suggests a defect in NH_4^+/NH_3 availability in the renal medullary interstitium whereas a high urine pH (> 7) suggests that the limiting step is H^+ secretion in the distal nephron (Equation 7) [53 – 57].

$$H^+ + NH_3 \quad NH_4^+ \quad (7)$$

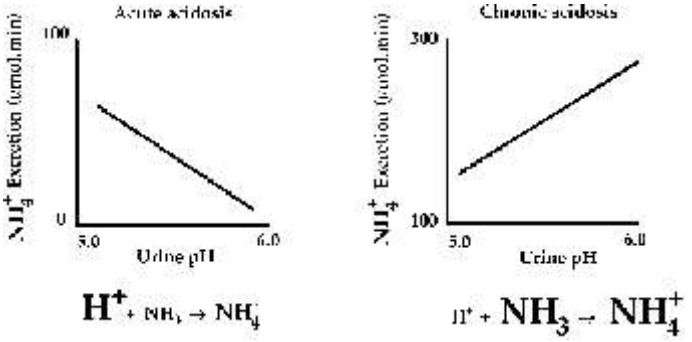

Figure 12. Use of the urine pH to detect U_{NH4}. As shown on the left, during acute metabolic acidosis, the rate of excretion of NH_4^+ is only modestly higher while the urine pH is low. This is because there is enhanced distal H^+ secretion, but a time lag before the rate of renal production of NH_4^+ is augmented. In contrast, during chronic metabolic acidosis shown on the right, the rate of renal production of NH_4^+ is so high that the availability of NH_3 in the medullary interstitial compartment provides more NH_3 in the lumen of the MCD than H^+ secretion in this nephron segment. Therefore note the much higher NH_4^+ excretion rate at a urine pH of 6. Reproduced with permission [187].

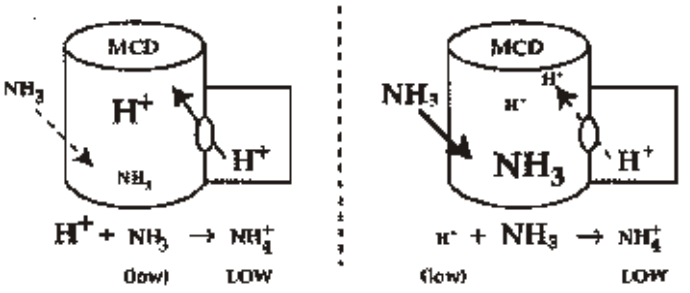

Figure 13. The urine pH reveals the basis for the low U_{NH4}. A decreased availability of NH_4^+/NH_3 in the medullary interstitial compartment is the defect shown on the left side of the figure by the dashed arrow. Its main features are a low excretion of NH_4^+ and a high urine H^+ concentration (low urine pH). A defect in distal H^+ secretion is shown by the dashed arrow in the right side of the figure. Its main features are a low excretion of NH_4^+ and a low urine H^+ concentration (high urine pH). Reproduced with permission [187].

Test for the Capacity to Synthesize NH_4^+ in the PCT

Once one knows that the rate of excretion of NH_4^+ is low in a patient who has a low urine pH, one can assess the rate of production of NH_4^+ in vivo by measuring the rate of excretion of NH_4^+ following the administration of a loop diuretic [58]. At peak diuresis, the rate of NH_4^+ excretion in a normal adult is close to 60 mol/min and this reflects the capacity for renal ammoniagenesis. A lower peak rate of NH_4^+ excretion would imply a low rate of production of NH_4^+ in PCT cells [37, 59].

Tests to Evaluate H^+ Secretion

A low rate of excretion of NH_4^+ in a patient with metabolic acidosis could be due to a defect in H^+ secretion in the PCT and/or the distal nephron.

Tests to Evaluate the Secretion of H^+ in the PCT

Some patients have metabolic acidosis associated with a lower than normal capacity to reabsorb filtered HCO_3^- [60]. Usually the site of the defect in renal H^+ secretion is in the PCT, but at times, it may also involve the distal nephron. Notwithstanding, these patients also have a reduced rate of excretion of NH_4^+ and this is a very important cause of their metabolic acidosis. To detect a defect in H^+ secretion in the PCT, one generally measures the rate of excretion of HCO_3^- and/or its reabsorption after an infusion of $NaHCO_3$. Another test that helps in this assessment is the rate of excretion of citrate at a given pH of plasma.

Fractional excretion of HCO_3^- (FE_{HCO3}): The bulk of filtered HCO_3^- is reclaimed (reabsorbed indirectly) in the PCT [61], but an appreciable portion (close to 15%) is normally reclaimed by H^+ secretion downstream in the nephron. To perform this test, enough $NaHCO_3$ is infused to raise the P_{HCO3} to 25 mM. At this point, if the FE_{HCO3} exceeds 15%, there is a defect in H^+ secretion [61, 62]. A high FE_{HCO3} could be expected if there is a very large defect in H^+ secretion in the PCT or a smaller defect in PCT H^+ secretion plus a reduced distal capacity for H^+ secretion.

Citrate excretion: The rate of excretion of citrate seems to reflect the pH in PCT cells with a higher rate of citrate excretion if these cells have a more alkaline pH in PCT cells. The rate of excretion of citrate is very low during all forms of metabolic acidosis except in patients with the isolated form of proximal RTA where there is an appreciable degree of citraturia despite metabolic acidosis [63]. This led to the speculation that an alkaline PCT cell is the underlying lesion causing low HCO_3^- reabsorption, low NH_4^+ production, and citraturia in these patients [37]. The rate of excretion of citrate in children and adults consuming their usual diet is close to 400 mg/g creatinine [14, 64]. To ensure that citraturia reflects an alkaline PCT cell rather than a component of a more generalized PCT dysfunction (Fanconi syndrome), citraturia should disappear following a small additional acid load [65].

Tests to Evaluate the Secretion of H^+ in the Distal Tubule

If the PCO_2 in alkaline urine is 70 mmHg or higher, a major defect in distal H^+ secretion is unlikely [66] (Figure 14). Nevertheless, there

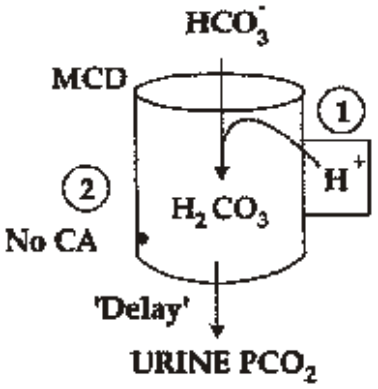

Figure 14. The urine PCO_2. When $NaHCO_3$ is given, there is a large delivery of HCO_3^- to the distal nephron so this HCO_3^- is virtually the only H^+ acceptor in its lumen. Because there is no luminal carbonic anhydrase (CA), the H_2CO_3 formed will be delivered downstream and form CO_2 plus water. Thus if the U_{PCO2} is appreciably higher than the plasma PCO_2, this provides evidence for distal H^+ secretion. Reproduced with permission [187].

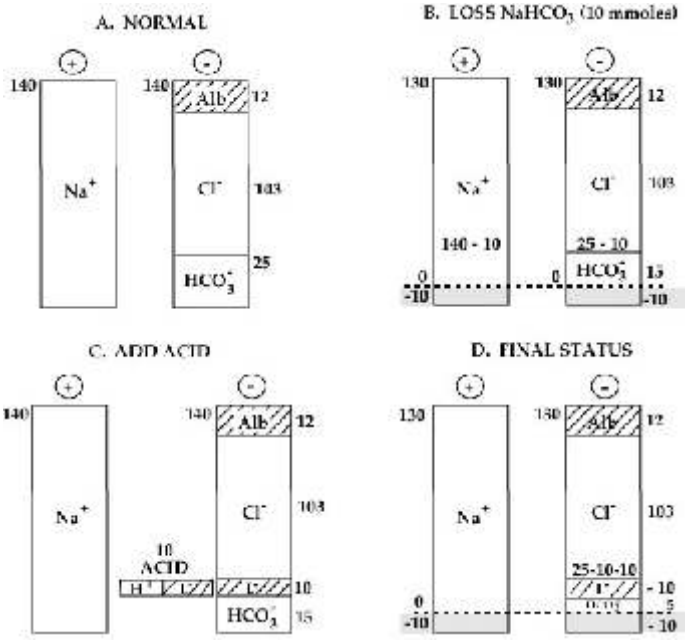

Figure 15. Mixed acid-base disturbance: Recognizing 2 types of metabolic acidosis. The sum of the valences on cations and anions in plasma are always equal. In this example, the missing anions (due largely to the anionic charge on albumin shown by the hatched symbol) are constant at 12 mEq/l; this value is 16 mEq/l if K^+ is included in the sum of cations in plasma. When Na^+ and HCO_3^- are lost (shaded area in panels B and D), there is no change in the plasma anion gap. When L-lactic acid is added, there is a fall in the concentration of HCO_3^- together with an equal rise in the plasma anion gap (panel C). The combination of both types of metabolic acidosis is shown in panel D.

are other factors such as a poor renal concentrating ability (low medullary interstitial PCO_2) that may cause the urine PCO_2 to be lower despite an intact distal H^+ secretion [67].

Detecting Mixed Acid-base Disorders

More than one acid-base disturbance can be present at one time. We shall illustrate how to identify the simultaneous presence of several acid-base disturbances from the history, physical examination, and laboratory results (Figure 15).

Clinical example: A 24-year-old person had severe diarrhea that resulted in a deficit of $NaHCO_3$ (Figure 15B). Because of the continuing loss of Na^+, his ECF volume became markedly contracted. As a result of the very low circulating volume, there was not enough oxygen delivery to tissues to meet their demand so anaerobic production of ATP was stimulated. This results in a net production of L-lactic acid. This accumulation of 10 mmol of L-lactate anion per liter of plasma should raise the plasma anion gap by 10 mEq/l (Table 4, Figure 15C). Simultaneously, the 10 mmol of H^+ added per liter will lower the P_{HCO3} by 10 mmol/l (Equation 8).

$$10\,\text{L-lactate}^- + 10\,H^+ + 15\,HCO_3^- \quad 10\,CO_2 + 10\,H_2O + 10\,\text{L-lactate}^- + 5\,HCO_3^- \qquad (8)$$

Continuing with this scenario, the release of aldosterone (due to a contracted ECF volume) stimulates the excretion of K^+ [68]. As a result, a deficit of K^+ occurs and this could lead to muscular weakness. If the respiratory muscles are involved, there may be an inability to lower the arterial PCO_2 to the expected degree. In summary, by working backwards beginning at the far right of Table 5, each of the 3 acid-base disorders can be identified.

– Respiratory acidosis: The PCO_2 in blood should be as low as possible (less than 20

Table 5. Identification of a mixed acid-base disorder. For details, see text. The value for albumin in plasma is 4 g/dl (40 g/l), a normal level which does not change throughout the course of illness in this patient. Hypoventilation in this case is due to a deficit of K^+. H●L = L-lactic acid.

Plasma		Normal	Loss $NaHCO_3$ (10 mM)	Gain H●L (10 mM)	Effect of hypoventilation
pH		7.40	7.30	7.13	6.83
HCO_3^-	mM	25	15	5	5
Anion gap	mEq/l	12	12	22	22
PCO_2	mmHg	40	30	15	30

mmHg) with such a low value for the P_{HCO3} (5 mM). Hence the arterial PCO_2 is too high for this clinical setting.

– Metabolic acidosis due to a gain of acid: The elevated value for the anion gap of 10 mEq/l with a normal concentration of albumin in plasma suggests that 10 of the 20 mM fall in P_{HCO3} was due to the added L-lactic acid.

– Metabolic acidosis due to loss of $NaHCO_3$: The fact that the fall in the P_{HCO3} is much greater than the rise in the plasma anion gap suggests a deficit of $NaHCO_3$. This deficit of $NaHCO_3$ is even larger than what is apparent from this calculation because of the significant ECF volume contraction (HCO_3^- concentration vs HCO_3^- content, Table 10).

Clinical Disorders

Metabolic Acidosis

Definition: In metabolic acidosis, there is a fall in the plasma pH and P_{HCO3}. Because other primary acid-base abnormalities may coexist, the plasma pH and/or P_{HCO3} may not be low. For example, if respiratory alkalosis is also present, the pH will be higher; if metabolic alkalosis is also present, the P_{HCO3} and plasma pH may not be low. Therefore clues from the history and physical examination together with additional laboratory data (plasma anion gap) must be integrated to know whether metabolic acidosis is present.

Clinical Classification

We divide the causes of metabolic acidosis into two subgroups, those with overproduction of acids and/or those in which there is a loss of $NaHCO_3$ (Table 6).

Overproduction of acids: When an acid (HA) is added to the body, the vast majority of H^+ are buffered by the bicarbonate buffer system (BBS) [4] and this leads to the loss of HCO_3^- together with a gain of new anions (A^-) (Figure 4). Quantitatively, for every mEq of HCO_3^- lost, there will be an equivalent net gain of A^-. Factors such as the volume of distribution of anions versus H^+, a change in the ECF volume, and the renal handling of these anions will affect the 1 : 1 ratio between the fall in the P_{HCO3} and the rise in plasma anion gap (Table 7). With a decrease in the ECF volume, the concentration of both new anions

Table 6. Mechanisms responsible for the development of metabolic acidosis.

A) Acid gain
- **(i) With retention of anions in plasma:**
  - L-lactic acidosis (hypoxia, problems with pyruvate metabolism)
  - Ketoacidosis (relative insulin lack and low GFR or CNS function)
  - Toxic alcohol ingestion (e.g., methanol, ethylene glycol)
  - D-lactic acidosis (and other organic acids produced by gastrointestinal bacteria)
  - Ingested acids
  - Pyroglutamic acidosis
- **(ii) With a high rate of excretion of anions in urine:**
  - Glue-sniffing (hippuric acid overproduction)
  - Diabetic ketoacidosis with excessive ketonuria

B) $NaHCO_3$ loss
- **(i) Direct**
  - Loss via the GI tract (e.g., diarrhea, ileus, fistula)
  - Loss in the urine (proximal RTA or low carbonic anhydrase II or IV activity)*
- **(ii) Low urinary excretion of NH_4^+ (look at urine pH to categorize further)**
  - **(a) Low urine NH_3 (urine pH ~ 5) = Problem with PCT ammoniagenesis:**
    Decreased GFR, hyperkalemia, alkaline pH in PCT cells, decreased glutamine availability, fuel competition (e.g., TPN)
  - **(b) Defect in net distal H^+ secretion (urine pH often ~ 7):**
    H^+ ATPase defect or alkaline -intercalated cells (e.g., carbonic anhydrase II deficiency)
    H^+ back-leak (e.g., amphotericin B)
    HCO_3^- secretion in the collecting ducts (anion exchanger trafficking disorder)
  - **(c) Problem with both distal H^+ secretion and NH_3 availability (urine pH ~ 6):**
    Diseases involving the renal interstitial compartment

*These patients also have a low rate of excretion of NH_4^+.

Table 7. Content vs concentration of $HC0_3^-$ in the ECF compartment. An 8-year-old 20 kg female presented with an extremely high P_{Glu} (2,000 mg/dl, 110 mM), a venous plasma pH of 7.19, a P_{HCO3} of 25 mM, and a severely contracted ECF volume (2 vs her normal 4 l) [69]. Metabolic acidosis is present because of the reduced content of HCO_3^- in her ECF compartment (H^+ + -HB^- + HCO_3^- anion gap + CO_2 + H_2O). Reproduced with permission [187].

	ECF (l)	P_{HCO3} (mM)	ECF HCO_3^- content (mmol)	Plasma anion gap (mEq/l)
Normal state	4	25	100	12
Hyperglycemia	2	25	50	24

and HCO_3^- will rise. Thus there will be a larger increase in the unmeasured anion gap and a smaller fall in the P_{HCO3} [69], disturbing the expected 1 : 1 ratio in these parameters.

In most cases where metabolic acidosis is associated with an increased value for the anion gap in plasma, there is an overproduction of acids where many of the anions produced

along with H^+ are retained in the ECF. The major exception to this rule is renal failure because in this setting, metabolic acidosis is present with an increase in the plasma anion gap, but there is no excess production of acids. On the other hand, metabolic acidosis caused by an excessive production of acids need not be accompanied by a significant rise in the anion gap in plasma if the accompanying anion is rapidly excreted in the urine (e.g., hippurate anion in glue sniffing [21]).

There are many different causes for the development of metabolic acidosis, each having a specific implication for therapy. In most cases, the rise in the concentration of H^+ per se is not the major threat to survival; those causes associated with acute potentially life-threatening consequences are listed in Table 8. Many of the causes of metabolic acidosis and an increased plasma anion gap are associated with a reduced "effective" ECF volume (diabetic ketoacidosis (DKA), alcoholic ketoacidosis, and most cases of type A L-lactic acidosis, Table 3). Should one find a relatively normal ECF volume, the basis for the metabolic acidosis is usually renal failure, toxic alcohol ingestion (methanol or ethylene glycol), or possibly excessive production of acids such as D-lactic acid by bacteria in the gastrointestinal (GI) tract.

Loss of $NaHCO_3$

In this type of metabolic acidosis, almost no new anions are present in plasma. There are 2 major groups for this type of metabolic acidosis, one is the direct loss of $NaHCO_3$ and the other is an indirect loss of $NaHCO_3$ due to a low rate of excretion of NH_4^+ (Figure 4).

Loss of $NaHCO_3$ via the GI tract: The most common site for the loss of $NaHCO_3$ is via the GI tract. While $NaHCO_3$ may be lost in diarrhea fluid, for an appreciable degree of chronic metabolic acidosis to be sustained, there is usually a simultaneous defect in NH_4^+ excretion by the kidney. In more detail, in a 70 kg adult with chronic metabolic acidosis and normal kidneys, the rate of excretion of NH_4^+ would be close to 200 mmol per day. If 1 liter of diarrhea solution contains 50 mmol of HCO_3^-, this GI loss would have to be about 4 liters per day to cause a continuing fall in the P_{HCO3}. The deficit of Na^+ would be enormous and life-threatening without a large input of NaCl. Hence it follows that chronic acidosis in this setting implies either a very large or an acute GI losses, a renal problem with NH_4^+ excretion (e.g., due to low GFR), and/or overproduction of organic acids via the GI tract (Equation 9) [70, 71].

$$Na^+ + HCO_3^- + H^+ + \text{D-lactate}^- \quad Na^+ + \text{D-lactate}^- + CO_2 + H_2O \qquad (9)$$

Indirect loss of $NaHCO_3$: A low rate of excretion of NH_4^+ is the key finding in patients with distal RTA [56]; it is also a prominent feature in certain patients with proximal RTA [37]. In a patient with metabolic acidosis, with no increase in the plasma anion gap, and a low rate of excretion of NH_4^+ (Figure 15, left-hand side), the basis for low NH_4^+ excretion can be deduced from the urine pH. If the urine pH is greater than 7, one should suspect a defect in H^+ secretion. The PCO_2 in alkaline urine can be used to assess distal H^+ secretion (Figure 14) [66] and the FE_{HCO3} can be used to assess proximal H^+ secretion. A high rate of excretion of citrate in a patient with metabolic acidosis suggests that an alkaline PCT cell could be the cause of diminished PCT H^+ secretion [37]. In contrast, if a patient had similar findings to the above, but had a low value for the urine pH (e.g., < 5.3), this would suggest that there is a defect in NH_3 availability in the renal medullary interstitial compartment

Table 8. Threats to life in association with metabolic acidosis.

Setting of acidosis	Threat to life	Clinical clues
L-lactic acidosis due to low cardiac output (shock)	"Energy crisis", H^+ load	Low plasma pH, high plasma anion gap, high $P_{Lactate}$
Renal failure	Hyperkalemia	Low GFR, high plasma anion gap
Distal RTA, diarrhea, treatment of DKA	Hypokalemia	Normal plasma anion gap, arrhythmias, muscle weakness
Methanol or ethylene glycol intake	Toxic products	History, high plasma anion gap, high plasma osmolal gap
DKA or, alcoholic ketoacidosis	Low ECF volume, rarely acidosis per se	Type 1 diabetes mellitus, ethanol, P_{Glu}, ketoacid screen

(Figure 13). The usual causes for the low NH_4^+/NH_3 are a low GFR and/or hyperkalemia. In their absence, we would look for low levels of glutamine in blood and/or a high level of fat-derived fuels (e.g., patients on total parental nutrition) because these fuels compete with glutamine as the source for regeneration of ATP in the cells of the PCT. If none of these is present, we would suspect an alkaline proximal cell pH. This entity of an alkaline proximal ICF pH remains speculative because there are no hard data in humans and suitable experimental models in animals are lacking.

Loss of "Potential" HCO_3^-

In some patients, there is excessive loss of the conjugate base of the acid in the urine (or in stool). While overproduction of acids is the major basis for the acidosis in these patients, yet the loss of these anions in the urine represents the loss of potential HCO_3^- as their metabolism could have resulted in the removal of H^+ (Figure 4, [72]).

Likelihood of a Major Threat to Life

Disorders that cause metabolic acidosis can harm patients through a variety of mechanisms (Table 8). We shall consider 4 major categories:

Very Fast Rate of Production of H^+

In essence, the only condition associated with extremely rapid net production of acid is L-lactic acidosis due to hypoxia (Table 2). The threat here is that ATP may not be regenerated quickly enough. Quantitatively, the rate of acid addition can be approximated by

Table 9. Causes of metabolic acidosis associated with hyperkalemia. Specific disorders causing hyperkalemia in patients with metabolic acidosis are described. In addition, if tissue necrosis has occurred in a patient with metabolic acidosis, hyperkalemia may also be present.

Cause	Pathophysiology	Total K^+ content
Renal failure	Low renal excretion of K^+ (and NH_4^+)	High
Low aldosterone bioactivity	Low renal excretion of K^+ (and NH_4^+)	High
DKA	Insulin deficiency leads to shift of K^+ out of the ICF	Low

noting the rate of increase in the plasma anion gap and the rate of excretion of anions in the urine.

H^+ Binding to Intracellular Proteins

The important factors here are not only the magnitude of H^+ load, but also the tissue PCO_2 as this determines the distribution of buffering of H^+ load between the BBS and intracellular proteins. A high venous PCO_2 implies that the tissue PCO_2 is also high and that more H^+ are buffered by intracellular proteins. Hence it follows that in the setting of metabolic acidosis associated with a low cardiac output, a very important measure to correct the intracellular acidosis is aggressive restoration of the cardiac output (Figure 7). In addition, if the arterial PCO_2 is not low enough, mechanical ventilation is essential.

Coexisting Problems of K^+ Balance

Many of the risks associated with metabolic acidosis may come about through associated disturbances of K^+ balance. Both hyperkalemia and hypokalemia may occur (Table 9). We shall be succinct here because issues concerning K^+ are discussed in the accompanying Chapter on K^+.

Hyperkalemia may be involved in the etiology of metabolic acidosis, because hyperkalemia impairs NH_4^+ excretion [32]. In contrast, if metabolic acidosis is seen in the setting of renal failure, a low excretion of K^+ and hyperkalemia may be present. Hyperkalemia is commonly seen in the setting of DKA despite the total body K^+ deficit, because K^+ tend to shift out of cells during insulin deficiency [73]. Finally, tissue necrosis or ischemia can lead to both L-lactic acidosis and release of K^+ from cells. Regardless of the pathophysiology, hyperkalemia can be life-threatening due to cardiac arrhythmias, and must be aggressively treated. Fortunately, one of the measures employed in the therapy of DKA, insulin, enhances K^+ entry into cells, and therefore reduces the degree of hyperkalemia.

Hypokalemia may occur either in association with the chronic metabolic acidosis of distal RTA, diarrhea, or metabolic acidosis caused by toluene (e.g., glue sniffing). Hypokalemia may also occur as a complication of insulin therapy in patients with DKA. Because insulin causes K^+ to enter cells (Figure 9), it may unmask the total body K^+ deficit and lead to the life-threatening complications

Table 10. Factors to consider in the use of $NaHCO_3$.

A. Factors favoring the use of $NaHCO_3$
- Hyperkalemia.
- P_{HCO3} less than 5 mM.
- Absence of an anion that can be metabolized into HCO_3^- (longer term consideration).
- Low likelihood that kidneys will be able to excrete NH_4^+ at a high rate (longer term issue).
- Independent benefit likely to arise (e.g., in salicylate overdose to limit entry of salicylate into brain cells and to favor its urinary excretion).
- High net rate of H^+ production (e.g., inability to rapidly reverse hypoxic L-lactic acidosis).

B. Factors that suggest a danger for the use of $NaHCO_3$
- Hypokalemia.
- Coincident use of insulin in a patient with a large K^+ deficit.
- Elevated ECF volume.
- Hypernatremia (minor).

of acute hypokalemia, particularly cardiac arrhythmias.

Specific problems related to the cause of the acidosis: In fact, in some of the causes of metabolic acidosis, the acidosis serves as a marker or a "symptom" of a serious underlying disease (e.g., methanol or ethylene glycol toxicity, Table 8). Clearly, these underlying processes must be addressed with specific therapy to avoid the adverse consequences that are independent of the acidosis.

Management

The management of a patient with metabolic acidosis requires a consideration of both general measures that are applicable to most patients as well as attention to specific issues relative to the cause of the disorder. We shall focus initially on the use of alkali because the use of mechanical ventilation was considered earlier, and treatments to deal with hyperkalemia or hypokalemia will be considered in the Chapter on K^+.

One cannot draw a definitive conclusion as to whether $NaHCO_3$ should or should not be used to treat a patient with metabolic acidosis because there are no firm data upon which to base this conclusion. Suggestions for and against the use of $NaHCO_3$ are summarized in Table 10.

Arguments Favoring the Use of $NaHCO_3$

It seems intuitively obvious that at some point, too many H^+ may become bound to proteins and compromise cellular functions. For example, myocardial contractility in vitro [74] and binding of adrenaline to its receptors are decreased when the fall in pH is large [75]; these effects may be reversed by lowering the concentration of H^+. Notwithstanding, the administration of $NaHCO_3$ does not seem to enhance the contractility of the ischemic myocardium in vivo [76].

There are data in experimental animals that might help. The administration of a large dose of $NaHCO_3$ appeared to be beneficial in the setting of hypoxic L-lactic acidosis in rats induced by ventilation with a hypoxic gas mixture. The survival period in these rats was extended even though $NaHCO_3$ led to an enhanced rate of production of L-lactic acid [77]. If these data apply to humans with hypoxia-induced L-lactic acidosis, the admin-

istration of $NaHCO_3$ might be viewed as a temporary measure that "buys time" to allow for more direct interventions to deal with the underlying cause(s) for the metabolic acidosis to be employed. Nevertheless, one must not administer too much $NaHCO_3$ because it may lead to the development of pulmonary edema unless very high rates of Na^+ removal could be achieved.

In a patient who has metabolic acidosis due to a low rate of excretion of NH_4^+, metabolic acidosis will persist unless $NaHCO_3$ is given. In this case, one must give enough $NaHCO_3$ to titrate H^+ that have accumulated, then maintain that person on enough alkali to match the net positive H^+ balance (usually 20 – 40 mmol/day in an adult).

Arguments Against the Use of $NaHCO_3$

Increased production of CO_2

When $NaHCO_3$ is administered, HCO_3^- reacts with H^+ and CO_2 is produced. Some have argued that this represents an important deleterious effect of HCO_3^- therapy because this CO_2 can enter cells and cause a paradoxical acidification of the ICF. This is a circular argument because if the source of the H^+ that titrate the administered HCO_3^- is H^+ bound to intracellular proteins (Figure 7), the ICF should have been alkalinized and not acidified. In contrast, if the source of these H^+ was due to the production of ATP in the process of anaerobic glycolysis, stimulation of L-lactic acid production by alkali could also be beneficial because it was accompanied by the conversion of ADP to ATP [77]. A possible acute danger in this latter case could occur if some of the CO_2 produced was retained because pulmonary function was not adequate or mechanical ventilation was not appropriately adjusted.

Concern about the possible adverse effects of enhanced production of CO_2 following therapy with $NaHCO_3$ in the acidotic patient prompted the development of carb-bicarb ($Na_2CO_3 \bullet 2(NaHCO_3)$). The titration of 4 mmol of H^+ by $NaHCO_3$ leads to the production of 4 mmol of CO_2, whereas similar buffering with carb-bicarb leads to the production of 3 mmol of CO_2. Since metabolic production of CO_2 is normally close to 10 mmol/min, and the rate of alkali administration might be close to 4 mmol/min during very aggressive alkali therapy, the difference in CO_2 production rate in fact will only be from 14 to 13 mmol/min with $NaHCO_2$ versus carb-bicarb, a trivial difference. There has been only limited clinical experience with this agent in patients with a severe degree of metabolic acidosis, the only setting in which it is rational to test it.

Failure to Detect Back-titration of Non-bicarbonate Buffers

Another argument against the use of $NaHCO_3$ or carb-bicarb to treat patients with a severe degree of metabolic acidosis comes from experiments in rats. The administered alkali to rats pretreated with HCl failed to yield an acute and significant back-titration of non-bicarbonate buffers [78]. This, however, could have been because of a rise in tissue PCO_2.

Fall in Concentration of Ionized Ca^{2+}

This occurs because addition of HCO_3^- leads to very rapid production of carbonate and precipitation of $CaCO_3$. It has been suggested that a fall in concentration of ionized Ca^{2+} in the interstitial fluid compartment might depress myocardial contractility [79]. Never-

theless, this might be more apparent than real if the HCO_3^- administered does not raise the P_{HCO3} markedly. If this were to be a problem, it should have been very obvious in situations where carb-bicarb was used because with carb-bicarb, carbonate is added directly.

Hypokalemia

Hypokalemia could be a problem when $NaHCO_3$ is given, especially if there is total body K^+ depletion as seen in patients with DKA [80 – 82], glue sniffers [21], or certain patients with distal RTA. The presence of a low P_K should prompt one to avoid the use of $NaHCO_3$, at least until the P_K has returned toward the normal range, or only to use it along with an appropriate amount of K^+ to avoid a cardiac arrhythmia (see accompanying Chapter on K^+).

ECF Volume Overload and Hypernatremia

This is only a problem in patients with metabolic acidosis who have an expanded ECF volume (patients with renal failure), in patients with a compromised circulation (cardiogenic shock), or those where enormous amounts of alkali might be used (e.g., hypoxic lactic acidosis). Hypernatremia may be produced and/or exacerbated if hypertonic $NaHCO_3$ is given.

Enhanced Production of L-lactic Acid

When $NaHCO_3$ is given to patients with L-lactic acidosis, the rate of production of L-lactic acid increases. This however may be considered beneficial if it reflects an increased rate of regeneration of ATP in vital organs [77], and if the H^+ so-produced are titrated by the BBS and not by intracellular proteins.

Rebound Metabolic Alkalosis

In metabolic acidosis due to overproduction of H^+ and anions (L- or D-lactate, or -hydroxybutyrate and acetoacetate), the acidosis will be improved when these anions are metabolized to HCO_3^-. If all the anions are converted to HCO_3^- and the patient also received $NaHCO_3$, the final plasma P_{HCO3} could be higher than normal if renal excretion of HCO_3^- did not occur [83]. The main clinical significance of rebound metabolic alkalosis is primarily when patients are being weaned from a mechanical ventilator, and the impact of HCO_3^- on the renal excretion of K^+, which can further exacerbate hypokalemia [84].

Recommendations

One must individualize the decision for each patient, balancing potential benefits versus adverse effects. None of these factors is an absolute indication or contraindication, but by examining each of them, it should be possible to make a reasonable decision. If the decision is made to administer $NaHCO_3$, an equally difficult issue is how much to give and how fast it should be given. It is important to recognize that as the baseline P_{HCO3} falls, a progressively greater amount of added H^+ are buffered on intracellular proteins. Therefore, when $NaHCO_3$ is given, the hope is that much of it will titrate these intracellular H^+, and will effectively disappear as CO_2 and water, and therefore the increment in the P_{HCO3} will be small. Moreover, CO_2 removal by the lungs

Table 11. Ketoacid turnover during chronic fasting. Values are presented as mmol/day.

Ketoacid metabolism	Organ	Turnover
Net production	Liver	1500
Oxidation	Brain	750
	Kidney	250
	Muscle, etc.	200
Conversion to acetone	?	150
Excretion	Kidney	150

Table 12. Causes of ketoacidosis.

1. Diabetic ketoacidosis
– usually Type 1 or IDDM; rarely Type 2 or NIDDM
– damage to -cells of the pancreas
– pancreatic destruction as in hemochromatosis

2. Alcoholic ketoacidosis
– low insulin due to low ECF volume (-adrenergic effect)
– metabolism of ethanol to ketoacids
– lower oxidation of ketoacids in brain (sedative effect of ethanol), and kidneys (low GFR)

3. Low stimulus to pancreatic -cells because of hypoglycemia
– starvation
– low production of glucose in the liver (e.g. glycogen storage disease or inhibition of gluconeogenesis)

4. High production of acetic and butyric acid by GI bacteria together with inhibition of hepatic acetyl-CoA carboxylase.

must keep up with the increment in CO_2 production.

A decision needs to be made on the initial target P_{HCO3} when a patient has an extremely low baseline P_{HCO3}. A reasonable target is either to double the P_{HCO3} or to aim for an absolute value of 5 – 6 mM. If the P_{HCO3} rises from 2 to 4 mM and the PCO_2 remains unchanged, the pH will rise by 0.3 units. Nevertheless, one cannot make an accurate assessment of the amount of $NaHCO_3$ to give because the volume of distribution HCO_3^- is unknown.

Specific Causes for Metabolic Acidosis

The list of causes of metabolic acidosis is provided in Table 6.

Ketoacidosis

Ketoacids are a fat-derived fuel destined for oxidation in the brain. The main signal for their formation is a relative lack of insulin (Figure 3). There are 3 major causes of ketoacidosis (Table 12). In biochemical terms,

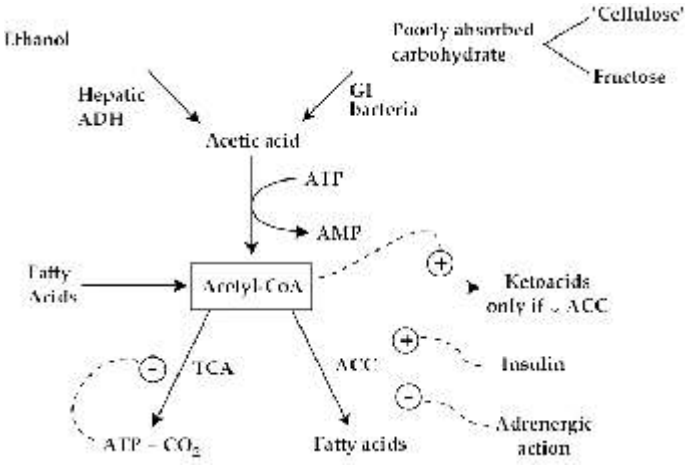

Figure 16. Metabolism of acetyl-CoA in the liver. There are two major sources of acetic acid and thereby hepatic acetyl-CoA, ethanol and acetic acid produced during the bacterial fermentation of poorly absorbed carbohydrates. Production of acetyl-CoA from these precursors bypasses the usual regulatory steps that involve fatty acid oxidation. Hence a high supply of these precursors and inhibition of acetyl-CoA carboxylase (ACC) by hormones such as adrenaline lead to the unregulated formation of ketoacids.

one must appreciate why there was a relative lack of insulin to favor ketoacid production and why the rate of removal of ketoacids was diminished. Production occurs in the liver whereas removal is largely the result of oxidation in the brain and kidneys (Table 11). The time course of events in patients with diabetic ketoacidosis (DKA) has an interesting feature. Towards the end-stage, the degree of ketoacidosis becomes more severe, and very quickly. Because there is little leverage to increase the rate of ketogenesis appreciably due to the control exerted by the limited rate of turnover of ATP in hepatocytes [85, 86], for ketoacidosis to worsen rapidly, there must be a major decline in the rate of utilization of ketoacids.

Brain: A decrease in the rate of turnover of ATP in the brain will lead to a decreased rate of oxidation of ketoacids. Should general anesthetics or sedatives be administered, or if coma be present, the degree of ketoacidosis will be more severe.

Kidney: If the GFR is very low, less Na^+ will be of filtered and this will decrease the reabsorption of Na^+ and thereby the renal need for regeneration of ATP. In quantitative terms, a low GFR can lead to the failure to remove several hundred mmoles of ketoacids per day.

Summary: One can appreciate why the natural history of DKA has a steep deterioration late in its course because of coma and prerenal failure.

Diabetic Ketoacidosis

DKA is the metabolic consequence of a lack of actions of insulin and it is characterized by the accumulation of glucose and ketoacids in the body [16]. The precipitating illness and the complications of this metabolic disturbance can be life-threatening. The changes in the hepatic metabolism that lead to overproduction of ketoacids are depicted in Figures 3 and 16.

Clinical Presentation

DKA may be the first indication of undiagnosed type 1 diabetes mellitus in children. The precipitating causes include an intercurrent illness (gastroenteritis, pancreatitis, infections), and situations where counter-regulatory hormones may be present in

excess (e.g., thyrotoxicosis, surgery, stress, pregnancy, and hyperadrenocorticism). With repeat episodes of DKA, failure to take insulin can be an important etiologic factor. Rarely, DKA occurs in older patients with type 2 diabetes mellitus when there is an unusually large decrease in the rate of oxidation of ketoacids due to impaired level of consciousness and a very low GFR.

The clinical manifestations are the expected consequences of the major biochemical changes, hyperglycemia, glucosuria, and ketoacidosis.

Hyperglycemia: Early signs and symptoms represent exacerbations of the classic features of diabetes mellitus in poor control – thirst, polydipsia, polyuria, weakness, lethargy, and malaise.

Glucosuria: Hyperglycemia causes an osmotic diuresis with loss of Na^+ and water, resulting in ECF volume contraction, low blood pressure, postural hypotension, and tachycardia.

Ketoacidosis: Metabolic acidosis results in an increased rate and depth of breathing (air hunger, Kussmaul respiration). The conversion of acetoacetic acid to acetone imparts the characteristic fruity odor to the breath.

Other findings: Not all the clinical findings, however, are completely explained in terms of biochemical aberrations. The state of consciousness does not correlate well with the concentration of ketoacids in blood. A much better correlation was found between the level of stupor and coma and the P_{osm} that in turn reflect the low circulating volume (and possibly, the higher PCO_2 in cells of the brain, Figure 7).

Another feature of DKA that remains unexplained is hypothermia, even in the presence of infection. This together with the fact that leukocytosis is a common finding in these patients may at times obscure an underlying infection.

Anorexia, nausea, vomiting, and abdominal pain are frequent nonspecific gastrointestinal complaints, especially in children. These symptoms, together with abdominal tenderness, decreased bowel sounds, guarding, and leukocytosis, may be severe, mimicking an acute abdominal emergency. Rebound tenderness is usually (but not universally) absent – the presence of hyperglycemia and ketonemia should signal the correct diagnosis. The cause for the abdominal pain is not entirely clear, but in some cases it may be related to hypertriglyceridemia and pancreatitis.

Signs and symptoms of the disorder that precipitated DKA should be appreciated – in fact, these may dominate the clinical picture.

Laboratory Evaluation

Hyperglycemia, ketonemia, glucosuria, and ketonuria are the 4 hallmarks of the laboratory diagnosis of DKA.

Hyperglycemia: The degree of hyperglycemia varies markedly – the P_{Glu} usually exceeds 250 mg/dl (14 mM). Higher P_{Glu} values are seen if there is a marked reduction in the GFR (usually with oliguria) or if the patient has consumed a large quantity of carbohydrate, for example, in the form of sweetened soft drinks to quench thirst (usually with polyuria) [87]. If the ECF volume is markedly contracted, not only will there be an exaggerated degree of hyperglycemia, but glucosuria may be reduced considerably because the filtered load of glucose may not exceed the tubular capacity for its reabsorption. In rare cases, hyperglycemia may be less marked for other reasons (e.g., a reduced rate of gluconeogenesis secondary to the intake of ethanol or biguanides or exaggerated renal glucosuria).

Ketoacids: In DKA, serum ketones are usually strongly positive in a dilution of 1 in

Table 13. Typical deficits in a patient with DKA.

	Quantity	Comment	Danger
Na^+	3 – 9 mmol/kg	Restore Na deficit, but not too quickly	Cerebral edema if early and too rapid
K^+	4 – 6 mmol/kg	Must await insulin action to shift K^+ into cells Examine P_K	Initial hyperkalemia > 1.5 h, hypokalemia
Water	Usually many liters	Half ICF, half ECF	Do not repair water deficit too early
Bicarbonate	Can be > 500 mmol of H^+ buffered	If increased anion gap, need not give $NaHCO_3$ unless very severe acidosis	Strong opinions held, but not backed up with clean data

8. However, only acetoacetate and acetone yield a positive reaction with the nitroprusside test (Acetest) used for clinical screening for ketoacids. If there is an increase in the $NADH^+$: NAD ratio, as occurs with hypoxia or ethanol oxidation, ketoacids will be predominantly in the form of -hydroxybutyric acid which is not detected by these clinical tests; a specific enzymatic analysis will be necessary to measure -hydroxybutyric acid. If the urinary excretion of ketoacid anions is larger than expected, as may occur with the intake of acetylsalicylic acid, or if there is a defect in reabsorption of ketoacid anions by the PCT, a hyperchloremic type of metabolic acidosis will be present [88].

Sodium: In patients with DKA, there is a large deficit of Na^+ (3 – 9 mmol/kg body weight, Table 13). This is the result of the osmotic diuresis.

Plasma Na^+ concentration: Much attention is given to the possibility that glucose will draw water out of cells and thereby, lower the P_{Na}. This occurs only when the addition of glucose is hyperosmolar to plasma. In contrast, when glucose is added as a solution that has an osmolality similar to or lower than the P_{osm}, there is no shift of water from cells. In this circumstance, the P_{Na} will be lower than seen with hypertonic glucose addition for an identical rise in P_{Glu} [89]. Therefore calculations based on the expected shift of water and thereby an expected fall in P_{Na} for a given P_{Glu} should not be done because the assumptions made are not valid [90 – 92]. Therefore we calculate the effective P_{osm} (Equation 10) to help clinical decision-making with regard to the appropriate tonicity of fluid therapy [93]. Corrections should be made for major changes in the P_K.

$$\text{Effective } P_{osm} = 2 \times P_{Na} + P_{Glu} \quad \text{(in mM terms)} \qquad (10)$$

Potassium: In patients with DKA and good renal function, there is always a decrease in the total body content of K^+, usually in the range of 4 – 6 mmol/kg body weight (Table 13). Despite this deficit of K^+, the P_K is usually increased to the mid-5 range [94] because K^+ has shifted from the ICF to the ECF

Table 14. Content of HCo_3^- in the ECF compartment in a patient with DKA. The example given is a 70-kg person who has an ECF volume of 15 L when normal (top line) and 12 L while in DKA (bottom line). The content of HCO_3^- is decreased by 75 mmol in DKA. Despite this loss, there is a 1:1 relationship between the fall in P_{HCO3} and rise in P_{-HB} because of an equivalent loss of -HB with Na^+ and/or K^+ in the urine. This represents the indirect loss of $NaHCO_3$.

	Plasma		ECF volume	ECF content		
	P_{HCO3} mmol/l	P_{-HB} mmol/l	liters	HCO_3^- mmol	Ketoacids mmol	$HC0_3^-$ + Ketoacids mmol
normal	25	0	15	375	0	375
DKA	10	15	12	120	180	300

compartment due to the lack of insulin (Figure 9) [73].

P_{HCO3}: In patients with DKA, the P_{HCO3} is low because H^+ were added to the ECF along with -hydroxybutyrate and acetoacetate anions. Nevertheless, there is also an indirect loss of Na^+ and HCO_3^- – this loss occurs early in the course of DKA because there is a lag period before there is a large increase in the rate of excretion of NH_4^+ [15]. As a result, ketoacid anions are excreted in the urine with Na^+ or K^+ and hence the indirect loss of $NaHCO_3$ (Figure 4). This component of the metabolic acidosis may not be appreciated because there is often a 1 : 1 relationship between the fall in P_{HCO3} and the rise in the plasma anion gap. This quantitative relationship occurs because *concentrations* rather than the *content* of HCO_3^- in the ECF compartment are considered (Table 14). This component of the HCO_3^- deficit becomes evident during therapy as the ECF volume is expanded [69, 95, 96].

PCO_2: There should also be a predictable degree of hypocapnia depending on the degree of metabolic acidosis (Table 4). Since hypothermia may occur in patients with DKA, one must take this into consideration when interpreting the PCO_2 and PO_2 values reported by the laboratory because the measurements are made at 37ºC.

GFR: Since patients with DKA often have a very low ECF volume, their GFR will be reduced whereas the concentrations of urea (P_{urea}) and creatinine (P_{creat}) will be elevated in plasma. The P_{urea} (BUN) is less reliable as an index of the GFR because it is also influenced by protein intake, tissue catabolism, rate of gluconeogenesis, catabolic drugs, and urine flow rate. Notwithstanding, there may also be errors in the measurement of creatinine depending on the method used. Higher P_{creat} values are reported with the picric acid method if the level of AcAc is elevated [97] whereas lower P_{creat} values are reported with severe hyperglycemia if the enzymatic assay for creatinine is performed on the Kodak analyzer [98].

Treatment of the Patient with DKA

DKA is a medical emergency that demands urgent treatment. Mortality is influenced by a number of factors that include its precipitating cause, the age of the patient, the level of

consciousness, and the severity of the biochemical abnormalities. In children, the leading cause of morbidity and mortality is the development of cerebral edema (discussed later) [99, 100]. Other causes of death are infection, vascular thrombosis, and shock. Early diagnosis, a better design of therapy, and dealing with the underlying causes of DKA may reduce the mortality rate. Our emphasis will be on the threats to the patient's life during therapy of DKA (Table 15). Treatment will be discussed under the following headings: body fluid compartments, insulin, bicarbonate, predisposing factors and how to avoid complications of therapy.

Table 15. Complications to avoid during therapy.

On admission
Shock
Aspiration pneumonitis
Thrombotic episodes
Hyperkalemia with cardiac arrhythmias
From 1.5 h onwards
Hypokalemia with cardiac arrhythmias
From 6 h onwards
Neuroglucopenia
From 5 – 15 h
Cerebral edema
Anytime
Complications of the underlying illness
Lack of insulin actions

Body Fluid Compartments

Focus on the ECF volume: The ECF volume should be re-expanded quickly only if there is a hemodynamic emergency. It is very difficult to assess the degree of ECF volume contraction on clinical grounds [101 – 103]. The following laboratory findings can help to provide a quantitative assessment of the patients' ECF volume [69]. The hematocrit (ratio of red blood cells (RBC) volume/blood volume) is particularly useful if the patient is not anemic. For example, if the initial hematocrit were 60%, this would suggest that the plasma volume is contracted by more than 50% (Equation 11). Moreover, the ECF volume is contracted to a greater degree than the plasma volume because the volume of RBC should remain constant (in the absence of a severely abnormal P_{Na}) and Starling forces should expand the plasma volume at the expense of the interstitial volume [69].

Normal: 0.40 = 2 l RBC volume/5 l blood volume (3 l plasma + 2 l RBC)

Patient: 0.60 = 2 l RBC volume/3.3 l blood volume (1.3 l plasma + 2 l RBC) (11)

We also find 2 other indices helpful to monitor changes in the effective vascular volume [69]. First, if the venous PCO_2 is appreciably higher than the arterial PCO_2 (> 10 mmHg), it suggests a slower blood flow rate past cells drained by that venous system (same CO_2 production, but CO_2 is carried away in fewer liters of blood, Figure 7). Second, a rise in urine output usually signals an increase in the GFR and thereby a higher filtered load of glucose and a larger osmotic diuresis. With the initial urine output rise, the rate of intravenous infusion should be increased by a similar volume to maintain the slow and steady re-expansion of the ECF volume.

The next decision concerns the composition of the infusate. There is still some dispute about which is the most appropriate intravenous solution to use. We strongly favor the initial administration of 0.9% saline (154 mM NaCl) to avoid a large fall in the effective P_{osm} (Equation 10). When the P_{Glu} falls below 250 mg/dl (15 mM), glucose should be added to the infusate. Further fluid therapy is determined by the clinical assessment, biochemical measurements, and calculated and/or expected losses.

Focus on the ICF volume: The deficit of ICF water should be replaced much more slowly. Once the hemodynamic emergency is dealt with, one can now safely switch to half isotonic saline in adults with DKA because cerebral edema is not common in these patients. The goals for ICF therapy differ in children with DKA as discussed later in the section on complications of therapy.

Insulin: Insulin plays a central role in arresting ketogenesis, but this is rarely an urgent aspect of therapy because the maximum possible rate of ketogenesis is only ~ 1 mmol/min [86]. In our view, the only emergency action of insulin needed is its effect to decrease the P_K by accelerating a shift of K^+ into cells in a patient with a significantly abnormal EKG due to hyperkalemia. While insulin will help lower the P_{Glu}, its hypoglycemic effects are minimal early in therapy. Rather, the P_{Glu} will fall initially as a result of re-expansion of the ECF volume (dilution) and glucosuria (decrease the glucose pool size) [104]. 6 – 8 hours after therapy began, insulin will increase the rate of oxidation of glucose (because competing fat fuels are no longer available) and by promoting the synthesis of glycogen [87].

Low-dose, short-acting insulin regimens are now commonly used. Given the uncertainty of absorption by other routes, the intravenous route is advisable. A typical dose in adults is 0.1 Units/kg as an intravenous bolus, followed by a constant infusion of 0.1 Units/kg/h. A bolus of insulin should not be used in children because it may lead to brain cell swelling [93]. The putative mechanism involves activation of the Na^+/H^+ exchanger in brain cell membrane with a resultant gain of ICF solutes (Na^+) [105].

Insulin therapy has potentially detrimental effects that should be anticipated and avoided. The major ones are hypokalemia (at 1 – 3 h) and hypoglycemia (at 6 – 10 h). The former risk is discussed below and the latter one is minimized by infusing glucose when the P_{Glu} falls to 250 mg/dl (~ 15 mM).

Potassium: Typically, the P_K on presentation in patients with DKA is in the mid-5 range [94]. A lower P_K indicates that a rather severe K^+ deficit exists and patients are at higher risk for cardiac arrhythmias, paralytic ileus, and muscle weakness that may also involve respiratory muscles after insulin is given. Once therapy has commenced, the P_K falls rapidly, often within the first hour. This is due primarily to the uptake of K^+ into the ICF (replacing Na^+ and H^+). Minor contributing factors are the loss of K^+ in the urine, correction of the acidosis, and dilution from re-expansion of the ECF volume.

The initial aim of therapy is to ensure a normal P_K during the acute stages of therapy. Replenishing the total deficit of K^+ in the body will take time because it requires the re-accumulation of intracellular anions (primarily organic phosphates). K^+ should be given as intravenous KCl, but only when the P_K is < 5.0 mM. Typical regimens are: give 20 mmol K^+/hour if the P_K is 4 – 5 mM; give 40 mmol K^+/hour if the P_K is 3.0 – 4.0 mM, and 40 – 60 mmol K^+/hour if the P_K is < 3.0 mM. The EKG as well as the P_K can be used to monitor the rate of replacement of K^+.

While it is prudent to consider the urine output, patients with oliguria may still need a supplement of K^+ if their P_K is distinctly low. When DKA has been corrected, oral supplementation of K^+ (and phosphate, usually from diet) should be continued over several days to replenish the deficits in the intracellular compartments.

Because hypokalemia is also a complication of therapy with $NaHCO_3$, if a patient presents with a low P_K and acidosis that is severe enough to require treatment with $NaHCO_3$, one could make a case for withholding insulin for an hour or so until suffi-

cient K^+ and HCO_3^- have been administered. Since the rate of net ketoacid production is ~ 1 mmol/min [86], withholding insulin for that hour will not have a major impact on the degree of acidosis because more HCO_3^- than this can be given.

$NaHCO_3$

Early therapy: $NaHCO_3$ is rarely needed. Nevertheless, it is difficult to resist giving $NaHCO_3$ when the P_{HCO3} is < 5 mM especially if there is a source of loss of $NaHCO_3^-$. A severe degree of hyperkalemia is also a possible indication for the use of $NaHCO_3$.

Later therapy: After the ketoacidosis has been largely reversed, some patients may have a lingering hyperchloremic type of metabolic acidosis due in part to a low rate of excretion of NH_4^+. These patients may need to ingest $NaHCO_3$ to raise their P_{HCO3}.

Phosphate

The usual deficit of phosphate is 1.5 – 2.5 mmol/kg body weight (Table 13). While only close to 10% of patients have hypophosphatemia at presentation, once therapy is instituted virtually every patient becomes profoundly hypophosphatemic. There are no controlled studies documenting the absolute benefits of the acute replacement of phosphate. A number of theoretical considerations, however, suggest that it may be beneficial to replace some of the deficit of phosphate early in therapy. The rate of infusion of phosphate should not exceed 50 mmol/8 h.

Complications Observed During Therapy

While hypokalemia, hypoglycemia, relapse of ketoacidosis, and thrombotic events may occur, we shall focus on cerebral edema in this section.

Cerebral edema: Typically, DKA is first diagnosed in childhood. Cerebral edema is more common during therapy in the first episode of DKA, possibly because there was a delay in suspecting that this may be the diagnosis by family members. Cerebral edema occurs in ~ 1% of cases and it is the major cause of mortality in this setting [99, 100]. Even though most children with cerebral edema survive, many are left with significant neurological deficits. Even those who seem to be neurologically intact may have subtle cognitive and behavioral deficits.

Cerebral edema is the result of a rise in brain water and hence intracranial pressure because of the fixed volume of the skull. At the clinical level, typically, the child who develops cerebral edema appears to be recovering normally from DKA, but takes a rapid turn for the worse close to 5 – 15 h after the onset of therapy. Nevertheless, 1/20 children developed cerebral edema prior to receiving therapy – a possible reason for this was discussed in reference [89]. The warning signs of impending cerebral edema are often subtle, including new onset of drowsiness and/or irritability that can progress rapidly to a disordered state of consciousness that may terminate with respiratory arrest and death.

While CT or MRI imaging will confirm this diagnosis, we are very reluctant to send patients suspected of having cerebral edema for these studies because they need extremely urgent medical treatment that cannot wait for even a few minutes. Moreover, they need to be observed very carefully and the imaging department does not have the facilities to do

Table 16. Anticipated results of therapy of DKA.

Glucose:	Will fall 5.5 mmol/l (100 mg/dl) over each of the first 6 hours. Reasons for fall are dilution (early), glucosuria (mid-time) and metabolism (late).
Sodium:	Rise in the P_{Na} of 1.6 mmol/l per 100 mg/dl (5.5 mmol/l) decline in P_{Glu} owing to a shift of water into the ECF.
Potassium:	Sudden fall over 1 – 2 hours owing to shift of K^+ into cells when insulin acts. This is the best early indicator of the biological actions of insulin.
Bicarbonate:	Will not rise for several hours. The P_{HCO3} will be close to 16 – 18 mmol/l once ketoacidosis largely disappears (6 – 8 hours later).
Ketoacids:	Slow steady decline over 8 hours to 1 mmol/l range. Serum quick test for ketones will be positive much longer. The Quick test may actually become more positive, despite less ketoacidosis owing to conversion of H● -HB to H●AcAc.
Anion gap:	Fall in parallel with ketoacids, will return to normal in 8 – 12 hours.
Complications:	See Table 15.

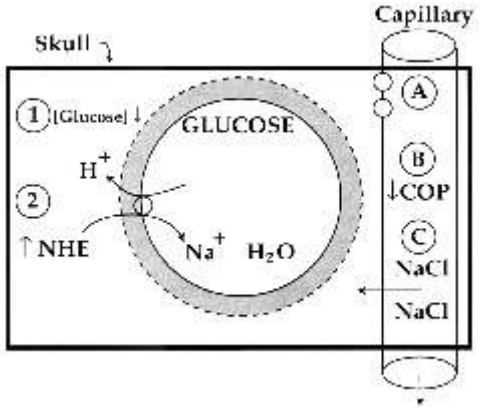

Figure 17. Risk factors for cerebral edema. The solid rectangle represents the skull. The 2 risk factors for swelling of brain cells are shown on the left and include a higher concentration of glucose and/or its metabolites in the brain due to rapid lowering of the P_{Glu} (site 1) and activation of the $Na^+ : H^+$ exchanger (NHE) by insulin (site 2). The factors causing expansion of the ECF volume are shown on the right and could be the result of a less restrictive blood brain barrier (site A), a fall in the colloid osmotic pressure (COP) in plasma (site B), and/or the excessive administration of saline (site C). Reproduced with permission [187].

this. Even when one has the results of the imaging studies, changes in the clinical state can occur so rapidly that this result may not mirror the current status in a timely fashion.

Pathophysiology of Cerebral Edema

A more detailed view of the pathophysiology of cerebral edema will be considered under the following headings (Figure 17).

Factors related to an expansion of the ECF compartment of the brain: One can think of these as early or later events. The early factors might include a less restrictive blood brain barrier (BBB), the use of an initial bolus of saline, especially if there is not a hemodynamic reason to give it, and an initial decline in the colloid osmotic pressure of plasma. In more detail, although somewhat controversial, there is evidence of subclinical cerebral edema before therapy is instituted when CT scans of the brain were examined [106 – 108]. This may be the result of a less restrictive BBB that permits the intracranial

ECF volume to increase, effectively bypassing the protective mechanisms that normally exist to prevent a rise in intracranial pressure. The initial bolus of saline will be distributed on first pass in the blood volume and cause a sudden rise in hydrostatic pressure and a fall in the colloid osmotic pressure of arterial blood. In addition to the fall in albumin concentration, the colloid osmotic pressure could decrease due to a fall in the Donnan force in plasma, possibly the result of a less anionic charge on albumin associated with rapid re-expansion of the ECF volume [109]. Hence Starling forces together with a less restrictive BBB could act in concert to expand the volume of the intracerebral ECF compartment further. The message we derive from these analyses is: a large bolus of saline should **not** be given unless there is frank hemodynamic collapse in children with DKA.

Factors associated with a rise in brain cell volume: There are two factors to consider, a fall in the effective P_{osm} and a rise in intracellular osmoles. Firts treatment regimens that have been associated with cerebral edema usually cause a significant fall in the effective P_{osm} (Equation 10). A rapid fall in the P_{Glu} may predispose to cerebral edema by allowing the shift of water into brain cells (a compartment with an osmolality that decreases less rapidly than the effective P_{osm}). As partial compensation for the high effective P_{osm} in a patient with DKA, the brain seems to accumulate osmoles such as sorbitol, fructose, taurine and glutamine that minimize the degree of water shift out of brain cells. Once the P_{osm} falls, however, these organic osmoles cannot be removed rapidly from brain cells and they will attract water, contributing to the development of cerebral edema [110]. Second, one should avoid an initial bolus of insulin because it may cause an increase in the number of particles in cells of the brain [105]. In more detail, insulin activates the Na^+-H^+ exchanger in the cell membrane (Figure 9). By causing an increase in the entry of Na^+ into brain cells along with the exit of H^+ that were bound to intracellular proteins, there will be a net increase in the number of particles in the ICF, and this will draw water into these cells.

The P_{Na} is typically much higher in children for a given degree of hyperglycemia (i.e., with a P_{Glu} of 50 mM (900 mg/dl), the P_{Na} is usually in the 125 – 130 mM range in adults [81, 104] but closer to 140 mM in children [93, 111]. We speculate that this could reflect the higher GFR early in type 1 diabetes mellitus leading to a higher rate of glucosuria for the same degree of hyperglycemia. Moreover, the $U_{Na} + U_K$ in this urine is close to $^1/_3 - ^1/_2$ isotonic saline (plus glucosuria). Hence there would be a larger excretion of electrolyte-free water in children.

Issues for Therapy

The best strategy is to prevent cerebral edema from developing. This can probably be achieved by avoiding therapies that will over-expand the ICF and ECF volumes of the brain. We would not administer a bolus of insulin to treat DKA in children. The initial saline infusion should be targeted to avoid circulatory collapse – we would not otherwise give a bolus of saline. Once the patient is hemodynamically stable, the Na^+ deficit should be replaced slowly, with an upper limit of 6 – 9 mmol/kg depending on the initial impression of the degree of ECF volume contraction (use the hematocrit if possible) [69].

In children, we use isotonic saline to avoid a fall in the effective P_{osm} (Equation 10). The target value for the P_{Na} in the first 5 – 15 hours is that which keeps a constant effective P_{osm}. Adding KCl, to isotonic saline is a good choice when the patient is undergoing a rapid

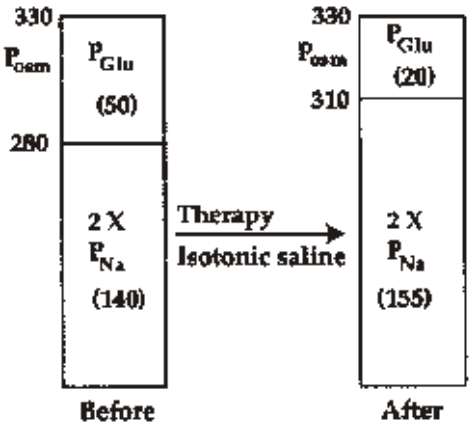

Figure 18. Fall in the effective plasma osmolality and the development of cerebral edema. For details, see text. A rise in the P_{Na} is needed to prevent a fall in the effective P_{osm} when there is a fall in the P_{Glu}. The P_{Na} must rise by $^1/_2$ the fall in the P_{Glu} to maintain a constant P_{osm} of 330 mOsm/kg H_2O.

glucose-induced osmotic diuresis because this will defend the effective P_{Osm} when the P_{Glu} falls. There is evidence to suggest that maintaining a constant "effective" P_{osm} at the expense of hypernatremia may protect against cerebral edema [93]. This can be accomplished by permitting the P_{Na} to rise by half the fall in P_{Glu} in mM terms (Equation 10), thereby keeping the effective P_{osm} constant (Figure 18). As mentioned earlier, the P_{Na} in children with DKA who have a P_{Glu} of 50 mM (900 mg/dl) is usually close to 140 mM [93, 111]. When this P_{Glu} falls by 30 mM (540 mg/dl), the P_{Na} would have to rise by 15 mM to 155 mM to keep the effective P_{osm} constant (Equation 10). To achieve this aim, the intravenous solutions must have the same effective osmolality as the P_{osm} in an oliguric patient or as the urine when the patient has a large urine output.

If signs of cerebral edema did develop, hypertonic saline or mannitol should be infused rapidly to reverse cerebral edema by drawing water out of the brain [112]. Our aim would be to give enough hypertonic solutes to see a prompt clinical response. Usually, this would require an increase in the effective P_{osm} of 10 mOsm/kg H_2O (administer 10 mmol of mannitol or 5 mmol of hypertonic NaCl/l body water using the clinical response as your guide).

Precipitating Events

During therapy for DKA, it is also necessary to treat any precipitating event or accompanying illness. Although clinical rhabdomyolysis is uncommon, enzymes of muscle origin (CPK, AST, and LDH) are often elevated in plasma. Thrombotic events in veins due to a slow blood flow rate should also be anticipated.

Alcoholic Ketoacidosis

Alcoholic ketoacidosis is seen following binge drinking of large amounts of ethanol complicated by poor food intake and vomiting (usually due to alcohol-induced gastritis) [113, 114]. The lack of food intake and the ECF volume depletion lead to suppression of insulin secretion via an -adrenergic effect [115]. This combination of hormonal changes both increases lipolysis in adipose tissue (stimulation of hormone-sensitive lipase) and diminishes hepatic lipogenesis (inhibition of hepatic acetyl-CoA carboxylase (ACC)) (Figure 16).

Ethanol, the principal carbon source for the formation of ketoacids, is metabolized in the liver to produce acetyl-CoA. Constraints set by the rate of turnover of ATP in hepatocytes limits the rate of oxidation of acetyl-CoA to

produce ATP [85, 86]. This, together with the inhibition of the synthesis of fatty acids in liver (inhibition of ACC by the low insulin and high circulating counter-insulin hormones such as adrenaline and glucagon), leads to the rapid formation of ketoacids. The acidosis may be quite severe and have a relatively rapid onset, with ketoacid anion levels of up to 20 mM; it is associated with an increase in the anion gap in plasma. Establishing the diagnosis of alcoholic ketoacidosis may not be straightforward. One reason is that there are frequently coexisting acid-base disturbances that result in the blood pH being normal or even alkalemic in up to 50% of patients. Metabolic alkalosis commonly occurs as a result of the vomiting, and respiratory alkalosis may occur due to stimulation of ventilation by alcohol withdrawal or aspiration pneumonia.

The second difficulty in diagnosis is that there is occasionally a falsely low or perhaps negative screening test for ketones [116]. The nitroprusside reagent reacts with acetoacetate and acetone. Acetoacetate is in equilibrium with -HB in a reaction catalyzed by the enzyme -hydroxybutyrate dehydrogenase (Equation 12). This is an NAD^+-NADH linked reaction and the ratio of end products depends on the NAD^+/NADH ratio which in turn reflects the redox state in liver cells. In alcoholic ketoacidosis, the NAD^+/NADH ratio in the liver is often more reduced than usual due in part to the metabolism of ethanol (which generates NADH) or to tissue hypoperfusion as a result of the marked degree of ECF volume contraction. In this setting, the more reduced NAD^+/NADH ratio increases the amount of -hydroxybutyrate relative to that of acetoacetate so that the screening test for ketones may be falsely low.

$$AcAc^- + NADH + H^+ \qquad -HB^- + NAD^+ \quad (12)$$

The diagnosis of alcoholic ketoacidosis is therefore suspected in light of the clinical situation and laboratory abnormalities noted above. A key finding is that the P_{Glu} is not very elevated as it would be in DKA. At times it is difficult to distinguish alcoholic ketoacidosis from methanol or ethylene glycol poisoning as the primary cause of acidosis. This diagnosis is very important to make because therapy differs. Both can cause metabolic acidosis, a high anion gap in plasma, an elevated value for the plasma osmolal gap, and a near-normal P_{Glu}. Nevertheless, there is one clinical clue that can help – if the ECF volume is not very contracted, one would suspect methanol or ethylene glycol overdose. A direct assay for methanol and ethylene glycol is needed to establish the diagnosis.

Treatment of Alcoholic Ketoacidosis

The treatment of alcoholic ketoacidosis is usually straightforward. Isotonic saline is required to correct the marked degree of ECF volume depletion [113]; if the P_{Glu} is definitely low, a small quantity of glucose should be added to raise the P_{Glu} to the high-normal range. The higher P_{Glu} should now stimulate insulin secretion and thereby, diminish the rate of ketoacid production. Attention must be paid both to K^+ and phosphate depletion, which are common in this disorder. Treatment with $NaHCO_3$ is rarely required because the degree of acidemia is usually mild and the net production of ketoacids can be reversed quickly with appropriate intravenous fluid therapy. One must bear in mind that a deficiency of thiamin might be present in a patient who is malnourished so this vitamin must be given with the initial therapy in this setting.

The prognosis is usually excellent; in one case series only about 50% of the patients required hospital admission, and the mortality

Table 17. Causes of L-lactic acidosis.

Type A (hypoxic)
- circulatory failure (cardiogenic shock or secondary to sepsis)
- severe hypoxemia (lung problem or high altitude)
- severe anemia
- excessive demand for oxygen (e.g. generalized seizure, vigorous exercise)

Type B (compromised metabolism of L-lactate)
- a variety of diseases that severely affect the liver
- inhibition of gluconeogenesis (e.g. by ethanol)
- inborn error of metabolism affecting pyruvate dehydrogenase, the tricarboxylic acid
- cycle, or the electron transport system
- thiamine deficiency
- riboflavin deficiency or low bioactivity
- isoniazide (vitamin B_6 deficiency)

rate was only 1% including problems related to underlying lesions such as pneumonia and pancreatitis [114].

Ketoacidosis of Prolonged Fasting

Ketoacidosis of fasting is usually a mild disorder with a P_{HCO3} that is characteristically close to 18 mM and an anion gap that is less than 19 mEq/l (suggesting that the accumulation of ketoacid anions is not more than 7 mM). The rate of production of ketoacids is close to that in DKA, but the rate of production is matched by the removal of ketoacids by oxidation in the brain and kidneys plus their excretion with NH_4^+ in the urine [46]. The P_{Glu} is usually close to 60 mg/dl (3 mM). Specific treatment for this form of ketoacidosis other than re-feeding is not required because it is rapidly cured by intake of carbohydrate.

L-lactic Acidosis

L-Lactic acidosis may be classified into two major categories depending on whether or not the supply of oxygen is matched to tissue demands for energy metabolism. In type A L-lactic acidosis, the production of L-lactic acid is increased and its removal impaired because of tissue hypoxia (Figure 19). In contrast, in type B L-lactic acidosis, hepatic removal of L-lactate is impaired for reasons other than hypoxia [117] (Table 17).

Type A Lactic Acidosis

Type A L-lactic acidosis is particularly frustrating to treat because its underlying cause

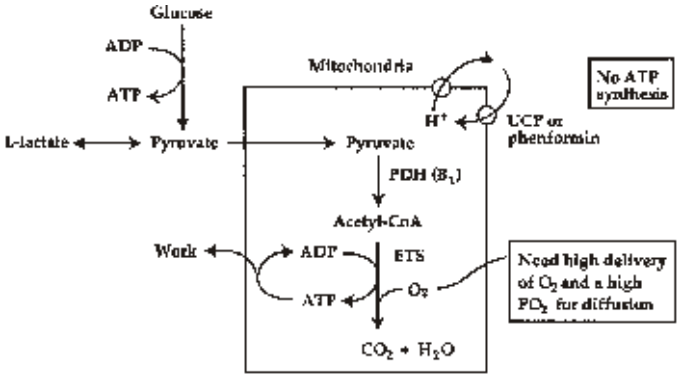

Figure 19. Biochemistry of L-lactic acidosis. The major production of L-lactic acid occurs when the supply of O_2 is inadequate to meet demand to support metabolic and physical work and/or uncoupling of oxidative phosphorylation due to open H^+ channels (UCP). Vitamin B_1 (thiamin), is a cofactor in the reaction catalyzed by pyruvate dehydrogenase (PDH). L-lactic acid can also accumulate when the ability to metabolize L-lactate is compromised.

may be extremely difficult to reverse. Examples include cardiogenic shock, septic shock, and multiple organ failure. It is also important to recognize that the rate of net L-lactate production may be extremely rapid, resulting in severe acidosis very quickly. It is widely believed that the accumulation of the L-lactate anion per se is not harmful and is important only as a sign of serious metabolic dysfunctions. Nevertheless, the L-lactate anion can chelate ionized Ca^{2+} [118 – 120], an ion that is critical for myocardial contraction [121]. In addition, Veech and Fowler [122] have suggested that a higher $NADH/NAD^+$ ratio can impair metabolism. Therefore there are theoretical reasons to suspect a primary role for the L-lactate anion in the poor outcome.

Hypovolemic shock: L-lactic acidosis caused by hemorrhage or extensive loss of Na^+-rich fluid (diarrhea, etc.) is the easiest of the causes to treat. Infusion of isotonic saline is the most appropriate initial therapy for most patients. In patients with severe hypoalbuminemia, colloids, such as albumin or plasma, may also be given. Whether one should add $NaHCO_3$ to the initial intravenous fluid depends on the factors discussed earlier – the severity of the acidosis, the respiratory compensation, the P_K, and probably most important, the likelihood of rapid reversal of the underlying cause of the hypovolemia. Usually, correction of hypovolemia will correct tissue hypoxia and rapid reversal of the L-lactic acidosis due to metabolic conversion of the accumulated L-lactate anions to HCO_3^- should be anticipated (~ 4 – 8 mmol of L-lactate may be removed per minute via oxidation or gluconeogenesis [2]).

Cardiogenic shock: This is much more difficult to manage, because the underlying cause of the tissue hypoxia – low cardiac output – is often difficult to reverse rapidly. Key issues to consider in patients with this diagnosis are ensuring that left ventricular filling pressure is adequate (which usually requires pulmonary capillary wedge pressure measurement) and that readily treatable causes of cardiogenic shock such as pericardial tamponade are not overlooked. The use of inotropes, afterload reducing agents, and/or an intraaortic balloon pump may be required. The administration of $NaHCO_3$ is often of limited use because of constraints imposed by ECF volume expansion and pulmonary edema.

Septic shock: L-lactic acidosis in a patient with sepsis is a grave prognostic finding. Treatment of the underlying infection with appropriate antibiotics, surgical drainage of an abscess if present, optimization of intravascular volume, and the use of inotropic agents are all essential, but often futile once multiple organ failure is present.

Use of dichloroacetate: One approach to treatment of patients with L-lactic acidosis is to use dichloroacetate (DCA) [123]. DCA activates the pyruvate PDH and thereby facilitates pyruvate (and therefore L-lactate) removal via metabolic conversion to acetyl-CoA and then to CO_2 and water. This may allow for more regeneration of ATP per molecular of O_2 consumed because now glucose or L-lactate rather than fatty acids are selected as the fuel to be oxidized [124]. DCA may have beneficial effects on myocardial function via a similar mechanism.

Early reports on the use of DCA in critically ill patients with L-lactic acidosis were somewhat encouraging. Notwithstanding, a prospective, randomized controlled trial of 252 patients with L-lactic acidosis, the majority of whom had sepsis and multi-organ failure, failed to show clinically significant benefit of DCA [125]. The results are not surprising considering that 18 mmol of H^+ are produced when 18 mmol of ATP are regenerated by anaerobic glycolysis, but only 1 mmol of H^+ is removed when the same amount of ATP is re-

generated by the aerobic oxidation of L-lactate [2]. Therefore one cannot overcome a rapid rate of production of L-lactic acid by enhancing its rate of removal unless anaerobic glycolysis is inhibited. Furthermore, as pointed out before, L-lactic acidosis per se maybe an epiphenomenon that reflects the presence of serious metabolic dysfunctions.

Type B L-lactic Acidosis

Hepatic disease: L-lactic acidosis is frequently seen in patients with acute hepatic necrosis with liver failure, such as that caused by viral hepatitis. It may also be seen as a more stable, chronic L-lactic acidosis where L-lactate removal is impaired in patients, for example, with malignancy that have liver metastases or infiltration with or without a large tumor burden outside the liver. The mechanisms that contribute to the L-lactic acidosis in these patients include replacement of a sufficient number of liver cells with tumor cells to impair L-lactate removal, production of metabolites by tumor cells such as the amino acid tryptophan that may lead to inhibition of hepatic gluconeogenesis, and/or the fact that tumor cells produce a quantity of L-lactic acid that exceeds the hepatic capacity to remove it in this setting.

Administration of $NaHCO_3$ to patients with type B L-lactic acidosis due to liver disease may have negative effects. First, the $NaHCO_3$ may increase L-lactate production (from glucose) by de-inhibiting phosphofructokinase-1 in malignant cells. Thus if the source of this glucose is ultimately from gluconeogenesis, a considerable amount of lean body mass may be lost [126]. Second, if for instance 150 mmol of $NaHCO_3$ were given along with 1 l of D_5W, the 276 mmol of glucose provided could be converted to 552 mmol of H^+ (2 L-lactate- and 2 H^+ per glucose), a quantity that exceeds the 150 mmol of HCO_3^- given.

Thiamin deficiency: Thiamin (vitamin B_1) deficiency is a specific example of type B L-lactic acidosis that merits emphasis. Thiamin is an essential cofactor of the PDH complex, an enzyme required for the regeneration of ATP from glucose [2, 127]. A special circumstance where the effect of thiamin deficiency can be very acute occurs when ketoacids were the main brain fuel (alcoholic ketoacidosis), but ketoacids disappeared when insulin levels rise (restoration of ECF volume, especially if hyperglycemia is also present). The target organ for a deficit of thiamin is the brain for two reasons: first, the brain is dependent on glucose as its energy fuel, and therefore flux through the PDH must occur in order to have ATP regeneration (unless ketoacids are present); second, there are very high rates of ATP turnover in certain areas of the brain. Hence, one can anticipate two hazards from a deficiency of thiamin, a local deficit of ATP, and a consequent local H^+ accumulation in an organ with limited buffer capacity. This may help explain why Wernicke-Korsakoff syndrome develops in these patients. Treatment is obviously thiamin replacement *before* the ketoacid concentration in plasma falls to very low levels.

Thiamin deficiency is most often seen in alcoholics who are poorly nourished, but it has also been described in patients receiving total parenteral nutrition when thiamin was not supplemented. The clinical manifestations of the L-lactic acidosis due to thiamin deficiency are confusion, hypotension, tachycardia, tachypnea and signs of congestive heart failure.

Ethanol: The acidosis observed in patients who have consumed large quantities of ethanol is frequently multifactorial. One component that may be observed in addition to ketoacidosis is L-lactic acidosis. The degree

of L-lactic acidosis is usually mild (< 5 mM) because it reflects the more reduced $NADH/NAD^+$ ratio due to ethanol metabolism that is largely restricted to the liver. A more severe degree of L-lactic acidosis suggests that there is L-lactic acid overproduction caused by hypoxia (resulting from shock due to gastrointestinal bleeding, for example), thiamin deficiency, seizures (alcohol withdrawal, delirium tremens, and/or a CNS lesion), or L-lactic acid underutilization due to severe liver disease. The management of this situation is mainly supportive, including normalization of the ECF volume and provision of thiamin. Once ethanol is completely metabolized, NADH levels will fall, L-lactate will be converted to pyruvate, and thereby to either glucose and/or CO_2 and water. This will lead to the regeneration of HCO_3^-, and the resolution of the L-lactic acidosis.

Biguanides: Biguanides are frequently used for patients with type 2 diabetes to lower the P_{Glu}. Initially, phenformin was the drug that was used, but because it led to the development of L-lactic acidosis [128], its use was curtailed. Currently, metformin is the drug of choice in this class – it does not seem to be a single cause of L-lactic acidosis [128b]. Biguanides, are lipophylic weak acids that can cross the mitochondrial membranes and cause uncoupling of oxidative phosphorylation in a fashion similar to dinitrophenol. The reason for the higher likelihood of L-lactic acidosis with phenformin than metformin is that phenformin has a larger hydrophobic end. Certain conditions lead to higher blood levels of these drugs, including renal insufficiency, reduced liver function or alcohol abuse, and heart failure and therefore, patients with these conditions are more predisposed to serious L-lactic acidosis with this class of drugs.

Antiretroviral drugs: L-lactic acidosis has been reported in patients with HIV infection treated with various antiretroviral agents. The agent most frequently associated with L-lactic acidosis is zidovudine [129], but didanosine, stavudine, lamivudine, and indinavir have also been implicated. Antiretroviral drug therapy is associated with mitochondrial myopathy as well as hepatic steatosis. Either muscle or liver involvement could, in theory, explain the L-lactic acidosis. Initially, mitochondrial myopathy, as manifested by ragged-red fibers and mitochondrial DNA depletion, was thought to be the main mechanism of L-lactic acidosis. Because the L-lactic acidosis did not become much more severe with exercise [129], we suspect that a more likely mechanism of the lactic acidosis might be the massive hepatomegaly and steatosis (Figure 20). This view was supported by the fact that a small dose of ethanol markedly increased the degree of L-lactic acidosis [129].

Riboflavin deficiency and/or tricyclic antidepressants: The active metabolites formed from vitamin B_2 (riboflavin), flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD), are components of the mitochondrial electron transport system, the principal pathway to regenerate ATP, and for the enzyme, glutathione reductance. Riboflavin must be activated via an ATP-dependent kinase to produce FMN and FAD (Figure 21). This kinase is inhibited by tricyclic antidepressant drugs, such as amitriptyline and imipramine [130]. The activity of the kinase is decreased in hypothyroidism. Decreased activity of this kinase in a patient with myxedema crisis was associated with pyroglutamic acidosis [131]. Patients who consume a diet that is poor in B vitamins and take this class of antidepressants, can develop a chronic form of L-lactic acidosis. The reason that this is a chronic steady state L-lactic acidosis is still not clear.

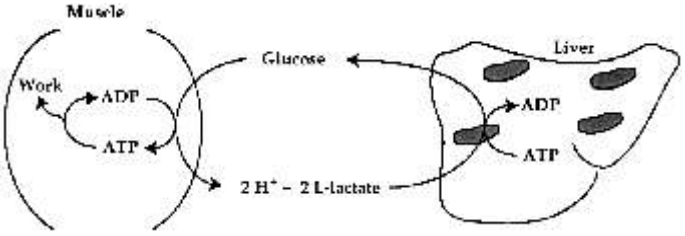

Figure 20. L-lactic acidosis and anti-retroviral drugs. The major basis for L-lactic acidosis is due to a problemwith L-lactic metabolism in the liver. While a lower activity of the mitochondrial electron transport system is possible, we favor the hypothesis that a large replacement of liver parenchyma by triglyderides (hepatic steatosis, depicted by the gray ovals) could explain why there is a reduced rate of L-lactic acid removal and a sensitivity to ethanol-induced L-lacitc acidosis.

The diagnosis is suspected by the history, and riboflavin deficiency is supported by finding a low activity of glutathione reductase in erythrocytes (a flavoprotein-dependent enzyme). Riboflavin supplementation leads to a prompt reversal of the metabolic acidosis in these patients suggesting that the defect is via competitive inhibition that is overcome by high riboflavin levels [132, 133].

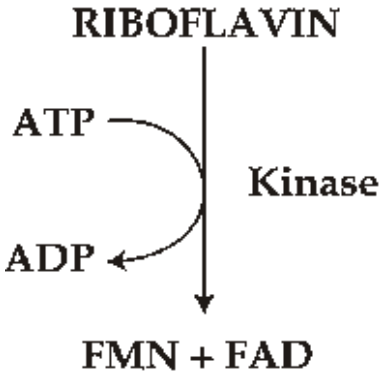

Figure 21. L-lactic acidosis and riboflavin deficiency. Riboflavin (vitamin B_2) must be activated to FMN or FAD to become an active component in the electron transport system, the mitochondrial pathway to regenerate ATP. Either a deficiency of riboflavin or inhibition of its kinase by tricyclic antidepressant drugs can lead to low levels of FMN and/or FAD.

Isoniazide: Prolonged convulsive seizure, regardless of cause, can lead to L-lactic acidosis. The seizure disorder induced by isoniazide is interesting because of its mechanism and clinical importance (Figure 22). Of note, the incidence of tuberculosis is rising worldwide and isoniazide is frequently used for its therapy.

The mechanism of the seizure and L-lactic acidosis may be the result of the formation of an isoniazide-vitamin B_6 complex, pyridoxal--isonicotinoyl-hydrazone, via a non-enzymatic reaction. This results in a rapid development of vitamin B_6 (pyridoxine) deficiency state [134]. Pyridoxal phosphate is a cofactor for the enzymatic reaction of glutamic acid decarboxylase in which glutamate is converted to gamma amino butyric acid (GABA). GABA is an inhibitory neurotransmitter. Therefore a deficiency of GABA could result in increased excitability and thereby lead to a seizure [135].

Patients on chronic hemodialysis are at increased risk of isoniazide-induced toxicity because they tend to be deficient in vitamin B_6 due to the efficient removal of this vitamin by hemodialysis. Vitamin B_6 deficiency can be suspected by finding a low activity of alanine aminotransferase in erythrocytes.

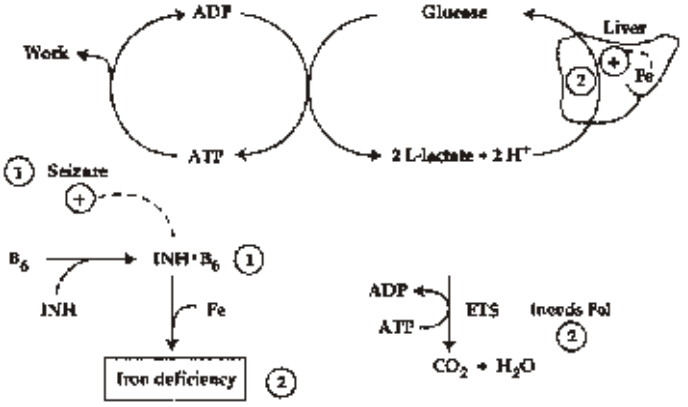

Figure 22. L-lactic acidosis due to the metabolism of isoniazide. For details, see text. The major cause of L-lactic acidosis is a seizure due to vitamin B_6 deficiency (site 1). A minor contributor to the development of lactic acidosis could be the chelation of iron (site 2) that diminishes the L-lactic acid removal rate, ETS electron transport system.

There are two factors that contribute to the degree of L-lactic acidosis (Figure 22). First, the deficiency of vitamin B_6 is responsible for isoniazide-associated seizure and thereby L-lactic acidosis. This is supported by the fact that there is a rapid and almost invariable cessation of seizure and recovery from L-lactic acidosis in response to a large dose of intravenous vitamin B_6 [136 – 138]. The recommended dose of vitamin B_6 for treatment of isoniazide toxicity is the same gram amount as the isoniazide dose ingested. If the amount of isoniazide is unknown, the recommended approach is to give 5 g of pyridoxine in 500 ml of fluid over 2 hours [138]. The second factor that could contribute to the degree of L-lactic acidosis is iron deficiency caused by chelation of iron by the isoniazide-vitamin B_6 complex. This could result in an electron transport defect and hence higher production of L-lactic and also a slower rate of its removal via gluconeogenesis because of the need for iron as a cofactor in both processes.

Methanol Poisoning

Methanol is metabolized by hepatic alcohol dehydrogenase. It is, however, a poor substrate for this enzyme and therefore high levels of methanol are needed for an appreciable rate of methanol metabolism. The molecular weight of methanol is only 32, so subjects do not need to ingest a large number of grams of methanol to produce an appreciable quantity of toxic metabolites. One can suspect that methanol is present from the history and the laboratory findings of a large plasma osmolal gap or metabolic acidosis accompanied by a large increase in the anion gap in plasma [139]. Note that the osmolal gap in plasma is due to methanol whereas the anion gap in plasma is due to formate anions. Therefore, later in the disorder when methanol has been largely oxidized, the plasma osmolal gap will not be elevated, but a high anion gap type of metabolic acidosis may be present.

The consequences of methanol ingestion may be classified as those arising from the effects of methanol itself and those of its metabolites. Methanol causes inebriation like ethanol. The serious toxicity of methanol arises from its metabolism to yield formaldehyde. Further metabolism of formaldehyde yields formic acid; however, acidosis is not usually the major concern. Formaldehyde is highly toxic to the central nervous system resulting in progressive coma and thalamic hemorrhage. The enzyme retinol dehydrogenase is located in the retina and it can catalyze the

conversion of methanol to formaldehyde and this leads to optic neuritis and blindness.

There may be difficulties in diagnosing methanol poisoning. In many cases, the origin of the ingested methanol is not recognized (e.g., substitution of methanol for ethanol in a recreational setting), so that clinical suspicion of the diagnosis may be lacking. Because methanol has such a low affinity for alcohol dehydrogenase, methanol toxicity can be delayed if ethanol is also ingested. Consequently, if one relies on finding metabolic acidosis, the diagnosis may be missed early on, even though plasma methanol levels are high. Accordingly, if there is the slightest suspicion that methanol may have been consumed and the plasma osmolal gap is significantly elevated, specific assays in blood for methanol should be undertaken. Another clue is that metabolic acidosis is present when the ECF volume is not appreciably contracted.

Treatment of Methanol Poisoning

First and foremost, the rate of metabolism of methanol to toxic end products should be slowed by giving ethanol or an inhibitor of alcohol dehydrogenase, 4-methylpyrazole (fomepizole, Antizol). The methods for administering Antizol and ethanol are described in the section on ethylene glycol.

Prognosis: The prognosis in methanol poisoning is closely related to the pH at presentation, with almost 100% mortality seen when the pH is less than 6.80. It is likely that the mortality is not caused directly by acidemia itself, but that the severity of acidosis reflects the generation of formaldehyde that causes the central nervous system toxicity. Therefore, although acidosis should be aggressively treated, the removal of methanol and its metabolites is the key to successful treatment.

Ethylene Glycol Poisoning

Ethylene glycol (automobile antifreeze, molecular weight 62) is readily available and is highly toxic. Like methanol, ethylene glycol is metabolized by the liver alcohol dehydrogenase to a variety of toxic end products. Patients with ethylene glycol poisoning have similar findings to those with methanol poisoning – CNS depression, increased anion gap metabolic acidosis and increased plasma osmolar gap. They differ in that they will often develop acute renal failure and pulmonary edema. The diagnosis may be suspected with the above findings plus abundant oxalate crystals in the urine, and confirmed by an assay that quantitates ethylene glycol in blood.

Treatment of Methanol and Ethylene Glycol Poisoning

The principles of treatment of ethylene glycol poisoning are virtually identical to that for methanol. They include administration of ethanol to achieve blood concentrations of about 20 mM (100 mg/dl) in order to reduce ethylene glycol metabolism, and removal of ethylene glycol and its metabolites by hemodialysis. One could administer fomepizole, an inhibitor of hepatic alcohol dehydrogenase, instead of ethanol. The major difference in treating ethylene glycol poisoning is that when acute oliguric renal failure is present, ECF volume overload or pulmonary edema may limit the amount of $NaHCO_3$ that can be administered so early dialysis is critically important.

Ethanol administration: Maintenance of a plasma ethanol level of about 20 mM (100 mg/dl) nearly completely inhibits methanol and ethylene glycol metabolism. Since ethanol distributes throughout total body water, administer a bolus of 0.6 g of ethanol per kg of body weight to increase its plasma level by 1

mg/ml (100 mg/dl). The maintenance dose should be equal to the expected metabolic removal rate for ethanol; at a plasma level in excess of 3 mM (14 mg/dl) – the hourly amount of ethanol removal is about 0.11 g per kg body weight [140]. In an alcoholic patient, the amount of ethanol metabolized is expected to be about 50% higher, and hence about 0.16 g of ethanol per kg body weight should be infused hourly. In a patient on hemodialysis, one can increase the rate of infusion of ethanol or add ethanol to the dialysis bath to achieve a concentration of 20 mM. The only way to ensure an optimal ethanol plasma level is to measure ethanol levels frequently and adjust its rate of infusion.

Administration of fomepizole (4-methylpyrazole): The target level of fomepizole in humans is 100 – 300 mol/l (8.6 – 24.6 mg/l) to assure near-complete inhibition of hepatic alcohol dehydrogenase. Its plasma half-life varies with the dose, even in patients with normal renal function. Fomepizole distributes rapidly in total body water. With multiple doses, fomepizole augments its own metabolism by inducing the cytochrome P450 mixed-function oxidase system; this effect increases the elimination rate by about 50% after about 30 – 40 hours. The side effects of fomepizole include headache, nausea, dizziness, and allergic reactions (rash and eosinophilia). Venous irritation and phlebosclerosis occur if the drug given is undiluted; therefore it should be diluted with at least 100 ml of 0.9% sodium chloride or D_5W.

The loading dose is 15 mg/kg, followed by 10 mg/kg q2h for four doses, then 15 mg/kg q12h (because of the P-450 enzyme induction) thereafter until the toxic alcohol level is less than 20 mg/dl. All doses should be administered as a slow intravenous infusion over 30 minutes. Fomepizole is dialyzable and the frequency of dosing should be increased to q4h during hemodialysis.

Salicylate Intoxication

The most common acid-base disturbance associated with salicylate intoxication is respiratory alkalosis due to central respiratory stimulation [141]. Metabolic acidosis may complicate the picture, however, especially in children. Because toxic levels of salicylate are considerably less than 10 mM (140 mg/dl), the elevation of the plasma anion gap in salicylate-associated metabolic acidosis is caused by the accumulation -HB, sometimes L-lactate anions, and other unidentified organic anions in addition to a small contribution by salicylates. Acidemia is uncommon because of coexisting respiratory alkalosis.

Treatment of Salicylate Intoxication

Treatment of salicylate intoxication is aimed at increasing urine salicylate excretion and preventing the accumulation of salicylates in brain cells. Salicylate is a weak organic acid that is transported across cells and renal epithelia, in its undissociated form. Alkalinizing the urine reduces salicylate reabsorption by the kidney and this may enhance its excretion; similarly, alkalinizing the ECF tends to prevent salicylate accumulation in cells, so acidemia should be avoided.

Alkalinizing the urine can be achieved with $NaHCO_3$ administration. The major risk of this therapy is excessive elevation of blood pH because of coexistent respiratory alkalosis and the risk of worsening pulmonary or cerebral edema. If the blood pH exceeds 7.55 as a result of this therapy, one dose of acetazolamide (250 mg) should be given to induce bicarbonaturia. Although acetazolamide causes an acid disequilibrium pH in the lumen of the PCT, it still promotes salicylate excretion [142]. One must avoid larger doses of acetazolamide as this may induce significant meta-

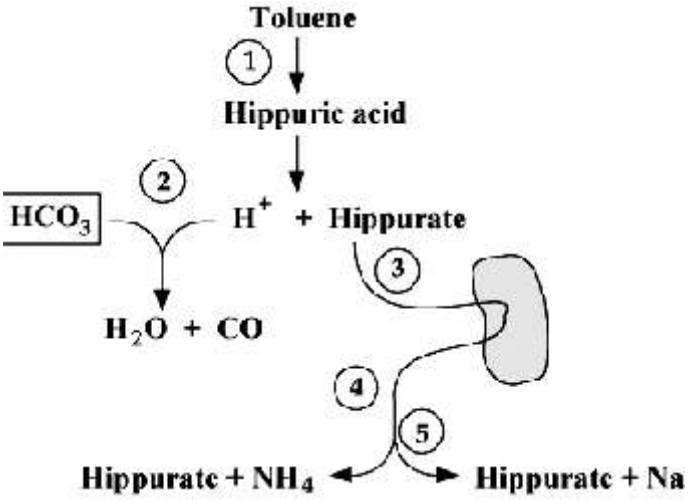

Figure 23. Metabolic acidosis due to the metabolism of toluene. The metabolism of toluene occurs in the liver. It is initiated by cytochrome P450, and then benzoic acid is produced via alcohol and aldehyde dehydrogenases. Hippuric acid is produced due to conjugation with glycine (all represented as site 1 for simplicity). The H^+ are titrated by HCO_3^- for the most part (site 2). The hippurate anion is secreted by the PCT and excreted in the urine, initially with NH_4^+ (site 4) and then with Na^+ and K^+ when the capacity to excrete NH_4^+ is exceeded (site 5). The excretion of hippurate anions with Na^+ and/or K^+ (and not NH_4^+) is the main reason for the metabolic acidosis.

bolic acidosis. Of more importance, acetazolamide will bind to albumin and displace bound salicylates thereby increasing its toxicity [143]. Acetazolamide also causes excessive losses of K^+ in the urine due to inducing bicarbonaturia.

In severe intoxications complicated by the adult respiratory distress syndrome, cardiovascular instability, evidence of cerebral edema, and possibly with severe elevations in salicylate level per se (greater than 6 mM), hemodialysis is the treatment of choice; if hemodialysis is not available, peritoneal dialsis may be used.

Metabolic Acidosis due to Glue-sniffing

Patients who sniff glue for its intoxicating properties absorb a significant quantity of toluene (methylbenzene). Toluene is metabolized via a series of reactions in the liver to hippuric acid that provides the load of H^+ (Figure 23). Despite the production of the hippurate anion, the plasma anion gap is generally not significantly elevated because the kidney, both via filtration and more importantly by tubular secretion, very efficiently excretes hippurate. As a result, there is the development of a hyperchloremic type of metabolic acidosis. Together with the anion excretion, variable amounts of urinary excretion of Na^+ and K^+ may be seen, leading to a degree of ECF volume contraction and hypokalemia, both of which aggravate the degree of intracellular acidosis (Figure 7). Even though there is an enhanced rate of excretion of NH_4^+, this does not result in a negative urine net charge (i.e., $U_{Na+K} > U_{Cl}$, Figure 11) because of the very high rate of excretion of the hippurate anion. The presence of NH_4^+ and hippurate in the urine could be detected by the presence of a significant urine osmolal gap (Figure 11). Thus the clinical features of toluene intoxication include metabolic acidosis, near-normal plasma anion gap, normal plasma osmolal gap, ECF volume contraction, hypokalemia, lower than expected BUN and

a high urine osmolal gap. It had formerly been thought that glue-sniffing was a cause of distal RTA [144], but the high rate of excretion of NH_4^+ in response to the metabolic acidosis in many of these patients means that they do not have distal RTA. Some patients may have another reason for a low rate of excretion of NH_4^+ (e.g., a low GFR) so they have two reasons for the metabolic acidosis, excessive overproduction of hippuric acid and a low rate of NH_4^+ excretion. If the GFR is low enough, there may now be a high anion gap in plasma [21].

Treatment of Metabolic Acidosis due to Glue-sniffing

The treatment of toluene inhalation requires that each of these clinical features be addressed. When the inhalation of toluene stops, ultimately the production of hippuric acid will be diminished, but there can be a lag of 1 – 3 days before there is little hippuric acid generation because of the large volume of distribution of toluene [21]. Hypokalemia and ECF volume contraction need to be corrected with the administration of KCl and saline, according to their severity. If metabolic acidosis is particularly severe, consideration should be given to the use of $NaHCO_3$ because there is no anion present in the body that can be metabolized to HCO_3^-. The major caveat to the use of $NaHCO_3$ in this setting is that coexisting K^+ depletion could be severe. Given the risk of a cardiac arrhythmia, the P_K must be raised first to the low 3 range before $NaHCO_3$ is administered because of the concern that $NaHCO_3$ may exacerbate hypokalemia.

Organic Acid Load from the GI Tract (D-lactic Acidosis)

Certain bacteria in the gastrointestinal (GI) tract may convert carbohydrate (cellulose and fructose) into organic acids. The three factors that make this possible are slow GI transit (blind loops, obstruction), change of the normal flora (usually with antibiotic therapy), and the supply of carbohydrate substrate to these bacteria (foods containing fructose or sorbitol [145] (Figure 24, [70]). The most prevalent organic acid is D-lactic acid [71]. Humans metabolize this D-isomer somewhat more slowly than L-lactate, but acidosis per se rarely is life-threatening. Although humans lack the enzyme D-lactate dehydrogenase, metabolism of D-lactate occurs via the enzyme D-2-hydroxy acid dehydrogenase.

There are three additional points that should be noted with respect to D-lactic acidosis. First, the usual clinical laboratory test for lactate is specific for the L-lactate isomer. Hence the usual laboratory measurement for lactate will not be elevated. Second, GI bacteria produce amines, mercaptans, and other compounds that may cause the clinical symptoms related to CNS dysfunction (personality changes, gait changes, confusion, etc.). Third, some of the D-lactate will be lost in the GI tract or in the urine (if the GFR is not too low) [146, 147]. Hence the degree of rise in the plasma anion gap may not be as high as expected for the fall in the P_{HCO3}.

Treatment should be directed at the GI problem. The oral intake of fructose and complex carbohydrates should be decreased. Antacids should be avoided to decrease the rate of fermentation. Insulin may be helpful by lowering the rate of oxidation of fatty acids and hence permit a higher rate of oxidation of organic acids (Figure 25). Antibiotics could be considered to change the bacterial flora.

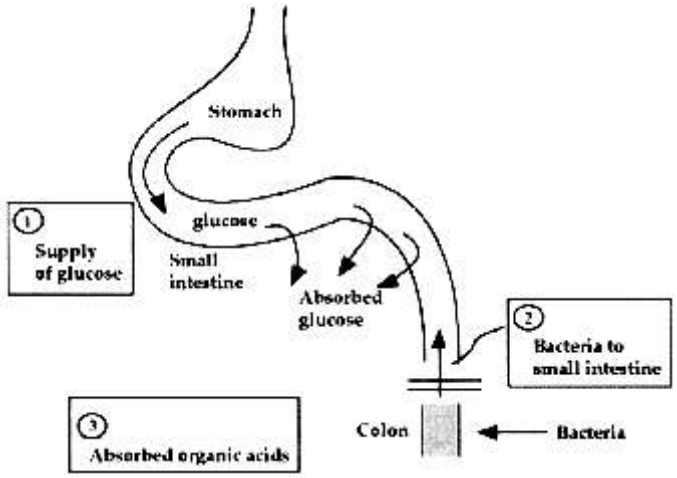

Figure 24. Organic acid production in the GI tract. Bacteria are normally segregated from dietary sugar by GI "geography". For overproduction of D-lactic acid, bacteria in the lower GI tract must mix with sugars. The supply of sugar is critical for organic acid production. Bacteria migrate up to and proliferate in the small intestine. When provided with sugar in this "friendly environment", fermentation produces a variety of organic acids and noxious alcohols, aldehydes and amines; more are produced if more alkali is supplied. There must also be enough mucosal surface area to transport these acids into the body and cause the high plasma anion gap; otherwise the H^+ produced might simply destroy luminal HCO_3^- from the secreted $NaHCO_3$ and lead to the loss of Na^+ plus D-lactate in the stool (a normal anion gap type of metabolic acidosis). The degree of the acidosis also depends on the rate that these organic acids can be oxidized and/or converted to glucose or fat (primarily in the liver).

Pyroglutamic Acidosis

The list of causes of metabolic acidosis with a high anion gap in plasma does not usually include pyroglutamic acidosis (PGA) because it was thought to represent primarily rare inborn errors of metabolism in the glutathione synthesis pathway (defects in 5-oxoprolinase or in glutathione synthetase, Figure 26) [148, 149]. Notwithstanding, there have been an increasing number of case reports where PGA accumulated and caused metabolic acidosis with an increase in the anion gap in plasma [131, 150 – 152]. When plasma levels of PGA rose to the 5 – 10 mM range, the 24-h urine contained 50 – 150 mmol of PGA [131, 150, 151]. The question raised by these observations is, what is responsible for the accumulation of PGA?

Key to the understanding of the accumulation of PGA is the fact that the reduced form of glutathione (GSH) feeds back to inhibit the enzyme (-glutamylcysteine synthetase) that catalyzes the first step in the cycle that leads to the synthesis of glutathione, the conversion of glutamate to -glutamylcysteine (Figure 26) [153].

A major function of reduced glutathione is to detoxify reactive oxygen species (ROS). In this process, the reduced form of GSH is converted to its oxidized form (GS-SG) (Equa-

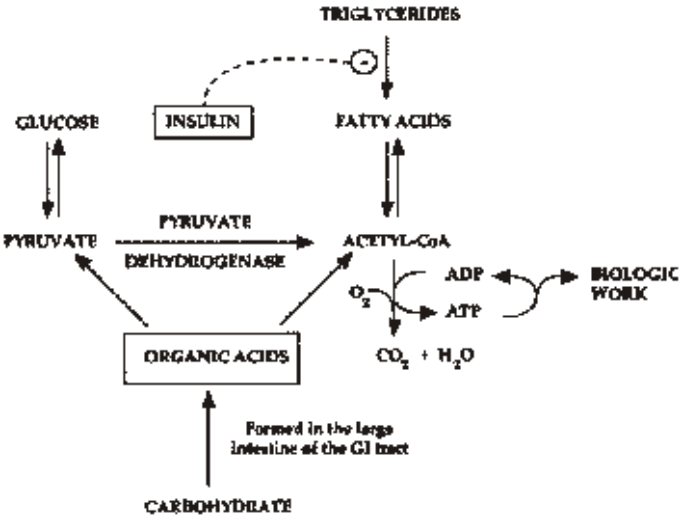

Figure 25. Strategies for therapy in D-lactic acidosis. There are two families of organic acids depending on whether they yield pyruvate or acetyl-CoA, bypassing pyruvate as a metabolic product. Organic anions that cannot be converted to pyruvate can only be oxidized, converted to storage fat, or be converted to ketoacids, but are not substrates for the synthesis of glucose. Fatty acid synthesis only occurs at appreciable rates when insulin levels are high (with meals). If insulin acts and depresses the rate of oxidation of fatty acids, more organic acids may be oxidized [70].

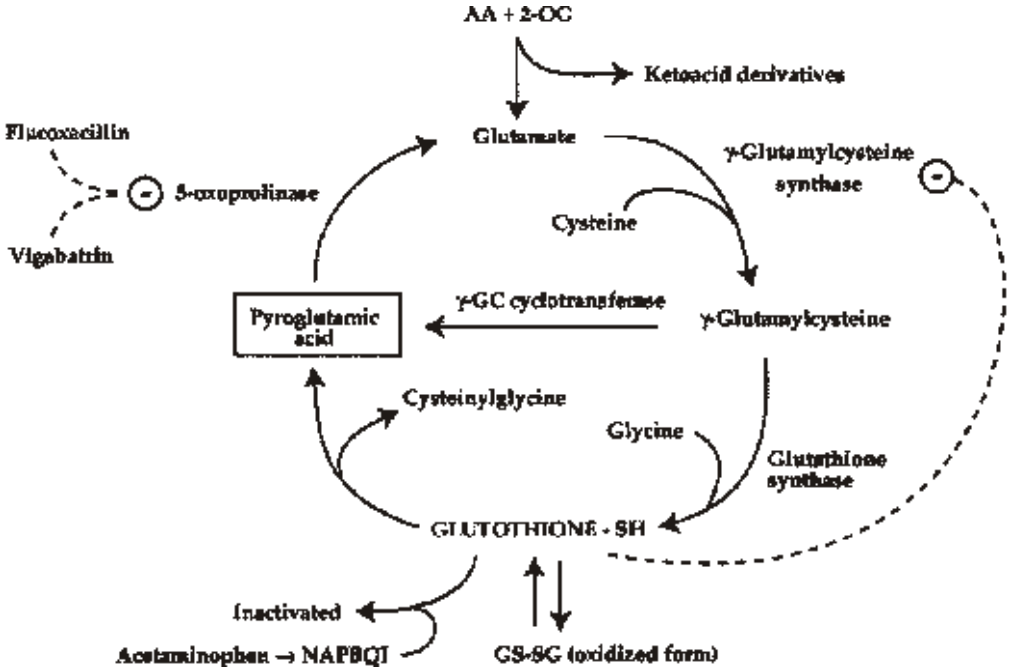

Figure 26. Production of pyroglutamic acid. The pathway begins with glutamate, a key intermediate in transamination reactions. When there are low levels of reduced glutathione (e.g., due to combination with a metabolite of acetaminophen), the production of -glutamylcysteine is stimulated. If the -glutamylcysteine so-formed accumulates, pyroglutamic acid will be formed. In addition, if 5-oxyprolinase is inhibited, pyroglutamic acid will also accumulate. As described in the text, a diminished ability to detoxify ROS is likely to be more important than the acidosis in this setting. Reproduced with permission [187].

tion 13). Hence when ROS accumulate, the concentration of GSH declines and this leads to an accelerated formation of -glutamylcysteine (-GC). This -GC will be converted to PGA by the enzyme -glutamylcysteine cyclotransferase when its concentration rises (Figure 26). Components of the glutathione cycle reside in different compartments of the cell [1]. This adds to the complexity of understanding the regulation of this feedback system.

2 GSH + ROS GS-SG + Inactive ROS (13)

PGA can be synthesized from glutamate when an internal peptide bond forms between its -carboxyl group and the free -amino group (i.e., if glutamate is free or the N-terminal amino acid is a peptide or protein) as long as the latter's -carboxyl group is in an activated state. A number of drugs have been identified as potential causes of PGA acidosis. Some like acetaminophen, after conversion to a metabolite N-acetyl-p-benzoquinonimide (NAPBQI), decrease the concentration of GSH, thereby driving the synthesis of -glutamylcysteine, and thereby PGA (Figure 26). Other drugs (e.g., the antibiotic flucloxacillin [150] and the anticonvulsant, vigabatrin [154]) may inhibit 5-oxoprolinase. A third mode of action could be with drugs or inborn errors of metabolism (e.g., G6PDH deficiency) that result in a diminished concentration of NADPH, the cofactor that reduces GS-SG to GSH [1] (Equation 13).

Acid-base aspects: Applying concept 1 to this pathway, H^+ will only accumulate when the precursor of pyroglutamic acid is glutamine providing that the NH_4^+ so-formed is metabolized to urea in the liver (Equation 14).

Glutamine Glutamate$^-$ + NH_4^+
Pyroglutamate$^-$ + NH_4^+ Urea + H^+ (14)

Renal Acidosis

As described in Table 6, renal disorders may cause metabolic acidosis with either a normal or an increased anion gap in plasma. Most causes have in common a reduced rate of NH_4^+ excretion [56]; in contrast, with a recent onset of proximal RTA, the excretion of HCO_3^- may also contribute to the degree of metabolic acidosis. Whether the plasma anion gap will be elevated or not depends primarily on the GFR. For example, if the GFR is very low, anions such as phosphate and SO_4^{2-} need to have higher concentrations in plasma to be excreted at their usual rate. This in turn leads to a rise in the plasma anion gap (Figure 6), but it does not usually exceed 22 mEq/l or about 10 mEq/l above normal. In this semiquantitative interpretation, it is important to examine the concentration of albumin in plasma because this is the most important constituent of the normal plasma anion gap and hypoalbuminemia is not an uncommon finding in this group of patients. The possible molecular basis for a low rate of excretion of NH_4^+ (Figure 5) or a high rate of excretion of HCO_3^- is shown in Figure 27.

Clinical Approach to a Patient with HCMA

Patients who have HCMA can be divided into three broad categories based on the rate of excretion of components of net acid (Table 18). Our approach to patients with HCMA starts with an assessment of the rate of excretion of NH_4^+ (Figure 28). A low rate of excretion of NH_4^+ is the key finding in patients with distal RTA; it is also expected in patients with proximal RTA and an alkalinized PCT ICF pH. In the latter group, the low rate of excretion of NH_4^+ is usually due to a diminished rate of production of NH_4^+ because of excessive distal delivery of HCO_3^- from the PCT. If an assay of urine NH_4^+ is not available, the

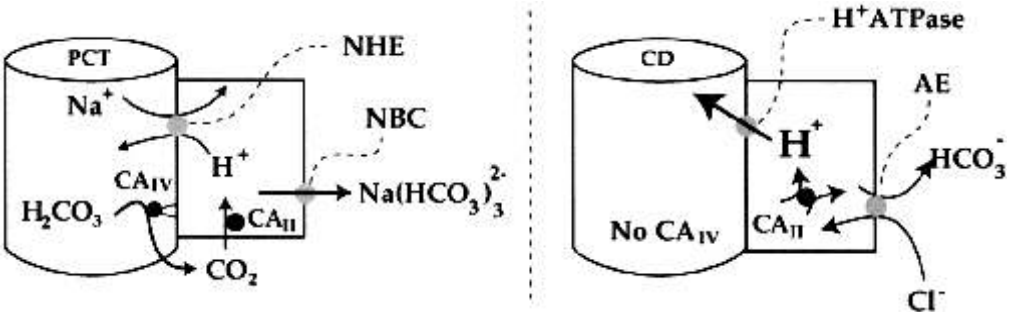

Figure 27. Molecular components for H^+ and HCO_3^- transport in the nephron. The events in the PCT are shown in the left portion of the figure and the events in the collecting duct (CD) are shown in the right portion of the figure. Carbonic anhydrase (CA) is depicted by the small solid circles. Abbreviations: NHE = Na^+/H^+ exchanger in the PCT; NBC = $Na(HCO_3)_3^{2-}$ exit step in the PCT; AE = Cl^-/HCO_3^- anion exchanger.

urine osmolal gap should be used to reflect this excretion rate (Figure 11).

If the rate of excretion of NH_4^+ is high in a patient with HCMA (e.g., overproduction of -hydroxybutyric acid) (Figure 28), a renal component to the acidosis could be present if there is a large loss of the metabolizable -hydroxybutyrate anions in the urine [155]. It should be clear that the main cause of the metabolic acidosis in this patient is overproduction of organic acids; nevertheless, the severity of the acidosis may be aggravated by the presence of a renal lesion that leads to the loss of organic anions (potential HCO_3^-) in the urine. An excessive rate of excretion of organic anions in the urine is suspected if the sum of $Na^+ + K^+ + NH_4^+$ in the urine greatly exceeds that of Cl^- (Figure 11).

In a patient with HCMA and a low rate of excretion of NH_4^+, the basis for low NH_4^+ excretion can be deduced from the urine pH. If the urine pH is greater than 7, one should examine the secretion of H^+ in the PCT (reabsorption of HCO_3^-) and in the distal nephron (Figure 28). We recommend examining the PCO_2 in alkaline urine to detect whether there

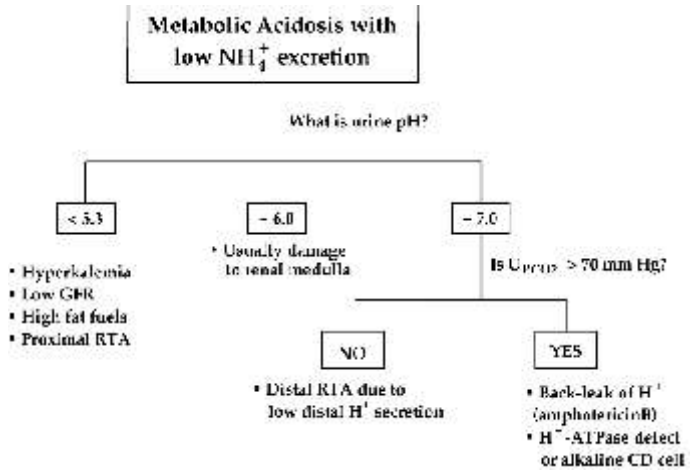

Figure 28. Approach to patients with HCMA. If there is a low rate of excretion of NH_4^+, the urine pH is helpful to determine whether a low distal and/or proximal H^+ secretion or a low NH_3 availability was the cause for the low rate of NH_4^+ excretion.

is a defect in distal H^+ secretion. If urine PCO_2 is < 70 mm Hg, a primary H^+ATPase pump defect or an alkaline -intercalated collecting duct cell pH (e.g., CA_{11} deficiency) should be suspected. This latter lesion also involves the PCT, causing proximal RTA. If urine PCO_2 > 70 mm Hg, suspect a back leak of H^+ from the collecting duct or a defect causing distal HCO_3^- secretion (e.g., a mis-targeted Cl^-/HCO_3^- anion exchange.

HCMA with a low rate of excretion of NH_4^+ and a low value for the urine pH (the actual value is difficult to define precisely, but we consider a low value to be less than 5.3) suggests that there is a reduced availability of NH_4^+/NH_3 in the renal medullary interstitial compartment (Figure 12). The usual causes for the low NH_4^+/NH_3 subgroup are a low GFR or hyperkalemia (Table 18). In their absence, we would look for low levels of glutamine [158], the substrate in plasma for renal ammoniagenesis, and/or a high level of fat-derived fuels (e.g., patients on TPN), because these fuels may compete with glutamine as the source for regeneration of ATP in cells of the PCT [159], and hence lead to a lower rate of production of NH_4^+. Patients with proximal RTA also have a low rate of excretion of NH_4^+. This could be due to an alkaline PCT cell or it could be part of a generalized PCT cell dysfunction (the Panconi syndrome [156, 157]). Both of these groups of patients will have hypercitraturia despite the presence of metabolic acidosis. In the former group, the hypercitraturia is due to an alkaline PCT cell and may disappear if an acid load were administered. In the latter group, the hypercitraturia is part of the generalized PCT cell transport defects.

Loss of $NaHCO_3$ in the Urine

The initial mechanism for the acidosis in patients with proximal RTA is the loss of HCO_3^- in the urine. In contrast, once a steady state supervenes, chronic metabolic acidosis is sustained because the rate of NH_4^+ excretion is much lower than expected in this setting [30, 31]. As mentioned above, these patients will have hypercitraturia despite having metabolic acidosis. The defect in proximal HCO_3^- reabsorption can be demonstrated by finding a FE_{HCO3} that exceeds 10 – 15% during $NaHCO_3$ loading. This, however, need not be performed because the diagnosis is usually evident when large doses of $NaHCO_3$ fail to the P_{HCO3} the normal range. Proximal RTA can occur as an isolated defect [160] or as part of a generalized proximal tubular cell dysfunction (Fanconi's syndrome with a glucosuria, phosphaturia, aminoacidosis, uricosuria and citraturia among others) [156]. The major causes of proximal RTA in adults include increased blood levels of monoclonal immunoglobulins found in patients with multiple myeloma and patients who use the carbonic anhydrase inhibitor, acetazolamide. In contrast, cystinosis [161] and the use of ifosfamide [162] are the most common causes of proximal RTA in children. The hereditary isolated proximal RTA is a rare autosomal recessive disease that can present with ocular abnormalities such as band keratopathy, cataracts and glaucoma [163]. Mutations in the gene encoding for the $Na(HCO_3)_3^{2-}$ cotransporter (NBC1) has been identified in these families. The autosomal dominant form may be caused by mutations in the gene for NHE [164].

Recently, the use of Chinese herbs was described as a cause of the Fanconi's syndrome [165]. Typical Chinese herb nephropathy is associated with acellular interstitial fibrosis and tubular atrophy. Some of these patients

have a profound degree of hypokalemia with muscle paralysis as the presenting feature [166]. Hypokalemia in other causes of the Fanconi's syndrome is usually absent or mild in degree.

The pathological mechanisms of Fanconi's syndrome due to Chinese herb remain unclear. Aristolochic acid found in the Chinese herb has an inhibitory effect on calcium-dependent phospholipase A_2. This may in turn lead to a defect in energy-producing or energy-linked transporting mechanisms and/or have a direct toxic effect on the brush-border membrane of the tubular cells that may cause renal tubule injury with the resultant Fanconi's syndrome.

From a therapeutic standpoint, the acidosis in these patients is usually mild and complications due to the acidosis are minor. These facts alone argue against alkali therapy in adults. In addition, if exogenous $NaHCO_3$ is given, as the P_{HCO3} rises temporarily, but its excretion will also rise markedly. A large increase in delivery of Na^+ and HCO_3^- to the CCD may augment the secretion of K^+ [84], resulting in hypokalemia and possibly nephrocalcinosis. In contrast, alkali therapy is useful in children to prevent growth retardation [167].

Cause of a Low Rate of Excretion of NH_4^+

Renal failure: As the GFR falls, the synthesis of NH_4^+ declines in the PCT due to ATP turnover constraints [33]. Metabolic acidosis is therefore a common finding with advanced renal insufficiency, although the degree of acidosis is variable. It is rarely severe enough to require urgent therapy with $NaHCO_3$. On the other hand, chronic metabolic acidosis may contribute to fatigue and anorexia, and also skeletal muscle wasting [168] and bone disease [169]. Therefore it is reasonable to give oral $NaHCO_3$ to these patients to maintain the P_{HCO3} close to 20 – 25 mM making certain that the Na^+ load does not lead to hypertension or congestive heart failure. With the onset of dialysis therapy, acid-base balance is maintained by the addition of $NaHCO_3$ or a metabolic precursor of HCO_3^- (e.g., acetate, L-lactate) added to the dialysis fluid.

Distal RTA (classical RTA): The hallmark of distal RTA is a low rate of excretion of NH_4^+ in a patient with chronic metabolic acidosis, a normal value for the anion gap in plasma, and a GFR that is not markedly reduced [56]. Having defined these components, the next step is to find out why the rate of excretion of NH_4^+ is lower than expected in this setting. We rely on the urine pH at this point to separate the patients into 3 categories, those with a primary problem with NH_3 availability (urine pH less than 5.3), those where there is a structural lesion in the renal medulla that compromises both medullary NH_3 availability and distal H^+ secretion (urine pH close to 6), and those with a defect in net distal H^+ secretion (urine pH close to 7). In this latter group, the low rate of excretion of NH_4^+ is due primarily to reduced distal H^+ secretion per se and/or to an excessive amount of HCO_3^- delivered to or secreted in the distal nephron (Figure 29). Generalized medullary damage with a urine pH that is close to 6 is the most common clinical subgroup [53]. Autoimmune disorders (such as Sjögren's syndrome and rheumatoid arthritis, hypergammaglobulinemia) are the most common causes of distal RTA with a very high urine pH in adults [56]. RTA in patients with Sjögren's syndrome seems to be due to a defect in H^+ secretion in the distal nephron. In some of these patients, there was an absence of the H^+-ATPase pump in intercalated cells of the collecting tubule as revealed by an immunocytochemical analysis of tissue obtained by renal biopsy [170]. It is not known how the immune injury leads to the loss of

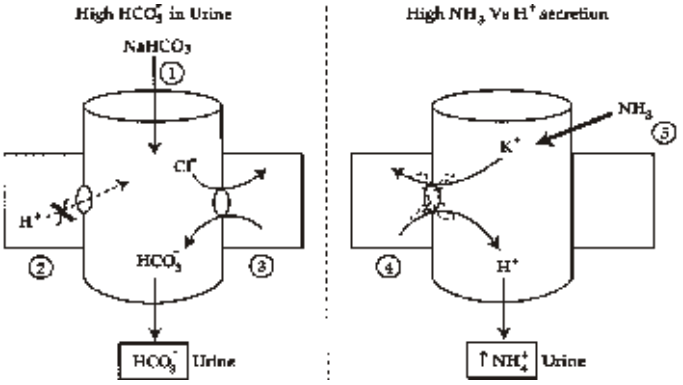

Figure 29. Basis for a high urine pH. There are two subgroups to consider. First, those where the net addition of HCO_3^- by failing to reabsorb $NaHCO_3$ in upstream nephron segments (site 1) or via secretion in the MCD via AE (site 2), exceeds the usual H^+ secretion by the H^+-ATPase in the CCD and MCD (site 2). Second, as shown to the right of the dashed line, those where there is a high medullary NH_3 concentration (due to enhanced PCT production of NH_4^+, site 5) exceeds the secretion of H^+ by the H^+/K^+ ATPase in the MCD (site 4).

H^+-ATPase activity. It has also been suggested that the defect may be due to autoantibodies against carbonic anhydrase II, as high levels of these antibodies were detected in some patients. If these antibodies could enter cells, one would also expect to find a defect in H^+ secretion in the PCT. Ifosfamide, an analog of cyclophosphamide, is also a cause of proximal and distal RTA in both children and adults [162].

Hereditary RTA is most common cause in children [171]. Familial distal RTA is inherited in both dominant and recessive patterns. The autosomal dominant form is associated with mutations in the gene encoding for the AE [172]. Red blood cells of these individuals display normal AE polypeptide abundance. These mutant forms show only a modest reduction in function and do not have a dominant negative effect when expressed in heterologous systems. It is not clear how these mutations lead to the phenotype of distal RTA. In vivo defects in stability, trafficking or sorting of these mutant anion exchangers are possible mechanisms. In Caucasians, AE1 has not been associated with the recessive form of distal RTA; however, AE1 mutations are the major cause of recessive distal RTA in Thailand, Malaysia and Papua New Guinea [173]. In those Southeast Asian patients in whom distal RTA is associated with ovalocytosis, compound heterozygotes of AE1 plus distal RTA mutations with the in-frame deletion ovalocytosis mutation were found [174]. Altered targeting of the mutant AE1 was suggested in one patient with distal RTA and Southeast Asian ovalocytosis because of a high U-B PCO_2 in alkaline urine [175].

Mutations in the gene encoding for the V_1 subunit B1 of the apical membrane vascular H^+-ATPase have been described to cause autosomal recessive distal RTA and bilateral sensorineural hearing loss [176]. Recessive distal RTA without deafness due to mutations in the a V_0 subunit of the H^+-ATPase have also been reported [177]. Mutations in the cytoplasmic carbonic anhydrase II are inherited in autosomal recessive fashion [178]. Patients with this disorder exhibit osteopetrosis, cerebral calcification and defect in H^+ secretion in both the PCT and the distal nephron.

While nephrocalcinosis may be a consequence of distal RTA, hypercalciuria and nephrocalcinosis seem to be the primary events leading to distal RTA in patients with

Dent's disease [179]. Dent's disease is characterized by low molecular weight proteinuria, hyperphosphaturia, hypercalciuria. The ClC-5 chloride channel has been identified as the mutated gene in patients with Dent's disease [180].

RTA with hypokalemia: Distal RTA is often complicated by hypokalemia [181] (the high luminal concentration of HCO_3^- stimulates net secretion of K^+ in the CCD [84], see Chapter on K^+ for more discussion). If distal RTA is present with a severe degree of hypokalemia (P_K < 2 mM), symptoms of muscle weakness or even paralysis might be present [182]. Of greater importance, there is a danger of a cardiac arrhythmia, especially if the EKG is significantly abnormal. Even if the degree of metabolic acidosis is severe, the administration of alkali alone could cause movement of K^+ into cells, worsening the degree of hypokalemia with resultant cardiac effects and/or acute respiratory acidosis. In this circumstance, there is a better strategy for therapy. KCl should be given first; larger amounts can be given safely by the oral or by a nasogastric tube than intravenously providing that the patient can absorb this K^+ load – i.e., that bowel sounds are present. Glucose-containing solutions should be avoided, since they may stimulate insulin release, which may cause an acute shift of K^+ into the cells. Although the addition of K^+-sparing diuretics such as amiloride will reduce the ongoing urine K^+ loss, their quantitative effect is very small and they may provoke hyperkalemia later on; hence we do not recommend their use in this setting. Administration or larger amounts of $NaHCO_3$ should be delayed until the P_K is above 3.0 mM. In the absence of serious hypokalemia, one then asks, how much alkali is required? The answer is not easy to deduce. One must ultimately give enough $NaHCO_3$ to bring the P_{HCO3} to the normal range. Thereafter, the dose of $NaHCO_3$ needed can be deduced. Since the daily normal acid load from the diet is usually about 70 mmol/day [7]. Since urine net acid excretion is usually reduced but not absent, considerably less $NaHCO_3$ is usually required. Supplemental K^+ is often needed as well.

Distal RTA with hyperkalemia: In some classifications, this is called type IV RTA. We do not think that this nomenclature is particularly helpful and prefer a classification that is based on pathophysiology (see reference Kamel et al. 1997 [56] for more discussion). Reduced excretion of NH_4^+ is commonly associated with hyperkalemia [32]. Hyperkalemia leads to reduced excretion of NH_4^+ primarily because it inhibits ammoniagenesis. This subtype of low excretion of NH_4^+ is recognized by finding a low urine pH (usually < 5.3) (Figure 30). A more detailed discussion of hyperkalemia can be found in the Chapter on Potassium in this book.

Therapy depends on the pathogenesis of the hyperkalemia and on the patients' ECF volume status. In patients with hypoaldosteronism due to adrenal disease, ECF volume and blood pressure are usually reduced and al-

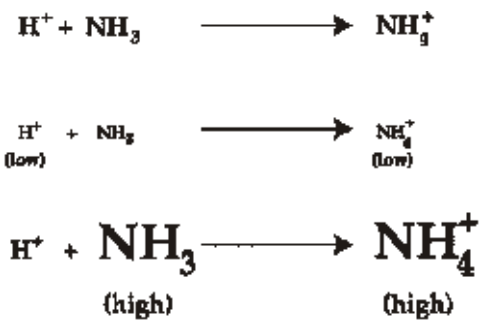

Figure 30. Types of incomplete renal tubular acidosis. The top line depicts the normal state. There are two major causes of a high urine pH. First, there is occult distal RTA due to low distal H^+ secretion in conjunction with the ingestion of a net alkali load (line 2). Second, there is an over-production of NH_4^+ in the PCT due to an acidified PCT cell, the result of a lower activity of the $Na(HCO_3)_3^{2-}$ exit step (see Figure 27).

dosterone replacement with 0.05 – 0.1 mg 9 -fludrocortisone per day plus saline administration is the treatment of choice. Glucocorticoid deficiency, if present, should be corrected. Patients with hyperkalemia due to a faster reabsorption of Cl^- in the CCD are frequently ECF volume expanded and hypertensive (see section on K^+ for more details) [183, 184]. In these patients, 9 -fludrocortisone is of no benefit for the treatment of the hyperkalemia and it may aggravate the degree of Na^+ retention. Additional therapeutic alternatives would include diuretics such as furosemide to increase the excretion of K^+ and Na^+. Correction of hyperkalemia by either mechanism should increase the excretion of NH_4^+ sufficiently to correct the metabolic acidosis.

Incomplete RTA: The cardinal features here are a high urine pH and the absence of acidemia. This persistently alkaline urine pH leads to a high urinary concentration of divalent phosphate and precipitation of Ca phosphate stones (brushite ($CaHPO_4$) stones). There are 3 possible subgroups included in this definition. In the first, a high dietary alkali load is responsible for the high urine pH. The rate of excretion of NH_4^+ is low and citrate excretion is high. The second subgroup of patients may have a high alkali intake plus reduced distal H^+ secretion. This group will have the unique finding of a low urine PCO_2 in alkaline urine. The third subgroup seem to have an acidified PCT pH despite the absence of systemic acidemia [185]. These patients have a high rate of excretion of NH_4^+ relative to their urine pH. Their intracellular acidosis in the PCT should stimulate the production of NH_4^+ and this will lead to a high concentration of NH_3 in the medullary interstitium (Figure 28). Accordingly, this higher delivery of NH_3 as compared the rate of H^+ secretion in the distal nephron will result in a urine pH that is high. Because of an acidified PCT cell pH, these patients have a very low rate of excretion of citrate, which also increases their risk of renal calcium-containing stones.

Respiratory Acid-base Disorders

Control of PCO_2 is important in acid-base physiology. Changes in the arterial PCO_2 result in alterations in the plasma H^+ concentration; far more important, however, is that a change in the venous PCO_2, which reflects the PCO_2 in cells, results in more or less binding of H^+ to intracellular proteins which could change their configuration, and thereby their function (Figure 7). The value for the arterial PCO_2 reflects the concentration of CO_2 in alveolar air required for balance between CO_2 production (metabolism) and CO_2 removal (alveolar ventilation).

CO_2 production: There is a very large production of CO_2 relative to the concentration of CO_2 in the plasma (i.e., 10 mmol of CO_2 are produced per minute, yet the arterial PCO_2 and H_2CO_3 are only 1.2 mmol of CO_2 per liter of blood). The rate of production of CO_2 is determined by the amount of metabolic and mechanical work, and to a lesser extent, the fuels being utilized (oxidation of carbohydrates yields more CO_2 relative to ATP production than does the oxidation of fat-derived fuels [2]).

CO_2 removal (alveolar ventilation): Normal ventilation is mediated by interaction between the central respiratory centers, peripheral chemoreceptors, respiratory muscles, and lung parenchyma. A major clinical task is to consider why ventilation is abnormal; this requires a detailed clinical analysis, but for brevity, it will not be provided here.

Effect of an abnormal PCO_2: With CO_2 accumulation, $H^+ + HCO_3^-$ are produced in equimolar amounts (Equation 3) even though

the P_{HCO3} normally exceeds the concentration of H^+ by close to 10^6-fold. Failure to remove CO_2 at a low enough concentration leads to respiratory acidosis because of the generation of H^+ by displacement of the BBS equilibrium to the left. Excessive ventilation causes a low PCO_2 and this results in respiratory alkalosis via displacement of the equilibrium to the right. In chronic respiratory acidosis, there is an increase in the rate of reabsorption of HCO_3^- by the PCT which results in an elevation in the P_{HCO3} which minimizes the fall in the plasma pH due to the respiratory acidosis; the converse changes occur in chronic respiratory alkalosis. Since these expected values differ in acute and chronic respiratory acid-base disturbances, it is important for the clinician to determine, on clinical grounds, whether the acid-base disturbance is acute or chronic in origin.

Although respiratory acid-base disorders are defined by changes in the arterial PCO_2, important clinical information can also be derived by interpreting the arterial PO_2. The arterial PO_2 is a function of the PO_2 of alveolar air, the diffusion of O_2 across the alveolar capillary membrane, and the degree of unsaturation of venous blood. The alveolar PO_2 is calculated as the inspired PO_2 – 1.25 X the arterial PCO_2. The A-a difference can also clarify whether hypoxemia is due to lung disease or central suppression of ventilation; in the latter case, the A-a difference should be normal. The normal value for the A-a difference depends on age and is up to 15 mmHg, but larger values are seen when more O_2 is extracted from each liter of blood in the capillary.

There are two major types of pulmonary lesions that cause the arterial PO_2 to be substantially lower than that of alveolar air:

– Blood could pass from the pulmonary artery to the pulmonary vein without perfusing alveoli that have a high PO_2 (i.e., a shunt that prevents a good exchange of air). Most lung diseases that cause hypoxemia are numerous small areas of shunting as well as areas of non-ventilated, non-perfused lung; together, these lesions lead to ventilation-perfusion mismatch.
– There might be a barrier to diffusion of O_2 from alveolar air to the capillaries in lungs. The magnitude of the A-a difference is a parameter to be evaluated when trying to decide if a pulmonary condition is improving or worsening.

While the A-a difference is widely used clinically, there are several pitfalls that must be kept in mind:

– For the calculation of the A-a difference, one utilizes the arterial PO_2 that provides a poorer reflection of the content of O_2 than does the O_2 saturation. Thus, the same reduction in O_2 content will have a different impact on the PO_2 at different sites on the oxygen-hemoglobin dissociation curve because this function is sigmoid rather than linear.
– If a fixed volume of venous blood is shunted into arterial blood, the lower its O_2 content, the greater the ultimate fall in arterial PO_2.
– If the cardiac output is lower, but the same volume of blood is shunted from the venous to the arterial side of the circulation as in normal subjects, the decline in arterial PO_2 will now be greater because more O_2 is lost on a per liter of arterial blood basis.
– The PO_2 of inspired air must be known. When patients are receiving O_2 by mask or nasal prongs, the inspired PO_2 may not be known with sufficient accuracy. Therefore, the A-a difference is most useful when patients are breathing room air or are on ventilators with a measured content of inspired PO_2.

– In the calculation of the alveolar PO_2, one must estimate the amount of O_2 removed and replaced by CO_2. To do so, one uses the arterial PCO_2 and assumes an RQ of 0.8. The RQ could be 1 if carbohydrate is the only type of fuel being metabolized and 0.7 with fat as the sole fuel.

Respiratory acidosis, clinical approach: Patients who hypoventilate can be divided into two groups: those who will not breathe appropriately (defective stimulus) and those who cannot breathe appropriately (defective respiratory "equipment"). In addition, patients with a fixed alveolar ventilation (i.e., those on ventilators) develop increased arterial PCO_2 if they have an increased rate of production of CO_2 or an increase in dead space (e.g., pulmonary embolus).

Diagnostic approach: The first step is to decide if the patient has chronic lung disease by the history, physical exam, and available past records. Next, one compares the acid-base status with that expected for that acid-base disorder (Table 4). If a discrepancy exists, a mixed disorder is present. In acute and chronic respiratory acidosis in patients who were previously normal, an empirical linear relationship has been found between the concentration of H^+ and the arterial PCO_2. In essence, there is close to a 3 – 3.5 mM change in the P_{HCO3} for every 10 mmHg parallel change in the arterial PCO_2 and close to a 1 mM change in the P_{HCO3} in acute disorders.

Patients with chronic obstructive pulmonary disease are often on diuretics and may have a coexistent metabolic alkalosis. Because H^+ stimulate ventilation, a lower concentration of H^+ can make the hypoventilation more severe. Interestingly, correction of the metabolic alkalosis in these patients does not result in a large change in their concentration of H^+; instead, there is a significant fall in both the P_{HCO3} and the arterial PCO_2, coupled with an increase in the arterial PO_2. These changes may be associated with a dramatic clinical improvement [186]. It is tempting to speculate that the clinical improvement is due, in part, to the reduction in H^+ buffering on the ICF proteins [4].

Respiratory alkalosis, clinical approach: Respiratory alkalosis is a common abnormality that is often ignored. The mortality rate associated with it in the hospital, which may well be greater than that for respiratory acidosis, reflects the importance of the underlying disease process. One can only be sure that the arterial PCO_2 is low by determining arterial blood gases in most patients. Respiratory alkalosis occurs when the ventilatory removal of CO_2 transiently exceeds its rate of production: thus, both the alveolar and arterial PCO_2 fall. At this lower level of arterial PCO_2, the daily production of CO_2 is then removed by the increased ventilation, which leads to a new steady state. A fall in tissue PCO_2 has an important impact on the concentration of H^+ in the ICF. A decrease in the concentration of H^+ results in back-titration of the protonated ICF proteins which may make these intracellular proteins less positively charged than normal, a change that could lead to altered function. Respiratory alkalosis may result from stimulation of the peripheral chemoreceptors (hypoxia or hypotension), the afferent pulmonary reflexes (intrinsic pulmonary disease), or central stimulation by a host of stimuli. In chronic respiratory alkalosis, there is a temporary small suppression of renal NH_4^+ production and excretion, and the P_{HCO3} falls (H^+ of dietary origin continue to consume HCO_3^- without equivalent renal formation of new HCO_3^-) until the plasma H^+ concentration approaches normal. Chronic respiratory alkalosis is the only acid-base disorder in which a normal plasma concentration of pH might be expected.

Hyponatremia and Hypernatremia

Manjula Gowrishankar, Kamel S. Kamel and Mitchell L. Halperin

Introduction

This chapter is divided into 2 sections: the major concepts concerning the physiology of sodium (Na^+) and water to provide a basis for understanding dysnatremia, followed by the clinical approach to patients with hypo- or hypernatremia. This approach at times begins with therapy rather than diagnosis, if one anticipates that the dangers for the patient are imminent and/or preventable. Following a consideration of emergency issues, a plan is constructed for investigation and longer term treatment. Case examples are used to illustrate major points.

Synopsis of the Physiology of Sodium and Water

This section will explain in more detail the forces that regulate the movement of electrolyte-free water (EFW) across cell membranes; how the distribution of fluid between the 2 major compartments of the extracellular fluid (ECF), the vascular and interstitial space, is regulated; and to emphasize that the volume of the intracellular fluid (ICF) compartment is reflected by the plasma Na^+ concentration (Na^+) for the most part, because the number of particles inside most cells does not change by an appreciable amount.

Composition of Body Fluids

Water usually accounts for 50 – 70% of body mass. It is not possible to relate total body water (TBW) to body weight by a single number because the relative proportion of fat and skeletal mass, the components of body mass with little water, are not constant. Women tend to have a higher proportion of fat and therefore a lower water content per body mass (50% body weight vs. 60% for males). The elderly also tend to have a relatively lower water content because of their high proportion of skeletal to muscle mass. Infants, on the other hand, have a higher proportion of water (70%) due to their smaller proportion of adipose tissue.

TBW is contained in 2 main compartments, the ICF and the ECF. The ICF is twice as large as the ECF compartment (Figure 1). The ECF consists of plasma fluid (4% of body weight) and interstitial fluid (16% of body weight). In certain disease states, excess fluid accumulates in the interstitial space of the ECF, resulting in edema, ascites, and/or a pleural effusion.

Water crosses cell membranes rapidly through aquaporin-1 (AQP-1) water channels in the cell membranes (Table 1) until the osmolality is equal on both sides of the membrane [1]. Not all materials dissolved in water disperse equally in the ICF and ECF because of differences in permeability, the presence of transporters, and/or active pumps that regulate their distribution. The volume of each

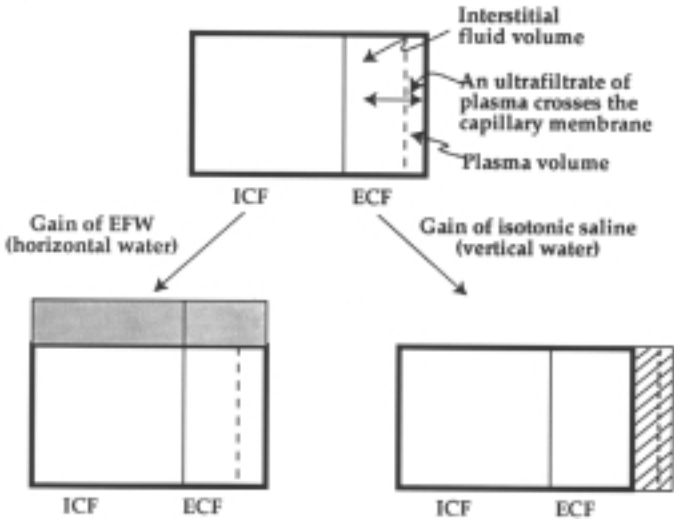

Figure 1. Body water. The rectangle in bold represents the body fluid compartments; the solid, thin, vertical line represents the membrane separating the ICF and ECF compartments; dashed, thin, vertical line separates the vascular and interstitial compartments. When there is a gain of EFW (bottom left), this water distributes in the ICF and ECF in proportion to their existing volumes (depicted by the horizontal, shaded rectangle above these normal compartments). It expands both volumes and therefore it leads to hyponatremia. In contrast, when there is a gain of isotonic saline, only the ECF volume expands (bottom right); this is depicted by the vertical, hatched rectangle. There is no change in the plasma [Na^+] or the ICF volume. Reproduced with permission [54].

compartment depends on the content of the predominant particles that are largely restricted to that compartment. Therefore, the content of Na^+ and its attendant anions in the ECF compartment determine its volume, since not only is the permeability of the cell membranes to Na^+ relatively low compared with that to K^+, but also any additional Na^+ that enters the cell is actively transported out of that cell by the enzyme Na^+-K^+-ATPase [2]. Likewise, the content of K^+ in the ICF compartment largely determines its volume. Under normal conditions, it is believed that there are roughly twice as many particles in the ICF compared to the ECF, and therefore the ICF volume is twice as large as that of the ECF (Figure 1). Some particles cross cell membranes rapidly, either via a transporter (urea) [3–5] or by diffusion (alcohol). Since their concentrations are virtually equal in the ECF and ICF of most cells they do not contribute to the "effective" osmolality or tonicity in these compartments.

The major factor responsible for water movement into cells is intracellular potassium (K^+) retention [6]. One reason for the retention is that the ICF anions are predominantly large macromolecular anions (organic phosphates) restricted to that compartment. Although these macromolecules do not exert a large osmotic pressure due to their small number, each of them bears a large number of anionic charges. Since the ICF macromolecules are largely organic phosphate esters (e.g. ATP, creatine phosphate, RNA, DNA, phospholipids) and are essential for cell function, only small net changes in their content occur in most cells. It follows that the total number of ICF particles is relatively fixed in most cells [7]. Therefore, changes in the par-

Table 1. Channels Influenced by AVP in the Nephron

I. Water channels	Most important location	Regulation by AVP
AQP-1 (also called CHIP-28)	Many cells; (e.g. proximal convoluted tubular cells)	None
AQP-2	Luminal or vesicle membranes of late distal nephron cells.	Activated, inserted, and synthesis increased.
AQP-3	Basolateral membrane of late distal nephron cells.	None
AQP-4	Basolateral membrane of late distal nephron cells.	None
II. Urea transporters (UT)		
UT	Descending thin limb of the loop of Henle and the descending vasa recta.	None
VRUT	Luminal membrane of late IMCD cells.	Yes.

AQP: aquaporin, UT: urea transporter (not vasopressin-reponsive), VRUT: vasopressin-reponsive urea transporter

ticle/water ratio in the ICF largely reflect a change in the intracellular water content. The particle/water ratio must be equal in the ECF and the ICF compartments because of the large magnitude of the osmotic pressure (100-fold greater than the mean arterial pressure). Thus, the ECF [Na^+] reflects the ICF volume in an inverse fashion in most cells, because Na^+ (and its attendant anions) accounts for virtually all of the "effective" osmolality of the ECF compartment. In contrast, brain cells can defend against large changes in their water content by varying the number of particles in their ICF compartment. This is termed regulatory volume control [8]. One mechanism used to return a swollen brain cell toward its original volume is to extrude electrolytes, which involves decreasing the content of K^+ (and usually chloride (Cl^-)) inside the cell. Another mechanism is to extrude small organic molecules such as myoinositol and other alcohols, taurine, and/or amino acids [9]. It is also possible that these osmotically-active particles are inactivated by binding rather than exrusion [10, 11]. Likewise, shrunken cells are returned toward their original volume by the influx of ions, typically Na^+. It is also possible to increase the number of small organic particles, such as amino acids or taurine [9].

Distribution of Fluid Across the Capillary Membrane

Factors controlling ultrafiltrate movement across the capillary membrane are shown in

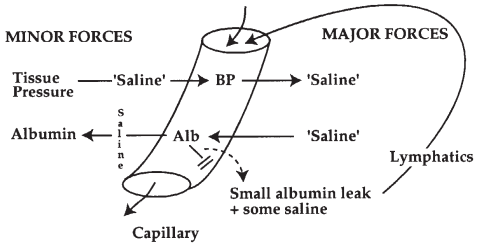

Figure 2. Events at the capillary membrane. The tubular structure is a capillary. The major outward-driving force is the capillary blood pressure and the major inward-driving force is the COP which is largely due to the effects of albumin (alb).

Figure 2. The major outward (vascular to interstitial) driving force is the hydrostatic pressure difference. When this hydrostatic pressure difference increases, as in venous hypertension (e.g. congestive heart failure (CHF)), more fluid moves from the vascular to the interstitial compartment. The major inward (interstitial to vascular) driving force is the colloid osmotic pressure (COP) difference. This is principally due to the concentration of albumin and its net anionic valence (Donnan effect). Since the intravascular compartment has a much higher concentration of albumin compared to the interstitial compartment, the COP causes fluid to move into the vascular space. When the concentration of albumin in plasma is very low, there may not be enough inward driving force and therefore the interstitial volume expands. Moreover, if capillaries become more permeable to albumin in a local area, edema fluid will accumulate. The final important component of the system is the lymphatics by which interstitial fluid is returned to the venous system.

The absolute pressure difference in mm Hg (hydrostatic pressure and COP) across a given capillary membrane is small but becomes a large force when the total capillary bed is considered. Therefore, another important factor here is the number of capillaries being perfused at any one time. If more are perfused, fluid can shift from the vascular to the interstitial compartment. If this flow exceeds lymphatic drainage, the vascular volume will be low. Since the interstitial fluid volume is so much larger than the vascular volume, any time one detects interstitial space expansion (edema), the patient will always have ECF volume expansion, even if the vascular volume may be reduced (e.g. hypoalbuminemia in patients with the nephrotic syndrome).

External Balances for Water

When a normal subject ingests EFW, it mixes with all body fluids. Two-thirds enters the ICF in steady state, while one-third remains in the ECF because water moves to osmotic equilibrium (Figure 1); thus, there is swelling of cells and hyponatremia.

Control of Water Intake

Thirst is stimulated by an increased tonicity. Particles like urea are not involved because they are not restricted to the ECF. Contraction of ECF volume is also a stimulus to thirst, but it is not a powerful one. Here, elevated levels of angiotensin II (Ang II) may act as a signal [13]. Other factors unrelated to a need for water may also stimulate water intake (e.g. dryness of the mouth, habit, social interactions). The major inhibitors of thirst are hypotonicity and, to a lesser degree, ECF volume expansion.

Control of Water Excretion

To return to steady state, the body must detect that there is a surplus of EFW (have a

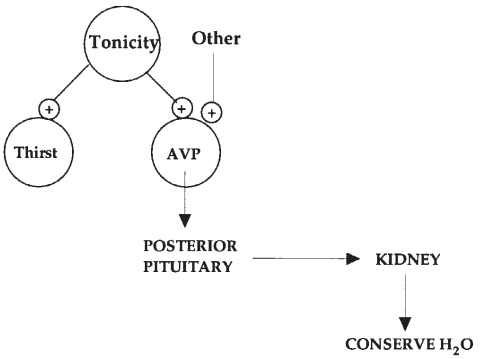

Figure 3. Control of the release of AVP and its actions on the kidney. For details, see text. The three circles represent the hypothalamic sensory system. The primary sensor is a group of cells that detect a change in their volume in response to a change in the "effective" osmolality of plasma (tonicity receptors). These cells are linked to other cells that control the intake of water (thirst center) and others that are responsible for the release of AVP. Other factors such as the "effective" circulating volume and afferent stimuli such as pain, nausea, anxiety, as well as a number of drugs also influence the release of AVP independent of the tonicity receptor influences.

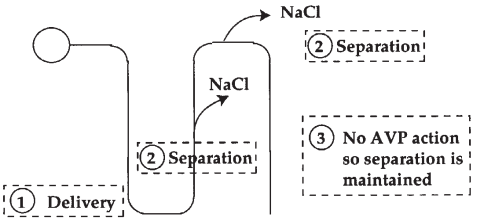

Figure 4. The excretion of dilute urine. The major structure is a stylized nephron. The numbers in the ovals represent the 3 major processes: the delivery of isotonic saline to the thick ascending limb of the loop of Henle (delivery, point 1), active resorption of NaCl from the thick ascending limb of the loop of Henle and in more distal nephron segments (separation, point 2) which generates EFW, and prevention of the reabsorption of EFW in more distal nephron segments because of a lack of AVP (maintain separation due to the absence of AQP-2 in the luminal membrane, point 3).

sensor), send a message to the kidney, and then direct the kidney to separate this EFW from its electrolytes (Na^+ salts) so that only the excess EFW can be excreted. The steps involved are as follows:

- *Sensor*: Tonicity receptors located in specialized cells in the anterior hypothalamus detect changes in cell volume [14]. This center is linked to both an area that drives thirst and another that releases arginine vasopressin (AVP) (Figure 3).
- *Messages*: Swelling of the tonicity receptor sends a message to the thirst center to diminish water intake and to the supraoptic nucleus to suppress the release of AVP. This absence of AVP translates into a message to the kidneys to excrete as much EFW as possible.
- *Renal events*: In the kidney, saline is filtered and some Na^+ and Cl^- are reabsorbed without water in the thick ascending limb of the loop of Henle and the distal nephron (Figure 4). The remaining EFW is excreted, because the luminal membrane of the distal nephron has a low permeability to water without AVP to insert aquaporin-2 (AQP-2) water channels (Table 1).

Excretion of a Dilute Urine

Excretion of EFW requires 3 steps: (1) delivery of Na^+, Cl^-, and water to distal diluting sites; (2) reabsorption of these ions without water (desalination); (3) ensuring that this EFW traverses the remainder of the distal nephron without being reabsorbed (maintenance of desalination) (Figure 4).

There are several nephron sites where Na^+ and Cl^- are reabsorbed, but water is not. The most important of these sites is the thick ascending limb of the loop of Henle. Other segments include the early distal convoluted tubule (DCT) (sparingly permeable to water

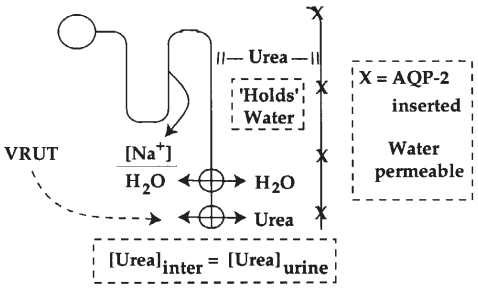

Figure 5. Formation of concentrated urine. For details, see text. There are 2 key elements operating at the renal level to excrete a concentrated urine. First, the "effective" osmolality of the medullary interstitial compartment must rise (this is represented as the Na^+/H_2O ratio in the interstitial compartment). Most important here is the active resorption of NaCl in the thick ascending limb of the loop of Henle. Second, water must be permeable across the luminal membranes of the late distal nephron (actions of AVP to insert AQP-2). The concentration of urea is elevated in the inner medullary interstitium largely because of actions of AVP to make urea permeable (VRUT is inserted) and a high concentration of urea in the urine.

even if AVP is present), the late DCT, and the collecting ducts (permeable to water in the presence of AVP).

Excretion of a Concentrated Urine

AVP action and an intact renal medulla are required to excrete a concentrated urine (Figure 5). The release of AVP from the posterior pituitary gland is stimulated by a rise in tonicity of body fluids and also by stimuli unrelated to tonicity (Figure 3) [15]. In the absence of water intake, the tonicity of body fluids rises because of ongoing EFW loss via the skin and the respiratory tract. This causes cells to shrink, particularly the tonicity receptor cells, which then causes thirst and AVP release.

AVP binds to its V_2 receptor on the basolateral membrane of cells of the late DCT and the collecting ducts, resulting in reabsorption of EFW. Three steps act to achieve this effect: the activation of AQP-2 water channels, their insertion in the luminal membrane, and the longer-term effect, the synthesis of more AQP-2 channels (Table 1) [1]. Most of the EFW is reabsorbed in the cortex when AVP acts [16]. To achieve this reabsorption, the "effective" osmolality of the interstitial fluid must exceed that of the lumen. This higher interstitial osmolality is due primarily to the active reabsorption of Na^+ and Cl^- in the thick ascending limb of the loop of Henle [16 – 18]. Thus, the passive transport of water down an osmotic difference is enhanced. As a result, a hyperosmolar urine is excreted and EFW is conserved.

Urea also contributes to the total osmolality of the interstitial fluid in the inner medulla and in the urine. In fact, it constitutes close to half the total osmolality in these locations in subjects who consume a typical Western diet. Nevertheless, if urea is permeable across the inner medullar collecting ducts (IMCD) because of the insertion of the vasopressin-regulated urea transporter (VRUT) [4, 5], it should not contribute to EFW conservation, a point illustrated in data from the rat [19]. Therefore, we prefer to think of the urine in "effective" osmolality terms rather than in total osmolality terms [20, 21].

Since one needs a hyperosmolar medullary interstitium to excrete a hyperosmolar urine, one cannot excrete a very concentrated urine in disease states where the medullary interstitium is damaged, regardless of the action of AVP.

External Balance for Na^+

People on a typical Western diet consume roughly 150 mmoles of NaCl daily. To remain in balance, 150 mmoles of NaCl must be

excreted daily. Thus, the Na^+ that was ingested must be sensed, the appropriate message sent to the kidney, and the reabsorption of filtered Na^+ in the kidney inhibited so that only the extra NaCl, and not water, will be excreted.

- *Sensor*: When NaCl is retained, the ECF volume expands. The most important component of the ECF is the "effective" circulating volume. Hence, baroreceptors in the arterial and central venous vessels detect changes in the "effective" circulating volume.
- *Messages*: The message of an increased "effective" circulating volume is delivered by renal nerves and hormones. Physical and hemodynamic factors also modulate the rate of reabsorption of Na^+ by the kidney.
- *Renal events*: In a normal adult, close to 27,000 mmoles of Na^+ are filtered each day. Of this large quantity, only a very small amount (150 mmoles, or about 0.5% of the filtered daily load) must be excreted to maintain balance for Na^+. Hence, Na^+ excretion is very tightly regulated, largely by changes in its reabsorption [22 – 24]. The first step required for the kidney to reabsorb Na^+ from the lumen is to create a driving force for the movement of Na^+ into the tubular cells. This is accomplished by lowering the $[Na^+]$ in the ICF of tubular cells, the result of the actions of the Na^+-K^+-ATPase in the basolateral membrane [2]. This transport system pumps 3 Na^+ out while transporting 2 K^+ into these cells. The Na^+-K^+-ATPase also creates an additional driving force for Na^+ reabsorption by creating a net negative voltage inside the cell. Since the luminal membrane is impermeable to Na^+, the second step required for the reabsorption of Na^+ is the insertion of specific transporters or Na^+ channels into this membrane. These transporters are specific for each nephron segment.

Na^+ Handling in the Proximal Convoluted Tubule (PCT): Of the 27,000 mmoles of Na^+ filtered each day, close to 18,000 mmoles (67%) are reabsorbed in the PCT. Co-transporters, e.g. glucose, and antiporters, e.g. H^+ on the Na^+/H^+ exchanger (NHE-3), are involved in these transport events. Electroneutrality is maintained by the reabsorption of the anions Cl^- and HCO_3^-. Since the luminal membrane here is permeable to water, the osmolality of the fluid leaving the PCT lumen is the same as that of the ECF. Ang II stimulates the reabsorption of $NaHCO_3$ in the PCT [25]. Water moves to osmotic equilibrium, thus raising the $[Cl^-]$ within the lumen. This creates a concentration difference for Cl^- which favors its passive reabsorption; Na^+ ions follow for electroneutrality.

Na^+ Handling in the Loop of Henle: Of the remaining 9 000 mmoles of Na^+ exiting the PCT lumen, 6 000 mmoles are reabsorbed in the loop of Henle. NaCl is actively transported by the Na^+-K^+-2 Cl^- co-transporter using the driving force (low $[Na^+]$ in the ICF) created by the Na^+-K^+-ATPase. The absolute reabsorption of Na^+ varies with delivery, and net reabsorption is stimulated by the action of AVP in the medullary thick limb. In the thick ascending limb, water reabsorption is negligible. Thus, the fluid exiting this nephron segment is hypotonic to plasma.

Na^+ Handling in the DCT: Close to 2 000 mmoles of the remaining 3 000 mmoles of Na^+ are reabsorbed in the DCT. Since the DCT is not permeable to water, EFW is created. Na^+ is reabsorbed with Cl^-, driven by the transepithelial $[Na^+]$ gradient across the luminal membrane of the DCT. The ion transporter

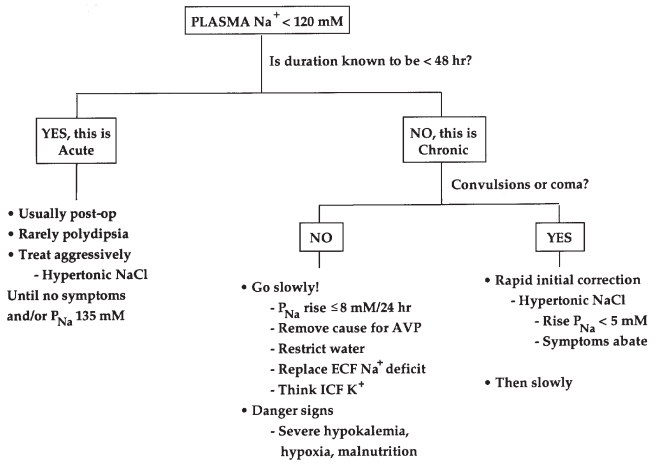

Figure 6. Approach to the patient with hyponatremia. Pseudohyponatremia and translocation type of hyponatremia should be ruled out. This figure should be examined together with Tables 3 and 4 for a more complete lists of conditions. Reproduced with permission [55].

is the Na^+-Cl^--co-transporter, which may be inhibited by thiazide diuretics. A molecular defect in this transporter causes Gitelman's syndrome (see chapter I-2, Potassium).

Na^+ Handling in the Collecting Duct: Close to 700 mmoles of the remaining 1 000 mmoles of Na^+ are reabsorbed in the cortical collecting duct (CCD) through a specific Na^+ ion channel [26]. Mineralocorticoids lead to greater opening of this channel [27], while amiloride, a K^+-sparing diuretic, inhibits it. The medullary collecting duct (MCD) reabsorbs about 150 mmoles of the remaining 300 mmoles of Na^+ delivered, so that 150 mmoles of Na^+ can be excreted to stay in Na^+ balance. In this segment, a high transepithelial [Na^+] gradient is maintained. Atrial natriuretic peptide (ANP) acts here to decrease the reabsorption of Na^+ [28], in ECF volume expansion. In contrast, during ECF volume contraction, the absence of ANP causes almost all of the Na^+ delivered to be reabsorbed.

Clinical Approach to the Patient with a Dysnatremia

General Aspects about a Patient with Hyponatremia

Is there a Major Threat to the Life of the Patient related to Hyponatremia?

The main danger in the patient in whom hyponatremia developed in < 48 hours (acute hyponatremia) is swelling of brain cells which may lead to seizures, herniation of the brain and death (Figure 6, Tables 2 and 3). In contrast, in the patient who becomes hyponatremic over a much longer time period (chronic hyponatremia), the main danger is an overly rapid rate of shrinkage of brain cell volume as a result of aggressive correction of hyponatremia. This may result in the development of an osmotic demyelination syndrome (ODS) and loss of higher cerebral functions [29]. It is important to remember that the acute discovery of a chronic condition does not make it an acute disorder.

Table 2. Overview of Hyponatremia

Type of hyponatremia	Clinical Setting	Main danger	Treatment
Acute (documented < 48 hour).	Usually postoperative.	Brain cell swelling.	Hypertonic saline to raise [Na^+] to 130 mM
Chronic	Many causes.	Osmotic demyelination.	Rise in the plasma [Na^+] should not be > 8 mM/day

Table 3. Classification of Hyponatremia

1. Acute hyponatremia (< 48 hour duration):
   a) Source of EFW:
      – Exogenous (IV or oral)
      – Endogenous = Desalination of IV or body fluids
         – Acute postoperative period
         – Cerebral salt wasting
         – Thiazide diuretics in an edematous patient
         – Giving isotonic saline to a patient with SIADH.
   b) Reason for AVP being present
      – Low "effective" ECF volume
      – Pain, anxiety, nausea, psychosis
      – Endocrine reasons (adrenal, thyroid, pituitary)
      – Metabolic disorder (e.g. porphyria)
      – Drugs
      – None of the above, see Table 5.
2. Chronic hyponatremia:
   a) Source of EFW is always needed
      – usually not the most important component of the problem.
   b) Reason for AVP (see above).

Has a Shift of Water Occurred across Cell Membranes in a Patient with Hyponatremia?

NO, the ICF volume did not change: This is the case when an isosmolar solution containing solutes other than Na^+ are added and these new solutes were retained primarily in the ECF compartment, e.g. retained lavage solution during a transurethral resection of the prostate (TURP). An example is provided in Table 4.

YES, the ICF volume has decreased in size (shrunken cells): This is the case when the solution added had both an osmolality greater than that of the ECF and the solutes that were added are retained in the ECF compartment (e.g. hyperglycemia or administration of a bolus of mannitol).

YES, the ICF volume has increased in size (swollen cells): This is the case when the solution added had an "effective" osmolality lower than that of the ECF (the addition of EFW) or hypotonic sorbitol or glycine (e.g. during a TURP) and/or the solutes added were distributed in the ECF and ICF compartments (e.g. urea or ethanol).

What is the Pathophysiology of Hyponatremia?

Two major factors should be considered and each must be analyzed independently.

There is a source of EFW: This is the more important factor in patients with acute hy-

Table 4. Comparison of EFW and isosmotic mannitol on the degree of hyponatremia. Examples are provided to illustrate the effects of retaining 3 L of EFW or 3 L of half-isotonic mannitol on the plasma [Na^+] and the volumes of the ICF and ECF. We assumed that the patient has 30 L of total body water in each case, 2/3 of body water is in the ICF compartment, mannitol will be excreted at a concentration of 300 mM during an osmotic diuresis [51, 53]. Notice the degree of change in the plasma [Na^+] when mannitol is excreted, a time with no change in the volume of the ICF compartment. This illustrates the problems relating the plasma [Na^+] and the ICF volume in translocational hyponatremia.

Parameter		Normal	Gain 3 L	Mannitol	
		Values	EFW	Gain 3 L	Excrete mannitol
Total body water	L	30	33	33	31.5
– ICF volume		20	22	21	21
– ECF volume		10	11	12	10.5
Plasma [Na^+]	mmM	140	127	114	133
– Change	mmM	0	– 13	– 26	– 7

ponatremia. In acute hyponatremia, the condition must be present for < 48 hours. As mentioned above, the major concern is brain swelling because the brain is enclosed by a rigid structure, the skull.

AVP is acting: This is the more important factor in patients with chronic hyponatremia. In the short term, one is primarily concerned with the fact that AVP might disappear and lead to too rapid a rate of correction of the hyponatremia and thereby, the development of ODS. In the long term, one is concerned with the underlying reason for AVP excess. Chronic hyponatremia includes all cases where there is a reasonable doubt about the plasma [Na^+] in the past 48 hours. If the patient is symptomatic (e.g. seizures) the worry is brain swelling and treatment is aggressive initially. If the patient is not severely symptomatic, the worry is the ODS with too rapid a rise in the plasma [Na^+].

Clinical Approach to the Patient with Acute Hyponatremia

Acute hyponatremia (developing over < 48 hours) implies insufficient time for swollen brain cells to shrink their volume back to a normal size. Due to the physical restriction imposed by the cranial vault, intracranial pressure (ICP) rises causing central nervous system symptoms, which may become serious (seizures or coma) or devastating (respiratory arrest and irreversible brain damage).

In the patient with acute hyponatremia, the emphasis at the bedside is on the source of EFW. The cause for the release of AVP is usually obvious (Table 4). The most common setting for acute, potentially life-threatening hyponatremia, is in the intra- and postoperative setting, and thus most of these cases occur in hospital. There are 3 obvious sources of EFW in this setting: (1) the administration of

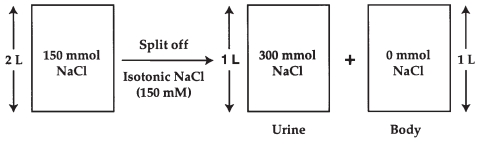

Figure 7. Desalination type of hyponatremia. The rectangles represent 1 L volumes. The [Na^+] in each L is shown in the rectangle. The left rectangle represents 2 L if IV infusions. The first rectangle to the right of the arrow represents the hypertonic urine, and the second rectangle to the right of the arrow represents the 1 L of EFW generated and retained in the body due to AVP actions. Reproduced with permission [55].

glucose in water (D_5W), or hypotonic saline as intravenous fluids (virtually always occuring in the perioperative period); (2) the intake of ice-chips or sips of water (also perioperative period); (3) the generation of EFW from the kidney excreting urine that is hypertonic to the infusate (or to body fluid in the absence of intravenous infusions [30]) (Figure 7).

Prevention: The best way to avoid acute postoperative hyponatremia is to avoid giving solutions that are hypotonic to the urine if polyuria is present, or hypotonic to body fluids in the oliguric patient. In addition, isotonic fluids should only be given to maintain systemic hemodynamics during surgery and to replace losses if they occur. One should be very suspicious of a "good" urine output because this might be hypertonic to the infused solutions and generate EFW (Figure 7). The plasma [Na^+] should be monitored in settings associated with AVP release (Table 4), particularly in patients who excrete more than 1 – 2 L of urine/day. Finally, caution should be used with the volume of fluid given to a small patient, as a large volume of fluid in a small patient translates into more EFW generation if the urine is hypertonic to the fluids administered. This is especially important in menstruous females, in whom acute hyponatremia may be more dangerous [31].

Emergency therapy: The immediate goal of therapy is to shrink the expanded ICF volume of the brain sufficiently to curtail the serious CNS symptoms. If hyponatremia is severe (< 120 mM) or symptoms are present, one should administer hypertonic saline until the plasma [Na^+] is close to 130 mM. When calculating the amount of Na^+ required, one must assume that its volume of distribution behaves as if the Na^+ will be dissolved in TBW, since the cell membrane is permeable to water, but not to Na^+ [32]. To clarify these points, consider the following illustrative case.

– *Case example:* Hyponatremia (plasma [Na^+] 120 mM) developed in a 50-kg person 24 hours after surgery; a seizure has just occurred. Therefore, the initial aim of therapy is to shrink the size of brain cells over 1 – 2 hours to the pre-seizure level. A reasonable target is to raise the plasma [Na^+] by 5 mM over the next 1 – 2 hours. In order to achieve this, 125 mmoles of Na^+ should be administered, given a TBW of 25 L (50% of body weight). Since 1 L of 3% saline contains close to 450 mmoles Na^+, 0.3 L of this solution should be administered. After the seizure is controlled, the rate of infusion may be slowed, with the goal of raising the [Na^+] to 130 mM. Careful observation is required to avoid the development of pulmonary edema.

Maintenance Therapy: Once the plasma [Na^+] has been raised to 130 mM, one should ensure that it does not fall any further. The tonicity balance approach (Figure 8) uses 2 general strategies to prevent a further fall in sodium in a patient who is excreting a large volume of hypertonic urine.

– Input: If the input is equal to the output with respect to Na^+, K^+, and water, there will be no change in the plasma [Na^+]. Since hypertonic saline is being excreted,

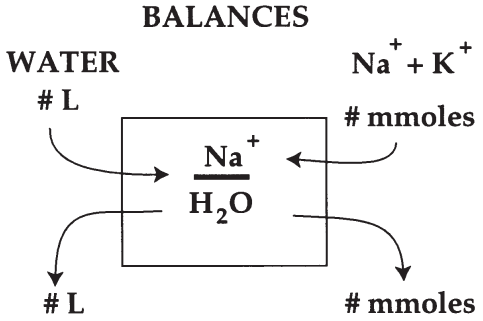

Figure 8. Tonicity balance. The rectangle represents all body compartments. To calculate a tonicity balance, one must have separate balances for water and $Na^+ + K^+$. The data can predict how the $[Na^+]$ in plasma should change; this should be compared to measured values. Reproduced with permission [55].

the same volume and the same composition of hypertonic saline must be administered.

– Output: Here the aim is to lower the concentration of Na^+ and K^+ ($[Na^+ + K^+]$) in the urine so that isotonic fluids can be administered. If the $[Na^+ + K^+]$ in the urine is very high [30], one can render it isotonic with the administration of a loop diuretic (e.g. furosemide) [33, 34] or an osmotic diuretic (e.g. urea) [35]. Isotonic intravenous fluids should be given at the same rate as that of the urine output. Once the reason for the release of AVP is no longer present, this therapy will not be required. The patient will begin to excrete dilute urine and hence the plasma $[Na^+]$ will rise [30].

Specific Examples

Acute hyponatremia in females: Most commonly, this follows otherwise uneventful gynecological surgery which leads to the sustained release of AVP for a number of reasons, such as pain, anxiety or drugs [31]. The ill-advised infusion of D_5W, the most common source of EFW in this setting, exacerbates the problem. Even isotonic saline can present the body with a large infusion of EFW [30] (Figure 7). The severity of hyponatremia may be worsened if the volume of fluid given is not scaled down to body size. This form of acute hyponatremia leads to brain cell swelling and rarely, death due to high ICP in some patients. A quantitative example is provided in Table 4.

Acute hyponatremia in males: The list of causes of acute hyponatremia in males reflects the type of surgical procedure they are likely to undergo. The most common surgery for males is TURP [36]. The main reason for hyponatremia in this setting is that large volumes of half-isotonic solutions of organic compounds are used to lavage the prostatic bed, some of which may be absorbed. The development of hyponatremia becomes clear when the absorbed fluid is divided into its two constituent parts (Table 4).

– *Gain of osmol-free (and electrolyte-free) water:* This simple EFW gain causes cells to swell, but it is not the major cause for the hyponatremia (fall of 7 mM in the plasma $[Na^+]$ in the example provided in Table 4).

– *Gain of isosmolar fluid:* Solutes such as mannitol, glycerol, or glycine distribute in the ICF compartment at a slow rate [37]. When they remain in the ECF, they cause hyponatremia because these solutions are Na^+-free. This transient form of hyponatremia is not associated with a change in brain cell volume, and so does not pose a threat of brain herniation [38]. A low plasma osmolality in the setting of acute hyponatremia following a TURP poses a threat of brain cell swelling. If that osmolality is close to normal, one should not be alarmed with the severity of the hyponatremia and the rapidity of its correction (Table 5). The symptoms

Table 5. Causes of High AVP Levels in Patients with Hyponatremia

1. AVP release in response to physiologic stimuli:
   – Low "effective" circulating volume
      – ECF volume depletion
      – Blood loss
      – Hypoalbuminemia
      – Low cardiac output.
   – Excessive pain, nausea, vomiting. or anxiety.

2. AVP release without a physiologic stimulus:
   – CNS or lung lesions.
   – Neoplasms and granulomas such as tuberculosis.
   – Metabolic lesions such as acute intermittent porphyria.
   – Administration of agents that simulate AVP
      – DDAVP (e.g. treatment for diabetes insipidus or urinary incontinence)
      – Oxytocin for labor induction.
   – Drugs that augment or stimulate AVP release:
   – Examples include nicotine, morphine, clofibrate, tricyclic antidepressants, antineoplastic agents, (probably via nausea and emesis), anticonvulsants such as tegretol.
   – Drugs that promote the actions of AVP on the kidney by increasing cyclic AMP levels or augmenting its bioactivity:
      – Examples include oral hypoglycemics (e.g. chlorpropamide), methylxanthines (e.g. caffeine, aminophylline), analgesics that inhibit prostaglandin synthesis (e.g. aspirin, non-steroidal anti-inflammatory drugs).

associated with hyponatremia when glycine is used as the lavage fluid during a TURP may be the consequence of hyperammonemia rather than swelling of cells of the brain [36].

Hyponatremia with primary polydipsia: Normally one cannot become hyponatremic simply from drinking EFW, because AVP will be absent and in this setting, normal kidneys can excrete close to 1 L of EFW/hour, more than almost anyone can drink and absorb [39 – 41]. Nevertheless, if there is a reason for AVP release, such as an appreciably low ECF volume, anxiety, pain, psychosis, or the intake of certain drugs (Table 4), the intake of EFW will result in hyponatremia [30].

Hyponatremia in an infant: Apart from unique disorders such as inborn errors, hyponatremia in this setting is most commonly due to a loss of Na^+ (e.g. diarrhea). This form of hyponatremia may be acute. AVP is released in response to the contracted ECF volume, and this leads to the retention of EFW that is ingested by the infant. If a hyponatremic infant is fed sugar water to rest the GI tract and avoid dehydration, this EFW will be retained. Thus, hyponatremia has 2 components: loss of Na^+ and gain of EFW. Its degree may be very severe. The 2 considerations for therapy include rapid re-expansion of the contracted ECF volume by infusing "isotonic to the patient" saline and avoidance of any further addition of EFW (this includes the generation of EFW by the kidneys if the rate of excretion of Na^+ were to rise while AVP is still acting, Figure 7).

Summary

– Do not give EFW to a subject with a plasma $[Na^+] < 138$ mM. Give a smaller volume if the patient is likely to have AVP released for nonosmotic reasons.
– Do not give more isotonic saline during surgery and in the acute postoperative time than is needed to maintain normal hemodynamics.
– Be careful if the urine output is larger than expected.
– Use a tonicity balance calculation to help understand the basis of hyponatremia and to plan therapy. Emphasis can be placed on changing the input or the output.

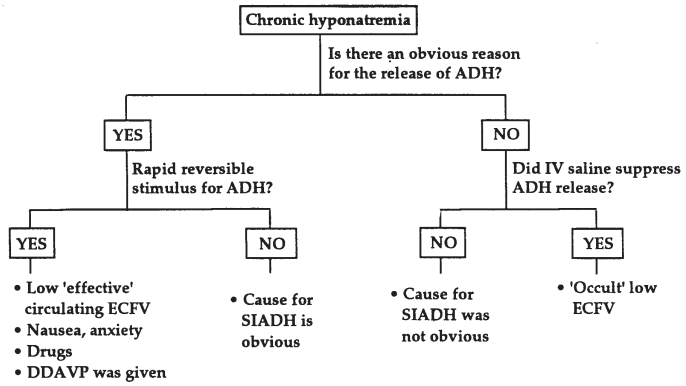

Figure 9. Steps to take in the patient with chronic hyponatremia. The focus in chronic hyponatremia is to determine why AVP is present. If the reason for the release of AVP is reversible, patients might be at risk of having a water diuresis if the release of AVP is suppressed – e.g. when their ECF volume is re-expanded. Reproduced with permission [55].

Clinical Approach to a Patient with Chronic Hyponatremia

Chronic hyponatremia is the most common electrolyte abnormality in hospitalized patients [42], but it rarely leads to significant symptoms (Figure 9). The patient with chronic hyponatremia is often identified by the determination of routine electrolytes, in which case the duration of the disorder is unknown. The fundamental issue here is that adaptive responses have had time to occur, the most important of which are in the brain. Brain cells have returned their volume virtually to normal (for review see [9]). The initial mechanism is the export of ions (K^+), providing that electroneutrality was not the result of the entry of Na^+ into their ICF (it is not clear which anion might be exported with K^+, but the defense of the ICF volume of cells of the brain would be most efficient if Cl^- were also exported from these cells). Over the next few days, organic molecules such as myoinositol, amino acids, and taurine are exported. Brain cells must reaccumulate solutes that were lost to achieve a normal ICF volume and composition; this provides the rationale for deciding the rate of correction of hyponatremia. The critical issue is that these cells, which have undergone volume regulation, are at risk of an acute decline in their volume if the plasma $[Na^+]$ is raised before these solutes are taken up. This is even more important if these cells do not have available organic osmolytes to re-establish their normal ICF osmole composition. For example, a patient with poor nutrition or a large deficit of K^+ may take longer to regain these intracellular organic osmolytes [43]. Correction of hyponatremia exceeding 6 – 8 mM/24 hours, can lead to the devastating neurologic syndrome, ODS [44].

Diagnostic Issues

To develop hyponatremia, a source of EFW (usually ingestion of water) coupled with a limitation to its excretion (release of AVP) must be present. Virtually everyone drinks EFW, so one need not dwell on this for diagnostic purposes unless the intake is very large. The diagnostic issue focuses on why the rate of excretion of EFW is so low. The challenge to the physician is to identify why AVP was released despite a low plasma "effective" osmolality (Table 5, Figure 9). The objective at the bedside is to determine whether AVP levels will decline rapidly, leading to an overly rapid rate of hyponatremia correction, thus predisposing the patient to ODS.

Several examples where the level of AVP might decline abruptly include chronic nau-

sea, vomiting, anxiety, and/or stress, or when desmopressin (DDAVP) is given to patients in a nursing home to minimize bed wetting. In addition, the apparent on-again, off-again release of AVP may be the result of a decreased "effective" circulating volume. When the "effective" circulating volume is low enough, AVP will be released, even if hyponatremia is present. This helps to defend the ECF volume at the price of an expanded ICF volume. Since thirst is also stimulated by a low "effective" circulating volume, both a source of EFW and the release of AVP to prevent its excretion are present. The problem is that a clinician may have great difficulty in deciding whether the "effective" circulating volume is contracted unless the changes are marked. One can use clues from the history. First, there may be excessive renal loss of Na^+. Its most common cause is the ingestion of a diuretic. Less often, renal salt wasting and/or an osmotic diuretic (e.g. glucose or urea) may cause excessive excretion of Na^+. In patients with renal salt wasting, examining the rate of excretion of K^+ may help determine the nephron site with defective handling of Na^+. A low rate of excretion of K^+ in the face of renal Na^+ loss and ECF volume contraction should suggest that there is a lesion in the CCD, for example a low aldosterone bioactivity. In contrast, a high rate of excretion of K^+ with renal Na^+ wasting suggests that an abnormal loss of Na^+ occurred in the PCT (usually with metabolic acidosis), the loop of Henle (as in patients with Bartter's syndrome), or the early DCT (as in patients with Gitelman's syndrome). Although one would expect a low rate of excretion of Na^+ and Cl^- when the ECF volume is low, there are notable exceptions to this rule. Na^+ may be excreted if there is a high rate of excretion of another anion such as HCO_3^- in the patient who has vomited recently. In this case, the excretion of Cl^- should be low. In contrast, if the loss of NaCl was due to diarrhea, the associated metabolic acidosis will cause a high rate of excretion of ammonium (NH_4^+) and because this NH_4^+ is excreted with Cl^-, the urine may be Cl^--rich but Na^+-poor (Table 6). Loss of Na^+ can also occur via nonrenal mechanisms. These are usually obvious (e.g through gastrointestinal tract or skin) and should be suspected when the urine is virtually Na^+-and/or Cl^--free *all* the time. The "effective" circulating volume is decreased either when the overall ECF volume is reduced or when the ECF volume is maldistributed so that there is insufficient volume in the "effective" vascular compartment, as in edema states (e.g. in patients with hypoalbuminemia). A second type of maldistribution occurs when the arterial volume is low and the venous volume is high, as when there is a primary decrease in cardiac function or venodilitation.

Table 6. Urine Electrolytes in the Differential Diagnosis of Hyponatremia. (These urine electrolyte levels do not apply to polyuric states.)

Condition	Urine Electrolyte Na^+	Urine Electrolyte Cl^-
– Vomiting		
Recent	High*	Low**
Remote	Low	Low
– Diuretics		
Recent	High	High
Remote	Low	Low
– Diarrhea or laxative abuse	Low	High
– Bartter's or Gitelman's syndrome	High	High

*High = Urine concentration > 15 mM, **Low = Urine concentration < 15 mM

Clinical Clues

Four laboratory tests might help indicate if the "effective" circulating volume is contracted.

- *Plasma [K^+]*: Either hypokalemia or hyperkalemia can suggest the reason for the release of AVP. When the ECF volume is low, release of aldosterone results in renal K^+ loss. This loss is especially high when volume and bicarbonate (HCO_3^-) delivery to the CCD are high. Therefore, hyponatremia associated with diuretics or vomiting should be suspected if hypokalemia and renal K^+ wasting are present. In contrast, patients who have hyponatremia and hypokalemia due to diarrhea may have a low rate of excretion of K^+ if their loss of K^+ occurred via the GI tract. Finally, in patients with Addison's disease (low aldosterone levels) and hyponatremia, hyperkalemia is usually present.

- *The plasma [HCO_3^-]*: The plasma [HCO_3^-] may be high in patients who have vomiting or diuretic-induced hyponatremia (metabolic alkalosis). In contrast, hyponatremia of hypoaldosteronism is generally accompanied by a mild fall in the plasma [HCO_3^-] to close to 20 mM, because of a low rate of excretion of NH_4^+ consequent to renal effects of hyperkalemia [45, 46].
- *The BUN*: In patients with the syndrome of inappropriate secretion of AVP (SIADH), the fractional excretion of urea increases, probably as a result of ECF volume expansion [47]. This together with dilution due to water retention and possibly a low protein intake results in a fall in the concentration of urea in plasma (BUN). In hyponatremia associated with a low "effective" circulating volume, there is a higher plasma urea level because the stimulus to AVP release (ECF volume contraction) leads to a fall in the GFR and an enhanced rate of reabsorption of filtered urea in the PCT.
- *The plasma urate level*: The plasma urate level may be quite low in patients with hyponatremia caused by SIADH. The mechanism is thought to be due to the expanded ECF volume in SIADH. If the ECF volume is contracted, more urate is reabsorbed and its level in plasma could rise.

Quantitative considerations: When AVP acts, the urine will contain very little EFW in patients who maintain their usual intake of salt. Nevertheless, to deduce what the anticipated changes are likely to be, one must examine the input and output, and perform a tonicity balance (Figure 8). The following examples illustrate these 2 points.

Example 1, emphasis on the source of EFW: Subjects on a normal Western diet consume 150 mmoles of NaCl and 50 mmoles of K^+, and excrete 1.5 L of urine a day. They remain in balance and their 24-hour urine [$Na^+ + K^+$] is 133 mM. Since the urine [$Na^+ + K^+$] can only rise to just over twice this value because of a limit set by medullary tonicity, positive balance for EFW can only be approximately 0.75 L/day. Said another way, it is difficult to have a large daily positive EFW balance, unless the intake of water increases appreciably and/or the intake of NaCl declines to a major extent.

Example 2, emphasis on the content of Na^+ in the ECF: An elderly woman consumes tea and toast. Her intake of EFW is not low because she drinks a large cup of tea by habit; however, her diet contains little $Na^+ + K^+$. To stay in balance, she must excrete urine with a very low [$Na^+ + K^+$]. If AVP is acting, the [$Na^+ + K^+$] in her urine can rise to close to 300 mM

[18]. Hyponatremia can develop quickly and now EFW will be generated rather than excreted (Figure 7). Hence, both the electrolyte and EFW intake, plus the capacity to have a high [$Na^+ + K^+$] in the urine, impact on the likelihood of developing hyponatremia and contribute significantly to its severity.

Clinical Settings for Chronic Hyponatremia

One first tries to identify patients with an "effective" circulating volume that is obviously contracted and those with SIADH, either from medications or a condition that may cause the release of AVP (Table 5).

SIADH: A persistently elevated level of AVP acts to limit the excretion of EFW. When EFW is ingested, much will be retained and cause hyponatremia. Initially, the ECF volume is expanded so Na^+ is excreted in the urine. Hence, the characteristic findings in steady state are hyponatremia, the absence of ECF volume contraction, and a urine which contains as much Na^+ and Cl^- as the patient is ingesting. A note of caution is needed here. Patients with SIADH who consume a low salt diet will have little Na^+ and Cl^- in their urine, so a high urine [Na^+] is not a requirement for this diagnosis. The urine osmolality exceeds the minimum value of 30 – 80 mosm/kg H_2O, which is the expected value if AVP is absent. Before establishing the diagnosis of SIADH in a patient with chronic hyponatremia, be sure that there is no reduction of the "effective" circulating volume. This might require an infusion of isotonic saline. When this is done, SIADH is ruled out if the urine osmolality declines to minimum values.

There are 4 subgroups of SIADH as shown by Robertson et al. [48]. The first subgroup is the patient with random high autonomous release of AVP. A common example is the patient with carcinoma of the lung. These patients represent 35 – 50% of those with SIADH.

The second subgroup is the patient with reset osmostat. These patients have normal regulation of the release of AVP, but it is controlled around a hypotonic setting. About 33% of patients with SIADH fall into this subcategory.

The third subgroup is the patient with failure to suppress AVP totally with hypotonicity. About 15% of patients will have SIADH in which the release of AVP is normal at a high tonicity of plasma, but not absent at low plasma tonicity.

The fourth subgroup consists of about 15% of patients with SIADH. They have no problems with the regulation of the secretion of AVP, but their kidneys are either overly sensitive to AVP, or there is a circulating AVP-like material present. Perhaps some of these patient have a very low delivery of Na^+ to the distal nephron. Because the IMCD has intrinsic permeability to water even in the absence of AVP [1], they can reabsorb water from the IMCD if their interstitial fluid compartment has a high "effective" osmolality. We have called this trickle-down hyponatremia [49].

Therapy for the Patient with SIADH

Treatment of the underlying illness is crucial, but beyond the scope of this discussion. We shall restrict our comments to the treatment rapidity of correction of hyponatremia.

– *Prevention*: Certain clinical situations are associated with chronic but reversible release of AVP (Table 5). These patients will be at risk for a more severe degree of

hyponatremia if they receive EFW, and are in danger of spontaneous excessive rapid rate of correction of their hyponatremia.

– *Active treatmen*t: Only in rare circumstances should the rate of correction of chronic hyponatremia be rapid, and then, only for a short period of time. Nevertheless, we start with rapid correction because it may be necessary in a medical emergency.

Rapid correction: Use aggressive treatment only for those patients whose symptoms are very serious (e.g. seizures or coma). In this setting, one wishes to shrink the size of brain cells to that present before onset of symptoms. In practice, this means that hypertonic saline should be given to raise the plasma [Na^+] to a level where the seizure activity is not present (usually a rise in serumNa of up to 5 mM). The amount of Na^+ without water to give is 5 mmoles/L of TBW. Nevertheless, do not let the rise in plasma [Na^+] exceed an overall 24-hour rate of 8 mM [44].

Caution: With an acute seizure, the plasma [Na^+] may rise by 10-15 mM because of an acute shift of water into muscle cells, so the plasma [Na^+] at the time of the seizure may be artificially elevated. Therefore, the plasma [Na^+] should not be raised by 8 mM above the first recorded plasma [Na^+] drawn immediately after a seizure.

Slow correction: The objective here is to choose a rate of correction with which virtually no patient is known to have developed ODS (< 8 mM/day) [44]. The rate of correction should be made even slower if the patient could have difficulty with the availability of K^+ and/or organic osmolytes (e.g. alcoholics, patients with hypoxia, malnutrition, or those with a catabolic state such as burn victim) [43].

Specific Emphasis for Therapy

We can identify 3 components which should be addressed in the patient with hyponatremia, each of which requires specific therapy. These will be discussed in the following paragraphs and then be applied to the management of 3 hypothetical patients.

– *Return the ICF volume to normal*: Cells have an excess of EFW which they must lose at a slow rate. This requires a negative balance for EFW. Hence, EFW input should be limited, and strategies should be employed to increase its loss.

– *Return the composition of the ECF to normal*: Most patients with SIADH have a near-normal ECF volume. Nevertheless, the ECF [Na^+] is lower than normal. Therefore, to maintain a normal ECF volume, when EFW is lost, there must be a positive balance for Na^+. By examining quantitative changes (Figure 8), one can appreciate the importance of the Na^+ deficit.

– *Return the composition of ICF to normal*: The issues regarding a surplus of EFW in the ICF compartment have been considered above; 2 remaining aspects are restorating the K^+ deficit, if needed, and restorating the organic osmolytes of the ICF of the brain. If a K^+ deficit was present, it should be replaced with KCl. In the ICF, KCl creates a positive balance for K^+ and a negative balance for Na^+ and H^+. In the ECF, there is a positive balance for Na^+ and Cl^-. Since the KCl is usually given in a hypertonic form, there will be a net gain of hypertonic NaCl in the ECF, a rise in natremia and an expanded ECF volume. If the ECF volume was normal to begin with, the final step is to facilitate the excretion of the extra ECF volume as "isotonic to the patient" NaCl. The time course needed to restore intracellular or-

ganic compounds lost in the development of hyponatremia is a very important consideration. An even slower rate of correction of hyponatremia is prudent when there is a hypokalemia in a patient who is malnourished or has an intensely catabolic state (e.g. burn victim), and/or hypoxia [43].

Case Examples

The following 3 cases are provided to emphasize that the first step in therapy might differ in individual patients with chronic hyponatremia.

- *Case 1, focus on the ICF volume:* You are asked to treat the hyponatremia in a 50-kg person with SIADH due to a tumor. Plasma [Na^+] is always approximately 126 mM and plasma [K^+] is 4.0 mM. No symptoms are attributable to hyponatremia. The ECF volume is normal and the patient consumes a usual diet (150 mmoles NaCl per day).
- *Discussion of Case 1:* There is no urgency here. This patient will need to lose close to 2 L of EFW (the plasma [Na^+] is decreased by 10% so, without a change in the number of particles in the ICF, the ICF volume would be expanded by 10% or 2 L, if the ICF volume in this patient is close to 20 L). The course for this therapy will be several days. The simplest approach is to reduce the intake of EFW to close to less than its rate of excretion. The deficit of NaCl in the ECF can be restored without supplement because the diet has an abundant amount of NaCl. If this therapy does not work, the next step would be to increase the excretion of EFW in the urine. The best way to increase the excretion of EFW is to add osmoles such as urea to force the excretion of water at a given high urine osmolality [35]. In general, the addition of 400 mmoles of urea (24 g) will cause the excretion of 1 L of EFW. Another strategy is to use a loop diuretic to cause the excretion of isotonic saline. In this case, replacing all the ions excreted without water will cause a loss of EFW [33, 34].
- *Case 2, focus on the ECF volume:* A 50-kg person who consumes a low salt diet had a thiazide diuretic prescribed for hypertension. Current symptoms are weakness, a lack of energy, and a feeling of light-headedness upon standing. The "effective" circulating volume is contracted on physical examination (blood pressure is now 135/70 mm Hg (previously160/90 mm Hg) and there is a 20 mm Hg postural drop in blood pressure). Hyponatremia (115 mM) and a low plasma [K^+] (3.4 mM) are present. Urine output is close to 1 L per day with diuretic use. What should the therapy be?
- *Discussion of Case 2:* For now, it is safe to ignore the ICF volume and its composition. The aim of therapy is to administer 1 to 2 L of "isotonic to the patient" saline to reexpand the ECF volume. However, there is a major potential risk in this patient. If the release of AVP was due to a low "effective" circulating volume, when this volume is re-expanded, secretion of AVP may cease and a large water diuresis could occur. If therapy is not changed, the plasma [Na^+] would now rise too rapidly, making ODS more likely. Therefore, AVP should be available at the bedside and be used if the patient excretes enough dilute urine to raise the plasma [Na^+] by more than 8 mM/day.
  One other point merits emphasis. Since the patient is consuming a low salt diet and has a large deficit of Na^+ in the ECF (a deficit of 2 L of ECF volume and a

deficit of 39 mmoles of Na^+ in each of the remaining 8 L of ECF (200 mmoles) because the plasma [Na^+] is 115 mM rather than the normal value of 140 mM), a positive balance of 400 to 500 mmoles of NaCl is needed. Once the ECF volume is near normal, the design of therapy reverts to contracting the ICF volume as described for Case 1 above.

– *Case 3, hyponatremia with a severe degree of hypokalemia:* A 50-kg person was placed on a low-salt diet and a thiazide diuretic for hypertension. The clinical condition of the patient has deteriorated over the past month. Several new findings are present: a poor attention span, a general lack of interest in events, profound weakness, and depression. There are no seizures or coma. On physical examination, the ECF volume appears normal (but it could be low). On laboratory examination, there is both a profound degree of hyponatremia (103 mM) and hypokalemia (1.8 mM). The EKG reveals changes consistent with hypokalemia, but there are no cardiac arrhythmias. What should the therapy be?

– *Discussion of Case 3:* The presence of this severe degree of hypokalemia has 3 major implications: a danger of a cardiac arrhythmia, a need to treat with K^+ rather than Na^+ salts, and a much greater risk of developing ODS [43]. Therefore, there are several issues here for acute therapy. One must first lessen the degree of hypokalemia to decrease the risk of developing a cardiac arrhythmia by giving oral KCl if bowel sounds are present (see Chapter I-2 on Potassium for details). Raising the plasma [K^+] to 3 mM is a reasonable initial target, but one cannot tell in advance how much K^+ will be required. If the load of KCl expands the ECF volume too much, a loop diuretic can be administered to return this volume to normal. DDAVP should be given if a large water diuresis occurs because of suppression of the release of AVP. The overall rate of correction of hyponatremia should not exceed 8 mM/day. There is also a greater danger of developing ODS in patients with hyponatremia and hypokalemia, so the rate of correction of hyponatremia should be even slower than usual (~ 5 – 6 mM/day). As in Case 2, one will need to add NaCl to the diet to repair a deficit of NaCl in the ECF.

Summary

– Do not let the plasma [Na^+] rise by more than 8 mM/day in a patient with chronic hyponatremia.
– Watch out for a water diuresis if AVP is likely to disappear.
– Do not give KCl quickly once the plasma [K^+] rises above 3.0 mM.

General Aspects about a Patient with Hypernatremia

Definition: Hypernatremia is a plasma [Na^+] > 144 mM. It is always associated with a low ICF volume; but the ECF volume may be normal, increased, or decreased.

Illustrative case: A 33–year–old woman has been on lithium for a bipolar affective disorder. While on the medication, her urine volume has increased appreciably, and she feels thirsty when she wakes up at night. She had a surgical procedure under general anesthesia early today. There were no complications in the operating room. Her perioperative intravenous fluid infusion was 3 L of isotonic saline. In the recovery room, she excreted 3 L

of urine, and her plasma [Na^+] rose to 149 mM. The urine osmolality was 107 mOsm/kg H_2O and the urine [Na^+] was 35 mM. What is the basis for her hypernatremia and how should she be treated?

Clinical Approach to the Patient with Hypernatremia

Hypernatremia indicates a negative balance for water and/or a positive balance for Na^+, although often both are responsible (Table 7). Four factors need to be assessed to determine the basis for the hypernatremia [50]. First, there will always be a disturbance of the thirst mechanism. Second, often there will be an inappropriate renal response. Third, in some cases, there will be a problem with excessive administration of Na^+, so one should evaluate the ECF volume. Fourth, one should ask about a loss of weight, since a negative balance of 1 L of EFW should cause a 1 kg weight loss.

– *Analysis of thirst:* The main defense against a reduced cell volume, as seen in hypernatremia, is to increase water intake by stimulating thirst. Because thirst is so effective, it is virtually impossible to increase the plasma [Na^+] by more than a few mM if water is available and the drinking mechanism is intact. Therefore, patients will only develop hypernatremia if they cannot appreciate thirst (e.g. patients who are unconscious or under anesthesia, as in this case example), are unable to communicate their desire for water, or if they have a decreased access to water (e.g. infants or elderly suffering from a stroke). Less frequently, hypernatremia occurs in patients with a primary defect in the thirst mechanism. Rarely, the basis for the negative water balance is reduced intake of water due to vomiting or mechanical obstruction of the upper GI tract (e.g. an esophageal tumor).

  In the above case, general anesthesia and a restricted access to water contributed to the development of hypernatremia.

– *Assessing the renal response:* The expected response to hypernatremia is the release of AVP. Therefore, urine volume should be as low as possible and the urine osmolality should be as high as possible. On a typical Western diet, one might expect a urine flow rate of approximately 0.5 ml/min and a urine osmolality > 900 mosm/kg H_2O. Failure to achieve these values indicates that an abnormal respon-

Table 7. Causes of Hypernatremia. Remember that hypernatremia is always accompanied by a reduced water intake.

A. Net primary water loss
– Reduced water intake
– Defective thirst due to altered mental state, psychological disorder, disease involving the osmoreceptor or cortical thirst center
– Inability to drink water
– Lack of water
– Increased water loss
– Renal loss: central DI, nephrogenic DI usually due to lithium or an osmotic diuresis
– Gastrointestinal loss: vomiting, osmotic diarrhea
– Cutaneous loss: sweating, fever
– Respiratory loss: hyperventilation, fever
– Water shift into the ICF
– Convulsion, rhabdomyolysis
B. Net primary Na^+ gain
– Infusion of NaCl with a higher concentration than that in the urine during polyuria
– Hypertonic NaCl or $NaHCO_3$ infusion
– Ingestion of sea water or NaCl replacing sugar in the feeding formula

DI: diabetes insipidus

se is present in most circumstances. The caveat is that one is comparing results in a patient whose osmolar excretion rate may not be the usual 600 – 900 mOsm/day.

A large loss of EFW usually occurs through the kidney (e.g. in diabetes insipidus (DI) or osmotic diuresis). Other sites of a large loss of EFW are the gastrointestinal tract (e.g. gastric suction or osmotic diarrhea) or the skin, because sweat is a hypotonic solution. Loss of water via the lungs can occur with hyperventilation, but the magnitude is not usually large.

In the above case, the low urine osmolality indicates that DI is present. The patient was given DDAVP, but there was no decrease in the urine flow rate or increase in its osmolality. Therefore, the diagnosis is nephrogenic DI, most likely due to lithium.

– *Excessive administration of Na^+:* Excessive intake of Na^+ in a normal subject does not lead to hypernatremia because the thirst mechanism is intact. Nevertheless, the basis for hypernatremia is revealed by calculating a tonicity balance (Figure 8). Excessive infusion of Na^+ can cause hypernatremia when there is an infusion of a large volume of fluid with a $[Na^+]$ higher than the urine $[Na^+]$ in a patient with polyuria due to diabetes mellitus (urine $[Na^+]$ approximately 50 mM [51]) or DI (even lower urine $[Na^+]$). Other examples include giving a large infusion of hypertonic NaCl inadvertently, the accidental entry of Na^+ into maternal circulation during abortion induced with hypertonic saline, or the administration of a large amount of hypertonic $NaHCO_3$ during cardiopulmonary resuscitation for the treatment of lactic acidosis.

In subjects who have contraction of their ECF volume and a dietary or intravenous source of Na^+, renal retention of Na^+ will contribute to hypernatremia. In fact, in patients with chronic hypernatremia due to water loss (e.g. DI), Na^+ retention may play a more important role than water loss to achieve hypernatremia.

In the above case, the tonicity balance reveals that there is an even balance for water (3 L in and 3 L out), but there is a positive balance for Na^+ of close to 300 mmoles (Figure 8). If her normal total body water is 30 L and the plasma $[Na^+]$ is normally 140 mM, then her plasma $[Na^+]$ should rise to 150 mM, close to the observed value of 149 mM. There should be a shift of 1.5 L of water from her ICF to her ECF in this case (new ECF volume = (149/140) × 10 L)). Clinically, however, this degree of ECF volume expansion may be difficult to detect on physical examination.

– *Loss of weight:* Since water is the most abundant constituent of the body, a loss of water leads to a loss of weight. Quantitatively, 1 L of water weighs 1 kg. However, weight changes are notoriously inaccurate unless the changes are large. If weight was measured in our case, there would be no loss of weight, suggesting that a gain of Na^+ was the basis for her hypernatremia. Similarly, there would be no change in weight in a patient where a shift of water into cells was the basis for the hypernatremia.

Treatment of the case patient: Hypernatremia can be treated either by the addition of water or the removal of Na^+. The choice depends on the Na^+ and water content in the patient. If depletion of water is the cause of hypernatremia, water needs to be added. If Na^+ excess is the cause, Na^+ needs to be

removed (Figure 8); this is the basis for hypernatremia in the case. We would recommend giving a loop diuretic to induce the excretion of isotonic saline and replace this volume with half-isotonic saline. Since this causes a net loss of 75 mmoles of Na^+ per L of urine, we anticipate that 4 L of exchange will be needed. Water should be given by the oral route as soon as possible.

Treatment of the Patient with Hypernatremia

– *Short-term treatment:* The principles here are to defend the ECF volume rapidly, if needed, while attending to the ICF volume more slowly. When the most important problem is a severe deficit of water, isotonic (0.9%) NaCl or 0.45% NaCl should be given initially to stabilize the "effective" circulating volume. In acute symptomatic hypernatremia, the plasma [Na^+] may be reduced by 2 mM/hour for the first 3 – 4 hours, but thereafter, the rate of decline should not exceed 1 mM/hour. As with hyponatremia, chronic hypernatremia usually does not cause central nervous system symptoms, and therefore does not require rapid correction. A safe rate of correction is a 10% fall in serum sodium over 24 hours. Avoid an excessive fall in the plasma [Na^+] because a rapid reduction of the plasma osmolality may result in brain cell swelling. The amount of water needed to correct hypernatremia can be estimated with the following equation: *Water deficit (in L) = TBW X (Target [Na^+] / Current [Na^+]).*
When the EFW deficit is mild, the oral route is the safest one. If aspiration is a concern, hypotonic fluids should be given intravenously. Give intravenous solutions that are hypotonic to the urine if polyuria is present, or hypotonic to the patient in the absence of polyuria (Figure 8). Do not give glucose if the patient is hyperglycemic. In an acutely ill patient, do not give more than 300 ml D_5W/hour, because a 70-kg patient is unlikely to metabolize glucose faster than 0.2 g/hour/kg body weight [50, 52].

– *Long-term treatment:* Disorders that require chronic preventive therapy include DI and primary hypodipsia. Although DI is often listed as a cause of hypernatremia, it should be very mild in the absence of thirst defect. Treatment is therefore directed toward the curtailment of polyuria and polydipsia which disrupt lifestyle. If hormonal deficiency is the cause of DI (central DI), DDAVP should be given either in the form of nasal spray or insufflation. In the case of nephrogenic DI, treatment should be directed towards reducing the flow to the collecting duct. This can be achieved by reducing the "effective" vascular volume with a thiazide diuretic in conjunction with decreasing the intake of salt. Loop diuretics interfere with urine concentrating mechanisms by preventing the development of a high osmolality in the medullary interstitium, through prevention of water resorption in the thin descending loop of Henle secondary to decreased Na^+ resorption in the thick ascending limb. Thus, they are not as effective as thiazide diuretics in reducing collecting duct flow.

Subjects with primary hypodipsia should be taught to drink on schedule. In some instances, the thirst center can be stimulated with chlorpropamide. When the cause of hypodipsia is a disease involving the cortical thirst center or a psychological disorder, a slight increase in water intake will restore

water balance, and hence prevent hypernatremia. When hypodipsia is caused by destruction of the osmoreceptor, increased water intake will be followed by a marked increase in urine output long before the correction of hypernatremia. As the effective circulating volume is expanded by an increase in water intake, the ECF volume depletion-mediated stimulation of AVP wanes. This in turn leads to unmasking of DI, accompanied by polyuria and polydipsia. These patients will therefore have to be treated with DDAVP, as well as the intake of a set amount of water.

Measurement of body weight at regular intervals can detect net water loss leading to hypernatremia. A clinically significant increase in the plasma [Na^+] will be accompanied by a substantial weight loss. For example, if a person with a total body water of 40 L were to increase his plasma [Na^+] from 140 mM to 155 mM by pure water loss, the amount of water loss would have to be close to 4 L, or a weight loss of 4 kg.

Weight changes can also be used to guide the curtailment of water intake in those treated with exogenous AVP. If AVP action is continuously maintained by exogenous AVP administration, these patients have a form of SIADH. Unregulated intake of water can lead to hyponatremia. Daily monitoring of weight will allow one to suspect excessive water retention without measuring the plasma [Na^+]. A substantial weight gain will be accompanied by a significant reduction in the plasma [Na^+]. Another approach one can take to prevent the development of hyponatremia in patients treated with exogenous AVP is to allow the patients to develop a diuresis every few days until the patient experiences thirst. Thirst is experienced when the plasma [Na^+] rises slightly above its usual normal level. This approach of course would not be feasible in those with a disease process involving the thirst center.

Summary

- *Danger:* Hypernatremia means ICF volume contraction; the main danger is an intracerebral hemorrhage due to a reduction in ICP.
- *Diagnosis:* Four questions dominate the clinical picture:
  1. Why is there a problem with thirst?
  2. Is the renal response appropriate?
  3. Is the ECF volume contracted?
  4.Was there a loss of weight (quantitatively reflecting the negative balance for EFW)?
- *Therapy:* Reexpand the ICF volume slowly (fall in serum sodium of close to 10% per day unless hypernatremia is very acute). Maintain a normal ECF volume.
- *Caution:* There is a danger of a glucose load in a patient who needs a large, intravenous input of EFW (as D_5W). In general, do not give more than 300 ml D_5W/hr and do not give D_5W if hyperglycemia is present.

Divalent Ion Regulation and Disorders

Esther A. González, Hatim Hassan and Kevin J. Martin

Calcium

Calcium Homeostasis

Calcium, the most abundant cation in the body, represents about 2% of the total body weight. More than 99% is in bone, and is unavailable for participation in the immediate regulation of calcium homeostasis, while the remainder is distributed in the teeth, soft tissues, and the extracellular space. A 70-kg man has approximately 1.2 kg of calcium, of which only 1.3 g is extracellular. In the normal human adult, neutral calcium balance is maintained over a wide range of intakes, 500 – 1500 mg/day. In plasma, normal calcium concentrations vary from 8.8 – 10.4 mg/dL and is composed of 3 fractions. Approximately 40% of the total serum calcium is protein bound (non-ultrafiltrable). Seventy-five to 90% of this fraction is bound to albumin, and the remainder to globulin. An additional fraction (10 %) of total serum calcium is complexed to various anions, including phosphate, bicarbonate, and citrate, but is ultrafiltrable. The remainder is free ionized calcium (50%). The ionized calcium is the physiologically important component, available for transport and cellular metabolism, and can easily be measured directly. In the absence of measurements of ionized calcium, one can attempt to correct the total calcium for changes in serum protein concentration and changes in blood pH. Thus, an approximation may be obtained as follows: for every gram/dL that serum albumin differs from 4 g/dL, the serum calcium should be adjusted by 0.8 mg/dL. Similarly, for every 0.1 increment in pH, serum calcium should be decreased by 0.12 mg/dL. Generally, as blood pH decreases, the ultrafiltrable and ionized fractions increase. This increase is due not only to a decrease in the affinity of albumin for calcium but also to a decrease in calcium complexed with plasma anions, especially phosphate and bicarbonate. However, when total plasma calcium is normal, the change in the ultrafiltrable and ionized fractions with blood pH is generally insignificant except in severe acidosis (pH < 7.30) or severe alkalosis (pH > 7.60) [1]. Total cell calcium concentration ranges from 1 to 5 mM; however, most of this is bound to the external cell membrane surface, resulting in an intracellular calcium of about 0.5 mM. Most of this is either sequestered in the endoplasmic reticulum and mitochondria or bound to cytoplasmic proteins and ionic ligands, resulting in an intracellular calcium concentration of about 100 nM [1]. The precise regulation of intracellular calcium is important for its role in regulating many biological processes.

Calcium Metabolism

Normal plasma calcium concentration is maintained by the close regulation of intesti-

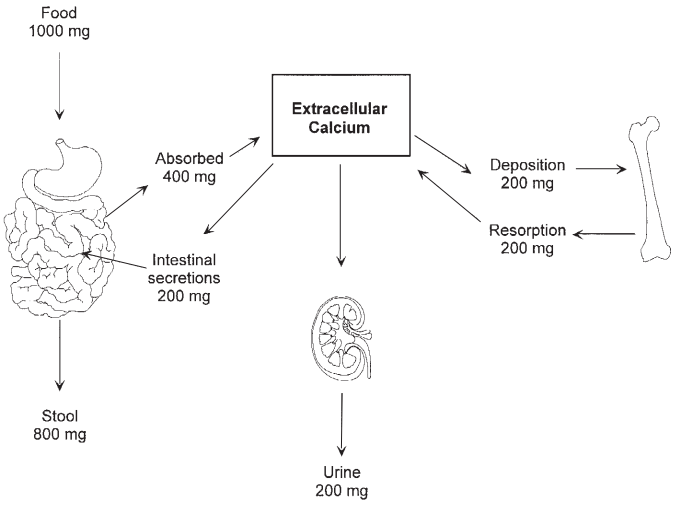

Figure 1. Scheme for calcium balance.

nal calcium absorption, renal calcium reabsorption, and retention and release of skeletal calcium. These 3 biological processes are regulated by the combined effects of parathyroid hormone (PTH) and vitamin D. The overall scheme for calcium balance is depicted in Figure 1. On a usual daily intake of approximately 1000 mg, a net absorption of 200 mg will occur. About 200 mg will enter and leave the bone, and approximately 200 mg will be excreted by the kidney to maintain balance. During growth, the need for positive calcium balance is substantial, and up to 400 mg of calcium/day can be deposited in the growing human skeleton. The level of ionized calcium in blood is tightly controlled despite a wide range of calcium influx from the intestine and bone. This tight control depends in a major way on the parathyroid glands that monitor plasma calcium and increase secretion of parathyroid hormone (PTH) in response to decreases in ionized calcium (Figure 2). This increase in PTH stimulates bone resorption resulting in the release of calcium and phosphorus. PTH acts upon the kidney to increase the reabsorption of calcium and stimulates production of calcitriol, which then increases intestinal calcium and phosphorus absorption. The increased influx of phosphorus from the intestine and bone is excreted by the actions of PTH upon the kidney, thereby restoring homeostasis.

The nature of the calcium sensing by the parathyroid gland has been recently elucidated following the cloning of a G protein-coupled, calcium-sensing receptor from bovine [2] and human [3] parathyroid glands, and rat [4] and human kidney [5]. The deduced amino acid sequence of this receptor shows the characteristic 7-membrane-spanning signature found in all G protein-coupled receptors, and it has some amino acid similarity to the metabotropic glutamate receptors in the central nervous system (CNS). A variety of cells can directly recognize and respond to small changes in their ambient calcium level through this receptor, and it may mediate several of the known effects of calcium on parathyroid and renal function. The physiological relevance of this receptor in calcium homeostasis in man has been demonstrated by the identification both of inactivating and activat-

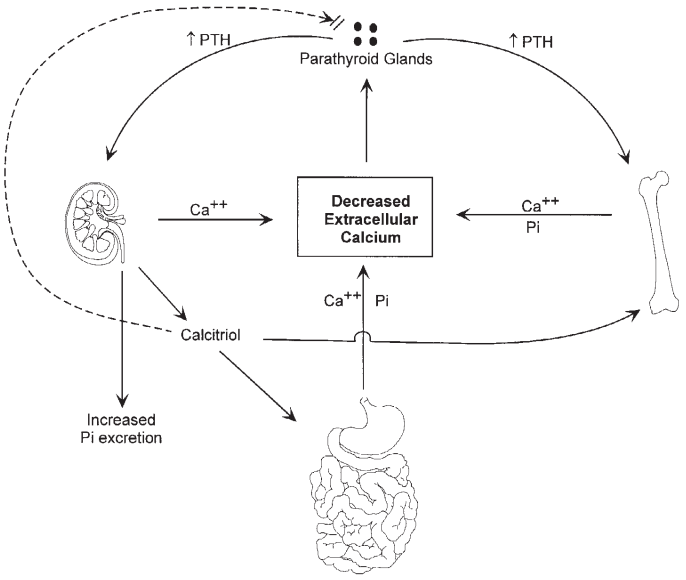

Figure 2. Parathyroid gland response to decreases in ionized calcium.

ing mutations in this calcium-sensing receptor, which result in hypercalcemic (familial hypocalciuric hypercalcemia) and hypocalcemic (neonatal severe hypocalcemia and autosomal dominant hypocalcemia) phenotypes, respectively [6, 7].

Intestinal Calcium Absorption

Net intestinal absorption averages 25 – 30% of a normal dietary intake [1]. The efficiency of intestinal absorption increases as dietary calcium is reduced, so that neutral calcium balance can be maintained at intakes as low as 150 mg/day. The efficiency of absorption normally increases during periods of increased skeletal mineralization, such as growth and pregnancy, and with administration of vitamin D metabolites. Intestinal absorption declines with age, during vitamin D depletion, and during increased intake of oxalate and phytic acid (abundant in many plant tissues).

Regulation of Calcium Absorption

Absorption of calcium across the intestinal mucosa is achieved by 2 processes that occur in tandem: an active transcellular transport (saturable and energy-requiring) and a passive paracellular diffusion process (nonsaturable) [1]. The duodenum is the major site of the active transport process, while the passive mechanism occurs throughout the small intestine and the colon. The absorption rate in all intestinal segments is increased by vitamin D, with the duodenum being the most responsive.

The active mechanism involves transport across the apical membrane, transport across the cytosol, and extrusion across the basolateral membrane. The initial entry involves calcium channels. Within the cell, calcium is bound to a calcium-binding protein, calbindin, which probably protects against toxic increases in cytosolic calcium and transports the calcium across the cell to the basolateral membrane. An ATP-dependent calcium pump in the basolateral membrane that has a higher

affinity for calcium than calbindin is responsible for the extrusion of calcium from the cell. The regulation of calbindin and the plasma membrane calcium pump is vitamin D dependent [8]. This active component becomes saturated at relatively low calcium intake (< 500 mg/day). When daily calcium intake exceeds 500 mg, passive paracellular absorption occurs, which depends on and varies linearly with intestinal calcium concentration and is driven by electrical and chemical gradients. It is nonsaturable; however, there is a possibility that tight junction mediated calcium transport may also be regulated by calcitriol.

The major regulator of intestinal calcium absorption is calcitriol which acts through genomic and nongenomic mechanisms. The genomic mechanism is analogous to that of other steroid hormones in that the ligand, calcitriol, binds to the vitamin D receptor (VDR). Calcitriol regulates the transcription of many genes including that for VDR, calbindin, and the plasma membrane calcium pump. Following administration of calcitriol, there are increases in VDR, calbindin and calcium pump, which correspond to an increase in calcium transport. In addition, there is strong evidence for a rapid nongenomic effect of calcitriol on calcium absorption (transcaltachia) that is independent of the requirement for gene transcription. This effect occurs very rapidly, within seconds to minutes, and is too rapid to be the result of gene transcription [9].

While vitamin D is the most important systemic factor involved in the regulation of calcium absorption, a variety of other factors may also play a role. Many of these factors, such as PTH, growth hormone, estrogen, and loop diuretics, increase intestinal absorption indirectly by increasing the synthesis of calcitriol. On the other hand, glucocorticoids, metabolic acidosis, and thiazide diuretics may decrease intestinal calcium absorption. Other substances within the intestinal lumen, such as phosphate, oxalate, long chain fatty acids, and fiber, decrease calcium absorption. Conversely, lysine, arginine, and lactose increase calcium absorption [10].

Renal Handling of Calcium

To maintain balance, the kidney needs to excrete an amount of calcium which is equal to the daily net intestinal calcium absorption (approximately 200 mg). Renal excretion of calcium begins with the filtration of the ultrafiltrable fraction of plasma calcium (UFCa). This and the glomerular filtration rate (GFR × UFCa) comprise the filtered load of approximately 9,000 mg/day. Therefore, 98 – 99% (8,800 mg/day) needs to be reabsorbed to allow the excretion of 200 mg/day, which is required to maintain balance. Approximately 70% of filtered calcium is reabsorbed in the proximal convoluted tubule (PCT), 20% in the thick ascending limb of the loop of Henle, 5 – 10% in the distal tubule, and < 4% in the collecting tubule. Transcellular transport across the renal tubular cell resembles that which occurs in enterocytes [1]. As in the intestine, a large proportion of the transport occurs via the paracellular pathway.

In the PCT, reabsorption of calcium is largely passive and is proportional to sodium and water reabsorption [11]. Reabsorption is enhanced by extracellular fluid (ECF) volume contraction and is diminished by ECF volume expansion. In the proximal straight tubule, calcium is transported against both electrical and chemical gradients, suggesting that the transport process is energy-requiring, active, and dissociable from sodium and water transport [12]. Most studies show that reabsorption of calcium in the medullary portion of the thick ascending loop of Henle is passive,

driven by the positive luminal potential, which depends on the activity of the Na-K-2Cl transporter. Hormonal regulation may also occur in this segment.

In the distal convoluted tubule (DCT), only 5 – 10% of calcium reabsorption occurs. The transport process is active, occurring against an electrochemical gradient, and it can be dissociated from sodium reabsorption by administering a thiazide. PTH also enhances calcium reabsorption independent of changes in sodium reabsorption or luminal potential, possibly by stimulating adenylate cyclase in the granular cells [13]. Less than 4% of calcium reabsorption occurs in the collecting duct. Current evidence suggests that the reabsorption process is active, occurring in the granular cortical collecting tubule and is independent of electrical potential or sodium transport [13]. This part of the nephron may play a role in the final regulation of renal calcium reabsorption.

Regulation of Calcium Excretion by the Kidney

Much of the regulation of calcium excretion occurs in the distal tubule where the effects of calciotropic hormones on calcium transport are localized. In general, the process appears to be similar to calcium transport in the enterocyte. A variety of factors may influence the renal handling of calcium [1].

A high intake of dietary calcium will increase urinary calcium excretion, both by increasing the filtered load, if serum calcium increases, and by suppressing PTH. Conversely, phosphate administration tends to decrease urinary calcium excretion by decreasing the filtered load of calcium and by stimulating PTH secretion.

PTH is thought to be the primary homeostatic regulator of renal calcium excretion and serves to increase calcium reabsorption by the kidney; however, increases in serum calcium as a result of the actions of PTH on bone may override this effect so that frank hypercalciuria may occur. Also, PTH has been shown to reduce GFR by altering the K_f of the glomerular capillaries [1]. This reduction in the filtered load of calcium, along with the enhancement of tubule reabsorption, results in decreased calcium excretion. The effects of calcitriol on renal calcium excretion remain ill-defined. It is likely, however, that the direct effect of calcitriol is to increase urinary calcium excretion independent of the changes in PTH and serum calcium.

In general, acidosis is associated with increases in urinary calcium by increasing the release of calcium from bone and by inhibiting tubular calcium reabsorption. Acidosis also increases the proportion of ultrafiltrable calcium by decreasing calcium binding to serum proteins. Alkalosis, on the other hand, tends to reduce urinary calcium by increasing calcium binding to proteins, therefore decreasing free calcium levels and increasing PTH secretion. It has also been shown that alkalosis enhances renal tubular calcium reabsorption independent of any change in PTH. Hypercalcemia of any cause leads to hypercalciuria, especially if PTH secretion is suppressed. Loop diuretics increase calcium excretion by decreasing calcium reabsorption in the loop of Henle. Thiazide diuretics, on the other hand, decrease calcium excretion. Glucose infusion enhances calcium excretion by decreasing calcium reabsorption in the proximal tubule. Insulin infusion and hyperinsulinemia are also associated with hypercalciuria.

Abnormalities in the recently described calcium receptor may also be associated with alterations in calcium excretion such as those found in patients with familial hypocalciuric hypercalcemia [6].

Calcium Metabolism in Bone

Under normal circumstances, there is constant mobilization of calcium from bone and deposition of calcium in newly-formed osteoid as part of the continuous process of normal bone remodeling that occurs throughout life. During growth, the net effect is to deposit calcium into the growing skeleton. The converse, an excessive rate of bone resorption, can be the result of disease states in which the normal coupling between bone formation and resorption is disturbed, leading to net skeletal loss. These diseases include hyperparathyroidism, hypercalcemia of malignancy, multiple myeloma, and osteoporosis.

Several hormones are known to regulate osteocyte and osteoclast activity in bone. PTH is the major regulator of bone turnover. The target cell for PTH is the osteoblast, and effects upon osteoclasts are thought to be indirect. Although PTH stimulates both bone formation and bone resorption, the net effect of sustained increases in PTH is loss of bone. Current evidence indicates that intermittent elevations of PTH may actually be associated with a net increase in bone formation. PTH also increases the conversion of mononuclear cells to osteoclasts. Like PTH, the principal target cell for calcitriol action is the osteoblast. While calcitriol appears to be essential for normal bone growth and mineralization, its net effect on bone formation depends on the balance between the negative effect on osteoblast number and its positive effect on bone formation per osteoblast. The actions of calcitriol are complex and likely related to multiple effects on bone cells, such as enhancing mineralization of osteoid and synthesis of subcellular organelles in osteoblasts and osteocytes, as well as altering the concentration of extracellular calcium and phosphorus. Calcitriol also exerts a permissive effect on PTH-stimulated osteoclastic resorption. Bone remodeling is regulated not only by PTH and calcitriol but also by other hormones such as insulin, growth hormone, calcitonin, IGF-1, glucocorticoids, sex hormones, thyroid hormones, and a variety of locally produced cytokines. Calcitonin inhibits bone resorption and induces hypocalcemia; however, its importance in the daily physiological regulation of skeletal calcium is not known. In addition, bone resorption may be altered by hormone-independent mechanisms such as systemic acidosis, in which bone mineral is released from the skeleton to buffer hydrogen ions.

Hypocalcemia

The hormonal systems responsible for the maintenance of normal plasma calcium concentrations are made up of PTH, vitamin D, and the target organs for these hormones, i.e. bone, kidney, and intestine. Because the presence of both PTH and vitamin D is required for full expression or activity of the other, hypocalcemia may commonly result from a defect in either the PTH or vitamin D system.

The causes of hypocalcemia can be classified into the following categories (Table 1):

Decreased PTH secretion may be due to idiopathic or acquired hypoparathyroidism [14]. Idiopathic hypoparathyroidism, which is relatively rare, may be familial or sporadic and can present at any age. Surgical hypoparathyroidism may result from thyroid, parathyroid, or radical neck surgery and may be transient or permanent [15]. Hypoparathyroidism has been reported with parathyroid infiltration by malignancy, iron, copper, and possibly amyloid [16 – 19], and also following neck irradiation. Hypomagnesemia causes hypocalcemia by decreasing the release of PTH and may impair PTH-induced

Table 1. Causes of Hypocalcemia

Disorders of the parathyroid
- Decreased PTH secretion
  - – Hypoparathyroidism
  - – Idiopathic, surgical, infiltrative, radiation-induced, magnesium depletion
- PTH resistance
  - – Pseudohypoparathyroidism Type 1a, 1b, 1c, 2
  - – Magnesium depletion
  - – Renal failure

Disorders of vitamin D metabolism
- Vitamin D deficiency
  - – Dietary
  - – Malabsorption
  - – Lack of exposure to sun
- Decreased production of 25(OH)D_3
  - – Severe liver disease
- Increased metabolism of 25(OH)D_3
  - – Anticonvulsant therapy
- Decreased production of calcitriol
  - – Renal failure
  - – VDDR I
  - – Hyperphosphatemia
  - – Oncogenic osteomalacia
- Vitamin D resistance
  - – VDDR II

Relocation of circulating calcium
- Extravascular deposition
  - – Hungry bone syndrome
  - – Pancreatitis
  - – Osteoblastic metastases
- Intravascular binding
  - – Citrate, EDTA, acute respiratory alkalosis

Miscellaneous
- Sepsis
- Drugs
  - – Gentamycin, cisplatin, mithramycin, bisphosphonates, phosphate salts
- Hypoproteinemia

release of calcium from bone (see sections on phosphate and magnesium). Resistance to the actions of PTH will also result in hypocalcemia and can occur in pseudohypoparathyroidism, renal failure, and magnesium depletion (see section on phosphate).

Disorders of vitamin D metabolism will also result in hypocalcemia. Vitamin D regulates intestinal calcium absorption, skeletal responsiveness to PTH, and normal bone turnover. Thus, the pathogenesis of hypocalcemia may reflect one or more of these physiologic actions of vitamin D metabolites. Vitamin D deficiency may result from abnormalities at any point in its metabolic pathway, including diminished intake or intestinal absorption, reduced formation of the precursor in the skin, and impaired hydroxylation in the liver and kidney including hereditary deficiency of 1-α-hydroxylase (vitamin D-dependent rickets). Vitamin D resistance may also occur because of disorders of the vitamin D receptor leading to defective action on the target organs.

Relocation of circulating calcium which may occur in several clinical circumstances also causes hypocalcemia. Profound hypocalcemia associated with hypophosphatemia and hypomagnesemia may occur after surgical correction of primary or secondary hyperparathyroidism associated with severe osteitis fibrosa cystica. This condition, known as the hungry bone syndrome or recalcification tetany, results from rapid and excess bone mineralization over bone resorption [20]. The severity of hypocalcemia correlates well with the severity of bone disease before treatment. Predictors of its occurrence after surgery for primary hyperparathyroidism include more severe hypercalcemia, higher alkaline phosphatase and PTH levels, renal insufficiency, and larger parathyroid adenomas. Hypocalcemia occurs in 40 – 70% of patients with acute pancreatitis, likely due to calcium deposition in areas of fat necrosis [21]. Hyperphosphatemia may cause hypocalcemia by precipitation of calcium phosphate complexes in soft tissues and by inhibition of 1-α-hydroxylase, which results in decreased formation of 1-α,25-$(OH)_2D_3$. Inhibition of calcium re-

lease from bone by hyperphosphatemia may also contribute to hypocalcemia. Renal failure may be associated with hypocalcemia by several mechanisms, including hyperphosphatemia, impaired production of calcitriol because of the reduced renal mass, skeletal resistance to vitamin D and PTH, and metabolic acidosis.

Increased intravascular binding of calcium may also result in hypocalcemia. Infusion of citrate (given with blood transfusion) or ethylene diaminetetraacetic acid (EDTA) can chelate calcium in the blood, thereby reducing the ionized calcium concentration without affecting total calcium. A similar effect is induced by acute respiratory alkalosis, which enhances calcium binding to albumin.

Miscellaneous causes of hypocalcemia include hypoalbuminemia which results in reduced total calcium with normal ionized calcium, which alone is not clinically significant. Several drugs may be associated with hypocalcemia. The anticonvulsants phenobarbital and diphenylhydantoin cause hypocalcemia by inducing hepatic microsomal P450 oxidase activity, leading to accelerated metabolism of vitamin D_3 and $25(OH)D_3$ into polar, hydroxylated, and biologically inactive products [22]. Cisplantin causes hypocalcemia by inducing renal magnesium wasting and hypomagnesemia [23]. The incidence of hypocalcemia in the critically ill or postsurgical patient may approach 80 %. The vast majority of these cases are due to hypoalbuminemia, and the ionized calcium concentration is normal.

Clinical Manifestations of Hypocalcemia

The clinical manifestations of hypocalcemia depend partly on the underlying cause. They may be subtle (e.g. depression) or florid (e.g. tetany), and their severity is not closely related to the degree of hypocalcemia. Asymptomatic hypocalcemia may contribute to cardiac dysfunction, including hypotension and heart failure [24]. Profound hypocalcemia may not be associated with any symptoms, as in many patients with renal failure. The concurrent blood pH, as well as other electrolyte abnormalities, is likely to influence the symptoms.

– *Neuromuscular manifestations*
The classic manifestation of neuromuscular irritability in hypocalcemia is tetany. It usually begins with circumoral and acral paresthesias and may progress to the typical cramps in the muscles of the hands (main d'accoucheur, with adduction of thumbs and flexion of MCP joints), larynx (laryngismus), or elsewhere. Latent tetany may be detected by observing a facial twitch on tapping the branches of the facial nerve (Chvostek sign, present in 25% of normal adults), or by observing carpopedal spasm, which is produced after 3 minutes of inflation of a sphygmomanometer cuff above systolic pressure (Trousseau's sign, more specific, but can be negative in 30% of patients with latent tetany). Acidosis protects against tetany, while alkalosis facilitates tetany [25]. Correction of the metabolic acidosis in patients with renal failure and severe hypocalcemia may precipitate tetany. Seizures may be the presenting manifestation of hypocalcemia. Hypocalcemia may be associated with mental retardation in children and dementia in adults. The latter may improve considerably with correction of hypocalcemia. Reversible emotional instability, anxiety, confusion, hallucination, and psychosis may occur in hypocalcemia.

– *Cardiovascular, ectodermal, and gastrointestinal effects*
EKG manifestations of hypocalcemia include prolongation of the Q-T interval and nonspecific T wave changes. Coarse, dry, and scaly skin; brittle nails; and thin and sparse hair have all been observed after hypocalcemia. Children with hypoparathyroidism may exhibit dental aplasia, hypoplasia, or caries. Psoriasis and eczema can be exacerbated by hypocalcemia. Bilateral cataracts may also occur, and treatment of hypocalcemia arrests their progression.

Diagnostic Approach to Hypocalcemia

Once hypocalcemia has been found on routine laboratory testing or is suspected on a clinical basis, the initial step should be an assessment of the serum ionized calcium. Both the history and physical examination may be helpful in providing clues, such as possible surgical hypoparathyroidism, idiopathic hypoparathyroidism (e.g. candidiasis), pseudohypoparathyroidism (somatic features), vitamin D deficiency (diet and intestinal disease), and magnesium deficiency.

Determination of the PTH level helps distinguish PTH deficiency from conditions in which responsiveness to PTH is impaired. Measurement of serum vitamin D metabolite levels, especially 25(OH)D and calcitriol, may be of great value in differentiating the various forms of vitamin D deficiency and vitamin D resistance.

Treatment

Treatment of hypocalcemia depends on severity, rapidity of onset, the presence of symptoms, and the underlying cause. It should be emphasized that correction of the underlying disease is generally required for persistent normalization of the plasma calcium concentration.

Mild asymptomatic hypocalcemia (plasma ionized calcium > 3.2 mg/dL) is well tolerated and can be managed initially by increasing dietary calcium intake or by oral calcium supplements (250 to 500 mg elemental calcium every 6 hours). Symptomatic hypocalcemia should be treated as a medical emergency and requires parenteral calcium, which should be given with caution to patients receiving digitalis to prevent toxicity. Initial therapy consists of 1 – 2 ampules of calcium gluconate (90 mg of elemental calcium per 10-ml ampule) in 5 – 10 mL of 5% dextrose given over 5 – 10 minutes, repeated as needed. Slow administration is critical, because the rapid IV infusion of calcium can cause serious cardiac dysfunction, including systolic arrest. An infusion of elemental calcium at a rate of 0.5 – 1.5 mg/kg/hour should follow initial treatment. Intravenous calcium should be continued until the patient is on an effective regimen of oral calcium and vitamin D.

Hypocalcemia due to magnesium depletion requires parenteral magnesium sulfate. Hypocalcemia after parathyroidectomy may be severe and may result from the hungry bone syndrome (especially in patients with osteitis fibrosa cystica) [20]. Careful monitoring is required to prevent potentially serious complications; therefore, plasma calcium should be measured 2 – 4 times daily for the first few postoperative days. Oral calcium (2 – 4 g of elemental calcium [50 – 100 mmol]/day) should be given when the patient is able to swallow. Intravenous calcium is indicated if the patient develops tetany, latent tetany, or a plasma calcium concentration < 7.5 mg/dL (1.9 mmol/L). Massive and prolonged supplementation of calcium may generally be re-

quired (1 – 4 mg/kg/hour of elemental calcium given in 1 L of 5% dextrose, initiated at 40 – 50 mL/hour, and titrated according to the plasma calcium) to maintain the plasma calcium above 8 mg/dL. Calcitriol (oral or IV, 2.0 – 3.0 μg/day) should be initiated if the foregoing measures are not adequate. For patients on dialysis who are deemed to be at high risk for the hungry bone syndrome, IV calcitriol (2 μg at the end of each dialysis) started 3 – 5 days before parathyroidectomy and continued postoperatively may help prevent severe hypocalcemia. Management of chronic hypocalcemia in patients with relatively normal renal function requires therapy with oral calcitriol together with oral calcium supplements. Care should be taken to avoid severe hypercalciuria by maintaining serum calcium at the lower limits of normal. Thiazide diuretics with dietary salt restriction may be useful adjuncts to such therapy.

Hypercalcemia

Hypercalcemia is a relatively frequent medical problem. The prevalence and causes of hypercalcemia are distinctly different among individuals in the general population and hospitalized patients. The prevalence in the general population is up to 0.1%, but may be higher in the hospital inpatient population [26]. Among its many causes, by far the most common are malignancy and primary hyperparathyroidism, which together account for up to 80 – 90%. Among ambulatory outpatients with hypercalcemia, the vast majority have primary hyperparathyroidism, and prompt identification of hypercalcemia and its causes becomes of paramount importance in preventing the morbidity and mortality associated with this metabolic disorder.

Table 2. Causes of Hypercalcemia

Parathyroid-related
Primary hyperparathyroidism
Adenoma, hyperplasia, carcinoma
MEA
Type 1 and 2
FHH
Tertiary hyperparathyroidism
Malignancy-related
Humoral hypercalcemia of malignancy
Lung, breast, renal, esophagus, cervix, head and neck
Skeletal involvement
Myeloma, lymphoma, metastases
Vitamin D-related
Vitamin D intoxication
Granulomatous disorders
Sarcoidosis, histoplasmosis, tuberculosis
Drug-related
Lithium, thiazides, vitamin D, vitamin A, aluminum intoxication
Miscellaneous
Immobilization, postrenal transplantation, Milk alkali syndrome, hyperthyroidism, Paget's disease

The causes of hypercalcemia are shown in Table 2. Primary hyperparathyroidism may occur as often as 1 in 500 individuals and is most often benign. Approximately 85% of patients with primary hyperparathyroidism have single adenomas, 10 – 15% have diffuse hyperplasia, and < 5% have parathyroid carcinomas. The principal systems affected include the kidney, bone, CNS and gastrointestinal tract. Hypercalcemia results from increased bone resorption, increased intestinal absorption of calcium secondary to a PTH-induced increase in $1,25(OH)_2D_3$, and also to

increased renal reabsorption of calcium mediated by the increased PTH. Renal sequelae of PTH excess and hypercalcemia include nephrolithiasis (in 10 – 15% of cases), nephrocalcinosis, polyuria, dehydration, renal insufficiency, and, rarely, renal failure. Skeletal manifestations of hyperparathyroidism include diffuse osteopenia, subperiosteal bone resorption, endosteal erosion, cortical striations, osteosclerosis, "rugger jersey spine", and osteitis fibrosa cystica [27]. The latter lesion is classic for hyperparathyroidism, but is rare. Patients with significant skeletal involvement may have progressive bone pain and pathologic fractures. Gastrointestinal complications of hyperparathyroidism include peptic ulcer disease and pancreatitis. Hyperparathyroidism can also be found in patients with multiple endocrine adenomatosis (MEA). Werner's syndrome (MEA type I) consists of pancreatic and pituitary tumors associated with parathyroid adenomas. Pheochromocytomas and medullary carcinoma of the thyroid are found in MEA type II. This condition is associated with hyperparathyroidism in type II a or with mucosal neuromas in type II b. Both MEA I and II are inherited as autosomal dominant traits.

Familial hypocalciuric hypercalcemia (FHH) is characterized by hypercalcemia beginning in the first decade of life, low fractional urinary calcium excretion (a value < than 0.01 suggests FHH is present), a tendency to develop hypermagnesemia, normal renal function, and failure of hypercalcemia to be corrected by subtotal parathyroidectomy [28]. It is inherited as autosomal dominant trait. Whereas chronic hypercalcemia in primary hyperparathyroidism is associated with severe impairment in urine concentrating ability, patients with FHH and long-standing hypercalcemia do not display such an impairment [29]. The FHH gene has been localized to the long arm of chromosome 3. Recently, as described above, the gene encoding the calcium receptor, which is highly expressed in the kidney and parathyroid gland and functions to sense physiologically relevant changes in serum calcium, was localized to the FHH locus on chromosome 3, and mutations in this gene explain this syndrome [6]. The lack of defective urinary concentration in FHH patients is likely explained by the effects of the calcium-sensing receptor on the function of the thick ascending loop of Henle, and on water reabsorption in the collecting duct [30].

Malignancy-associated hypercalcemia is the most common paraneoplastic syndrome, occurring in up to 10% of all patients with cancer [31]. Of all patients with hypercalcemia and malignancy, 44% have hematologic and 41% have solid neoplasms. Hypercalcemia complicates 11% of all the hematologic neoplasms, but only 6% of patients with solid neoplasms are hypercalcemic [32]. The most common malignancies associated with this disorder are breast, renal cell, and lung cancers along with multiple myeloma and squamous cell carcinomas of the head and neck [33]. The malignancy is almost never occult at the time when patients show hypercalcemia, and the occurrence of hypercalcemia is usually a poor prognostic factor. An exception to this rule is multiple myeloma, in which hypercalcemia may be the presenting symptom of the disease and the course may be more chronic [34]. The mechanisms responsible for the hypercalcemia are both humoral and local, and include production of a parathyroid hormone-related protein (PTHrP) by tumor cells and release of bone resorbing cytokines and growth factors by tumor cells metastatic to bone with resultant osteolysis [31]. Ectopic production of authentic PTH by tumor cells, which is extremely rare, has been documented for small cell lung cancer, ovarian cancer, and a primitive neuroectodermal cancer with extensive metastasis [35]. Pa-

tients with multiple myeloma have cystic bone lesions. The mediators of increased osteoclastic bone resorption in multiple myeloma include the interleukins IL-2 and IL-6, and tumor necrosis factor (TNF).

Vitamin D-related hypercalcemia is due to increased intestinal absorption of calcium and to increased bone resorption and can be produced with the administration of large doses of vitamin D or any of its metabolites. Sarcoidosis and other granulomatous disorders are significant causes of hypercalcemia. Hypercalciuria is a common feature of sarcoidosis (35 – 40% of unselected patients), while the incidence of hypercalcemia ranges from 2 – 25% in several studies [36]. The abnormal calcium metabolism in sarcoidosis may be the result of either excessive endogenous production or an abnormal sensitivity to calcitriol, and both sun exposure and vitamin D therapy have provoked frank hypercalcemia in affected patients [37]. Other renal complications in these patients include nephrocalcinosis and nephrolithiasis. Renal involvement in sarcoidosis can progress to acute and chronic renal failure (coexisting hypercalcemia may accelerate development of the latter). Typically, patients with hypercalcemia have elevated levels of $1,25(OH)_2$ vitamin D and suppressed PTH levels [36]. The elevated plasma levels of $1,25(OH)_2D_3$ in sarcoidosis result from its increased production by the macrophage, a prominent constituent of the sarcoid granuloma that possesses $25(OH)D_3$-1-α-hydroxylase [38]. The 1-α-hydroxylation reaction in macrophages is inhibited by glucocorticoids, and this explains in part why these agents are the mainstay of therapy of sarcoid-induced hypercalcemia [39]. Other granulomatous disorders associated with hypercalcemia include tuberculosis, histoplasmosis, coccidiomycosis, berylliosis, and leprosy. Evidence suggests that the pathogenetic mechanism is similar to that in sarcoidosis.

Drug therapy, including vitamin D and vitamin A therapy, must also be considered in the differential diagnosis of hypercalcemia. Thiazide diuretics can be associated with hypercalcemia, particularly when an underlying condition may perpetuate the increase in serum calcium. The mechanisms include a thiazide-induced volume contraction that may increase renal reabsorption of calcium, and contraction metabolic alkalosis that may lead to increased calcium binding by proteins. A direct effect of thiazides on distal tubular calcium reabsorption has been shown in the rat, and, a direct effect of thiazides on bone has been shown in dogs [40]. The latter finding is supported by the thiazide-induced hypercalcemia observed in hemodialysis patients. Lithium therapy has been reported to result in hypercalcemia with high levels of circulating immunoreactive PTH levels [41]. Lithium may increase the threshold at which serum calcium suppresses PTH secretion. Also, lithium carbonate can produce hypocalciuria, probably mediated in part by excess PTH secretion or direct enhancement of tubular calcium reabsorption. Calcium carbonate and acetate therapy in large doses, used as phosphate binders in patients undergoing dialysis, can lead to hypercalcemia. This tendency is accelerated in patients undergoing dialysis who have aluminum-induced low-turnover bone disease. Hypercalcemia can occur in these patients with or without the concomitant administration of calcitriol.

Additional causes of hypercalcemia include immobilization, especially in children, and Paget's disease patients in whom bone turnover is increased [42]. Hyperthyroidism may also be associated with hypercalcemia. Post-transplantation hypercalcemia with elevated serum PTH after successful renal transplantation can occur in 8 – 35% of cases [43]. Typically, hypercalcemia disappears within 6 months after transplantation but may last as

long as 24 months. Other contributing factors include osteomalacia, phosphate depletion, and the use of steroids and diuretics. The milk-alkali syndrome is characterized by hypercalcemia, metabolic alkalosis, and renal insufficiency. Hypercalcemia is caused by the ingestion of large quantities of calcium, which leads to increased serum calcium, together with the ingestion of alkali, which increases protein-bound calcium and renal reabsorption of calcium. Hyperphosphatemia may develop in this syndrome because of either the high phosphate content of milk or the concomitant renal insufficiency. The combination of hypercalcemia and hyperphosphatemia in the face of metabolic alkalosis may produce metastatic calcification and further renal damage. Dietary modifications are an essential part of therapy for this syndrome.

Consequences of Hypercalcemia

The clinical manifestations of hypercalcemia are influenced by the degree of hypercalcemia and the rate of onset. The clinical spectrum of hypercalcemia ranges from the asymptomatic patient found on a routine serum analysis to the patient with hypercalcemic crisis who presents in coma. The clinical manifestations of hypercalcemia reflect disturbances in gastrointestinal, cardiovascular, renal, and CNS function. CNS manifestations can range from subtle alterations in personality to acute psychosis. Specific manifestations include depression, bizarre behavior, apathy, drowsiness, memory impairment, obtundation, or even coma. Increased calcium in cerebrospinal fluid has been alleged to decrease the conduction of nerve terminals. Cardiovascular manifestations of hypercalcemia reflect the fact that calcium is an important regulator of excitation-contraction coupling of the heart and of smooth muscle tension in peripheral vessels. It exerts a positive inotropic effect on the heart and reduces heart rate, similar to the effect of cardiac glycosides. Hypercalcemia causes shortening of the Q-T interval in the EKG. Calcification of cardiac valves and narrowing of coronary arteries as well as extensive pulmonary calcification has been reported in chronic hypercalcemia. Renal manifestations include impairment of renal function as a result of decreased renal blood flow (RBF) and GFR. Impairment of sodium reabsorption, which results from inhibition of Na^+-K^+-ATPase in the thick ascending limb and distal tubules, leads to volume contraction in hypercalcemia [44]. Polyuria results from impairment of the renal concentration capacity, which may be mediated by the calcium-sensing receptor [30]. Calcium nephropathy, which presents clinically as interstitial nephritis, results from calcium deposition and interstitial inflammation.

Gastrointestinal manifestations include constipation, nausea, vomiting, and anorexia. Duodenal ulcer disease occurs in 10 – 20% of patients with hypercalcemia. Pancreatitis can occur in as many as 35% of patients in acute hypercalcemic crisis. Metastatic calcification of soft tissue may give rise to nephrocalcinosis and calcification of pancreatic ducts, gastric mucosa, intima or media of blood vessels, joint cartilage (chondrocalcinosis), cornea and conjunctiva (band keratopathy), skin, heart, lung, or other locations.

Diagnostic Approach to Hypercalcemia

Several principles guide the approach to the hypercalcemic patient. First, a PTH level elevated above the normal range in a patient with hypercalcemia is almost always indicative of primary hyperparathyroidism. Second, the number of patients with malignancy and ele-

vated PTH caused by ectopic production of authentic PTH is exceedingly small and is far fewer than the number of patients with coexistent malignancy and hyperparathyroidism. Third, malignancy-associated hypercalcemia is rarely the only manifestation of underlying malignancy. Fourth, the clinically asymptomatic patient with hypercalcemia detected by an autoanalyzer will almost always have primary hyperparathyroidism. Vitamin D or A intoxication, granulomatous diseases, milk-alkali syndrome, and other causes for hypercalcemia are usually obvious by initial history and physical examination.

With these principles in mind, the following approach is suggested. All patients with hypercalcemia should undergo a complete history and physical and routine laboratory studies including radiography of the chest and urinalysis. Any abnormality or organ-specific symptom complex should be further evaluated to rule out the presence of malignancy. In the absence of detectable malignancy, a PTH level should be obtained. A distinctly elevated midregion or intact PTH should be considered as evidence of primary hyperparathyroidism. If the PTH level is within the normal range, the diagnosis could still be hyperparathyroidism, but other known causes of hypercalcemia should be reviewed and other diagnostic tests considered based on suggestive clues in the history and physical. A urine calcium-to-creatinine ratio should be obtained to rule out familial hypocalciuric hypercalcemia. The presence of osteitis fibrosa, albeit rare, indicates hyperparathyroidism. An elevated level of 25(OH) vitamin D indicates vitamin D intoxication. In hypercalcemic patients without symptoms and with a normal serum PTH level and normal laboratory evaluation, the approach should be careful follow-up with repeated PTH measurements. If the PTH level is low and malignancy is not evident, and milk-alkali syndrome and vitamin D intoxication are unlikely because of history and physical exam, granulomatous diseases should be considered. Elevated angiotensin-converting enzyme and $1,25(OH)_2$ vitamin D levels and suppression of the hypercalcemia with steroids support the diagnosis of sarcoidosis.

Treatment of Hypercalcemia

The magnitude of the hypercalcemia is a key consideration in determining the need for immediate, aggressive therapy. On the basis of the serum calcium concentration alone, hypercalcemia may be classified as mild (< 12 mg/dL) moderate (12 – 15 mg/dL) or severe (> 15 mg/dL). In moderate and severe hypercalcemia, the serum calcium must be reduced expeditiously yet safely while diagnostic efforts are in progress and in preparation for definitive therapy. There are 4 basic goals for the therapy of hypercalcemia: 1) to correct dehydration, 2) to enhance the renal excretion of calcium, 3) to inhibit accelerated bone resorption, and 4) to treat the underlying disorder.

General measures include the intravenous administration of isotonic saline as the first step in the management of severe hypercalcemia. When the depleted intravascular volume is restored to normal, the serum calcium concentration should decline, at least by the degree to which dehydration raised it. The reduction usually amounts to 0.40 – 0.60 mmol/L (1.6 – 2.4 mg/dL), but hydration alone rarely leads to normalization of the serum calcium concentration in patients with severe hypercalcemia. The expansion of intravascular volume is also helpful because it increases renal calcium clearance by several mechanisms. First, the increase in the GFR leads to increased filtration of calcium. Second, proximal tubular sodium and calcium reabsorption decreases as the GFR increases.

Third, as more sodium and water are presented to distal renal tubular sites, an obligatory calciuresis ensues. The rate of saline administration should be based on the severity of the hypercalcemia, the extent of dehydration, and the tolerance of the cardiovascular system for volume expansion. A widely used regimen is to administer 2.5 – 4 L of isotonic saline daily, recognizing the need to adjust the rate of fluid administration or to administer a diuretic agent if symptoms and signs of fluid overload appear. Intake should be greater than output by at least 2 L in the first 24 hours.

In addition to hydration with saline, adjunctive therapy with a loop diuretic may be indicated to facilitate urinary excretion of calcium. Loop diuretics enhance the calciuric effects of volume expansion by inhibiting calcium reabsorption in the thick ascending limb of the loop of Henle. Thiazide diuretics should never be used in this situation because they enhance distal tubular reabsorption of calcium and thus may actually exacerbate hypercalcemia. Volume expansion must precede the administration of furosemide, because the effect of the drug depends on the delivery of calcium to the ascending limb. Intensive administration of furosemide (40 – 80 mg intravenously every 1 – 2 hours) with fluid and electrolyte replacement based on urinary losses is an effective regimen for the treatment of hypercalcemia. This aggressive approach will lead to marked hypercalciuria, but it requires frequent measurement of water and electrolyte excretion.

Four agents lower plasma calcium concentration by blocking osteoclast function: calcitonin, bisphosphonates, mithramycin, and gallium nitrate. Salmon calcitonin decreases serum calcium, predominantly by reducing bone resorption and less importantly by enhancing urinary calcium excretion. It can be given intramuscularly or subcutaneously in a dose of 4 – 8 U/kg twice a day. It is safe and nontoxic and when effective, works very rapidly to lower the plasma calcium concentration by a maximum of 1 – 2 mg/dL beginning within 2 – 3 hours [45]. Rapid loss of the effect of calcitonin can occur after 24 – 72 hours of treatment. This abolition of hypocalcemic action has been referred to as the "escape" phenomenon, which can be partly explained by down-regulation of hormone receptors, as well as by uncoupling of receptors from adenylate cyclase.

Mithramycin inhibits DNA-dependent RNA synthesis in osteoclasis. A dose of 25 μg/kg of body weight is infused in D5W over a period of 4 – 8 hours. The plasma calcium concentration begins to fall within about 12 hours and usually reaches a nadir by 48 hours. The hypocalcemic effect lasts for several days with repeated doses given at 3 – 7 day intervals [46]. Side effects include nausea, vomiting, anorexia, bone marrow suppression, and a bleeding phenomenon attributable to thrombocytopenia or decreased platelet function. Hepatoxicity and nephrotoxicity can also occur and toxicity is more likely to occur in patients with renal insufficiency because its excretion is largely renal. For these reasons, it is reserved for patients with severe malignancy-associated hypercalcemia who do not respond to other modalities, including a bisphosphonate.

Bisphosphonates are synthetic analogues of pyrophosphate not rapidly hydrolyzed in vivo. Their great affinity for bone and resistance to degradation account for their extremely long half-life in bone. They are excreted unchanged by the kidney. Their absorption from the gastrointestinal tract is generally poor, averaging < 10%, particularly when given with food. These agents inhibit osteoclastic bone resorption and retard (in a dose-dependent manner) the deposition of hydroxyapatite in bone collagen thereby increasing unmineralized osteoid and inhibiting

the formation of calcium phosphate crystals at higher doses. They are relatively nontoxic and are very useful in the management of moderately severe hypercalcemia [47]. The maximum effect is usually not seen for several days, so these agents are usually given with more rapidly acting modalities such as saline and calcitonin. Rarely, a significant response and even hypocalcemia can be seen within the first 24 hours. The bisphosphonates available in the United States are etidronate, pamidronate, and alendronate. Other bisphosphonates currently being developed or in the process of getting FDA approval, include ibandronate, tiludronate, and residronate. Pamidronate is more potent than etidronate and may produce a longer hypocalcemic response; it is probably the bisphosphonate of choice [47]. The usual IV dose varies with the degree of hypercalcemia. Up to 90 mg may be given usually as a single IV infusion over 4 or 24 hours, both of which appear to be equally effective. An oral regimen of 1200 mg daily for up to 5 days is also available. The dose should not be repeated until after a minimum of 7 days. This regimen is well tolerated and has minimal adverse effects, which include a mild transient fever, transient leukopenia, and a small reduction in serum phosphate levels.

Gallium nitrate is also useful for parenteral therapy of hypercalcemia. It appears to inhibit bone resorption by adsorbing to and reducing the solubility of hydroxyapatite crystals [48]. It has an additional effect of inhibiting PTH secretion in vitro; it may therefore be particularly effective in the treatment of hypercalcemia resulting from hyperparathyroidism. It is administered as a continuous IV infusion (200 mg/m^2 of BSA in 1 L of fluid daily for 5 days).

Because enhanced absorption of dietary calcium is primarily responsible for the hypercalcemia associated with excess vitamin D administration or with the endogenous overproduction of calcitriol, such as is seen in chronic granulomatous diseases and in occasional cases of malignant lymphoma, dietary calcium should be restricted in these cases. Glucocorticoids may also inhibit intestinal calcium absorption. The effect of steroids in the hypercalcemia of malignancy (usually hematologic) may be mediated through inhibition of osteoclastic bone reabsorption, cytolysis of tumor cells, and inhibition of prostaglandin synthesis.

Oral phosphate can decrease intestinal calcium absorption by forming insoluble calcium phosphate complexes both in the intestine and also in the plasma, thereby lowering the plasma calcium concentration. The risk of tissue calcium phosphate deposition, appears to be a limiting factor for the use of oral phosphate. This is a major concern with the use of IV phosphate, which is used only for severe, life-threatening hypercalcemia for which all other measures have failed, The usual dose is 250 mg qid, which can be increased to 500 mg qid, if severe diarrhea does not develop.

Chelation of ionized calcium using EDTA or IV phosphate has the advantage of almost immediate onset of action. However, toxicity limits the use of these agents to life-threatening refractory hypercalcemia. EDTA can cause acute renal failure (ARF), while phosphate therapy may lead to calcium phosphate precipitation in the tissues, potentially causing acute or chronic renal failure, vascular calcifications, and occasionally life-threatening arrhythmias. Hemodialysis with low or zero calcium dialysate and peritoneal dialysis (although slower) are both very effective modes of therapy. Dialysis is particularly useful in patients with renal insufficiency or congestive heart failure who cannot safely be given a saline load. However, rebound hypercalcemia may occur rapidly after cessation of therapy. Hemodialysis is the most effective

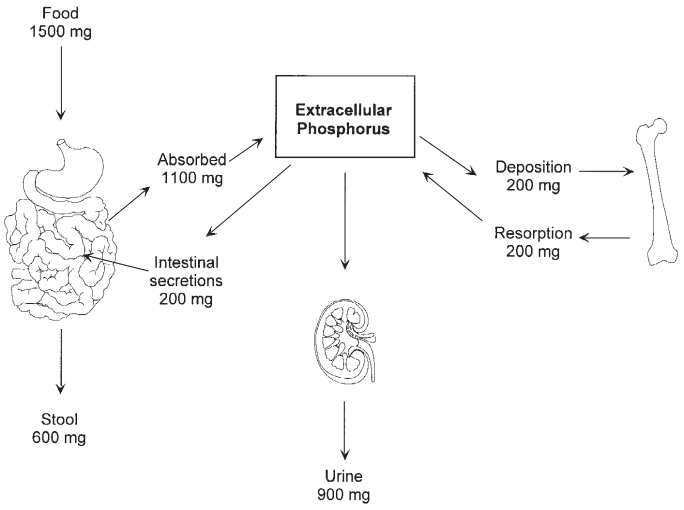

Figure 3. Normal phosphate homeostasis.

therapy for patients with severe hypercalcemia in the presence of end-stage renal disease (ESRD). Hourly removal of calcium is approximately twice that reported with saline and furosemide. It is advisable to perform hemodialysis under cardiac monitoring when using zero or low calcium dialysate.

Phosphorus

Normal Phosphate Homeostasis

The normal human body contains approximately 700 g, of phosphorus, of which 85% is contained within the bone mineral, 14% is present within the cells, and 1% is in the extracellular fluid [49, 50]. Most intracellular phosphorus is present as organic phosphate compounds which are necessary for the maintenance of cellular integrity and metabolism. Although the amount of inorganic phosphate in the cell is relatively small, it plays a critical role in cellular function because it constitutes a major source of phosphorus for the synthesis of ATP.

Plasma phosphorus concentration in adults is maintained between 2.5 and 4.5 mg/dL. The kidney and the gastrointestinal tract are the 2 major organ systems involved in maintaining phosphorus homeostasis. While phosphate absorption by the intestine may intermittently provide the extracellular fluid with a phosphate load, the kidney continuously maintains phosphate homeostasis by excreting the precise amount absorbed in excess of the body requirements. In the steady state, urinary phosphate excretion reflects the amount of phosphate absorbed by the intestine. As shown in Figure 3, the average daily intake of phosphorus is 1,500 mg, of which two-thirds is absorbed mainly in the duodenum and jejunum, and one-third is excreted in the stool. Intestinal secretions contain approximately 200 mg of phosphorus that re-enters the intestinal lumen. Approximately 200 mg of phosphorus enters and leaves the bone each day. Thus, the net intestinal absorption of phosphate is approximately 900 mg, which is excreted by the kidneys.

Intestinal Phosphate Transport

The majority of phosphate absorption takes place in the duodenum and jejunum, although the ileum and colon can absorb smaller amounts of phosphate. In normal individuals, there is a linear relationship between net phosphate absorption and dietary phosphorus intake. Intestinal phosphate absorption takes place via 2 mechanisms: 1) a diffusional process via the paracellular pathway and 2) a cellularly mediated active transport. Under normal circumstances, intestinal phosphate absorption occurs almost entirely through the diffusional process, which explains the observation that net phosphate absorption in humans is a linear function of dietary phosphate intake. Thus, the fractional absorption of phosphate from the intestine remains constant over a wide range of phosphate intake. The active component is likely to play an important role only under extreme circumstances such as severe dietary phosphate deprivation [49].

The cellularly-mediated active transport of phosphate involves sodium-dependent entry through a sodium-phosphate cotransporter in the brush border membrane. The active component of phosphate absorption is regulated by a variety of hormonal and non-hormonal factors including calcitriol. Although calcitriol increases both calcium and phosphate absorption in the intestine, different cellular mechanisms are involved in each case; thus, intestinal phosphate absorption is not necessarily coupled with calcium absorption. Other hormones that may enhance intestinal absorption of phosphate include PTH, thyroxine, estrogens, growth hormone, calcitonin, and glucocorticoids. PTH and estrogens may act mostly by increasing the synthesis of calcitriol. The mechanisms by which the other hormones affect phosphate absorption remain unclear. Nonhormonal factors may also regulate active phosphate transport. Variations in dietary phosphate intake can alter sodium-dependent phosphate transport; however, this effect is likely mediated by changes in calcitriol levels resulting from the effects of phosphorus on 1-α–hydroxylase in the kidney. The presence of aluminum in the intestinal lumen decreases phosphate absorption. Likewise, calcium-rich diets will impair phosphate uptake by the intestine.

Renal Handling of Phosphate

As already discussed, the kidney is the principal organ involved in the regulation of phosphate homeostasis. Most circulating inorganic phosphorus is ultrafiltrable. Factors that alter urinary phosphate excretion do so by changing either the filtered load or the tubular reabsorption of phosphate, because little phosphate is secreted by the kidney. Approximately 80% of the filtered load is reabsorbed by the renal tubules. Tubular reabsorption of phosphate and its regulation are determined by specific cellular events localized mostly in the proximal tubule, where 60 – 70% of renal reabsorption of phosphate takes place. Significant phosphate reabsorption occurs between the early distal tubule and the final urine. Although little is known about the mechanisms involved, there is evidence for regulated phosphate reabsorption in the distal nephron [49, 50].

– *Cellular mechanisms for proximal tubular phosphate transport*
  The transport of phosphorus in the proximal tubule is largely transcellular. It involves uptake across the brush border membrane, translocation across the cell, and efflux across the basolateral membrane. The uptake of phosphorus across

the brush border membrane is mediated by the sodium phosphate cotransporter and depends on the sodium gradient maintained by the basolateral Na-K-ATPase. Much has been learned about the nature of the sodium-phosphate (NaPi) cotransporter following its cloning in several species [51]. Once inside the cell, phosphorus may be incorporated into several organic compounds or extruded at the basolateral membrane. Little is known about the mechanisms involved in phosphate transport across the cell. At the basolateral membrane, the electrochemical gradient favors the extrusion of phosphate; however, diffusion across the basolateral membrane is limited to avoid depletion of cytosolic phosphate. Phosphate transport across the basolateral membrane appears to occur primarily by sodium-independent anion exchange mechanisms, which remain poorly understood.

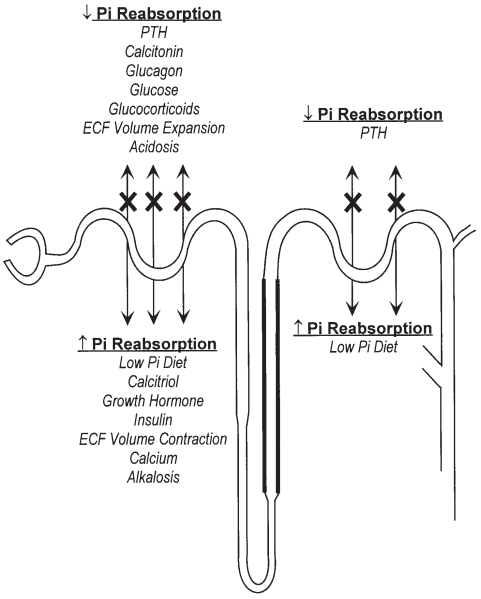

Figure 4. Tubular phosphate reabsorption.

– *Factors influencing renal handling of phosphate*

The overall tubular reabsorption of phosphate is controlled by a variety of dietary, metabolic, and hormonal factors as shown in Figure 4. Of these, PTH and dietary intake of phosphate primarily determine renal tubular phosphate reabsorption. The kidney responds to alterations in the filtered load of phosphorus by altering the excretion of phosphorus in the urine as appropriate. Urinary phosphate excretion decreases markedly in response to dietary phosphorus restriction. The adaptation of the renal tubule to dietary phosphate appears to involve alterations in Na^+-dependent phosphate transport, as suggested by studies demonstrating changes in NaPi cotransporter messenger RNA (mRNA) and protein induced by changes in dietary phosphate intake [52 – 54]. Furthermore, vitamin D metabolites may also contribute to the adaptive response to dietary phosphate restriction. The enhanced phosphate transport observed in phosphate depletion is resistant to phosphaturic agents such as PTH and calcitonin [55, 56], indicating that phosphate deprivation is a powerful stimulus for renal tubular phosphate reabsorption.

PTH is the major regulator of phosphate reabsorption by the kidney. PTH administration causes phosphaturia, and parathyroidectomy causes a decrease in urinary phosphate excretion. The primary site of action of PTH on phosphate transport is the proximal convoluted tubule and the proximal straight tubule. There is also evidence demonstrating PTH-sensitive phosphate transport in the distal nephron. The effects of PTH at the cellular

level are mediated by the PTH/PTHrP receptor located on the cell surface, which activates both adenylate cyclase and phospholipase C [57]. The effect of PTH to decrease phosphate reabsorption is thought to be largely mediated by cAMP; however, the protein kinase C pathway has also been implicated [58 – 61]. PTH has been shown to decrease NaPi cotransporters within the apical membrane resulting in decreased phosphate transport, and it has been suggested that exposure to PTH causes internalization of NaPi cotransporters by activation of endocytic mechanisms [62, 63]. The phosphaturic effect of PTH can be modified by a variety of factors. As discussed above, the increased phosphate reabsorption induced by dietary phosphate restriction can override the phosphaturic action of PTH.

Other hormones may also affect tubular phosphate reabsorption. The effect of vitamin D_3 metabolites on renal phosphate handling remains controversial. In general, acute administration of these agents is antiphosphaturic. The recent finding of vitamin D responsive elements in the Na-Pi promoter supports a direct role of vitamin D in phosphate reabsorption [64]. The antiphosphaturic effect of vitamin D may also be influenced by changes in serum calcium and PTH. Increased tubular reabsorption by growth hormone has also been recognized. Calcitonin has been shown to inhibit tubular phosphate reabsorption; however, the physiologic importance of this effect is not clear. Insulin and the insulin-like growth factors may also modulate phosphate transport. Insulin has modest antiphosphaturic effects. It has been shown to directly stimulate phosphate uptake by proximal tubules. Glucagon and glucose are both phosphaturic. The effect of glucose may be partially due to the concomitant osmotic diuresis, which inhibits proximal tubule transport. Glucocorticoids may cause phosphaturia independently of PTH. The effect of glucocortoids appears to be mediated by glucocorticoid receptors in the proximal tubule [1, 65].

Hypercalcemia has both direct and indirect effects that may contribute to increased phosphate reabsorption. The indirect effects include changes in GFR, RBF, and Kf, as well as changes in PTH levels which have profound effects on tubular phosphate handling. In addition, calcium has been shown to directly increase phosphate transport. Extracellular fluid volume expansion results in increased phosphate excretion, whereas volume contraction decreases phosphate excretion. Although the effects of volume status on tubular phosphate transport may be indirect, evidence suggests that volume expansion directly inhibits phosphate reabsorption independent of filtered load, plasma calcium, and PTH. Acid-base status can also influence renal phosphate handling. In general, acidosis is associated with decreased phosphate reabsorption, whereas alkalosis increases phosphate reabsorption; however, differences in phosphate transport also depend on whether the changes in acid-base status are acute or chronic. Diuretic agents such as acetazolamide and loop diuretics may decrease phosphate reabsorption. Phosphatonin, an as yet uncharacterized factor, has been implicated in the hyperphosphaturia of patients with X-linked hypophosphatemia and oncogenic osteomalacia [66, 67].

Hyperphosphatemia

The signs and symptoms of hyperphosphatemia are mostly related to the associated hypocalcemia and soft tissue calcification. The hypocalcemia may or may not be accompanied by tetany. Possible mechanisms for the decrease in serum calcium include deposition of calcium-phosphate salts in the soft tissues

and decreased production of calcitriol. Soft tissue calcification may occur when the calcium × phosphate product is > 70, especially in tissues with high pH, because the solubility of calcium-phosphate is lower in alkaline pH. Thus, the conjunctiva and the lung are at risk for calcium-phosphate precipitation because outward diffusion of carbon dioxide allows the local pH to increase. Consequently, band keratopathy and pulmonary calcifications may occur. ARF with intratubular precipitation of calcium and phosphorus may occur following a phosphate load. In chronic renal failure, hyperphosphatemia may lead to soft tissue calcification in the kidney, which in turn may accelerate the progression of renal failure [68]. Hyperphosphatemia plays a critical role in the development of secondary hyperparathyroidism in chronic renal failure.

Table 3. Causes of Hyperphosphatemia

Increased phosphate load	
Exogenous	
	Oral ingestion
	Vitamin D intoxication
	Intravenous administration
	Blood transfusions
	White phosphorus burns
Endogenous	
	Acidosis
	Tumor lysis syndrome
	Hemolysis

	Malignant hyperthermia
Decreased urinary excretion	
Decreased GFR	
	Acute renal failure
	Chronic renal failure
Increased tubular reabsorption	
	Hypoparathyroidism
	Pseudohypoparathyroidism
	Hyperthyroidism
	Acromegaly
	Postmenopausal state
	Glucocorticoid withdrawal
	Tumoral calcinosis
	Bisphosphonates

Causes of Hyperphosphatemia

As shown in Table 3, the causes of hyperphosphatemia can be grouped into 2 major categories: 1) increased phosphate load and 2) decreased urinary excretion. Pseudohyperphosphatemia may occur in hyperproteinemic states such as multiple myeloma, as well as in patients with hyperlipidemia, depending on the method used to measure phosphorus.

– *Increased phosphate load*
An increased phosphate load can result from either exogenous or endogenous sources. Under normal circumstances, the hyperphosphatemia is usually mild unless significant renal insufficiency or increased renal phosphate reabsorption coexist. The gastrointestinal tract is a common route of entry for exogenous phosphorus. Thus, dietary supplementation of phosphorus, particularly in combination with vitamin D, as well as phosphate-containing enemas may result in hyperphosphatemia. Likewise, hyperphosphatemia may result from the intravenous administration of phosphorus, and it usually occurs during the treatment of hypophosphatemia when the tubular reabsorptive mechanisms are adjusted to retain nearly all the filtered phosphate. Blood transfusions and infusions of lipid emulsions for total parenteral nutrition may also produce hyperphosphatemia. Phosphorus can be absorbed from the

skin, and hyperphosphatemia may develop in white phosphorus burns.

Hyperphosphatemia from endogenous sources may be caused by a shift of phosphate from intracellular stores or by a release of phosphate from the cells following tissue necrosis. Acidosis, particularly organic acidosis, may promote shifts of phosphate from the cells. The mechanism may involve the breakdown of organic phosphate with a release of inorganic phosphate into the extracellular fluid. Elevations in lactic acid are implicated in the hyperphosphatemia that may accompany major abdominal and thoracic surgery, as well as that associated with strenuous exercise. Respiratory acidosis may also lead to hyperphosphatemia. The mechanism appears to involve the decrease in intracellular pH that inhibits glycolysis, and the resultant decreased incorporation of inorganic phosphate into organic compounds leads to an increase in the efflux of phosphate from the cells.

Severe hyperphosphatemia may occur following significant tissue damage such as that seen in the tumor lysis syndrome, which occurs following chemotherapy for various malignancies, particularly lymphomas and leukemias. Acute hemolysis and rhabdomyolysis can both result in hyperphosphatemia. The hyperphosphatemia associated with malignant hyperthermia may be partially due to rhabdomyolysis.

– *Decreased urinary excretion of phosphate*

Reduced clearance of phosphorus may result from a decrease in GFR or from enhanced tubular phosphate reabsorption. Both acute and chronic renal failure can result in hyperphosphatemia. Several metabolic consequences of chronic renal failure prevent the development of significant hyperphosphatemia. These include increased PTH levels and low levels of calcitriol which decrease phosphate reabsorption. With progressive decline in GFR, however, hyperphosphatemia eventually develops.

Increased tubular reabsorption of phosphorus may occur in a variety of conditions, but it is most commonly seen in a spectrum of disorders characterized by PTH deficiency or resistance. The most common cause of hypoparathyroidism is surgical removal of the parathyroid glands, which often occurs in association with thyroid surgery, parathyroidectomy, or radical neck resections. Therapy with radioactive iodine may also result in hypoparathyroidism. Parathyroid insufficiency can also result from infiltrative processes involving the parathyroid gland, such as metastatic carcinoma and hemochromatosis. Hypoparathyroidism may be part of autoimmune endocrine failure. Hereditary hypoparathyroidism may occur in isolation or in association with Di George syndrome, characterized by defective development of the thymus, mucocutaneous candidiasis, and cardiac abnormalities.

End-organ resistance to PTH results in pseudohypoparathyroidism which involves a variety of disorders with biochemical features of hypoparathyroidism, including hyperphosphatemia and hypercalcemia, but usually with increased levels of PTH. Patients with type I pseudohypoparathyroidism (Albright hereditary osteodystrophy) have low urinary cAMP levels and phosphate excretion in response to PTH. About two-thirds of the patients with type I pseudohypoparathyroidism have somatic abnormalities as

originally described by Fuller Albright in 1942, including a short neck, round face, and shortening of the metacarpals and metatarsals. The underlying defect in type I pseudohypoparathyroidism involves the PTH receptor-cAMP generating system, and 3 types have been described: 1) type Ia is due to abnormalities of the guanine nucleotide-binding stimulatory protein [69 – 71], 2) type Ib may involve abnormalities of PTH receptor expression or function [72], and 3) type 1c is due to abnormalities of the adenylate cyclase catalytic subunit [73]. The majority of patients with somatic abnormalities have a defect in guanine nucleotide regulatory protein and, as expected, they have multiple endocrinologic defects, including hypothyroidism and gonadal dysfunction [74]. Patients with type II pseudohypoparathyroidism have high urinary cAMP but low phosphate excretion in response to PTH. Thus, in contrast to type I pseudohypoparathyroidism in which the defect is proximal to the generation of cAMP, in type II pseudohypoparathyroidism the defect is distal to the generation of cAMP. Patients with pseudohypoparathyroidism and renal tubular resistance to PTH may have normal response to the hormone at the level of the bone. Thus, these patients have somatic features of pseudohypothyroidism and hyperphosphatemia; however, they have bone changes of osteitis fibrosa.

Hyperphosphatemia may occur in association with hyperthyroidism and acromegaly. The cause of hyperphosphatemia in hyperthyroidism is likely due to a combination of factors, including increased intestinal absorption, increased bone resorption, and increased tubular reabsorption of phosphate. The mechanisms involved in the increased phosphate transport in hyperthyroidism are poorly understood. Growth hormone decreases phosphate excretion in humans. During menopause, low levels of estrogen and elevated levels of growth hormone are associated with hyperphosphatemia, which appears to result from increased tubular reabsorption of phosphate. Glucocorticoids inhibit sodium-dependent phosphate uptake by renal proximal tubular cells, and glucocorticoid withdrawal has been associated with hyperphosphatemia [75].

Tumoral calcinosis is a familial disorder associated with increased tubular reabsorption of phosphate These patients have hyperphosphatemia and calcifications in soft tissues and around large joints. PTH levels and PTH responsiveness are both normal. The exact mechanisms involved in the increased phosphate reabsorption in this syndrome are not clear. Bisphosphonate treatment of patients with Paget's disease has been associated with increased tubular reabsorption of phosphate and hyperphosphatemia [76].

Management of Hyperphosphatemia

The treatment of hyperphosphatemia should be aimed not only at the removal of phosphate from the circulation, but also at prevention [77]. Prevention includes eliminating exogenous or endogenous phosphate sources, as well as maintaining renal function. Thus, in patients receiving therapy for lymphoma who are at high risk for developing the tumor lysis syndrome, prevention of uric acid nephropathy by the administration of allopurinol and the maintenance of an alkaline diuresis may prevent severe hyperphosphatemia. Induction of an alkaline diuresis may also protect renal function and prevent severe hyperphosphatemia in patients with

rhabdomyolysis. In chronic renal failure, dietary phosphate restriction and the use of phosphate-binding antacids to impair intestinal phosphate absorption are commonly used to prevent hyperphosphatemia. In patients with severe hyperphosphatemia and dangerously elevated calcium-phosphate product, dialysis offers a means of removing phosphorus from the circulation.

Hypophosphatemia

Hypophosphatemia is a relatively common finding in hospitalized patients. A patient might have low serum levels of phosphorus with little deviation from normal in intracellular phosphorus (p-deprivation), or there might be low serum levels with low intracellular phosphorus (p-depletion). The latter represents a clinically very serious abnormality and is associated with numerous complications and organ abnormalities. In view of the important role of phosphorus as a source of energy, virtually all organ systems are affected in severe hypophosphatemia [49, 50]. Three basic underlying mechanisms affect cellular function in hypophosphatemia. First, severe hypophosphatemia results in decreased levels of erythrocyte 2,3-diphosphoglycerate (DPG), which increases the affinity of hemoglobin for oxygen, thus impairing oxygen release at the tissue level. Second, low levels of inorganic phosphate in the cell impair the synthesis of high-energy phosphate compounds such as ATP. And third, deficiency of intracellular organic phosphate may impair glycolysis. Thus, the manifestations of hypophosphatemia may involve a variety of organ systems; however, symptoms usually do not develop until the serum phosphorus level is < 1 mg/dL. Severe hypophosphatemia can affect the CNS and lead to a metabolic encephalopathy. The cardiopulmonary system can also be affected with impaired myocardial contractility leading to congestive heart failure (CHF) and weakness of the diaphragm resulting in respiratory failure. In bone, hypophosphatemia results in increased release of calcium from the bone and hypercalciuria. Prolonged hypophosphatemia may lead to a mineralization defect resulting in rickets and osteomalacia. Hypophosphatemia can affect both skeletal and smooth muscle with the latter resulting in ileus and dysphagia. Skeletal muscle dysfunction can present as a proximal myopathy or rhabdomyolysis. The hematopoietic system may also be affected by hypophosphatemia in the form of hemolysis, impaired phagocytosis and chemotactic activity, as well as thrombocytopenia.

Causes of Hypophosphatemia

As shown in Table 4, the mechanisms underlying hypophosphatemia can be grouped into three categories:

- decreased intestinal absorption of phosphorus,
- shifts of phosphorus into cells, and
- increased renal excretion of phosphate.

These mechanisms may occur singly or in combination. If none of the above mechanisms is present, pseudohypophosphatemia should be suspected, which is usually due to factors such as mannitol administration and hyperbilirubinemia that interfere with the assay used to measure serum phosphorus.

- *Decreased intestinal absorption of phosphate*
  Hypophosphatemia may occur in malnourished or starved patients who ingest

Table 4. Causes of Hypophosphatemia

Decreased intestinal absorption	
	Decreased dietary intake

	Fanconi syndrome
	Postrenal transplantation
	Metabolic acidosis
	Diuretics

a diet high in carbohydrates and deficient in phosphorus. Phosphorus-deficient diets are more likely to result in the development of hypophosphatemia in children than in adults. Vitamin D deficiency may lead to hypophosphatemia by decreasing intestinal phosphate absorption. Phosphate-binding antacids are used in chronic renal insufficiency and in hypoparathyroidism for the control of hyperphosphatemia, and their use may lead to hypophosphatemia. Severe vomiting and a variety of malabsorptive disorders may also lead to hypophosphatemia.

Chronic alcoholism and alcohol withdrawal are among the most common causes of severe hypophosphatemia [78]. The mechanisms involved have not been extensively studied, but it likely results from a variety of factors. Decreased intestinal absorption of phosphate because of poor dietary intake, vomiting, diarrhea, or routine use of antacids may lead to phosphate depletion. Renal losses of phosphate may result from repeated episodes of ketoacidosis with loss of phosphate from the cells into the urine; in addition, renal phosphate wasting may occur as a result of tubular dysfunction associated with alcohol. Intracellular shifts of phosphate secondary to glucose infusions or respiratory alkalosis may also contribute to hypophosphatemia in these patients.

– *Intracellular shifts of phosphate*

Inorganic phosphate is required for the synthesis of a variety of organic compounds. With stimulation of metabolic pathways, phosphate moves from the extracellular pool into the intracellular space, resulting in hypophosphatemia. One of the common causes of hypophosphatemia in the hospital setting is respiratory alkalosis due to the hyperventilation induced by a variety of factors, including pain, sepsis, depression, and alcohol withdrawal. The rise in intracellular pH in this setting results in activation of glycolysis, which increases the utilization of inorganic phosphate. Hypophosphatemia in hospitalized patients is also commonly caused by the intravenous administration of carbohydrate, usually in the form of glucose. Glucose administration may cause hypophosphatemia by increasing insulin release, which promotes phosphate uptake by the cell, and by the enhanced incorporation of phosphate into compounds involved in the glycoly-

tic pathway. The hypophosphatemia induced by glucose administration may be severe in patients with starvation. In diabetics, the decrease in serum phosphate following glucose administration is usually mild because of impaired insulin release. Fructose may cause a more severe hypophosphatemia than glucose because of its unregulated uptake by the liver [50]. The nutritional recovery syndrome occurs during the rapid refeeding of patients with starvation, and it is associated with hypophosphatemia, hypokalemia, and hypomagnesemia. Transient hypophosphatemia may occur during recovery from hypothermia because of the associated stimulation of glycolysis with rewarming. The hungry bone syndrome may occur following parathyroidectomy and is characterized by hypocalcemia and hypophosphatemia due to accelerated bone mineralization [79].

– *Increased renal excretion of phosphate*
Hyperparathyroidism causes hypophosphatemia by decreasing renal tubular reabsorption of phosphorus, as discussed earlier. Hypophosphatemia may accompany malignant neoplasms [80]. PTHrP may be produced by certain tumors and act via the PTH/PTHrP receptor in the kidney to decrease phosphate reabsorption. Some tumors of mesenchymal origin may be associated with hypophosphatemia, low levels of calcitriol and osteomalacia. These patients have normal levels of PTH and PTHrP and markedly reduced renal phosphate transport. Calcitriol administration may not improve the phosphate transport defect. Tumors associated with this syndrome are thought to secrete a phosphaturic substance that acts directly in the renal tubular cells by inhibiting sodium-dependent phosphate uptake [66].

Disorders of vitamin D metabolism, such as vitamin D deficiency and vitamin D-dependent and vitamin D-resistant rickets, are associated with decreased renal reabsorption of phosphate and hypophosphatemia. Decreased intestinal phosphate absorption may also contribute to the hypophosphatemia in these disorders. In vitamin D deficiency, the decreased tubular reabsorption of phosphate is mediated by the high levels of PTH from hypocalcemia. Vitamin D-resistant rickets or familial X-linked hypophosphatemic rickets (XLH) is similar to oncogenic osteomalacia with regard to the pathophysiologic process of hypophosphatemia. The genetic abnormality in XLH is based on mutations in the PEX gene (*p*hosphate-regulating gene with homologies to *e*ndopeptidases on the *X*-chromosome) [81]. The abnormal endopeptidase activity of the mutated gene product has been postulated to result in impaired degradation of a phosphaturic factor.

Vitamin D-dependent rickets (VDDR), also a familial disorder associated with a tubular defect in phosphate reabsorption, has been classified into types I and II. Type I VDDR is an autosomal recessive disorder that presents in early childhood with hypophosphatemia, hypocalcemia, rickets, low serum levels of calcitriol, and elevated serum levels of 25(OH)D. Patients respond to therapy with small doses of calcitriol, suggesting abnormal production of calcitriol by the kidney as the primary abnormality. Indeed, the human 1-α-hydroxylase gene has been recently found to map to the previously identified disease locus for type I VDDR, which strongly suggests that mutations of this gene are the basis for this disorder [82]. Type II VDDR is actually a form of vitamin D resistance, and it is associated with end-organ resistance to calcitriol because of mutations in the gene encoding the vitamin D receptor [83, 84]. Clinically, type

II VDDR is indistinguishable from type I VDDR except that calcitriol levels are elevated, and treatment with calcitriol is ineffective.

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is also characterized by decreased renal reabsorption of phosphate and is thought to represent a primary defect in tubular phosphate reabsorption. Idiopathic hypercalciuria may potentially represent a milder form of this disorder [85]. X-linked recessive nephrolithiasis with renal failure is a form of hereditary renal disease associated with renal phosphate wasting [86] and may represent a generalized defect in proximal tubular function. The Fanconi syndrome is a generalized impairment in proximal tubular function because of either hereditary abnormalities or acquired conditions, such as multiple myeloma. The resultant injury to the proximal tubular epithelium induces urinary losses of solutes normally reabsorbed in this nephron segment such as phosphorus, glucose, amino acids, bicarbonate and uric acid. Successful kidney transplantation may be associated with hypophosphatemia that is mostly due to a tubular phosphate leak secondary to persistent hyperparathyroidism. However, a variety of other factors may also contribute to post-transplant hypophosphatemia, including glucocorticoids, chronic volume expansion, and diuretics as well as the shift of phosphate and calcium into bone associated with the correction of hyperparathyroidism.

Metabolic acidosis decreases renal tubular reabsorption of phosphate and may cause hypophosphatemia. In addition, acidosis results in shifts of phosphate from the intracellular pool because of the breakdown of intracellular organic compounds. The released phosphate is excreted in the urine and may contribute to phosphate depletion. In diabetic ketoacidosis, the catabolic effects of insulin deficiency also contribute to the shift of phosphate into the extracellular fluid, thus worsening the phosphaturia. A variety of drugs such as thiazide diuretics and high doses of estrogen can induce renal phosphate wasting and cause hypophosphatemia.

Management of Hypophosphatemia

Patients with moderate hypophosphatemia (serum phosphorus between 1 and 2.5 mg/dL) who do not have a history of GI or renal phosphate losses rarely require phosphate replacement; rather, the treatment is aimed at the underlying cause. For example, in patients with uncomplicated diabetic ketoacidosis, the hypophosphatemia usually corrects spontaneously with normal dietary intake, and it may not be necessary to treat the hypophosphatemia per se. Likewise, patients with hypophosphatemia due to vitamin D deficiency respond to therapy with vitamin D supplementation. Phosphate supplementation, either orally or intravenously, is indicated in patients who are symptomatic; however, the latter should be reserved for patients with life-threatening complications or for those who are unable to tolerate oral feeding.

Magnesium

Normal Magnesium Homeostasis

Magnesium is the second most abundant intracellular cation. Fifty to 60% of total body magnesium is in bone, with the remainder in the soft tissues [87]. Intracellular magnesium

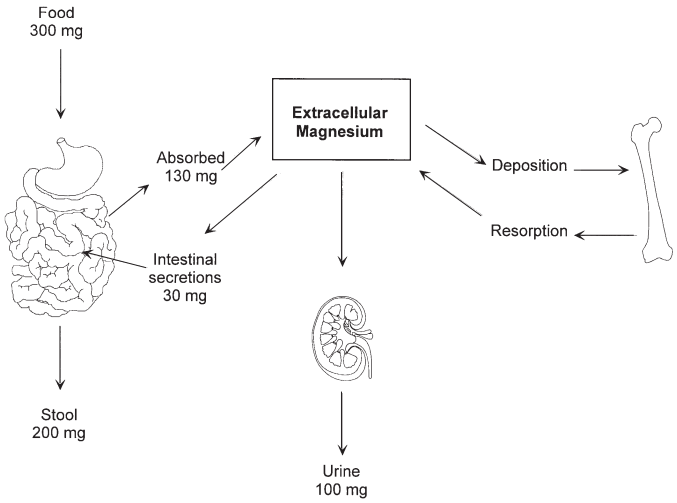

Figure 5. Normal magnesium homeostasis.

concentration is 8 – 10 mM and is mostly bound to ATP and other nucleotides and enzymes. Free magnesium concentrations are approximately 10% of total. Less than 1% of body magnesium is in the extracellular fluid and therefore, serum magnesium, like serum potassium, is not a very sensitive indicator of body stores. Serum magnesium is in 3 fractions: ionized (60%), complexed, usually with citrate or phosphate (15%) and bound to protein, mainly albumin (25%). Normal serum magnesium concentration is 1.7 – 2.3 mg/dL, of which 75% is ultrafiltrable.

Intestinal Absorption of Magnesium

The average daily intake from a variety of foods is 300 mg. As illustrated in Figure 5, approximately one-third of the ingested magnesium is absorbed, principally in the small bowel, by a saturable as well as by a passive diffusional process [88]. Some magnesium is also secreted into the intestine (approximately 30 mg). Thus, net absorption is about 100 mg. Little evidence exists for regulation of magnesium absorption in the intestine.

Renal Handling of Magnesium

In contrast to most other cations, the proximal tubule is not the major site of reabsorption of magnesium, and only 15 – 20% of filtered magnesium (ionized plus complexed) is absorbed in this segment. The major site of magnesium reabsorption is the thick ascending loop of Henle, in which 60 – 70% of the filtered magnesium is reabsorbed [89 – 91]. A large portion of the reabsorption of magnesium in this segment is by the paracellular route and is driven by the lumen positive potential resulting from the activity of the Na-K-2Cl transporter. There is also evidence that magnesium reabsorption in this segment can be regulated by hormones, e.g. PTH, suggesting additional transcellular absorption mechanisms [92].

However, hormonal effects could also be explained by alterations in sodium chloride reabsorption. Little is known about the mechanisms of magnesium reabsorption in the distal nephron, but it is believed to occur by entry through luminal magnesium channels and exit via a Na/Mg exchanger [91, 93].

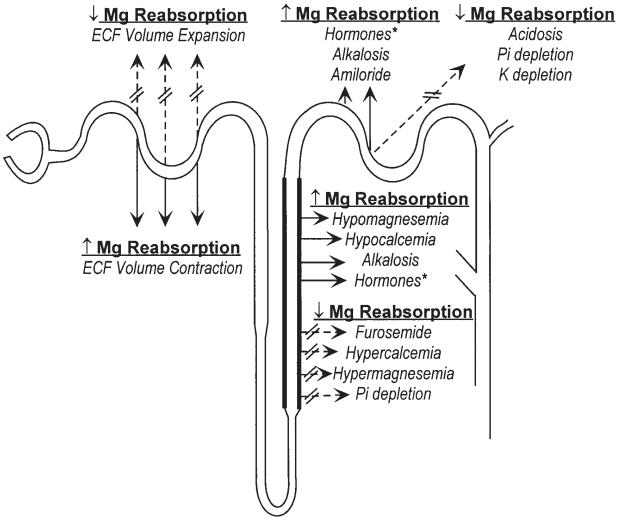

Figure 6. Factors regulating magnesium excretion
*Hormones: Parathyroid hormone, Calcitonin, Glucagon, Vasopressin.

Regulation of Magnesium Excretion

Factors regulating magnesium excretion are illustrated in Figure 6. Alteration in magnesium excretion is mainly a consequence of changes in the level of plasma magnesium, which is a potent regulator of magnesium reabsorption in the thick ascending limb [94]. Thus, hypermagnesemia decreases magnesium reabsorption, and hypomagnesemia is associated with a marked decrease in magnesium excretion. The recently described calcium-sensing receptor, which may also bind magnesium, may be involved in this regulation of magnesium reabsorption [2, 4, 95, 96]. Hypercalcemia, which inhibits magnesium reabsorption, may also affect this mechanism. Magnesium reabsorption is stimulated by PTH in this segment. Phosphate depletion [97] and systemic acidosis [98] are associated with marked hypermagnesuria. Alcohol administration, volume expansion, and glycosuria also increase magnesium excretion [99, 100]. Diuretics, both distally acting thiazides and the loop diuretics, increase magnesium excretion.

Table 5. Causes of Hypermagnesemia

Decreased renal excretion	
	Acute Renal Failure
	Chronic Renal Failure
Increased entrance to extracellular fluid	
	Magnesium-containing laxatives
	Magnesium-containing enemas
	Magnesium-containing IV fluids
	Parenteral magnesium, e.g. treatment of eclampsia

Hypermagnesemia

In normal subjects, ingested magnesium is readily excreted by the kidneys and hypermagnesemia is uncommon. Infused magnesium loads are excreted within 48 hours. Causes of hypermagnesemia are listed in Table 5. Hypermagnesemia occurs in the presence of renal failure or after large loads given by infusion or by enema. In renal failure, serum magnesium remains in the normal range until renal failure is advanced, and even

then, only modest elevations occur [101]. Severe hypermagnesemia only occurs following the injudicious ingestion or administration of magnesium-containing antacids or enemas. These should be avoided in patients with advanced renal failure. Magnesium infusions may be administered for eclampsia and usually achieve a blood concentration of 6 – 8 mg/dL. Other causes of elevations of serum magnesium are uncommon and mild.

Clinical Consequences of Hypermagnesemia

The principal manifestation of hypermagnesemia is neuromuscular toxicity shown first by decreases in reflexes (4 – 6 mg/dL) followed by somnolence and muscular paralysis, including respiratory paralysis, as magnesium rises to higher levels [102]. Hypermagnesemia acts as a calcium channel blocker in the heart and as intracellular magnesium increases, potassium channels also become blocked [103]. These effects lead to bradycardia and hypotension with abnormal ECG changes of prolonged PR interval, widened QRS, and an increase in QT interval. Complete heart block may occur, and cardiac arrest may occur at magnesium concentrations > 15 mg/dL. Elevations in magnesium can also decrease the secretion of PTH, and thus hypocalcemia may occur, but is usually transient and mild. A variety of non-specific symptoms may also occur such as nausea, vomiting, and flushing.

Hypomagnesemia

Hypomagnesemia is common in hospitalized patients (10%) and may reach 50% in patients in intensive care units [104 – 106]. The main factors involved in this setting are poor nutrition, hypoalbuminemia, and aminoglycosides. The causes of hypomagnesemia are listed in Table 6. These causes should serve to raise the awareness of potential problems in these settings and prompt the measurement of serum magnesium [107]. Decreased intake may be the cause of hypomagnesemia in protein-calorie malnutrition and in patients who have received intravenous fluids for prolonged periods. Decreases in intestinal absorption may occur with malabsorption syndromes, either from nontropical sprue or Crohn's disease or following extensive bowel resections. Biliary fistulae and prolonged nasogastric suction may also cause magnesium

Table 6. Causes of Hypomagnesemia

Decreased intake

	Blood transfusions
	Hungry bone syndrome

depletion. Urinary losses also account for a number of cases of magnesium deficiency. Diuretic therapy is often associated with hypomagnesemia, and increased renal magnesium losses occur in glycosuric states such as diabetic ketoacidosis, primary hyperaldosteronism, volume expansion, following acute tubular necrosis (ATN), and from a variety of drugs including aminoglycosides, cyclosporine, and cisplatin. Some cases of Bartter syndrome and all cases of Gitelman syndrome are hypomagnesemic [108 – 110]. Phosphate depletion is associated with magnesuria although the mechanism is not well understood. An additional category which should be considered is that of redistribution of magnesium within the body such as might occur after parathyroidectomy, i.e. hungry bone syndrome [20, 111] or in association with acute pancreatitis [112]. The renal losses are most commonly due to diuretic therapy and generally are mild because the volume contraction results in increased proximal reabsorption.

Clinical Consequences of Hypomagnesemia

Hypomagnesemia is often associated with other electrolyte abnormalities so that it may be difficult to ascribe the particular symptom to the low levels of magnesium. However, typical signs of magnesium deficiency are tetany and positive Chvostek and Trousseau signs as a manifestation of neuromuscular irritability [113]. Tetany may occur without frank hypocalcemia, but hypocalcemia is commonly present in severe magnesium deficiency. Abnormal cardiac function may be manifested by wide QRS with peaking of T waves and increased ventricular arrythmias. Hypokalemia is associated with hypomagnesemia in almost 50% of cases, possibly indicating that the causes for decreases in these electrolytes are similar. However, hypokalemia may be refractory to potassium supplementation until the magnesium deficit is corrected [114]. Severe hypocalcemia may coexist, and this is related to a profound defect in PTH secretion [115]. Magnesium replenishment results in a rapid increase in the release of PTH within minutes of administration [116]. The hypocalcemia of magnesium depletion is also due to a skeletal resistance to the actions of PTH [117].

Diagnosis and Therapy of Hypomagnesemia

Since measurement of magnesium is not routine, magnesium deficiency can often go unrecognized. Magnesium should be measured in the clinical circumstances mentioned above, and if low, should be replenished and the cause identified and corrected. Distinction between GI and renal losses can be made by measurement of 24-hour urine magnesium values or the fractional excretion of magnesium, since the normal renal response to magnesium deficiency is to increase magnesium reabsorption and to decrease magnesium excretion to low levels. Prophylactic administration of magnesium may be considered in certain clinical circumstances if renal function is normal. Potassium-sparing diuretics may be considered in cases of renal magnesium wasting. Replacement therapy should be by the oral route if possible, but parenteral administration can be utilized if the manifestations of hypomagnesemia are severe or if oral administration is not possible or limited because of the diarrhea induced by oral supplements.

Primary Glomerulonephritis

Claudio Ponticelli and Giovanni B. Fogazzi

Approach to the Patient with Proteinuria and Microscopic Hematuria

Proteinuria and/or microscopic hematuria are typical findings in patients with glomerulonephritis (GN). However, they can also be associated with other renal or extrarenal disorders. Therefore, a stepwise approach is advisable for a proper evaluation (Figures 1 and 2).

When proteinuria (or more appropriately albuminuria) is detected by dipstick, a false positive should first be ruled out. This can be caused by urinary density > 1.025, urinary pH

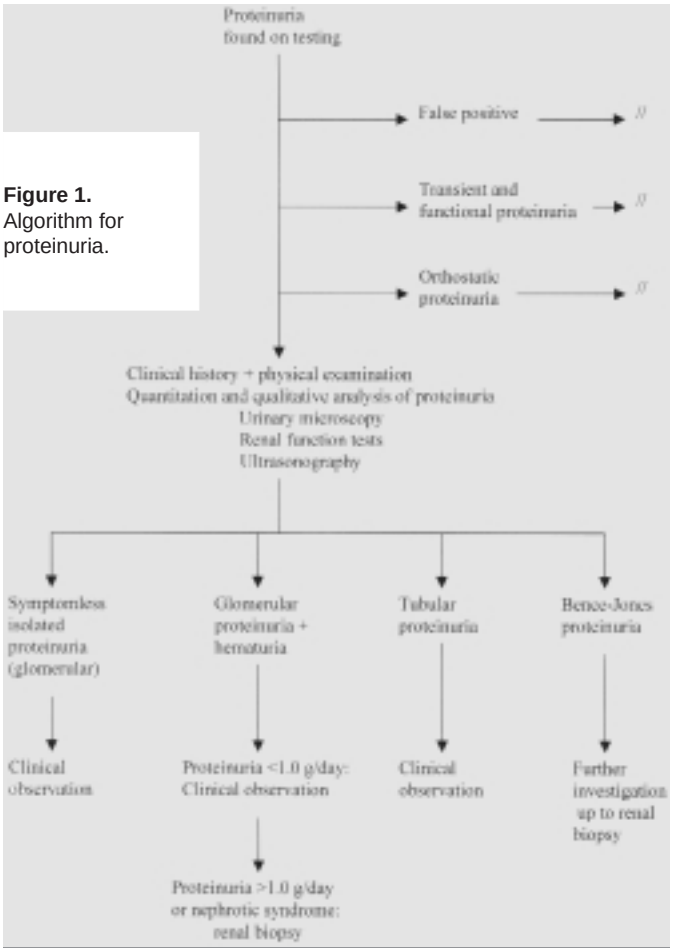

Figure 1. Algorithm for proteinuria.

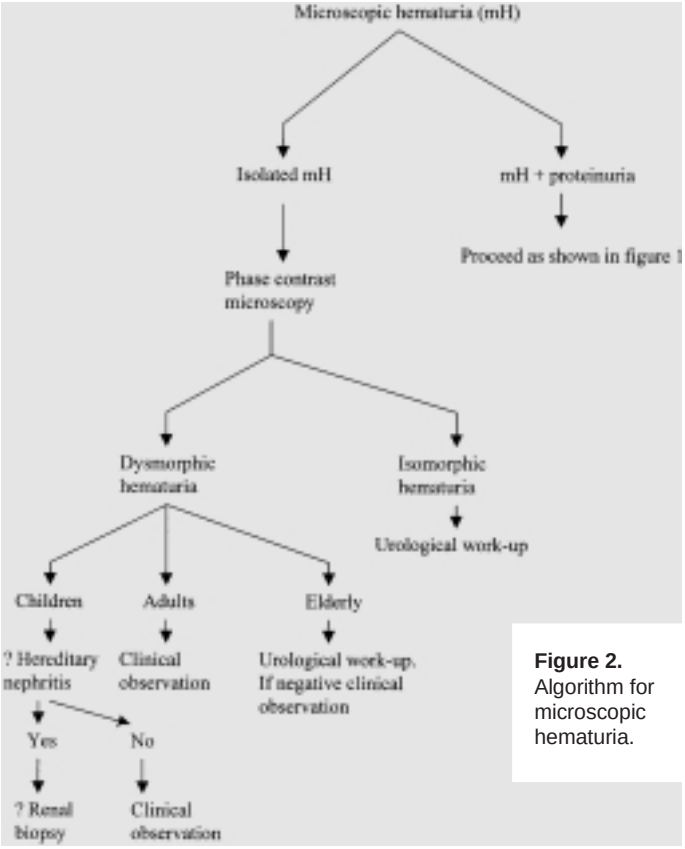

Figure 2. Algorithm for microscopic hematuria.

> 8.0, contamination of urine by quaternary ammonium compounds or phenazopyridine used for disinfection of urine containers, or by immersion of the dipstick in the urine for too long a period of time. It is also important to exclude clinical conditions that can cause transient and functional albuminuria, such as vigorous physical exercise, fever, or acute congestive heart failure (CHF) (Table 1). Especially in adolescents and young males, proteinuria may be purely orthostatic. This condition is characterized by the presence of proteins in urine collected on a standing position and complete absence in urine collected during recumbency. Even when orthostatic proteinuria is quantitatively important, the long-term prognosis is favorable, and no further investigation is needed. Clearly, orthostatic proteinuria differs from the quantitative increase of proteinuria that can be found in most patients with GN while they are standing [194].

If persistent nonorthostatic proteinuria is found, a complete work-up is necessary. This includes clinical history and physical examination, evaluation of renal function, the quantitation of proteinuria in g/24 hours or as albumin/creatinine ratio, the qualitative analysis of proteinuria by electrophoresis on cellulose acetate or agarose, or by sodium dodecyl sulfate-polyacryl-amide gel electrophoresis (SDS-PAGE) or other techniques, other appropriate laboratory tests, and ultrasonography of the kidneys and urinary tract.

In case of glomerular proteinuria, which is by far the most frequent condition seen in clinical practice, the clinical history may be

Table 1. Classification of Proteinuria and Main Clinical Associations

Transient/functional proteinuria
Strenuous physical activity
Fever
Acute congestive heart failure
Orthostatic proteinuria
Glomerular proteinuria
Primary and secondary glomerulonephritis
Isolated symptomless proteinuria
Proteinuria in morbid obesity
Tubular proteinuria
Acute and chronic tubulointerstitial diseases
Toxins and drugs
Primary and secondary glomerulonephritis
Overflow proteinuria
Monoclonal gammopathies (immunoglobulin light chains
Intravascular hemolysis (hemoglobin)
Rhabdomyolysis (myoglobin)
Leukemia (lysozyme)
Tissue proteinuria
Acute inflammation of urinary tract
Neoplasia of urinary tract

characterized by hereditary renal diseases, by a family predisposition to renal or systemic diseases such diabetes mellitus (DM) or systemic lupus erythematosus (SLE), or by allergy. In other cases, there may be a history of exposure to hydrocarbons or solvents, the use of potentially nephritogenic drugs, or a preceding infection. Physical examination may be normal or reveal arterial hypertension, morbid obesity (possibly associated with focal segmental glomerulosclerosis (FSGS) [152]), generalized or local edema with weight gain, weight loss, skin or joint changes, enlarged liver and spleen, macroglossia, lung disease, vascular disease, neurologic abnormalities or other findings. Basic laboratory tests include serum creatinine and/or glomerular filtration rate (GFR), glycemia, total serum proteins and protein electrophoresis, serum cholesterol, hemogram, plasma immunoglobulins, C3 and C4 levels, the search for HBs antigen and of hepatitis C antibodies, and tests for syphilis. More targeted tests are the search for neoplastic markers, antistreptolysin titer (ASO), cryoglobulins, antinuclear (ANA) and/or anti-DNA antibodies, rheumatoid factor (RF), antineutrophilic cytoplasmic antibodies (ANCA), or antiglomerular basement membrane (anti-GBM) antibodies. Ultrasonography may reveal normal or enlarged kidneys or reduction of size with increased hyperechogenicity or scarring.

If glomerular proteinuria does not exceed 1.0 g/24 hours and is associated with normal renal function and there is no hematuria, negative clinical history, negative physical examination, and normal ultrasonography, a diagnosis of symptomless isolated proteinuria can be made. In this case, no immediate further investigation is necessary, although long-term follow-up is indicated. For patients with proteinuria and microscopic hematuria, monitoring over time may be sufficient if proteinuria is < 1.0 g/day, but renal biopsy may be indicated for prognostic or genetic reasons. With proteinuria > 1.0 g/24 hours, renal biopsy is advisable. If proteinuria is in the nephrotic range (i.e. > 3.5 g/24 hours), with or without hematuria, renal biopsy is indicated unless there are unacceptable risks of complications. A frequent exception is represented by children with a selective proteinuria, which is usually caused by minimal change nephropathy responsive to glucocorticoids.

Tubular proteinuria usually does not exceed 1.5 – 2.0 g/24 hours. It may be caused by acute or chronic tubular disorders such as interstitial nephritis or heavy metal nephropathy. Tubular proteinuria is also present in GN with associated tubulointerstitial changes [9]. A pure tubular proteinuria needs to have the

Table 2. The Main Causes of Microscopic Hematuria (modified from [57])

Renal parenchymal disease	*Urinary tract disease*
Primary and secondary glomerulonephritis	Trauma/surgery
Glomerular C3 deposition	Neoplasia
Alport's syndrome	Angioma
Thin glomerular basement membrane disease	Obstructive uropathy
Interstitial nephritis	Cysts
Analgesic nephropathy	Varices/teleangiectasia
Pyelonephritis	Papillary necrosis
Sickle cell disease	Periureteritis
Polycystic kidney	Ureterocele
Loin pain hematuria syndrome	Endometriosis
Trauma/surgery	Infections
Renal biopsy	Infestations
Jogger's nephritis	Radiation
	Diverticulum
Renal vessel disease	Cyclophosphamide-induced cystitis
C3 arteriolar deposition	Ex vacuo hematuria
Arteriolar emboli or thrombosis	Prostatitis
Renal vein thrombosis	Prostatic hypertrophy
Arterial or venous malformations	Urethritis
Arteriovenous fistula (idiopathic, cirsoid, acquired)	Urethral prolapse
Nutcraker's syndrome	Urethral caruncle
	Meatal ulcers
	Condyloma acuminatum
	Foreign bodies
	Catheters
	Long-distance running
	Systemic coagulation disorders
	Platelet defect
	Coagulation protein deficiency
	Scurvy
	Anticoagulant treatment

cause identified. In these cases, clinical history is of particular importance. Tests exploring the function of proximal tubules are necessary. No renal biopsy is usually needed. Observation over time is advisable.

Among the various types of overflow proteinuria, the most clinically relevant is represented by the increased excretion of monoclonal immunoglobulin light chains, better known as Bence-Jones proteinuria. This is caused by monoclonal gammopathies such as multiple myeloma, AL amyloidosis, light chain deposition disease, or some types of cryoglobulinemia. It is worth remembering that dipsticks do not react with immunoglobulin light chains, leading to false negative results. In some of these disorders a glomerular proteinuria can also be found because of the damage caused by the deposition of light chains in the glomeruli. Immunofixation is the best method to characterize the monoclonal component. Further clues to the diagnosis are the search for a monoclonal peak in the blood, quantitation of plasma immuno-

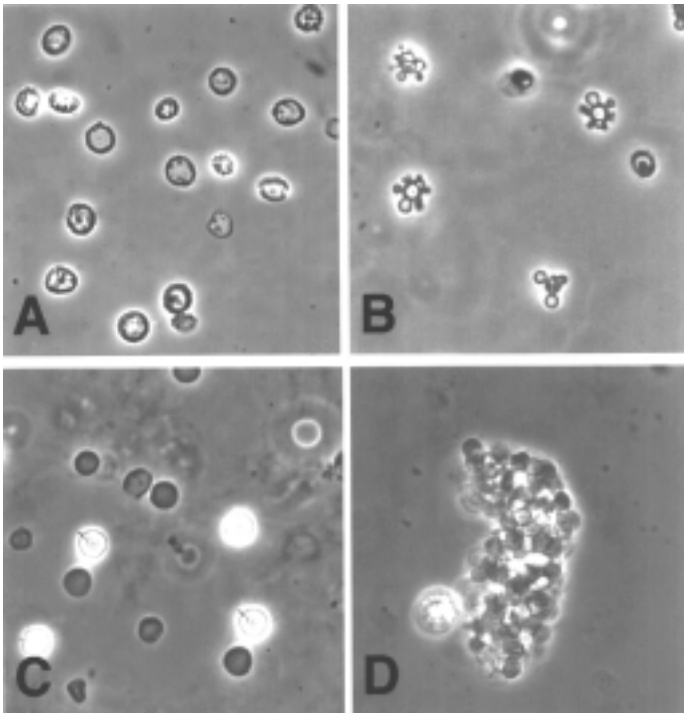

Figure 3. A: dysmorphic urinary erythrocytes. B: acanthocytes. C: isomorphic erythrocytes. D: erythrocyte cast. (Phase contrast microscopy, 400x).

globulins, bone marrow aspiration or biopsy, bone X-rays, abdominal fat pad or rectal biopsy, and renal biopsy.

Microscopic hematuria indicates the presence in the urine of an abnormal amount of erythrocytes, which can be the consequence of a large number of disorders (Table 2). When microscopic hematuria is associated with proteinuria, a diagnosis of GN is likely. The cause of symptomless, isolated, microscopic hematuria can be much less clear. This is usually found by chance by dipsticks, which have a 91 – 100% sensitivity and a 65 – 99% specificity [198]. False negative results can occur with high concentrations of urinary ascorbic acid [22], while false positives are caused by myoglobinuria or bacteriuria [107]. Microscopy is necessary, not only to confirm a positive dipstick, but also to separate a glomerular from a nonglomerular bleeding on the basis of erythrocyte morphology. In fact, when hematuria is caused by a glomerular disease, "dysmorphic" erythrocytes and acanthocytes predominate in the urine (Figures 3A and 3B), while normal or "isomorphic" erythrocytes (Figure 3C) predominate in nonglomerular bleeding [45, 100]. The presence of erythrocyte/hemoglobin casts (Figure 3D) is pathognomonic of bleeding of the renal parenchyma. However, the sensitivity is low, approximately 20 – 30%. Phase contrast microscopy is by far superior to conventional bright field microscopy in revealing these findings.

We consider the analysis of the urinary sediment as a key step in the work-up of patients with isolated microscopic hematuria [57]. When dysmorphic hematuria is found on repeated examination, a diagnosis of chronic glomerular disease is likely. All glomerular diseases can cause symptomless isolated microscopic hematuria, but immunoglobulin A (IgA) nephropathy, non-IgA mesangial or focal proliferative glomerulonephritis (FPGN),

and thin basement membrane disease are the most frequently found when renal biopsy is performed [77, 185]. The work-up of these patients differs according to their age. In children and adolescents, hereditary nephritis such as Alport's syndrome or thin basement membrane disease has to be suspected first. An accurate family history should be taken and family members investigated for microscopic hematuria, renal function impairment, deafness, and/or ocular abnormalities. A renal biopsy should be performed in case there is a suspicion of Alport's syndrome. However, when the family findings suggest benign hematuria the indication for renal biopsy is less definite. If the family history and investigation are negative for hereditary nephritis, renal biopsy is not strictly necessary, and clinical observation may be sufficient. However, ultrasonography of the kidneys and of the urinary tract is always necessary to exclude urological disorders.

In young and middle-aged adults, dysmorphic microscopic hematuria is more likely caused by primary glomerulonephritis such as IgA nephropathy or other less defined glomerular diseases, although thin basement membrane is still a possibility. The measurement of serum immunoglobulins may show increased IgA levels, which are found in 30 – 50% of patients with IgA nephropathy. A persistent decrease of C3 serum level may indicate a type II membranoproliferative glomerulonephritis (MPGN) or, especially in young women, SLE. Rarely, microscopic hematuria may be the only sign of anti-GBM disease, of systemic vasculitis, or of other systemic diseases. Clinical observation is needed, and renal biopsy should be considered in case of appearance of proteinuria, renal function impairment, or definite signs of a systemic disorder. For these patients, ultrasonography of the kidneys and the urinary tract is mandatory in the initial work-up to exclude other causes of microscopic hematuria such as stones, polycystic kidney, and tumors.

In the elderly, especially in males, microscopic hematuria is frequently the first and only sign of tumor of the urinary tract. Thus, even in the presence of a dysmorphic hematuria, a full urological work-up is recommended. If no urological abnormalities are found, an underlying GN is possible, as in the previous categories [185]. Clinical observation is sufficient, although a tumor of the urinary tract can be associated with a glomerular disease.

The prognosis of patients with symptomless isolated microscopic hematuria of renal origin is usually good, as demonstrated by several studies both in children and adults [77, 133, 170]. In fact, most patients continue to have microscopic hematuria, although it completely disappears in other patients. A minority of patients develop hypertension with or without proteinuria, but renal function impairment usually does not occur.

Pathogenesis, Complications, and Treatment of the Nephrotic Syndrome

The term nephrotic syndrome refers to a clinical condition characterized by heavy proteinuria, hypoalbuminemia, edema, and hyperlipidemia. The nephrotic syndrome is often seen with urinary protein excretion > 3.5 g/24 hours and is almost invariably present when proteinuria is > 5 g/24 hours. The nephrotic condition may expose the patient to disabling and even life-threatening complica-

Table 3. Main Complications of the Nephrotic Syndrome

Complication	*Pathogenesis*	*Treatment*
Proteinuria	Alterations in glomerular barrier	Moderate protein restriction ACE inhibitors AT1 receptor antagonists, NSAID
Hypoalbuminemia	Urinary loss Increased catabolism Insufficient liver synthesis	Reduction of proteinuria
Lipid abnormalities (Increased LDL, VLDL, lipoprotein(a))	Increased synthesis Reduced catabolism	CoA reductase inhibitors
Edema	Hypoalbuminemia (underfill mechanism) Resistance to ANP (overfill mechanism)	Thiazide agents Loop diuretics
Hypercoagulability	Increase in prothrombotic factors Decrease of anticoagulant proteins	Oral anticoagulation (?)

tions such as infections, bone disease, intravascular thrombosis, and cardiovascular disease (Table 3). Moreover, the onset of the nephrotic syndrome is a marker for bad prognosis for most glomerular diseases.

Proteinuria

Proteinuria is a consequence of the disruption of the permeselectivity caused by the disease-related functional and/or anatomical damage of the glomerular basement membrane (GBM). Plasma proteins, particularly albumin, are allowed to pass through the glomerular capillary wall, exceeding the tubular reabsorptive capacity. There is now evidence that proteinuria may play a role in the progression of chronic renal failure (CRF). The abnormal filtration of proteins brings them into contact with the mesangium and with the proximal tubular cells. Mesangial accumulation of proteins may produce mesangial cell injury, mesangial cell proliferation, and increased production of mesangial matrix that eventually lead to glomerulosclerosis [158]. The proximal reabsorption of proteins may trigger upregulation of inflammatory and vasoactive genes such as MCP-I and endothelins. The corresponding molecules formed in an excessive amount by renal tubuli are secreted toward the basolateral compartment of the cell and give rise to an inflammatory reaction that leads to renal scarring [158].

Eradication of the underlying glomerular disease represents the best treatment for proteinuria. Some reduction of urinary protein excretion may also be obtained with diet and/or drugs. While a high-protein diet increases proteinuria, a low-protein diet may reduce urinary albumin excretion and increase serum albumin levels, at least in the short-term [93]. ACE inhibitors can have an

antiproteinuric effect, which is dose-dependent. The effect may require some weeks to be complete and is blunted by sodium intake [74]. Angiotensin II (ANG II) receptor AT1 antagonists have a comparable antiproteinuric effect [61]. ACE inhibitors may also slow the progression of chronic renal insufficiency. This beneficial effect may be independent of the blood pressure reduction and is particularly marked in patients with proteinuric glomerular diseases [117]. Diet protein restriction, around 0.8 g per kg/day plus urinary losses, in combination with ACE inhibitors at the highest tolerated doses and restricted sodium intake may be recommended in patients with glomerular diseases to reduce urinary protein excretion and preserve renal function. It is possible but still unproven that the addition of AT1 receptor antagonist may further potentiate the antiproteinuric effect.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce proteinuria by ≥ 50% or more. The effect is rapid (within 1 week) and reverses after cessation of treatment. Indomethacin (150 mg/day) and meclofenamate (200 – 300 mg/day) are the 2 agents used most frequently. These agents can cause hyperkalemia, sodium retention, and acute renal failure (ARF) triggered by vasoconstriction or interstitial nephritis. Thus, careful monitoring of renal function is mandatory during treatment of nephrotic patients. The association with ACE inhibitors potentiates the antiproteinuric effect but increases the risk of renal function deterioration and hyperkalemia.

Hypoalbuminemia

Hypoalbuminemia plays a pivotal role in many complications of the nephrotic syndrome, including edema, malnutrition, hyperlipidemia, and cardiovascular disease. The urinary loss of albumin is not sufficient to explain hypoalbuminemia. There is also an increased catabolism of albumin that might contribute to hypoalbuminemia. However, the most important mechanism is the inability of the liver to increase the albumin synthesis in response to urinary losses and/or increased catabolism [93].

Neither albumin infusion nor a high-protein diet may increase serum levels of albumin because these measures result in increased urinary losses of albumin.

Lipid Abnormalities

In nephrotic patients, there is an increase in low density lipoproteins (LDL), very low density lipoproteins (VLDL), and lipoprotein (a) (Lp(a)) levels while high density lipoprotein (HDL) levels are either normal or decreased. The composition of lipoproteins is also altered with a relative increase in cholesterol. These abnormalities are caused both by an increased hepatic synthesis and by a decreased clearance of lipids and lipoproteins. Experimental and clinical studies showed that cholesterol synthesis increased in response to hypoalbuminemia, serum cholesterol being inversely proportional to serum albumin. In addition to the increased synthesis, there are alterations in catabolism of lipids in nephrotic syndrome caused mainly by a decreased activity of the enzyme lipoprotein lipase. This may be related either to the urinary loss of some activators of the enzyme or to an increase in free fatty acids that are known to inhibit lipoprotein lipase activity. The reduction of HDL levels may be attributed to the urinary loss of lecithin-cholesterol acyltransferase and/or to its inhibition caused by the increased levels of free lysolecithin produced in hypoalbuminemia [73]. There has been controversy in the past about the possible role

of hyperlipidemia in favoring cardiovascular complications. More recently an association between lipid abnormalities and coronary artery disease has been demonstrated in nephrotic patients [138].

A lipid-lowering diet (< 200 mg/day of cholesterol, total fat < 30% of total calories, and polyunsaturated fatty acids about 10% of total calories) is usually recommended as the first therapeutic step in patients with hypercholesterolemia. However, for many nephrotic patients, diet is not sufficient to correct hyperlipidemia. Various lipid-lowering drugs such as probucol, nicotinic acid, resins, and fibric acid derivates have been used with little success because these agents are either poorly tolerated or have little efficacy. At present, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors are considered the drugs of choice for treating the hyperlipidemia of nephrotic patients. These agents may decrease serum cholesterol 30 – 40%, LDL about 40%, and apolipoprotein B 30%, but do not reduce the elevated levels of the atherogenic LP(a). The tolerance is usually good. Mild and transient increase in serum transaminase is rarely seen. Myositis and myalgias are rare but can occur with large doses.

Edema

Edema is one of the cardinal features of the nephrotic syndrome. Its pathogenesis is incompletely understood. Two main theories have been proposed: the classical underfill theory and the overfill theory. According to the classical view, hypoalbuminemia represents the "primum movens" of edema. Decreased plasma oncotic pressure favors translocation of fluid from the intravascular space into interstitial space. Reduction of plasma volume activates the renin-angiotensin system, secondary salt and water retention, plasma dilution, and further aggravation of hypoalbuminemia. However, only a minority of nephrotic patients have a decreased intravascular volume. The majority show normal or expanded plasma volume. Moreover, the plasma levels of renin, angiotensin, and aldosterone show large variations in nephrotic patients. Finally, maneuvers that increase plasma volume do not always result in a natriuretic response [139]. The overfill theory attributes a key role to the inability of the diseased kidney to excrete salt and water, with consequent intravascular expansion, increase in capillary hydrostatic pressure, and transudation of fluid into the interstitial space. The enhanced tubular NaCl avidity is mainly caused by post-receptor resistance to the action of atrial natriuretic peptide, due to enhanced activity of cyclic GMP phosphodiesterase [80]. Although the overfill theory may account for most cases of nephrotic edema, it is possible that underfill mechanisms are involved in few other cases, especially during the edema acquisition phase.

In milder cases, edema may be handled by restricting dietary sodium intake. Diuretic therapy may be required in patients who do not respond to a low-sodium diet. The first step may consist of administration of hydrochlorothiazide (12.5 – 50 mg/day), preferably in combination with a potassium-sparing agent such as amiloride, triamterene, or spironolactone. Loop diuretics, such as furosemide, ethacrynic acid, or bumetanide are needed for more severe edema. Furosemide is the most-used agent because of its flexibility and good tolerance. The drug may be given by mouth or intravenously, at doses ranging between 25 and 2000 mg/day. Binding of the drug to tubular fluid albumin can blunt the diuretic response. In patients who do not respond to high-dose furosemide, combining it with diuretics acting at different

levels, such as hydrochlorothiazide (25 – 50 mg/day) or metolazone (2.5 – 10 mg/day), may maximize the diuretic response.

Coagulation Abnormalities

In the nephrotic syndrome, there is an imbalance between procoagulant/antithrombotic factors. Usually there is an increase of prothrombotic factors such as fibrinogen, factors V and VIII, factor VII, platelets, and platelet hyperaggregability. Anticoagulant proteins such as active protein S, active protein C, antithrombin III are decreased, due to loss in the urine. In addition, nephrotic patients may show hyperviscosity favored by hyperlipidemia and impaired fibrinolysis, caused by elevated Lp(a) and ANG IV levels that promote the synthesis of plasminogen activation inhibitor. These hemostatic abnormalities promote the synthesis of plasminogen activation inhibitor and determine a hypercoagulable state that may cause thromboembolic complications. Renal vein thrombosis, deep vein thrombosis and pulmonary embolism are the most frequent thrombotic complications of the nephrotic syndrome and are roughly correlated with the magnitude of the depression of serum albumin. Their incidence is lower in children than in adults, but children are more exposed to the risk of arterial thrombosis.

Anticoagulant drugs can reduce the risk of thrombosis. However, because they carry a substantial risk of hemorrhagic complications, their use is generally restricted to situations such as prolonged bed rest, surgery, and episodes of dehydration. On the other hand, decision analysis studies reported that the benefits of prophylactic anticoagulants outweigh the risks, at least in nephrotic patients with membranous nephropathy who are particularly exposed to the risk of intravascular thrombosis [162].

Infections

Nephrotic patients have an increased susceptibility to infections. Several factors may be responsible: urinary loss of immunoglobulins, urinary loss of complement factors B and D, defective cellular immunity caused by the urinary loss of zinc, transferrin and vitamin D, and malnutrition. The concomitant use of high-dose glucocorticoids and immunosuppressive agents may further increase the risk of infections.

Endocrine Abnormalities

Nephrotic patients have significant urinary losses and reduced plasma concentration of $25(OH)D_3$. However, the vitamin D binding protein is also reduced in the nephrotic syndrome, so that the free $1,25(OH)_2D_3$ remains at normal plasma levels. Hypocalcemia is frequently seen in nephrotic patients. In most cases, it may be attributed solely to the reduction in protein-bound calcium secondary to hypoalbuminemia. Thus, while many nephrotic patients may show decreased serum levels of $25(OH)D_3$ and calcium, the serum-free $1,25(OH)_2D_3$ and ionized calcium are normal so that treatment with vitamin D is not necessary. However, vitamin D supplements are indicated in a minority of patients who demonstrate evidence of reduced serum ionized calcium, reduced intestinal calcium absorption, and secondary hyperparathyroidism.

Urinary losses of thyroxin-binding globulin can occur in the nephrotic syndrome. However, the serum levels of T4 and thyrotropin are normal, and clinically most patients are euthyroid.

Table 4. Factors Associated with Minimal Change Nephropathy

Drugs	*Tumors*
Nonsteroidal anti-inflammatory drugs	Hodgkin's lymphoma
Lithium	Non-Hodgkin's lymphoma
Thiola	Leukemia
Gold	Mesothelioma
Trimethadione-paramethadione	Carcinoma of colon, prostate, pancreas, or lung
Mercury	Nephroblastoma
Penicillamine	Waldenstrom's
Ampicillin	
Interferon	
Other diseases	
Diabetes mellitus	*Allergy*
Dermatitis herpetiformis	Pollens
Schistosomiasis	Food allergy
Virus infections	House dust
Immunizations	Bee stings

Minimal Change Disease (MCD)

MCD, also called minimal change nephropathy, nil disease or, lipoid nephrosis, is the most common cause of the nephrotic syndrome in children but may also occur in adults and the elderly. Clinically, MCD is characterized by a pure nephrotic syndrome. There are few or no abnormalities on light microscopy and immunofluorescence. The typical lesion is represented by a diffuse effacement of the foot processes of the podocytes on electron microscopy. The disease usually responds to glucocorticoids. In many patients the course is punctuated by alternating remissions and relapses of the nephrotic syndrome. Although there is evidence that MCD and FSGS may represent the 2 extremes of the same disease, we will treat these entities separately as they have a different histologic picture, clinical presentation and outcome, and response to therapy.

Etiology and Epidemiology

MCD may affect siblings in 3.5% of cases. An indication for a possible genetic predisposition is the reported association with certain HLA antigens such as B12, B8, and Drw 7. However, not all studies confirm this association [169]. Atopic diseases such as asthma, eczema, and hay fever may be present in almost one-third of patients with MCD. In a number of patients MCD may develop after allergic episodes.

Although MCD is usually idiopathic, rare cases occurring in association with drugs or other diseases have been reported (Table 4). MCD and acute interstitial nephritis may develop after the use of NSAIDs. Most of the affected patients are elderly and develop a nephrotic syndrome with ARF while taking the drug. Renal signs usually improve after discontinuing the drug with or without glucocorticoids [161]. Lithium and thiola, a drug used for treating cystinuria, may also cause MCD. Some cases of nephrotic syndrome and MCD have been observed during administra-

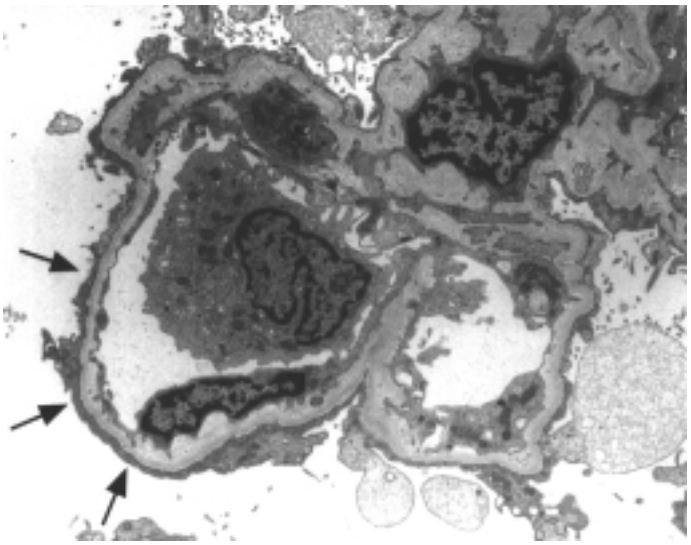

Figure 4. Minimal change nephropathy. Severe effacement of foot processes (arrows)(electron microscopy, 7,500x).

tion of interferon [44]. Usually nephrotic syndrome reverses after discontinuation of the drug. MCD may also be associated with DM, schistosomiasis, and other diseases, including neoplasias. The most frequent association with malignancy is with Hodgkin's lymphoma, while the association with non-Hodgkin's lymphoma or solid tumors is rare.

Pathology

On light microscopy, glomeruli may be completely normal with normal capillary walls and cellularity. However, a mild and focal mesangial hypercellularity may be noted. On morphometric analysis, glomerular hypertrophy may be seen in some cases. This finding may predict the progression to focal glomerulosclerosis [58]. Immunofluorescence is usually negative, but mesangial IgM deposition may be seen in some cases, with or without a slight increase in mesangial matrix. Some investigators have proposed that the presence of IgM deposits could identify a separate entity, but affected patients can neither be differentiated clinically from patients without IgM deposition nor have a different outcome and response to treatment. Also, the presence of mesangial IgG should be considered as nonspecific.

Electron microscopy shows the typical features of MCD consisting of an effacement of the foot processes of podocytes (Figure 4). The GBM is mostly normal; no parietal deposits are present. The endothelial cells are often swollen.

Pathogenesis

A number of studies have suggested that alterations in glomerular charge sites play an important role in MCD. A decreased glomerular negative charge has been found in rats with nephrotic syndrome caused by puromycin aminonucleoside [15]. Intrarenal arterial infusion of polycations causes selective proteinuria and foot processes effacement [8], and a decreased staining for glomerular polyanions has been observed in renal biopsies from patients with MCD [21]. The loss of

anionic charges on glomerular structures prevents the electrostatic repulsion between negatively-charged structures, which is a fundamental constituent of glomerular filtration barrier. As a consequence, there is retraction and effacement of foot processes, which are normally negatively charged, and there is a passage of lower macromolecules, such as serum albumin, into the urine. However, it is possible that the disturbance in charge is not confined to the glomerulus. Ghiggeri et al. showed that the charge and conformation of serum albumin were modified in the nephrotic phases of MCD but returned to near normal values after steroid-induced remission of proteinuria [62]. Levin et al. found an early reduction of surface negative charge on red blood cells (RBCs) and platelets preceding reduction of serum albumin during relapses [111]. Thus, MCD may result both from loss of negative glomerular charge (due to a loss of glomerular polyanions) and from a generalized electrochemical disorder with increased positive charge of some extrarenal structures, including serum albumin (Figure 5).

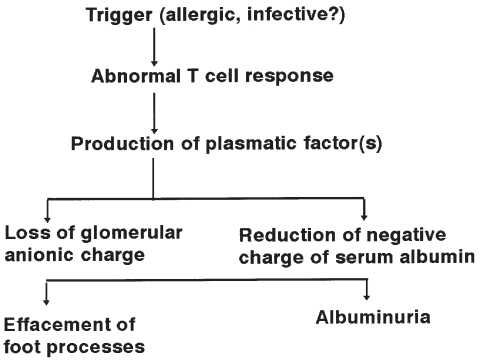

Figure 5. Possible pathogenesis of minimal change nephropathy.

What is the primary cause of these electrostatic defects? The abnormalities might be a consequence of failure to synthesize the charged group, loss of anionic charges due to degradative process, or neutralization. These mechanisms might arise from a circulating charge-neutralizing factor that could be produced by T cells in response to an infective or allergic trigger. A number of studies reported that during MCD relapses, lymphocytes have impaired responses to polyclonal activators, probably caused by prostaglandins secreted by macrophages. The response returns to normal during remission. On the other hand, there is an increase in T-suppressor activity during relapse that reverses after treatment. However, it is still unclear whether these and other abnormalities of the cell-mediated immunity are the cause or the consequence of the nephrotic syndrome and/or of circulating factor(s). Several lymphokines, including interleukin-2, and vascular permeability factors were isolated in the supernatant of cultured lymphocytes. These factors might be responsible of the loss of anionic charges and increased glomerular permeability, but their pathogenic role is still far from being established.

Clinical Presentation and Course

MCD is the major cause of the nephrotic syndrome in children, accounting for 90% of cases under the age of 6. The disease is not limited to children, however. It may occur in adulthood and also in the elderly.

Patients with MCD generally present with full-blown nephrotic syndrome. The onset of the disease is usually acute and frequently follows a viral upper respiratory infection, an allergic episode, or a vaccination. The degree of pedal and periorbital edema may be variable, but most patients have a severe fluid retention that can also result in ascites and pleural effusion. Blood pressure is usually in a normal range but is higher than in normal

Table 5. Definitions of Responses and Relapses in Patients with Minimal Change Nephropathy

Complete remission	Proteinuria < 4 mg/m^2/day in children or < 0.2 g/day in adults for 3 consecutive days
Partial remission	Proteinuria between 4 and 40 mg/m^2 day in children or between 0.21 and 3.5 g/day in adults for 3 consecutive days
Relapse of proteinuria	Proteinuria > 4 mg/m^2/day in children or > 0.2 g/day in adults for at least one week in patients who were in complete remission
Relapses of nephrotic syndrome	Proteinuria > 40 mg/m^2/day in children or > 3.5 g/day in adults for at least one week in patients who were in remission
Frequent relapsers	Patients with ≥ 2 episodes of the nephrotic syndrome in 6 months or ≥ 3 episodes of the nephrotic syndrome in 12 months
Steroid-dependent	Reappearance of the nephrotic syndrome within 2 weeks after reduction or discontinuation of glucocorticoids

subjects of the same age. About 20 – 30% of patients are hypertensive. On the other hand, hypovolemic shock may sometimes occur as a consequence of massive urinary loss of albumin. Proteinuria ranges between 3 and 20 g or more per day. It is typically selective with heavy loss of smaller macromolecules, such as albumin and transferrin, while proteins of higher molecular weight are retained. Severe hypoalbuminemia and hypercholesterolemia are common. Microscopic hematuria can be found in about one-third of cases. Renal function is usually normal. However, moderate to severe renal failure can occur, particularly in older patients.

It is difficult to assess the natural course of MCD because today most patients are treated with glucocorticoids and other effective drugs. Before the use of these agents, the 5-year mortality rate in children was as high as 67%, with the remaining patients undergoing spontaneous remission [6]. The major causes of death were infection, particularly peritonitis and pneumonia, and renal failure. A beneficial alteration in the course of MCD was achieved with glucocorticoids (see below). Approximately 95% of children and 80% of adults can obtain complete remission of proteinuria under glucocorticoid therapy. In those who respond, the remission is permanent in only about 20 – 25%. Another 20 – 25% of patients will have infrequent relapses, while the rest become frequent relapsers or steroid-dependent (see Table 5). The risk of relapse seems to be inversely correlated with age, being higher in children younger than 6 years than in older children [186]. The risk is lower in adults [60] and even lower in the elderly [113]. The risk of frequent relapses and/or steroid dependency is lower in patients who had a good response to glucocorticoids, a prolonged initial treatment [24], and a prolonged remission after the first episode [112]. As already mentioned, the presence of glomerular hypertrophy on morphometric analysis is a bad prognostic sign, because it may herald progression to FSGS [58]. Although in the past mesangial hypercellularity

and mesangial IgM deposits were thought to be associated with a decreased response to glucocorticoids and steroid dependency, the current opinion is that these findings are not associated with outcome or response to treatment different from those of patients with classic MCD. Eventually, about 65 – 75% of patients may enter a prolonged remission within 10 years from clinical onset, but some children need 20 – 30 years before attaining a definitive remission.

Progression to CRF is exceptional in children but may occur in adults and particularly in elderly patients. Sporadic cases of ARF have also been reported. These can be due to hypovolemia, renal vein thrombosis, or interstitial nephritis, but are more often caused by diuretics or hemodynamic factors [177]. ARF is more frequent and severe in elderly patients but can also rarely occur in children. MCD patients are exposed to the complications of the nephrotic syndrome, such as infections and intravascular thrombosis, or its treatment. Some patients may die as a result of these complications. The mortality rate ranges around 2% for children [112], 65 – 10% for adults [167], and 35 – 45% for elderly patients [113]. Death is particularly frequent in patients with renal dysfunction and in those untreated or refractory to treatment [135].

Diagnosis

MCD may occur in the first year of life but this is rare. In these cases, it is difficult to distinguish MCD from the Finnish type of congenital nephrotic syndrome and diffuse mesangial sclerosis. Congenital nephrotic syndrome is more common in Finland but has also been observed in other countries. It is an inherited autosomal recessive disease characterized by a severe nephrotic syndrome from the first days of life. There are no definite histopathologic criteria that allow differentiation between it and MCD. Diffuse mesangial sclerosis is another entity which also has an early onset and a severe nephrotic syndrome but differs in its rapid progression to end-stage renal failure and by histopathologic lesions characterized by a combination of thickened basement membranes and expansion of mesangial matrix with no increase in the number of mesangial cells [25].

It is difficult to differentiate MCD from other glomerular diseases on clinical grounds. Selective proteinuria is more frequent in MCD but can also be found in the initial stages of membranous nephropathy and FSGS. Hypertension, hematuria, and renal insufficiency are more common in other glomerular diseases, but there is considerable overlap. Because MCD is responsible for most cases of nephrotic syndrome in children, treatment with glucocorticoids is usually initiated on empirical grounds, and renal biopsy is performed only if an 8-week trial does not induce remission of proteinuria. In adults MCD is a rarer cause of the nephrotic syndrome. A trial with glucocorticoids is not helpful for an early diagnosis, as only 50 – 60% of adults show disappearance of proteinuria after 8 weeks of prednisone. Thus, renal biopsy is required in adults.

Treatment

MCD is very sensitive to treatment with glucocorticoids. Although remission may occasionally be obtained with relatively moderate doses, most authorities suggest an aggressive initial treatment. In children the standard treatment for the first episode of nephrotic syndrome consists of prednisone at a dose of 60 mg/m^2/day for 4 weeks, followed by 40 mg/m^2 given on alternate days for 4 more weeks [24]. With such a regimen, proteinuria

can be expected to disappear in about 50% of children within one week, in 80 – 85% within 4 weeks, and in 90 – 95% within 8 weeks. In a few children, however, complete remission of proteinuria occurs only after more prolonged treatment or after intravenous (IV) high-dose methylprednisolone [25].

Adults are usually treated with lower doses of prednisone, i.e. 1 mg/kg body weight/day. Proteinuria disappears only in 50 – 60% of adults within 8 weeks. However, about 80% of patients become free of proteinuria if treatment is prolonged to ≥ 16 weeks [60, 134]. Thus, it is now clear that the concept of steroid resistance, which was previously applied to patients who did not respond to high-dose prednisolone within 4 – 8 weeks, should be reviewed. Many adults and some children who were considered as steroid resistant in the past were simply undertreated.

There is, however, a small proportion of patients with the histological appearance of MCD who do not respond even to a prolonged treatment with steroids. These patients usually show FSGS on repeated biopsy and should be treated accordingly.

After remission is obtained, some 20 – 30% of patients do not relapse, and a similar number have only infrequent relapses. Patients with infrequent relapses are usually treated with high-dose prednisone until remission, followed by 4 weeks of alternate-day prednisone at a dose of 40 mg/m^2 in children and 0.75 mg/kg in adults [147]. Spontaneous remission is also possible, particularly when relapse follows an intercurrent infection.

Unfortunately, many initial responders either become frequent relapsers or show steroid dependency. There is some evidence that the risk of relapse is greater in children given a short course of treatment for the initial attack than in children given long-term treatment [24]. Thus, after remission has been obtained, it is advisable to prolong treatment to prevent further relapses. If well tolerated, low-dose prednisone can be given every other day for 6 – 12 months. The doses of steroid should be tapered gradually to prevent relapses that may be triggered by secondary hypoadrenalism.

The treatment of frequently relapsing or steroid-dependent patients is difficult. For inducing remission, schedules based on alternate-day prednisone, low-dose hydrocortisone, and IV high-dose methylprednisolone followed by low-dose prednisone can reduce iatrogenic toxicity. However, in spite of these schedules, a number of patients develop steroid-related side effects, including obesity, diabetes, osteoporosis, Cushingoid features, hypertension, infection, and growth retardation in children.

Levamisole, cytotoxic agents, and cyclosporin have been suggested as potential alternative treatments. Levamisole is an antihelminthic drug with immunomodulating properties. Some retrospective studies reported that this agent could reduce the risk of relapses. Conflicting results have been obtained with controlled trials. In one study [23], 61 steroid-dependent children, in whom remission had been achieved with prednisone, were randomly assigned to receive placebo or levamisole at a dose of 2.5 mg/kg every other day. After 112 days, 4 of 30 patients given placebo vs. 14 of 31 given levamisole maintained remission, the difference being significant. However, another controlled trial could not find any significant difference in the median duration of remission between children given placebo and those given levamisole [41].

Cytotoxic agents, such as cyclophosphamide and chlorambucil, can produce more lasting remission than steroids. Remission seems to be more stable in adults than in children. More than 60% of adults given cyclophosphamide because of multiple relapses remained in remission for at least 5 years [115,

134], while a pediatric review reported that the rates of remission at 5 years in children ranged from 36 – 66% [25]. Duration of treatment is also important. Pennisi et al. reported complete remission at one year in 92% of children given cyclophosphamide for 10 – 12 weeks vs. 42% of children treated for 6 – 8 weeks [141].

Alkylating agents may cause leukopenia, hemorrhagic cystitis, oncogenic effects, and gonadal toxicity, testes being more vulnerable than ovaries. Therefore, their use should be limited to those patients who are at risk of developing steroid toxicity. To prevent leukopenia, high daily doses should not be used (we suggest 2 mg/kg/day for cyclophosphamide and 0.1 – 0.15 mg/kg/day for chlorambucil). To prevent azoospermia, cumulative doses of 200 – 250 mg/kg for cyclophosphamide or 10 – 15 mg/kg/day for chlorambucil should not be exceeded. With these cumulative doses, the oncogenic risk is minimal. Forced diuresis and/or 2-mercaptoethanesulphonate (MESNA) can protect from the bladder toxicity of cyclophosphamide.

Cyclosporin is another therapeutic option. Most steroid-dependent patients can be maintained in remission with cyclosporin, which is usually started after remission has been induced with steroids [145]. After cyclosporin is stopped, an early relapse of nephrotic syndrome usually occurs, but some patients may maintain remission, particularly if cyclosporin dosing has been tapered gradually after prolonged treatment. A number of side effects may be associated with the use of cyclosporin. Hypertrichosis, gum hyperplasia, gastrointestinal symptoms, and hypertension are the most frequently reported. There has been much concern about the potential nephrotoxicity of cyclosporin. In patients with nonrenal autoimmune diseases, a cyclosporin-related nephropathy characterized by interstitial fibrosis and progressive renal disease can develop. This is usually preceded by a typical arteriolopathy with either nodular proteinaceous deposits in the arteriolar wall or mucinoid thickening of the intima. Older age, high doses of cyclosporin, and an increase in plasma creatinine to > 75% over the basal values are the most important variables associated with the risk of developing irreversible cyclosporin nephropathy [55]. The importance of the size of the dose in inducing nephropathy is confirmed by some studies based on iterative renal biopsies in patients with MCD [70, 123]. On the other hand, there is evidence that cyclosporin arteriolopathy, which precedes the development of interstitial fibrosis, can be reversible if cyclosporin is stopped or given at lower doses [129]. Thus, cyclosporin can be used in patients with resistant disease, but careful monitoring is needed with its use in patients with renal diseases. We suggest as an initial dose 4 mg/kg/day of the new microemulsion in adults and 100 mg/m^2/day in children. Trough blood levels should be maintained between 75 and 200 ng/mL. The doses should be reduced if plasma creatinine rises > 30% over the basal values. The drug should be stopped if plasma creatinine rises > 75% over the basal values.

In summary, we suggest the following approach in MCD. An aggressive and prolonged (if tolerated) course of glucocorticoids should be used to treat the first episode of nephrotic syndrome in an attempt to achieve remission and prevent relapse. Infrequent relapses can be treated with shorter courses of glucocorticoids. In frequently relapsing/steroid-dependent patients, levamisole may be tried in an attempt to reduce steroid doses in responders. Although the efficacy of this drug is controversial, the tolerance is usually good. If levamisole is not successful, patients may be treated with continuous alternate-day prednisone and IV methylprednisolone pulses dur-

ing relapses. Those patients who do not tolerate steroids may be given a trial with a cytotoxic agent for 12 weeks at cumulative doses not exceeding 250 mg/kg for cyclophosphamide or 12 mg/kg for chlorambucil. If further relapses occur, cytotoxic therapy should not be repeated, as potential toxicity may be cumulative. Those patients can be switched to cyclosporin at an initial dose of 4 mg/kg/day in adults and 100 mg/m^2 in children, trying to gradually taper off the drug after 1 – 2 years.

Table 6. Causes of Secondary Focal Glomerulosclerosis

Elderly	Malignancy
Morbid obesity	Familial dysautonomia
Reduced renal mass	IgA nephritis
Reflux nephropathy	Membranous nephropathy
Obstructive uropathy	Segmental hypoplasia
AIDS	Diabetes mellitus
Heroin addiction	Sickle cell disease
Analgesic nephropathy	Transplantation
Hypertension	Oligomeganephronia

Focal Segmental Glomerulosclerosis (FSGS)

FSGS is a clinicopathologic entity characterized by proteinuria, often in nephrotic range, and by focal and segmental sclerosis, which initially predominates in the juxtamedullary glomeruli and then spreads to the outer cortex. The primary form of FSGS affects both children and adults. It may represent an evolutionary stage of MCD. A morphologically similar lesion to FSGS may result from a number of disorders and may create problems of differential diagnosis with the primary form. Most patients with FSGS and the nephrotic syndrome develop renal failure within 10 – 15 years.

Etiology

The current opinion is that MCD and FSGS represent the 2 extremes of the same disease. Both entities are characterized by massive proteinuria as well as by the effacement of the foot processes of epithelial cells on electron microscopy and insignificant deposition of immunoglobulins and complement. The etiology of primary FSGS is unknown as it is for MCD.

Segmental sclerosing lesions may also develop in different clinical instances and can even complicate other glomerular diseases (Table 6). In a number of cases, these secondary forms of FSGS are caused by maladaptive glomerular hemodynamic alterations, leading to glomerular hyperfiltration and hypertension, with eventual development of segmental glomerular scars. FSGS may be a rare complication of obesity and can also develop in heroin addicts and in patients with the aquired immunodefeciency syndrome (AIDS), where the variant of collapsing glomerulopathy seems to be particularly frequent.

Pathology

The initial lesions develop in a portion (segmental) of some glomeruli (focal) (Figure 6). Early lesions affect the deeper juxtamedullary glomeruli. The segmental lesions affect a few capillary loops that stick together, either at the

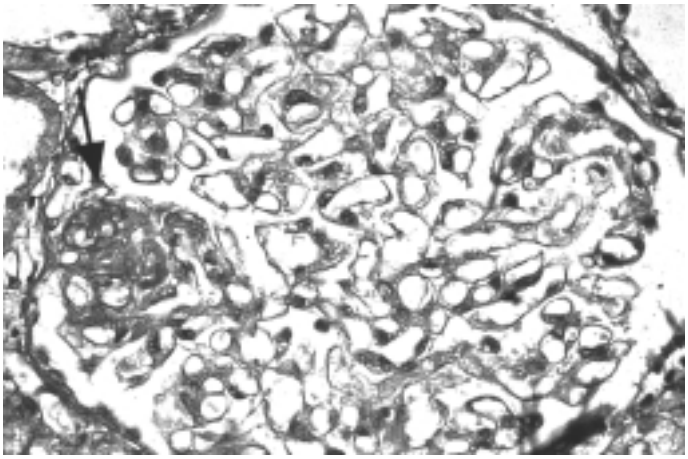

Figure 6. Focal segmental glomerulosclerosis. Typical sclerosis (arrow) of a circumscribed area of the glomerular tuft (500x).

periphery of the tuft (tip lesions) of at the hilum. Hyaline material is often present in the sclerosed areas, which are usually surrounded by a clear halo and always lined by a layer of severely altered and effaced podocytes. Initially, the rest of the tuft and the other glomeruli show only minimal changes, but mesangial hypercellularity may be present. Immunofluorescence is usually negative, but some deposition of IgM and C3 may be seen in the sclerotic areas. Electron microscopy usually reveals diffuse effacement of podocytes and their detachment from the GBM. A form of collapsing glomerulopathy has also been described. It is characterized by glomerular capillary collapse, visceral epithelial swelling, and hyperplasia. It seems to be more frequent in black patients.

Sclerosis progressively destroys the glomerulus, evolving to widespread sclerosis of the whole tuft. With progression of the disease, the lesions extend to the deeper cortex first and then to the outer cortex. Besides the glomerular lesions, there are also tubular and interstitial changes. Initially, there are focal tubular lesions, and foam cells may be seen in the interstitium. In more advanced phases, there is atrophy and interstitial fibrosis of various degree. Interstitial fibrosis is particularly severe in collapsing glomerulopathy, out of proportion to the glomerular process.

Pathogenesis

The pathogenesis of FSGS is similar to that proposed for MCD. The disease could represent a T cell-mediated disorder in which an aberrant clone of T cells secretes a circulating factor that impairs the negative charges of the glomerular structures and probably also of serum albumin and other extrarenal material. Podocytes could be the primary target in FSGS. The initial alterations consisting of an effacement of foot processes may lead to their detachment from the basement membrane. This could result in hyperfiltration, accumulation of subendothelial protein, capillary occlusion, and the formation of synechia between the tuft and the capsule [110]. Massive production of circulating factor(s), genetic predisposition, hyperlipidemia, and hypercoagulation may contribute to the development of FSGS. Another factor that may favor the development of FSGS is an excessive produc-

tion of fibrogenic growth factors. In the animal model, platelet-derived growth factor B and transforming growth factor beta have been implicated in the induction and progression of glomerulosclerosis [90].

The role of circulating factor(s) in eliciting the pathogenesis of FSGS has been further substantiated by experience with renal transplantation. A number of patients who lost their native kidney function because of FSGS show recurrence of proteinuria and the typical lesions of FSGS at renal biopsy after transplantation. Plasmapheresis and/or immunoadsorption with protein A may reduce proteinuria in these cases [39], suggesting that the recurrence of FSGS may be caused by a plasmatic factor. Recently, Savin et al. isolated a circulating factor from patients with recurrence of FSGS after renal transplantation [164]. This factor has a molecular weight of about 50 kd, larger than any known lymphokine, and does not precipitate with immunoglobulins. It might be a nonimmunoglobulin protein or a fragment of an immunoglobulin. However, it is unlikely that this factor neutralizes the anionic-charge barrier, because it is not strongly cationic. Its activity, in very small amounts, might be compatible with that of a cytokine-like molecule that directly injures podocytes.

Clinical Presentation and Course

FSGS accounts for up to 20% of glomerular lesions in children and adults presenting with proteinuria. It is more frequent in the black than in the white population. The clinical presentation is similar at any age, although nephrotic syndrome is more frequent in children and hypertension is more frequent in adults [103]. Some 70 – 90% of patients have a nephrotic syndrome at presentation. Microhematuria is found initially in about half of cases, while macroscopic hematuria is rare. Renal insufficiency may be present in about 20 – 25% of cases at clinical onset.

The disease is usually progressive, and about two-thirds of cases develop end-stage renal disease (ESRD) within 10 – 15 years. A few patients with severe nephrotic syndrome may progress rapidly to renal failure, often associated with arterial hypertension and thrombotic complications. Spontaneous remission of the nephrotic syndrome is exceptional. Complete remission can occur in less than 3% of untreated patients [103].

Several factors may have prognostic significance. The 2 most important clinical features are the level of proteinuria and serum creatinine. Patients with nephrotic range proteinuria reach ESRD within 6 – 8 years in 50% of cases, while the 10-year renal survival is > 90% for patients with non-nephrotic proteinuria [31]. The presence of massive proteinuria, (> 10 g/day, is associated with a particularly poor prognosis, with half of patients reaching ESRD within 3 years [31]. There is also general agreement that impaired renal function at presentation indicates a poor prognosis. Among histologic features, location of sclerotic lesions at hilar pole, glomerular hypertrophy, mesangial hypercellularity, and collapsing glomerulopathy have been considered to be associated with poorer prognosis, by some investigators but not by all. Interstitial fibrosis is universally considered as the strongest prognostic predictor among the histologic features. The response to therapy is also a useful clinical indicator of outcome. A review of the literature showed that < 3% of patients who attained complete remission with therapy developed ESRD by 5 years compared with 55% of nonresponding patients [103]. Even a partial remission is associated with a more favorable course compared to persisting nephrotic syndrome.

Diagnosis

As with most other primary glomerulonephritis, the diagnosis of FSGS also requires renal biopsy. The presence of a single glomerulus with segmental hyalinosis is sufficient to make a diagnosis of FSGS. In the initial phases, however, the diagnosis may be impossible if only the glomeruli of the outer cortex are represented in the histologic sample.

In some instances it can be difficult to recognize whether FSGS is idiopathic or secondary to other diseases or conditions. The forms caused by maladaptive glomerular hemodynamic alterations may be distinguished by the absence of hypoalbuminemia, hypercholesterolemia, and edema in spite of nephrotic levels of proteinuria. Human immunodeficiency virus (HIV) and heroin-associated forms rapidly progress to ESRD within a few months. At renal biopsy, the secondary forms may have large glomeruli with hilar lesions, while tip lesions recall idiopathic FSGS. The presence of mesangial hypercellularity is more typical of the idiopathic form. Probably the most reliable sign for idiopathic FSGS is represented by the effacement of foot processes at electron microscopy.

Treatment

Almost all the studies of FSGS treatment are retrospective. A review of uncontrolled trials reported that 29% of children and 17% of adults [167] treated with glucocorticoids entered complete remission of proteinuria. The majority of these patients were given glucocorticoids for no more than 4 – 8 weeks. Better results have been obtained when patients were given more prolonged glucocorticoid therapy. A review of the literature indicated that 51% of patients treated with prednisone for ≥ 6 months entered complete remission of proteinuria [144]. Most responders maintained normal renal function over time. Unfortunately, no clinical or histologic feature can predict the response to glucocorticoids.

The potential role for immunosuppressive agents is even less clear. The results of retrospective studies suggest that, as with prednisone, the longer the treatment the higher the rate of response, but the cumulative rate of remission is similar to that obtained with glucocorticoids [7]. A randomized trial in children did not show differences between alternate-day prednisone alone or combined with cyclophosphamide for 3 months [184]. On the other hand, at least in adults, the length of remission in responders seems to be longer in patients given cyclophosphamide or chlorambucil. In our own retrospective experience, only 18% of patients who responded to cytotoxic therapy had one or more relapses of nephrotic syndrome vs. 40% of patients who responded to glucocorticoids [7].

Mendoza et al. have proposed an aggressive approach for steroid-resistant children [121a]. Their regimen consisted of high-dose IV methylprednisolone pulses given initially every other day, then at progressively longer intervals for more than one year. The children were also given prednisone, 2 mg/kg every other day. If no response was obtained, cyclophosphamide or chlorambucil was added. Their most recent analysis showed that at the end of a mean follow-up of 6 years, 21 out of 32 children treated were in complete remission, 3 were in partial remission (non-nephrotic proteinuria), 5 had reduced creatinine clearance, and 3 had progressed to ESRD [187]. These results were not confirmed by Waldo et al. who gave a similar regimen to 10 children with FSGS [192]. After 47 months, 6 patients had developed ESRD, 2 had developed renal insufficiency, and the other 2 pa-

tients were still nephrotic. However, 8 of their 10 patients were black, and this may have affected the response rate because blacks may have more severe disease than white patients.

Cyclosporin has also been used in FSGS. A review of the literature found that 40% of patients treated with cyclosporin could be maintained in remission from nephrotic syndrome, the response being similar in children and in adults [103]. Ingulli et al. treated 21 children with cyclosporin for a mean period of 27 months [83]. Proteinuria and cholesterol significantly decreased. When compared with a historical population, the rate of patients who progressed to ESRD was lower in cyclosporin-treated children (24% vs. 78%). This apparent benefit of cyclosporin on proteinuria was also supported by an Italian controlled trial [149]. Nephrotic patients who had not responded to a 6-week course of high-dose prednisone were randomly assigned to supportive therapy or to cyclosporin (5 mg/kg/day in adults and 6 mg/kg/day in children) for 6 months. In the first year, 32% of treated patients entered complete remission, another 27% had partial remission, and only 16% of untreated controls had a partial and transient remission. The mean levels of creatinine clearance did not differ between the 2 groups. However, 66% of patients had a relapse in nephrotic syndrome after cyclosporin was stopped. Thus, a prolonged treatment is needed to avoid nephrotic syndrome. Is this approach safe? Worsening of kidney lesions at repeat renal biopsy has been reported in cyclosporin-treated patients with FSGS [124]. It is not clear however, whether the renal lesions seen on repeat biopsy represent progression of the underlying FSGS in nonresponders or represent cyclosporin toxicity. Whatever the mechanism, the risk of severe tubulointerstitial lesions in patients treated with cyclosporin for FSGS seems to be particularly high when there is an abnormal baseline serum creatinine, when a high proportion of glomeruli with sclerosis is seen at renal biopsy, or when the initial dose of cyclosporin is high. On the basis of the available knowledge, we do not recommend prescribing cyclosporin to patients with abnormal renal function, severe hypertension, tubulointerstitial lesions, or extensive glomerular sclerosis.

In spite of some evidence that a prolonged treatment with glucocorticoids, cytotoxic agents, or cyclosporin may bring about remission and protect renal function in a subset of patients, the optimal treatment regime for FSGS is still unclear. There is general agreement that no specific therapy is needed for patients with asymptomatic proteinuria. There is also consensus about using an 8-week course of high-dose prednisolone in nephrotic patients in order to recognize the few early responders.

What to do with nephrotic patients who do not respond to short-treatment is controversial. Many clinicians do not give any specific therapy, whereas others are quite aggressive and give prolonged steroid and/or cytotoxic treatments. Our practice is that, unless steroid toxicity develops, prednisone should be continued for another 4 – 6 months. One alternative is to give an alkylating agent for 6 months or alternate steroids and an alkylating agent every other month for 6 months, with a schedule similar to that used in membranous nephropathy (MN) [150] in order to reduce the risk of steroid toxicity and to induce a longer remission in responders. If nephrotic syndrome persists, a trial with cyclosporin (initial doses with the new microemulsion 4 mg/kg/day in adults or 100 mg/m^2/day in children) may be offered provided that creatinine clearance and blood pressure are normal and that a recent renal biopsy does not show severe tubulointerstitial lesions. If no improvement of proteinuria is seen within 3 months, cyclosporin should be stopped, as it

Table 7. Causes of Secondary Membranous Nephropathy

Infections	*Association with other diseases*
Malaria	Carcinoma
Schistosomiasis	Non-Hodgkin's lymphoma
Hepatitis B	Hodgkin's disease
Hepatitis C	Chronic lymphocytic leukemia

Tuberculosis	Autoimmune thyroiditis
Leprosy	Sarcoidosis
Filariasis	Sjögren's syndrome
Streptococcal infection	Sickle cell disease
HIV infection	Diabetes mellitus
Rectal abscess	Dermatitis herpetiform
	Bullous pemphigoid
Drugs and Toxins	Psoriasis vulgaris
Non-steroidal anti-inflammatory drugs	Primary biliary cirrhosis
Captopril	Guillain-Barré syndrome
Penicillamine	Mixed connective tissue disease
Gold	Periaortic fibrosis
Mercury	Myasthenia gravis
Hydrocarbons	Rheumatoid arthritis
Formaldehyde	Renal transplantation

is unlikely that more prolonged treatment will result in remission. In patients who respond, cyclosporin can be continued for another 1 – 2 years at the minimal effective dose. If nephrotic syndrome reappears after stopping cyclosporin, a renal biopsy may be repeated before deciding whether or not therapy with cyclosporin should be continued.

Membranous Nephropathy (MN)

MN is a glomerular disease characterized clinically by proteinuria and histologically by a diffuse thickening of the GBM due to deposition of subepithelial immune-complexes. MN is idiopathic in the majority of cases, but in some instances it is secondary to well-defined causes. The course of the disease may be variable. Some patients maintain normal renal function with or without remission of proteinuria, but others progress to renal failure or die from complications related to the nephrotic syndrome.

Etiology

Exceptionally, MN may affect siblings. An association between MN and human leukocyte antigen (HLA)-DR3 antigen has been reported by many studies in white patients. In Japanese patients there is an increased incidence of HLA-DR2 [174].

In most cases of MN no etiological factor can be identified. However, in about one-fourth to one-third of cases, MN is associated with identifiable causes (Table 7). The overall prevalence of secondary MN appears to be

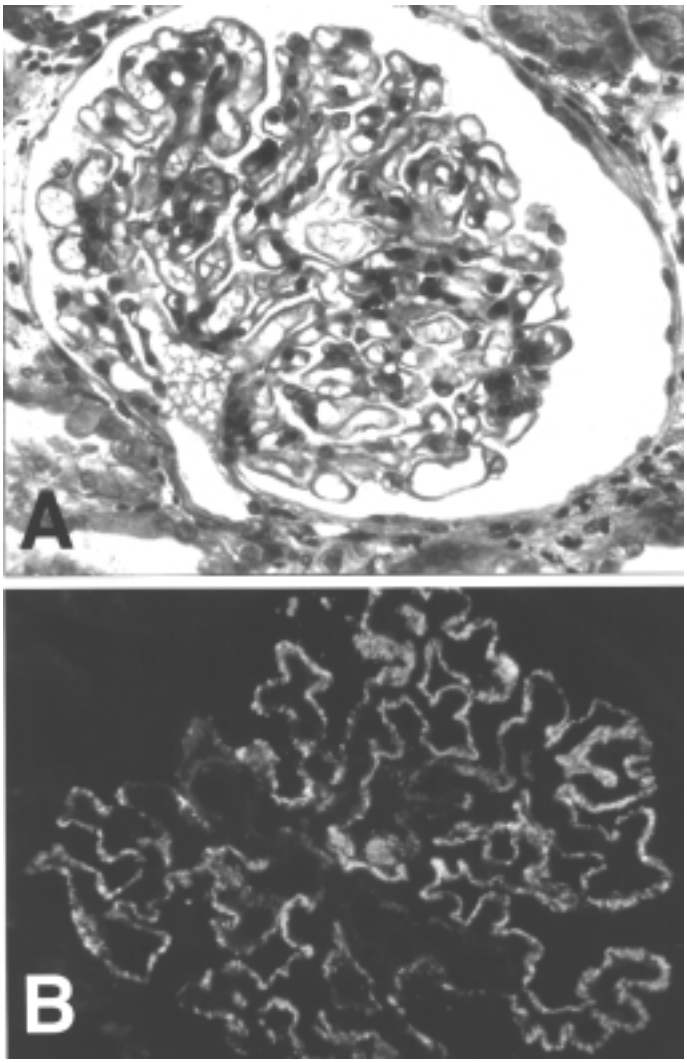

Figure 7. Membranous nephropathy. A: diffuse and homogeneous thickening of the glomerular capillary walls (500x). B: granular deposition of IgG as seen by immunofluorescence (500x).

higher in children and in older adults. Worldwide, malaria and schistosomiasis are the most common causes of secondary MN. Hepatitis B and C are also frequent causes of MN, particularly in endemic areas [106]. MN may be the first manifestation of SLE and may precede serological abnormalities by several years. In some 10% of patients, MN is associated with malignancy. In 40 – 45% of these cases, renal disease may antedate the initial manifestations of the underlying cancer by months or even years [29]. In a number of cases, MN can be secondary to toxic agents or drugs. Penicillamine and gold are 2 well-known causes of MN, but NAIDs are probably the most frequent etiologic drugs of secondary MN. In a recent report, these drugs were responsible for 10% of stage I MN [155]. Recognition of the toxic agent or drug as a cause of MN is important because proteinuria usually remits after the removal of the offending agent.

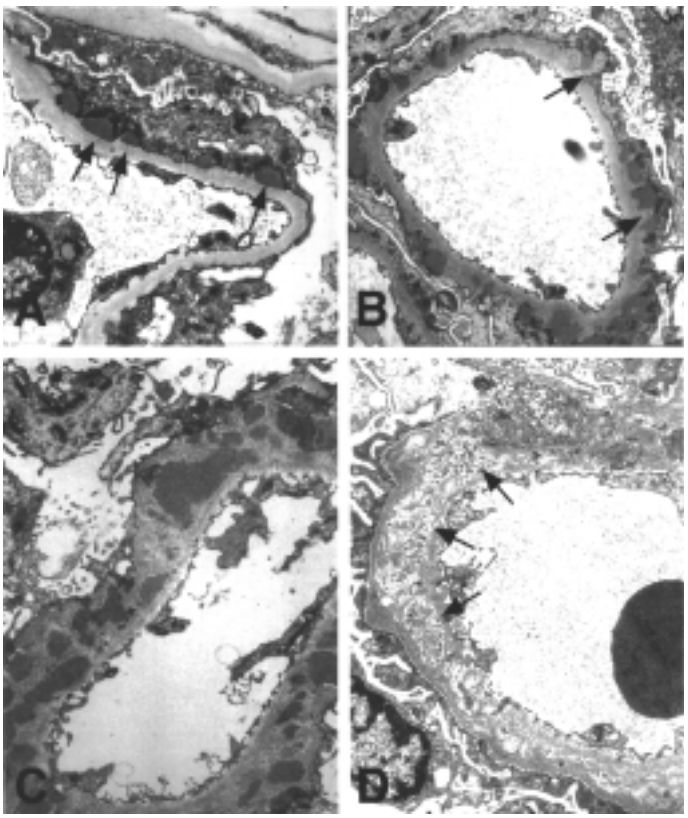

Figure 8. Membranous nephropathy as seen by electron microscopy. A: stage I, with few electron-dense deposits (arrows) on the subepithelial side of the GBM. B: stage II, with projections of the GBM (arrows) around the electron-dense deposits. C: stage III, with electron-dense deposits incorporated within a thickened GBM. D: stage IV, with partially reabsorbed deposits (arrows) and irregular thickening of the GBM. (7,000 – 8,000x)

Pathology

MN is characterized by typical alterations of the GBM caused by subepithelial deposition of immune deposits (Figure 7). Ehrenreich and Churg described 4 glomerular stages of the disease (Figure 8) [52]. In stage I, the glomeruli appear almost normal at light microscopy, but at electron microscopy there are small, spaced, subepithelial electron-dense deposits and diffuse foot process fusion. Immunofluorescence shows diffuse granular deposits of IgG and C3 along the capillary loops. In stage II, light microscopy shows a diffuse, uniform thickening of the GBM, with characteristic spikes on silver stain. By electron microscopy, these are due to projections of the GBM. The deposits are larger, more uniform, and numerous. In stage III, the deposits are incorporated within the GBM, which appears thickened at light microscopy. In stage IV, the GBM is markedly but irregularly thickened. By electron microscopy there is rarefaction of deposits due to resorption. The intensity of the deposits at immunofluorescence may be rather low. These stages are common to all forms of MN, but in secondary forms subendothelial deposits as well as mesangial proliferation may be present. They are not usually found in idiopathic MN. The finding of IgA or C1q by immunofluorescence also suggests a secondary MN.

Although some investigators have found that patients with stage I – II glomerular lesions are unlikely to develop renal failure [52], others did not find any correlation between the glomerular stage and the renal out-

come [97, 150, 196]. An unfavorable prognostic role has been attributed to the finding of a superimposed focal glomerulosclerosis [191]. There is general agreement, however, that interstitial fibrosis and tubular atrophy, rather than glomerular changes, are the histologic findings more strictly associated with a poor prognosis [97, 150, 196].

Pathogenesis

As shown by immunofluorescence and electron microscopy, MN is characterized by the subepithelial deposition of immune complexes. Two hypotheses regarding the immune deposits formation have been considered. First, circulating immune complexes of intermediate size escape phagocytosis from the reticuloendothelial system, pass the GBM, and deposit in the subepithelial space. This mechanism might be operating in some cases of secondary MN. Circulating complexes have been detected in MN associated with SLE, hepatitis B, or neoplasia; and in some cases the antigen has been eluted from glomeruli [183]. However, such a pathogenesis is unlikely in idiopathic MN, as a number of clinical studies failed to detect circulating immune complexes. Second, immune complexes could form in situ by antibody reacting with antigens planted in the glomeruli or with endogenous glomerular antigen.

The Heymann nephritis model has been largely used to understand the pathogenesis of idiopathic MN. There are 2 models of Heymann nephritis. Both of them lead to an autoimmune-mediated glomerulonephritis that has functional and immunopathologic features similar to human idiopathic MN. Active nephritis is induced by immunization of susceptible strains of rat with crude proximal tubular brush border extract. The passive Heymann nephritis is induced by injecting antibodies against this extract. Two main antigenic determinants have been identified in Heymann nephritis: megalin and receptor-associated protein. Megalin, previously called gp 330, is a member of low-density lipoprotein receptors located in the brush border of tubular cells and, in lower amounts, in glomerular epithelial cells. The receptor-associated protein binds to megalin and may serve as its intracellular chaperon [54]. There is now evidence that in Heymann nephritis subepithelial deposits do not derive from trapped circulating immune complexes but are caused by in situ complex formation [95]. Antibodies penetrate the GBM and bind to antigens located at the base of the epithelial cells. The immune deposits grow in size by repeated cycles of immune complex formation and new formation of megalin. A similar mechanism is thought to be operating in human idiopathic MN, although the target antigen has yet to be identified.

The subepithelial deposition of immune complexes activate the complement system with formation of the C5b – C9 complex (membrane attack complex). This results in release of potential inflammatory mediators such as prostaglandins, oxidants, and proteinases leading to damage of the glomerular epithelial cells and altered glomerular barrier function [36]. An important role in the progression of renal disease has been attributed to cytokines, particularly transforming growth factor β, which can stimulate the synthesis of collagens, fibronectin, and proteoglycans and contribute to the accumulation of extracellular matrix material within the damaged kidney [18, 173].

Clinical Presentation and Course

Idiopathic MN is rare in children while it occurs in adults usually between 30 and 50

years. In people aged > 60 years MN has an annual incidence 2.5 fold higher than in younger population [175]. Overall there is a predominance of males at 2 : 1 ratio [79]. Proteinuria, usually non-selective, is the hallmark of the disease. Some 70 – 80% of patients have a nephrotic syndrome at presentation and others may become nephrotic later. Microscopic hematuria is found in about half of patients. Gross hematuria and red blood cell casts are rare. Arterial hypertension and renal dysfunction may be present at clinical onset.

Idiopathic MN may have a variable outcome. Some patients may show spontaneous reduction or even disappearance of proteinuria over time, others may remain nephrotic with stable renal function, and others may slowly progress to ESRD or die from extrarenal complications. It is difficult to assess the natural course of the disease and the relative importance of these events because the inclusion criteria in the available studies were very different. Moreover, most studies included both treated and untreated patients, and the length of follow-ups was quite different. Some studies that considered both patients with and without nephrotic syndrome at presentation and followed for 5 – 6 years concluded that MN is a benign disease with a high rate of spontaneous remission [32, 50, 168]. Other series that included only nephrotic patients with longer follow-up reported a 10-year kidney survival of around 50% [51, 81].

A number of studies tried to identify which clinical and/or histologic factors could predict the renal course at presentation. The conclusions were often contradictory. With univariate analysis, male sex, age > 50 years, HLA-DR3 genotype, superimposed glomerulosclerosis, heavy proteinuria, and arterial hypertension at presentation were found to be associated with a poorer prognosis by some investigators but not by others. When multivariate analyses were performed, the factor more strongly associated with renal failure was the presence of interstitial fibrosis and tubular atrophy at initial renal biopsy [97, 150, 196].

More information may be obtained by the follow-up of the patients. It has been pointed out that most patients who progress to renal failure have some increase in plasma creatinine after 2 – 3 years [195]. Pei et al. described a model that predicted outcome in a semiquantitative fashion by evaluating the persistence of certain levels of proteinuria over time [140]. The risk of chronic renal failure was 66% for patients with proteinuria ≥ 8 g/day for at least 6 months, 55% when proteinuria exceeded 6 g/day for ≥ 9 months, and 47% for proteinuria > 4 g/day for ≥ 18 months. These data were recently validated by extending the study to 360 MN patients from 3 different countries who were followed for a mean of > 6 years [34]. Complete remission of proteinuria, whether spontaneous or induced by treatment, probably represents the most reliable clinical predictor of a favorable outcome in the long term. The published data show that only 1 of 157 patients who attained complete remission had to undergo dialysis [146].

It is even more difficult to predict which patient may have spontaneous remission of proteinuria. We studied the influence of several factors on the development of remission. Among the numerous variables taken into consideration, only treatment with steroids and cytotoxic agents and glomerular stage I – II at initial biopsy significantly increased the probability of remission [148].

Patients with MN are also exposed to extrarenal complications. Thrombotic events are frequent in nephrotic patients. Among primary glomerulonephritides, idiopathic MN has the highest risk of renal vein thrombosis. This may occur in about 10% of patients and is frequently complicated by pulmonary em-

boli [203]. Deep vein thrombosis may develop in about 11% of patients with MN [10]. Arterial occlusion may also complicate the course of this disease. MacTier et al. reported 14 cases of arterial occlusion in 37 untreated patients with MN followed for a mean period of 64 months [114].

Diagnosis

The diagnosis of MN may be suspected on clinical grounds but requires renal biopsy to be confirmed. After the histologic diagnosis has been obtained, efforts should be made to identify possible causes of MN. In most instances, a thorough history and clinical examination are sufficient to recognize the secondary cause. Because hepatitis may be occult, a serological screening for hepatitis virus B and C (HBV and HCV) is mandatory. Two underlying diseases may pose diagnostic problems: SLE and neoplasia. MN may be the first manifestation of SLE and may precede serologic abnormalities even by years. The diagnosis of lupus MN may be suspected whenever IgA and C1q as well as subendothelial and mesangial deposits are found, but only the presence of virus-like particles or tubular basement deposits at electron microscopy may be considered to be specific for SLE [87]. In some 10% of cases, MN may be associated with cancer and in 40 – 45% of patients with cancer, neoplasia may antedate the initial manifestations of cancer by months or years [29]. It is still debated how extensively an underlying cancer should be investigated. We feel it is appropriate to recommend a stool guaiac examination, renal ultrasonography, chest X-ray, and prostatic antigen. Mammography and colonoscopy should also be performed in patients older than 50 years. Aged patients should be closely followed because neoplasia is more frequent in the elderly and may be undetectable on initial screening.

Treatment

Patients with idiopathic MN and subnephrotic proteinuria do not need any specific treatment because the risk of developing renal failure is minimal [50, 51]. Moreover, these patients are asymptomatic and are not exposed to the risk of nephrotic complications. The only treatment we suggest is the use of ACE inhibitors or antagonists of Ang II receptors that may reduce proteinuria.

Whether or not patients with nephrotic syndrome should receive specific treatment is still a matter of debate. A meta-analysis of controlled studies with glucocorticoids concluded that these agents are of no benefit either in favoring remission or in improving kidney survival [79]. Controlled trials with cytotoxic agents gave conflicting results although generally showing a favorable effect on proteinuria [146]. Unfortunately, most studies were performed on small groups of patients and follow-ups were short. A combination of steroids and chlorambucil was assessed in an Italian controlled trial. Patients with idiopathic MN and nephrotic syndrome were randomly assigned to receive symptomatic therapy or methylprednisolone (1 g for 3 days IV, then 0.4 mg/kg/day orally for 1 month) alternated every other month with chlorambucil (0.2 mg/kg/day for 1 month) for 6 months. The actual probability of surviving without developing ESRD at 10 years was significantly better in patients given steroids and chlorambucil (92%) than in untreated controls (60%). The slope of the reciprocal of plasma creatinine was also significantly better in treated patients than it was in controls. The probability of having complete or partial re-

mission as a first event was significantly better for treated patients (88% vs. 47%). Among the numerous variables taken into consideration, only treatment was significantly associated with remission. At the last follow-up visit 17 of 42 treated patients vs. 2 of 39 untreated patients were without proteinuria. Four of 41 patients had to stop therapy because of adverse events, which were reversible. No disquieting morbidity was observed in the long term [151]. On the basis of available studies, we feel that a 6-month regimen alternating glucocorticoids with an alkylating agent (either chlorambucil or cyclophosphamide) offers good chances of obtaining remission and preserving renal function. Some 10% of patients may develop side effects that are usually reversible. Leukopenia and infection are the most frequent side effects. Thus, it is recommended that the blood cell count be checked at least every 10 days during cytotoxic treatment. The alkylating agent should be halved when leukocytes fall < 5,000/mm^3 or stopped if they fall < 3,000/mm^3. A main concern with the use of cytotoxic agents is the possible development of cancer. We pooled all patients who were treated with chlorambucil in our controlled studies. We observed 3 cases of malignancy (one probably preexisting) out of 662 patient-years, with a cumulative risk of 4.5/1000 per year similar to the 4.3/1000 per year observed in the white general population. Thus, it would seem that there is little if any oncogenic risk of a cumulative treatment of 3 months with chlorambucil.

On the basis of these results, we feel that patients with MN and persisting nephrotic syndrome can benefit from a 6-month course with steroids alternated with a cytotoxic drug. In patients who have contraindications to glucocorticoids, a 6- to 12-month course with cyclophosphamide alone may be tried, although the oncogenic risk as well as the bladder and gonadal toxicity increase with more prolonged cytotoxic treatment. Cyclosporin can also be used. In a review it was found that of 73 adults with MN treated with cyclosporin, 20% entered complete remission and 25% had partial remission [123]. Remission was usually obtained within 6 months. However, most patients relapse after cyclosporin is stopped.

Table 8. Therapeutic Decisions in Patients with Idiopathic Membranous Nephropathy and Slowly Progressive Renal Insufficiency

	Treat	Do not treat
Pl. creatinine	< 5 mg/dL	> 5 mg/dL
Ultrasonography		
size	Normal	Reduced
Hyperechogenicity	+/++	+++
Renal biopsy		
Tubulointerstitial lesions	+/++	+++
Immune deposits	yes	No

In patients with renal insufficiency, a rapid decline of renal function may be caused by an acute renal vein thrombosis, by a superimposed extracapillary glomerulonephritis, by an interstitial nephritis caused by diuretics, nonsteroidal anti-inflammatory drugs or other drugs, or simply by dehydration. Thus, whenever a sudden increase in plasma creatinine occurs, efforts should be made to recognize and appropriately treat any possible superimposed complications. For patients with slowly progressive renal failure, the indication to treatment depends on the degree of renal dysfunction, the characteristics of kidney at ultrasonography, and the histologic findings at renal biopsy (Table 8). In fact, as patients with renal insufficiency are more exposed to the risk of side effects caused by glucocorticoids and cytotoxic drugs, treatment should be lim-

ited to those cases having actual chances of improving. Several therapeutic approaches have been used. The best results have been obtained with 1 – 2 years of cyclophosphamide associated with low-dose prednisone [27, 88] or with a 6-month course with methylprednisolone and chlorambucil [26, 119, 157].

Most investigators reported numerous and sometimes severe treatment side effects in patients with renal insufficiency. In order to reduce iatrogenic morbidity, the doses of the chosen agents should be reduced. If a schedule based on prolonged cyclophosphamide is chosen, the daily dose should not exceed 1.5 mg/kg/day. If the methylprednisolone-chlorambucil regimen is preferred, the pulses of methylprednisolone should be 0.5 g each, and the daily dosage of chlorambucil should be around 0.1 mg/kg.

Membranoproliferative Glomerulonephritis (MPGN)

MPGN or mesangiocapillary glomerulonephritis is a disease characterized by mesangial hypercellularity and proliferation with broadened capillary loops. Four types of primary MPGN have been described. The clinical expression of these types is similar, with nephritic or nephrotic syndrome, hypertension, and often hypocomplementemia. Some 50 – 60% of patients develop renal failure within 10 years from clinical onset. The treatment of idiopathic MPGN is still controversial.

Table 9. Disorders Associated with Membranoproliferative Glomerulonephritis

Autoimmune diseases	*Neoplasias*
Lupus nephritis	Lymphomas
Mixed cryoglobulinemia	Leukemia
Sjögren syndrome	Nephroblastoma
Sarcoidosis	Light-chain disease
Complement deficiencies	
Rheumatoid arthritis	*Miscellaneous*
	Sickle cell disease
Infectious diseases	Castleman's disease
Hepatitis B and C	Thrombotic microangiopathy
Visceral abscesses	
Shunt nephritis	
Quartan malaria	
Schistosomal infection	
Mycoplasma infection	
HIV	

Etiology

Idiopathic MPGN is a rare disease. The incidence of type I MPGN is decreasing in the developed world but remains relatively common in underdeveloped countries. The incidence of type II has remained unchanged. Children and adolescents are affected more frequently than adults, but there is not a substantial difference between sexes. It has been reported that the haplotype HLA-B8, DR3, SC01, GL02 is more frequent in patients with type I MPGN [197]. Some familial cases of type I and II have also been described. An association with partial lipodystrophy has been reported in some cases of type II MPGN. Among the 4 types of MPGN, type I is by far the most common, accounting for almost 80% of cases; type II represents 15 – 20% of cases; type III accounts for < 5% of cases; and type IV is very rare. A histologic pattern of MPGN may be observed in a number of autoimmune diseases, chronic infections, paraproteinemias, and neoplasia (Table 9). Lupus nephritis and mixed cryoglobulinemia are the most frequent causes of secondary MPGN.

Table 10. Main Histological Features in Membranoproliferative Glomerulitis

Common features: increase in mesangial cells and matrix, thickening of capillary walls.

	Location of deposits	Immunofluorescence pattern
Type I	Mesangial and subendothelial	IgG and C3 (C1q – C4) granular pattern
Type II	Mesangial and dense intramembranous	C3 (early complement components and IgG usually negative)
Type III – IV	Mesangial, subepithelial and subendothelial	C3 (early complement components and IgG usually negative)

Pathology

The 4 major types of MPGN have been identified with different findings, particularly on electron microscopy and immunofluorescence. Light microscopy is similar in each type with increase in mesangial cells and matrix and thickening of the capillary walls (Table 10).

Type I is also called subendothelial MPGN (Figure 9A). In type I the cellular increase is due to mesangial cells and infiltrating neutrophils. The thickening of the capillary wall is caused by the interposition of mesangial cells and matrix as well as neutrophils into the capillary wall. In many cases the silver staining shows a typical aspect of double contour ("tram-track"), caused by the staining of the true basement membrane and of a false membrane produced by mesangial interposition. The mesangial increase may accentuate the lobular form of the glomeruli leading to a lobular appearance. A nodular form has also been described. It is characterized by centrolobular sclerosis associated with dilation of glomerular capillaries. Although the changes are generally diffuse, focal and segmental abnormalities have been described in a few cases. Immunofluorescence shows granular deposits of C3 (Figure 9B) often associated with IgG and less frequently IgM. C1q and C4 may be present in about half of cases while properdin is always present. These components deposit along the internal side of the capillary walls and less prominently in the mesangium. In a few cases there is a lobular pattern. The deposits outline a lobulated tuft while there are no deposits in the mesangium. Electron microscopy confirms the lesions observed by light microscopy and shows typical electron-dense deposits mainly located in the subendothelial areas (Figure 9C).

Type II MPGN is also called dense deposits disease. The cardinal feature is a ribbon-like aspect of the basement membranes of glomeruli, tubules, peritubular capillaries, and Bowman's capsules (Figure 9D). Subepithelial humps similar to those seen in post-streptococcal glomerulonephritis may be seen in about one-third of cases. In some patients, however, the dense deposits may be missed at light microscopy. Immunofluorescence shows linear staining of C3 along the capillary walls and bright granules in the mesangial regions. Deposits of C1q, C4, properdin, and IgG are rare. The intramembranous deposits are negative for immunofluorescence. Electron microscopy clearly shows dense amor-

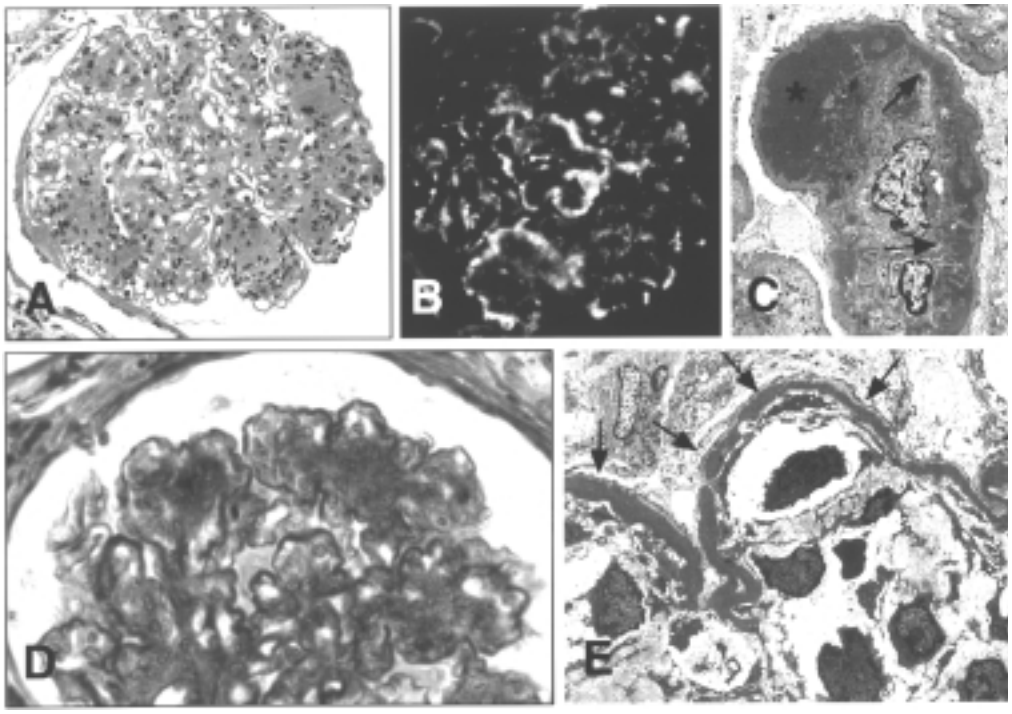

Figure 9. Membranoproliferative glomerulonephritis. A: type I MPGN with a typical lobular appearance (400x). B: typical coarse deposits of C3 along the glomerular capillary walls as seen by immunofluorescence (500x). C: large (*) and small (arrows) subendothelial electron-dense deposits as seen by electron microscopy (3,500x). D: type II MPGN with the typical ribbon-like appearance of the glomerular capillary loops (630x). E: type II MPGN with continuous electron-dense deposits in the context of the GBM as seen by electron microscopy (3,500x).

phous osmiophilic deposits in the basement membrane and in the mesangium (Figure 9E). The deposits are not continuous, and some capillary walls may appear normal.

Type III MPGN is also called mixed membranous and proliferative glomerulonephritis. The main lesions are similar to those observed in type I MPGN. However, the deposits are subepithelial rather than subendothelial, with interspersed projections of basement membrane. Immunofluorescence shows C3 but no or minimal deposition of immunoglobulins.

Type IV MPGN is characterized by a disruption of the basement membranes. Both subendothelial and subepithelial deposits may be seen. Whether types III and IV should actually be considered as separate entities or variants of type I is still controversial.

Pathogenesis

The findings of immunofluorescence and electron microscopy strongly support the hypothesis that type I MPGN is an immune-complex mediated disorder. The demonstration of circulating complexes and the frequent hypocomplementemia with a classic activation pathway are also consistent with this hypothesis. However, the nature of the anti-

gen(s) involved remains unknown. Also, it is unclear whether the complex deposition is actually the triggering event leading to endothelial damage, mesangial activation and expansion, and peripheral interposition of mesangial material.

The pathogenesis of type II MPGN is even less understood. A role for immune complexes can be excluded, because immunoglobulin deposits are usually absent and dense deposits do not show any of the typical characteristics of immune-complex deposits. The frequent recurrence of the disease after transplantation also excludes a primary defect of the GBM. Rather, it suggests that type II MPGN is a systemic disorder that causes the aggregation of basement membrane-like material on renal basement membranes. In patients with type II MPGN, a circulating IgG called C3 nephritic factor can activate the alternative pathway of complement. This has raised the hypothesis that complement abnormalities may play a primary pathogenetic role. However, despite much study the importance of serum C3 nephritic factor remains undefined, as there is no relationship between the serum levels of C3 nephritic factor or complement and the clinical course. It is possible that hypocomplementemia may represent the consequence rather than the cause of the capillary wall damage. The increased consumption of complement could be triggered by complement binding to the abnormal basement membranes. The presence of large deposits of lipids in the dense deposits suggests that this material is the result of a deposition of substances of extrarenal origin [130]. Immunological mechanisms, still poorly elucidated, might contribute in amplifying the damage to the membranes and in sustaining hypocomplementemia.

The pathogenesis of types III and IV MPGN is also unclear. The presence of discrete deposits on electron microscopy may suggest an immune-complex mechanism, although there are minimal deposits of immunoglobulins on immunofluorescence.

Clinical Presentation and Course

MPGN may present with the abrupt onset of hematuria, heavy proteinuria, and hypertension sometimes preceded by an infection of the upper respiratory tract. In other cases, the disease is discovered because of the insidious appearance of edema or because of the finding of microscopic hematuria and proteinuria on a routine urinalysis. At least half of patients have a nephrotic proteinuria, one-third have arterial hypertension, and 20% have renal insufficiency at presentation. Hematuria and cellular and granular casts are usually found on urinalysis. Hypocomplementemia is present in about 50% of cases with type I MPGN and in 70 – 80% of cases with type II MPGN. In type I, complement is activated by the classic pathway, possibly in response to the immune-complex formation. As a consequence, there is a moderate reduction of serum C3 associated with low levels of the early components of complement, such as C4. In type II, there is an activation of the alternate pathway, probably caused by C3 nephritic factor, which induces the cleavage of C3. In the serum of these patients, the early components of complement are normal but there is a profound reduction of C3.

Most patients have a progressive course. This is usually slow so that many patients show normal or subnormal renal function in the first few years after clinical onset. By 10 years, however, some 40% of patients with type I and 50% with type II MPGN [31, 64] have reached ESRD. In a few patients there is a rapidly progressive course. A superimposed crescentic glomerulonephritis may be seen at renal biopsy in some of these cases. Other

patients may show acute nephritic episodes triggered by infections of the upper respiratory tract, with rapid deterioration of renal function, which is sometimes reversible.

Several clinical and histologic features affect the likelihood of progressing to renal failure. A large amount of proteinuria, arterial hypertension, and increased serum creatinine at presentation are usually associated with a poor prognosis [37]. On the contrary, the pattern of complement levels and their fluctuations have little impact on prognosis. As for other glomerular diseases, severe tubulointerstitial lesions at initial renal biopsy represent the most important prognostic factor among morphologic features. Superimposed crescents may also affect the prognosis adversely.

Diagnosis

The acute nephritic presentation of MPGN may mimic poststreptococcal glomerulonephritis (PSGN), lupus nephritis, IgA nephritis, and cryoglobulinemic nephritis. A differential diagnosis may be made on certain clinical clues. Distinguishing between MPGN and PSGN may be difficult because both disorders can be triggered by upper respiratory infections. Usually in PSGN there is a longer free interval between infection and the first renal signs, the nephrotic syndrome and renal failure are more rare, and hypocomplementemia returns to normal within 6 – 8 weeks.

If present, hypocomplementemia can rule out a suspicion of IgA nephritis. Serum cryoglobulins may be found in idiopathic MPGN, but the presence of purpura, arthralgias, positivity for HCV, and high levels of RF allow the diagnosis of mixed cryoglobulinemia. The simultaneous decrease of serum C3 and C4 indicates an activation of complement through the classic pathway, which can be found in type I MPGN, while low levels of C3 with normal serum levels of C4 express an activation by the alternative pathway characteristic of type II MPGN.

In most cases, however, the diagnosis of MPGN can be made only by renal biopsy. The histologic material should be investigated by optic microscopy, immunofluorescence, and electron microscopy to obtain an adequate classification. An extensive search for underlying disease should be done to evaluate whether MPGN is primary or secondary. This should include anti-DNA antibodies, cryoglobulins, serum and urine protein immunoelectrophoresis, serology for hepatitis B and C, and in older patients investigations for malignancy. Blood cultures should be performed in case of bacterial infections [64].

Treatment

Several therapeutic approaches have been tried in MPGN. The Cincinnati group for many years has used long-term, high-dose, alternate-day prednisone therapy in children. Prednisone is begun at a dose of 2 – 2.5 mg/kg (maximum dose 80 mg) every other day and slowly reduced it to 1 – 1.5 mg/kg every other day after 2 years and 0.2 – 1.0 mg/kg every other day after 4 years. Of 71 pediatric patients, survival at 10 and 20 years from the time of diagnosis was 82% and 56%, respectively. Steroids were usually well tolerated [120]. The efficacy of this regimen has been evaluated by a randomized, placebo-controlled trial organized by the International Study of Kidney Diseases in Children [183b]. A total of 80 children with primary MPGN were randomly assigned to receive placebo or prednisone 40 mg/m^2 every other day for a mean duration of 41 months. Only 12% of placebo patients had stable renal function over the first 10 years vs. 61% of treated patients. However, the difference was not significant. Repeat re-

nal biopsy showed no important differences between treated and placebo patients. Unfortunately, the power to detect substantial differences was small. Many patients stopped either treatment or placebo because of renal failure or side effects. Differences in renal function were observed only after 90 months, but at that time only 18 patients were still under observation. Other uncontrolled studies suggested that the results with glucocorticoids in children may be improved if treatment is started early after diagnosis and if it is tailored to the severity of the disease. Ford et al. used IV methylprednisolone pulses followed by high-dose oral prednisone in patients with creatinine clearance < 50 mL/min, while low-dose alternate day prednisone was given in children with normal renal function [59]. The average creatinine clearance increased from 78 to 126 mL/min after a mean follow-up of 6.5 years and a mean duration of treatment of 38 months. Repeat renal biopsies showed reduced inflammatory activity in the majority of cases. The results with glucocorticoids in adults are limited. An analysis of the available trials concluded that glucocorticoids do not show any benefit in adults [49].

Immunosuppressive drugs, alone or in combination with anticoagulants or indomethacin, have been claimed to be of benefit in some noncontrolled studies. However, a controlled trial failed to show favorable effects of a combination of cyclophosphamide with oral anticoagulants and dipyridamole [32].

Donadio et al. found that a combination of aspirin (975 mg/day) and dipyridamole (225 mg/day) could significantly delay the deterioration of renal function over the first 4 years, although there was no modification of proteinuria or hematuria [46]. However, this advantage was lost in the long-term, the 10-year renal survival being 49% in treated patients and 41% in untreated patients [49].

In summary, the treatment of MPGN remains elusive. We do not recommend any specific treatment in patients with normal renal function and asymptomatic proteinuria. A trial with alternate-day glucocorticoids may be attempted in patients with severe nephrotic syndrome who usually have a bad prognosis. Oral prednisone may be given at a dose of 2 mg/kg every other day for 2 months with gradual decrease in the following period. If proteinuria does not vary within 4 – 6 months, the steroid should be stopped. If there is considerable reduction of proteinuria, the steroid may be continued at the minimal effective doses. In patients with rapidly progressive decline of renal function, a renal biopsy should be obtained. In the presence of an extracapillary glomerulonephritis or a superimposed interstitial nephritis, an aggressive treatment with high-dose IV methylprednisolone pulses, oral prednisone, and cyclophosphamide may obtain a recovery of renal function in several patients.

IgA Nephritis (IgAN)

IgAN, also called Berger disease [13], is the most common primary glomerulonephritis in the world. It may present with macroscopic hematuria or with microscopic hematuria and mild proteinuria. In other cases, the diagnosis is made on the occasion of the discovery of renal insufficiency. In spite of intensive investigation, the pathogenesis of IgAN is unclear, and there is not yet a definite treatment.

Etiology and Epidemiology

The cause of IgAN is still unknown. Even though in a number of cases it may be associ-

Table 11. Main Conditions Associated with Mesangial IgA Nephropathy

Primary
IgA nephropathy (Berger disease)
Systemic
Henoch-Schönlein purpura
Secondary
Chronic liver disease
Crohn's disease
Celiac disease
Dermatitis herpetiformis
Psoriasis
Episcleritis
Sjögren syndrome
IgA monoclonal gammopathy
Carcinomas (lung, pancreas, mucin-secreting)
Mycosis fungoides
Ankylosing spondylitis
Reiter's disease
Leprosy
Toxoplasmosis
HIV infection
Thin basement membrane disease

ated with other conditions (Table 11), IgAN is mainly a primary renal disease. In about 50% of patients, IgAN presents after upper respiratory infections, either viral or bacterial. Much less frequently IgAN may be preceded by other infections (e.g. intestinal or urinary) or by surgery, vaccination, or heavy physical efforts. In the remaining cases, precipitating factors cannot be found.

IgAN is ubiquitous, but its prevalence varies in different geographical areas. Of all patients with glomerulonephritis, IgAN constitutes approximately 8% in Canada, 12% in the United States, 20 – 27% in Southern Europe, 40% in Japan, and > 50% in Singapore [82]. At least in part, this distribution reflects different attitudes towards the screening of renal diseases and different indications for renal biopsy in patients with only mild urinary changes.

IgAN can affect any age, but the highest prevalence is in the second and third decades of life. Males are more frequently affected than females, with a ratio ranging from to 2:1 to 6:1 according to race. All races are affected, but IgAN is less common in blacks than in Caucasians and Asians.

Occasionally, IgAN can affect several members of the same family [91, 172]. In some families one member can suffer from IgAN and another from Henoch-Schönlein purpura (HSP) [121], which is an additional element in favor of the common pathogenesis of the 2 conditions. Immunogenetic studies have shown that IgAN may be associated with different HLA antigens, even in the same country [165].

Pathology

By light microscopy, a large spectrum of patterns can be found, from almost normal kidneys to diffuse proliferative or sclerosing forms. In most cases the typical pattern consists of focal and segmental proliferation of mesangial cells associated with expansion of the mesangial matrix (Figure 10A). Although small epithelial crescents are frequent, a true crescentic form is rare [1]. In a minority of cases focal-segmental glomerulosclerosis can be seen [69]. In patients with gross hematuria, acute tubular necrosis (ATN), thought to derive from tubulotoxic effects of erythrocyte components, can superimpose to the glomerular lesions [56, 98]. At a cellular level, increased numbers of macrophages can be observed in the glomeruli in the initial phases of the disease [132]. Increased numbers of monocyte/macrophages and T lymphocytes as well as myofibroblasts can be found in the

interstitium, especially in progressive cases [3, 68].

Immunohistology is mandatory for the diagnosis of IgAN. IgA is the dominant glomerular antigen, which is present in *all* glomeruli, including those that are normal by light microscopy. In typical cases, IgA deposits located in the mesangium appear as confluent masses with moderate-to-high intensity stain (Figure 10B). Extension to the paramesangial areas is frequent, but deposits in peripheral areas of the glomerular capillaries are less common. Other immunoglobulins such as IgG and IgM can also be found, the latter being observed especially in the areas of sclerosis. C3 is almost as frequent as IgA, with a similar pattern but lower intensity stain. C4 and C1q are negative, which is useful to distinguish IgAN from other proliferative nephritis [84]. Fibrinogen can also be observed in the mesangium.

The IgA deposited in the glomeruli belongs to IgA1 subclass [131] and contains mostly lambda light chain [105]. The finding of the J chain, which is a subunit of dimeric and polymeric immunoglobulins, suggests that the glomerular IgA is polymeric [126].

Electron microscopy shows mesangial cell proliferation, increased mesangial matrix, and electron-dense deposits in the mesangium. Electron-dense deposits can also be seen at the periphery of the glomerular capillaries, either in the subendothelial or subepithelial location, often in association with irregularities of the GBM. Some patients have abnormally thin basement membrane (< 264 nm) [14].

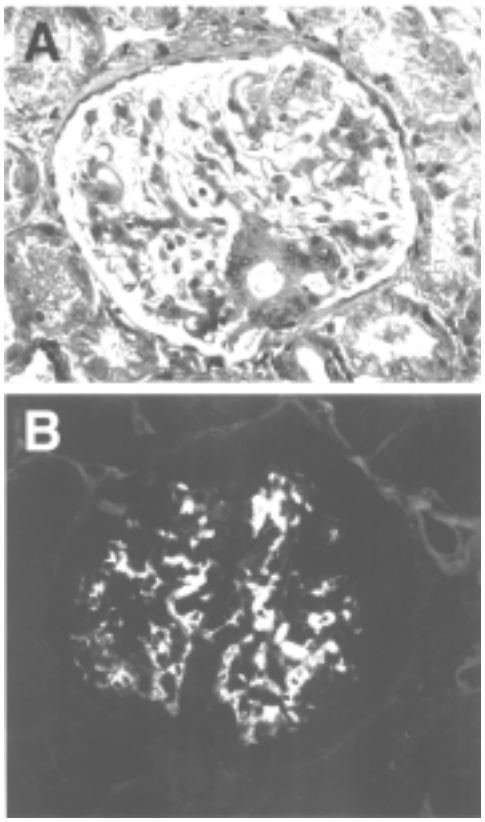

Figure 10. IgA nephropathy. A: mesangial enlargement and hypercellularity (400x). B: coarse and confluent mesangial deposits of IgA (immunofluorescence, 500x).

Pathogenesis

Many aspects of the pathogenesis of IgAN are still unclear. A number of factors that might be involved have been identified, but the data are often conflicting or uncertain. Several abnormalities have been described, not only in the kidneys, but also in the circulation and in other organs.

The findings of immunohistology and of electron microscopy support the hypothesis of an immune-complex disease. Furthermore, the frequent recurrence of the disease in transplanted kidneys and the finding of IgA1 in the glomeruli together with increased amounts of circulating IgA1 and IgA1-containing immune complexes suggest that the immune complexes derive from the circulation.

Although it is not yet established whether there is a reduced clearance of circulating

IgA1 and IgA1-containing immune complexes, it is accepted that there is a an overproduction of IgA1, which is likely to occur in the bone marrow [72]. It is also possible that some abnormalities in the IgA1 molecules may play a pathogenetic role. These might have an abnormal reactivity against specific exogenous or endogenous antigens. Moreover, the deposition of IgA in the mesangium might be favored by a more negative electric charge or by an abnormal *O*-linked glycosylation of the IgA1 [4]. On the other hand, the mesangial cells can have an active role in producing the glomerular and interstitial damage because they can synthesize a number of inflammatory cytokines in response to IgA deposits.

Several other factors might also be involved in the progression of the disease. For example, the angiotensin-converting enzyme (ACE) DD genotype is associated with renal function deterioration [71]. Also, the presence of myofibroblasts in the interstitium may stimulate progressive fibrosis [68], or the peritubular deposition of the complement complex C5b-9 may recruit and activate a number of inflammatory substances [2].

Clinical Presentation and Course

Some patients present with gross hematuria of variable duration. This presentation is more frequent in children than in adults and varies in different geographical areas, being more frequent in North American and European than in Asian-Pacific countries. In about 50% of cases, gross hematuria occurs 24 – 72 hours after a precipitating factor such as pharyngitis, gastroenteritis, urinary infection, fever or strenuous physical effort. Usually gross hematuria is asymptomatic and is not associated with renal function impairment, hypertension, or edema. In some cases, however, there is loin pain, malaise, or myalgia. Rarely, there is a rapid decline of renal function caused by either extracapillary proliferation [1] or by ATN induced by hematuria itself [98]. Recognizing these 2 conditions is important, because patients with the crescentic form require aggressive immunosuppressive treatment, while patients with ATN have a spontaneous recovery of renal function after clearing of gross hematuria.

Asymptomatic microscopic hematuria, either isolated or associated with proteinuria, is the other most frequent presentation in patients with IgAN. This is often found by chance during screening performed for any reason. Microscopic hematuria can be mild or severe and is mixed or dysmorphic by morphology. It is worth remembering that among glomerular diseases IgAN is the most frequent cause of isolated microscopic hematuria [185]. Proteinuria, when present, is mild in the initial phases, < 1 g/day. Exacerbations are possible during infections.

About 5 – 8% of patients present with the nephrotic syndrome. Usually this is associated with renal insufficiency, hypertension, and chronic damage at renal biopsy. However, in rare patients renal function and blood pressure are normal, and at renal biopsy only minor changes are found [182].

Approximately 15 – 20% of patients already have chronic renal insufficiency and hypertension at presentation. However, it is likely that the real prevalence of renal failure caused by IgAN is underestimated due to the reluctance to perform renal biopsies in hypertensive patients with renal insufficiency and hyperechoic kidneys.

IgAN is a chronic disease with variable course. Some patients may do well for many years, while others develop ESRD in short periods of time. The renal survival at 10 years after biopsy varies among different countries, being 67% in North America, 74% in Japan,

81% in Germany, 83% in the United Kingdom, 86% in Australia, and 94% in France [48]. Hypertension, elevated serum creatinine concentration, and increased protein excretion are considered the most important clinical risk factors for renal survival [48]. Among the biopsy finding, glomerular hyalinosis, interstitial fibrosis, and extension of IgA deposits to the peripheral capillary walls are the more reliable indicators of a poor outcome [38].

IgAN can recur after transplantation and, in contrast with a previous view, recurrence is now considered a cause of late graft loss in a considerable number of cases [96, 136].

Diagnosis

The diagnosis of IgAN is based on renal biopsy with the typical finding of dominant IgA at immunohistology. The absence of arthralgia, bloody diarrhea, abdominal pain, and purpura rules out HSP. However, one must be aware that in the latter disease the extrarenal symptoms may rarely develop even months after the renal disease. Recurrent bouts of gross hematuria associated with pharyngitis are rather typical of IgAN but can occasionally also occur in patients with thin basement membrane disease. Asymptomatic microscopic hematuria and proteinuria may suggest a diagnosis of IgAN, but most other glomerular diseases can have a similar presentation. Increased levels of serum IgA, which belong to IgA1 subclass, are observed in 30 – 50% of patients. Usually the serum levels of IgA, either normal or increased, are stable over time. Circulating immune complexes, IgA RF, or circulating levels of some C3 fragments may be found in some cases, but their measurement is more important for research than for clinical practice.

Treatment

The observation that IgAN can lead to renal failure has stimulated a large number of therapeutic trials based on many different approaches, including gluten-free diet, tonsillectomy, phenytoin to reduce serum IgA levels, danazol to dissolve immune complexes, sodium chromoglycate to reduce the mucosal permeability to antigens, antiplatelet/anticoagulant agents and others [108]. These treatments may obtain some reduction of hematuria, serum IgA levels, and/or circulating immune complexes, but there is no clear evidence that any of these treatments could interfere with the progression of the disease.

Uncontrolled trials conducted in small groups of patients showed that glucocorticoids given daily or on alternate days for > 1 year stabilized renal function and reduced proteinuria both in children [193] and in adults [99], with few major side effects. A retrospective study reported that long-term azathioprine at the dose of 2 mg/kg/day together with small amounts of prednisolone preserved renal function [67]. Severe side effects were observed in 3% of patients. Unfortunately, no controlled studies with either glucocorticoids or azathioprine are yet available.

Fish oil, which limits the production or action of eicosanoids and cytokines released during inflammation, has been given with contrasting results in recent controlled studies. Bennet et al. and Petterson et al. did not obtain positive results [11, 142]. However, in a recent, large, multicenter, controlled trial, 12 g/day of fish oil were given for 2 years to IgAN patients with a proteinuria of ≥ 1 g/day or with an increase in serum creatinine of ≥ 25% in the 6 months preceding entry into the study [47]. At an average follow-up of 3 years, renal function was significantly better in the 55 treated patients than in the 56 patients of the placebo group. Compliance to

fish oil was high and side effects minimal. It is possible that the difference with the negative results of the previous controlled trials is due to the higher dosage of fish oil and to the more prolonged treatment used by Donadio et al. It is worth remembering that with this approach the treatment cost is higher.

Several papers showed that ACE inhibitors have a protective effect on renal function and can frequently, but not always, reduce proteinuria [74, 117]. Fosinopril 20 mg once daily or placebo were randomly administered in 4-month sequences to adult patients with normal renal function and normal blood pressure but persistent proteinuria of > 1 g/24 hours [118]. At the end of the period with fosinopril, there was a significant decrease of mean blood pressure, proteinuria, and fractional clearance of albumin and IgG, but there was no effect on creatinine clearance. Recent studies have shown that the response to treatment with ACE inhibitors may be influenced by ACE polymorphism [201].

Considering the available knowledge, we feel that treatment should be limited to the cases at risk of renal failure, namely patients with proteinuria > 1 g/day and/or hypertension. ACE inhibitors are usually well tolerated and can represent the drug of choice in these patients. The results of ongoing controlled studies will be forthcoming. In the meantime, a 6- or 12-month trial with glucocorticoids and/or azathioprine may be attempted to reduce the risk of renal insufficiency. We usually give IV methylprednisolone pulses (0.5 – 1 g each) for 3 consecutive days followed by oral prednisone, 0.5 mg/kg every other day, for 2 months. This course is repeated 3 times for a cumulative treatment of 6 months. Clearly, careful monitoring of side effects is mandatory so that a treatment with still unproven efficacy can be stopped, if necessary.

For 2 subgroups of patients with IgAN, there is a sound indication for treatment. Patients with nephrotic syndrome and minimal change disease at biopsy usually respond well to glucocorticoids, in spite of frequent relapses that remain steroid-sensitive [182]. Patients with rapid decline of renal function due to extensive extracapillary proliferation have a high risk of a poor outcome in the short-term. In these cases, therapy must be aggressive and based on IV methylprednisolone pulses and cytotoxic agents [108]. However, one must be aware that even with this approach the evolution can be unfavorable.

Poststreptococcal Glomerulonephritis (PSGN)

PSGN is characterized by the abrupt onset of hematuria and proteinuria, often in association with edema, hypertension, and mild/moderate renal insufficiency. The disease usually develops several days after a pharyngeal or cutaneous infection caused by group A beta-hemolytic streptococci. The prognosis of PSGN is usually good in the short and long term, but some patients have excessive salt and water retention, and others may slowly progress to renal failure.

Etiology and Epidemiology

PSGN is associated with infections caused by a limited number of strains of group A beta-hemolytic streptococci. These nephritogenic streptococci may be identified by serotyping of a cell wall antigen called M protein. In most cases, streptococcal infection occurs in the upper respiratory tract or in the skin.

Less commonly, PSGN may be preceded by otitis or endocarditis, and may be triggered by other streptococci such as *Streptococcus viridans, Streptococcus mitis* or *Streptococcus mutans*. It must be remembered that in several cases acute GN is not caused by streptococci but is associated with a bacteremic state or with viral or parasitic diseases.

PSGN is the most common primary GN in developing countries, while in the Western world it has become an uncommon disease [166, 175], suggesting that it is favored by low socioeconomic status and poor hygienic conditions. This is also confirmed by the cases occurring in clusters and epidemics, which at times may be even cyclic.

All ages can be affected by PSGN. However, most patients are between 2 and 12 years old. PGN is twice as common in males as in females.

Pathology

In the early phases, there is diffuse mesangial and endothelial cell proliferation, associated with infiltration of the capillary lumens by polymorphonuclear leukocytes and mononucleated cells (Figure 11A). Extracapillary proliferation may involve a few glomeruli, while diffuse and extensive circumferential crescent formation is uncommon, although possible. Cells expressing interleukin-8 (IL-8) and transforming growth factor-beta (TGF-β) [125], as well as cells with increased expression of intercellular adhesion molecule-1 (ICAM-1) can be found both in glomeruli and interstitium [156]. IL-8 correlates with glomerular neutrophil infiltration, while TGF-β correlates with mesangial matrix expansion. The tubulointerstitial compartment is usually normal, but in the most proliferative forms acute cellular infiltrates can be seen.

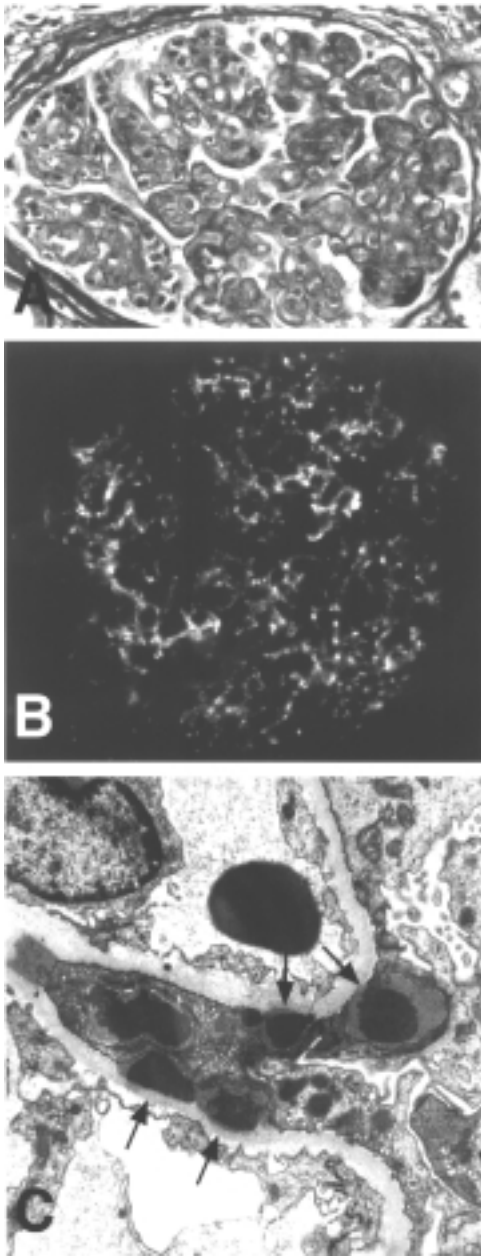

Figure 11. Poststreptococcal glomerulonephritis. A: typical endocapillary proliferation and lobular appearance (400x). B: typical "starry sky" pattern of C3 by immunofluorescence (500x). C: several "humps" (arrows) in subepithelial location (electron microscopy, 7,000x).

The typical immunohistologic pattern is characterized by abundant and well-defined granular deposits of C3 along the outer aspects of the glomerular capillary walls. These deposits confer the appearance known as "starry sky" (Figure 11B). IgG and IgM are present in 60 – 70% of cases. C1q and C4 are generally lacking. Fibrinogen is seen only in crescents.

By electron microscopy, coarse electron-dense subepithelial deposits are the distinguishing feature of PSGN. Due to their shape, the deposits are defined as humps (Figure 11C). However, intramembranous and subendothelial deposits, as well as mesangial deposits, can also be found.

In later phases of the disease, endocapillary proliferation and polymorphonuclear infiltration are less evident, and prominent mesangial deposits can be observed [179]. In other cases, subepithelial deposits are confluent, so that the humps are replaced by apparently elongated deposits, which confer a garland-like pattern at immunohistology [178]. In cases without complete resolution, the typical endocapillary disease can transform, over time, into a mesangiocapillary pattern.

Pathogenesis

Some data suggest that PSGN is an immune-complex disease, in which some components of nephritogenic streptococci are likely to act as antigens. Cell membrane antigens, streptococcal cationic proteinase, extracellular plasmin-binding protein, and endostreptosin or preabsorbing antigen have been proposed as possible triggers for the formation of the immune complexes. On the other hand, anti-immunoglobulin antibodies could be involved in the pathogenesis of PSGN, as demonstrated by the high titers of rheumatoid factor and by the presence of anti-immunoglobulin deposits in the renal biopsy of some patients [159]. An important role in conferring antigenicity to immunoglobulins can be played by another streptococcal component, the neuraminidase. This, in fact, can cause desialization and consequent modifications of autologous immunoglobulins. Moreover, neuraminidase can desialize leukocytes and favor their deposition in the glomeruli and interstitium [116].

Cellular immunity may also be involved in the pathogenesis of PSGN, as suggested by glomerular and interstitial infiltration of granulocytes, monocyte/macrophages, and T lymphocytes [156], increased IL-8 and TGF-β in the kidneys [125], and increased IL-6 and tumor necrosis factor-α (TNF-α) in the circulation [180].

Clinical Presentation and Course

The typical presentation of PSGN is an acute nephritic syndrome, i.e. oliguria, edema, hypertension, and gross hematuria 10 – 21 days after an upper respiratory tract or a skin infection. Nonspecific symptoms such as malaise, weakness, and nausea are frequent. Dull lumbar pain is present in 5 – 10% of patients. Although rare, an extrarenal disease is possible in patients with PSGN, as demonstrated by the association with scleritis or cerebral vasculitis. Decreased GFR and salt and water retention are the main causes of edema and hypertension, as documented by the finding of increased plasma volume and cardiac output in most patients with PSGN. In children, edema is usually generalized, while in adolescents and adults it is more frequently confined to face and legs. Hypertension is observed in > 80% of patients, but in only 50% of cases require treat-

ment. In rare cases, however, hypertension may be severe and cause hypertensive encephalopathy. Especially in elderly patients, oliguria and fluid retention can cause heart failure and death. Proteinuria is common in PSGN; however, nephrotic proteinuria is rare, especially in children.

In other patients, PSGN can be asymptomatic and cause only transient serum complement decrease and/or mild urinary abnormalities such as isolated microscopic hematuria [202], with or without hypertension. Prospective studies in families have shown that this presentation is more frequent than the overt clinical presentation described above [160]. Very rarely, PSGN is not associated with urinary abnormalities in spite of clinical symptoms and the presence of endocapillary glomerulonephritis at biopsy.

Usually the nephritic symptoms spontaneously reverse 4 – 7 days after the onset. However, urinary changes, mild renal function impairment, or hypertension can persist or develop months or years after the acute episode. These abnormalities can be found in approximately 20% of patients 1 – 2 decades after the onset. Usually children do better than adults. Patients with a nephrotic syndrome at presentation and those with extensive deposits in the peripheral capillary loops have a poorer prognosis [190]. Patients with crescentic disease may recover spontaneously. However, the prognosis is poor when crescents involve > 60% of glomeruli [127]. In some patients with subclinical presentation, persistent or intermittent microscopic hematuria may be seen at long-term follow-up [202].

Diagnosis

Several renal and systemic diseases can present with an acute nephritic syndrome: IgA nephropathy (IgAN), mesangiocapillary glomerulonephritis, anti-GBM disease, SLE, cryoglobulinemia, HSP, and systemic microscopic vasculitis. However, the finding of a preceding infection of the upper respiratory tract or of the skin, increased antistreptolysin (ASO) titers, decreased C3 levels, and the lack or rareness of extrarenal symptoms strongly suggest a diagnosis of PSGN.

In PSGN the infection typically precedes the nephritis by 10 – 21 days, while the episodes of gross hematuria in IgA nephropathy usually follow infections by hours or only a few days. In addition, while IgA nephropathy tends to cause repeated episodes of gross hematuria, PSGN is rarely recurrent.

Increased ASO titers are observed in 40 – 90% of patients with PSGN. This is much less common in other conditions. In PSGN, > 90% of patients have a decrease of C3 and normal C4 serum levels, indicating an activation of the alternative pathway of complement. In most cases C3 returns to normal in < 8 weeks, even though a prolonged decrease of C3 is possible [42]. The behavior of complement distinguishes PSGN from lupus nephritis in which both C3 and C4 are usually reduced in active phases. In type II cryoglobulinemic nephritis, usually only C4 is strongly decreased. In type II MPGN, similar to PSGN, C3 is low while C4 is normal. However, C3 remains persistently low because of the presence of C3 nephritic factor.

Usually there are no extrarenal symptoms in PSGN besides edema and hypertension. This differentiates PSGN from systemic diseases causing acute nephritic syndrome. However, it should be remembered that in occasional patients with PSGN extrarenal symptoms such as scleritis and cerebral vasculitis may be present, and that even a positive ANCA is possible [5].

PSGN can be easily diagnosed in epidemic or family cases, even when there are only

transient and minor clinical and urinary changes. However, for sporadic cases with only persistent urinary abnormalities, distinguising between IgA nephropathy, thin basement membrane disease, or other conditions can be difficult without renal biopsy.

Is renal biopsy indicated for patients with acute nephritic syndrome caused by PSGN? For patients presenting with a typical history and clinical picture, the diagnosis is easy and does not need a confirmatory biopsy. However, renal biopsy may be indicated for patients with atypical history or presentation, and especially for cases with severe or prolonged renal failure, which can be caused by crescentic disease.

Table 12. Classification of Crescentic Glomerulonephritis

Type I: Anti-GBM disease
(linear deposition of IgG along the BM)
Renal disease only
Renal and pulmonary disease (Goodpasture's disease)
Type II: Immune-complex associated disease
(granular immunodeposits in the glomeruli)
Primary glomerular diseases
Secondary glomerular diseases
Type III: Pauci-immune disease
(no or scanty immunodeposits in the glomeruli)
ANCA-associated disease
Idiopathic crescentic glomerulonephritis

Treatment

Patients with oliguria, edema, and hypertension need close observation and care. Restriction of sodium and fluid intake are mandatory. Furosemide or other loop diuretics are frequently needed. In many patients, hypertension reverses with the correction of fluid overload and edema. However, in some patients antihypertensive agents are needed. Antistreptococcal antibiotics such as penicillin, cephalosporins, erythromycin or derivatives should be given to patients with positive throat or skin cultures.

Glucocorticoids or immunosuppressive agents are not indicated in PSGN because of spontaneous resolution of the disease in most cases. However, in patients with extensive crescent formation and slow resolution of symptoms, a short course of high-dose glucocorticoids may be considered.

Crescentic Glomerulonephritis (CGN)

CGN encompasses several diseases with different etiologies and pathogenetic mechanisms that have in common a rapid deterioration of renal function and the presence of crescents in > 50% of glomeruli at renal biopsy. The natural course is usually poor. However, early and vigorous treatment can significantly improve the prognosis of these disorders.

According to the immunopathology findings, the various forms of CGN can be grouped into 3 categories (Table 12).

Type I CGN

The hallmarks of type I CGN, or anti-GBM disease (anti-GBM disease), are the presence of anti-GBM autoantibodies in the circulation

and their linear fixation along GBMs. When these antibodies also fix to the basement membrane of pulmonary alveoli, a pulmonary-renal disorder ensues, which is known as Goodpasture's disease.

Anti-GBM disease accounts for approximately 10% of all CGN [86].

Etiology and Epidemiology

Genetic factors play a role in the etiology of the disease, as demonstrated by several familial cases [176]. Immunogenetic studies have shown a linkage with HLA-DR2 and -DR4 antigens, as well as a negative association with HLA-DR7 and -DR1 [28].

Environmental factors are also important. The disease can appear or recur after infections or exposure to organic solvents, hydrocarbons, or cigarette smoking [94, 200]. The clustering of cases in different geographic areas further supports the role of environmental factors.

Anti-GBM disease can be associated with a number of other disorders including lymphoma, crescentic membranous nephropathy [104], and ANCA-positive vasculitis [19].

Anti-GBM disease is rare, but occurs more commonly in Caucasians than other races. Males are more frequently affected than females. All ages can be involved, the peaks being in the third, sixth, and seventh decades of life. Children are more rarely and less severely affected than adults [63].

Pathology

In the early phases, renal biopsy may show focal or diffuse mesangial proliferative GN. In the most typical cases, there are extensive crescents and necrosis of the glomerular tufts (Figure 12). Crescent formation is initiated by

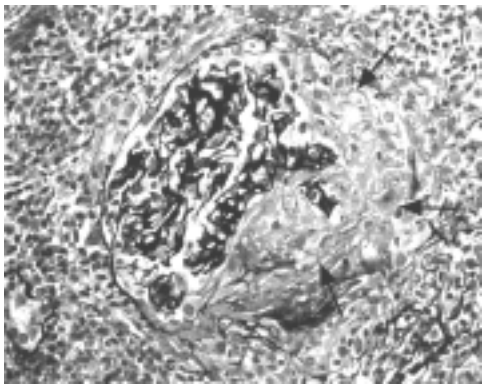

Figure 12. Extracapillary glomerulonephritis with a large fibro-cellular crescent (arrows) occupying the Bowmans space (400x).

holes in the GBM, caused by the antibody attack [17]. Leakage of intravascular content into Bowman's space follows, with consequent fibrin generation and cell recruitment. Several types of cells are found in crescents including visceral and epithelial cells, monocytes, and T lymphocytes [20]. Collagen is then produced, either by the cells forming the crescents of by fibroblasts invading the Bowman's space from ruptured Bowman's capsules [181]. This is followed by fibrotic transformation of the crescents and permanent glomerular damage.

Interstitial inflammation is frequent. Its severity is correlated with the extent of antibody fixation to the tubular basement membranes of the distal tubules. Vasculitis of the kidney is also possible [199].

By immunohistology, linear staining of IgG along the basement membrane of glomeruli (Figure 13), distal convoluted tubules, and collecting ducts is a typical and constant feature of anti-GBM disease. In 60 – 70% of cases, linear deposits of C3 can also be seen.

By electron microscopy, irregularities and breaks of the GBM are the most typical findings.

In the lungs there is often intra-alveolar hemorrhage associated with thickening,

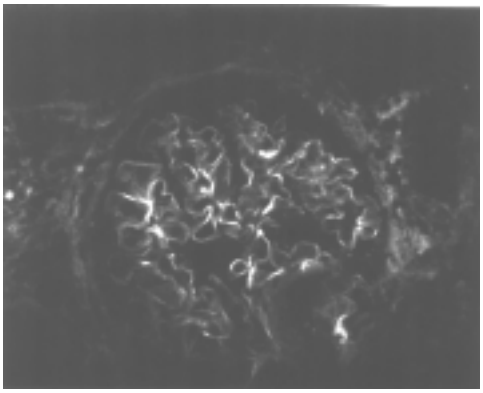

Figure 13. Anti-glomerular basement membrane disease. Linear IgG along the GBM (immunofluorescence, 500x).

edema, and fibrosis of the alveolar membrane. In addition, there are siderin-containing macrophages, deposits of fibrin, and leukocyte infiltration. By immunohistology, there is a typical linear fixation of IgG along the alveolar basement membranes with a patchy distribution.

Pathogenesis

Anti-GBM disease is due to the production of autoantibodies directed against the so-called Goodpasture antigen. The autoantibodies belong to IgG1 and IgG4 subclasses of IgG. However, autoantibodies of IgA class may rarely be found in both the circulation and in tissues [163]. Goodpasture antigen is located on the 230 amino-acid, carboxyterminal, noncollagenous domain of the α-3 chain of type IV collagen, which is one of the main components of the basement membrane [189].

As in other antibody-mediated conditions, there is activation of cell-mediated immunity. T-lymphocytes of patients with anti-GBM disease proliferate when exposed to purified or recombinant Goodpasture antigen [43], and there are a number of T-lymphocytes among the cells infiltrating the kidney [135].

Clinical Presentation and Course

Two-thirds of patients with anti-GBM disease have both renal and lung disease at presentation, while one-third apparently have only renal disease. Lung disease is more common in younger patients and in men. Renal disease is more common in older patients and in women [188].

Malaise, mild arthralgia, and mild weight loss can precede the renal and lung manifestations. These symptoms can be more severe in patients with associated vasculitis and positivity for ANCA. However, some ANCA-positive patients do not have systemic symptoms.

In sporadic cases the renal disease may be mild, causing only minor urinary abnormalities such as isolated microscopic hematuria. Occasionally there may be a history suggesting a subacute or chronic GN. However, in most cases the renal disease is severe and rapidly progressive, so that many patients present with renal failure associated with a nephritic urinary sediment and/or oliguria. Gross hematuria is also common. Proteinuria is constant but is rarely in the nephrotic range. Hypertension is uncommon.

Hemoptysis, trivial or severe, is the most typical sign of lung disease. However, there may be patients without hemoptysis who have life-threatening alveolar bleeding. This can cause microcytic anemia, which is frequent in patients with anti-GBM disease.

If treated promptly and vigorously, anti-GBM disease can subside without recurrences, but in some patients the disease may lead to irreversible renal lesions. Usually lung disease resolves without persistent damage. In other cases, the course may be marked by

remission and recurrences of either renal or lung disease or both, months to years after the first manifestation. Recurrences may be favored by infections or exposure to organic solvents. The reappearance of circulating anti-GBM antibodies without clinical symptoms is also possible [76].

After renal transplantation, anti-GBM antibodies can deposit on transplanted kidneys but frequently without clinical consequences. To reduce the probability of recurrence, transplantation should be postponed until 6 months or more after the disappearance of circulating antibodies. Rarely, an anti-GBM crescentic GN without lung involvement may develop in renal transplant recipients with Alport syndrome [137]. Patients with Alport's syndrome are unable to synthesize α-5 chains of type IV collagen, due to a mutation in the gene COL4A5 on the X chromosome. After renal transplantation, the α chains are recognized as foreign antigen by the recipient immune system, with consequent production of anti-GBM antibodies and development of renal disease [92].

Diagnosis

The presence of a rapidly progressive renal disease with active urinary sediment, hemoptysis, and sideropenic anemia should always raise the suspicion of an anti-GBM disease. Circulating IgG antibodies are the clue for differential diagnosis with other diseases that an also cause a similar clinical picture, such as SLE, HSP, cryoglobulinemia, and pauciimmune systemic vasculitis. Radioimmunoassays or enzyme-linked immunosorbent assays (ELISA) are sensitive and specific methods to detect and titer these antibodies. While antibody titers correlate with the severity of renal damage [75], no correlation has been found with the severity of lung disease.

ANCA can be positive in a number of patients with anti-GBM disease [19]. In most cases, positivity is perinuclear by indirect immunofluorescence (p-ANCA). However, cytoplasmic positivity (c-ANCA) is also possible. As in systemic vasculitis, ANCA titers can be used to monitor the activity of the disease [85]. Because of their possible association, ANCA and anti-GBM antibodies should always be sought in either disorder.

Chest X-rays show symmetrical or asymmetrical lesions of variable size, which can clear 48 hours after bleeding. Increase of carbon monoxide uptake by the lungs, caused by the presence of free hemoglobin in the alveoli, is typical of Goodpasture's disease [53]. The patchy distribution of linear IgG in the pulmonary alveoli makes the diagnosis of anti-GBM disease by transbronchial biopsy unreliable [89].

Treatment

In the last 3 decades, patient and renal survival has dramatically improved. The 1-year mortality rate decreased from 96% in 1964 [12] to 7% to 11% in the 1990s [75, 122], and renal survival increased from 4% to about 40%. Improvement of supportive therapies, such as dialysis and artificial ventilation, and a more refined specific treatment have both contributed to the improved prognosis.

The aim of therapy should be to remove circulating antibodies, prevent the formation of new antibodies, and reduce the inflammatory consequences of antibody deposition on basement membranes. Today, the specific treatment of anti-GBM disease is based on plasma exchange associated with immunosuppressive agents [188]. A suggested schedule for patients with lung and renal disease includes oral prednisolone 1 mg/kg/day, oral cyclophosphamide 3 mg/kg/day, and daily

plasma exchange for 14 days or until the circulating antibodies are suppressed. High-dose IV methylprednisolone pulses can also be used at the beginning of therapy in patients with rapidly a progressive course, but when given alone they are of little efficacy. With such an approach, pulmonary hemorrhage is generally arrested in 24 – 48 hours, and substantial improvement of renal function is usually achieved. However, for patients who present with oliguria and/or a serum creatinine of > 6.8 mg/dL (600 μM) and/or a high percentage of crescents at biopsy, renal survival is still poor despite aggressive therapy [75, 89]. The duration of treatment should be decided on the basis of the clinical data and of circulating antibody titer. After remission, prednisone can be progressively reduced, and therapy may be withdrawn in about 3 months [188]. If severe renal or pulmonary disease recurs, the full treatment should be reinstituted. However, the risk of potentially life-threatening infections favored by immunosuppression must always be kept in mind.

Type II CGN

Type II CGN accounts for approximately 30% of cases of CGN [86]. This type includes a heterogeneous group of renal diseases characterized by glomerular deposits of immunoglobulins and/or complement at immunohistology (Table 13).

Etiology

The majority of the disorders causing type II CGN belong to primary or secondary proliferative glomerular diseases. However, non-proliferative forms, such as membranous nephropathy (MN) [104] and amyloidosis [128], can sometimes be complicated by severe extracapillary proliferation.

Table 13. Main Immune Complex Glomerular Diseases that can be Associated with Extensive Extracapillary Proliferation

Primary Glomerular Diseases
Acute post infectious glomerulonephritis
IgA nephropathy
Mesangiocapillary glomerulonephritis
Membranous nephropathy
Secondary Glomerular Diseases
Lupus nephritis (especially class IV)
Henoch-Schönlein purpura nephritis
Cryoglobulinemia
Amyloidosis
Light chain deposition disease
Glomerular diseases associated with malignancies

Pathology

As a general rule, type II CGN shows fewer necrotizing glomerular lesions on light microscopy than type I and type III CGN. On the other hand, immune complex-mediated CGN has more prominent intracapillary proliferation, mesangial expansion, and thickening of the glomerular capillaries.

Clinical Presentation and Course

The clinical presentation is characterized by rapidly progressive renal failure associated with active urinary sediment, possible oliguria or gross hematuria, and hypertension. In secondary renal diseases, the development of a crescentic form can be associated with an exacerbation of the extrarenal symptoms and/or an abrupt increase of serological markers.

The outcome of untreated forms is usually poor. As in type III CGN, reversal of renal failure and other symptoms can be achieved by early treatment based on high-dose corticosteroids and immunosuppressive drugs (see type III CGN).

More information about the forms belonging to this group is found in Volume 1 Chapter I.8.

Type III CGN

Type III CGN accounts for about 60% of all cases of CGN [86], and includes renal diseases with scanty or absent immune deposits at immunohistology or on electron microscopy.

Etiology

Some patients only have renal symptoms while others have features suggesting a systemic disorder. More than 80% of patients with type III CGN are ANCA-positive, especially p-ANCA [153]. In addition, most patients with type III CGN, even those without extrarenal symptoms, have small vessel vasculitis, such as microscopic polyarteritis, Wegener's granulomatosis, Churg-Strauss syndrome, or other more rare forms.

It is not clear whether the minority of patients without any clinical or laboratory signs of vasculitis actually have an idiopathic CGN or are affected by a vasculitis with negative serological markers and only renal disease [65].

Pathology

By light microscopy, there is extracapillary glomerulonephritis often associated with segmental fibrinoid necrosis of the glomerular tuft. At immunohistology there are no immune deposits. In some cases, scanty granules of immunoglobulin or complement can be seen. No specific findings are observed by electron microscopy.

Clinical Presentation and Course

At presentation, most patients have constitutional symptoms that include fever, weight loss, and malaise. Renal function is variably impaired, with or without reduced urine output. Urinalysis indicates nephritic urinary sediment and variable proteinuria. Normochromic anemia, leukocytosis, and thrombocytosis are common.

Treatment

Irrespective of the presence of systemic symptoms and ANCA antibodies, type III CGN deserves early treatment.

The treatment of type III and type II CGN is based on the association of high-dose IV methylprednisolone pulses with immunosuppressive agents, while the role of plasma exchange is less established.

Even though no controlled therapeutic trials are available, methylprednisolone pulses represent the mainstay therapy for type III CGN. About 75% of patients with type III and almost 90% of patients with type II CGN can obtain improvement of renal function with IV methylprednisolone pulses [16]. The response is usually rapid, and failure to respond within 2 weeks can be considered as a sign of advanced nonresponsive disease [65]. Methylprednisolone pulses are usually well tolerated, even though transient side effects such as tremor, flushing, dysgeusia, epigastric pain, seizures, hyperglycemia, renal function

impairment, cardiac arrhythmias, or hypercoagulability can occur [143]. Usually a course includes 3 – 5 IV pulses of methylprednisolone of 0.5 – 1 g each given daily or every other day. Repeated courses can be given to relapsing patients. After an IV pulse course, oral prednisone is started at a dose of 0.5 – 1 mg/kg/day. Tapering of the dosage is also empirical, being modulated on the evaluation of the general clinical conditions and the severity of the disease.

Glucocorticoids are usually combined with cyclophosphamide, which proved to be efficacious in patients with vasculitis [78]. The drug is preferably given orally at a dosage of 2 – 3 mg/kg/day, which should be halved in patients with renal failure to reduce side effects. In CGN the IV route (500 – 1000 mg/m^2 every month or every 3 months) is usually limited to patients who do not tolerate oral administration. As for oral prednisone, the duration of treatment is based on the evaluation of the clinical situation. Some physicians prefer to switch from cyclophosphamide to azathioprine after 3 months to reduce the risk of myelotoxicity, hemorrhagic cystitis, and neoplasia. Others prefer to give cyclophosphamide for more prolonged periods of time to maximize the chances of renal function recovery [65].

While plasma exchange has a key role in the treatment of anti-GBM disease, its role in type II and type III CGN is still debated. In 2 randomized trials comparing plasma exchange plus immunosuppressive agents vs. immunosuppressive agents alone in non-anti-GBM disease patients, no difference could be seen between the 2 treatments [35, 66]. A third controlled study has reported that the addition of plasma exchange to immunosuppressive agents can more frequently obtain a partial recovery of renal function in dialysis-dependent patients [154]. However, even in the latter trial the beneficial effects of plasma exchange were short lived, because most patients in whom renal function improved had to start dialysis or died at further follow-up. Thus, it seems reasonable to limit plasma exchange to severely ill patients who have not responded to more conventional treatment.

Diabetic Nephropathy

Julia Breyer Lewis

Key Points

Both alterations in systemic and glomerular hemodynamics and changes in metabolism due to hyperglycemia are crucial factors in the pathogenesis of diabetic nephropathy.

Microalbuminuria and proteinuria are key markers which identify patients with diabetes mellitus (DM) who have developed diabetic nephropathy. Intensive glycemic control dramatically reduces the risk of developing diabetic nephropathy.

Blood pressure control slows the progression of diabetic nephropathy even after deterioration of renal function starts. Angiotensin-converting enzyme (ACE) inhibition slows the progression of diabetic nephropathy and is indicated for all normotensive or hypertensive diabetic patients who have microalbuminuria or proteinuria.

Diabetic nephropathy is the most common cause of end-stage renal disease (ESRD) in the United States leading to enrollment in the Medicare ESRD program. Patients with DM currently account for 35% of the population requiring renal replacement therapy. Patients with Type II diabetes mellitus (DM) constitute 60% of the diabetic population in the ESRD program. The cost to Medicare for these patients' renal replacement therapy alone exceeds 2 billion dollars per year [1]. In addition to its significant impact on health care costs, diabetic kidney disease significantly shortens the lifespan of the patient with diabetes. It has been estimated that patients with Type I DM and nephropathy (manifested by proteinuria) have a 100-fold greater risk of death relative to a nondiabetic population. Patients with DM without kidney disease have only a 2-fold increase in relative mortality [2].

Epidemiology

The cumulative incidence of nephropathy in patients with Type I DM of 40 years duration is 40%. Several reports suggest that the cumulative incidence of diabetic nephropathy is declining, which may reflect better blood sugar control in the diabetic population as a whole. The annual incidence peaks just before 20 years duration of DM and declines thereafter (Figure 1) [2]. The decline in the annual incidence of diabetic nephropathy over time

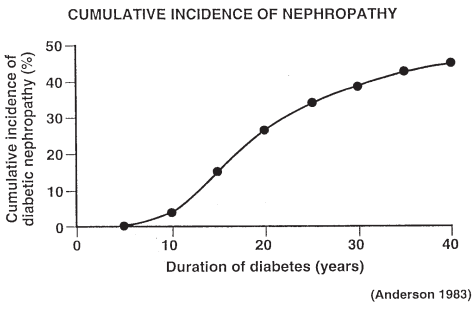

Figure 1. Cumulative incidence of diabetic nephropathy in relation to duration of diabetes in 907 Type I patients.

suggests that the pool of susceptible patients becomes exhausted. Diabetic nephropathy with proteinuria rarely develops before 10 years duration of DM or after 30 years of DM. Thus, the development of diabetic nephropathy is not simply a function of duration of DM nor an inevitable complication in all patients. Rather, the data suggest that only a subset of 40% of patients with Type I DM develop diabetic nephropathy, perhaps because of a genetic susceptibility or an environmental exposure.

Reports of familial clustering of diabetic nephropathy are consistent with a genetic susceptibility to the development of this complication. In families with multiple siblings who have Type I DM, those of a proband with diabetic nephropathy are more likely to have proteinuria and renal insufficiency secondary to diabetic nephropathy than the siblings of duration-matched pro-bands without nephropathy. Similar data supporting genetic susceptibility to diabetic nephropathy have also been reported in families with Type II DM.

Early studies suggested that the cumulative incidence of diabetic nephropathy in patients with Type II DM was less than in patients with Type I DM. However, a recent careful natural history study done in Pima Indians with Type II DM reported a cumulative incidence of diabetic nephropathy comparable to that found in Type I DM patients [3]. Furthermore, in Western Europe it has been reported that up to 40% of patients with Type II DM developed nephropathy, a cumulative incidence quite similar to that found in Type I DM [4]. In part, some of the discrepancies between these reports may reflect the very high mortality rate from atherosclerotic disease in patients with Type II DM and renal disease, resulting in a bias against the progression to ESRD.

For most Type II patients, the age of onset of DM is unknown and may precede the diagnosis by many years. Some patients with Type II DM already have diabetic nephropathy at the time of diagnosis of DM. However, in the Pima Indian study, the age of onset of DM is well documented and precedes proteinuria from diabetic nephropathy by approximately 20 years. Assuming that the natural history of diabetic nephropathy in Pima Indians is representative of all patients with Type II DM, the duration of DM required to develop nephropathy may be similar for Type I and Type II DM.

Finally, there are important racial differences that contribute to the risk of developing diabetic nephropathy. African Americans, Mexican Americans, American Indians, Maori, and Polynesians with DM have a greater risk of developing diabetic nephropathy and a more rapid progression to ESRD than Caucasians [3]. It is not known whether these racial differences are the result of genetic, environmental, or other factors.

Pathogenesis and Risk Factors

Many factors have been postulated to be important in the pathogenesis of diabetic nephropathy. It appears that exposure to both the systemic hemodynamic effects of DM and to the diabetic milieu are critical factors for the development of diabetic kidney disease. In studies with diabetic rats and humans, unilateral renal artery stenosis has been reported to protect the kidney distal to the blocked renal artery from developing the morphologic changes of DM. Thus, exposure to the systemic blood pressure appears to contribute to the development of diabetic kidney disease.

Normal kidneys transplanted into patients with DM develop diabetic lesions over time,

whereas kidneys inadvertently harvested from patients with DM transplanted into non-diabetic ESRD patients showed resolution of their diabetic lesions on microscopy. This suggests that exposure to the diabetic milieu, rather than an intrinsic defect in the kidneys predisposes these patients to the development of diabetic nephropathy.

Hyperglycemia, insulin insufficiency, augmented glucagon and growth hormone levels, and increased ketogenesis have all been implicated in the pathogenesis of diabetic nephropathy. More recently, it has been demonstrated that hyperglycemia results in the glycosylation of long-lived proteins that crosslink to form advanced glycosylation end products (AGEs) [5]. In animal models, the accumulation of AGEs is associated with the end-organ complications of DM. Similarly, in humans the accumulation of AGEs is increased in patients with renal insufficiency. Inhibitors of AGE formation are beneficial in retarding the progression of diabetic nephropathy in experimental animals and are currently being tested in human clinical trials.

Hyperglycemia also leads to the shunting of glucose down the polyol pathway with the accumulation of sorbitol in the lens, nerves, and kidney. In animal models, this pathway has been implicated in the development of diabetic nephropathy, but it is unclear what role it may play in human diabetic kidney disease [6].

Alterations in the renin-angiotensin system also contribute to the development of diabetic nephropathy in animal and human models, as do abnormal intraglomerular pressures in animal models. In the diabetic rat, decreasing intraglomerular pressures by decreasing angiotensin (Ang) II-mediated efferent arteriole resistance preserves glomerular structure and function [7]. Similarly, in humans, interrupting the renin-angiotensin system (see below) slows the progression of diabetic kidney disease. Together, these studies imply that alterations in the renin-angiotensin system play an important role in the pathogenesis of diabetic nephropathy. Additional important factors in this process may be alternations in the production of prostaglandins or kinins.

Identifying the risk factors for development of diabetic nephropathy in humans may help identify important pathogenic mechanisms in the development of this disease [8]. Significant risk factors include a family history of diabetic nephropathy, the presence of hypertension, poor glycemic control, smoking, and increased plasma pro-renin activity. In large population studies, patients with DM have significantly elevated blood pressures compared with non-diabetic controls. The presence of proteinuria in these patients is predictive of the presence of hypertension. Some, but not all, studies suggest that at the time of diagnosis of DM, patients destined to develop diabetic nephropathy have significantly higher mean arterial blood pressures than those patients with DM who never develop nephropathy. Furthermore, patients with both Type I and Type II DM and nephropathy have a predisposition to hypertension, as indicated by elevated sodium-lithium counter transport activity in erythrocytes and a strong parental history of hypertension as compared to diabetic patients without nephropathy. Combined, these data make a compelling arguement that a genetic predisposition to hypertension is a risk factor for developing diabetic nephropathy. However, since it has been reported that up to 25% of patients with Type I DM and established diabetic nephropathy are normotensive, a genetic susceptibility to hypertension cannot be the only risk factor in the development of diabetic nephropathy.

Hyperglycemia is clearly necessary for the development of diabetic nephropathy in animals and humans. Many retrospective clinical studies have documented a relationship be-

tween poor blood sugar control and the subsequent development of diabetic nephropathy. Patients with poor blood sugar control develop diabetic nephropathy earlier. Poor glycemic control also synergistically increases the risk for diabetic nephropathy in patients genetically predisposed to hypertension.

Smoking is a risk factor identified in multiple epidemiological studies for the development and more rapid progression of diabetic nephropathy. The mechanism for the effects of smoking on kidney disease is unclear. Increased plasma pro-renin activity has also been associated with an increased risk of patients developing diabetic retinopathy and nephropathy, although there is considerable overlap in the plasma pro-renin activity between patients with and without complications.

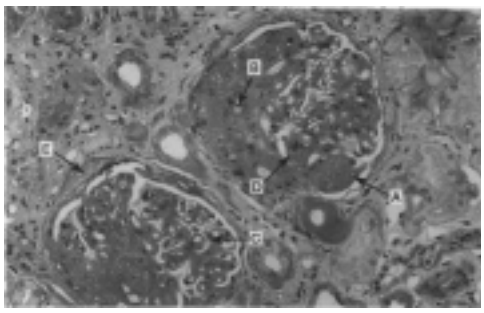

Figure 2. Five distinctive lesions in glomeruli of patients with insulin-dependent diabetes mellitus. A = Kimmelstiel-Wilson nodule; B = intercapillary glomerulosclerosis;C = thickening of glomerular basement membrane; D = mesangial expansion; E = fibrin cap lesion.

Pathology

Renal biopsies are normal in patients at the time of diagnosis of Type I DM. Within as little as 1 – 2 years, however, morphologic changes appear, including glomerular basement membrane thickening, mesangial expansion, nodular and diffuse forms of intracapillary glomerulosclerosis, the capsular drop lesion, and the fibrin cap and arteriolar hyalinosis (Figure 2). Glomerular basement membrane thickening is a sensitive indicator for the presence of DM, but does not predict which patients will develop clinically significant nephropathy. In contrast, mesangial expansion has been demonstrated to correlate with clinically significant diabetic nephropathy [9]. Glomerular filtration rate (GFR), as measured by creatinine clearance, declines linearly with the degree of mesangial expansion. Although DM is primarily a vascular (including glomerular) disease, alterations in the structure and function of the renal tubulointerstitium are also present. The degree of interstitial fibrosis also correlates with the reduction in GFR. Many patients will have morphologic changes in the kidney consistent with the effects of DM but never develop proteinuria or other clinical manifestations of diabetic nephropathy.

The morphologic changes found in patients with Type II DM and diabetic nephropathy were long thought to be indistinguishable from those in patients with Type I DM. Careful prospective biopsy studies have demonstrated that patients with Type I and Type II DM share the nodular form of intracapillary glomerulosclerosis (Kimmelstiel-Wilson-lesions). However, patients with Type II DM have more prominent non-nodular glomerulosclerosis, arteriolar hyalinosis, and other vascular changes.

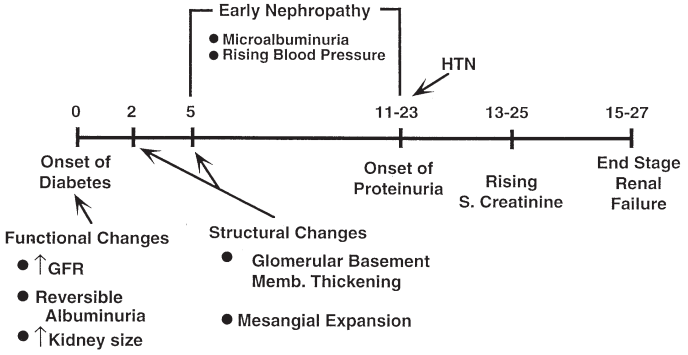

Figure 3. The natural history of diabetic nephropathy.

Natural History

The natural history of diabetic nephropathy is best understood in patients with Type I DM and is illustrated in Figure 3.

At the time of diagnosis of Type I DM, functional changes in the kidney are manifested in virtually all patients [7]. Within a few years, morphologic changes occur in the kidneys of most patients. Glomerular hyperfiltration, elevations in the systemic mean arterial blood pressure, and poor blood sugar control all appear to be important features in this early period. Nephropathy is manifested early by microalbuminuria, with the majority of patients progressing to overt proteinuria. On average, proteinuria is present in the 40% of patients who were destined to develop diabetic nephropathy 10 – 25 years after the onset of Type I DM. Once proteinuria is established, renal function declines inexorably, with 50% of patients reaching ESRD within 7 – 10 years.

Patients with Type II DM frequently have an unknown age of onset of DM and many co-existing illnesses complicating their course. For example, Type II diabetics have a high cardiovascular mortality and often do not survive long enough to develop ESRD from diabetic nephropathy. However, as noted above, studies of the Pima Indians indicate analogous progression in Type II DM compared to Type I [3, 4].

Functional Changes

At the onset of DM, kidney size is increased and albuminuria is present, but these changes usually reverse with blood sugar control. The iniation of insulin therapy also lowers the dramatically increased GFR, although it remains supranormal compared to a nondiabetic population. In both retrospective and prospective studies, higher GFRs at the time of diagnosis of DM predicted the later development of diabetic nephropathy [10]. A GFR of 125 mL/min or less had a negative predictive value of 95% in Type I patients, while a GFR > 125 mL/min had a 53% positive predictive value for the development of nephropathy. However, because of overlap in these patient populations, an early measurement of GFR alone cannot solely predict diabetic renal disease. In patients with Type II DM, reports vary widely about the presence or absence of glomerular hyperfiltration. This may reflect the difficulty in establishing the length of DM in these patients. In the Pima Indians, early glomerular hyperfiltration similar to that reported in patients with Type I DM has been documented.

In animal models of DM, glomerular hyperfiltration is associated with increments in renal flow because of renal dilatation and increases in the glomerular transcapillary hydraulic pressure gradient. These changes lead to accelerated glomerulosclerosis. It is likely that similar glomerular damage associated with glomerular hyperfiltration occurs in humans. Glomerular hyperfiltration has also been associated with increased glomerular surface area and renal hypertrophy.

Microalbuminuria

The presence of microalbuminuria (albumin excretion of 30 – 300 mg/24 hour) in patients with DM is highly predictive of the progression to proteinuria and renal insufficiency in the next 10 – 15 years. The reported prevalence of microalbuminuria in patients with Type I DM varies widely, depending, at least in part, on how the population is selected in terms of DM duration. Overall, approximately 20% of patients with Type I DM will have microalbuminuria in cross-sectional studies. Poor glycemic control and elevations in mean arterial blood pressures also correlate with the development of microalbuminuria [11]. Once present, microalbuminuria is highly predictive of progression to overt proteinuria and renal insufficiency. Between 75% and 100% of patients with documented microalbuminuria go on to proteinuria and declining renal function. The GFR in patients with microalbuminuria is well preserved or increased, but may begin to decrease once the urinary albumin excretion rate exceeds 100 μg/min. Type II patients also develop microalbuminuria, which also predicts progression to proteinuria and ESRD. However, microalbuminuria is associated with a high mortality rate due to atherosclerotic events in these patients, many of whom do not survive to develop proteinuria or ESRD.

Proteinuria and Declining Renal Function

For the vast majority of patients with diabetic nephropathy, proteinuria inevitably progresses to renal decline. In patients with either Type I or Type II DM, the proteinuria typically ranges from 0.5 gm to more than 20 gm/24 hour. In early nephropathy, albuminuria is secondary to a loss of the anionic charge barrier, whereas in established nephropathy, proteinuria results from an increased number of nonselective enlarged pores. Proteinuria typically occurs 17 years (± 6 years) after the onset of Type I DM.

Once proteinuria is established, GFR begins to decline, with an average reported rate of loss between 3 – 12 mL/min/yr. The decline in renal function can be hastened by other diabetic complications such as neurogenic bladder, urinary tract infections, papillary necrosis, and exposure to renal toxins such as IV contrast. Other factors that predict a faster progression include uncontrolled systemic hypertension, uncontrolled blood sugars, higher protein excretion rates, hypercholesterolemia, smoking, and a parental history of DM. Certain racial groups, such as African Americans, Mexican Americans, Native Americans, Polynesians, and Maori, all have a faster rate of progression to ESRD than Caucasians with diabetic nephropathy [4].

End-stage Renal Disease (ESRD)

Once patients with DM reach ESRD, their options include hemodialysis, peritoneal dialysis, or transplantation. ESRD patients with DM have higher mortality rates than nondiabetic ESRD patients. Peritoneal dialysis avoids the problems associated with hemodialysis, such as vascular access, hemodynamic instability, and systemic heparin, but is complicated by increased glucose loads, worsening triglyceride levels, and peritonitis. Hemodialysis provides higher small molecular weight substance clearances. Some studies suggest that higher clearances decrease mortality, particularly in patients with DM and ESRD, although no prospective studies have yet directly compared these two modalities.

Survival is longer for diabetc patients receiving a living related donor transplant compared to patients remaining on dialysis. Two-year renal graft survival and patient survival in Type I DM with living related donor transplants are comparable to survival in nondiabetic ESRD patients. However, Type I DM patients who receive a cadaveric renal transplant have a higher morbidity and mortality than nondiabetic ESRD patients. Patients receiving combined renal and pancreas transplants have a higher morbidity rate than those undergoing renal transplant alone, but have improved hyperglycemia, and both motor and sensory nerve function. No benefits are demonstrable for pancreatic polypeptide secretion, preservation of kidney function, or retinopathy.

The increased morbidity and mortality rates observed in ESRD patients with DM are mainly secondary to complications of atherosclerotic disease. Many investigators have shown that the risk for cardiovascular disease in diabetic patients with renal disease far exceeds that in duration-matched patients with DM without nephropathy. Other morbidity stems from an excessive rate of cerebral and peripheral vascular complications. Low serum albumin and infection also complicate renal replacement therapy for patients with DM. Thus, despite advances malnutrition, infection, and atherosclerotic diseases shorten the life of the patient with DM and ESRD.

Clinical Manifestations and Diagnosis

Microalbuminuria appears to be an important marker for the development of proteinuria and declining renal function. Current recommendations are that all patients with Type I DM of greater than 5 years duration should be screened yearly for microalbuminuria. It is important to specifically order testing for urinary albumin excretion or microalbuminuria, because of the low sensivity of routine urine protein determinations for this condition [10]. Urinary albumin excretion rates exceed 300 mg/day in patients with proteinuria measured either by dipstick or by the traditional 24-hour urine protein assay. With sensitive assays for microalbuminuria, urinary albumin excretions < 30 mg/24 hour can be detected. Patients with normal kidneys have urinary albumin excretion rates < 30 mg/24 hour or 20 μg/min, while microalbuminuria is defined as albumin excretion rates of 30 – 300 mg/24 hour or 20 – 200 μg/min.

The presence of microalbuminuria can be evaluated in a 24-hour urine collection, an overnight urine collection that can be extrapolated to 24 hours, or a spot urine measurement of the albumin-creatinine ratio (Table 1).

Table 1. Measurement of Microalbuminuria

- Test Type I DM patients of greater than 5 years duration every year.
- Test Type II DM patients at the time of diagnosis and every year.
- Rule out causes of transient microalbuminuria: hyperglycemia, UTI, PE, essential HTN, CHF, water loading.
- If the albumin excretion rate is elevated, repeat 3 times over 3 to 6 months to define persistent microalbuminuria.
- Normal albumin excretion: <30 mg/24 hour; microalbuminuria: 30 – 300 mg/24 hour; proteinuria: >300 mg/24 hour.

UTI: urinary tract infection; PE: physical exercise; HTN: hypertension; CHF: congestive heart failure.

Transient causes of microalbuminuria such as hyperglycemia, urinary tract infection (UTI), physical exercise, uncontrolled hypertension, congestive heart failure, or water loading should be considered. Thus, an elevated albumin excretion rate should be repeated on 3 occasions over 3 – 6 months to confirm persistent microalbuminuria. Patients with Type II DM should be screened at the time of diagnosis and yearly thereafter [12]. Identifying patients with microalbuminuria allows measures to be implemented to slow or halt the progression of their kidney disease much earlier, before significant renal insufficiency develops.

Proteinuria in a diabetic patient warrants evaluation. In patients with Type I DM, the onset of proteinuria occurs between 10 and 25 years after diagnosis. Thus, patients who first present with proteinuria before 10 years or after 25 years duration of DM should be suspected of having another cause of kidney disease. In patients with Type I DM, 90 – 95% of patients with diabetic nephropathy have diabetic retinopathy. Therefore, the absence of diabetic retinopathy as determined by either 7 field fundus photos or fluorescein angiography should again suggest the presence of an alternative diagnosis. Only 60 – 65% of patients with Type II DM and diabetic nephropathy have diabetic retinopathy, making it a less helpful factor in their evaluation. All patients with DM and proteinuria should be evaluated carefully for the presence of other systemic diseases that can cause proteinuria, such as a gammopathy, hepatitis B, systemic lupus erythematosus (SLE) or amyloidosis. Abnormalities in the urinalysis, e.g. hematuria or red blood cell casts, should also alert one to the possibility of another kidney disease. A renal ultrasound will rule out anatomic abnormalities and evaluate the patient for kidney size. Most patients with diabetic nephropathy have large kidneys, especially in relation to their decreased GFR.

In a prospective biopsy series in patients with Type I DM and more recently Type II DM, ≤ 10% of the patients who had the typical clinical features noted above were found to have a diagnosis by biopsy other than diabetic nephropathy. Of those patients with an alternate diagnosis, even fewer had a diagnosis identified for which there was a specific therapy indicated. Thus, in the vast majority of patients with DM and proteinuria, a renal biopsy is not necessary. If, however, the patient has any atypical clinical features as outlined above, a renal biopsy should be performed.

There are unique aspects to the management of the patient with DM and progressive renal insufficiency. Insulin requirements decrease in uremia, both because the kidney is responsible for 30 – 40% of the metabolism of insulin and the loss of appetite as renal function declines. Thus, the majority of patients on insulin will have decreased insulin requirements, and many Type II patients will

have decreased oral hypoglycemic requirements as ESRD nears. Further, many oral hypoglycemic agents are excreted by the kidney, and their half-life is prolonged in patients with renal insufficiency. Thus, it is important to counsel both Type I and Type II patients about hypoglycemia and to monitor their oral hypoglycemic or insulin use. Metformin is contraindicated in patients with serum creatinines greater than 1.5 mg/dL and cannot be used in patients with significant renal insufficiency.

DM is the most common cause of Type IV renal tubular acidosis, which results in hyperkalemia and a hyperchloremic metabolic acidosis. Thus, patients with this tubular transport defect can have an electrolyte pattern that is disproportionately abnormal for the degree of renal insufficiency.

Patients who develop nephropathy frequently have gastroparesis resulting from diabetic neuropathy. Symptoms of gastroparesis such as nausea and vomiting can mimic those of uremia.

It is important to evaluate patients with DM frequently to document the onset of diabetic nephropathy to allow optimal management and preventative measures. Avoiding excessive use of nonsteroidal anti-inflammatory agents, the unnecessary use of aminoglycoside antibiotics, and exposure to IV radiocontrast agents is important. Proper interventions for UTI and neurogenic bladder can also help preserve remaining renal function.

Patients with DM appear to require renal replacement therapy earlier than patients with other renal diseases. They have lower GFRs for any given serum creatinine than nondiabetic patients with renal insufficiency, most likely related to lower muscle mass. It is not uncommon for diabetics to be near ESRD with serum creatinines as low as 2 – 3 mg/dL. Diabetic patients have symptoms of uremia and require the initiation of renal replacement therapy at higher GFR levels than do patients with nondiabetic kidney disease. Choosing the best renal replacement therapy for diabetic patients is complex and requires the consideration of many factors, including their body habitus, vasculature, and extent of atherosclerotic disease and heart function. Lastly, patients with DM have a high prevalence of cardiovascular disease. Thus, transplant evaluation in these patients requires careful cardiac testing. Many of these patients with documented cardiovascular disease also have peripheral vascular disease, which can complicate their course. For all these reasons, dialysis teaching and transplant evaluation should begin early in patients with diabetic nephropathy.

Therapeutic Interventions

The major therapeutic interventions that have been evaluated for patients with diabetic nephropathy include antihypertensive therapy, treatment with ACE inhibitors, improved DM control, inhibitors of AGEs formation, the restriction of dietary protein intake, and treatment of dyslipidemia, as well as a variety of less well-studied interventions (Table 2).

Blood Pressure Control

A close correlation exists between the onset and degree of microalbuminuria and the onset and degree of hypertension. Similarly, the presence of hypertension in patients with proteinuria is associated with a more rapid decline in GFR. Multiple studies have shown that reducing the systemic blood pressure in

Table 2. Therapeutic Interventions in Diabetic Nephropathy

Proven Benefit	Possible Benefit
Blood sugar control Blood pressure control ACE inhibition	Low protein diet Treatment of dyslipidemia Smoking cessation Prevention of AGEs formation

diabetic patients with proteinuria and declining renal function slows the rate of decline of renal function and improves survival. These studies primarily used conventional antihypertensive agents, which at the time did not include calcium channel blockers or ACE inhibitors. Although the studies were performed with relatively few numbers of highly selected patients and achieved only modest blood pressure control, a clearly decreased rate of renal decline was observed. Similarly, in studies of patients with microalbuminuria, reducing the mean arterial blood pressure resulted in decreases in urinary albumin excretion rates. Even in normotensive patients with microalbuminuria, the lowering of systemic blood pressure was associated with decreased urinary albumin excretion.

The definition of adequate blood pressure control in patients with diabetic nephropathy has been unclear. The Fifth Joint National Commission defines high normal blood pressure as 140/90 mmHg, and physicians have traditionally used this as a blood pressure goal for patients with hypertension. A number of epidemiological studies indicate that the progression of renal disease correlates closely with increased systemic blood pressure. This effect was linear, with no lower threshold for the benefits of lower blood pressure. Recently, the Collaborative Study Group randomized patients with Type I DM and proteinuria to 2 levels of blood pressure control (a mean arterial blood pressure < 92 mmHg or to a mean arterial blood pressure of 100 – 107 mmHg) to better define the optimal blood pressure for preservation of kidney function. All patients in this study received an ACE inhibitor (Ramipril). Preliminary analysis of these results suggests that the lower blood pressure goal conferred greater benefit. Indeed, many of the patients with the lower blood pressure did not have demonstrable decline in renal function, but rather a regression in their degree of proteinuria, in some cases to near normal ranges. Thus, available data suggest that the blood pressure goals for protecting the kidney against progressive diabetic nephropathy may be lowered to mean arterial blood pressures < 92 mmHg.

In addition a reduction in urinary protein or albumin excretion might be an appropriate end point of antihypertensive therapy independent of its effect on systemic blood pressure. Several major studies in nondiabetic kidney disease demonstrate that an early reduction in urinary protein or albumin excretion predicts a long-term beneficial effect of the intervention. Thus, it has been suggested that antihypertensive therapy should be advanced as tolerated to help reduce urinary protein excretion.

ACE Inhibition

Data from experiments in diabetic rats first suggested that specific antihypertensive agents (ACE inhibitors) could preserve renal function and structure independent of their effect on systemic blood pressure. In these studies, glomerulosclerosis was only partially mitigated by the use of conventional antihypertensive agents, including hydralazine, re-

serpine and hydrochlorothiazide. However, with ACE inhibitors, albuminuria and glomerulosclerosis were ameliorated. The mechanism of protection was postulated to be the reduction of the tonic constrictor effect of Ang II on the efferent arteriole, leading to lower glomerular intracapillary pressures.

A number of studies were then conducted in humans with diabetic nephropathy. A meta-analysis of antihypertensive therapy in patients with diabetic nephropathy, showed only ACE inhibitors decreased proteinuria and preserved GFR independent of changes in systemic blood pressure.

A recently completed clinical trial of ACE inhibitors randomized 409 patients with Type I DM and proteinuria to receive either Captopril three times per day or placebo [13]. Patients enrolled in this trial had urinary protein excretion rates > 500 mg/day and serum creatinine concentrations ≤ to 2.5 mg/dL [13]. The primary outcome of the trial was the time to doubling of serum creatinine (to ≥ 2 mg/dL), representing a halving of the GFR. The use of Captopril led to a risk reduction of 48% for doubling of creatinine compared to the placebo group. Captopril was equally effective in reducing the risk of doubling of serum creatinine in normo- and hypertensive patients and in African American and Caucasian patients. Its efficacy was not explained by differences in baseline urinary protein excretion or follow-up mean arterial blood pressure. Importantly, patients receiving ACE inhibitors had a risk reduction of 50% in the combined clinical outcome of either death or ESRD. Again, this effect of ACE inhibitors was independent of any effect on systemic blood pressure. There were few adverse effects reported, with no ARF and only 6 hyperkalemic events. Thus, this study convincingly demonstrated that ACE inhibition is renoprotective in both normo- and hypertensive patients with Type I DM and clinically evident proteinuria.

Treatment in patients with early diabetic nephropathy characterized by microalbuminuria has also been demonstrated to have a beneficial effect [14]. Studies in patients with both Type I and Type II DM demonstrated that the use of ACE inhibitors leads to a decrease in the urinary albumin excretion with far fewer patients progressing to overt proteinuria. The consistent finding of a beneficial effect of ACE inhibitors in patients with microalbuminuria strongly suggests that these patients should be considered for such therapy to preserve their remaining renal function. Added benefits of ACE inhibitors are improved insulin sensitivity, and plasma lipid profile.

Far fewer studies have been performed examining the efficacy of calcium channel blockers in patients with diabetic nephropathy [15]. These studies were performed in small numbers of patients, most of whom had Type II DM. Recently, it has been suggested that a combination of ACE inhibitors and calcium channel blockers may be of additional benefit. Further investigation is needed to clarify the role of calcium channel blockers in the treatment of patients with DM and diabetic nephropathy.

Improved Blood Sugar Control

Intensive blood sugar control prevents the development of diabetic nephropathy and ameliorates established diabetic nephropathy in animal studies. In humans, the Stockholm Diabetes Intervention Study and the Diabetes Control and Complications Trial have now conclusively demonstrated that intensive blood sugar control in Type I diabetics can delay the development or slow the progression of diabetic nephropathy [16]. Patients in these trials achieved intensive blood sugar control ($HgbA_1C$ ~7.0%) with insulin deliv-

ered either by an insulin pump or by 3 or more injections daily. These patients had a dramatic decrease in the risk of developing microalbuminuria or progressing from microalbuminuria to proteinuria compared to the patients in the conventional therapy group who achieved hemoglobin A_1Cs of approximately 9%. Intensive blood sugar control in these studies not only dramatically reduced the risk of nephropathy, but also the risk of retinopathy and neuropathy. The chief adverse event associated with intensive therapy was a 2 – 3-fold increase in severe hypoglycemic episodes requiring assistance. These hypoglycemic episodes occurred in the intensive therapy group despite careful study management and support measures beyond what most clinics could provide. Secondary analysis of these studies demonstrated reduced nephropathy risk for any reduction in hemoglobin A_1C levels [17]. This reflects the absence of a threshold effect, indicating that any improvement in blood sugar control achievable in the routine clinical setting would reduce the risk of developing diabetic nephropathy. Thus, all patients with Type I DM should achieve the tightest blood sugar control that can be safely achieved in their clinical setting. In Type II diabetics, however, it has not yet been conclusively demonstrated that glycemic control confers a similar advantage. One relatively small study done in Japan has indicated a beneficial effect of tighter blood sugar control in the Type II population. Tight blood sugar control in this population is very difficult to achieve and may have more associated risks.

Prevention of the Formation of AGEs

It has been demonstrated that AGEs accumulate in tissues of diabetic patients and may, at least in part, be responsible for the end-organ complications of DM [5]. Aminoguanidine is a nucleophilic hydrazine compound that prevents the formation of AGEs and glucose-derived collagen crosslinks in vitro and in vivo. Its use in diabetic rats decreases albuminuria and glomerulosclerosis. Clinical trials using aminoguanidine in patients with Type I and Type II DM and established nephropathy are ongoing. This drug is currently available only in research settings.

Dietary Protein Restriction

In many experimental animal models of renal disease, including DM, high dietary protein intake accelerates the deterioration of renal function. Low-protein diets improve glomerular hemodynamics in animal models by vasoconstriction of the afferent arteriole, resulting in decreased glomerular intracapillary pressures. In humans with DM, low protein diets have been demonstrated to reduce glomerular hyperfiltration, decrease urinary albumin excretion, and slow the rate of decline of renal function. Although, individual studies in patients with DM have enrolled small numbers of patients, a recent meta-analysis supported the efficacy of low protein diets in patients with diabetic nephropathy [18].

Lipid-lowering Agents

Dyslipidemia is common in the diabetic state and worsened by coexistent diabetic nephropathy. Patients with poor glycemic control usually have hypertriglyceridemia. The presence of diabetic nephropathy is associated with higher levels of plasma low-density lipoprotein (LDL) cholesterol and lipoprotein B (Lp(b)), and lower levels of high-density lipoprotein (HDL) cholesterol. In

many animal models of kidney disease, dyslipidemia is implicated in causing direct renal injury and hastening the progression of established renal diseases. Treatment of dyslipidemia in these animals leads to reduced glomerular injury. In humans with diabetic nephropathy, hyperlipidemia has been identified as a risk factor for a more rapid rate of decline in GFR and increased mortality. Recently, several small uncontrolled preliminary studies in diabetic patients with proteinuric renal disease showed that treatment with β-hydroxy-β-methyl glutaryl-COA (HMG-CoA) reductase inhibitors can lead to a stabilization and improvement of renal function [19]. Because dyslipidemia is closely related to the progression of cardiovascular disease, and highly prevalent in diabetics, lipid-lowering agents are recommended, irrespective of their potential effect on diabetic nephropathy.

Miscellaneous Interventions

Smoking is an important risk factor for the development and progression of both diabetic nephropathy and atherosclerotic disease. Smoking cessation is an important part of the management of all diabetics.

A variety of other pharmaceutical interventions have been applied to a small number of patients in preliminary studies or in animal models. Pentoxifyline decreased microalbuminuria and proteinuria in Type I patients in a placebo-controlled trial. This drug induces membrane changes that increase erythrocyte deformability, reducing blood viscosity. Similarly, dipyramadole has been shown to decrease urinary albumin excretions in Type I patients with microalbuminuria. Octreotide, a somatostatin analogue, reduced GFR and kidney size in 11 patients with Type I DM and glomerular hyperfiltration. It has also been shown to decrease urinary albumin excretion and renal hypertrophy in rats with streptozotocin-induced DM. Although the potential mechanism of the beneficial effect is unknown, it may be mediated by inhibition of insulin-like growth factor-1.

Lastly, DM has been characterized by an increase in plasma levels of thromboxane B_2. Thromboxane synthetase inhibitors significantly lower urinary protein excretion in diabetic rats. In a recent randomized, double-masked, placebo-controlled trial in 30 patients with DM and microalbuminuria, picotamide (a dual antithromboxane ag-coent that inhibits thromboxane synthetase and blocks the thromboxane receptor) significantly lowered urinary albumin excretion compared to placebo.

The Kidney in Systemic Diseases

Patrick H. Nachman, Ronald J. Falk and J. Charles Jennette

Introduction

When the kidney is involved in a systemic disease process, it may either be the most conspicuously damaged organ or play a minor role in diseases that affect other tissues. The kidney may be injured at the outset of the disease or affected relatively late in the course of the disease. For instance, in some patients with systemic lupus erythematosus (SLE), nephritis is a presenting manifestation of disease. In others, dermatologic and serologic evidence of SLE may predate the onset of renal disease by months to years. In some systemic disorders, the kidney is one of many affected organs, as in primary amyloidosis, which simutaneously affects the heart, liver, and kidney. In some patients, the extra-renal manifestations of systemic injury mirror the course of renal injury, whereas in others, the extra-renal disease may differ with respect to onset, severity, and course. This chapter will consider systemic diseases that frequently involve the kidney, including diseases due to vascular inflammation, infections, liver disease, paraneoplastic syndromes, and dysproteinurias. The systemic diseases that result in tubulointerstitial disease, thrombotic microangiopathy, and cancers of the kidney are discussed in other chapters.

Presentation of Systemic Diseases in the Kidney

The clinical manifestations of many systemic diseases involving the kidney can be divided into major clinical and pathological syndromes, including

- nephrotic syndrome,
- nephritic syndrome,
- tubulointerstitial disorders (covered in Chapter I.8),
- renal-pulmonary syndrome,
- renal-dermal syndrome, and
- liver disorders.

Some systemic disorders consistently present with nephrotic syndrome (e.g. the dysproteinemias) (Table 1), others consistently with the nephritic syndrome (e.g. antineutrophil cytoplasmic autoantibodies (ANCA) small-vessel vasculitis), and still others with features of both syndromes (e.g. SLE).

The clinician should first assess the patient with history and physical examination to determine the scope and nature of the systemic disease process. Laboratory studies, including serological findings, and assessment of complement cascade activation, may increase or decrease the likelihood of certain diseases (Tables 2 and 3). Some diseases activate complement primarily through the classical pathway, resulting in diminution of C4 to a greater

Table 1.

Systemic Diseases that Usually Present with Nephrotic Syndrome

Systemic lupus erythematosus
Dysproteinemias
- Amyloidosis (AL and AA)
- Light chain deposition disease
- Fibrillary glomerular diseases
- Immunotactoid glomerulonephritis

Paraneoplastic syndromes

Cirrhosis
- Focal segmental sclerosis

Infections
- Human immunodeficiency virus (especially in African Americans)
- Syphilis
- Malaria
- Leprosy
- Filariasis
- Toxoplasmosis
- Schistosomiasis (especially *S. mansoni*)

Systemic Diseases that Usually Present with Glomerulonephritis

Systemic lupus erythematosus

ANCA small vessel vasculitis

Henoch-Schönlein purpura

Cryoglobulinemia

Infections
- Hepatitis B, C
- Bacterial pneumonias: Pneumococcus, Staphylococcus, Legionella, Klebsiella, Mycoplasma
- Human immunodeficiency virus (especially in Caucasians)
- Viral infection with Coxsackie, Epstein-Barr, Rubella
- Toxoplasmosis
- Trichinosis

Paraneoplastic Syndromes

Cirrhosis
- IgA glomerulonephritis

extent than C3. In contrast, other disease processes result in activation of the alternative complement pathway, resulting in near-normal levels of C4 but a diminution of C3 (Table 3) [53].

Many systemic diseases that have renal involvement can be grouped in recognizable syndromes, such as renal-pulmonary, renal-dermal, renal-cardiac, or renal-liver syndromes (Table 4). For instance, patients with glomerulonephritis and pulmonary infiltrates or nodules and hemoptysis may fall into the spectrum of a small-vessel vasculitis that affects both the kidney and the lung. In other patients, the presentation of palpable purpura in the lower extremities and nephritis raises the possibility of Henoch-Schönlein purpura (HSP) in a young child, or microscopic polyangiitis or cryoglobulinemia in an adult. Thus, these syndromes provide clinicians with clues to the nature of the systemic disorder.

The clinician should approach a patient who may have a systemic disorder affecting the kidney with the following questions in mind:

- What is the renal presentation of the clinical disorder? Is it predominantly nephrosis, nephritis, or tubulointerstitial disease?
- Are there serologic findings that increase or decrease the likelihood of a specific systemic disease?
- What are the predominant extra-renal organ systems involved by the systemic disease process?
- Is the kidney the dominant organ involved?
- Would a kidney biopsy provide a pathological diagnosis of the disorder?

Frequently, patients with systemic disease are not cared for primarily by nephrologists. When a systemic disease affects the kidney, it may do so in an explosive fashion resulting in a rapid, sometimes irreversible, decline in re-

Table 2. Serologic Findings in Patients with Renal Disease and Systemic Illness

Systemic Illness	Serologic Findings
Systemic lupus erythematosus	ANA/Anti-double-stranded DNA
Small-vessel vasculitis	ANCA
Wegener's granulomatosis	PR3-ANCA > MPO-ANCA
Microscopic polyangiitis	MPO-ANCA > PR3-ANCA
Churg-Strauss syndrome	MPO-ANCA
Cryoglobulemic vasculitis	Mixed cryoglobulins
	Anti-Hepatitis C antibodies
Amyloid (primary amyloidosis)	Lambda monoclonal immunoglobulins
Light chain deposition disease	Kappa monoclonal immunoglobulins
Membranous nephropathy	Infections
	Anti-Hepatitis B antibodies
	Antitreponemal antibodies
HIV nephropathy	Anti-human immunodeficiency virus antibodies
Post-infectious glomerulonephritis	Anti-streptococcal antibodies/anti-DNAse b
Goodpasture's syndrome	Anti-GBM antibodies
Polyarteritis nodosa	Anti-Hepatitis B antibodies
Thrombotic microangiopathy	Anticardiolipin antibodies
Systemic sclerosis	Anti-DNA topoisomerase
Sjögren's syndrome	Anti-RO, anti-LA antibodies
Mixed connective tissue disease	Anti-RNP

Table 3. Complement Profiles in Systemic Disease

Disorders that activate complement primarily through the classical pathway (low C4)
– Systemic lupus erythematosus
– Cryoglobulinemia

Disorders that activate complement through the alternative pathway (low C3)
– Post-infectious disorders
– Post-streptococcal glomerulonephritis
– Infective endocarditis
– Partial or total lipodystrophy
– Atheroembolic emboli

nal function. This is especially true of the small-vessel vasculitides and SLE. In these cases, the nephrologist must ask yet another question.

– Does the rapid decline in renal function require urgent diagnosis and emergency therapeutic intervention?

Vascular Inflammatory Disease

Systemic Lupus Erythematosus (SLE)

Pathology

The diagnosis of SLE is based on combined clinical, pathological, and laboratory findings. The classification of patients with lupus is based on criteria established by the Ameri-

Table 4. Clinical Pathological Syndromes in Systemic Diseases

Renal-pulmonary syndromes
– ANCA small-vessel vasculitis
– Goodpasture's syndrome
– Systemic lupus erythematosus
– Cryoglobulinemic vasculitis
– Progressive systemic sclerosis
Renal-dermal syndromes
– ANCA small-vessel vasculitis

IgA nephropathy
Focal sclerosis

can Rheumatism Association [97]. To establish a diagnosis of SLE, patients must exhibit at least 4 of the 11 signs or symptoms listed in Table 5. The clinical diagnosis of renal lupus is most likely made following a renal biopsy diagnostic of lupus nephritis in the presence of positive serology and characteristic extrarenal manifestations of disease.

Lupus nephritis is the prototypic immune complex glomerulonephritis. Most, if not all, lupus patients have deposition of immunoglobulin and complement, even if there is no clinically significant renal dysfunction. The location and quantity of immune reactants and the host response to these immune reactants results in a spectrum of renal lesions categorized by the World Health Organization (WHO) into different classes of lupus nephritis.

WHO class I (absence of pathologic lesion) is the mildest pathologic expression of lupus nephritis. Class II lupus nephritis is a consequence of immune complex localization confined to the mesangium. The deposits are readily identified in all mesangial regions by immunofluorescence and electron microscopy. By light microscopy, there may be no identifiable glomerular lesions (class IIA), or varying degrees of focal to diffuse mesangial hypercellularity (class IIB). Class II lupus nephritis usually causes only a mild nephritic picture with asymptomatic hematuria and proteinuria.

When nephritogenic immune complexes are deposited not only in mesangial but also in subendothelial regions of the glomeruli, they result in increased inflammation. This results in focal proliferative (class III) or diffuse proliferative (class IV) lupus nephritis. The glomerular lesions are characterized by complex endocapillary hypercellularity caused not only by mesangial and endothelial proliferation, but also by leukocyte infiltration. The most active lesions are complicated by necrosis and crescent formation. Because SLE is often a persistent, although relapsing and remitting, disease, inflammation usually results in chronic changes, such as glomerular sclerosis, adhesions, fibrous crescents, interstitial fibrosis, and arteriosclerosis. The relative histologic markers of active inflammation and chronic injury can be expressed as activity and chronicity scores, the prognostic importance of which is controversial [4].

When capillary wall immune complexes are localized predominantly in the subepithelial zone rather than the subendothelial

Table 5. ACR Criteria for Systemic Lupus Erythematosus

Criteria	Description
Malar rash	Flat or raised erythema
Discoid rash	Scaly, erythematous plaques
Photosensitivity	Sun-induced or exacerbated rashes
Oral ulcers	Ulcerations of mucous membrane
Arthritis	Nonerosive, nondeforming arthritis of small joints
Serositis	Pericarditis or pleuritis
Renal disorders	Proteinuria greater than 500 mg/day or cellular casts
Neurological disorders	Seizures or psychosis
Hematologic disorders	Hemolytic anemia, leukopenia, lymphocytopenia, or thrombocytopenia
Immunologic disease	Positive LE test, anti-double-stranded DNA antibodies, anti-SM antibody, or false-positive serologic test for syphilis (STS)
Anti-nuclear antibody	Abnormal titer (in absence of predisposing drugs).

Modified from Tan EM et al. Arthritis Rheum 1982; 25:1271-1277 with permission.

zone, they are not in direct contact with circulating inflammatory mediators, and a membranous glomerulonephritis results (class V lupus nephritis). Class V lupus nephritis tends to cause more nephrotic than nephritic disease, unless there is a substantial proliferative component along with the membranous pattern. Specimens with exclusively membranous changes are sometimes designated class Va, those with concurrent mesangial hypercellularity Vb, those with concurrent focal endocapillary proliferative changes Vc, and those with concurrent diffuse proliferative changes as Vd. In essence, so-called class Vd lesions are a combination of class IV and class V lesions and thus have massive accumulations of mesangial, subendothelial, and subepithelial immune complexes. Patients with class Vc and Vd lupus nephritis follow a clinical course resembling that of focal or diffuse proliferative lupus glomerulonephritis (class III and IV), whereas patients with class Va and Vb have a predominantly nephrotic course. Therefore, it is our bias to treat patients with combined membranous and proliferative lesions (class Vc and Vd) as if they had class III or IV lupus nephritis.

Several types of vascular abnormalities can be found in the setting of lupus nephritis. The most common is an arteriolopathy caused by accumulation of immune complexes in the walls of hilar arterioles without induction of overt vasculitis. True vasculitis with mural infiltration by leukocytes is rare. The presence of hypertension, which may reach the malignant range in aggressive lupus nephritis, leads to typical hypertensive arterial and arteriolar changes. Some lupus patients develop a thrombotic microangiopathy, possibly associated antiphospholipid antibodies or an overlap with systemic sclerosis. This complication is characterized by subendothelial expansion in glomerular capillaries, fibrinoid necrosis of arterioles, and edematous intimal expansion in arteries. The resultant narrowing of lumens, as well as superimposed thrombosis, can cause severe and rapid renal failure and microangiopathic hemolytic anemia.

One difficulty of managing a patient with lupus nephritis is that the pathological lesion may change from one form of glomerular injury to another. It is common for a class III lupus nephritis to progress to a class IV lupus nephritis. Both class III and class IV lesions can transform into membranous lupus nephritis, either spontaneously or with immunosuppressive therapy. It is less common, but possible, for membranous lesions to transform into more proliferative lesions. Even repetitive clinical evaluations may not be sufficiently insightful, and repeated renal biopsies are sometimes needed.

The Role of Renal Biopsy

The pathologic manifestations of lupus nephritis span the spectrum from mild mesangial proliferation to severe necrotizing and crescentic glomerulonephritis. The array of clinical findings may range from intermittent episodes of hematuria and proteinuria to acute nephritis with renal insufficiency, and from mild elevations of creatinine, proteinuria, hypertension, and hematuria (with or without red cell casts) to a picture compatible with rapidly progressive glomerulonephritis. As progressive glomerular sclerosis and interstitial fibrosis ensue, fixed proteinuria develops, as does reversible renal insufficiency. The nephrotic syndrome commonly occurs and is usually associated with either class V lupus nephritis or with chronic proliferative disease that has developed focal glomerular sclerosis, which is also typically associated with renal insufficiency. In fact, the nephrotic syndrome may be the predominant clinical manifestation of disease in fully half of lupus patients with renal involvement. At the time of initial presentation, 20 – 25% of patients with SLE already have some degree of renal insufficiency. The clinician faces the question of whether proteinuria is a consequence of membranous nephropathy, diffuse proliferative glomerulonephritis, or chronic disease with extensive glomerular sclerosis. Furthermore, in some patients, there is a dissociation between the pathological and clinical features of the disease. Patients may present with severe extra-renal SLE and a picture of acute nephritis, but only have mild class II lesions by biopsy. In others, a diffuse proliferative glomerulonephritis may present clinically with only minimal degrees of hematuria and proteinuria.

One of the most difficult clinical pictures is that of a patient with long-standing lupus nephritis and a history of intermittent episodes of nephritis, who develops a rising serum creatinine. In these individuals, it is not always clear whether the renal insufficiency is caused by progressive glomerular and interstitial scarring or by the recrudescence of active nephritis.

The role of a renal biopsy in the evaluation of patients with systemic lupus erythematosus and nephritis has been extremely controversial. Extensive debate continues concerning the correlation between pathologic findings of classic lupus nephritis, the activity of the injury, the degree of chronic changes, and long-term outcome [6]. In our view, the renal biopsy helps to clarify the clinicopathologic syndrome. The biopsy allows for a reasonable separation of membranous lupus from predominantly proliferative disease. It may also restrain the impulse for immunosuppressive therapy in individuals with marked renal insufficiency and proteinuria, who on pathologic examination have only chronic disease with extensive glomerular sclerosis, but no active inflammation. The renal biopsy can be a key factor in determining if a rise or decline in renal function is a consequence of recrudescence of active inflammation or of progressive glomerular sclerosis. Similarly, it

is important to perform a renal biopsy for a patient with lupus nephritis who suddenly develops acute decompensation in renal function. The biopsy will determine whether this sudden deterioration is caused by worsening of the lupus nephritis (e.g. with extensive crescentic formation), the development of a thrombotic microangiopathy (possibly associated with antiphospholipid antibodies), or the development of a process not directly caused by lupus (e.g. tubulointerstitial nephritis caused by the use of an antibiotics or nonsteroidal anti-inflammatory drug (NSAID)).

Laboratory Studies

Antinuclear antibodies (ANA) are more than 90% sensitive for SLE but are only 70% specific. These antibodies are also found in patients with other rheumatic diseases, with infections, and in older age groups. In contrast, up to 10% of patients who fulfill the ACR criteria for lupus do not have a positive ANA. A proportion of ANA-negative patients actually have a positive ANA, if HEp-2 or Kb culture cell lines are used as the target substrate.

Tests for antibodies to nuclear or cytosolic antigens other than DNA are more specific for SLE. For example, antibodies to the SM antigen, one of the so-called extractable nuclear antigens (ENA), are very specific for lupus but found in only 25% of patients. It has been suggested that patients with anti-Sm antibodies have a higher risk of severe lupus, renal disease, CNS disease, cutaneous vasculitis, and death [7, 8].

Complement studies are frequently performed in patients with lupus, both for diagnosis and to measure disease activity. The total hemolytic complement (CH50), as well as C4 and C3, are typically low during active disease. Because decreased synthesis of complement components also results in depressed complement levels, a depressed complement value may not always indicate active disease. Repeated analysis of these factors may provide an insight into the relative state of complement activation.

Prognosis

There is a general assertion that the long-term survival of patients with SLE has improved over last 50 years. Some of this progress is a consequence of the broadened appreciation of the picture of SLE, and some may be attributed to the judicious use of corticosteroids and the introduction and refinement of the use of cyclophosphamide and azathioprine. Overall, lupus mortality is still more likely to result from cerebritis or myocarditis than a loss of renal function, largely due to the availability of dialysis and transplantation. The other major cause of death is overwhelming infection after immunosuppressive therapy.

Certain prognostic factors affect the long-term outcome of renal disease. In a recent study of patients with diffuse proliferative glomerulonephritis treated with cyclophosphamide, poor outcome was more likely for black patients and for those whose biopsies revealed interstitial fibrosis [32]. Using multivariate analysis, black race was a more significant predictor of poor outcome than the entry serum creatinine. From the available data, it was not clear why black patients fared poorly. Hypertension and the rapidity of diagnosis do not appear to be critical variables in these analyses. Whether the poor prognosis is a consequence of a genetic factor or of a lower socioeconomic status is not certain and is the subject of ongoing investigation.

In other studies, the entry serum creatinine [6] and the biopsy findings have been suggested as predictors of eventual renal failure. While no specific numerical cutoff on the chronicity index scale is invariably associated to long-term outcome, it is reasonable to suggest that individuals with substantial interstitial fibrosis, glomerulosclerosis, and tubular atrophy will progress to end-stage renal disease (ESRD) over the course of years, especially if they suffer additional episodes of active inflammation.

Patients with lupus membranous glomerulonephritis (WHO class Va and b) appear to follow a similar course to that of patients with idiopathic membranous nephropathy [82]. Patients with WHO class Vc and d with proliferative glomerulonephritis, necrosis and crescent formation have a similar course to those with aggressive Class IV disease. In our view, classifying cases of severe diffuse proliferative glomerulonephritis in the setting of lupus membranous nephropathy as Class V (c and d) lupus has only served to confuse the nomenclature and clinical evaluation of the disease process. Certainly, membranous nephropathy can transform to a diffuse proliferative glomerulonephritis and result in a worse prognosis for the patient. In a study by Sloan [92], a group of 79 patients with lupus membranous nephropathy were examined and divided into 3 groups:

- (1) WHO class Va and Vb,
- (2) WHO class Vc (with <50% glomeruli involved), and
- (3) WHO class Vc (with >50% glomeruli involved) and Vd.

At the end of five years, the renal survival was 86%, 72%, and 49% in each of these 3 groups respectively, and 72%, 48%, and 20% at 10 years. The entry serum creatinine was the only clinical predictor of renal outcome.

Treatment Issues

Few areas of medicine generate as much discussion and controversy as does the subject of therapy for SLE and lupus nephritis. Whether patients should be treated only with corticosteroids, with intravenous cyclophosphamide, or with oral cyclophosphamide or azathioprine has never been truly resolved. Nor is it resolved whether corticosteroids should be used in high-dose oral form, as some have asserted a role for parenteral methylprednisolone (pulse methylprednisolone). Rarely has an identical protocol been employed in different uncontrolled – or even controlled – trials. Despite the morass of conflicting literature, the general practice of nephrologists has been altered by several investigations from the National Institutes of Health in the mid-1980s. These studies promulgated the beneficial effects of combined prednisone with parenteral cyclophosphamide, oral cyclophosphamide or oral cyclophosphamide and azathioprine [6]. More recently, Boumpas et al. [13] conducted a prospective trial treating patients with severe diffuse proliferative glomerulonephritis with either pulse methylprednisolone alone or either a long or short course of cyclophosphamide. The short course involved either three pulses of intravenous methylprednisolone or monthly pulses of intravenous cyclophosphamide for six months. In the long course, six months of monthly pulses of intravenous cyclophosphamide were followed by a dose every three months for two years. Similar amounts of corticosteroids were used. After 5 years of follow-up, the pulse methylprednisolone group experienced a doubling of the serum creatinine in almost half of the patients, and 25% developed ESRD. In the short-course cyclophosphamide group, the serum creatinine doubled in one third of the patients; 25% also developed ESRD. In the long-

course cyclophosphamide group, the serum creatinine doubled in only 15% of the patients and only 10% developed ESRD.

The most prominent side effects of this form of therapy are infection, ovarian failure (especially inpatients treated with long-course cyclophosphamide), bone disease, and cataract formation. The incidence of malignancies (especially bladder cancer) with this form of therapy is not known. Studies of long-term oral cyclophosphamide treatment for patients with Wegener's granulomatosis suggest that 15% of patients will develop transitional cell carcinoma of the bladder over the course of 5 to 10 years [100]. The rate at which patients with lupus nephritis treated with intravenous cyclophosphamide (which is associated with a smaller incidence of hemorrhagic cystitis than the oral form) will develop bladder cancer is not yet ascertained.

Our own studies of patients with diffuse proliferative glomerulonephritis reveal that Caucasian patients treated with intravenous cyclophosphamide have an excellent 5-year survival rate (95%), compared to only 57% at 5 years in blacks [32]. It is thus likely that the controversy about optimal treatment of patients with lupus nephritis stems in part from the enrollment of patients of different ethnicity, degrees of renal insufficiency, and WHO classifications of nephritis [5].

Because patients with lupus nephritis are frequently young women, the development of ovarian failure is of a substantial worry [72]. Whether there are forms of therapy that can protect the ovary is not yet known. Studies using leuprolide acetate to induce a temporary state of ovarian shutdown are under way. The results, and the usefulness of high-dose estrogen and progesterone are still unknown.

The best approach to therapy relies on an assessment of several factors. The clinician should assess disease activity, disease severity, the patient's previous history of disease activity, and the patient's own response to corticosteroid and immunosuppressive drugs.

The clinician must differentiate between disease severity and disease activity. Disease severity may be a consequence of previous organ system dysfunction, e.g. previous glomerular crescent formation and subsequent glomerular scarring. There can be severe renal damage that is no longer amenable to immunosuppressive therapy. In contrast, active disease may respond to corticosteroids and immunosuppressive activity. There have been several attempts at quantitating organ system dysfunction, including the development of a damage index [44].

There are several markers of disease activity. The clinical history is usually most helpful for assessing overall symptomatology. Renal disease activity may be indicated by numerous red cells and red cell casts found on urinalysis. The presence of proteinuria may relate to previous renal damage rather than to an acute process, except in cases of membranous nephropathy and its attendant nephrotic syndrome. Overall lupus activity may be ascertained by using serological markers as adjunctive tests. Rises in the anti-double-stranded DNA titer, or declines in complement levels, especially CH50, are particularly helpful. Nonspecific markers of disease activity, such as erythrocyte sedimentation rate or the C-reactive protein, are probably no more useful than an overall "sick index". There has been some interest in differentiating rises in C-reactive protein levels during infections from rises that occur during episodes of inflammation. Nonetheless, there are patients with clear evidence of renal exacerbation who do not have hypocomplementemia or elevated levels of anti-DNA antibodies. When there is a progressive rise in serum creatinine and development of significant hematuria, patients more than likely have aggressive renal disease. A renal biopsy is particularly useful for patients

with a history of a prior episode of glomerulonephritis and immunosuppressive treatment. The finding of widespread glomerular scarring, interstitial fibrosis, and tubular atrophy in a patient with moderate renal insufficiency may result in a less aggressive approach then when active inflammation is found with lesser amounts of sclerosis.

Treatment Recommendations

Our treatment strategy is based on persistent supportive management, including careful attention to blood pressure and nutrition, and a prophylactic approach to the surveillance and treatment of infections. Attention to the development of osteoporosis is considered in all patients. In nonrenal-failure patients having received any prednisone at all, specific recommendations include 1.2 grams of calcium/day. If the patient then has evidence of osteoporosis by bone densitometry scanning (T scores that are 2 standard deviations below the mean), use of an antiresorber (alendronate or calcitonin) is recommended. However, if the creatinine clearance is less than 50mL/min, alendronate would not be used. The specific recommendation for treatment of musculoskeletal complaints is the use of nonsteroidal anti-inflammatory agents and an anti-malarial (plaquenil) for mild to moderate arthritis or dermatitis.

We treat major episodes of Class III and IV glomerulonephritis with cyclophosphamide and prednisone. Prednisone is given at a dose of 1 mg/kg/day for the first month, leading to alternate-day doses in the second month. Each week, the prednisone dose is lowered by 10 mg every other day, (e.g. 60 mg alternating with 50 mg every other day, followed by 60 mg alternating with 40 mg one week later). Frequently, extra-renal manifestations of the disease require the continued use of daily oral prednisone at doses between 5 and 10 mg/day. Once patients reach a dose of 10 mg/day, the dose of prednisone is decreased by 1 mg/month until the corticosteroid dose is zero.

In the patient presenting with crescentic lupus diffuse proliferative glomerulonephritis (WHO class IV), pulse methylprednisolone is given at 7 mg/kg on 3 consecutive days. Intravenous cyclophosphamide is given according to the National Institutes of Health protocol, once a month for 6 consecutive months. The dosage is determined on the basis of the leukocyte nadir; the white count should not sink below 3000 cell/mm^3. The dosage is titrated upward during the first 6 months, starting at a dose of 0.5 g/m^2 body surface area and increasing by 0.25 g/m^2 on successive treatments, provided that the 2-week leukocyte count is acceptable. The dosage never exceeds 1 g/m^2. After the first 6 months, the NIH long-course therapy is used; then consolidating treatments, every 3 months for a total of 24 months. Patients with significant renal impairment (serum creatinine > 4 mg/L) may need a reduction in the first dose of parenteral cyclophosphamide.

For patients with focal proliferative glomerulonephritis (WHO class II and III), it is most difficult to determine when treatment is needed. Most patients are treated with corticosteroids for their extra-renal manifestations of disease. Whether additional high-dose prednisone, cyclophosphamide, or azathioprine is indicated for focal proliferative disease is not clear. However, when there is necrosis or crescent formation in addition to the focal proliferative disease, and when 50% of glomeruli are affected, the long-term outcome is probably similar to that of diffuse proliferative glomerulonephritis (Class IV) and should be treated in the same fashion.

Since the renal prognosis of membranous WHO Class Va or b lupus is usually excellent, a trial of corticosteroid therapy should only be considered in certain individuals. In patients with severe debilitating nephrotic syndrome or declining renal function, it may be useful to employ both corticosteroid and even cyclophosphamide therapy. It is not clear whether the degree of proteinuria represents an additional risk. The role of cyclosporine is under investigation. In our experience, patients treated with cyclosporine have a high relapse rate when therapy is discontinued.

Careful attention must be paid to the development of serious infection during the first few weeks of treatment. The results of a recent study by Ward [105] evaluated the cause of death in a cohort of 408 patients with systemic lupus erythematosus, 144 of whom died. Deaths were a consequence of lupus activity in 34%, 22% died of infections, 16% of cardiovascular disease, 6% of cerebral vascular disease, and 6% of cancer. Alarmingly, deaths due to lupus and to infection were more common in the younger age groups, whereas deaths due to cancer were more common in older patients. Patients at substantial risk for infection are those treated with pulse methylprednisolone, corticosteroids, and cyclophosphamide. Careful attention is given to avoid side effects of gastric complaints by avoiding the concomitant use of nonsteroidal anti-inflammatory drugs and corticosteroids, with or without the use of H_2 receptor blocking agents. The association of lupus with cancer is not solely attributable to the use of immunosuppressive agents; there may be a risk of lymphoma and other cancers in patients with lupus who have not received immunosuppressive therapy. The most effective way to diminish the side effects of therapy is to terminate the immunosuppression as soon as possible.

Ascertaining the effectiveness of immunosuppressive therapy may be difficult. Evidence for a substantial reduction in the number of urinary red blood cells or red cell casts, or at least stabilization of renal function, are the best indicators of response. Whether there is value to normalizing the CH50 or anti-double-stranded DNA antibodies is a matter of debate, although such normalization portends a favorable long-term outcome.

Plasmapheresis

Plasmapheresis is clearly not indicated in this population. The national cooperative prospective study randomly assigned patients to receive prednisone or cyclophosphamide, with or without plasma exchange [70]. The study failed to demonstrate any benefit of plasma exchange with respect to renal survival or overall survival. Whether other approaches using plasma exchange are efficacious, such as the synchronous use of plasmapheresis with pulse cyclophosphamide, is under investigation [34].

Treatment of Resistant Lupus

In many patients, existing treatment protocols with prednisone and cyclophosphamide are less successful, particularly patients of the black race [32]. One approach has been to use mycophenolate mofetil by itself or with corticosteroid treatment. The efficacy of this drug has been evaluated in two uncontrolled pilot studies, including one of our own for patients with resistant lupus nephritis [52, 77]. Some degree of clinical stabilization has been observed, but these studies are too small and too preliminary to draw conclusions. Two other

approaches have been evaluated in an anecdotal fashion. Pooled intravenous immunoglobulin and total lymphoid irradiation are promising approaches that have not been systematically evaluated.

There are several novel therapies currently under investigation, including lupus tolerogens, anticytokine antibodies, antibodies to the CD40 ligand, and antibodies to the fifth component of complement (anti-C5 antibodies). At this time, these trials are either beginning or are under way, and the utility of any of these agents remains to be determined.

Antiphospholipid Syndrome

In some patients, the antiphospholipid antibody syndrome is associated with SLE [38, 43]. Three types of antiphospholipid antibodies have been characterized, including lupus anticoagulants, anticardiolipin antibodies, and antibodies that cause a false-positive Venereal Disease Research Laboratories (VDRL) test. Patients with these antibodies may develop both arterial and venous thrombosis, thrombocytopenia, or thrombotic microangiopathy. (The diagnosis may be elicited on careful past history of patients who have experienced recurrent fetal loss.) In addition to their lupus, these patients develop glomerular and vascular thrombi. Renal involvement is characterized by fibrin thrombi in small arteries, and glomerular capillaries. Unfortunately, immunosuppresive therapy is usually not effective in reducing the level of antiphospholipid antibodies. Therefore, it is useful to continue long-term anticoagulation therapy with Warfarin, especially for patients with pathological confirmation of glomerular thrombi. It is not clear whether there is a correlation between the use of anticoagulants and renal outcome for patients with lupus.

Small-Vessel Vasculitis (SVV)

Nomenclature of SVV

The nomenclature of small-vessel vasculitis (SVV) has a rich and interesting history and has recently been reviewed [106]. The most recent approach is that proposed by the Chapel Hill Nomenclature Conference, the details of which can be seen in Table 6 [61]. Pauci-immune forms of SVV are microscopic polyangiitis, Wegener's granulomatosis, or the Churg-Strauss syndrome. These different forms of SVV have several similarities, not only on the basis of the blood vessels that they involve (predominantly capillaries, venules, arterioles, and small arteries), but also with respect to the clinical phenotype of the diseases and their association with ANCA.

Pathology

The characteristic feature of the glomerular lesion in SVV is a focal necrotizing glomerulonephritis. Associated with the necrotizing lesions are cellular or fibrocellular crescents that usually involve 50 – 100% of glomeruli. The glomerulonephritides associated with ANCA SVV and antiglomerular basement membrane (anti-GBM) disease are characterized predominantly by necrosis rather than hypercellularity. The reverse is true for immune complex glomerulonephritis, which tends to have prominent proliferative changes. Identification of vasculitis in vessels other than glomerular capillaries is seen in only approximately 10% of renal biopsies from patients with ANCA SVV. Occasionally, "sausage-shaped" pseudoaneurysms are observed within the small arteries of patients with small-vessel vasculitis. Interstitial necrotizing granulomatous inflammation is

Table 6. Names and definitions of vasculitis adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis

	Large-Vessel Vasculitis
Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery.
Takayasu arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 40.
	Medium-Vessel Vasculitis
Polyarteritis nodosa (classic polyarteritis nodosa)	Necrotizing inflammation of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries or venules.
Kawasaki disease	Arteritis involving large, medium and small arteries, and associated with mucocutaneous lymph node syndrome. *Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children.*
	Small-Vessel Vasculitis
Wegener's granulomatosis	Granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small-to medium-sized vessels (capillaries, venules, arterioles and arteries).
Churg-Strauss Syndrome	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small- to medium-sized vessels, and associated with asthma and blood eosinophilia.
Microscopic polyangiitis (microscopic polyarteritis)	Necrotizing vasculitis with few or no immune deposits affecting small vessels (capillaries, venules or arterioles). Necrotizing arteritis involving small- and medium-sized arteries may be present.
Henoch-Schönlein purpura	Vasculitis with IgA-dominant immune deposits affecting small vessels (capillaries, venules, or arterioles).
Essential cryoglobulinemic vasculitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis.

Modified from Jennette JC, Falk RJ, Andrassy K et al. Nomenclature of systemic vasculitides: the proposal of an international consensus conference. Arthritis and Rheumatism 37:187-192, 1994, with permission.

rarely observed in renal biopsies from patients with Wegener's granulomatosis. Bowman's capsule is frequently disrupted in the inflammatory process and induces a somewhat granulomatous periglomerular inflammation. However, this is a relatively nonspecific reaction that occurs with any form of severely necrotizing glomerulonephritis. Some patients do not have any identifiable glomerular lesions, but rather have tubulointerstitial nephritis or a medullary peritubular leukocytoclastic angiitis.

The necrotizing glomerulonephritis heals with regions of focal sclerosis. In any biopsy specimen, it is possible to observe both acute necrotizing lesions and chronic lesions asso-

ciated with focal sclerosis. The cellular crescents first heal in fibrocellular and then fibrous crescents, resulting at times in complete obliteration of the glomerular tuft. The tubulointerstitial compartment develops interstitial fibrosis and tubular atrophy along with interstitial infiltration by chronic inflammatory cells.

Most patients with ANCA glomerulonephritis and SVV have little or no glomerular staining for immunoglobulin by immunofluorescence microscopy (i.e., they have pauci-immune disease). On electron microscopy, there are often no electron-dense deposits or only a few scattered small deposits within the mesangium. However, it is important to realize that some patients appear to have necrotizing ANCA-glomerulonephritis concurrent with anti-GBM disease or immune complex disease, in which case there is a well-defined background linear or granular staining for immunoglobulins.

Clinical Manifestations

Most patients with ANCA SVV present with constitutional findings such as fever, myalgias, arthralgias, and malaise. The majority of patients describe a flu-like prodrome early in the course of their disease that may occur within days or weeks prior to the onset of their illness. The flu-like prodrome is statistically more frequent in late fall, winter, and spring than in the summer months [35]. Arthralgias, especially a migratory polyarthropathy involving small and large joints, is a frequent prodrome to the clinical presentation of SVV. About 10% of patients will have a frank arthritis with synovial thickening and erythema of the joint.

The renal manifestations of necrotizing glomerulonephritis are hematuria, with or without red cell casts, and proteinuria that can at times be mild to moderate (< 1 to 2 g), or of nephrotic range (as much as 16 g) [90, 91]. Patients may first present with an acute nephritis that is manifested by hematuria, proteinuria, hypertension and renal insufficiency. One of the most common presentations of necrotizing glomerulonephritis is a rapidly progressive glomerulonephritis associated with rapidly-rising creatinine, hematuria, proteinuria, and hypertension. These cases will progress to ESRD if the individuals are not treated emergently.

Alternatively, some patients have clinically undetectable episodes of focal necrosis and hematuria, undergo a remitting and relapsing course which results in the development of substantial glomerulosclerosis and a picture most compatible with chronic glomerulonephritis. Episodes of focal necrosis may resolve by themselves with a loss of hematuria (and red cell cast formation), resulting in proteinuria associated with the pathological finding of focal sclerosing glomerulonephritis. These individuals usually do not respond well to immunosuppressive therapy and eventually require dialytic support.

Some patients present with a renal-dermal vasculitic syndrome. The most common lesion consists of a leukocytoclastic angiitis with purpuric lesions in the lower extremities. However, several other cutaneous lesions have been observed, including ecchymoses, erythematous tender nodules, focal necrosis, ulceration, and livido reticularis. Interestingly, a picture of urticaria that may have been previously treated with antihistamines is also a manifestation of ANCA SVV. This must be differentiated from hypocomplementemic urticarial vasculitis in which there is a depression of C3 and C4.

Pulmonary disease is found in 50% of patients with ANCA SSV and glomerulonephritis. The spectrum of pulmonary lesions varies

from focal infiltrates that wax and wane, to alveolar infiltrates associated with hemoptysis and, in the extreme, to fulminate hemorrhagic alveolar capillaritis resulting in life-threatening massive pulmonary hemorrhage. In many instances, a prodrome of waxing and waning infiltrates, with or without hemoptysis, may antedate the more fulminate phase of disease by months to years. Patients may have been treated with antibiotics with the presumption of bacterial pneumonia, only to discover that the pulmonary process was not affected by this form of therapy. In patients who have a granulomatous component to their disease (that is, Wegener's granulomatosis or Churg-Strauss syndrome), more nodular and occasionally cavitary lesions are found. These nodules and cavities may be very small and only found on spiral CT scans, but they are frequently large enough to be observed by routine chest x-rays. In Churg-Strauss syndrome, pulmonary involvement is the most predominant form of the disease and is associated with asthma and eosinophilia. The acute inflammatory and necrotizing pulmonary lesions evolve into chronic, nonspecific, sclerotic lesions, such as interstitial fibrosis, organized intra-alveolar fibrosis, and bronchiolitis obliterans.

Of the clinical manifestations of ANCA SVV, the upper respiratory tract is the most difficult to diagnose and treat. The vascular inflammation of upper respiratory tract lesions may include nasal erosions, ulcers, and necrosis of the nasal septum. Patients may have serous otitis with involvement of the middle ear and entrapment of the seventh nerve, resulting in facial paralysis. Sinusitis is found in one-third of patients, typically involving more than one sinus cavity, resulting in a picture of pansinusitis. Patients with Wegener's granulomatosis may have bony erosion into surrounding areas, including the orbit. The encrusting of the nasal cavity is difficult to differentiate from concomitant infection, especially in those who have been treated with immunosuppressive therapy. Patients with Wegener's granulomatosis may also have tracheal inflammation, especially in the subglottic region, resulting in stridor. When this subglottic region is profoundly inflamed, critical airway narrowing may ensue, requiring emergency tracheotomy. These lesions are difficult to treat with corticosteroids and cyclophosphamide and may have a relapsing course.

Approximately one-third of patients with ANCA SVV and glomerulonephritis have abdominal complaints, largely similar to those of patients with peptic ulcers that are not amenable to conventional ulcer disease management. In fact, some of these patients have nonhealing gastric ulcers due to vasculitis that only respond to immunusuppressive therapy. These lesions raise a diagnostic challenge for clinicians in differentiating whether they are the result of vasculitis or of corticosteroid therapy. Biopsy of the affected tissue may provide an insight into the pathogenesis. Other sources of abdominal complaints are due to pancreatic inflammation with elevations of amylase and lipase.

The most catastrophic abdominal complication of small-vessel vasculitis is involvement of small arteries or arterioles in the small or large bowel. Such involvement causes transmural ischemic ulcers and bowel perforation resulting in polymicrobial sepsis and bacterial peritonitis. It is important to note that ANCA SVV may also involve the renal, celiac, and mesenteric arteries. Thus, some patients may have aneurysmal formation of these vessels, resulting in bowel wall, renal, or liver infarction.

One quarter of patients with ANCA SVV and glomerulonephritis will develop a neurological disease. This may be a mononeuritis multiplex that results in focal peripheral neu-

ral lesions with either sensory or motor deficits. Rarely, patients may present with seizures as a result of central nervous system vasculitis.

Cardiac disease is uncommon in patients with small vessel vasculitis, but when it does occur, there are two different clinical phenotypes. One is the development of pericarditis with the clinical picture of a serositis-type chest pain. The other phenotype is coronary artery disease as a consequence of vasculitis that results in either subendocardial or transmural myocardial infarctions. Since the average age of patients with ANCA SVV is 55 years, it is difficult to differentiate atherosclerotic coronary artery lesions from those attributable to vasculitis. Other vascular beds can also be affected by ANCA SVV, including the eye. Patients may have iritis or uveitis resulting in red eyes that may or may not be painful. These subtle changes are discernible only by slit lamp examination by an ophthalmologist.

Serology

Approximately 90% of patients with ANCA SVV have either a myeloperoxidase ANCA (MPO-ANCA) or a proteinase 3 ANCA (PR3-ANCA) [48]. MPO-ANCA is predominant in patients with microscopic polyangiitis and the Churg-Strauss syndrome, or with necrotizing and crescentic glomerulonephritis without extrarenal manifestations. PR3-ANCA predominates in patients with Wegener's granulomatosis. Nonetheless, 20 – 30% of patients with Wegener's granulomatosis will have an MPO-ANCA, and approximately 20 – 30% of patients with necrotizing glomerulonephritis with no obvious extrarenal manifestations will have a positive PR3-ANCA. Most patients have normal complement levels, and approximately 10% of patients have a positive ANA.

Prognosis

The long-term prognosis of patients with ANCA SVV depends on two different variables. Mortality is largely related to the occurrence of massive pulmonary hemorrhage, which accounts for at least half of all deaths in the fulminant phase of disease. The long-term renal prognosis is largely associated with the entry serum creatinine [54]; the higher the serum creatinine, the higher the risk of developing ESRD. The combined pathological activity and chronicity indices may also play a prognostic role in patients with substantial active disease.

Treatment Recommendations

Treatment of ANCA SVV can be divided into three phases: induction, maintenance of remission, and treatment of relapse before tissue destruction occurs [78].

Several protocols have been used for induction therapy. Our approach is to use intravenous methylprednisolone at a dose of 7 mg/kg on 3 consecutive days, especially for patients with renal and pulmonary involvement. The use of plasmapheresis has been promulgated largely in Europe, especially in Great Britain, where the vast majority of patients with SVV receive this form of therapy [84]. The relative benefits of intravenous methyl prednisolone versus plasmapheresis are the subject of an ongoing clinical investigation.

To complete the induction therapy, all patients are given 1 mg/kg/day of prednisone for one month. Corticosteroids are then tapered

to an alternate-day regimen during the second month of treatment and eventually discontinued by the end of the fourth or fifth month.

Once induction therapy is complete, there are 3 options for immunosuppressive therapy. The first approach is to use intravenous cyclophosphamide on a monthly basis, given at a dose of 0.5 g/m^2. The dosage is adjusted on the basis of the 2-week leukocyte nadir in order to affect a leukocyte count of 4000 cells/mm^3. In some cases of especially severe systemic vasculitis, the initial dose may be repeated at week 3 if the symptoms of the vasculitis are breaking through high-dose prednisone therapy. A second alternative is to use oral cyclophosphamide, given at a dose of 2 mg/kg/day [55]. To prevent severe leukopenia, careful attention to the leukocyte count must be maintained throughout this therapy. The patient must be admonished to drink plenty of fluids, because adequate diuresis is essential to avoid hemorrhagic cystitis. A third alternative, largely used in Great Britain, is to treat with cyclophosphamide for 3 months and then to switch to oral azathioprine [84]. The use of prednisone alone for the treatment of ANCA SVV is no longer justified on the basis of a lower remission rate and a 3-fold higher incidence of relapse [78].

The optimal duration of alkylating therapy is still very much a matter of controversy. Some investigators suggest 6 months, provided the patient is in clinical remission, while others recommend a full year of therapy. If the patient no longer has any evidence of microscopic hematuria, mild to moderate amounts of proteinuria (less than 2 g/24 hours), and no extrarenal manifestations of disease at 6 months, the treating physician may comfortably cease alkylating therapy. Conversely, additional therapy is warranted if the patient has persistent signs of ongoing glomerulonephritis with red cells and red cell casts, or if there are signs and symptoms of extrarenal manifestations of disease (especially in the upper respiratory tract, the nose, and subglottic region). Alkylating therapy should be continued, either intravenously on a monthly basis or with daily oral cyclophosphamide. Continuation of oral azathioprine is considered a matter of course in Great Britain.

For some individuals, the usual induction therapy is not successful. These individuals are primarily those who have massive pulmonary hemorrhage. In our own experience, the institution of plasma exchange, in addition to pulse methylprednisolone, is warranted in these individuals. The consequence of early and aggressive institution of plasma exchange has substantially diminished the mortality associated with massive pulmonary hemorrhage; the plasma exchange is given on a daily basis for the first week and then every other day for a total of 14 days. The role of pooled intravenous gammaglobulin for this disease is largely anecdotal, although some investigators feel that this drug enhances early induction therapy by diminishing pulmonary symptoms.

The conventional therapy for treatment of relapse is to reinstitute the same form of therapy used in the initial induction and remission protocol. Whether intravenous methylprednisolone is necessary again depends upon the total amount of corticosteroid that has been administered to the patient over the course of the disease, as well as the severity of the relapse. Six months of cyclophosphamide, either intravenously or orally, is again recommended. If the patient is in remission, the question becomes whether long-term immunosuppressive therapy is indicated. Some investigators would suggest that no additional therapy should be used, while others suggest that low-dose prednisone and azathioprine should be maintained for the long term.

With the use of alkylating agents of any kind, remission rates of between 70% and

85% have been noted. Individuals who relapse will either do so immediately after therapy is stopped or within a mean of 13 months. The value of ANCA titers in predicting relapse is a matter of controversy, although most investigators would suggest that they are, at best, adjunctive to clinical history and physical and laboratory examination of the patient. If a patient has an ANCA titer that becomes negative and then suddenly becomes positive again at sufficient titer, it is wise to follow those patients vigilantly to detect early relapse. The treatment of frequent relapse can be particularly challenging in patients with nasal or subglottic vasculitis and destruction. In fact, it may be impossible to withdraw patients with this phenotype from long-term therapy.

Patients who require dialysis at the onset of their disease may or may not respond to induction treatment. Whether plasma exchange or pulse methylprednisolone improves the chances of a dialysis-free interval is a matter of conjecture. In our own experience, only half of the patients who began dialysis responded to treatment. When response did occur, dialysis-free intervals lasted from 3 months to 3.5 years. Half of the patients did not respond to any form of therapy and remained dialysis dependent. There were untoward complications of the treatment regimen, including death.

Alternative Treatment Strategies

There has been substantial interest in alternative therapy to prevent the recurrence of vasculitis. This has been most demonstrated with the use of trimethoprim-sulfamethoxazole combinations. In a study by Stegeman et al. [95], the prophylactic use of cotrimoxazole resulted in a significant decrease in the relapse rate of patients with ANCA SVV. Close inspection of the data reveals that the significant diminution of the vasculitis relapse rate was entirely attributable to the amelioration of the nasal and upper respiratory tract relapse. These data would support those derived from DeRemee et al. [107] who suggest that trimethoprim-sulfamethoxazole combinations are the best forms of therapy for local disease of the head and neck. At this time, there is no apparent benefit associated with the use of these antibiotics for disease outside of this area.

Methotrexate has been evaluated in the treatment of SVV as well. Its use is primarily for individuals without substantial renal involvement, because the risk of mucositis is greatly increased when the creatinine is above 2 mg/dL [93]. Preliminary data suggest that methotrexate might be a useful agent to prevent relapse of SVV outside the kidney. Further studies are necessary in this regard.

On an experimental basis, mycophenolate mofetil has recently been tried as an alternative therapy to maintain remission and treat relapse. This form of therapy has not undergone extensive evaluation, but may be of specific benefit in lesions of the subglottis.

Renal Transplantation

Currently, the value of ANCA tests should not alter the timing of renal transplantation. In renal transplant recipients, there is a 15 – 20% incidence of relapse in the transplanted kidney or elsewhere. Whether newer immunosuppressive therapy, e.g. mycophenolate mofetyl, decreases the risk of relapse is not known. In patients with relapse, substitution of cyclophosphamide for other immunosuppressive therapy is warranted.

Medium- and Large-vessel Vasculitis

Polyarteritis Nodosa and Takayasu Arteritis

Classic polyarteritis nodosa, by the definitions of the Chapel Hill consensus conference, affects arteries but not other vessels. Therefore, by this definition, patients with polyarteritis nodosa do not have glomerulonephritis. Thus, the renal vascular disease is largely that of aneurysm formation in renal arteries resulting in infarction and/or hemorrhage. In some studies, most patients with polyarteritis nodosa have hepatitis B infection (considered later in this chapter) [47].

Patients with Takayasu arteritis may have disease involvement at the origin of the renal artery, resulting in renal artery occlusion and decline in renal function or, in rare individuals, precipitous infarction of an entire kidney. The most common presentation, however, is that of renal vascular hypertension associated with mild renal insufficiency.

Henoch-Schönlein Purpura (HSP)

HSP is mostly seen in children, although adults may also be affected. The clinical picture includes leukocytoclastic vasculitis of the skin, abdominal pain, arthralgias, arthritis, and glomerulonephritis. The skin lesions are similar to those of other renal-dermal vasculitic syndromes. There are typically crops of macular and palpable purpuric rashes on the lower extremities, buttocks and flanks, as well as urticarial lesions. The rash may be accompanied by constitutional symptoms such as malaise and fever, especially in children. The abdominal symptoms are vomiting, abdominal pain, frequent colic, melena, and hematochezia. Patients may present with arthralgias, and occasionally with frank arthritis of the large joints. The percentage of patients with HSP who develop clinically significant renal disease varies. When renal disease occurs, it is typically noted within days to weeks after the onset of symptoms. Most patients present with microscopic or, at times, macroscopic hematuria with red cell casts. Proteinuria is typically mild, although some patients may have the nephrotic syndrome. While there is usually a correlation between the clinical manifestations of disease (including urinalysis and serum creatinine) and the pathologic findings, the light microscopic features of the disease appear more severe in some individuals.

Pathology

The glomerular picture of HSP is identical to that of IgA nephropathy, with a spectrum of lesions ranging from mild mesangial proliferation to diffuse endocapillary proliferation, with or without crescent formation (see Chapter 7). By immunofluorescence microscopy, there is IgA deposition, as well as complement components such as C3. By electron microscopy, electron-dense deposits are found, almost always in the mesangium. Capillary wall deposits are most common in patients with severe glomerulonephritis.

Skin biopsy typically reveals a leukocytoclastic vasculitis involving postcapillary venules. While this finding is present in other renal-dermal vasculitic syndromes, the presence of IgA deposition in vessels is relatively specific for IgA nephropathy.

No specific laboratory tests are either sensitive or specific markers of HSP.

Clinical Course and Treatment Recommendations

In most children, HSP is a self-limited disorder. This is especially true of the dermal and joint complaints. The gastrointestinal symptoms may be severe and prompt numerous diagnostic studies and even exploratory laparoscopy. Corticosteroids clearly improve the extrarenal manifestations of the disease, including the abdominal pain.

In general, the disease process follows a relapsing and remitting course. The renal lesions vary as well. In individuals with mild mesangial hypercellularity, it is unlikely that any anti-inflammatory or immunosuppressive therapy is appropriate. Because a large number of patients develop spontaneous remission, there is limited enthusiasm for the use of corticosteroids and cyclophosphamide. However, among patients who have acute nephritis or rapidly progressive glomerulonephritis, a substantial proportion (up to 44%) have persistant hypertension or a decline in GFR [45]. Nephrologists tend to use therapies similar to those used in other forms of crescentic glomerulonephritis, including pulse methylprednisolone and cytotoxic drugs.

One of the critical issues concerning HSP is whether the disease process is different in adults than children. In a recent study of 162 patients, including 46 adults, cutaneous lesions were the main clinical presentation in both [11]. Upper respiratory tract infection was more frequent in children, whereas adults had a statistically lower frequency of abdominal pain and fever, and a higher frequency of joint pain. Adults were significantly more severely affected with renal disease and required the use of corticosteroids and/or cytotoxic agents. The outcome was good in both groups, with complete recovery in 94% of the children and in 89% of the adults.

Progressive Systemic Sclerosis (PSS)

Pathology

The histologic findings in the acute renal crisis of PSS are those of a thrombotic microangiopathy. There is glomerular consolidation caused by subendothelial expansion and capillary thrombosis, fibrinoid necrosis of arterioles and edematous intimal expansion in arteries. The chronic changes of PSS resemble chronic hypertensive injury and include fibrotic intimal thickening in arteries and glomerular sclerosis. As a consequence of the vascular changes, there may be signs of chronic tubulointerstitial disease, including interstitial fibrosis, tubular atrophy, and glomerular obsolescence. Some of the tubulointerstitial and glomerular disease may be a consequence of the thrombotic microangiopathy, whereas others are a consequence of hypertension.

The Role of Kidney Biopsy

The kidney biopsy may not provide a definitive diagnosis of PSS, for the findings may be that of hypertensive changes without indicating an underlying thrombotic microangiopathy or acute artery changes. A renal biopsy is indicated in patients with acute renal failure who do not have extrarenal manifestations of PSS, and those for whom the diagnosis is uncertain. A renal biopsy may also be of value in those patients who have an overlap syndrome of PSS and SLE, ANCA SVV, or other forms of mixed connective tissue disease [31, 71]. The clinical dilemma occurs in those patients who have evidence of SLE, dermatomyositis, or a clinically nonspecific manifestation of PSS. In these individuals, a renal biopsy may be most useful.

Laboratory Findings

A positive ANA reponse with a speckled or nucleolar pattern occurs in 70% of scleroderma patients. More specific autoantibodies found in these patients react with DNA topoisomerase I (anti-Scl-70). These more specific antibodies are found in up to 30% of patients with diffuse cutaneous disease. Anticentromere autoantibodies are relatively specific for the CREST syndrome. Antibodies to double-stranded DNA or other nuclear antibodies are uncommon.

Clinical Syndromes

The clinical picture of PSS includes involvement of the skin and subcutaneous tissues with localized or diffuse thickening of the extremities, face, and trunk. This thickening results in hardening of the skin and sclerosis of the fingers (sclerodactyly). Variants of PSS include the CREST syndrome defined by calcinosis, Raynaud's phenomenon, esophageal hypomotility, sclerodactyly, and telangiectasias. In these patients, it is uncommon to have either kidney or other organ system involvement. Similarly, localized forms of scleroderma or limited cutaneous systemic sclerosis are not associated with renal disease.

Raynaud's phenomenon is found in > 90% of PSS patients. Whether Raynaud's phenomenon is associated with PSS or a limited and benign phenomenon can be tested at the bedside by careful examination of the periungual nail beds. The absence or drop-out of capillaries in the nail beds is typical of patients PSS but not in patients with benign Raynaud's phenomenon. Esophageal hypomotility or loss of esophageal sphincter tone is found in 75% of patients with PSS, resulting in gastroesophageal reflux. Small and large bowel hypomotility produces a plethora of symptoms, including malabsorption and bacterial overgrowth. Pulmonary fibrosis occurs in > 50% of patients.

The renal involvement tends to occur early in the course of the disease, usually within 2 – 5 years after the onset. It is possible that the disease process may occur more commonly in the fall and winter.

As many as 75% of all patients with PSS have evidence of renal damage, and 50% have clinically evident renal disease. Some patients have mild proteinuria (typically less than 3 g/day) and varying degrees of mild renal insufficiency and hypertension. Scleroderma renal crisis, characterized by the relatively sudden onset of hypertension and acute onset of renal disease in a patient with no prior evidence of renal injury, occurs in 10 – 15% of cases. In the series from Black et al. [10], severe sclerodermal renal disease occurred in approximately 12% of those patients who had diffuse cutaneous scleroderma, but only 1.6% of those with limited cutaneous scleroderma. The incidence was increased in blacks (21% compared to 7% in whites), and the concomitant use of high-dose corticosteroids and perhaps cyclosporine or tacrolimus (FK 506) accelerated the disease process. Considering the nonspecific nature of these predictive factors, prudence dictates close monitoring of patients with PSS with repetitive measurements of blood pressure, serum creatinine concentrations and urinalyses.

Treatment Recommendations

The pathogenesis of scleroderma renal crisis remains controversial. It is possible that the crisis is analogous to a Raynaud's phenomenon: severe and persistent vasospasm may lead to overelaboration of renin and angiotensin II, resulting in, or at least perpetu-

ating, vasoconstriction. ACE inhibitors are the agents of choice, resulting in improvement in hypertension in up to 90% of patients. While most treatment studies rely on captopril, it is likely that other ACE inhibitors have a similar affect. It is not known whether Ang II receptor antagonists are equally effective. With blood pressure control, there may be reversal of renal insufficiency, diminution of proteinuria, and amelioration of the extrarenal manifestations of systemic sclerosis, including improvement in Raynaud's phenomenon and even improvement of the sclerodermatous skin changes.

In a report reviewing the course of 108 patients with scleroderma renal crisis [108], the 1-year survival before the introduction of treatment with ACE inhibitors was 18%, improving to 76% with these agents. Nonetheless, long-term data indicate that renal failure or death still occurred in half of those patients treated with ACE inhibitors. A significant number of patients with scleroderma renal crisis require renal replacement therapy. These patients may pose substantial difficulties with respect to vascular access, perhaps as a consequence of the hardening of the skin overlying the vascular access and the vasoconstrictive propensity of larger arteries. Peritoneal dialysis may be complicated by fibrosis of the peritoneal membrane altering peritoneal clearance. There are very few reports PSS of transplantation in patients PSS.

Other Rheumatologic Diseases that Affect the Kidney

Patients with rheumatoid arthritis may have several forms of renal injury, including amyloidosis as a complication of long-standing, severe rheumatoid arthritis. These patients, as well as those with seronegative arthropathies, can have proliferative glomerulonephritides, either associated with pauci-immune glomerulonephritis or IgA nephropathy. Patients who are HLA-B27 positive with ankylosing spondylitis or Reiter's syndrome usually have an IgA nephropathy [62].

Relapsing polychondritis is an unusual condition associated with ANCA SVV and a pauci-immune necrotizing and crescentic glomerulonephritis, although other proliferative glomerular lesions have been described.

Patients with Sjögren's syndrome and sarcoidosis typically have a renal presentation of an interstitial nephritis associated with interstitial fibrosis. In both of these circumstances, corticosteroid therapy may have a salutary effect, especially in sarcoidosis where substantial response to glucocorticoids may occur.

Dysproteinemias

There are several dysproteinemias or paraproteinemias with deposition of abnormal proteins in the kidney. These include amyloidosis, light chain nephropathy, cast nephropathy, amyloid (AL and AA), fibrillary glomerulonephritis and immunotactoid glomerulonephropathy, and Waldenström's macroglobulinemia (Table 7). The dysproteinemias, especially light chain-related diseases that cause tubulointerstitial lesions including Fanconi's syndrome or tubular interstitial nephritis, are described in Chapter 8.

Pathology

Many dysproteinemias cause distortions of the glomerular architecture by deposition of the abnormal proteins in distinctive patterns

Table 7. Types of Glomerular Extracellular Fibrillar and Microtubular Structures

Disease	Approximate Diameter and Usual Range (nm)	Most Common Composition
AL or AA amyloidosis	10 (8 – 15)	Light chains or AA protein
Fibrillary glomerulonephritis	20 (15 – 30)	Oligoclonal immunoglobulin
Cryoglobulinemia	30 (25 – 35)	Cryoglobulins
Immunotactoid glomerulopathy	40 (20 – 50)	Monoclonal immunoglobulin

(Table 7). By light microscopy there often is an increase in acidophilic material in the glomeruli. Amyloid is characterized histologically by fluffy pale acidophilic deposits with specific staining properties by Congo red (i.e., apple-green birefringence when viewed with polarized light). These deposits appear as masses of thin nonbranching fibrils by electron microscopy. Amyloid deposits may also be found in small vessels, including arterioles and arteries, and along tubular basement membranes. Primary amyloid (AL) can be differentiated from secondary (AA) amyloid on the basis of immunofluorescent staining of the amyloid deposits with anti-AA protein antibody or antibodies to lambda or kappa light chains.

Light chain deposition disease is characterized histologically by nodular glomerulosclerosis that is identical to diabetic glomerulosclerosis. By electron microscopy, glomerular and tubular basement membranes are thickened by finely granular material, rather than by fibrils like those seen with amyloidosis. Unlike amyloid, the deposits of light chain deposition disease do not stain with Congo red stain. In renal biopsy specimens, approximately 80% of AL amyloid is composed of lambda light chains, whereas approximately 80% of light chain deposition disease is caused by kappa light chains.

Clinical Features, Course, and Therapy

Light chain deposition disease and primary amyloidosis may have similar clinical presentations. In amyloidosis, proteinuria and renal insufficiency are the major renal manifestations of disease. Proteinuria ranges from asymptomatic, non-nephrotic-range to severe, resulting in morbid edema, hypercholesterolemia, and marked hypoalbuminemia. Patients with amyloid frequently have disease in organs other than the kidney, especially the heart, liver, skin, gastrointestinal tract, and synovium. In most patients, multiorgan system involvement is present, with 50% of patients having renal disease and ≥ 40% having cardiac amyloid deposits. In an individual with carpal tunnel syndrome and nephrotic syndrome, the diagnosis of amyloid must be considered, since 25% of patients with primary amyloidosis have carpal tunnel syndrome.

The renal manifestation of light chain deposition disease is nephrotic syndrome and can appear very similar to AL amyloidosis. Both disorders affect the heart, liver, and nerves. AL amyloid more frequently affects the gastrointestinal tract and the lungs, while light chain deposition disease rarely affects those organs. Patients with light chain deposition

Table 8. Causes of Secondary Amyloidosis

Chronic infections

disease have a higher plasma creatinine concentration at the time of biopsy and less proteinuria than those patients with primary amyloidosis. In our own studies [51], the plasma creatinine concentration was 2.4 mg/dL in the light chain deposition disease patients, whereas the patients with amyloidosis had a serum creatinine of 5.1 mg/dL. In contrast, patients with light chain deposition disease had a protein excretion rate of 3.7 g/24 hours, and patients with amyloidosis had 6.9 g/day.

The diagnosis of amyloidosis requires the presence of amyloid deposits in tissue. While kidney and liver biopsy are positive in 90 – 95% of cases, abdominal fat pad aspiration is positive in 60 – 90% of cases, bone marrow biopsy in up to 50% of cases, and rectal biopsy in 50 – 80% of patients. Most recently, an alternative to tissue biopsy has been suggested by the use of serum amyloid P component scintigraphy. This test is performed by the intravenous injection of technetium-labeled serum amyloid P component [101]. Scintigraphy has a sensitivity of nearly 100% with uptake in the spleen, kidney, and adrenal. Unfortunately, this test is not widely available, and substantial concern exists that the serum amyloid P protein obtained from numerous blood donors may be contaminated by infectious particles.

A clinical distinction between primary and secondary amyloidosis is based on the presence of systemic disease, especially inflammatory disease associated with secondary amyloidosis (Table 8).

Treatment Recommendations

Unfortunately, patients with primary amyloidosis have a dismal long-term prognosis with a five-year survival rate of <20%. Patients die either of malnutrition or congestive heart failure. While there are occasional responses to a combination of colchicine, prednisone, and melfalan, most patients do not appear to respond to these forms of therapy. In the largest study to date, 220 patients with biopsy-proven amyloidosis were randomly assigned to three different groups: colchicine alone, melfalan and prednisone, or melfalan, prednisone and colchicine. Patients were stratified according to whether they had renal disease, cardiac disease, or peripheral neuropathy. The median survival was only 8.5 months in the colchicine group, 18 months in those assigned to melfalan and prednisone, and 17 months in those assigned to melfalan, prednisone, and colchicine. In this important

study, the overall length of survival was 50 months among those who had a reduction in serum or urine monoclonal protein by 12-months, and 15% of patients survived for ≥ 5 years. This study concludes that treatment with melfalan and prednisone results in prolonged survival and a response to treatment as compared with colchicine alone, and forms the basis of current treatment recommendations. It is important to note that the use of melfalan is associated with melfalan-induced acute myelogenous leukemia (AML) and pancytopenia in about 6 – 20% of patients, depending on the duration of treatment and apparent response of the amyloid [66].

At the cutting edge of treatment, autologous bone marrow transplantation with stem cell rescue or stem cell rescue after ablative chemotherapy has recently been tried in a small number of patients. The relative success of this approach is not certain.

Therapy for secondary amyloidosis is aimed at the treatment of the underlying disorder except in familial Mediterranean fever, where colchicine is most useful in decreasing the severity of the attacks of serositis and arthritis [9]. Colchicine decreases, or at least slows, the accumulation of deposits in the kidney. The symptoms of familial Mediterranean fever are those of episodic attacks of serositis and fever. The use of colchicine in dosages of 1 – 3 mg/day has resulted in substantial diminution in the number of attacks in three-quarters of patients studied.

Other Paraproteinemias

There are several glomerular diseases due to nonamyloid fibrillar deposits. These lesions include fibrillary glomerulonephritis, immunotactoid nephropathy, and fibronectin glomerulopathy. Fibrillary glomerulonephritis is characterized on light microscopy by capillary wall thickening, mesangial matrix expansion, and varying degrees of hypercellularity and inflammation. The fibrils are larger than those of amyloid, but are smaller than those of immunotactoid glomerulonephropathy (Table 7). The deposits of fibrillary glomerulonephritis usually stain intensely for IgG (usually predominantly IgG4) and C3 [60].

Fibrillary glomerulonephrosis is found primarily in Caucasians, with a slightly increased female predominance. The clinical course of all of these forms of fibrillar deposition is largely that of nephrosis, although some patients have hematuria and hypertension as well. Half of all patients develop ESRD despite various forms of experimental therapy. Currently, it is not clear that any form of therapy is of benefit. In fact, most patients do not respond to either prednisone or cyclophosphamide. After 24 months of follow-up, there is only 48% renal survival [60].

Immunotactoid glomerulopathy is a different disorder in which the fibrils are larger and have a microtubular organization. Patients with immunotactoid glomerulopathy are more likely to have a circulating monoclonal immunoglobulin than patients with fibrillary glomerulonephritis. Immunotactoid deposits resemble those of cryoglobulinemia, which usually contain a monoclonal rheumatoid factor component.

The most recently described nonamyloid fibrillar deposition disease is fibronectin glomerulopathy. This extremely rare disease is characterized by massive amounts of fibronectin deposited in the mesangium. These deposits do not stain with Congo red. By electron microscopy, the fibrils are approximately 12 nm in diameter and are composed of fibronectin instead of immunoglobulin.

Paraneoplastic Nephropathies

The concept of paraneoplastic nephropathy is not new. The first report of a nephrotic syndrome associated with Hodgkin's disease dates back to 1939 [79]. In 1996, Lee et al. reported on a series of adults over the age of 40 with nephrotic syndrome [69]. In that cohort of patients, 11% developed neoplasms, all carcinomas. This corresponded to an incidence ten times greater than the age-matched actuarial rate. Interestingly, the renal disease antedated diagnosis of cancer in two-thirds of patients.

The prevalence of paraneoplastic nephropathy among patients with cancer is probably below 0.1% [3]. Conversely, the prevalence of cancers among older patients with glomerulonephritis may be quite high. For example, as many as 20% of patients 60 years and older with membranous nephropathy may have a concurrent cancer. Based on these findings, the search for occult malignancy is recommended in all elderly patients presenting with a glomerular disease.

The spectrum of glomerular diseases associated with concurrent cancers is wide. The most commonly reported nephropathies include membranous glomerulonephritis, minimal change disease, membranoproliferative glomerulonephritis, crescentic and necrotizing glomerulonephritis with or without a rapidly progressive glomerulonephritic syndrome, IgA nephropathy, and focal segmental glomerulosclerosis (FSGS).

Certain nephropathies tend to be associated with specific neoplasms. Membranous glomerulopathy accounts for about 30% of nephrotic syndrome in adults. Whereas it usually presents with proteinuria, as many as 40% of patients in this patient population may not have the nephrotic syndrome. There is a strong association of membranous nephropathy with epithelial cancers, especially those of bronchial or digestive tract origin. In fact, membranous nephropathy has been said to account for 60% to 70% of glomerular involvement in patients with these types of cancer. Conversely, the prevalence of membranous nephropathy among patients with nephrotic syndrome and hematologic cancers is only about 1%.

The characteristic histologic findings of classic or idiopathic membranous nephropathy is characterized by subepithelial immune complex deposits as seen by electron microscopy, however in cases of membranous nephropathy secondary to systemic disease such as SLE or neoplasms, one may find mesangial and/or subendothelial immune complex deposits in addition to the subepithelial deposits. These findings may be a clue for the presence of a secondary membranous nephropathy and should prompt the treating physician to search for an occult malignancy.

Minimal change disease (MCD) accounts for about 25% of nephrotic syndromes in the adult. In adult patients, especially the elderly, there is a higher incidence of hypertension and ARF than is seen in childhood disease. About 15 – 20% of adults may also present with microscopic hematuria. Minimal change disease is strongly associated with Hodgkin's lymphoma. Although the incidence of minimal change disease among patients with Hodgkin's is quite low, accounting for only 0.4% (7/1700 cases), MCD is, conversely, the most common finding in patients with Hodgkin's lymphoma and the nephrotic syndrome. The course of the nephrotic syndrome with MCD has been reported to parallel that of the lymphoma with treatment. The nephrotic syndrome and proteinuria may disappear when the Hodgkin's lymphoma goes into remission. There have also been reports of re-

current proteinuria heralding the recurrence of the lymphoma. MCD has also been reported with non-Hodgkin's lymphoma, chronic lymphocytic leukemia, and carcinomas.

Membranoproliferative glomerulonephritis (MPGN) may present as the nephrotic syndrome but may also present as an acute nephritic syndrome with renal failure, microhematuria, and hypertension. It is usually associated with low levels of C3, circulating C3 nephritic factor and circulating immune complexes. It may be the most common cause of nephrotic syndrome in patients with chronic lymphocytic leukemia. MPGN is also pathogenetically associated with essential mixed cryoglobulinemia. Whereas greater than 90% of patients with essential mixed cryoglobulinemia have been reported to be infected with the hepatitis C virus, in those patients who are HCV negative, the cryoglobulins have been suggested to be the result of a monoclonal expansion of B cells producing them and IgM rheumatoid factor.

IgA nephropathy presents in patients between the ages of 10 and 30 years of age in 65% of cases, although it may occur in the elderly population. It usually presents with microscopic hematuria, but may also present with frank proteinuria, hypertension, renal failure and even macroscopic hematuria with tea-colored urine. In one series, 6/66 patients greater than 60 years old with IgA nephropathy were found to have a concomitant cancer, whereas 0/158 patients younger than 60 years old had a cancer. IgA nephropathy was also reported in association with bronchogenic, head and neck, and pancreatic carcinomas.

In a compendium of all glomerular diseases associated with non-Hodgkin's lymphoma, Harper and Adu found that the most common nephropathy associated with B cell non-Hodgkin's lymphoma was focal segmental necrotizing glomerulonephritis (FSNG) [50]. This diagnosis accounted for 12/23 patients with glomerulonephritis and non-Hodgkin's lymphoma. The second most common diagnosis, accounting for 7/23 patients, was MPGN. Interestingly, 6/12 patients with FSNG had no evidence of immune complex deposits by indirect immunofluorscence microscopy. Those reports make no mention of ANCA testing or ANCA positivity. The pauci-immune histology reported raises the possibility that this could be associated with the presence of circulating antineutrophil cytoplasmic autoantibodies. In our experience in a cohort of 206 patients with ANCA SVV and glomerulonephritis, 11 patients developed 12 cancers. Four patients had prostate cancer, 3 colon cancers, and one each stomach, lung, bladder, and skin cancer. One patient had an unknown primary cancer site. Of these 11 patients, 5 were diagnosed with cancer either at presentation with their ANCA SVV or within 3 months thereafter. In these patients, it is unlikely that the development or the rapid growth of the cancer would have been secondary to immunosuppression or the use of cytotoxic drugs. In fact, 2 of these patients never received any cytotoxic drugs, and one patient received cytotoxic drugs for less than 4 weeks.

Kidney Abnormalities Associated with Liver Disease

The kidney is affected in a number of ways once there is liver damage, including derangement of salt and water balance, acute azotemia (especially in the hepatorenal syndrome), and

in association with several glomerular diseases (Table 9). It is beyond the scope of this review to consider the alterations of salt and water disturbances in liver disease or the causes of acute renal insufficiency. Rather, this chapter will focus on the viral hepatitides and the association of IgA glomerulopathy in cirrhosis.

Table 9. The Kidney in Liver Disease

- Sodiumretention
- Water retention
- Acute renal insufficiency
  - Prerenal azotemia
  - Acute tubular necrosis
  - Hepatorenal syndrome
- Viral hepatitis (Hepatitis B, Hepatitis C)
- Cirrhosis
  - Sclerosing glomerulonephritis
  - IgA glomerulonephritis

Hepatitis B

Hepatitis B causes several glomerular syndromes including serum sickness, membranous nephropathy, MPGN, and polyarteritis nodosa. Serum sickness is found in up to 25% of patients with hepatitis B, with associated arthralgias and arthritis, purpura, fever, and transient renal disease.

Membranous nephropathy has long been associated with hepatitis B, especially in Asia and Australia, where the majority of children with membranous nephropathy have hepatitis B. The proof that viral infection has a pathogenetic role in glomerular disease has been demonstrated in a number of ways. The most specific evidence is the immune complex deposits in membranous nephropathy containing hepatitis B antigen and especially the Hbe antigen [63]. In addition, both hepatitis B viral DNA and RNA have been observed in glomerular and tubular cells in patients with renal disease. Fortunately, in children with hepatitis B, spontaneous remission almost always accompanies the disappearance of hepatitis Be antigenemia and conversion to a positive hepatitis Be antibody state, contraindicating treatment with immunosuppressive drugs so as not to either stimulate viral replication or alter the development of an antibody state.

Whether there is a role for alpha-interferon therapy in hepatitis B and other types of glomerular injury is controversial. Conjeevaram et al. treated 15 chronic hepatitis B glomerulonephritis patients with alpha-interferon [23]. Of these individuals, half had a long-term serological response with loss of the serum hepatitis B antigen and hepatitis B viral DNA. Seven of 8 patients had a gradual improvement in proteinuria, although their liver disease improved more quickly. All 8 had membranous glomerulonephritis. Interestingly, of the other 7 patients, 4 had MPGN. This study suggests that the interferon-α may have an ameliorative role in the treatment of hepatitis B-associated membranous nephropathy in adults.

Polyarteritis nodosa has been associated with hepatitis B [47]. The symptoms of the disease may vary from subtle weight loss and malaise to sudden perforation of the abdominal viscus and renal infarction. The spectrum of injury includes mononeuritis multiplex, abdominal pain from ischemic injury to the bowel wall, central nervous system infarctions including central retinal arteritis, coronary arteritis resulting in myocardial infarctions, deep nodular lesions in the skin, and arterial damage in other vascular beds with

associated tissue destruction [47]. The treatment of hepatitis B-related polyarteritis nodosa is best described in a recent study by Guillevin. Of 41 patients with hepatitis B-associated polyarteritis nodosa, 35 were treated with the antiviral agent vidarabine, and 6 patients were treated with interferon α and plasma exchange. Fifty two percent of patients converted to hepatitis B antibody and 24% also seroconverted to anti-hepatitis B surface antibody. In fact, half of the patients no longer had serologic evidence of hepatitis B viral disease at all. Eight patients died.

The treatment strategy at present is short-term steroid therapy, antiviral agents, and plasma exchange. The use of corticosteroids and cyclophosphamide, which may or may not facilitate viral replication, is not indicated.

Hepatitis C (HCV) -related Glomerulonephritis

Cryoglobulins are composed of different types of immunoglobulins, which may be separated into 3 types. Whereas type I cryoglobulins are characterized by the presence of monoclonal antibodies, usually IgM, type II and type III are mixtures of monoclonal and polyclonal, or polyclonal with polyclonal immunoglobulins, respectively. In type II mixed cryoglobulins, the monoclonal component is usually an IgM with a kappa light chain. The polyclonal component is usually an IgG, with either type of light chains [2]. A growing number of reports have linked HCD infection and type II cryoglobulin [16, 33, 81].

Cryoglobulins are detectable in up to 30% of patients with HCV, but the clinical syndrome of mixed cryoglobulinemia occurs only in 1 – 2% of patients with HCV infection. Misiani et al. studied the association between HCV infection and cryoglobulinemia in 51 patients, using as controls 45 patients with non-cryoglobulinemic glomerulonephritis [74]. The authors looked for the presence of HCV by a number of different techniques, including a c100 ELISA and a c22/c200 ELISA, a recombinant immunoblot assay (4 RIBA), and a serum HCV RNA by PCR. Depending on the assay used, up to 98% of patients with type II cryoglobulinemia had evidence of HCV infection compared to only 2% in the control group. In addition, the study of the cryoglobulin precipitate revealed detectable anti-HCV activity in the cryoglobulin precipitate from 94% of patients after the use of dithiothreitol, a substance that destroys the IgM antibodies with rheumatoid factor activity. Similarly, Agnello et al. demonstrated that the concentrations of HCV, RNA, and anti-HCV antibody, but not antibodies to EBV or rubella, were much higher in the cryoglobulin precipitate than in the corresponding serum [1].The high prevalence of HCV infection and type II cryoglobulinemia, as well as the demonstration of anti-HCV antibodies and HCV RNA in the cryoglobulin precipitate, provides compelling evidence of an association between HCV infection and the development of type II cryoglobulinemia.

The mechanism by which HCV infection might lead to the development of type II cryoglobulinemia is unclear. The recent finding that peripheral blood leukocytes, especially B cells, can be the site of extrahepatic HCV replication has led to the postulation that direct active viral replication in B cells induces type III mixed cryoglobulins by triggering the activation of B cells to hyperproduce polyclonal IgM rheumatoid factors in a subgroup of patients with chronic infection. Some other uncharacterized event might induce the abnormal proliferation of a single clone, leading to the production of a monoclonal IgM rheumatoid factor and type II mixed cryoglobulinemia.

Pathology

The most common renal lesion in patients with type II mixed cryoglobulinemia is type I MPGN. Pathologic characteristics include endocapillary hypercellularity due to proliferation of mesangial and endothelial cells, and infiltration of monocytes and T lymphocytes. There are typically large amorphous eosinophilic, PAS-positive, Congo red-negative deposits that may fill the capillary lumina ("hyaline thrombi"). The basement membrane is typically thickened with a "double contour" appearance. A few patients have fibrinoid necrosis of the walls of arterioles and venules. Electron microscopy may reveal subendothelial electron dense deposits consisting of a microtubular structure of hollow fibers, 100 to 1000 nm long. By immunofluorescence microscopy, there is granular-to band-like staining of the vessel walls for IgM, IgG, and complement C3 (144). Some patients exhibit intense staining of large deposits that fill the capillary lumen.

Clinical Manifestations

Type II mixed cryoglobulinemia is most often diagnosed in the fifth and sixth decade of life, often many years after the first symptoms appear. Cryoglobulinemic vasculitis is often characterized by purpura, weakness, arthralgias, arthritic vasculitis, neuropathy and proliferative glomerulonephritis. Renal involvement occurs in 8 – 58% of patients and is more common in women with mixed cryoglobulinemia. Manifestations of renal involvement typically appear many years after the first symptoms of cryoglobulinemic vasculitis develop. The renal disease may occasionally appear concomitantly with the extrarenal manifestations, but rarely before. The most frequent renal findings are isolated proteinuria and microscopic hematuria with moderate chronic renal insufficiency. Twenty to 30% of patients may present with an acute nephritic syndrome with ARF, severe proteinuria, hematuria and hypertension. Twenty percent of patients may present with a nephrotic syndrome.

Clinical Course and Prognosis

The clinical course of type I MPGN associated with HCV varies. Ten to 15% of patients attain complete remission, even when presenting with an acute nephritis, while 30% of patients follow an indolent course that does not progress to ESRD despite the persistence of abnormal urinary sediment and chronic renal insufficiency and 20% of patients may have recurrent episodes of acute nephritis that may go into remission either spontaneously or in response to high-dose corticosteroids and/or plasmapheresis. The latter course usually leads to chronic renal insufficiency. According to the data of D'Amico et al., only about 15% of patients progress to ESRD over a mean period of 10 years [41]. These authors, however, report a high mortality rate over the same period of time secondary to extrarenal disease. Based on a cohort of 105 patients diagnosed over 25 years [98] and followed up for a median of 72 months post-biopsy, the 10-year probability of survival without ESRD was 49%. The major causes of death in that group were due to cardiovascular disease, infection, liver failure, and neoplasia. The main risk factors were age > 50, vascular purpura, splenomegaly, cryocrit level > 10% and C3 plasma levels < 54 mg/dL. As with other glomerulonephritides, a serum creatinine > 1.5 mg/dL was an important risk factor for chronic renal failure or death (relative risk of 1.25, 95% confidence interval of 1.11).

Treatment Recommendations

The recognition of an association between HCV infection and type I MGPN has led to great interest in the treatment of this glomerular disease with antiviral agents. While a large body of data has accumulated over the last several years concerning the treatment of HCV infection, most knowledge is derived from the treatment of hepatic disease. Several subtypes of interferon alpha have been employed. One of the first reports, by Misiani et al., was a randomized study of the use of interferon alpha in the treatment of patients with HCV-related mixed cryoglobulinemia [75]. Patients were treated thrice weekly for 24 weeks versus symptomatic therapy in the control group. Treatment with interferon p–α resulted in improvement in cutaneous vasculitis, cryocrit, and serum creatinine, and a decrease in HCV RNA. However, the viremia and cryoglobulinemia recurred in all patients after discontinuation of interferon alpha. Carithers et al. performed a meta-analysis of interferon alpha 2b trials [19]. The results are expressed as biochemical response (correction of alanine amino-transferase, ALT) or serologic response (decrease in or disappearance of HCV virus titers). Response is defined as either "end of treatment response" or "sustained response", referring to the result six months after discontinuation of treatment. The authors report a biochemical end of treatment response of 47% and 29% for virologic response. The sustained response dramatically drops to 23% and 8%, respectively. Treatment for prolonged periods (12 to 24 months versus 6 months) or with high-dose interferon alpha might lead to a very modest improvement in these results. Most patients experienced mild to severe influenza-like symptoms.

The results of the use of interferon alpha alone led to the evaluation of combination therapy including interferon alpha and the nucleoside analog ribavirin [87]. Three randomized placebo-controlled studies comprising more than 150 patients have shown that therapy with Ribavirin alone for 24 – 48 weeks resulted in an improvement ALT levels, but no substantial reduction in HCV RNA levels. ALT levels increased to pretreatment values when therapy was discontinued. However, ribavirin in standard doses combined with interferon alpha in doses of 3 million units, 3 times weekly for 6 months, was found to significantly improve the sustained biochemical and virological response rates compared to interferon alpha alone. No study has yet been reported as to the use of this combination therapy in the treatment of HCV-related mixed cryoglobulinemia or MPGN.

There are currently 2 non-randomized case series on the use of plasmapheresis with or without small doses of corticosteroids in the treatment of acute exacerbation of cryoglobulinemic MPGN [12, 39]. These case series report a beneficial effect of plasmapheresis in the treatment of acute exacerbation of vasculitis. Patients with acute deterioration of renal function seemed to benefit the most, whereas patients with chronic stable renal insufficiency had a less marked benefit from the treatment. Of note is that in 5/9 patients [39] plasma exchange led to sustained remission without clinical relapse when the procedures were reduced in frequency or discontinued.

Cirrhosis

Cirrhosis of the liver is associated with two syndromes. First, in many cirrhotic patients, there is an associated diffuse glomerular sclerotic process that has been called "cirrhotic glomerulosclerosis". By immunofluorescence microscopy, some of these samples

have IgA or IgM deposition. The second, and most common histologic finding is a process indistinguishable from idiopathic IgA nephropathy. In fact, IgA deposition with variable degrees of MPGN is found in 50% of autopsy subjects who have died with alcoholic liver disease. The IgA deposition in this circumstance (clinical course of IgA nephropathy) is reviewed in the previous chapter.

Kidney in Infectious Disease

Acute Post-streptococcal Glomerulonephritis (APSGN)

APSGN is the prototype disease of an acute glomerulonephritis associated with an infectious etiology. The first description linking an acute glomerulonephritis to an infectious etiology dates back to the early 18th century after scarlet fever epidemics in Florence and Vienna. The association was also described in 1838 by Bright, again in association with scarlet fever [109]. Rammelkamp et al. further refined the association of post-streptococcal glomerulonephritis with specific serotypes of Streptococci [85].

APSGN is a disease that affects primarily children, with a peak incidence between ages 2 and 6 years. Children younger than age 2 and adults older than age 40 account for only about 10 – 15% of patients affected with APSGN. The disease is often subclinical and the incidence of subclinical nephritis outnumber that of overt nephritis by a ratio of 4 – 10:1. Males are more likely to have overt nephritis than females.

APSGN may occur as part of an epidemic or as sporadic disease. The clinical syndrome preceding APSGN may be either pharyngitis or a skin infection. In temperate countries, the pharyngitis is more common, whereas impetigo and pyoderma predominate, in the tropics.

Pathology

On light microscopy, APSGN is marked by an acute diffuse proliferative glomerulonephritis. The hypercellularity results both from endogenous mesangial and endothelial cell proliferation, and infiltration of the glomerular tuft by inflammatory cells, especially neutrophils. The early “exudative phase” of disease is characterized by the infiltration of the capillary tuft by neutrophils, eosinophils, lymphocytes, and monocytes. These cells may be present both in the capillary lumen and the mesangium. After 4 – 6 weeks, polymorphonuclear neutrophils (PMN) are usually no longer present and the hypercellularity is mostly residual mesangial hypercellularity.

During the exudative phase and acute disease, there is often occlusion of the capillary lumina. During that time, the capillary walls are thickened by the deposition of large subepithelial immune complexes. In severe cases, crescent formation occurs.

By immunofluorescence microscopy, APSGN is characterized by granular deposits of IgG and C3 distributed in a diffuse granular pattern within the mesangium and along the capillary walls. The IgG usually disappears within a few weeks, leaving a C3-dominant staining that may persist for several months.

By electron microscopy, APSGN is characterized by the deposition of dome-shaped electron-dense deposits (humps) in the

subepithelial zone. These electron-dense deposits are typically seen early in the course of disease, and tend to disappear within two months as the acute glomerulonephritis resolves. Subendothelial, mesangial, and intramembranous deposits also occur in variable amounts and usually persist longer than the subepithelial deposits.

Clinical Manifestations

The glomerulonephritis associated with post-streptococcal disease is typically abrupt in onset. There is a latent period of 7– 14 days after an upper respiratory tract infection, or 14 – 28 days after a pyodermal infection. The most common clinical manifestations of APSGN include symptoms of nephritis, hematuria, hypertension, edema, and oliguria. Anuria and renal insufficiency are uncommon. Patients typically present with mild to moderate hypertension. The hypertension is the most likely cause of headaches that are typically of mild to moderate intensity. However, severe neurological manifestations have been described, including hypertensive encephalopathy with headaches, ocular disturbances, and even stupor, coma, and seizure activity. Excessive intravascular fluid results in pulmonary vascular congestion that may lead to clinical symptoms of dyspnea, orthopnea, and – even in these young individuals – evidence of congestive heart failure (CHF) with pulmonary edema, pleural effusions, and a gallop rhythm. Children typically have systemic symptoms including nausea, vomiting, and abdominal pain with mild fever.

The clinical course in APSGN is usually a self-limited one; resolution of the disease is marked by the institution of a diuretic phase within 1 – 2 weeks after the onset of illness. Associated with the diuresis is amelioration of hypertension and vascular congestion. Interestingly, the hematuria and proteinuria disappear in the vast majority of children within 6 months; in adults, proteinuria may be present in half of patients for more than a year, and one-third may have proteinuria over a longer term. Thus, the long-term prognosis in children is relatively benign, exept in some children with severe crescentic disease, in whom it is likely that evidence of chronic glomerulonephritis persists indefinitely. Some long-term studies of adult patients suggest that complete recovery may take as much as a decade, while some patients may progress to ESRD [17]. Importantly, the episodes of ASPGN that occur in epidemics respond more favorably than do those that occur as sporadic infections.

Treatment Recommendations

No specific treatment is indicated in the care of patients with APSGN. Treatment of hypertension is usually responsive to diuretics as well as other antihypertensive medications, namely calcium channel blockers, or ACE inhibitors. Treatment of acute uremia and advanced renal failure may be indicated, requiring the transient institution of dialysis. No immunosuppressive regimens have been studied and evaluated in the treatment of APSGN. Kobrin and Madaio [65] suggest the use of high-dose corticosteroids for 3 – 5 days only in patients with an rapidly progressive glomerulonephritis (RPGN) and the findings of crescents in > 30% of glomeruli on renal biopsy. These recommendations are not based on clinical trial data. Specific treatment of the streptococcal infection is essential. Both the patient and exposed family members should be treated with penicilline G or erythromycin. It is unclear as to whether treatment of the streptococcal infection prevents the occurrence of nephritis.

Infective Endocarditis, Shunt Nephritis, and Visceral Sepsis

Infective endocarditis, shunt nephritis and visceral sepsis-induced glomerulonephritis are examples of immune-mediated glomerulonephritis. The pathology of each of these syndromes includes a spectrum of proliferative lesions that range from focal proliferative glomerulonephritis, to acute diffuse proliferative glomerulonephritis, to membranoproliferative glomerulonephritis. Evidence of immune deposition is found both by immunofluorescence microscopy and electron microscopy. Granular deposition of immunoglobulins and complement forms along the glomerular capillary wall and in the mesangium. Immunostaining for IgM often is more intense than staining for IgG.

The responsible pathogen in infective endocarditis, shunt nephritis, and visceral sepsis may be different for each condition. Previously, infective endocarditis was largely due to staphylococcal and streptococcal disease, but now includes gram-negative organisms and opportunistic organisms as well, primarily in immunocompromised hosts and those who use intravenous drugs [76]. The same is true for visceral sepsis. Shunt nephritis is associated predominantly with *Staphylococcus sp.*, but also with other organisms, both gram-positive and gram-negative. Interestingly, ventriculoperitoneal shunts are more resistant to infections than are ventriculo atrial shunts.

The clinical manifestations of all of these diseases are very similar, resulting in either microscopic or gross hematuria and proteinuria. While glomerulonephritis is the predominant manifestation, some individuals (up to 25%) present with nephrotic syndrome. Fever, chills, rigors, and leukocytosis are clues to early detection and institution of appropriate antimicrobial agent therapy. The total complement (CH50) and C3 levels are frequently decreased. Cryoglobulins and circulating immune complexes are detected in some individuals. Among patients with visceral sepsis and infective endocarditis, as many as one-third will have dermal manifestations of injury as well, including peripheral emboli in infective endocarditis and purpura.

The treatment of these conditions depends on identification and eradication of the pathogenetic microorganism. In the case of shunt nephritis oraprosthetic heart valve, removal of the foreign body may be required.

Protozoal and Other Parasitic Infections

Nephrotic syndrome is a common consequence of protozoal and parasitic infections. In areas of Africa, especially Uganda, as many as one third of nephrotic children have quartan malaria. Nephrotic syndrome also occurs in other parasitic and protozoal infections, predominantly those associated with Schistosoma mansoni, as noted in Table 1. In patients with typical nephrotic syndrome, glomerular lesions are variable, including membranous glomerulopathy, focal glomerular sclerosis and minimal change glomerulopathy. Fully one third of patients have focal or diffuse proliferative glomerulonephritis, often with a membranoproliferative pattern. A distinctive entity associated with quartan malarial infection is a pattern of glomerular sclerosis with formation of new matrix material in the subendothelial zone, resulting in basement membrane replication and thickening.

Unfortunately, the long-term prognosis of these conditions is poor; there does not appear to be spontaneous remission when nephrotic syndrome is attributable to malaria. Antimalarial drugs do not help, and the effects of

anti-inflammatory and immunosuppressive drugs are unknown. *Schistosoma mansoni* may respond to antiparasitic medications in combination with a variety of anti-inflammatory and immunusuppressive drugs.

Human Immunedeficiency Virus Associated Nephropathy (HIV-AN)

The occurrence of kidney disease in the setting of HIV infection is common and the spectrum of renal disease is very broad. In a retrospective review of 449 patients with acquired immune deficiency syndrome (AIDS) admitted to Bellevue Hospital in New York [103], almost 20% suffered an acute episode of renal insufficiency. In 5% of patients this led to ARF, with a rise in serum creatinines to > 6 mg/dL. In the subset of patients with severe renal failure, the mortality rate was over 50%. In survivors, recovery of renal function was almost complete, except when nephrotoxic antimicrobial drugs were the cause of renal failure.

The etiology underlying ARF in patients with HIV infection or acquired immunodeficiency syndrome (AIDS) is related, directly or indirectly, to sepsis in up to 75% of the cases [88]. Other important causes of ARF are volume depletion with hypotension and acute tubular necrosis precipitated by nephrotoxic drugs, e.g. aminoglycosides, pentamidine, trimethoprim-sulfamethoxazole and NSAIDs. Pathological changes include acute tubular necrosis (ATN), acute interstitial nephritis, and other findings such as nephrocalcinosis, carcinoma, streptococcal abscesses and various glomerular lesions.

HIV-associated nephropathy refers to a specific glomerulonephritis seen in the setting of HIV infection. Its presenting features are those of nephrotic-range proteinuria and renal insufficiency. Most patients present with a full nephrotic syndrome, including edema, hypoalbuminemia and hyperlipidemia. Some patients, however, present with sub-nephrotic-range proteinuria as well as with microscopic hematuria and sterile pyuria.

The course of HIV nephropathy usually progresses rapidly to renal failure. Initially, Rao and Carbone reported a progression to ESRD within a period of about 3 – 4 months among patients with HIV-AN [18, 87]. In the study by Carbone et al., the median length of survival from diagnosis of renal disease to death was determined by the stage of the underlying HIV infection. The longest median survival period (9.7 months) was among asymptomatic patients, as compared to that of patients with AIDS-related complex (ARC) or clinical AIDS, who had median survival periods of 3.6 and 1.9 months, respectively. (It is important to note that these data were derived from the "pre-zidovudine (AZT)" era.) HIV-AN may occur at any stage in the HIV infection, possibly most commonly in asymptomatic HIV-infected patients [18].

From the earliest reports of HIV nephropathy, a geographic discrepancy in the incidence of HIV-AN was noted with a predominance of cases reported from East Coast centers, and a very low prevalence of the disease in San Francisco. This geographic difference in prevalence suggested possible associations with the mode of transmission of the infection, with IV drug use, or with racial differences. It is now apparent that there is a strong racial predominance of African-Americans in HIV-AN that is independent of concomitant intravenous drug use. A study by Bourgoignie et al. also describes a much more severe form of the disease among the black population, with blacks being more likely to have nephrotic-range proteinuria and renal insufficiency [14]. This racial difference is also seen in other glomerular diseases such as idiopathic focal segmental glomerulosclerosis,

hypertension and diabetes. The basis for this predilection of HIV-AN among African-Americans is currently unknown.

The incidence of HIV-AN in autopsy and biopsy-based series has varied, depending on geographic location, criteria for diagnosis and indications for biopsy. Overall the incidence appears to be somewhere between 1 – 10%. In the study by Bourgoignie, no relationship was found between the development of nephropathy and patient age, duration of HIV infection or types of opportunistic infections [14].

Pathology

Pathologically, HIV-AN has features of a collapsing form of FSGS, characterized by focal to global wrinkling, thickening and retraction of the GBM, and expanded mesangial matrix, resulting in obliteration of capillary lumens. There is no associated increase in mesangial cellularity. A characteristic feature of collapsing FSGS associated with HIV-AN is hypertrophy and hyperplasia of the visceral epithelial cells overlying the glomerular tuft. These visceral epithelial cells may also show numerous intracytoplasmic protein resorption droplets. There is interstitial edema, fibrosis, and inflammation with variable degrees of tubular atrophy. There often is focal microcystic dilatation of tubules containing proteinaceous casts.

By indirect immunofluorescence microscopy, some degree of staining for IgM, and C3 (and, less commonly, C1q) is seen in the mesangium and in areas of glomerular sclerosis. There may be staining for IgG, IgA, and albumin within the visceral epithelial cell resorption droplets.

By electron microscopy, one can see collapse of the glomerular tufts with wrinkling and retraction of segments of the GBM. There is extensive foot process effacement of podocytes, as well as microvillus transformation. Over 90% of HIV-AN biopsies reveal numerous tubuloreticular inclusions within endothelial cells. These inclusions consist of 24 nm tubular structures located within the endoplasmic reticulum. These structures (also seen in SLE) are thought to be the result of interferon α activation.

There is some controversy as to whether one aspect of HIV-AN consists of diffuse mesangial hypercellularity. A milder mesangial lesion appears to be more common in children and caucasian patients, and is associated with less severe proteinuria.

Treatment Recommendations

No specific treatment for HIV-AN is currently available. The care of patients with HIV-AN consists of 3 goals: (1) the reduction in proteinuria in an attempt to minimize the nephrotic syndrome, (2) the delay of progression to ESRD, and (3) the provision of renal replacement therapy when ESRD is reached.

– *Minimizing proteinuria.* To date, 3 studies involving small numbers of patients with nephrotic syndrome and HIV infection have documented a reduction in proteinuria resulting from treatment with an ACE inhibitor. This benefit appears to be associated with stabilization in renal function. Overall, the use of ACE inhibitors in HIV-AN seems to be of benefit. However, this intervention is sometimes limited by the development of hyperkalemia, especially in patients concomitantly receiving trimethoprim-sulfamethoxazole.
– *Delay of progression to ESRD.* Two lines of intervention currently available are (a) treatment with antiretroviral drugs, and (b) immunosuppression with high-dose corticosteroids. Several reports involving

series of patients with HIV and the nephrotic syndrome suggest that treatment with AZT decreases the degree of proteinuria and delays the progression of HIV-AN to ESRD.

Some of these studies are case controlled, others are prospective studies compared with historic control subjects [59], and other studies are uncontrolled [67, 73]. It is likely that the effect of AZT may depend, in part, on the stage of histologic progression and the degree of azotemia attained at the time treatment is instituted. It is noteworthy that these were derived in the early days of HIV treatment; at the time when treatment of HIV was almost entirely dependent on the institution of AZT. No new data are currently available on the effect of combination therapy with reverse transcriptase inhibitors or protease inhibitors. Likewise, there are no data concerning the effect of combination therapy on the incidence of HIV nephropathy.

The other line of treatment to delay progression of azotemia to ESRD has been based on immunosuppression, with reports of improvement in renal function and proteinuria in response to high-dose corticosteroids. Most reports are single cases, although a few case series that have included HIV-infected children and adults. Whereas the use of high-dose corticosteroids seems to improve proteinuria and delay the decline of renal function, this treatment appears to be associated with a high incidence of life-threatening infections. Based on these results, it is difficult to recommend the use of high-dose corticosteroids to all patients with HIV-AN.

Renal Replacement Therapy

The issues of renal replacement therapy in HIV-infected patients pertain to (1) long-term survival after reaching ESRD, and (2) the choice of renal replacement therapy modality.

Long-term Survival

Early reports of dismal survival prospects for patients with ESRD has led to reluctance to start replacement therapy in these patients. More recent studies, however, have documented a stratification of the survival rate of patients with HIV infection and ESRD that depends on the stage of their HIV infection. It now appears that patients with HIV infection and ESRD have a survival rate similar to that of stage-matched patients without ESRD. However, the survival of patients on dialysis with AIDS remains poor, with a mean survival of about 3 months, as opposed to about 16 months for patients with ESRD and asymptomatic HIV infection. A recent cross-sectional study [58] assessed the survival of HIV-infected patients requiring dialysis. Of 34 subjects, 29 patients had clinical AIDS. Surprisingly, only 6 patients were receiving an antiretroviral medication (AZT = 5; dideoxyinosine (DDI) = 1). In 68% of cases, AIDS was diagnosed before ESRD; the remaining patients were diagnosed with HIV infection only after initiation of maintenance hemodialysis. In this cohort, the mean duration of ESRD was 57 months, with a range of 4 to 196 months. The mean survival is remarkably improved over the initial reports by Rao [88] and others [57, 80], when the mean survival of AIDS patients on hemodialysis was about 3 months. The authors suggest that the improved survival may be attributed to several factors, including more aggressive institution of dialysis, more aggressive dialysis, improved treatment of opportunistic infection, improved management of uremia including the use of erythropoietin, and perhaps the improvement in anti-retroviral medication. The latter point is not directly supported by

this study, in which only 17% of patients received anti-retroviral medication.

Choice of Modality of Renal Replacement Therapy

There was considerable fear of transmission of HIV infection from patients to staff or other patients in the setting of the use of hemodialysis. This fear has not been substantiated by any reports of patient-to-patient or patient-to-staff transmission of the disease in hemodialysis units in the United States. To date, the cases of patient-to-patient spread of the infection in a dialysis unit in Columbia, South American can be attributed to the reuse of access needles in that country. The same measures taken to prevent spread of the Hepatitis B virus are sufficient to minimize the risk of HIV transmission.

The early interest in the use of peritoneal dialysis in patients infected with the HIV virus stems from the concern to minimize risk of disease transmission to staff and other patients. Whether the rates of peritonitis in this patient population is higher than in control populations remains to be confirmed, as current reports are conflicting. There is no comparison of survival among patients treated with peritoneal dialysis versus hemodialysis.

Emerging Infections

Two viruses of note have emerged that may prove to be important causes of glomerular and tubular interstitial injury. The Hanta virus infection, known to cause hemorrhagic fever with renal involvement, was of substantial consequence during the Korean War. Recently, cases have been described in the United States, primarily causing respiratory distress. The renal lesions in these patients was confined to slight mesangial alterations with tubulointerstitial inflammation and ARF.

The parvovirus B19 has been recently associated with FSGS and especially the collapsing variant of FSS. Whether this association leads to improved understanding of the pathogenesis of this condition remains uncertain.

The Kidney in Pregnancy

Claudia Peano and Susan Hou

Anatomic Changes in the Kidney during Pregnancy

Anatomical changes occur in the kidney during pregnancy. Renal length is increased by 1 to 1.5 cm [1]. A physiologic dilatation of the ureters gives rise to hydronephrosis, with urinary stasis of up to 300 cc in the ureters, a change which predisposes to urinary tract infection (UTI) [2]. The ureteral dilatation occurs as early as 12 weeks gestation in response to increased estrogen and progesterone as well as increased prostaglandin E_2 (PGE_2), which decreases ureteral peristalsis. Dilatation is later aggravated by the expansion of the uterus, and hydronephrosis may become more marked. The role of obstruction has been raised by the observation that dilatation is more marked after 4 months gestation and at distances greater than 5 – 10 cm above the ureterovesicular junction. The obstructive component of ureteral dilatation is aggravated by upright posture. By the third trimester, hydronephrosis graded as severe on ultrasound may be seen in normal pregnancy [3]. The increase in renal size usually reverses during the first week postpartum, but hydronephrosis may persist for 12 weeks postpartum. Stasis of urine in the dilated collecting system makes timed urine collections difficult, and it is important to verify the adequacy of collection by measuring total creatinine production. Establishing a brisk diuresis before starting a timed urine collection will minimize the likelihood of inaccuracy resulting from urine stasis. Methods of measuring glomerular filtration rate (GFR) that rely on radioisotopes such as iothalamate cannot be used in pregnancy.

Changes in Renal Physiology during Normal Pregnancy

Dramatic changes in renal function occur during pregnancy (Table 1). Renal plasma flow increases to 50 – 70% above normal during the first two trimesters and remains 40% above normal in the third trimester [4]. An increase in GFR begins by the fourth week of gestation, peaks at 150% of normal at 13 weeks, and continues almost until term. There is dilatation of both afferent and efferent arterioles, and increased renal blood flow is the major determinant of GFR. There is little pressure change across the glomerular basement membrane (GBM) [5]. Mean blood urea nitrogen (BUN) is 9 mg/dL and mean serum creatinine is 0.5 mg/dL. Despite an average decrease in serum albumin of 1.5 gm/dL

Table 1. Renal Changes in Normal Pregnancy

Anatomic
- 1 cm ↑ in length
- Dilatation of the collecting system

Physiologic
- 50% ↑ in GFR: normal
- BUN 9 mg/dL, creatinine 0.5mg/dL
- Respiratory alkalosis: normal PCO_2 27 – 32 mm Hg, HCO^-_3 18 – 21 mEq/L
- Decreased serum osmolality: normal 276 – 278 mOsm/L
- Doubling of uric acid clearance: normal 3 – 4 mg/dL
- ↓ Tubular reabsorption of glucose
- 40% ↑ in renal blood flow
- Decreased afferent and efferent arteriolar resistance
- Decreased BP: normal < 125/75 mm Hg 2nd trimester, < 125/85 mm Hg 3rd trimester
- ↑ Renin (8x), angiotensin (4x), aldosterone (10 – 20x)
- ↑ Prostacyclin and thromboxane

(from 4.7 to 3.2 g/dL), a significant decrease in the oncotic gradient across the glomerular basement membrane has not been found in animal models.

Tubular function also changes. The threshold for reabsorption of glucose increases, and glycosuria may occur without hyperglycemia [4]. Amino acid excretion is increased.

Uric acid clearance is increased in pregnancy from 6 – 12 mL/min to 12 – 20 mL/minute [6]. Increased glomerular filtration is the primary cause of increased uric acid clearance, but a role for decreased tubular reabsorption is suggested by an increase in the ratio of urate to inulin clearance. Normal uric acid in pregnancy is 3 – 4 mg/dL, and an increase in serum uric acid is a sensitive indicator of preeclampsia.

Salt and Water

Pregnancy is accompanied by retention of 900 mEq of sodium and 6 – 8 liters of water, of which 4 – 6 L is in the maternal intravascular and interstitial space. Plasma aldosterone begins to increase early in the first trimester and reaches 5 fold elevation by 16 weeks gestation and a 7–10 fold elevation by term. Early in the third trimester, serum aldosterone levels are 7–10 times greater than in the nonpregnant state, with greater elevations in urinary aldosterone [7]. Plasma renin activity (PRA) increases 4 fold early in pregnancy and then plateaus. Angiotensin II (Ang II) levels double early in pregnancy and rise to 3–4 times normal by term. Despite increased serum levels, pregnant women retain sodium and shut off aldosterone secretion in response to exogenous mineralocorticoid administration.

Osmolality

The osmostat is reset such that thirst is experienced at a level 10 mOsm below the nonpregnant normal, and serum sodium is about 5 mEq/L below nonpregnant normal. The set point for ADH release is decreased from a serum osmolality of 285 to 276 – 278 mOsm/L. While ADH is released at a lower serum osmolality, the rate of metabolic breakdown of ADH is increased because of vasopressinase produced in the placenta [8]. A short-lived diabetes insipidus (DI) secondary to excessive placental vasopressinase may occur in the third trimester. The syndrome is classified as neither central nor nephrogenic. It does not respond to ADH but does respond to synthetic desmopressin (DDAVP), which is not broken down by the enzyme [9]. Women with mild central DI suffer a worsen-

ing of their disease during pregnancy because they cannot increase vasopressin production.

Acid-base Metabolism

Pregnancy is accompanied by a chronic respiratory alkalosis caused by increased ventilation in response to progesterone [10]. Normal partial pressure of CO_2 (Pco_2) is 27 – 32 mm Hg, and normal serum bicarbonate is 18 – 21 mEq/L. The urine is usually alkaline. Changes in acid-base status should be kept in mind when evaluating maternal conditions associated with an increase in serum bicarbonate, such as vomiting and diuretic use. Increases in serum bicarbonate to the high 20s or low 30s may reflect critical alkalemia.

Hemodynamic Changes

Diastolic blood pressure decreases by 7 – 10 mm Hg during the first trimester and returns to prepregnancy levels in the third trimester. Changes in systolic blood pressure are less marked because the increase in cardiac output that occurs in normal pregnancy offsets the vasodilatation. The drop in blood pressure in normal pregnancy occurs despite sodium retention and increased levels of renin, angiotensin, and aldosterone. There is resistance to the hypertensive effects of both endogenously- and exogenously-administered angiotensin. The resistance has been attributed to production of prostacyclin by placental endothelial cells as well as other vasodilators, the relative importance of which is an area of intense study.

Hypertensive Disorders of Pregnancy

Hypertension complicates about 2 – 10% of pregnancies in the United States and is the most important cause of maternal morbidity [11]. In a previously normotensive woman, a rise in systolic blood pressure of 30 mm Hg or a rise in diastolic blood pressure of 15 mm Hg on 2 measurements taken 6 hours apart is considered hypertension. Women with a mean arterial pressure > 90 mm Hg in the second trimester have an increased frequency of stillbirth and neonatal death [12].

Classification

Most centers in the United States use the classification for hypertension in pregnancy proposed by the American College of Obstetricians and Gynecologists in 1972 [11]. This classification divides the hypertensive disorders of pregnancy into preeclampsia, chronic hypertension, chronic hypertension with superimposed preeclampsia, and gestational hypertension. The latter is a retrospective diagnosis. Hypertension occurs late in pregnancy without proteinuria and resolves postpartum. It may recur in subsequent pregnancies and is predictive of hypertension in later life.

Preeclampsia

Clinical Presentation

Preeclampsia is characterized by the triad of edema, hypertension, and proteinuria occurring after 20 weeks gestation. Risk factors for preeclampsia are listed in Table 2. Preeclampsia and eclampsia may develop post-

Table 2. Risk Factors for Preeclampsia

– Primigravida
– Different father in pregnancy for multigravida
– Diabetes
– Preexisting hypertension
– Renal disease
– Twin gestation
– Hydatidiform mole
– Fetal hydrops
– Family history

Table 3. Signs and Symptoms of Severe Preeclampsia

– Thrombocytopenia
– Microangiopathic hemolytic anemia
– Elevated transaminases
– Disseminated intravascular coagulation (DIC)
– Congestive heart failure (CHF)
– Retinal detachment
– Ascites
– Seizures
– Cortical blindness
– Acute renal failure (ARF)
– Hepatic rupture

partum, with 20% of the severe form of preeclampsia referred to as HELLP syndrome (see below) [13] and 4 – 10% of seizures [14] occurring postpartum.

Although the development of edema is part of the classic description of preeclampsia, clinically it can be difficult to interpret. Eighty percent of pregnant women develop edema during pregnancy, and, paradoxically, edema may be absent in some women with severe preeclampsia. Nonetheless, the first manifestation of preeclampsia is often a rapid weight gain that may precede the development of hypertension and proteinuria. The latter conditions usually appear after weight gain, and preeclampsia is unlikely in their absence. Symptoms of severe preeclampsia include headache, visual disturbances, and right upper quadrant pain. Objective observation of blood pressure or proteinuria is more important than subjective symptoms in making the diagnosis of preeclampsia because 59% of women who progress to eclampsia have no premonitory symptoms [15].

Severe preeclampsia is a multisystem disease (Table 3). The most common abnormalities are microangiopathic hemolytic anemia, elevated liver enzymes, and low platelets, giving rise to the acronym HELLP.

Hemolytic anemia is characterized by schistocytes on peripheral smear. The magnitude of hemolysis may be masked by intravascular volume contraction, which leads to a hematocrit higher than it otherwise would be. The platelet count may drop below 20,000 platelets/mm^3 as a result of platelet activation and consumption. There is consumption of clotting factors even in the absence of changes in prothrombin time (PT) and partial thromboplastin time (PTT). In approximately 20% of instances, frank disseminated intravascular coagulation (DIC) is seen [13]. There is an association of abruptio placentae with the development of DIC.

The liver disease of preeclampsia presents with right upper quadrant pain and elevated bilirubin and transaminases. Preeclampsia is one of a handful of conditions that can result in transaminase levels > 1000 U/L. Pathology is characterized by periportal hemorrhage and deposition of fibrin and fibrinogen in the sinusoids. The most severe manifestation is hepatic rupture, which may result in exsanguination.

GFR is generally decreased in preeclampsia but may remain within the nonpregnant normal range. Severe preeclampsia may give rise to acute renal failure (ARF) with acute tubular

necrosis (ATN) and, rarely, cortical necrosis (see section below on acute renal failure).

Loss of vision has been described in preeclampsia. There are rare reports of retinal detachment [13]. A second uncommon cause of blindness is occipital ischemia, which gives rise to low-density areas on computed tomography (CT) scan and hyperintense lesions on magnetic resonance imaging (MRI) [16]. This occipital blindness is generally reversible.

Ascites occurs in as many as 10% of patients with HELLP syndrome and is associated with a 26% incidence of congestive heart failure (CHF) [17]. Although pulmonary edema may occur in severe preeclampsia, information about hemodynamic changes in preeclampsia is conflicting. There is a marked increase in peripheral resistance and a decrease in intravascular volume, despite sodium retention. Measurements of pulmonary capillary wedge pressure prior to treatment tend to be low normal but are increased in patients with CHF.

The risk of eclampsia in women with preeclampsia depends in great part on prenatal care and management once preeclampsia is present. Eclampsia occurs in < 1% of patients with preeclampsia in some large centers with extensive experience in managing such patients [18]. Severe preeclampsia has been defined by a blood pressure > 160/110, heavy proteinuria, or neurological symptoms, but making the distinction is fraught with hazard. While any one of the manifestations listed above is associated with a high risk of eclampsia, seizures may occur even without proteinuria and when the blood pressure is only mildly elevated or not elevated at all. Douglas and Redman reported on every instance of eclampsia occurring in England in 1992. Nine percent had neither proteinuria nor elevated blood pressure before seizure. Eighty-five percent of seizures occurred within 1 week of a prenatal visit, and only 26% were judged to have had substandard prenatal care. These data suggest that eclampsia cannot be anticipated in some instances. They also suggest that the distinction frequently made between mild and severe preeclampsia may lead to a false sense of security and decreased vigilance in caring for women thought to have mild preeclampsia.

Pathology

The characteristic pathologic changes in the kidney of women with preeclampsia include swelling of the endothelial cells (glomerular endotheliosis), ballooning of capillary loops into the tubule, fibrinogen and lipid in endothelial cells, and occasional foam cells. Rarely, changes similar to focal sclerosis occur, with reversal postpartum. Ischemic changes are less marked than in other organs. The renal pathologic changes resolve 2 – 4 weeks postpartum [19].

Pathophysiology

Preeclampsia is an endothelial cell disorder that may develop in response to placental ischemia resulting from an inadequate trophoblastic migration into the uterine spiral arteries [20]. In normal pregnancy at 16 weeks, the spiral arteries in the uterus lose their musculoelastic tissue and widen to allow an increase in uterine blood flow. In preeclampsia, this loss of musculoskeletal tissue may not occur and there may be necrosis, which gives the spiral arteries the appearance of acute atherosclerosis. Endothelial cell dysfunction leads to increased production of vasoconstrictors and activation of the clotting system. There is increased vascular permeability.

Much of the study of preeclampsia has centered on the pathophysiology of vasoconstriction. The study of the vasoactive substances is confounded by the difficulty of interpreting the effect of changes in the systemic levels of substances that have their greatest effect at the site of production. During normal pregnancy, production of both vasodilator (prostacyclin) and vasoconstrictor (thromboxane) by endothelial cells is increased, and the balance favors the effects of prostacyclin [21]. In preeclampsia, the ratio of thromboxane and prostacyclin production changes, with decreased prostacyclin production and increased thromboxane production, resulting in the predominance of thromboxane effect with diffuse vasoconstriction [21]. Resistance to the pressor effects of angiotensin decreases. In normal pregnancy, endothelin (ET) production by endothelial cells is decreased. Serum levels increase in women with preeclampsia, and because ET is a vasoconstrictor and facilitates platelet aggregation, the possibility that it plays a role in the pathogenesis of preeclampsia has been raised [22]. It is not clear whether increased ET production is a cause or effect of endothelial cell damage.

Decreased endothelial cell production of nitric oxide (NO) has also been suggested as playing a role in the development of preeclampsia. In animal models, blockade of NO production can produce a syndrome similar to preeclampsia [23]. However, serum from preeclamptic women does not change NO production by endothelial cells in vitro. Much of the end-organ disease seen in preeclampsia can be attributed to hypoperfusion resulting from vasoconstriction. Activation of platelets and the intrinsic coagulation pathway also plays a role, producing fibrin deposition and hemorrhage in the liver and generalized bleeding. The pathophysiology of seizures in this disorder is not known. Neurologic manifestations of preeclampsia may be from a combination of mechanisms, including hypoperfusion, bleeding, and cerebral edema. The decreased GFR appears to be caused by a combination of hypoperfusion and capillary occlusion by swollen endothelial cells.

Prevention of Preeclampsia

Numerous attempts have been made to develop a test which will identify women at high risk for the development of preeclampsia. All have been either too invasive for practical use or simply inaccurate. Two interventions have been extensively investigated to determine whether they prevent preeclampsia: low-dose aspirin and calcium supplementation. Despite initial promise, the effects of these two treatments have been disappointing in large trials.

Aspirin Prophylaxis of Preeclampsia

The discovery of the changes in prostacyclin and thromboxane ratios in preeclamptic pregnancies led to efforts to prevent preeclampsia in high-risk women by giving low-dose aspirin. Several small studies demonstrated the usefulness of low-dose aspirin in preventing preeclampsia in women identified as being at high risk [24 – 26]. A placebo-controlled study of 3135 healthy nulliparas found a rate of preeclampsia of 4.6% in the aspirin-treated group and 6.3% in the untreated group ($p = .05$) [27] The Low Dose Aspirin Study in Pregnancy [28] is the largest study of the efficacy of low-dose aspirin in the prevention of preeclampsia. Women ($n = 9364$) at risk for preeclampsia or intrauterine growth retardation (IUGR) were randomized to either low-dose aspirin (60 mg/day) or placebo. This study showed a 12% lower frequency of preeclampsia in the aspirin-treated group, a difference which was not statistically significant. Aspirin administration was associated with a

significant decrease in preterm delivery (19.7% vs. 22.2% for control.) Although the difference in the frequency of preeclampsia was not different for the two groups as a whole, aspirin did reduce the frequency of very early preeclampsia in which the risk of delivery to the fetus is greatest. In both these studies, the effectiveness of aspirin may have been diluted by the inclusion of low-risk women. Three other recent randomized, double-blind, placebo-controlled trials including over 11,000 high-risk women [29 – 31] have not found an effect, even in the subset of women with severe, early-onset preeclampsia. When the data in 2 of these studies were analyzed taking compliance into account, aspirin still had the effect of reducing preeclampsia [32].

The 1993 study found a slight increase in the frequency of abruptio placentae in the aspirin-treated group. The Collaborative Low Dose Aspirin Study in Pregnancy (CLASP) found that the use of low-dose aspirin in pregnancy carries a very low risk of dangerous bleeding, although there was a slight increase in the number of women requiring peripartum transfusions.

Even with the limitations of these studies and the suggested benefit of aspirin in some of the subanalyses, any dramatic benefit from aspirin should have been apparent in studies including >20,000 women. However, women with preexisting renal disease are among those at highest risk for preeclampsia, and the safety of aspirin in these large trials allows defending its use in this subgroup while awaiting the results of subanalyses.

Calcium Supplementation

The results of a prospective, randomized study involving 1194 nulliparous women were reported in 1991. A group receiving 2 g of elemental calcium was found to have a frequency of preeclampsia of 9.8% compared to 14.8% in a placebo-control group [33]. No effect on IUGR or perinatal death was noted. The findings were supported by several other small studies.

The US National Institute of Heath and Human Development has recently completed a prospective, randomized, double-blind, placebo-controlled study that found no difference in the frequency of preeclampsia in 2295 women taking 2 g of calcium daily and 2294 women taking placebo [34]. Nonetheless, pregnant women should routinely receive calcium supplements for bone protection and for calcification of the fetal skeleton.

Treatment of Preeclampsia

The definitive treatment for preeclampsia is delivery of the baby (see Table 4). The manifestations of preeclampsia must be managed until delivery can be effected, or when preeclampsia occurs very early in gestation and is mild enough to warrant an attempt to prolong the pregnancy.

A woman with suspected preeclampsia should be hospitalized because of the difficulty in predicting seizures. A number of pro-

Table 4. Treatment of Preeclampsia

– Admit to hospital
– Anticonvulsants: magnesium sulfate
– Antihypertensive drugs: hydralazine, labetolol
– Indications for delivery
≥ 36 weeks gestation
BP ≥ 160/110 after 24 hours of hospitalization
HELLP syndrome
≥ 3 g of protein in 24 hours
Rising serum creatinine
Headache, blurred vision, scotomata, right upper quadrant pain, clonus

tocols have been developed for intensive home monitoring of women with mild preeclampsia after initial hospitalization. The burden of proof of their safety in comparison to hospitalization rests with their advocates.

There is no reason to delay delivery if the pregnancy has reached 36 weeks gestation. Other indications for delivery include any manifestation of the HELLP syndrome, neurologic symptoms, rising serum creatinine, a blood pressure > 160/110 after 24 hours of hospitalization, and impending or actual seizures. Attempts have been made to manage severe preeclampsia at < 28 weeks gestation [35] and even to prolong pregnancy following a seizure, but we consider this approach too dangerous for general use.

Seizure prophylaxis is required while preparations for delivery are made. There has been a long-standing transatlantic difference in the approach to seizure prevention. Magnesium sulfate has been widely used in the United States, while European centers have favored other anticonvulsants, such as phenytoin and benzodiazepines. Magnesium sulfate appears to be preferable, based on a large, prospective, randomized study [18] in 1089 preeclamptic women assigned to treatment with phenytoin and 1049 assigned to treatment with magnesium sulfate. There were 10 instances of eclampsia in the phenytoin-treated group, but none in the magnesium-treated women. Magnesium sulfate was also more effective than phenytoin and diazepam for prevention of recurrent seizures in 1687 women who had had eclampsia [36]. The mechansim of action of magnesium sulfate has been attributed to its direct vasodilator effect and a possible effect in increasing prostacyclin production. It should be remembered, however, that magnesium sulfate is excreted by the kidneys, and oliguric women or women with preexisting renal insufficiency should be monitored carefully and treated with lower doses. Magnesium is a calcium channel blocker and its use with other calcium channel blockers may result in profound hypotension.

The combination of sodium retention and intravascular volume contraction have led to treatment of preeclampsia with both diuretics and with volume expansion. Both approaches are misguided. Diuretics aggravate hypoperfusion of vital organs and should be reserved for women with congestive heart failure. Volume expansion increases the risk of pulmonary edema. Hemodynamic monitoring by Swan-Ganz catheter is advised before using either of these interventions.

Treatment of hypertension does not reverse preeclampsia, and may even disguise progression, but is required to prevent the most severe complications of preeclampsia, including cerebral hemorrhage. Treatment is usually started when the diastolic blood pressure is 105 mm Hg but should be instituted earlier in women with very low blood pressures early in pregnancy. The drugs used to treat hypertensive emergencies in pregnancies are discussed below. The goal of blood pressure reduction is a diastolic blood pressure of 90 – 100 mm Hg.

Chronic Hypertension

Essential hypertension more often affects mothers in the later childbearing years. With the growing number of late pregnancies and even postmenopausal pregnancies, the importance of this problem can be expected to increase.

Almost half of the women with essential hypertension have a fall in blood pressure into

the normal range during the second trimester with a return to baseline elevated levels in the third trimester. This drop makes it difficult to determine whether a woman seen for the first time in the second trimester with normal blood pressure has essential hypertension or preeclampsia when the blood pressure rises in the third trimester.

Women with chronic hypertension have an increased risk of preeclampsia, perinatal mortality, small for gestational age (SGA) babies, premature delivery, and, in some series, gestational diabetes [37].

Women with severe essential hypertension (BP > 170/110) are at the greatest risk for preeclampsia and are also at risk for cerebral hemorrhage and abruptio placentae. The frequency of superimposed preeclampsia in this group is high: 52% in one group of 44 such women [38]. The perinatal mortality was 25% in the latter report. Seventy percent of infants were premature and 43% were SGA. Maternal complications included one instance of abruptio placentae, deterioration of renal function in 20 (permanent), and one episode of hypertensive encephalopathy. The frequency of superimposed preeclampsia in women with mild hypertension ranges from approximately 5.2 – 18.4%. Maternal and fetal morbidity are increased even with mild hypertension, but the efficacy of pharmacologic treatment in preventing complications in women with mild hypertension and the level of blood pressure at which treatment should be instituted are a matter of debate. There is conflicting evidence whether treatment of mild hypertension prevents worsening of hypertension later in pregnancy and whether treatment lowers perinatal mortality [39 – 43]. We take the position that safe medications are available for the treatment of hypertension during pregnancy, and treatment should begin at a blood pressure > 140/90.

Antihypertensive Medications

The effects of various antihypertensive medications in pregnancy are reviewed in Table 5. The Food and Drug Administration (FDA) designation (see appendix for explanation) is included, but does not adequately reflect the risks and safety of the various drugs.

Angiotensin Converting Enzyme (ACE) Inhibitors

ACE inhibitors are contraindicated in pregnancy. Animal studies reported a high frequency of stillbirths in animals exposed to ACE inhibitors during pregnancy, resulting in a recommendation against their use in human pregnancy by a committee of the National Institutes of Health [44]. Exposure to ACE inhibitors in the second and third trimester has been associated with renal tubular dysplasia, hypocalvaria, hypoplastic lungs and limb contractures [45]. Renal tubular dysplasia has been attributed to fetal hypotension and decreased renal perfusion. ACE inhibitors are associated with decreased fetal urine output and oligohydramnios. Amniotic fluid is required for normal pulmonary development, and oligohydramnios is responsible for the instances of hypoplastic lungs. Many of the neonatal deaths in infants exposed to ACE inhibitors are the result of respiratory failure. Oligohydramnios also accounts for limb contractures. Direct pressure of the uterine muscle on the fetal skull is thought to result in abnormal calcification of the skull. Several instances of patent ductus arteriosus have been described. This effect is thought to be the result of the effects of ACE inhibitors on prostaglandin metabolism.

Two studies, involving 46 and 86 infants, respectively, showed no adverse effect of exposure to ACE inhibitors in the first trimester

Table 5. Antihypertensive Drugs in Pregnancy

Drug (Category)	Comments
Chronic hypertension	
ACE inhibitors(D)	Contraindicated. 2nd and 3rd trimester use associated with pulmonary hypoplasia, hypocalvaria, renal dysplasia, neonatal anuria, contractures. No known harm in 1st trimester.
Methyldopa (C)	Safe. 40-year use. Careful developmental testing of children at ages 4 and 7.
Beta Blockers (C)	Probably safe. Fetal bradycardia, hypoglycmia, respiratory depression at birth, intrauterine growth restriction
Labetolol (C)	Limited first trimester experience. Less bradycardia and growth restriction than β blockers.
Clonidine (C)	Probably safe. Limited 1st trimester exposure.
Calcium channel blockers (C)	Profound hypotension with when used magnesium. Limited experience. Reserve for severe hypertension.
Hydralazine (C)	Safe. Long experience with use in pregnancy. No increase in birth defects.
Minoxidil (C)	Very limited experience. Hypertrichosis in the infant.
Prazocin (C)	Limited experience. No problems noted.
Thiazide diuretics (D)	Increased congenital anomalies with chlorthaldone. Decreased intravascular volume expansion,neonatal thrombocytopenia, hemolytic anemia, electrolyte abnormalities
Hypertensive crisis	
Hydralazine (C)	Used for 40 years without serious side effects
Labetolol (C)	Shorter length of use. Appears safe.
Nitroprusside (C)	Fetal cyanide toxicity
Diazoxide (C)	Fatal maternal hypotension reported. Limit dose to 30 mg boluses. Decreased uterine contraction. Neonatal hyperglycemia.

[46]. In the latter report, there were 4 congenital anomalies, a number not significantly different from the 3 expected [46]. However, our understanding of the role of the renin-angiotensin system in early renal development is incomplete, and an as-yet unrecognized adverse effect of ACE inhibitors on this process is possible. The absence of demonstrated ill effects of ACE inhibitors following first trimester exposure is of considerable importance. Women with inadvertent first trimester exposure need not be advised to terminate the pregnancy. A more important issue is whether women with nephropathy taking ACE inhibitors for their renoprotective effect need to discontinue them in planning for pregnancy if there is some assurance that pregnancy can be diagnosed promptly and the drug stopped at that point. For women with normal renal function where conception can be expected to occur within a year, stopping ACE inhibitors in planning pregnancy is warranted. However, for women with moderately impaired renal function who may not conceive for years, discontinuation of ACE inhibitors may not be necessary.

There is less experience with Ang II receptor blockers, but it is expected that problems caused by decreased angiotensin effect will be similar.

Diuretics

The obstetric community is strongly averse to using diuretics during pregnancy. At one point, diuretics were widely used in the hope that by reducing edema and hypertension might prevent preeclampsia. These drugs did not prove to be effective for this purpose, and they aggravated the decreased intravascular perfusion seen with preeclampsia, possibly contributing to organ hypoperfusion [47]. The failure of diuretics to prevent preeclampsia now discounts the observation that their use in women with edema was rarely associated with adverse effects. A report documenting a subnormal expansion of intravascular volume in women with essential hypertension treated with diuretics did not show increased perinatal mortality [48]. For essential hypertension, other drugs are preferred, but diuretics may be useful in hypertension associated with renal insufficiency and salt-sensitive hypertension. There are some reports of neonatal thrombocytopenia, hemolytic anemia, jaundice, and electrolyte abnormalities with thiazides, but most of the concern about their use centers on their effects on intravascular volume [49, 50].

Beta Blockers

There have been several case reports of neonatal bradycardia, hypoglycemia and respiratory depression associated with beta blockers, but these problems are generally easily managed by the neonatologist [51]. Data are mixed concerning whether beta blockers are associated with IUGR and there are reports of SGA infants born to mothers treated with beta blockers for diseases not usually associated with growth restriction [52]. There are also data from animal models suggesting a decreased ability of the fetus to withstand anoxic stress [53]. None of these problems has turned out to be a major contraindication to the use of this category of drugs. Fetal bradycardia may make it difficult to interpret antenatal monitoring, which depends on changes in fetal heart rate.

Labetolol

Labetolol is not associated with fetal bradycardia and IUGR and it is widely used in preference to beta blockers. Nonetheless, data on first trimester effects of the drug are still limited. Moreover, controlled studies have not shown it to be superior to other antihypertensive agents [41, 46, 54].

Methyldopa

Methyldopa has been used in pregnant women for over 40 years and is still the drug of choice for essential hypertension. Careful developmental studies have been done in children at 4 and 7 years of age exposed to the drug in utero, and no problems have been found [55]. One study of 242 women with diastolic blood pressures of 90 – 110 mm Hg randomized to treatment with methyldopa versus placebo showed decreased fetal loss in the methyldopa-treated group [56].

Clonidine

Clonidine is a centrally acting α2-agonist reported in one study to have efficacy and safety similar to methyldopa [57]. In view of the limited experience with it, there is no reason to use it in preference to methyldopa.

Calcium Channel Blockers

Nifedipine, nicardipine, and verapamil have been used in severe hypertension. They do not appear to be associated with any increase in congenital anomalies when used in the first trimester. These drugs have been used for tocolysis in the third trimester. There is limited experience with diltiazem. Calcium channel blockers may potentiate the hypotensive effects and neuromuscular blockade of magnesium, and the interaction should be kept in mind when the drugs are used in women at risk for preeclampsia [58, 59]. Because of limited experience, their use is best restricted to severe hypertension unresponsive to other drugs.

Prazocin

No adverse effects on the fetus have been demonstrated with prazocin drugs, but the experience with it is more limited than with labetolol, methyldopa, and β blockers, and it does not appear to offer any advantage. The drug can be continued in women whose blood pressure is well controlled on it at the time of conception.

Hydralazine

Hydralazine has been used safely during pregnancy for 40 years. It is ineffective as a single oral agent but can be added to a first-line drug if the latter is ineffective alone.

Minoxidil

The more potent vasodilator, minoxidil has been associated with hypertrichosis and congenital anomalies in one case report [60]. It is ineffective unless combined with a diuretic and a sympatholytic agent.

Drugs for Hypertensive Emergencies

Hydralazine

Intravenous hydralazine in doses of 5–10 mg every 20 – 30 minutes is the drug of first choice for hypertensive crisis in pregnancy. A single study has shown a higher frequency of malignant ventricular arrhythmias in eclamptic women treated with hydralazine than in women treated with labetolol [61]. Nine studies comparing hydralazine with other drugs, most often intravenous labetolol, have found no advantage of one drug regimen over another [62].

Labetolol

Intravenous labetolol given either as a 20 mg loading dose followed by 20 – 60 mg every 30 minutes, or a 1 – 2 mg/min drip is the second most commonly used regimen for treating hypertensive emergencies in pregnant women. There are occasional reports of fetal bradycardia, and the newborn should be monitored for hypotension.

Diazoxide

There is extensive experience with the use of diazoxide in pregnancy, but the drug is now primarily of historic interest. In doses of 150 – 300 mg, it has been associated with at least one maternal fatality from hypotension. It is also associated with decreased uterine contractions and neonatal hyperglycemia. Its only

advantage is a long duration of action, which may make it useful in a woman who must be transported with minimal monitoring capability, or when other drugs have failed. It should be used only in 30 mg boluses every 1 – 2 minutes until the desired blood pressure is reached.

Nitroprusside

Nitroprusside carries the risk of fetal cyanide toxicity, and it should be used with caution, especially in women with renal insufficiency.

Nifedipine

Because of its interaction with magnesium sulfate and the general movement away from using short-acting nifedipine for hypertensive emergencies in nonpregnant patients, nifedipine should not be used as a first-line drug in hypertensive emergencies of pregnancies.

Chronic Hypertension with Superimposed Preeclampsia

Ten percent of women with mild hypertension and up to 50% of women with severe hypertension develop superimposed preeclampsia. The diagnosis depends on an increase in blood pressure over baseline levels and development of proteinuria. Since there is frequently a modest increase in blood pressure in hypertensive women in the third trimester, proteinuria is more important to the diagnosis. The absolute level of blood pressure is frequently higher in these women than in women with isolated preeclampsia. It is the group of women with superimposed preeclampsia in whom the frequency of abruptio placentae and cerebral hemorrhage is increased.

Secondary Hypertension in Pregnancy

Secondary hypertension in pregnancy is generally uncommon, but several causes bear discussion.

Pheochromocytoma

Pheochromocytoma is exceedingly rare, but is associated with a 50% maternal mortality rate if it is undiagnosed, and it should be excluded if the suspicion arises [63]. The maternal mortality rate is 11%, even if the diagnosis is made antepartum. Catecholamines do not cross the placenta and the fetus is not exposed to high levels, but there may be placental hypoperfusion secondary to vasoconstriction. Hypertension can be precipitated by labor. Urine and plasma norepinephrine and epinephrine are unchanged in normal and preeclamptic pregnancy, and the usual biochemical screening can be used. Surgery is generally the treatment of choice after two weeks of treatment with α blockers. An unusual complication of pregnancy is compression of an extra-adrenal pheochromocytoma located at the aortic bifurcation in the organ of Zuckerkandl by the expanding uterus.

Cocaine

Cocaine use is a common cause of secondary hypertension in young women and may

have a similar clinical presentation to pheochromocytoma. Serum and urine screening usually makes the diagnosis and α blockers are required for treatment. Cocaine use is associated with an increased risk of abruptio placentae [64].

Hyperaldosteronism

Hyperaldosteronism is uncommon in pregnancy. Basal aldosterone levels in pregnancy are elevated but are suppressible by salt loading and exogenous mineralocorticoid [63]. Plasma renin is usually but not always, suppressed rather than showing the usual pregnancy-associated elevation. Progesterone counteracts the potassium-wasting effect of aldosterone, and hypokalemia may be absent. Bilateral disease is treated medically. Spironolactone, used in nonpregnant individuals, is an antiandrogen and may cause abnormal genital development in male fetuses. Amiloride can be used in pregnancy to treat primary hyperaldosteronism.

Renal Artery Stenosis

Renal artery stenosis is uncommon, and its effect on pregnancy is related to the severity of the hypertension. Management is complicated by the inability to use ACE inhibitors, but other medications are frequently effective. Angioplasty has been successfully carried out during pregnancy [65].

Long-Term Prognosis of Hypertensive Disorders

Studies of the long-term effects of hypertensive disorders of pregnancy have been confounded by the failure of many reports to distinguish preeclampsia from chronic hypertension. Chesley followed 270 women who had survived eclampsia in a landmark study of the long-term consequences of the disease. Only one-third of the women who had subsequent pregnancies developed hypertension. In a separate study of 354 subsequent pregnancies in 151 nulliparous women who survived eclampsia, severe preeclampsia recurred in 5.3% and eclampsia recurred in 2% [66]. The risk of recurrence of the HELLP syndrome is approximately 20% [67]. Chesley followed 197/206 nulliparous women with eclampsia for an average of 33 range (23 – 42) years, by which time > 81% of the women were older than 50 years of age [68]. The frequency of hypertension, mortality (16.6%) and cardiovascular mortality (4.8%) in white women was similar to the general population. Mortality in 19 nulliparous black women who survived eclampsia was twice that of white women, but was not increased compared to the general black population. The mortality rate for the 59 multiparous white women was 56%, but 100% and for the 5 black multiparous women surviving eclampsia. By using eclampsia to define the group, Chesley excluded women with simple chronic hypertension, while including women with preeclampsia superimposed on chronic hypertension. The conclusion is that preeclampsia is a predictor of mortality and cardiovascular disease only when it is superimposed on essential hypertension.

Renal Infections in Pregnancy

Asymptomatic bacteriuria, defined as > 10^5 colony-forming units (CFU) of a single organism cultured from a clean-catch midstream urine specimen, occurs in 5% to 10% of pregnancies. While this frequency is no higher than for normal nonpregnant women, the consequences are greater, as up to 30% of pregnant women with asymptomatic bacteriuria will go on to develop pyelonephritis if untreated [69]. In recent years, screening programs and treatment of asymptomatic bacteriuria have led to a decline in the frequency of pyelonephritis in pregnant women. In one report, the incidence of pyelonephritis declined from 1.8% – 0.6% of pregnancies [70]. Screening by urine culture should be done at the first prenatal visit. Other tests for bacteriuria, such as urine dipstick for nitrate and leukocyte esterase, have not proven to be sensitive enough for use in screening [71], and the urine sediment may contain an increased number of white blood cells during pregnancy, even in the absence of infection.

A positive urine culture should be treated for 7 – 10 days with antibiotics chosen on the basis of sensitivity of the organism and safety in pregnancy. Surveillance cultures should be done a week after the completion of treatment and every 4 – 6 weeks thereafter to monitor for relapse. A second positive culture warrants another course of treatment, and a relapse within a week of the initial antibiotic therapy should be treated with a different drug. For patients who relapse a second time, the usual course of antibiotics is followed by suppressive therapy for the rest of the pregnancy. Women with 2 or more relapses should undergo urologic evaluation when they are 12 weeks postpartum, i.e. after pregnancy-induced changes in the urinary tract have had sufficient time to revert to normal [69, 72]. Patients who have a negative urine culture at initial evaluation and no other risk factors for urinary tract infection do not need additional testing unless symptomatic. In most cases, asymptomatic bacteriuria represents a preexisting condition, because the risk of acquiring asymptomatic bacteriuria during pregnancy peaks near term at 2% [73].

The most commonly occurring organisms in asymptomatic bacteriuria are gram negative bacteria, with *Escherichia coli* responsible for up to 90% of positive cultures, followed by the *Klebsiella Enterobacter* group (5 – 15%), *Proteus* species (1 – 10%), and gram positives such as coagulase-negative *Staphylococcus* (1 – 11%), *Streptococcus faecalis* (1 – 4%), and group B *Streptococcus* (1 – 4%). Antibiotics should be chosen carefully in pregnancy. Ampicillin is safe in pregnancy; however, up to 30% of E. coli are resistant to it [69], and antibiotic sensitivities are continuously changing. First-generation cephalosporins, e.g. cefazolin and cefalexin, are safe in pregnancy. Cephalosporins with a methyltetrathiazole moiety (cefoperozone, cefotetan, moxalactam, and cefamandole) are usually avoided in pregnancy because studies have shown infertility in animals [74]. Nitrofurantoin, an antibiotic specific for the urinary tract, is safe in pregnancy and effective against the most common causative organisms. It cannot be used in women with renal insufficiency. It can cause hemolysis in the male fetus of a woman who carries glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, and patients should be screened for this history prior to use. Sulfa drugs, such as sulfamethoxazole, can be used in the early part of pregnancy but should be avoided in the latter part because of the risk of kernicterus. Trimethoprim and trimethoprim-sulfamethoxizole combinations are generally avoided because of the

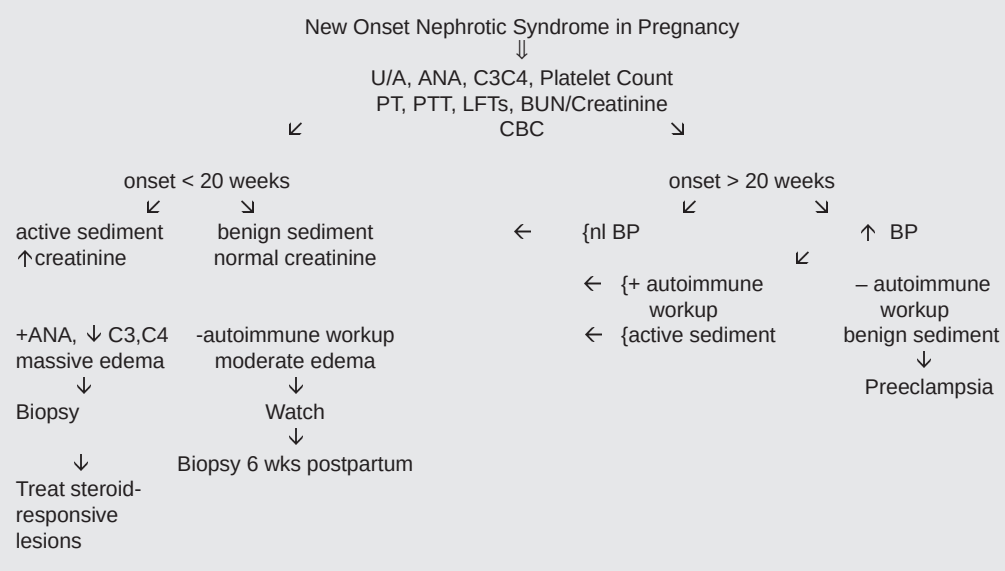

Figure 1. New Onset Nephrotic Syndrome in Pregnancy.

teterogenicity of folic acid antagonists. In practice, significant increases in congenital anomalies have not been noted with these drugs. The quinolone antibiotics should be avoided in pregnancy because they have been associated with weakened cartilage in young animals. Aminoglycosides should also be avoided because of their association with eight nerve damage [74].

Pyelonephritis in pregnancy is a severe infection associated with bacteremia, hypotension, premature labor, and, in 2% of patients with respiratory failure. Pyelonephritis during pregnancy is often associated with a decline in GFR. In a study of 220 women hospitalized for pyelonephritis, Whalley and colleagues observed that 25% of women had a creatinine clearance < 80 cc/min [75]. On reevaluation 3 – 8 weeks after treatment, 18 women whose creatinine clearance had fallen to < 70 mL/min had had a return to normal or near-normal renal function. Pregnant women with pyelonephritis should be treated aggressively with antibiotics and fluid resuscitation. Hospitalization and initiation of intravenous antibiotics have been the traditional standard of care. Relatively stable pregnant patients with pyelonephritis treated on an outpatient basis with intramuscular ceftriaxone showed recurrence rates similar to those of women treated with intravenous cefazolin. Antibiotic therapy should be continued for 2 weeks, and suppressive therapy may be continued for the remainder of the pregnancy. Women who fail to improve within 3 days of antibiotic therapy should undergo ultrasound evaluation to rule out nephrolithiasis. Ultrasound may be difficult to interpret because of hydronephrosis and, if suspicion is high, additional radiographic tests may be needed.

Nephrolithiasis in Pregnancy

Several changes in pregnancy might be expected to lead to increased stone formation. Urinary stasis in the dilated collecting system is accompanied by hypercalciuria, increased supersaturation levels of calcium, oxalate, and phosphate, and an alkaline urine. However, there is an increased excretion of magnesium citrate as well as the glycoprotein nephrocalcin, which inhibit stone formation [76]. Nephrolithiasis is a common cause of abdominal pain in pregnant women and may be overlooked when evaluation focuses solely on obstetric problems. The seriousness of infection associated with stone disease outweighs any potential adverse fetal effect of radiation required to diagnose and treat stone disease. Stones may be difficult to visualize on plain abdominal films because they may be obscured by the fetal skeleton late in pregnancy, and ultrasound is difficult to interpret. Intravenous pyelography (IVP) or spiral CT scan can be used to diagnose and locate the stone. Retrograde pyelography for diagnostic purposes or stent placement can be performed but requires considerable urologic finesse late in pregnancy. The effects of lithotripsy during pregnancy are not known, and it should not be used.

Development of Proteinuria

When proteinuria develops de novo in a woman receiving regular prenatal care, much of the diagnostic evaluation has already been done: glucose tolerance testing, screening for infectious causes of nephrotic syndrome, e. g. HIV, hepatitis B and C, and syphilis, and a history of prescription, over-the-counter and illicit drug use. The remaining crucial issues that need to be addressed are presented in Figure 1.

Diagnosis of Preeclampsia

Preeclampsia is the most common cause of proteinuria in pregnant women, and most women are presumed to have preeclampsia unless there is some atypical feature that points to another renal disease. The likelihood of another renal disease is very high if the onset of proteinuria occurs before 20 weeks gestation, if there is no hypertension, if there is an active urine sediment, or if serum complements are depressed. Only 25% of multigravidas with proteinuria have uncomplicated preeclampsia [77], but previous pregnancy is not as strong an indicator of other renal disease as are the other factors mentioned previously.

When to Biopsy for Proteinuria

Diagnosis of Systemic Lupus Erythematosis (SLE)

SLE is the other most important cause of proteinuria which presents more frequently during pregnancy. Usually SLE can be distinguished from preeclampsia by an active urine sediment or positive lupus serologies. Both SLE and preeclampsia can be multisystem diseases, and there is some overlap in their extrarenal manifestations. Thrombocytopenia and hemolytic anemia are common manifestations of both. In preeclampsia, hemolytic anemia is distinguished by microangiopathic changes on peripheral smear. Both SLE and preeclampsia may be characterized by hyper-

tension, rapidly progressive renal failure, and seizures. The pulmonary hemorrhage of SLE may appear similar on chest X-ray to pulmonary edema in preeclampsia. However, pericarditis, joint pain, and skin rash are not characteristic of preeclampsia, and markedly elevated transaminases are not common in SLE. If thrombocytopenia occurs before hypertension and proteinuria, the possibility of SLE arises. When the diagnosis of SLE is made or strongly suspected during pregnancy, a renal biopsy is warranted. SLE that develops during pregnancy frequently has the histology of diffuse proliferative glomerulonephritis and may require the prompt initiation of aggressive treatment.

Loss of Renal Function (See Acute Renal Failure)

When there is a deterioration of renal function during pregnancy and the cause is not apparent, biopsy should be done. Usually the diagnosis of preeclampsia or hemolytic uremic syndrome (HUS) as a cause of proteinuria and rising serum creatinine can be made without biopsy. Acute glomerulonephritis may require biopsy to determine whether treatment is indicated or likely to be effective.

Severe Nephrotic Syndrome

When renal function and blood pressure are normal in a patient who appears to have a primary renal disease, it is not usually necessary to make a specific histologic diagnosis. Occasionally the edema and hypoalbuminemia associated with nephrotic syndrome are so severe that treatment with steroids is considered. In this situation, renal biopsy is helpful. High-dose steroids have been used extensively in pregnancy for a wide variety of conditions, but are associated with an increased risk of hypertension and glucose intolerance as well as adrenal suppression in the infant. Their use should be confined to minimal change disease (MCD) or focal sclerosis where there is a substantial chance of response. In patients with focal sclerosis, treatment should be continued only in women who have an early response (within a month) rather than using a prolonged trial that might be undertaken in a nonpregnant patient.

Differentiating Preeclampsia from Primary Renal Disease

In some situations, it is difficult to distinguish between primary renal disease and preeclampsia. Since the definitive treatment for preeclampsia is delivery, certainty about the diagnosis has therapeutic implications. Practically, it is rarely possible to take advantage of a brief window of opportunity when proteinuria is heavy enough to raise the question of another renal disease and before the blood pressure is too high to do the biopsy safely.

In some women, pregnancy is the first occasion for a urinalysis in adult life, and the discovery of proteinuria at the first prenatal visit may reflect preexisting renal disease. The distinction between preeclampsia and primary renal disease is made on the basis of the same diagnostic features that differentiate the two diseases when the onset of proteinuria is known to have occurred during pregnancy.

Treatment of Nephrotic Syndrome

Treatment of nephrotic syndrome unresponsive to steroids is problematic during pregnancy. Proteinuria increases during pregnancy and edema may become massive, lead-

ing, in some cases, to skin breakdown and bladder outlet obstruction. Low doses of diuretics have been shown to be fairly low risk in the absence of preeclampsia, and the use of low-dose diuretics in women with disabling edema is reasonable. Unfortunately, patients with nephrotic syndrome frequently require doses much higher than those shown to be safe in studies of pregnant women. When furosemide is used in pregnant women, fetal urine output increases, and high doses might be expected to carry the risk of volume contraction and electrolyte abnormalities in the fetus. Pregnancy may aggravate the hypercoagulability associated with nephrotic syndrome. Women with previously documented renal vein thrombosis should be fully anticoagulated with heparin throughout pregnancy. Although there are no clear data, it is reasonable to give low-dose heparin (5000 U subcutaneously twice daily) to women with membranous nephropathy and profound hypoalbuminemia (albumin < 2 g/dL). Treatment of elevated cholesterol should be deferred until after delivery because lovostatin has been associated with congenital anomalies.

Chronic Renal Disease

Hypertension

Hypertension is a common complication of pregnancy in women with renal disease even with good renal function. Worsening hypertension is usual. The diagnosis of preeclampsia can be difficult because all manifestations of preeclampsia can occur from the renal disease itself. The approach to the control of blood pressure in women with preexisting renal disease is similar to that in women with chronic hypertension, but control of blood pressure should be initiated early and an attempt should be made to keep the blood pressure < 140/90. We recommend teaching women with underlying renal disease to measure their own blood pressure at home between obstetric visits because increases in blood pressure can be abrupt.

Proteinuria

Proteinuria generally increases in women with glomerular disease and preexisting proteinuria who become pregnant, but pregnancy does not precipitate a relapse in women whose nephrotic syndrome is in remission [78]. Heavy proteinuria early in pregnancy has been associated with an increased rate of fetal loss, prematurity, and IUGR, an observation that provides support for steroid treatment of susceptible lesions. Nephrotic-range proteinuria occurring later in pregnancy does not adversely affect fetal outcome.

Accelerated Decline in Renal Function

The most important determinant of the effect of pregnancy on underlying renal disease is the level of renal function at the time of conception rather than the nature of the underlying renal disease. If a woman with renal disease conceives when her renal function is normal or only mildly decreased, the progression of her renal disease is not usually accelerated, although her pregnancy is still likely to be complicated by hypertension and increased proteinuria [79]. Three retrospective studies examined the course of renal disease in women who had a least one pregnancy compared with concurrent controls [80 – 82]. The largest study included 171 women with a

variety of glomerular diseases who became pregnant and 189 women who did not become pregnant after the onset of glomerulonephritis. There was no difference in the frequency of ESRD with a mean follow-up of 15 years [81].

In contrast, decline in renal function accelerated in women with moderate to severe renal insufficiency who become pregnant. There is disagreement about the level of renal function at which pregnancy becomes a factor in the acceleration of the disease, but the most widely used marker is a serum creatinine of 1.4 mg/dL. Multiple studies support this observation [83 – 86], but are flawed because of small numbers and the absence of controls. A larger report published in 1996 included 82 pregnancies in 67 women with primary renal disease and serum creatinine of 1.4 mg/dL. prior to conception or in the first trimester [87]. Twenty percent of women had a deterioration in renal function during pregnancy, and 23% had a deterioration in the first 6 weeks postpartum. At 6 months postpartum, 8% had recovered renal function and an additional 10% had deteriorated. The likelihood of an accelerated decline in renal function was greater in women whose first measured serum creatinine was > 2 mg/dL. One of 49 women with serum creatinine between 1.4 and 1.9 mg/dL. experienced accelerated decline, in contrast to 7/ 21 pregnancies in women with serum creatinine of ≥ 2.0 mg/dL. Eight women progressed to ESRD within a year of pregnancy, including 7 women with pregnancy-associated decline in renal function.

With the obstetric and neonatal care currently available, fetal survival in the setting of chronic renal disease is high. The fetal prognosis even for women who conceive with impaired renal function has improved over the last 2 decades. Several recent outcome studies have reported fetal survival > 90% in such pregnancies [87, 88] and infant survival > 70% even in pregnancies in women whose renal function deteriorated to the point of needing dialysis [89]. Prematurity and IUGR, however, are still common. Over 70% of infants are born prematurely in some series [84, 85, 87], and the frequency of IUGR from 43 – 57% [84, 87].

Arguments have been made that the outcome of pregnancy and the effect on maternal disease is worse in certain glomerular diseases, including IgA nephropathy, focal segmental glomerulosclerosis (FSS), and membranoproliferative glomerulonephritis (MPGN) [78]. However, there is no solid evidence that the risk factors for poor outcome in these diseases, specifically hypertension and renal insufficiency, are different from other renal diseases.

Diabetic Nephropathy

At least 4 reports involving 136 women with diabetes mellitus (DM) and nephropathy conclude that pregnancy does not have an adverse effect on the progression of the disease [90 – 93]. Most of the reports investigating the effect of pregnancy on established diabetic renal disease included very few women with impaired renal function. Only 12 of the 90 women in the reports that gave individual baseline renal function had initial serum creatinine > 1.4 mg/dL. At least 6 of these women experienced an accelerated progression of renal disease during pregnancy. In one study in which 12 women had ESRD at follow-up, it was unclear whether these were women with preconception serum creatinine ≥ 1.4 mg/dL. Purdy and colleagues recently reported on 14 pregnancies in 11 women with

diabetic nephropathy and serum creatinine of ≥ 1.4 mg/dL prior to pregnancy or in the first trimester. Forty-five percent of the women showed accelerated progression of renal disease [94], as determined by a change in the slope of 1/Cr during pregnancy and postpartum, and by comparison with a nonpregnant control group. Another report of 7 pregnancies in 6 patients with preconception serum creatinine of 1.5 mg/dL found no change in the slope of 1/Cr, but 3 women had reached ESRD at 30-month follow-up [95]. In diabetic nephropathy, as in other renal diseases, the level of renal function at conception is the most important determinant of the effect of pregnancy on the progression of the disease.

Patients with diabetic nephropathy, with or without severe renal insufficiency, have a high frequency of hypertension during pregnancy (53 – 97%). Hypertension is common before pregnancy, frequently worsens during gestation, and often develops in previously normotensive women. DM is a recognized risk factor for preeclampsia, but even low level proteinuria (190 – 499 mg/24 hours) identifies a group at higher risk for preeclampsia than women with diabetes alone [96]. Coombs and colleagues followed pregnancies in 311 women with DM with varying degrees of first trimester proteinuria. For women with 24 hours urine protein < 190 mg/day, the risk of preeclampsia was 10%, only slightly higher than the general population. The risk of preeclampsia in the groups with 190 – 499 mg/day and ≥ 500 mg/ day was 40% and 47%, respectively.

Proteinuria increases during pregnancy in women with diabetic nephropathy, as it does in women with other renal diseases. The frequency of nephrotic-range proteinuria in the 5 reports cited above ranged from 41 – 73%. Nephrotic-range proteinuria develops in > 50% of women who have lower levels of proteinuria before conception.

Despite serious maternal problems, long-term infant survival was > 95% with no stillbirth or neonatal death in the two reports of women with moderate renal insufficiency. However, approximately half of the infants were born prematurely and 15% had long-term developmental problems, often related to congenital anomalies resulting from poor glucose control during organogenesis.

Lupus Nephritis

Course of Lupus Nephritis in Pregnancy

Although some investigators argue that pregnancy per se does not aggravate lupus nephritis, the bulk of the data supports the contention that pregnancy has an adverse effect on the course of the disease, and there is a risk of renal failure and even death in women with lupus nephritis who become pregnant. In 276 women reported in 19 studies who had a diagnosis of lupus nephritis at conception, 133 (48%) experienced a worsening of renal disease during pregnancy [97 – 115]. Thirty exacerbations were characterized by ARF and, of these, 18 progressed to ESRD or resulted in maternal death. An additional 8 had a decline in renal function that was permanent but did not lead rapidly to ESRD. At least 44 women became nephrotic. Even in the absence of evidence of a lupus flare, hypertension and preeclampsia were common, and episodes of eclampsia were reported. While the majority of studies were uncontrolled, several studies using both nonpregnant women and the index subjects before and after

pregnancy as controls showed an increase in the frequency of SLE flares during pregnancy. In studies where renal histology was known, the frequency of exacerbations during pregnancy was higher for women with membranous nephropathy than for those with diffuse proliferative glomerulonephritis, even though membranous lupus is generally thought to have a more indolent course. Women with lupus nephritis were also at risk for severe extrarenal manifestations of SLE, including cerebritis, pericarditis, and mesenteric vasculitis. The risk of exacerbation is lower in women whose disease has been in remission for > 6 months before conception [101].

Effects of SLE on the Fetus

Several characteristic problems occur in the infants of women with SLE. Women with anticardiolipin antibody have an increased risk of fetal loss [116]. Several studies of prednisone treatment for this disorder show no benefit from steroid treatment. Many lupus-associated autoantibodies are IgG and cross the placenta. Neonatal lupus may be associated with skin rashes, thrombocytopenia, and hemolytic anemia [117]. These manifestations resolve over 6 months as maternal antibody disappears. Anti-SSA is deposited in the conducting system of the fetal heart and is associated with irreversible congenital heart block [118 – 120]. Some infants die in childhood from related myocardial fibrosis and heart failure, and others require long-term pacemakers.

Pregnancy in Renal Transplant Recipients

Over 6,000 pregnancies have been reported in women of childbearing age who have received a renal transplant. Transplant recipients are advised to wait 2 years after transplantation before contemplating pregnancy. Pregnancy should be undertaken only if blood pressure is controlled and renal function is stable with a serum creatinine of < 2.0 mg/dL.

Effect of Pregnancy on Graft Function

The question has been raised whether the hyperfiltration that occurs during pregnancy might have a detrimental effect in women with renal transplants whose GFR is lower at conception than in healthy women. Permanent loss of graft function during or after pregnancy in women with renal transplants is approximately 10% in a large number of reports. Several case-control studies have attempted to determine whether decline in renal function was caused by pregnancy [121 – 124].

First and colleagues reported on graft function in 18 women who underwent 25 pregnancies, compared with 26 female controls and 23 male controls [121]. Mean follow-up for the women who became pregnant was 11.8 years after transplantation and 6.9 years after pregnancy, with similar periods of follow-up for the control groups. At last follow-up, graft survival was 77.8% in women who had become pregnant, 69.2% in the female controls, and 69.8% in the male controls (NS). Both women who had become pregnant and the female controls had had an increase in serum creatinine over time. However, only 3 women

had serum creatinine > 1.5 mg/dL at conception, and in only one was it > 2.0 mg/dL. Only 5 of the 18 women who became pregnant were treated with cyclosporine.

A single controlled study suggests that graft function is adversely affected by pregnancy [122]. Salmela et al. reported on long-term graft function in 22 female transplant recipients with 29 pregnancies, compared to 38 female controls matched for cause of renal failure, kidney source, immunosuppression, time from transplantation, and serum creatinine. During the follow-up period, 8 of the women who became pregnant lost their grafts, one at one month postpartum. The remainder of the grafts were lost between one and 11 years postpartum, but deterioration of graft function began during pregnancy in 3 women. At 10-year follow-up, graft survival was 100% for the control group and 69% for the group who had had pregnancies ($p < .005$). Graft loss could not be correlated with elevated serum creatinine at the time of conception. The general applicability of the conclusions drawn in this report is limited by the paucity of centers achieving 100% 10-year graft survival similar to what was seen in the control group.

Infection

UTIs are the most common bacterial infections in pregnant transplant recipients, occurring in 40% of pregnancies [125]. Monthly urine cultures and prompt treatment of asymptomatic bacteriuria are needed. The pathogenic organisms occurring in immunosuppressed patients that are of particular concern for pregnant women are Listeria, Herpes, Cytomegalovirus (CMV) and Toxoplasma. Transplant recipients should be evaluated for previous infection with the latter 3 before pregnancy or at the first prenatal visit.

Immunosuppressive Drugs in Pregnancy

Cyclosporine

There are a number of theoretical concerns about cyclosporine metabolism in pregnancy. The increase in plasma volume and interstitial fluid, as well as increase in red cell mass would be expected to decrease the cyclosporine levels at a given dose. Because there is a greater increase in plasma volume than in red cell mass, a greater portion of any increase in cyclosporine dose would be distributed in the plasma and less would be red cell bound. It is not known whether sex steroids might slow the metabolism of cyclosporine through their inhibition of hepatic microsomes [125].

Although predictions about the effect of cyclosporine suggest forces working in opposite directions, the clinical observation is that cyclosporine levels drop and an increase in dose may be required to maintain the same plasma levels.

The most striking finding in transplant recipients treated with cyclosporine compared to those treated with other immunosuppressive regimens is an increase in SGA babies. The American Registry for Pregnancy in Transplant Recipients noted a low birth weight (< 2500 g) in 49.5% and a very low birth weight (< 1500 g) in 17.8% of 107 infants born to mothers treated with cyclosporine [126] during pregnancy. The frequency of low and very low birth weight for 207 infants born to mothers treated with prednisone and azathioprine was 39.1% and 7.7% respectively. The difference in gestational age was not significant (35.6 vs. 36.2 weeks.)

There was a higher frequency of maternal comorbid conditions in women treated with cyclosporine; 51.7% of cyclosporine-treated women were hypertensive prior to conception

compared to 18.5% of women treated with other regimens. More women in the cyclosporine-treated group had prepregnancy serum creatinine > 1.5 mg/dL (23.6% vs. 14.3%). It is not known whether hypertension and renal insufficiency before pregnancy account for the increase in IUGR.

The use of cyclosporine raises the question of its effect on the renal response to pregnancy in a renal transplant recipient. In transplant recipients treated with prednisone and azathioprine who have good renal function prior to conception (serum creatinine < 1.3 mg/dL), GFR, as measured by creatinine and inulin clearance, increases by a third by the tenth week of gestation and remains at an increased level until the third trimester when it returns to baseline [127]. The increase in GFR is less in women with lower prepregnancy GFR. It has not been determined whether cyclosporine, either by a direct effect or by virtue of the higher prepregnancy serum creatinine in cyclosporine-treated women, interferes with this response to pregnancy.

Experience with tacrolimus (FK 506) in pregnancy is extremely limited. It crosses the placenta and dose adjustment does not appear to be required for pregnancy. Severe IUGR was observed in one infant exposed to tacrolimus [128]. In one study of 9 pregnancies, hyperkalemia was seen in 5/ 7 surviving infants and one infant was anuric for 36 hours [129]. A recent report of 25 infants born to liver transplant recipients did not find IUGR, however neonatal hyperkalemia and renal insufficiency occurred [130]. Experience with the use of mycophenolate mofetil in pregnancy is even more limited.

Long-term survival of infants whose mothers were treated with cyclosporine during pregnancy is no different than for infants whose mothers were treated with azathioprine and prednisone alone. At present, taking cyclosporine out of the regimen is not warranted. Unless there is a clear indication for using tacrolimus or mycophenolate mofetil, the better studied combination of cyclosporine, azathioprine, and prednisone is preferable.

Pregnancy in Dialysis Patients

Fertility is decreased in dialysis patients. The American Registry for Pregnancy in Dialysis Patients reports a frequency of conception of 0.5% per year in women under the age of 44. For unclear reasons, conception is two to three times more common in hemodialysis patients than in peritoneal dialysis patients [89]. In 1980, the European Dialysis and Transplant Association reported on 115 pregnancies in women on dialysis [131]. Twenty-three percent of pregnancies not electively terminated resulted in surviving infants. The outcome was somewhat better in 344 pregnancies reported by the American Registry for Pregnancy in Dialysis Patients [89]. In the 187 pregnancies not electively terminated occurring in women receiving dialysis at conception, the likelihood of a surviving infant was about 40%. In contrast, the prognosis for the 59 pregnancies in women who began dialysis during gestation was better, with a fetal survival of approximately 70%.

Both hemodialysis and peritoneal dialysis have been used during pregnancy. There is no advantage of one modality over the other, either in fetal survival or in degree of prematurity.

When hemodialysis is used, it is common practice to increase the intensity of dialysis, based on the observation that women with residual renal function have a better outcome than women with no residual renal function. There is a suggestion of increased survival and less prematurity in pregnancies where the mother was dialyzed ≥ 20 hours per week [89].

Technical problems are not markedly increased with peritoneal dialysis, and catheters can be placed at any time during pregnancy. In the third trimester, abdominal discomfort usually makes it necessary to decrease exchange volume. There are few data on the effects of peritonitis on pregnancy outcome.

A substantial percentage of fetal loss occurs late in pregnancy, with 16.5% of pregnancies ending in second trimester spontaneous abortion and 6.4% in stillbirth. Of live-born infants, 18.2% die in the neonatal period, mostly from complications of prematurity. Little long-term follow-up is available on the surviving infants, but 11 of 49 infants where follow-up was available had developmental problems [89].

The frequency of complications is high, with > 75% of women suffering from hypertension, often severe. A drop in hematocrit is almost inevitable unless erythropoietin doses are increased 2 – 4 fold early in pregnancy. Almost all women not treated with erythropoietin require transfusion [89]. Two maternal deaths have been reported.

Acute Renal Failure (ARF)

ARF in pregnancy is largely a preventable problem resulting from obstetric complications and not intrinsic renal disease. Pregnancy-related ARF can thus be viewed more as a public health problem than a nephrologic problem. Historically, ARF in pregnancy once represented 20 – 40% of all cases of ARF and was responsible for 50% of cases in women [132]. In 1958, the estimated incidence of ARF in pregnancy was as high as 1 in 1400. Today, in industrialized countries, the approximate incidence is 1 in 20,000 [133]. In pregnancy, ARF occurs with a bimodal distribution. A peak in early pregnancy is associated with septic abortion, while a third trimester peak is associated with late obstetric complications, such as preeclampsia, abruptio placentae, postpartum hemorrhage, amniotic fluid embolism, and retained dead fetus [134, 135].

In industrialized countries where most women have access to high-quality prenatal care and where abortion has been legalized, there has been a marked decline in pregnancy-related ARF, with near elimination of the first peak [133]. The legalization of abortion in France was followed by a decrease in the percentage of cases of ARF attributable to obstetric causes, from 40% in 1966 to 4.5% in 1978 [133]. When abortion was made illegal in Romania in 1966, complications of illegal abortion became a major cause of ARF. In a report of 653 patients dialyzed for ARF between 1966 and 1989, 131 cases (20%) ARF resulted from complications of illegal abortion [136]. Between 1990 and 1992 after legalization of abortion, obstetric ARF accounted for only 1.52% of the total.

In developing countries, obstetric ARF remains a serious problem. Randeree et al. described the changing picture of obstetric ARF as the health care system in South Africa improved [137]. Between 1978 and 1991, the frequency of ARF in a hospital serving an impoverished community fell from one in 450 pregnancies to one in 900 pregnancies. With improvement in prenatal care, the proportion of obstetric ARF secondary to septic abortion decreased from 65% to 19%, while the percentage of obstetric ARF from preeclampsia increased from 10% in 1978 to 48% in 1991. With further improvement in obstetric care and early recognition of preeclampsia, the frequency of ARF from this cause would be expected to decrease.

ARF can occur after postabortal sepsis from any organism but is most common and dramatic with infection by *Clostridium welchii*, which produces a toxin that causes hemolysis and renal failure [138]. The infection may follow a fulminant course, characterized by severe abdominal pain and vascular collapse. *Clostridium welchii* is difficult to culture, and clostridia species are part of normal vaginal flora, but characteristic gas in the uterine wall on x-ray is highly suggestive. Care is supportive and is aimed at fluid resuscitation and infection control. The need for hysterectomy has been debated but can often be avoided with early aggressive conservative treatment [139, 140].

ARF in the Third Trimester

Bilateral Cortical Necrosis

In a majority of instances, ARF secondary to preeclampsia or peripartum hemorrhage follows a course typical of ATN with recovery. In obstetric ARF, a substantial minority of patients develop bilateral cortical necrosis, in which renal function may fail to recover or recovery may be partial with later progression to ESRD. Bilateral cortical necrosis may occur in any type of ischemic ARF, but a disproportionate number of cases occur in obstetric patients. In a report of 38 instances of cortical necrosis that occurred at Necker Hospital between 1953 and 1972, obstetric patients accounted for 26 (68%) [141]. The incidence of cortical necrosis was 2% in the nonpregnant adults with ARF and 21% of obstetric patients with ARF. There may be a vulnerability of the renal vasculature which is peculiar to pregnancy. It is notable that the Schwartman reaction can be induced in pregnant animals after one exposure to endotoxin, whereas nonpregnant animals develop it only after a second exposure [142]. Cortical necrosis can be diagnosed by CT scan or angiography [143]. The diagnosis is made primarily for prognostic purposes.

ARF in Preeclampsia

Decreased GFR, renal blood flow and sodium excretion are characteristic of preeclampsia, but frank renal failure is unusual. ARF in preeclamptic women occurs most often when another obstetric complication such as abruptio placentae is present, or when preeclampsia has progressed to the HELLP syndrome [144 – 146]. In the largest series of patients with HELLP, 7.7% suffered ARF. In one report of 17 preeclamptic women with ARF, 80% of women who developed cortical necrosis had abruptio placentae compared to one third of those who recovered renal function [145]. When ARF follows preeclampsia, there is substantial risk of maternal mortality (9.6% in one study) [144]. Pulmonary edema occurs in > 50% of women with ARF secondary to preeclampsia, emphasizing the need for judicious fluid administration in women with preeclampsia. Women who survive ARF in the setting of preeclampsia without essential hypertension or underlying renal disease have normal renal function at long-term follow-up. When ARF occurs in women with underlying chronic renal disease and renal insufficiency, as many as 80% are dialysis dependent at follow-up [144]. In these women, it is frequently difficult to distinguish between ARF secondary to preeclampsia and the poorly understood acceleration of renal failure in women with preexisting renal insufficiency, particularly because these women are frequently hypertensive when they lose renal function.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy is an obstetric emergency. If left untreated, it may progress to fulminant hepatic failure which is life threatening for both mother and fetus. The disease most often presents in the third trimester, with complaints of headache, fatigue, malaise, nausea, and abdominal pain. Late signs include jaundice, bleeding, seizures, and hepatic encephalopathy that may progress to frank coma. Liver biopsy shows microvesicular fatty infiltration of hepatocytes in a centrilobular distribution [147]. The maternal mortality rate for the disease has improved from 80 – 85% in the 1970s to less than 20% in recent series, with the lowest mortality rate reported being 6.6% [148 – 150]. The improvement in outcome can be attributed to earlier recognition and treatment, the recognition of milder cases, and better supportive care of fulminant hepatic failure. Acute fatty liver is frequently accompanied by preeclampsia, and there may be a link between the 2 syndromes. The etiology of the syndrome is unknown, but recent investigations have found a familial metabolic defect in fatty acid metabolism [151 – 153].

Some degree of ARF occurs in up to 90% of women with acute fatty liver of pregnancy [148, 149]. Renal biopsy findings in acute fatty liver of pregnancy include ATN, fatty vacuolization of tubular cells, and occlusion of capillary lumens by fibrin-like material. Clinically, the ARF in this syndrome may resemble hepatorenal syndrome, with low fractional excretion of sodium (FE_{NA}) and benign sediment. Treatment includes delivery of the baby and supportive care. ARF usually resolves postpartum, as does the liver failure. The availability of orthotopic liver transplant offers a life-saving treatment to women who do not recover postpartum. The timing of liver transplant is difficult. Waiting may result in the patients' deterioration and increase transplantion mortality. A transplant done prematurely may commit a woman to life-long immunosuppression when she might have had a complete recovery.

Postpartum Hemolytic Uremic Syndrome (HUS)

Initially described in children with antecedent diarrheal illness and in association with verotoxin, HUS is characterized by a microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. It is also recognized in adults in association with diarrheal illnesses, certain forms of adenocarcinoma, medications, and pregnancy. Early reports of postpartum HUS refer to the syndrome as postpartum renal failure. Although it usually occurs between one day and 3 months postpartum, HUS may occur before delivery as well [154, 155]. Thrombotic thrombocytopenic purpura (TTP), considered to be related to HUS along a continuum, typically occurs during, but occasionally after pregnancy. Renal failure in both HUS and TTP is often severe enough to require temporary dialysis, and patients may suffer residual renal damage, some severe enough to require chronic dialysis or transplant [156].

In a review of 68 adults with HUS/TTP of various etiologies diagnosed between 1980 and 1982, Conlon found a normal urinalysis at presentation in only 3%. Eighty-six percent had microscopic hematuria and 89% had proteinuria [157]. In one study of 11 women with pregnancy-associated HUS, 81% had impaired renal function at presentation.

The mainstay of treatment for HUS/TTP is plasma exchange. Before the advent of plasmapheresis, the maternal mortality rate was 90%. With this treatment, maternal survival has increased to 70 – 80%. Plasma exchange

during pregnancy has not shown adverse effects on the fetus [158, 159]. It is thought to work by removing factors that promote platelet aggregation and replacing inhibitory factors that may be lacking in the serum of patients with HUS/TTP. The number of treatments necessary varies among patients, ranging from 5 – 47 days in one study of 67 women [160]. The duration of treatment is determined by monitoring hematologic, neurologic, and renal parameters. Other treatments have included prednisone, aspirin, dipyridamole, heparin, immunoglobulin, vincristine, and splenectomy. These should be considered only as adjuncts to plasma exchange.

Recurrence of HUS has been described both in subsequent pregnancies and in response to other inciting factors, including oral contraceptives, infections, and drugs such as cyclosporine.

It is sometimes difficult to distinguish between HUS/TTP and severe preeclampsia accompanied by the HELLP syndrome. Thrombocytopenia, microangiopathic hemolytic anemia, renal insufficiency, proteinuria, and hypertension may occur in both. Some distinguishing features include isolated elevation of lactate dehydrogenase (LDH) in HUS/TTP, as opposed to elevation of transaminases in preeclampsia/HELLP. Elevations of PT and PTT are unusual in HUS/TTP and suggest preeclampsia. Preeclampsia generally improves after delivery, although there may be transient worsening for 48 hours. TTP/HUS is not improved by termination of pregnancy. The distinction is important because preeclampsia resolves with supportive care after delivery, but HUS/TTP is generally irreversible without plasma exchange.

Biopsy findings in HUS/TTP include glomerular capillary endothelial swelling and subendothelial deposition of fibrinoid material that may cause occlusion of capillaries [157]. Thrombi composed of fibrin and platelets are found within capillaries and arterioles [157].

The pathophysiology of microthrombus formation in HUS/TTP is thought to involve endothelial injury along with other factors contributing to enhancement of platelet aggregation or a decrease in inhibitors to platelet aggregation. Among those factors, abnormally large multimers of von Willebrand factor have been observed in TTP, and these can cause aggregation of activated platelets. Calpain, a cysteine protease capable of causing aggregation of normal platelets and enhancing platelet binding by von Willebrand factor, has been found in some patients with active TTP. Decreased fibrinolysis may play a role. Plasminogen activator inhibitor type 1, the major inhibitor of plasminogen activator, is increased in some cases of postdiarrheal HUS. Decreased synthesis and increased degradation of prostacyclin have been suggested on the basis of studies using plasma from individuals with TTP [161]. There may also be some genetic predisposition to HUS/TTP. There are known familial occurrences, and pregnancy-associated HUS has been reported in sisters [162 – 164].

Although advances in treatment have dramatically increased patient survival in obstetric HUS/TTP, it still poses a significant threat to both mother and child, particularly if not diagnosed and treated promptly. Patients with pregnancy-associated HUS/TTP should be aware of the possibility of recurrence in future pregnancies and with estrogen-containing oral contraceptives, although at present there is no method to identify those who will be affected a second time.

Appendix

Food and Drug Administration categories evaluating the risk of drugs to the fetus.

A. Controlled studies fail to demonstrate risk to the fetus even in the first trimester and the possibility of fetal harm appears remote.

B. Either animal reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women, or animal reproduction studies have shown an adverse effect (other than decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of risk in later trimesters).

C. Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal effects or others) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

D. There is positive evidence of human fetal risk, but the benefits from use in pregnant women may justify the risk.

X. Studies in animals or human beings have demonstrated fetal abnormalities, and the risk of using the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Tubulointerstitial and Vascular Diseases

Georg M. Fiedler, Volker Becker and Gerhard A. Müller

Tubulointerstitial Nephritis

Mechanisms of Tubulointerstitial Nephritis

The tubulointerstitial compartment accounts for 80% of the renal mass [1]. It consists of renal tubuli, the tubular basement membrane, vascular structures, and interstitial cells as well as the surrounding extracellular matrix. The interstitial cells can be divided mainly into renal fibroblast cells and cells of the monocyte/macrophage system including dendritic cells [1]. The tubulointerstitial compartment is involved in the course of almost all renal diseases [2]. As a rule, changes begin with an interstitial inflammation that is the hallmark of tubulointerstitial nephritis (TIN). TIN can exist in an acute and a chronic form and can affect the tubulointerstitial space primarily or in the setting of primary glomerular or vascular diseases. All forms of interstitial disease are quite common. It has been estimated that up to 15% of all cases of acute renal failure (ARF) are caused by primary interstitial nephritis [3]. In addition, up to 25% of all cases of end-stage renal disease (ESRD) are attributable to primary chronic TIN [4]. According to the European Dialysis and Transplant Association (EDTA) registry, 20.2% of ESRD was caused either by pyelonephritis, interstitial nephritis, or toxic nephropathy. These forms are characterized by primary TIN [5]. More recent data, however, suggest a less prominent role, with about 4.5% of cases of chronic renal failure (CRF) in the US attributable to primary interstitial diseases [6]. Moreover, secondary tubulointerstitial injury is one of the most important factors for the outcome of primary glomerular and vascular diseases [7] because interstitial nephritis is the common pathway of almost all forms of progressive renal disease and one of the most common lesions in nephrology [8]. Immune response in interstitial nephritis can be antibody dependent or cell mediated but, in contrast to glomerular diseases, cell-mediated reactions predominate [9].

In TIN, T lymphocytes are the predominant infiltrating cells with a great abundance of CD4+ T helper cells (CD4/CD8-ratio often > 1). These T helper cells need MHC-class II (HLA-D) restricted presentation of responsible antigens to become activated. Antigen presentation in the renal interstitium can be provided efficiently by infiltrating macrophages and interstitial dendritic cells [10]. In addition, data on glomerular diseases suggest that tubular epithelial cells may serve as antigen presenters as well [11]. In interstitial nephritis, predominantly CD8+ T effector cells become activated in turn and result in renal tissue damage by 2 mechanisms: they can be cytotoxic due to the release of perforans, or they can lead to a delayed-type hypersensitivity reaction with the release of inflammatory

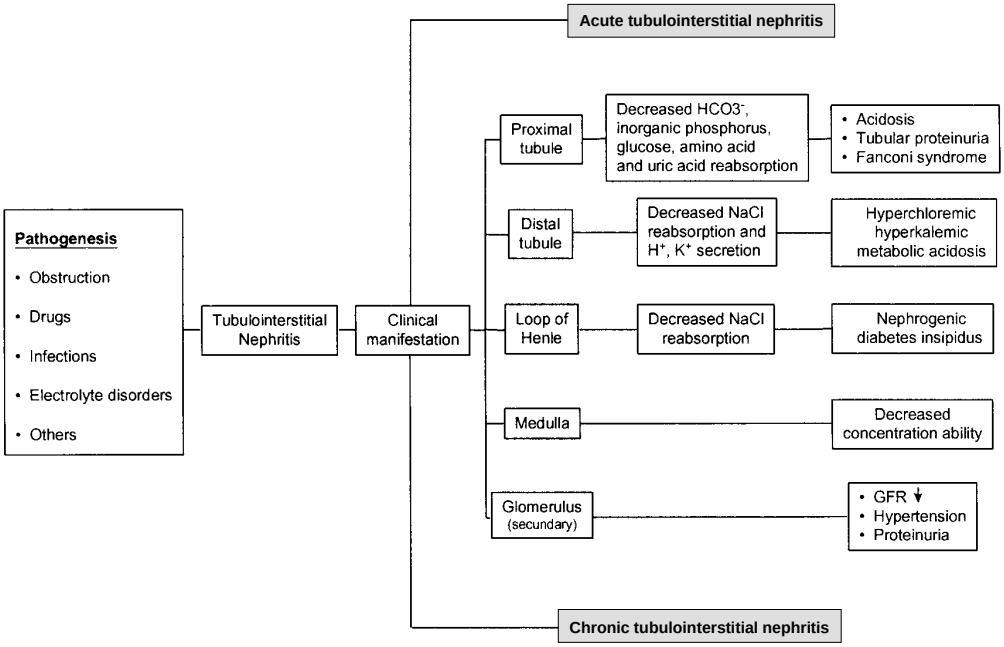

Figure 1. Pathogenesis and clinical manifestations of tubulointerstitial nephritis. Modified from [Kuhlmann U., Walb D, Luft FC: Nephrologie. 3rd ed., Thieme, Stuttgart 1998] with permission.

cytokines [12]. Only occasionally, deposition of immune complexes within the interstitium may be found, especially in patients with underlying systemic autoimmune disorders. In rare cases of specific antitubular basement membrane disease, linear deposition of immunoglobulin along the tubular basement membrane can be detected (additionally in up to 70% of cases with primary antiglomerular basement membrane (anti-GBM) disease). The target antigens for humoral immunity in human TIN remain poorly defined [13, 14]. Only the target antigen of experimental antitubular basement membrane (TBM) disease in mice has been characterized as glycoprotein 3M-1 and is secreted by proximal tubular cells [15, 16]. Apart from native renal antigens, drug/hapten conjugates, microbial antigens, and foreign antigens that induce cross-reactive immunity to autoantigens (molecular mimicry) are believed to be of importance in TIN. Irrespective of the type of immune reaction, in the course of sustained primary or secondary interstitial inflammation and tissue damage, activation of interstitial cells can initiate processes of interstitial proliferation and fibrogenesis that inevitably result in renal scarring and chronic renal failure.

Figure 1 summarizes the pathogenesis and clinical manifestations of TIN.

Acute Tubulointerstitial Nephritis (ATIN)

ATIN is a heterogeneous disorder in etiology, clinical presentation, laboratory findings, and outcomes. The incidence of ATIN for cases of clinically encountered ARF is diffi-

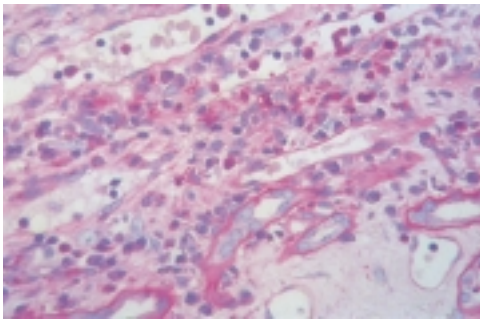

Figure 2. Acute drug-induced tubulointerstitial nephritis (ibuprofen) in a 60-year-old woman. Observe the dense lymph/plasma cell and eosinophil (characterized by their dark cytoplasm) infiltration (PAS, magnification x 400).

cult to establish. It has been estimated that up to 15% of all cases of ARF are caused by primary interstitial nephritis [3, 8]. The proportion of CRF attributable to ATIN is fortunately much lower, in the range of 1‰. ATIN is slightly more common among men than in women (about 2 – 3 : 1) and can be observed in any age. Elderly patients are more often affected, however, probably because of the more abundant use of drugs in this group.

Pathology

The principal morphologic changes that characterize all forms of ATIN are interstitial expansion caused by edema and infiltration of inflammatory cells as well as pathological changes in the tubules. Usually, the glomeruli and renal vascular structures appear unaffected. The nature of the cellular infiltrate varies according to the underlying disease. In general, the infiltrating cell population is composed mainly of neutrophils, T and B lymphocytes, macrophages, natural killer (NK) cells, plasma cells, and eosinophils [9, 17 – 21] (Figure 2). The infiltrate is typically T lymphocytes and monocytes/macrophages [22] in interstitial nephritis associated with glomerular disease. The interstitial infiltrates are often diffuse, but focal patterns of injury are also seen. Granuloma formations may be found as well, and drugs are a common cause of these lesions in acute settings [23 – 25]. However sarcoidosis, granulomatous vasculitis, or tuberculosis should be considered in such cases [24, 26 – 28]. In cases of Wegener granulomatosis, glomerular and vascular structures are almost always involved [27]. The tubular changes range from cell swelling and vacuolization to tubular cell necrosis with disruption of the tubular basement membrane [20]. A marked expression of adhesion- and HLA-class-II molecules by tubular cells can be observed by immunohistochemistry and may be of great importance for the disease process [19, 29, 30]. In contrast to glomerular diseases, deposition of immunoglobulins or complement are of minor importance [17].

Clinical Features

In ATIN, a rapid decrease in renal function is typical at presentation. A careful evaluation of the history is essential in this setting because most patients will be asymptomatic or will complain only of unspecific symptoms. For example, the clinician should be on the alert for a new medication, especially in the elderly patient, or systemic illness, particularly streptococcal infections in children. While there are no pathognomonic clinical findings in ATIN, certain systemic manifestations may point to the diagnosis if present. The classical descriptions of patients with methicillin-induced interstitial nephritis go back to the early 1960s. Systemic manifestations such as

- low-grade fever (70 – 100%),
- fleeting skin rash (30 – 50%), and
- diffuse arthralgias (up to 20%)

Table 1. Laboratory Features of ATIN

Blood	Eosinophilia IgE-Elevation
Proteinuria	< 3 g/day (exception: some cases of NSAID) Tubular pattern (α1-microglobulin, β2-microglobulin, N-acetyl-beta-glucosaminidase)
Sediment	White blood cells (free and casts) Microhematuria (rarely gross hematuria, red casts uncommon) Eosinophiluria
Functional parameters	Glucosuria, aminoaciduria, hyperphosphaturia Renal tubular acidosis (bicarbonate loss, impaired acid secretion) Hyperkalemia Salt wasting Impaired concentration ability

together with signs of ARF make ATIN a probable diagnosis [31].

However, the entire constellation has been reported in the minority of ATIN cases (4 out of 27 in one study) [32]. In most cases only nonspecific constitutional symptoms such as fever, fatigue, or nausea are present. In addition, some patients may complain of lumbar pain due to distension of the renal capsule from diffuse swelling of the kidney. In contrast to glomerular diseases, oliguria, edema, and hypertension are less common in ATIN. As a consequence of an impaired tubular reabsorptive capacity, polyuria and nocturia may develop. Long-term consumption of nonsteroidal anti-inflammatory drugs (NSAIDs) may lead to a type of ATIN, accompanied by glomerular proteinuria sometimes severe enough to cause full-blown nephrotic syndrome. ATIN histologically characterized by granuloma formation within the interstitium can clinically appear months after drug ingestion. Typically, classic allergic symptoms are lacking. Therefore, diagnosis is often delayed in these cases, and progression to renal failure often occurs.

Laboratory Findings

The first clinical presentation of ATIN is variable, and specific findings that point to diagnosis are often lacking. Several findings on blood and especially urine analysis may point of ATIN (Table 1). Elevated plasma creatinine and blood urea nitrogen (BUN) values should be investigated to discover the cause of impaired renal function. Especially in drug-related ATIN, further blood tests may reveal transient eosinophilia and elevated plasma IgE levels, but these findings occur only in about 30% of cases [33 – 35]. In addition, nonspecific elevations of C-reactive protein (CRP) levels and an accelerated erythrocyte sedimentation rate (ESR) may be present. In > 75% of cases, mild to moderate proteinuria and hematuria can be found [36, 37]. Proteinuria is tubular in the majority of cases. Nephrotic-range proteinuria is not usually found. However, NSAID-induced interstitial nephritis is often characterized by serious renal injury including the glomeruli (minimal change lesions). Hence, this form of ATIN may be accompanied by nephrotic syn-

drome [38]. Gross hematuria rarely occurs in ATIN, but careful examination of the urinary sediment is essential. In approximately 75% of patients, red and white blood cells (sterile pyuria) will be found [37]. Occasionally, white and red blood cell casts may be observed, but the latter strongly suggest a glomerular lesion. Eosinophiluria is suggestive of allergic interstitial nephritis. Eosinophils in the urine can be detected by either Wright's stain or Hansel's stain, the latter being approximately 5 times more sensitive [39, 40]. However, eosinophiluria can be observed in many other cases such as rapid progressive glomerulonephritis (GN), urinary tract infections (UTI), prostatitis, and atheroembolic disease, as well as in episodes of renal allograft rejection. Therefore, it may help to distinguish ATIN from acute tubular necrosis (ATN), but the positive predictive value of this parameter is < 40% according to recent studies [41].

As a consequence of tubular injury and interstitial inflammation, various tubular dysfunctions may be observed in the course of ATIN. Lesions affecting the proximal tubule may result in glucosuria, aminoaciduria, uricosuria, and hyperphosphaturia. A proximal loss of bicarbonate along with an impaired acid secretion within the distal segments can result in renal tubular acidosis. Hyperkalemia and renal salt wasting together with a reduction of renal concentration ability may point to a dysfunction of the distal tubule or collecting duct. In a report of 9 patients with biopsy-proven ATIN, isosthenuria was present in all patients with a mean urinary osmolality < 350 mOsm/L and a urine/plasma osmolality ratio of 0.9. Urinary sodium was > 40 mEq/L in 8 out of the 9 patients studied [42]. However, signs of tubule dysfunction such as Fanconi syndrome and renal tubular acidosis are rarely observed in the course of ATIN and are more common in patients with chronic tubulointerstitial disease.

Table 2. Etiological Factors of ATIN

Drugs
Infections
Idiopathic
Associated with Uveitis (TINU-Syndrome)

Diagnosis

Tubulointerstitial nephritis is a pathological phenomenon and not a clinical syndrome. Many features in clinical presentation and in laboratory analysis may suggest ATIN but only renal biopsy can establish the diagnosis with certainty in this setting. Therefore, renal biopsy should always be considered in any patients with ARF of unknown origin.

Ultrasonography is useful in the detection of ATIN. Because of the increased interstitial volume, the kidneys may appear swollen and the cortical echogenicity may be increased. Additionally, renal scanning with gallium-67 has also been reported to detect ATIN in some patients [35, 43]. This method is very sensitive; however, the specificity is relatively low. Therefore, this method is not reliable in identifying noninfectious interstitial nephritis [44].

Etiology

The etiological factors that can lead to acute interstitial nephritis may be divided into 3 categories (Table 2). Drugs are the most im-

Table 3. Drugs Causing ATIN

Antibiotics	*Diuretics*
Penicillins and derivatives	Thiazides
Cephalosporins	Triamterene
Azithromycin	Hydrochlorothiazide/ Amiloride
Chloramphenicol	Furosemide
Ciprofloxacin	Indapamide
Erythromycin	Chlorthalidone
Ethambutol

Histoplasmosis	*Mycoplasma hominis*
Leptospira	*Rickettsia rickettsii*
Leishmania donovani	*Schistosoma mekongi*
Mycobacterium tuberculosis	*Toxoplasma gondii*

portant causative agents, followed by systemic infections, particularly in children. Less common are autoimmune and systemic disorders or idiopathic origin [22].

Drugs

With the introduction of sulfonamides in the 1940s, an association of nephritis with these substances was recognized. Classical reports of drug-induced ATIN are those with maculopapular rash, fever, and eosinophilia after the ingestion of methicillin [45 – 47]. Hence, most studies were performed on β-lactam antibiotics in the past. Currently, quinolones and proton pump inhibitors are the leading causative agents, followed by 5-aminosalicylate and NSAIDs. As drug-related ATIN seems to be due to a hypersensitivity reaction, it can be induced by virtually any drug. However, certain drugs are more prone to induce ATIN (Table 3).

Drug-induced ATIN may occur in a variety of forms (Figure 3). Depending on the drug involved and the individual response, the clinical symptoms can range from full-blown hypersensitivity (fever, rash, eosinophilia, and oliguric renal failure) to asymptomatic courses with only laboratory findings. Altogether, drug-induced ATIN should always be considered in patients with an abrupt deterioration of renal function and signs of tubular dysfunction.

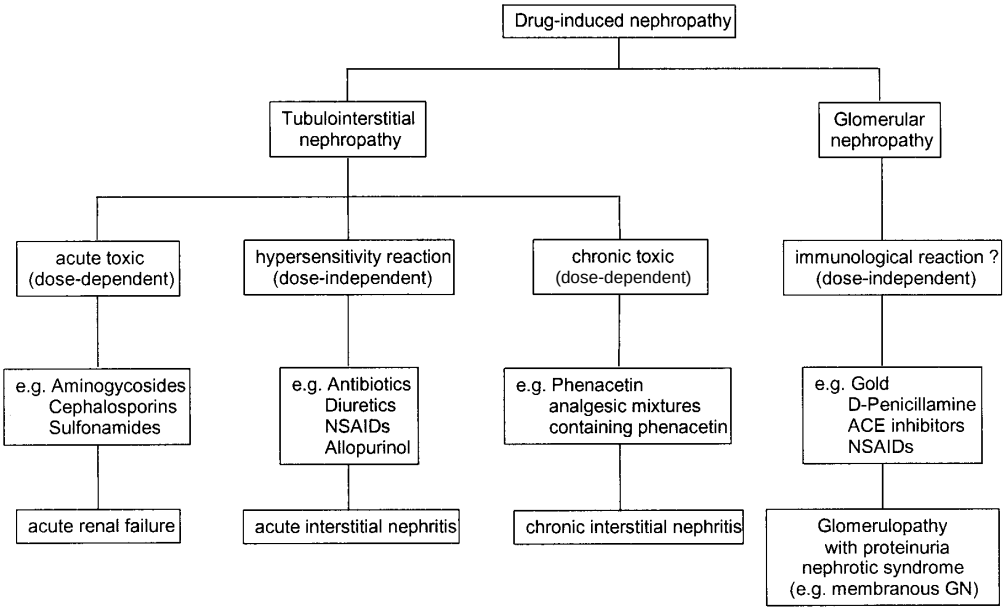

Figure 3. Drug-induced nephropathy. Modified from [Kuhlmann U., Walb D, Luft FC: Nephrologie. 3rd ed., Thieme, Stuttgart 1998] with permission

Infections

Infection-mediated ATIN (Table 4) is usually caused by an ascending infection with *Enterobacteriacae* (most commonly *E. coli*) and *Streptococcus faecalis*. In hospitalized patients, UTIs with other organisms such as *Serratia marcescens* or *Pseudomonas aeruginosa* are more common due to exposure to these bacteria and concurrent antibiotic treatment. Tubulointerstitial infections are dependent on the presence of urinary reflux and on bacterial virulence factors. Because of its high prevalence, the most extensively studied pathogen is *E. coli* [48]. One virulence factor that seems to be very important is the presence of fimbriae that enable the bacterium to adhere to epithelial cells [49]. P-fimbriae play an important role in first attacks of pyelonephritis due to their capability to mediate adhesion to human P blood group receptors [49]. Thus, although only 10 – 15% of all *E. coli* strains that cause UTI are P-fimbriated, 70 – 100% of all cases of nonobstructive pyelonephritis are caused by P-fimbriated *E. coli*. Another potential virulence factor is the presence of α-hemolysine [50]. The importance of all virulence factors seems to be linked to their neutrophil activation ability [48]. Polymorphonuclear neutrophils (PMN) may directly activate fibroblasts and thus cause interstitial fibrosis. However, experimental data to support this hypothesis are still lacking. Nevertheless, direct interaction of PMNs and fibroblasts has recently been demonstrated [51]. The role of lymphocytes and cytokines in acute and chronic phases of infection is not as well defined as in other forms of TIN. Nevertheless, it is known that even in infectious TIN T lymphocytes accumulate within a few days [52]. CD4+ from lesions in experimental pyelonephritis displayed MHC-restricted proliferative responses to a variety of *E. coli* and related strains, but not to other gram-negative bacteria [52]. Thus, it seems possible that many forms of chronic infec-

tious TIN are mediated by the same immune mechanisms as noninfectious forms. Cytokines that play a role in infectious TIN include interleukins IL-1 and IL-6, granulocyte-colony stimulating factor (G-CSF), granulocyte-monocyte-colony stimulating factor (GM-CSF), and tumor necrosis factor (TNF)-α according to a study by Rugo et al. [53]. The role of obstruction itself is often underappreciated. Obstruction, albeit often the cause of chronic infection, can lead directly to tubulointerstitial injury. An increase in fibrogenic cytokines has been demonstrated in models of ureteral obstruction. For example, Kaneto et al. demonstrated increased transforming growth factor (TGF)-β1 mRNA expression in the tubules of rats with unilateral ureteral obstruction [54]. Moreover, sterile urine reflux caused cortical tubulointerstitial scarring in pigs [55], a mechanism potentially initiated by the extravasation of Tamm-Horsfall glycoprotein at high backflow pressures [56]. Another form of ATIN is observed in systemic infections in which there is no evidence of direct parenchymal invasion by an organism. However, the pathogenesis of this entity is unknown.

Idiopathic ATIN

In a proportion of cases, no etiological factors can be identified. This form of ATIN cannot be distinguished from other forms by any specific symptoms or other characteristic findings [57]. In most cases it is reversible. Pathologically, mononuclear cells predominate within the interstitium. However, the resulting lesions are heterogeneous and occasionally, as with other clinical settings, anti-TBM-antibodies can be found. Thus, the idiopathic form(s) of ATIN can only be distinguished from other forms by exclusion of infections, history of drug ingestion, or immune disorders.

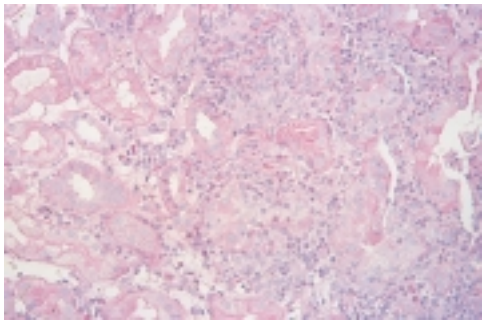

Figure 4. Tubulointerstitial nephritis in a 17-year-old girl with TINU syndrome. The interstitium shows dense lymph/plasma cell infiltration with focal tubulitis. Some eosinophils are scattered in between (PAS, magnification x 200).

The association of acute tubulointerstitial nephritis and acute uveitis observed in several patients (in adolescent girls or occasionally in adults) has led to the identification of a specific syndrome with a very particular symptomatology and course, the so-called tubulointerstitial nephritis/uveitis (TINU; Figure 4). The etiology of TINU syndrome remains to be elucidated but a recent report suggests underlying infection with *Chlamydia*. The prognosis of TINU seems to be excellent in younger patients, with or without steroid treatment. In adults, however, CRF ensues in a substantial proportion [58, 59, 60].

Course and Treatment

The clinical spectrum of ATIN ranges from mild and short to severe cases with oliguric renal insufficiency. The primary therapeutic step in ATIN is to identify and withdraw the drug or offending agent, or to treat the underlying infection. Most patients will recover fully from renal failure within several days. In cases of ongoing and progressive renal insufficiency, a kidney biopsy should be performed to exclude other diseases (e.g. myeloma kidney, rapid progressive glomerulonephritis, or atheroembolism).

Although corticosteroids have been reported to be beneficial in some patients [31, 61], controlled clinical trials are not yet available. In the absence of a prompt response after withdrawal of a drug or offending agent, Kelly and Neilson suggest a trial of corticosteroids (1 mg/kg/day prednisone) in patients without infection. Improvement in renal function should begin within 1 – 2 weeks of initiation of treatment, in which case the course can be discontinued after 4 – 6 weeks [62]. If no improvement is seen within the first 2 weeks, an additional therapy with cyclophosphamide (2 mg/kg/day) with appropriate monitoring of the white blood cell count should be considered [62]. If successful, this regimen should be continued up to one year. When no evidence of improvement exists after 6 weeks, the combined therapy should be discontinued [62].

Most patients will have complete recovery of renal function within one year. However, up to one-third of patients with drug-induced acute interstitial nephritis (and more in the case of rifampicin) require dialysis treatment before resolution of the disease [62].

Chronic Tubulointerstitial Nephritis (CTIN)

Pathology

The pathological findings in patients with chronic forms of tubulointerstitial nephritis display characteristic changes in interstitial architecture observed in virtually all forms of chronic renal injury, e.g. of primary glomerular, vascular, cystic, or interstitial origin [7, 21]. Interstitial fibrosis along with tubular atrophy are the hallmarks of chronic interstitial disease. As an expression of ongoing inflammation, mononuclear cell infiltrates

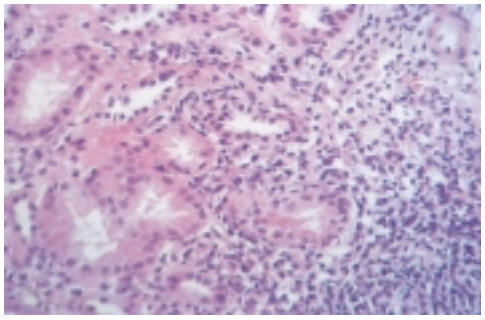

Figure 5. Secondary tubulointerstitial nephritis in Sjögren's syndrome, 68-year-old woman. Focally dense lymph/plasma cell infiltration (PAS, magnification x 400).

(mainly lymphocytes) in the interstitium and within the tubular epithelium (tubulitis with resulting cellular casts) can be seen (Figure 5). Although in CTIN the glomeruli mainly remain unaffected by the primary lesion, signs of secondary glomerular injury may be found as the disease progresses towards ESRD [10, 19, 63 – 65].

Clinical Features

Usually, CTIN does not cause any specific clinical symptoms unless a primary systemic disease is present. Hence, some cases are diagnosed because of findings in screening tests (abnormal urinalysis or elevations in plasma creatinine and BUN). However, many patients unfortunately present with nonspecific symptoms of chronic renal failure late in the course of the disease [66].

Laboratory Findings

When patients with CTIN present late, they have marked impairment of renal function and typical laboratory findings of chronic renal failure. Earlier cases of CTIN may present

with nonnephrotic-range proteinuria of a predominant tubular protein pattern and microscopic hematuria as well as pyuria. Surprisingly, positive urine cultures can be found in as many as 28% of patients [66]. As with acute TIN, glucosuria, renal tubular acidosis (RTA), and concentration defects reflect the degree of tubular dysfunction. Anemia develops relatively early (compared to glomerular diseases), and systemic hypertension occurs in about 50% of cases.

Diagnosis

Renal biopsy is the only means for definite diagnosis in all forms of TIN, whether acute or chronic. Neither clinical features nor laboratory findings are specific. In CTIN associated with a primary disease, diagnosis may be suggestive in many cases but biopsy is still of great value, especially for informed judgement on individual prognosis and required therapeutic decisions. Nevertheless, a thorough investigation of the patient's history will provide the only reasonable basis for diagnosis in many patients with established late-stage renal failure.

Etiologic Factors

CTIN can occur in association with a variety of underlying primary diseases of diverse etiology. Table 5 gives a concise overview of common and rare causes of CTIN, which are discussed in more detail in other chapters.

Endemic Nephropathy

Endemic nephropathy, so-called Balkan nephritis, is a form of CTIN that is endemic in areas of the Balkan states. Usually, the disease occurs in middle-aged adults and progresses slowly towards ESRD. No diagnostic tests are

available, and its cause remains unknown (environmental agents, infections, and genetic factors are proposed). A higher incidence of uroepithelial tumors is suggested in these patients. As with other forms of TIN, elevated excretion of tubular proteins (especially β2-microglobulin) as well as additional signs of tubular dysfunction can be observed early in asymptomatic patients [67]. At this time there is no specific treatment regimen that can alter the rate of progression towards renal failure. Thus, elimination of known progression factors is essential.

Sarcoidosis (M. Boeck)

Most commonly, aberrations of calcium metabolism, including hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis, are responsible for the renal manifestations of sarcoidosis (Table 6). Recent studies suggest that the calcium abnormalities are associated with high blood concentrations of calcitriol and that calcitriol may be synthesized by mononuclear macrophages in the granulomas [68]. Up to one-third of patients with sarcoidosis are reported to have granulomas within the renal interstitium, which may also produce severe derangements of renal function. GN can occur with sarcoidosis, although the pathogenesis remains unclear [69 – 72].

Table 6. Renal Manifestation of Sarcoidosis

1. Disturbance of calcium metabolism
– Hypercalcemia and hypercalciuria
– Nephrolithiasis
– Nephrocalcinosis
2. Granulomatous tubulointerstitial nephritis
3. Different pattern of glomerular disease

Clinically apparent kidney dysfunction is rare unless hypercalcemia and hypercalciuria are present (about 10 – 15% of all patients). Mild to moderate albuminuria, microscopic hematuria, and sterile pyuria predominate. A protein excretion of > 3 g/24hours may indicate a concomitant glomerular lesion. Hypertension is usually absent and renal size is well preserved. Urinary concentration defects (including nephrogenic diabetes insipidus), renal tubular acidosis, and inappropriate glucosuria may also be seen [73]. In patients with sarcoidosis-associated granulomatous TIN, renal disease is usually accompanied by other organ involvement. No factors are known to identify patients at high risk, but men are reported to be more prone to develop this entity. The findings in renal biopsy are distinct from other forms of TIN. Interstitial inflammation with noncaseating granulomas and epithelioid and multinucleated giant cells is the usual histologic picture (Figures 6a and 6b). There is no positivity for complement or immunoglobulins. Rarely, nonspecific glomerular or vasculitic changes can be observed. Pathologically, other granulomatous inflammatory processes like silicosis, tuberculosis, histoplasmosis, and Wegener granulomatosis or scattered infiltration by lymphoma cells (with reactive granuloma formation) may have to be distinguished in single cases. Interestingly, in a series of 6 patients with sarcoidosis and clinically significant renal insufficiency, 4 patients differed from the typical patient with sarcoidosis in that they lacked the usual clinical constellation of skin, eye, and pulmonary involvement [71].

The diagnosis is supported by clinical findings of sarcoidosis involvement of other organs and should be suspected on the basis of elevated or paradoxically normal serum calcium concentrations, due to increased plasma concentrations of calcitriol, while immunoreactive circulating parathormone concentra-

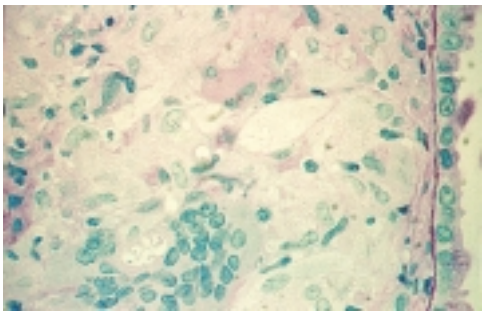

Figure 6b. Giant cell in the same patient (PAS, magnification x 400).

tions are depressed. An elevated 24-hour urine calcium concentration is consistent with the diagnosis but is not specific. Additionally, angiotensin-converting enzyme (ACE) activity is elevated in the serum in approximately two-thirds of patients with sarcoidosis. However, false-positive and false-negative results are common. Calcitriol as well as ACE could represent unregulated secretion products from granulomatous tissue, and their plasma concentrations may roughly reflect activity of the disease.

Response to corticosteroid therapy is often excellent, but in rare cases, the administration of cyclophosphamide may be of value when corticosteroids do not prove efficacious. Still, progressive interstitial fibrosis may result and these patients, a small subgroup of cases with nonresponding disease, may eventually develop CRF [62, 69, 71, 74].

Analgesic Nephropathy

Analgesic nephropathy (AN) is a slowly progressive chronic renal disease characterized by renal papillary necrosis or calcifications and interstitial nephritis caused by excessive consumption of analgesic mixtures [75].

Since the discovery of an association between phenacetin use and the development of chronic interstitial nephritis, it has been recognized that drug-related renal disease is in large part a preventable disease. Discontinuation of heavy analgesic use may slow or stop progression of renal disease [76]. However, replacement of phenacetin with its major metabolite acetaminophen has not always been followed by a reduction in the incidence of analgesic nephropathy, suggesting that other drugs may play a role in this disease [77]. Several-case controlled studies and 2 prospective studies demonstrated the association between analgesic abuse and nephropathy [75]. However, the nephrotoxicity of the different analgesic products has not been clearly established [78]. The prevalence of analgesic nephropathy is related to the persistent daily consumption of widely available over-the-counter (OTC) mixtures containing 2 analgesic components plus caffeine and/or codeine [79]. This relationship could not be observed for analgesics containing only one analgesic component plus caffeine and/or codeine, although experimental data suggest nephrotoxicity of single analgesics [77, 78, 80]. The prevalence of analgesic nephropathy in patients with terminal kidney disease receiving dialysis varies widely between countries in Europe and outside Europe. In the early 1990s

the incidence was 0.8% in the US, 2% in Europe, and 9% in Australia [79]. In Scotland, Switzerland, Belgium, and Australia, it is a relatively common cause for chronic renal failure accounting for 10 – 20% of patients with ESRD. Recent analysis shows a changing pattern of prevalence and age distribution of analgesic nephropathy as a cause of ESRD. The EDTA registry reveals a declining incidence of analgesic nephropathy in the last decade in the age group under 64 years, while the incidence in the older age group remained high [81]. The same trends are observed in Australia [82]. These data indicate a real reduction in the incidence of analgesic nephropathy.

– *Pathology:* The pathologic abnormalities in analgesic nephropathy are nonspecific. The development from the earliest detectable lesions to end stage with bilateral shrinkage of the kidneys can be subdivided into the following 3 steps. The earliest detectable morphological lesion in patients with analgesic nephropathy is capillary sclerosis, which is found to be especially pronounced in the vessels of the renal pelvis and ureteral mucosa. The most pronounced capillary alterations are found in the proximal ureter. As a further morphological alteration, renal papillary necrosis follows. This lesion represents damage to the inner renal medulla that may be based on capillary sclerosis. Perhaps as a consequence of papillary necrosis, TIN may develop. Light microscopic investigations show a fibrotic interstitium with tubular atrophy and sporadic mononuclear cell infiltration. Sometimes concomitant focal glomerular sclerosis and interstitial calcifications can be found. At the time of clinical presentation, the kidneys are typically small [83 – 85].

– *Pathophysiology:* Experimental data show that the combination of acetylsalicylic acid with phenacetin or paracetamol induces severe medullary lesions more frequently than does either of these agents alone [77]. These results are in accordance with clinical and epidemiological observations in patients with analgesic nephropathy. The pathogenesis of analgesic nephropathy is related to the ability of the kidney to concentrate drugs in the papillae. For example, after ingestion of phenacetin and aspirin, phenacetin is converted in the gut and liver to acetaminophen by first-pass metabolism. Acetaminophen is normally metabolized in the liver and kidney by cytochrome P450 enzymes. After ingestion of large quantities, acetaminophen becomes concentrated in the papillae of the kidney during physiologic antidiuresis and undergoes oxidative metabolism by prostaglandin H synthase to biologically reactive intermediates. These are normally intercepted by reduced glutathione, which is present in excess within the renal cells. If acetaminophen is ingested alone, sufficient glutathione is generated in the papillae to detoxify the reactive intermediates [86, 87]. However, if acetaminophen is ingested with aspirin, the aspirin is converted to salicylate, which becomes highly concentrated in the cortex and papillae of the kidney. Salicylate is a potent depletor of glutathione. The mechanism is not completely understood. However, the inhibition of NADPH production via the pentose shunt is a possible explanation. With the cellular glutathione depletion, the biologically reactive intermediates of acetaminophen then produce peroxides and arylation of tissue proteins, resulting in cellular dysfunction and necrosis of the

papillae [88, 89]. In addition, the inhibition of prostaglandin synthesis can exacerbate medullary damage from ischemia [90]. No evidence exists for the development of analgesic nephropathy with acetaminophen alone. Experimental data suggest that aspirin seems to be the most nephrotoxic of the commonly available analgesics and that combination therapy with aspirin is required for medullary damage in rats [91, 92].

– *Clinical Features*: The clinical course of analgesic nephropathy is frequently asymptomatic for years until the late stages of renal insufficiency. The earliest renal manifestation is caused by impaired tubular function. As a result of decreased urine concentrating ability, patients develop increased urinary frequency or urgency and nocturia. Additionally, an acquired form of RTA may contribute to the development of nephrocalcinosis. More than half of patients have pyuria, which, if persistently associated with sterile urine, provides an important clue to the diagnosis. Additionally, slight proteinuria may be present, whereas a protein excretion of more than 3g/24 hour may indicate a concomitant glomerular lesion. Macroscopic and microscopic hematuria may appear in the course of sloughing and elimination of fresh renal papillary necrosis, as a result of UTI, or, especially in the later stage, as a sign of uroepithelial carcinoma, which occurs with increased frequency in these patients. It is not known which analgesics predispose to carcinogenesis, seen after an average latency period of > 20 years [93, 94]. Therefore, even after termination of analgesic abuse, regular urine cytology and evaluation of the urinary tract should be undertaken for hematuria in these patients. Arterial hypertension is present in about 50% of patients with analgesic nephropathy. The hypertension seems to be renin dependent, because it may be exacerbated by volume depletion [95]. Additionally, acute papillary necrosis can evoke hypertensive crisis. Occasionally, shedding of papillary necroses into the efferent urinary tract may be associated with hematuria and even renal colic owing to obstruction of a ureter by necrotic tissue. Bacterial UTIs occur frequently and are late complications. With decreasing glomerular filtration rate (GFR), all metabolic signs of renal insufficiency may be present [95, 96].

  Besides the renal manifestations, a broad spectrum of extrarenal complications of chronic analgesic abuse can occur and often precedes the signs of analgesic nephropathy (Table 7). Women are affected 5 – 7 times more than men [95, 96].

– *Diagnosis:* Because there is no gold standard in the diagnosis of analgesic nephropathy, clues suggestive of the disease include a history of regular analgesic consumption, symptoms of an analgesic abuse syndrome, especially anemia, out of proportion to the degree of azotemia, renal colic without signs of nephrolithiasis, papillary necrosis, and sterile pyuria.

  CT scan without contrast medium is recommended to diagnose analgesic nephropathy in all patients with ESRD as well as those with mild and moderate renal insufficiency. The demonstration of bilateral decreased renal mass combined with either bumpy contours or papillary calcifications was found to have a high diagnostic value [97, 98].

– *Therapy:* There is no specific treatment for analgesic nephropathy. The primary goals of treatment are to prevent further

   – vegetative symptoms

renal damage. All suspect analgesics, particularly OTC medications, must be stopped to slow or stop progression of renal disease [76, 99].

The early treatment of complications, such as arterial hypertension, volume and sodium depletion, acute UTI, and urinary tract obstruction caused by renal papillary necrosis is important. Signs of kidney failure should be treated as appropriate for the extent and severity of the renal failure. Counseling, behavioral modification, or other interventions may assist in developing alternative methods for chronic pain control.

Patients undergoing renal transplantation as a result of analgesic nephropathy are at high risk of developing transitional cell carcinoma of the upper urinary tract. These tumors tend to be of high grade and stage, and affected patients have a poor outcome. Screening by urine analysis and voided urine cytology does not appear to be reliable for the early diagnosis of upper renal tract transitional cell carcinoma in the renal transplant patient. Therefore, annual cystoscopy and retrograde ureteric catheterization with washings, brushings, and radiological imaging should be performed to diagnose upper tract transitional cell carcinoma at an early stage. These patients should also be screened before transplantation using the same technique [100]. Considering the high mortality from urothelial carcinoma despite regular tumor screening in patients with analgesic nephropathy after renal transplantation, other investigators suggest that a bilateral nephroureterectomy should be performed prophylactically in patients with proven analgesic nephropathy [101].

Multiple Myeloma

Multiple myeloma is a malignant proliferation of plasma cells characterized by excessive production of monoclonal immunoglobulins (IgG ≈ 53%, IgA ≈ 25%, or IgD ≈ 1%) or light chains (Bence-Jones proteins) (≈ 20%). Renal dysfunction occurs in > 50%

of patients and can precede the nonrenal manifestations. The clinical presentation is characterized by renal failure, which is a major cause of death. The kidneys of patients with multiple myeloma can be damaged by multiple mechanisms (Table 8) [102].

Table 8. Factors Contributing to Nephropathy in Patients with Multiple Myeloma

– Excretion of light chains which may cause the following renal diseases:
Myeloma kidney
Light chain nephropathy
AL-Amyloidosis
– Hypercalcemia
– Hyperuricemia
– Dehydration
– Recurrent infectious pyelonephritis
– Renal plasma cell infiltration
– Contrast media or nephrotoxic agents

The myeloma kidney or cast nephropathy is the most common lesion resulting from light chain toxicity. It is characterized by large proteinaceous intratubular casts surrounded by multinucleated giant cells, probably of monocyte-macrophage origin [103]. The casts typically consist of Tamm-Horsfall protein and light chains [104]. As a consequence of cast formation, intratubular obstruction may develop. The tubules are extensively damaged and show tubular atrophy and fibrosis [105]. Additionally, plasma cell and mononuclear cell infiltration of the kidney, nephrocalcinosis, and amyloid deposits in the vessels and glomeruli may also be present. Light chain deposits can typically be observed by means of immunofluorescence staining in renal basement membranes (tubular, glomerular, and vascular) [106]. In addition, there is often concomitant deposition in the glomerular mesangium.

The pathogenetic causes of cast nephropathy are still unknown. When Bence-Jones proteins of patients with multiple myeloma or AL amyloidosis are injected into mice, the animals reproduce renal lesions identical to those observed in patients [107]. Myeloma casts develop in the distal nephron when cast-forming light chains bind to a specific portion of Tamm-Horsfall protein, secreted by cells of the thick ascending limb of the loop of Henle, to form an insoluble protein complex. Light chains are normally synthesized by plasma cells in excess of heavy chains. Because of their low molecular weight (approximately 22 kD), light chains are filtered at the glomerulus, reabsorbed by the proximal tubule, probably by receptor-mediated endocytosis, and catabolized [102, 108]. However, in the course of multiple myeloma and other diseases, light chain production is dramatically increased. With the increase in amount of light chains presented to the tubules, the proximal tubular reabsorptive capacity is overwhelmed, which leads to the urinary excretion of light chains as Bence-Jones proteins. The tubular damage results either directly from nephrotoxic effects of Bence-Jones proteins or indirectly from intrarenal obstruction from cast formation [105]. Interestingly, there are unexplained individual variations in the toxicity of Bence-Jones proteins [109, 110]. Some patients who excrete large amounts of light chains develop no renal dysfunction. Others show a nephropathy despite small urinary amounts of light chains.

A variety of factors modify the interactions between the light chains and Tamm-Horsfall protein and thus influence the development of renal failure [102, 111]. The coaggregation depends on the ionic environment and physicochemical factors, such as light chain concentration [112], isoelectric point [113], acidic intraluminal pH of the distal nephron [114], tubular flow rate [112], and presence of complete Tamm-Horsfall protein [115]. In-

Defect in urinary concentration

creasing concentrations of sodium or calcium but not magnesium facilitate coaggregation [115]. Patients who excrete large amounts of Bence-Jones proteins in the urine are the most prone to renal failure. Some investigations suggest that cast-forming Bence-Jones proteins have isoelectric points > 5.1. This may explain the observation that aciduria independent of urinary flow rate increases the nephrotoxicity of Bence-Jones proteins [114] and that an acidic intraluminal pH of distal nephron may give an optimal environment for the precipitation [102]. Conditions in which the intraluminal flow rate are reduced, such as volume depletion, can accelerate tubular obstruction. Furosemide augments coaggregation and accelerates intraluminal obstruction in rats, possibly by increasing the intratubular sodium and calcium concentration [112].

Experimental data suggest that ionic interaction between Bence-Jones proteins and a specific peptide binding site on Tamm-Horsfall protein promotes heterotypic coaggregation [116]. However, the carbohydrate moiety of Tamm-Horsfall protein is also essential for coaggregation, perhaps by facilitating homotypic aggregation [116]. Deglycosylated Tamm-Horsfall protein does not coaggregate with Bence-Jones proteins and colchicine, which seems to remove the carbohydrate component of Tamm-Horsfall protein, thus prevents coaggregation of Tamm-Horsfall protein and toxic light chains in rats [112].

Table 9 summarizes the factors affecting cast formation.

– *Clinical Features:* Renal failure occurs in nearly 25% of patients, whereas renal dysfunctions occur in > 50% of patients. Recurrent bacterial infections, especially pyelonephritis, are presenting features in about 25% of cases. The clinical presentation of renal involvement in multiple myeloma is characterized by acute or chronic progressive renal insufficiency. However, according to the multifactorial pathogenesis of the renal dysfunction, clinical features are variable (Table 10). Proteinuria is found in 70% of all patients with multiple myeloma and may often be the initial symptom. It reflects overflow of monoclonal Bence-Jones proteins. Generally, there is very little albumin in the urine because glomerular function is usually normal. When the glomeruli are involved, the proteinuria is nonselective. The presence of a nephrotic syndrome and a monoclonal kappa or lambda light chain in the urine almost always indicates primary amyloidosis or light-chain depo-

sition disease, and a newly diagnosed albuminuria in patients with multiple myeloma is suspicious of AL amyloidosis. In addition, > 70% of patients show signs of tubular defects, such as impaired acidification or adult Fanconi syndrome, which is characterized by excessive increased urinary loss of glucose, phosphate, and all glomerular filtrated amino acids. In addition, loss of bicarbonate induces RTA (type 2 proximal RTA), and the urinary concentrating ability may also be diminished [109, 117 – 120].

– *Diagnosis:* The diagnosis of multiple myeloma should always be considered when a patient > 50 years of age develops renal failure and proteinuria of unknown origin. The classic triad of multiple myeloma is a bone marrow specimen containing > 10% atypical or immature plasma cells, lytic bone lesions, and a serum and/or urine M component. Additionally, multiple myeloma should be considered when renal insufficiency is accompanied by hypercalcemia, inadequate anemia, and/or elevated erythrocyte sedimentation rate (ESR). Characteristically, dipsticks for detecting proteinuria are not reliable at identifying light chains. However other qualitative techniques that depend on precipitation of protein, such as the sulfosalicylic acid (SSA) method, are useful in detecting Bence-Jones proteinuria. Thus, the constellation of a negative dipstick test and a positive precipitation test can be due to the presence of Bence-Jones proteins. This should be further evaluated by electrophoresis and immunoelectrophoresis. Typically, a decreased anion gap can be found in patients with multiple myeloma because the M component is cationic, resulting in retention of chloride. The kidneys are normal size on ultrasound.

Table 11. Potential Therapies for Cast Nephropathy [102]

– **Chemotherapy to decrease Bence-Jones protein**
– Plasma exchange to remove light chains from plasma
– Increase free water intake to 2–3 L/day as tolerated
– Treat hypercalcemia
– Avoid exposure to furosemide and radiocontrast agents
– Alkalinize urine
– Colchicine to decrease amount and carbohydrate content of Tamm-Horsfall protein
– Reducing agents that alter the light chain binding site on Tamm-Horsfall protein

– *Therapy:* Treatment strategies for myeloma kidney (Table 11) are somewhat controversial. The principle of therapy has been chemotherapy to decrease production of the abnormal monoclonal immunoglobulins and immunoglobulin light chains. Clinical data indicate that plasma exchange associated with chemotherapy rapidly removes large amounts of light chains and improves both renal function and long-term survival expectancies of patients suffering from ARF due to multiple myeloma with Bence-Jones proteinuria [121, 122]. Little attention has been given to understanding and disrupting the pathophysiologic mechanisms involved in production of intraluminal casts. Noncontroversial elements include the supportive treatment of hypercalcemia (corticosteroids, hydration, 0.9% sodium chloride infusion, calcitonin, bisphosphonates) and hyperuricemia (allopurinol, hydration, urinary alkalinization). Adequate hydration is necessary (daily intake of 2 – 3 L of fluids as long

as there are no signs of renal failure or heart insufficiency) to keep the urine flow high. Additionally, the sodium chloride concentration in the distal nephron should be lowered. Experimental data in rats show that urinary alkalinization prevents renal failure from Bence-Jones proteins. However, comparable results in human patients are missing. Radiocontrast media and nephrotoxic agents should be avoided. Furosemide can increase distal tubular sodium chloride and calcium concentrations and can enhance, in a concentration-dependent fashion, toxicity of cast-forming proteins in vivo. Particularly in the setting of volume depletion, loop diuretics should be used with caution because of their capability to augment coaggregation of light chains with Tamm-Horsfall proteins. Experimental data in rats suggest that treatment with colchicine prevents aggregation of cast-forming Bence-Jones proteins, apparently by decreasing the excretion and removing the carbohydrate moiety of Tamm-Horsfall protein [112]. Colchicine, in daily doses of 1 – 2 mg, is standard therapy in preventing renal amyloidosis from familial Mediterranean fever. Colchicine in this dosage might also be efficacious in managing patients with cast nephropathy. Additionally, reducing agents such as cysteamine (beta-mercaptoethylamine) alter the tertiary structure of Tamm-Horsfall protein sufficiently to diminish subsequent binding to light chains. However, the possible role of colchicine and reducing agents in the management of myeloma kidney requires further clinical studies [102].

Kidney transplantation has been performed in a small number of patients with myeloma kidney. Although recurrence of cast nephropathy has been described, the results support the strategy of offering cadaver renal transplantation to carefully selected individuals who require long-term dialysis and whose myeloma is in remission after chemotherapy [123 – 125].

Uric Acid

Hyperuricemia can cause different renal disorders (Table 12). The term gouty nephropathy is used for the chronic interstitial nephritis with hyperuricemia and gouty arthropathy. While it is commonly accepted that hyperuricemia can cause ARF this has not been unequivocally established for chronic interstitial disease [126]. Experimental data support the hypothesis that interstitial deposits of urate and uric acid in the kidney may be derived from intratubular deposits that react with the tubular epithelium and pass into the interstitium. Loss of tubular integrity may not be a prerequisite for crystal migration [127]. However, there are no convincing data to verify an association between an overproduction of uric acid and progressive renal failure. Moreover, it has been reported that lead intoxication may be the pathogenically relevant agent in gouty nephropathy [128]. However, many patients with impaired renal function present with high serum uric levels secondary to diminished GFR and tubular effects of diuretic drugs. Lowering of uric acid production could be important in these patients if hyperuricemia leads to acceleration of renal dis-

Table 12. Hyperuricemia-associated Renal Disorders

Gouty nephropathy

ease. Besides encouraging water intake (urinary volume > 2 L/day), a restriction of alimentary purine, alkalization of urine, and allopurinol in doses adjusted to renal excretory function should be considered in patients with serum uric acid > 10 mg/dL (600 μM) [127].

Heavy Metal Intoxication

Chronic lead and cadmium exposure injure the proximal tubular cells initially. Hence, tubular transportation defects may be detected. However, as stated above, these findings are not specific in tubulointerstitial diseases. The pathogenetic mechanisms by which tubular lesions in heavy metal nephropathies result in chronic tubulointerstitial inflammation and fibrosis remain to be elucidated. Expression of pro-inflammatory mediators by injured epithelial cells may lead to mononuclear cell infiltration and activation of cytotoxic T lymphocytes. CTIN in chronic lead and cadmium intoxication will be discussed in more detail. In addition, intoxication with several other metals such as mercury, thallium, chromium, lithium, and nickel may lead to CTIN [129].

– *Lead Nephropathy:* Chronic exposure to lead can be associated with CRF displaying the pathological features of CTIN (see also above) [130]. Lead ingestion can arise from occupational exposure as well as from household sources (e.g. pottery, crystal, old water pipes). Lead accumulates in the S_3 portion of the proximal tubular cells, leading to dysfunction ranging up to full expression of the Fanconi syndrome [131]. Proximal tubular lesions are usually accompanied by additional chronic interstitial nephritis with interstitial fibrosis, atrophy, and nephrosclerosis [132]. Clinical signs of lead nephropathy are hyperuricemia and hypertension. Recurrent gout in the presence of CRF is a useful marker of chronic lead poisoning [133]. The diagnosis of lead nephropathy is based on an augmented urinary lead excretion (>0.6 mg/24hours) following EDTA administration (2 doses of 1 g), while blood lead levels are less useful to determine a chronic exposure [134]. EDTA chelation therapy is suggested thereafter until lead mobilization becomes normal again, with a favorable outcome in some cases. In contrast to the course in adults, lead exposure in children only rarely results in CRF [134].
– *Cadmium Nephropathy:* Occupational and less often environmental (itai-itai disease) [135, 136] excess cadmium exposure result in tubular injury and interstitial nephritis. Metallothionin-bound cadmium is pinocytosed into proximal tubular cells leading to proximal tubular dysfunction and especially to hypercalciuria. A high incidence of metabolic bone disease and complications due to nephrolithiasis are special features of this entity, often being the initial symptoms. The diagnosis can be confirmed by the finding of a high urinary excretion of cadmium. Besides symptomatic treatment of bone disease and complications, there are to date no specific therapeutic options in cadmium nephropathy. Large amounts of cadmium are stored within the liver and kidneys, and the half-life ($t^{1/2}$) is > 10 years .

Hypercalcemia

The kidneys can be affected in many ways by hypercalcemia. Elevated serum calcium levels and excessive hypercalciuria in diseases with high calcium turnover often lead to an acute deterioration of renal function. Increased cholecalciferol in sarcoidosis or in

patients with excessive vitamin D intake are less frequent causes than paraneoplastic calcium release due to parathormone-related peptide or bone metastases. Tubular transportation disorders with ensuing hypercalciuria are rare. In hypercalcemia, it is believed that direct vasocontractory effects, a reduction in glomerular filtration coefficient, and volume depletion due to a vasopressin-resistant concentrating defect result in a decline of GFR [137, 138]. Apart from acute effects on renal function, hypercalcemia may also lead to a deposition of calcium within the tubulointerstitium (especially medullary tubular basement membrane, collecting ducts, and finally throughout the interstitium), so-called nephrocalcinosis [63, 139]. These tubulointerstitial calcium lesions in turn lead to inflammatory infiltration and chronic tubulointerstitial disease. Nephrocalcinosis can be diagnosed either by ultrasonography or by computed tomography (CT) as well as by plain X-ray imaging techniques. Diagnosis of the underlying disease is essential to enable specific treatment. Treatment and nonrenal complications of hypercalcemia itself are discussed in chapter I.5. In general, the outcome of acute deterioration of renal function is good if treated early depending on the cause of the hypercalcemia. In nephrocalcinosis, treatment results are less favorable than with all other forms of chronic tubulointerstitial disease.

Hypokalemia

Chronic hypokalemia is another albeit rare electrolyte disorder that can cause tubulointerstitial nephritis. Inherited forms of hypokalemia are primary renal tubular transportation defects that lead to wasting of potassium into the tubular lumen (often accompanied by acid-base disorders and other defects). These forms of CTIN usually show slow progression towards ESRD. Hypokalemia nephropathy is characterized morphologically by vacuolization of proximal tubular cells, the origin of which is unknown. In addition to the histologic findings of chronic tubulointerstitial nephritis and fibrosis, periodic acid-Schiff (PAS)-positive intracytoplasmic granules and cyst formations within the renal medulla can be observed. Functionally, hypokalemia can lead to marked polyuria that is resistant to antidiuretic hormone (ADH). Experimental data in rats reveal that excessive synthesis of ammonia may initiate an inflammatory response, with tubulointerstitial damage caused by concurrent complement activation [140]. Potassium repletion is essential and can reverse both functional and structural abnormalities in many cases.

Oxalosis

Hyperoxaluria can be caused by at least 2 hereditary disorders of oxalate metabolism: excessive oxalate load or an increase in bowel absorption of oxalate. Though relatively rare, inborn oxalate disorders often result in chronic renal disease and early end-stage insufficiency. Primary hyperoxaluria (PH) type 1 is characterized by the deficiency of the liver enzyme alanine glyoxylate aminotransferase, and the very rare PH type 2 is based on a defect of the D-glycerate dehydrogenase [141, 142]. Patients with lesions of large portions of the small bowel, especially the terminal ileum in inflammatory bowel disease, or with short bowel syndrome after surgery may have increased absorption of oxalate. An increased bile acid load in the large bowel is believed to capture calcium from calcium-oxalate complexes, thereby releasing free oxalate for absorption. In addition, ethylene glycol poisoning or ascorbic acid overdoses can result in excessive metabolic oxalate production and tubulointerstitial damage. Deposition of cal-

cium-oxalate crystals in many tissues and organs is the pathogenically relevant lesion. Besides renal involvement, deposition in the bones, in arteries, and in nervous tissue results in severe lesions that lead to a clinically prominent bone disease with fractures, ischemic damage, and polyneuritis as well as retinal lesions. In the kidney, nephrolithiasis, obstruction of the tubular lumina, and interstitial deposition of crystals are the main manifestations. Measures to lower oxalate often are ineffective to prevent CRF (and extrarenal damage). The most effective prophylactic treatment is increasing urinary output by augmenting water intake to 3 – 4 L/m^2/day. Administration of citrate, orthophosphate, or magnesium can prevent crystal formation and should be given additionally. Some cases of PH type 1 also respond to pyridoxine (a cofactor of enzyme activity). Patients with ESRD due to PH type 1 are reported to benefit from combined liver-kidney transplantation with good results in a number of cases associated with improvement of extrarenal manifestations [143, 144].

Radiation Nephritis

Radiation nephritis has become rare during recent years because administration protocols for radiation were changed to lower the total dose on the kidneys when nearby target organs are to be treated. However, total body irradiation in patients receiving bone marrow transplantation is an increasing cause of radiation damage of the kidneys. Radiation nephritis is clinically divided into acute forms with a clinical onset within one year and more delayed reactions to radiation after several years.

Acute forms present with hypertension and chronic anemia as well as edema. In most cases, a progressive renal insufficiency will result in ESRD. Occasionally, varying degrees of proteinuria and microscopic hematuria are found. Especially in children, acute radiation nephritis may be associated with intravascular hemolysis, making differentiation from the hemolytic uremic syndrome (HUS) difficult.

In chronic forms, patients may present with often isolated hypertension or mild proteinuria even after more than a decade. Malignant hypertension can occur, probably due to lesions of the renal arteries, at least in some cases. Severe forms of CRF with hypertension and proteinuria can also be seen.

Histologic lesions of chronic tubulointerstitial fibrosis are found in radiation nephritis. Acute forms display signs of marked glomerular endothelial lesions as well. Inflammatory infiltrates are usually absent, probably secondary to the therapy and primary disease. The pathogenesis of radiation injury of the kidneys is believed to be primarily vascular with endothelial cell damage resulting in progressive vascular disease with ensuing tubular atrophy and generalized ischemic lesions of the tubulointerstitium. In addition, the tubular epithelium is affected primarily by irradiation. Recent data on fibroblast cell regulation suggest that parenchymal cells and especially fibroblasts may be in part responsible for fibrogenesis after radiation [145, 146]. As with other forms of progressive renal disease, administration of ACE inhibitors could prove advantageous [147]. Hypertension due to unilateral disease may respond to nephrectomy of the affected kidney. Radiotherapy involving the kidneys exacerbates the risk for renal toxic injury by nephrotoxic drugs (radiocontrast agents, antibiotics, and especially cytotoxic drugs). Hence, careful management of radiation along with additional therapy is necessary.

Course and Treatment

In most forms of CTIN, the primary disease cannot be treated sufficiently (specific therapies of some special entities have been discussed before). Moreover, even if further renal injury can be prevented, renal function slowly but inevitably deteriorates towards CRF, once a certain degree of tubulointerstitial damage and especially fibrotic changes have occurred (in cases of CTIN as well as in essentially all chronic renal disorders). The most important maneuver is controlling blood pressure (lowest tolerable blood pressure ≤ 140/85 mmHg) preferably with ACE inhibitors unless otherwise contraindicated [148]. These drugs seem to possess a higher nephroprotective potency than other antihypertensive substances Angiotensin II type I receptor antagonists may prove comparably effective in the future [149]. To date, however, evidence for the nephroprotective properties of ACE inhibitors is only documented in type-I diabetes mellitus [150]. Thus, treating elevated blood pressure, irrespective of the individual antihypertensive agents, remains the main goal. In addition, treatment of accompanying abnormalities such as hyperuricemia, metabolic acidosis, and hyperphosphatemia is advisable. The impact of a low protein diet on the progression of CRF is not clear [151 – 153]. We advise our patients to restrict protein intake to 0.8 g/kg/day (plus urinary losses). However, great care must be taken to prevent a catabolic state in these patients.

Vascular Diseases of the Kidney

A large variety of renal diseases are of vascular origin. They may be classified as lesions affecting the large blood vessels (renal artery and vein) or primarily the small vessels and capillaries of renal parenchyma. The latter disorders and subtotal renal artery stenosis associated with hypertension are discussed elsewhere in chapter I.21. Thus, this chapter will focus on diseases of the large vessels only, namely renal artery thrombosis and embolism, cholesterol embolism syndrome, and renal vein thrombosis. These entities are similar in that they are usually associated with acute failure of the affected kidney. Hence, depending on pre-existing renal function and the extent of the lesion (unilateral or bilateral), they may cause acute azotemia. Table 13 summarizes renal vascular diseases.

Renal Artery Thromboembolism

The term renal artery thromboembolism implies thromboembolic phenomena to the main renal arteries and the development of thrombosis in the renal artery.

The source of thromboembolic phenomena is usually the left atrium in patients with atrial fibrillation or the left ventricle with wall-adherent thrombi, shortly after myocardial infarction [154 – 156]. Less often, embolism might arise from endocarditis-associated thrombotic lesions (bacterial or aseptic). Additionally, rheumatic valvular disease and prosthetic heart valves are predisposing factors [155, 156]. Incidences with paradoxical embolism from venous thrombi through asso-

Table 13. Renal Vascular Diseases

Diseases of the renal artery and branches
Renal artery thrombosis
- – Renal vascular hypertension / ischemic disease
- – Atheromatous
- – Fibromuscular dysplasia

Renal artery embolism
- – Atrial or ventricular embolism
- – Aortal origin
- – Septic embolism (endocarditis)
- – Lupus anticoagulant syndrome

Dissection (aortal)
Cholesterol embolism syndrome
Large vessel vasculitis
- – Takayasu
- – Polyarteritis nodosa

Diseases of the small renal vessels
Small vessel vasculitis
- – Wegener granulomatosis
- – Microscopic polyangiitis
- – Henoch-Schönlein purpura

Renal allograft rejection
Radiation nephritis (see CTIN)
Lupus anticoagulant syndrome
Disseminated intravascular coagulation
Toxemia of pregnancy
Hemolytic uremic syndrome / thrombotic-thrombocytopenic purpura

Diseases of the renal vein
Renal vein thrombosis
- – Nephrotic syndrome
- – Heparin-induced thrombopenia type II
- – Hyperviscosity syndromes (e.g. Polycythemia vera, Leukemias, Thrombocytosis)
- – Diseases of the clotting system (inherited, lupus anticoagulant syndrome, etc.)
- – Infiltration by tumor (e. g. renal cell carcinoma)

Compression of the renal vein
- – Lymphoma
- – Pancreatic carcinoma

Oral contraceptives

ciated right to left shunting are very rare [157]. Diseases such as tumors and aneurysms may result in embolism and must be considered [158, 159]. Percutaneous intraarterial catheterization and aortography can cause an embolism involving the renal artery and aorta [160]. Renal artery embolism is bilateral in up to one-third of cases.

Renal artery thrombosis (RAT) is much less common than renal artery occlusion by emboli [161]. The latter is usually superimposed on an atheromatous plaque (as in coronary thrombosis). In addition, intimal lesions of the renal artery arising from trauma or surgery as well as inflammatory injury can cause thrombotic occlusion [162]. Numerous other factors have been associated with RAT. For example, ACE inhibitors may induce RAT in patients with renal artery stenosis [163 – 165]. RAT can also be associated with erythrocytosis, factor V Leiden mutation, antiphospholipid syndrome, or elevated cyclosporine levels [166 – 169]. Spontaneous renal artery thrombosis is a rare phenomenon [161].

Clinical and Laboratory Features

Initially, patients usually complain of a sudden onset of flank pain, abdominal or chest pain, nausea, and vomiting. Fever and chills may occur. The physical examination often reveals abdominal or flank tenderness, sometimes accompanied by clinical signs of peritoneal irritation. The extremities and central nervous system (CNS) should be carefully evaluated for signs of embolization. Considering the nonspecific symptoms, an early diagnosis of renal arterial thromboembolism is often difficult [170, 171].

Laboratory findings include leukocytosis, proteinuria, hematuria, and elevated levels of lactic dehydrogenase (LDH), serum glutamic-oxalacetic transaminase (SGOT), se-

rum glutamic-pyruvic transaminase (SGPT), alkaline phosphatase, and creatinine kinase (CK) [170, 172, 173]. CK isoenzyme assay for CK-MB may be falsely high, due to a release of CK-BB activity from renal tissue. Deterioration of renal blood flow results in acute oliguric failure of the affected kidney, which can be compensated from a functioning contralateral organ. Anuria suggests the presence of bilateral emboli. Another result of renal ischemia is renin release leading to arterial hypertension [174]. If the onset is rather slow and occlusion is subtotal, only hypertension may result.

Various techniques can be employed to establish the diagnosis. Dopplerultrasonography, perfusion scintigraphy, and CT scan as well as magnetic resonance imaging (MRI) with contrast agents are highly sensitive and specific techniques [175 – 179]. Intraarterial angiography is the definitive method for the diagnosis of renal artery thromboembolism [159]. However, this technique should be used only when a therapeutic intervention is planned because of the risk of ARF induced by contrast media.

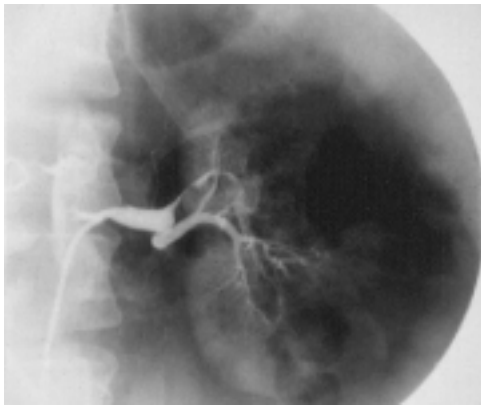

Figure 7a. Preinterventional intraarterial angiography of a 48-year-old-man with patent foramen ovale who had an embolism to the anterior main branch of the left renal artery. Consequently, renal perfusion was dramatically diminished.

Figure 7b. Intraarterial angiography after successful intraarterial thrombolysis (urokinase) shows recanalization of the affected arterial branch and restoration of renal blood flow.

Therapy

Intraarterial angiography allows immediate therapy in many cases. This will mean percutaneous transluminal angioplasty (PTA) and embolectomy with or without stenting of the vessel wall [180 – 182]. In some instances, vascular surgery will be needed. However, traditional methods of repair (e.g. in situ repair, bypass graft, and thrombectomy) have poor success rates. Renal autotransplantation was successfully performed in a patient with bilateral RAT [183]. If none of these therapeutic options can be employed, intraarterial or systemic thrombolysis (e.g. streptokinase or urokinase) should be considered to prevent irreversible loss of the organ [154, 184, 185] (Figures 7a and 7b). In any event, therapy should be started as soon as possible [186]. However, even after a one day delay, renal function in some patients will still profit from therapy because renal parenchyma may be perfused via collateral vessels or by minimal flow rates through the affected vessel [187, 188]. Conservative treatment by anticoagula-

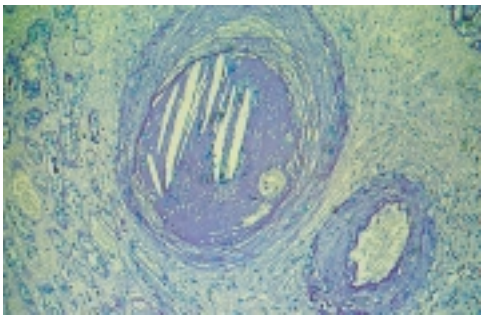

Figure 8. Renal cholesterol atheroembolism of an interlobular artery in a kidney transplant of a 70-year-old male. A fibrinous thrombus, containing typical cleft-like spaces of cholesterol crystals, is obstructing the lumen. Note edema and the ischemic tubular lesions in the surrounding interstitium (PAS, magnification x 125).

tion with heparin and acetylsalicylate is usually not sufficiently effective. However, long-term anticoagulation may be required in some patients to prevent embolization to other vital organs.

Cholesterol Crystal Embolism

Cholesterol crystal embolism syndrome (CCE) occurs mainly in elderly patients (>60 years) frequently with a history of hypertension, atherosclerotic cardiovascular disease, renal failure, and aortic aneurysms (25%) at presentation (Figure 8). To a lesser extent, patients with thrombolytic or anticoagulant therapy are also affected. Possible predisposing factors are operative, radiological, and vascular procedures. Finally, there are reports that cholesterol embolism can occur spontaneously. Multiple showers of cholesterol emboli that stem from atheromatous plaques may lodge in medium-sized vessels (diameter < 200 μm). Here they initiate a progressive inflammatory reaction. Initially, an infiltrate of macrophages and giant cells is found. This is followed by a process of intimal proliferation and fibrosis and results in irreversible occlusion of the arteries [189 – 191].

Clinical and Laboratory Features

CCE frequently presents with nonspecific manifestations that mimic other systemic diseases. The onset can be abrupt, but more chronic courses of progressive loss of organ functions can also be found. Clinical manifestations vary, depending on the affected organs, up to multiorgan failure. The brain, retinal arteries, and visceral vessels (pancreas, gut) are often involved. Also, embolism of muscles and skin is usually found. Thus, ischemic necrosis of the toes (blue toe syndrome) and livedo reticularis may occur and may be mistaken for vasculitis. In the kidneys, embolism results in deterioration of renal function and a mixture of mild proteinuria, microscopic hematuria, and leukocyturia. Additionally, nonspecific signs and symptoms such as fever, weight loss, myalgias, and headache may appear. Only one-third of CCE cases are diagnosed premortem, most commonly by biopsy of the muscle, skin, and kidney. Mortality is high and is most commonly due to multifactorial, cardiac, and renal etiologies. CCE should always be considered in elderly patients with atherosclerotic vascular disease with onset of renal insufficiency and cutaneous manifestations. In addition, thorough inspection of the retinal arteries may reveal cholesterol emboli. The emboli may be seen as bright copper yellow plaques, usually lodged at the bifurcations of retinal arterioles. In many cases however, the diagnosis will be missed unless renal biopsy demonstrates the presence of cholesterol emboli within the smaller arteries [190 – 192].

Laboratory findings are indistinct, but eosinophilia and increased ESR are often present.

Diagnosis of this disorder is difficult, as findings in urinalysis are rather nonspecific. Eosinophilia may be suggestive in combination with a history of predisposing procedures and skin findings [190 – 192].

Therapy and Prognosis

To date, there is no specific treatment available, and CRF (as well as marked impairment from other manifestations) can often develop. Treatment of arterial hypertension may slow progression of renal insufficiency. ACE inhibitors may be beneficial to control arterial hypertension. Cholesterol-lowering agents are used as well [193]. They may stabilize the vascular plaque and therefore prevent further embolization. Prostacycline analogs are novel candidates for the treatment of cholesterol embolism [194]. The role of anticoagulation is controversial. It may predispose patients to the development of CCE [195]. Case reports of catastrophic cholesterol embolization temporally associated with thrombolytic therapy patients have suggested a causal relationship. The prevalence of cholesterol embolization in patients with acute myocardial infarction treated with thrombolytic therapy is not significantly higher than in those treated without thrombolytic therapy. Isolated case reports of severe cholesterol embolization temporally associated with thrombolytic therapy do not represent a phenomenon with widespread subclinical occurrence [196].

Renal Vein Thrombosis

Thrombosis or occlusion of one or both renal veins occurs in a variety of settings (Table 14).

Table 14. Causes of Renal Vein Thrombosis

– Extrinsic compression (tumor, lymph nodes, aneurysm, retroperitoneal mass)
– Invasion of the renal veins or inferior vena cava by renal cell carcinoma
– Trauma
– Hemoconcentration (children in association with dehydration)
– Nephrotic syndrome
– Kidney transplantation (OKT3 and cyclosporine therapy)
– Steroid administration
– Pregnancy or oral contraceptives
– Constitutional protein S deficiency [197]
– Acute pyelonephritis [198]
– Primary antiphospholipid syndrome [199, 200]

The association between renal vein thrombosis (RVT) and nephrotic syndrome was first described by the French nephrologist Rayer in 1840 [201]. In the past, most cases of RVT were diagnosed postmortem. Later, with the development of more advanced imaging techniques and selective catheterization, antemortem diagnosis of RVT was made possible and the number of described cases increased. So far, however, there is controversy about the real incidence of RVT in adults with the nephrotic syndrome. The incidence of RVT in the adult population is difficult to establish, because RVT frequently occurs without a specific clinical presentation, and therefore the diagnosis is often missed.

Thromboembolism is one of the most serious complications of the nephrotic syndrome [202, 203]. The most frequent site of thrombosis is the renal vein, with a reported incidence varying from 2 – 42% (average incidence 9%) [204]. The prevalence of RVT in patients with all types of nephrotic syndrome other than membranous nephropathy (MN) who were submitted to venography was 13% [204]. On the other hand, the mean frequency of RVT in patients with the nephrotic syndrome caused by MN was 15.4% (5 – 62%)

and increased to 29.6% when renal venograms were performed [204]. It is generally accepted that MN is the most common nephropathy associated with RVT. Other forms of nephropathy such as membranoproliferative glomerulonephritis (MPGN), lupus nephritis, and amyloidosis are not frequently associated with RVT [205]. For poorly understood reasons, nephrotic syndrome due to diabetes mellitus, focal sclerosis, and minimal change disease does not carry a high risk of RVT. It remains unexplained why there is a selective association between MN and RVT that does not completely exclude a possible pathogenetic correlation between primary RVT and the subsequent MN in selective patients [204]. It seems that the disease process underlying the nephrotic syndrome may play a paramount role in the genesis of RVT or thromboembolic phenomena [205]. In addition, RVT is very frequently complicated by pulmonary emboli. Approximately 42% of all patients with the nephrotic syndrome have thromboembolic complications that were more frequent in MN compared with other types of the nephrotic syndrome [204].

RVT is thought to be a result of the profound metabolic disorder due to the nephrotic syndrome. Alterations of many coagulation factors and clotting inhibitors as well as defects in the fibrinolytic system and platelets may arise. Table 15 summarizes the major factors that may contribute to the hypercoagulable state in the nephrotic syndrome [203, 204, 206].

In summary, the hypercoagulable state of the nephrotic syndrome seems to be characterized by occasionally low zymogen factors, a marked increase in cofactors, an increase in plasma fibrinogen, sometimes a decrease in antithrombin III, and an increase in α 2-antiplasmin. Additionally, thrombocytosis and increased platelet aggregation are observed. However, none of the various laboratory tests used so far can predict the development of thrombotic complications [207]. Additionally, hypoalbuminemia also might play a role in the platelet hyperaggregability in the nephrotic syndrome because albumin normally binds arachidonic acid, thus limiting its conversion to thromboxane A2 by platelets. Hypoalbuminemia might cause increased platelet archidonic acid metabolism, and therefore platelet hyperactivity may result [208]. As a consequence of these abnormalities in blood coagulation, a hypercoagulable state may develop. In addition, further clinical events or individual predisposition such as increased blood viscosity, intravascular volume deple-

tion, or other therapeutic maneuvers (e.g. steroid therapy, diuretics) may trigger the disease.

Clinical Features

Only 10% of patients with RVT present with clinical symptoms [203]. Acute RVT should be considered whenever an acute change in renal function or increase in proteinuria is noted in a setting of nephrotic syndrome. A sudden onset of persistent flank pain, which may be colicky at times, marked costovertebral angle tenderness, macroscopic hematuria, changes in urinary protein excretion, and increased renal size are features of acute RVT superimposed on nephrotic syndrome. When acute RVT arises bilateral, acute decline in GFR and marked oliguric ARF may develop. On the other hand, chronic RVT may frequently be clinically silent. The presence of pleuritic pain or hemoptysis in a patient with NS should alert the clinician to the possibility of RVT and pulmonary emboli. Additional clinical signs of RVT may be back pain, thrombophlebitis in the lower extremity, asymmetric edema, left varicocele, and dilated abdominal veins. Greatly elevated urinary fibrin-fibrinogen products may be helpful in screening for RVT in asymptomatic nephrotic syndrome patients [209, 210].

Color Doppler ultrasound is already the modality of choice for the detection of acute RVT [211, 212]. This noninvasive technique essentially measures the renal venous flow velocity. CT together with intravenous infusion of contrast media also allows a noninvasive evaluation of RVT [213]. Renal magnetic resonance angiography is also a noninvasive method for diagnosing RVT [214]. A major potential advantage in using this technique is the avoidance of iodine contrast media. Confirmation of RVT may be obtained by arteriography with delayed films during the venous phase, by inferior venacavograms, or, preferably, by selective renal venography. However, when renal function is normal, the high rate of renal blood flow leads to a rapid wash out of the contrast media and therefore may render the venography procedure difficult. Digital subtraction venography also seems to be a simple, safe, noninvasive, and quite efficient method to diagnose RVT [215].

Therapy

The treatment of RVT is usually conservative with the use of heparin (clotting time 2 – 2.5 times normal) followed by oral anticoagulation (warfarin) or antiplatelet drugs [216]. Anticoagulation may be of prophylactic value for the occurrence of pulmonary emboli. Additionally, in patients with acute RVT, anticoagulant therapy reduces massive proteinuria and improves renal function in association with demonstrable recanalization of renal veins [217 – 219]. In most cases of chronic RVT, however, anticoagulant therapy has little effect on renal function, and thrombosis may recur in the recanalized veins when the therapy is discontinued. Altogether, the impact on renal function caused by treating asymptomatic chronic RVT is undetermined, but anticoagulation for chronic RVT is associated with relatively few complications [202]. In cases of nephrotic syndrome caused by MN, the anticoagulant therapy should be administered as long as the patient has nephrotic proteinuria, an albumin level < 20 g/L, or both. In patients with other causes of chronic nephrotic syndrome, a more cautious approach may be indicated, and prophylactic anticoagulation should be considered only if the risk of thromboembolism is high [203]. Because of the increased platelet function, platelet-aggregation inhibitors (low-dose aspirin) are a rational choice, although no infor-

mation from controlled studies is available [203].

Thrombolytic therapy (streptokinase, urokinase) can be used safely as long as there are no contraindications. However, this therapy should be reserved for those patients with the most severe disease or worse prognosis and seems to be warranted in the presence of bilateral RVT with ARF, massive clot size with high risk of acute embolic events, or recurrent pulmonary emboli [220 – 222].

The value of surgical thrombectomy in acute RVT has not been determined. However, this procedure may be useful in patients with acute RVT when complications develop such as pulmonary embolism and inferior vena cava thrombosis, right renal vein thrombosis without collateral flow, and acute RVT with shock, and patients are not otherwise expected to survive the acute episode [223].

Whether the high incidence of thromboembolic events in patients with the nephrotic syndrome justifies prophylactic administration of oral anticoagulants remains controversial. A carefully performed Markov-based decision analysis has concluded that for nephrotic patients with MN, the benefits of prophylactic anticoagulation outweigh the risks such as serious bleeding events [224]. However, decision analysis models do not replace the need for prospective, randomized clinical trials. Altogether, it may be prudent, unless contraindicated, to recommend long-term oral anticoagulation to nephrotic patients with MN, when the nephrotic syndrome is anticipated to persist. Additionally, when serum albumin concentration falls < 2.0 – 2.5 g/dL (high risk of thromboembolic events), prophylactic oral anticoagulation seems to be indicated. Also, patients with a history of thromboembolic complications should receive long-term oral anticoagulation. Immobilized nephrotic patients should probably receive short-term, low-dose parenteral heparin during their immobilization followed by oral anticoagulation [224, 225].

Acknowledgments

We are indebted to Dr. B. Sattler (Department of Pathology, Georg-August University, Göttingen, Germany) and PD Dr. K.-H. Scholz (Department of Cardiology, Georg-August University, Göttingen, Germany) for providing histologic and angiographic pictures, respectively.

Hereditary, Cystic and Congenital Diseases of the Kidney and the Urinary Tract

Dominique Joly, Shuta Ishibe and Jean-Pierre Grünfeld

The most severe forms of inherited kidney diseases are seen in children, but the most prevalent disorders, such as autosomal dominant polycystic kidney disease, are first seen and managed in adults. All nephrologists are therefore confronted with inherited kidney diseases. Recent progress in molecular genetics has dramatically improved the understanding and classification of these diseases and consequently has made genetic counseling more accurate.

Cystic Kidney Diseases

Please refer to Table 1 for an overview of cystic diseases.

Table 1. Cystic kidney diseases.

Hereditary

Autosomal dominant
- Autosomal dominant polycystic kidney disease
- von Hippel-Lindau disease
- Tuberous sclerosis
- Medullary cystic diseases
- Renal cysts and diabetes
- Glomerulocystic kidney diseases

Autosomal recessive
- Autosomal recessive polycystic kidney disease
- Nephrophthisis
- Meckel-Gruber syndrome
- Bardet-Biedl syndrome
- Zellweger syndrome

X-linked
- Orofaciodigital syndrome, type 1

Chromosome disorders
- Aneuploidies (trisomy 13)

Nonhereditary

Congenital
- Multicystic dysplasia
- Paraplegic cysts
- Medullary sponge kidney

Acquired
- Simple cysts
- Acquired renal cystic disease (chronic renal failure)
- Hypokalemia

Autosomal Dominant Polycystic Kidney Disease (ADPKD)

ADPKD is one of the most common inherited monogenic disorders, occurring in approximately 1 in 600 – 1,000 live births. ADPKD is a systemic disorder characterized by the development of multiple renal cysts, and variably associated with liver, cardiovascular, gastrointestinal, and genital abnormali-

ties. In Western countries, ADPKD accounts for 5 – 10% of end-stage renal disease (ESRD). However, the exact prevalence depends on detection, as the disease is often clinically silent.

Genetics

About 85% of families with ADPKD are linked to the PKD1 locus on chromosome 16 (PKD1 disease). In the remaining families, the genetic defect is linked to the PKD2 locus on chromosome 4 (PKD2 disease). Recent identification of pedigrees unlinked to either of these loci raises the possibility of at least a third locus, yet unmapped (PKD3 disease). De novo mutations probably account for < 10% of all cases of ADPKD. The proteins encoded by PKD1 and PKD2, polycystins 1 (Pc-1) and 2 (Pc-2), are transmembrane proteins that are able to interact, function together as a nonselective cation channel, and also induce several distinct transduction pathways. The "polycystin complex" may have three different subcellular localizations and associated putative functions: at lateral membranes of the cells (with a role in cell-cell interaction); at the basal pole of the cell (with a role in cell-extracellular matrix interaction); at the apical primary cilia of the cells (with a role in the mechanotransduction of the urinary flux) [1]. In ADPKD renal cysts, somatic mutations of the wild-type allele of PKD1 and PKD2 and subsequent loss of the functional polycystin complex presumably trigger a cascade of signaling and gene expression events, ultimately leading to cyst formation.

Renal Pathology

Cyst formation occurs in < 10% of nephrons. Initially, cysts are dilatations of intact tubules, filled by glomerular filtration. Enlarging cysts lose their connection to functioning nephrons. Secretion of fluid into the cysts is responsible for their progressive growth over time, and some kidneys may reach 40 cm in length and 8 kg in weight.

Renal Manifestations of ADPKD

ADPKD often leads to progressive renal failure due, in part, to continued cyst enlargement. Other renal manifestations are flank and abdominal pain, hematuria, urinary tract infection (UTI), nephrolithiasis, and hypertension. Renal cell carcinoma (RCC) is uncommon.

Flank and Abdominal Pain

Flank and abdominal pain, often described as dull and chronic, is the presenting symptom in 20 – 30% of the patients, and its frequency increases with the age as well as with cyst size. Possible mechanisms are stretching of the renal capsule and traction on the renal pedicle. Hepatic cysts may also contribute to right-sided pain. Acute pain suggests a cystic complication (e.g. hemorrhage or infection) or urinary obstruction (e.g. urolithiasis or clot). Nonnarcotic analgesics provide substantial pain relief for the great majority of patients. Analgesic-resistant pain (sometimes severe enough to alter the quality of life) requires evaluation by ultrasonography or computed tomography (CT) scan. Any large cyst detected in the area of pain deserves consideration. Imaging-guided percutaneous aspiration has proved to be minimally invasive and efficient in relieving the pain. Yet, the recurrence of pain is common. The third-line treatment is surgical intervention, either by open surgery or laparoscopic decompression, which is invasive but efficient when applied

to highly selected cases. Cyst decompression does not have any effect on renal function or rate of renal failure progression.

Hematuria

Macroscopic hematuria occurs at some time in the course in 30 – 50% of patients with ADPKD and may be the presenting symptom in 15 – 20%. A precipitating event, such as trauma or strenuous physical activity, is frequently identified. The most likely explanation is rupture of a cyst into the collecting system, but UTI or urolithiasis should be considered. Hematuria usually resolves within a few days with bed rest and hydration to prevent renal colic by clot migration. Blood transfusion or surgical treatment is rarely needed. Some cyst hemorrhage presents with pain but no hematuria, as many cysts do not communicate with the collecting system, in which case CT scan shows a high-density cyst.

Urinary Tract Infection (UTI)

Many ADPKD patients will have one or more UTIs during their lifetime. Lower UTI, infected cyst, and acute pyelonephritis are more likely to occur in women (68%) than men (19%) and can be potentially severe. The initial symptoms of dysuria and frequency, and the presence of Gram-negative enteric bacteria suggest ascending contamination from the bladder. The primary clinical manifestations of renal infection in ADPKD are fever and flank pain. In acute pyelonephritis, urine culture is positive with frequent white cell casts. Bacteremia is rare, and response to conventional antibiotic therapy is good. In cyst infection, a new area of tenderness appears, urine culture is often negative, white cell casts are absent, blood culture is often positive, and response to conventional antibiotic therapy is poor. Hemorrhage into a cyst can mimic infection, with symptoms of pain, transient fever and leukocytosis. Complicated UTI, e.g. associated with a stone, should be excluded by radiologic studies. Patients with renal infection should receive the conventional antibiotic therapy recommended for acute pyelonephritis: third-generation cephalosporin, fluoroquinolones, or trimethoprim-sulfamethoxazole. Short-term aminoglycosides (2 – 3 days) should be reserved for hospitalized patients with severe infection. Fluoroquinolones, or trimethoprim-sulfamethoxazole, are also adequate treatment for cyst fluid infection, because they easily diffuse into the cysts. The duration of therapy ranges from 10 – 20 days, but some patients with presumed infection of a cyst have been treated for as long as 4 – 6 weeks [2].

Nephrolithiasis

Kidney stones occur in up to 20% of patients with ADPKD. In contrast to the predominance of calcium oxalate in idiopathic stone formers, more than one-half of stones in ADPKD are composed of uric acid. Both mechanical changes induced by the large cysts and metabolic abnormalities may contribute to stone formation. These abnormalities include low urinary pH, hypocitraturia and, less often, hyperuricuria and hypercalciuria. Establishing the diagnosis by ultrasonography is more difficult than in idiopathic stone formers because of the large cysts and possible calcifications in cyst walls. CT scanning has good sensitivity for the detection of small or radiolucent stones. The treatment of obstructing stones is more difficult than in patients with idiopathic stone disease. Percutaneous nephrostomy and extracorporeal shock-wave lithotripsy have both been used successfully [3].

Hypertension

Hypertension is a common and early finding in ADPKD, occurring in 33% of the patients with normal renal function and in up to 80% of patients with renal failure. Affected children or young adults may have a higher blood pressure and a higher left ventricular mass index when compared with age-matched unaffected relatives. Renin release in areas of renal ischemia around growing cysts and extracellular volume expansion may play an important role in hypertension. The main objective of antihypertensive treatment in ADPKD patients is to prevent cardiovascular complications. Mean blood pressure is less correlated to the rate of progression of renal failure than in other nephropathies, although the usefulness of an early intervention has not been tested. In some ADPKD patients (usually with massive cystic disease), ACE inhibitors may induce an early and reversible decline in glomerular filtration rate (GFR). However, these drugs, like any other antihypertensive agents, may be used in ADPKD, provided their dosage is adjusted to the degree of renal insufficiency [4].

Chronic Renal Failure

Progressive renal failure is frequent in ADPKD. Recent studies suggest that only $^1/_4$ – $^1/_2$ of the patients with ADPKD will survive without ESRD. When renal failure develops, mean GFR decline is 6 ml/min/year. ESRD is typically reached at 55 years of age, and 75% of the patients start regular dialysis between ages 40 and 60. ESRD is very rare among ADPKD children, and the likelihood of requiring dialysis is < 5% under age 40 and 20% after 60. However, precise individual prediction of renal prognosis is difficult, because there is little intrafamilial concordance. The main determinants of progression are

- sex: males reach ESRD 5 – 6 years before females;
- genotype: PKD2 disease is less aggressive than PKD1, with ESRD occurring later (69 vs. 55 years);
- black race, especially if sickle cell trait is present. Low-protein diet or ACE inhibitors do not reduce the rate of progression of renal failure [5].

Renal Cell Carcinoma (RCC)

RCC is a rare complication among ADPKD patients, occurring with the same frequency as in the general population. However, tumors are more often bilateral at presentation, multicentric, and sarcomatoid in type. The diagnosis of von Hippel-Lindau disease (vHL) (see below) should be considered in any polycystic patient with bilateral RCC.

Extrarenal Manifestations of ADPKD

ADPKD is frequently associated with cysts in the liver (and occasionally pancreas or spleen), and this finding can help in confirming the diagnosis. Other abnormalities, both vascular and extravascular, are consistent with a generalized dysfunction of extracellular matrix or epithelial cell differentiation.

Liver Cysts

Liver cysts develop later than renal cysts; they are very rarely found before 20 years of age and their prevalence reaches 80% after 60 years of age. The cysts, which appear to be derived from biliary epithelium, are more commonly seen in patients with advanced renal disease. They are more prevalent and are

observed earlier and more extensively in females than in males. Most patients remain asymptomatic with preserved hepatic function. Persistent and severe pain may require cyst decompression. Cyst infection is rare, occurring mainly in dialysis or transplant patients, and requires antimicrobial therapy with occasional percutaneous drainage.

Massive polycystic liver may lead to gastrointestinal tract compression with abdominal pain. Posterior cysts may compress the suprahepatic veins and intrahepatic vena cava, resulting in portal hypertension and ascites. Percutaneous puncture and sclerosis (with alcohol or minocycline), laparoscopic fenestration, partial hepatic resection and even liver transplantation have been attempted with some success in these patients [6].

Intracranial Aneurysms

The prevalence of asymptomatic intracranial aneurysm in ADPKD patients has been found to be approximately 8%, compared to 1.2% in the general population. The rupture of an intracranial aneurysm, resulting in subarachnoid or intracerebral hemorrhage, is the most serious complication in ADPKD, as death or severe disability occurs in 50% of cases. The risk is 2 – 4 times greater in patients who have a positive familial history of intracranial aneurysm. Mean age at rupture is 41 years, with 10% of the patients being less than 21 years of age. One half of patients have normal renal function at this time. In $^1/_3$ of the cases, rupture is preceded by premonitory symptoms, e.g. unusual headaches, often acute and posterior. Patients with ruptured aneurysm should be managed in a neurosurgical unit. Non-enhanced CT scanning is the first-line diagnostic procedure, detecting both the aneurysm and blood in the cerebrospinal fluid. If CT scan is negative, a lumbar puncture should be performed to look for the presence of red blood cells, followed by arteriography. The middle cerebral artery is usually involved, and some patients have multiple aneurysms.

Should asymptomatic ADPKD patients be screened for intracranial aneurysm? At present, routine screening is recommended only for selected patients: those with previous rupture, positive family history of aneurysm, a high-risk occupation, and before major elective surgery. The issue of screening in other ADPKD patients is still unresolved. Spiral CT scanning and, preferably, magnetic resonance angiography are the two major screening procedures able to detect small aneurysms (5 mm in diameter). The indications for prophylactic treatment (surgery or radiologic intervention) depend on the size, number, and location of the detected aneurysm(s). If observation is elected, a second radiological evaluation should be performed 6 – 12 months later. If screening is negative in an at-risk patient, tests should be repeated every 3 – 5 years, as cerebrovascular disease is progressive [7].

Cardiac Valve Disease

Mitral valve prolapse and aortic regurgitation are detected by cardiac ultrasonography in up to 30% of patients with ADPKD, a rate 10 times that of the general population. Mitral regurgitation and aortic root dilatation are less frequent. The vast majority of these lesions are asymptomatic but may progress over time and become severe enough to require valve replacement. Antimicrobial prophylaxis is mandatory whenever murmurs are audible. Aortic and coronary aneurysms and dissection of cervical arteries have occasionally been reported.

Table 2. Diagnostic criteria of overt ADPKD (PKD1 disease).

Positive family history, with an autosomal dominant inheritance pattern

– Ultrasonography of patient's parents may help establish autosomal dominant inheritance if family history negative.

*Enlarged kidneys with multiple bilateral renal cysts on ultrasonography (or CT scanning)**

– patients < 30 years
  2 cysts (unilateral or bilateral)
– patients aged 30 – 59
  2 cysts in each kidney
– patients > age 60
  4 cysts in each kidney

Direct genetic testing (mutation identification) or indirect genetic testing (linkage analysis) are not routinely performed in ADPKD.

*In difficult cases, demonstration of cysts in the liver, pancreas, and spleen is useful.

Digestive Abnormalities

Colonic diverticula is a frequent finding in ADPKD patients with ESRD. The frequency of umbilical and inguinal hernias is increased in ADPKD.

Diagnosis and Screening of ADPKD

The diagnosis is usually easy to establish in overt disease, since most patients present with a familial history of ADPKD and enlarged kidneys with multiple bilateral cysts on ultrasonography [8] (Table 2).

Cyst formation can rarely be detected during fetal life. In PKD1 disease, 8% of children < 10 years old have cysts demonstrated by ultrasonography. This probability increases to virtually 100% by the age of 30. A negative ultrasound cannot definitely exclude the disease until the patient is older than 30, although the false negative rate at age 20 is only about 4%. Since symptomatic disease is relatively uncommon in young children, ultrasound screening is usually not recommended before the age of 18. These criteria (Table 2) do not apply to patients with the PKD2 disease, who form cysts at a later age, have a slow rate of progression, and a low risk for renal failure.

A case for precise presymptomatic screening is the young adult who is a potential renal transplant donor. If ultrasonogram is negative, genetic linkage analysis may be indicated.

Pregnancy

Information on the specific risks during pregnancy should be provided. Although normotensive ADPKD women usually have successful and uncomplicated pregnancies, the relative risks of hypertension (16%) and preeclampsia (10%) are 2.5 times greater than in the general population. ADPKD women with preexisting hypertension are at high risk for fetal and maternal complications [9].

Renal Replacement Therapy

When ESRD is reached, maintenance hemodialysis is initiated. The tolerance of this treatment has been found to be even better in ADPKD patients than in patients with other renal diseases, possibly because of less severe anemia, at least before the introduction of recombinant human erythropoietin (rHu-EPO). Peritoneal dialysis is not advisable in patients with very large polycystic kidneys. Kidney transplantation should be considered in patients who are < 65 years old, provided that careful cardiovascular work-up is performed in older patients. Elective nephrectomy, uni- or bilateral, is advised when kidney size is an

obstacle to transplantation or when recurrent renal infection or gross hematuria has occurred. The results of transplantation are similar to those obtained in patients with other renal diseases and similar ages. ADPKD itself has no negative impact on overall survival in renal replacement therapy. Liver cysts are rarely symptomatic. The incidence of major valvular heart disease is not strikingly increased when compared to the general population of patients in renal replacement therapy [10].

von Hippel-Lindau Disease (vHL)

vHL is transmitted as an autosomal dominant trait. Individuals inheriting a mutant vHL gene are predisposed to develop hemangioblastoma of the cerebellum, brain stem, spinal cord, and retina; renal cysts and cancers; pheochromocytoma; pancreatic cysts and carcinoma; and epididymal cystadenoma. In a vHL family, diagnosis can be made if an individual develops one of the above cardinal manifestations (except renal cysts). In the absence of a typical familial history, two cardinal manifestations must be present, including hemangioblastoma of either the retina or central nervous system.

The vHL gene has been localized to chromosome 3p25-26, and acts as a tumor suppressor gene. Tumor formation depends on the so-called "2-hit" theory of Knudson. One copy of the vHL gene is mutated in the germline of vHL patients (first hit), and a somatic inactivation of the second copy (second hit) initiates tumorigenesis. Cells lacking vHL protein overproduce products of the hypoxia inducible factor (HIF), such as vascular endothelial growth factor (VEGF) or transforming growth factor (TGF) [11].

Identification of the germline vHL mutation in a given vHL family is useful. Any at-risk member of this family should be tested for this mutation. If negative, no further medical testing is necessary; if positive, periodic testing for occult manifestations of vHL disease is highly recommended.

Renal involvement in vHL disease is characterized by multiple and bilateral renal cysts and renal cell carcinomas (RCC) with increasing frequency as the patient ages. It is estimated that cysts will develop in 95% and RCC in 70% of patients who survive to age 80. Cysts typically appear earlier than RCC; the youngest reported patient with RCC was 16 years old. In at-risk individuals above this age, annual renal ultrasound screening should be performed and, if abnormal, should be complemented with RMI or CT scan.

Typical cysts cause few problems. RCC is of greater concern, accounting for more than 25% of deaths in vHL patients. Renal-sparing surgery, e.g. tumorectomy or partial nephrectomy, whenever possible, provides safe and effective treatment for RCC in vHL patients. This conservative approach, rather than total nephrectomy, has been advocated to delay ESRD. Surgery is recommended when the diameter of the largest solid tumor is above 2.5 – 3 cm; only atypical cysts should be removed. Tumors recur in approximately 30% of patients at five years after surgery and 85% at 10 years, leading to repeated surgery. Renal failure in vHL patients is mainly related to repeated surgeries with parenchymal resection. ESRD due to cysts and infiltrative RCC is rare. Some vHL patients with RCC but no metastasis have now undergone kidney transplantation 1 – 2 years after bilateral nephrectomy [12].

Tuberous Sclerosis (TS)

TS (also called Bourneville's disease) is a rare autosomal dominant disease. Its preva-

lence ranges from 1/5,800 – 1/14,500. Familial history is often negative, mainly because of the high incidence of de novo mutations (60 – 70%), and variable penetrance of the genetic defect in the remaining cases. Two different genes can cause the disease: TSC1 (encoding hamartin), localized to chromosome 9q34, and TSC2 (encoding tuberin), localized at 16p13 and adjacent to the PKD1 gene. TSC1 and TSC2 act as tumor suppressor genes.

Extrarenal lesions of TS involve central nervous system cortical tubers, subependymal nodules, calcifications and astrocytoma and retinal hamartoma; hypopigmented spots on the trunk, facial angiofibroma, ungual fibroma (Koenen tumors), café-au-lait spots, shagreen patch and molluscum fibrosum pendulum of the skin; rhabdomyoma; and, rarely, pulmonary lymphangiomyomatosis.

Kidney involvement is also inconstant. The most common and characteristic renal lesions are multiple and bilateral angiomyolipomas. These benign tumors often grow over time and may require surgery or embolization if larger than 4 cm, symptomatic, or complicated by bleeding. Bilateral renal angiomyolipomas make the diagnosis of TS highly probable, whereas a single solitary lesion is very common in the general population. Some patients present with multiple growing cystic lesions, similar to those seen in ADPKD, with potential complications such as pain, bleeding into the cyst, hematuria, hypertension, and progressive renal failure. Some of these patients have a chromosomal deletion including both the TSC2 and PKD1 genes ("contiguous gene" syndrome). Patients with TSC1 disease do not form cysts. RCC is found in < 5% of patients, but should be considered if periodic ultrasonography or CT scanning shows any atypical cyst or angiomyolipoma. Finally, focal segmental glomerular sclerosis, interstitial fibrosis, small kidneys, and ESRD have been reported in a few patients [13].

Medullary Cystic Kidney Diseases

Autosomal dominant medullary cystic kidney disease (MCKD) and familial juvenile nephrophthisis (NPHP) have for many years been described together as the NPHP-MCKD complex. However, MCKD mainly affects adults and is inherited with an autosomal dominant mode, while NPHP mainly affects children or young adults and is inherited with an autosomal recessive mode (see below). Recent research has also shown that these two entities are genetically different. Moreover, it now appears that two different genes are responsible for MCKD.

Medullary Cystic Kidney Disease Type 1 (MCKD1)

Patients with MCKD1 have few symptoms, except for early polyuria and polydipsia related to renal salt wasting in some cases. In the early stages of the disease, renal cysts are absent in 50% of the patients on ultrasonography. Medullar cysts become apparent in most of the patients in advanced stages and towards ESRD, reached at a median age of 62 years. MCKD1 locus has been mapped on chromosome 1q23.1 [14].

Medullary Cystic Kidney Disease Type 2 (MCKD2) and Familial Juvenile Hyperuricemic Nephropathy (FJHN)

MCKD2 and FJHN were initially described separately; they share many features, includ-

ing polyuria, progressive interstitial fibrosis with renal failure, hyperuricemia, and gout. Corticomedullary cysts are well-documented in MCKD2, but their presence in FJHN is not well-documented. However, it is now clear that these two diseases form the same entity. MCKD2 and FJHN result from allelic mutations of a common gene, UMOD, which codes for uromodulin (or Tamm-Horsfall protein), the most abundant protein in normal urine.

Renal Cysts and Diabetes Syndrome (RCAD)

Heterozygous mutation in the gene encoding hepatocyte nuclear factor (HNF)-1 , a DNA transcription factor, was initially described as one of the main molecular causes of maturity-onset diabetes of the young (MODY). It now appears that renal anomalies are the key feature of HNF-1 phenotype and often precede the onset of diabetes. Renal cysts and progressive renal failure are frequent; glomerulocystic kidney disease and renal hypoplasia have been reported. Abnormal liver function tests, hyperuricemia and urogenital malformations have also been related to HNF-1 mutations [15].

Autosomal Recessive Polycystic Kidney Disease (ARPKD)

ARPKD is a rare condition, with an estimated prevalence of 1 : 20,000 live births. Renal cysts develop only from the collecting ducts, and are constantly associated with a hepatic lesion, congenital hepatic fibrosis, or fibroadenomatosis. Mutations at a single locus, polycystic kidney and hepatic disease 1 (PKHD1), are responsible for all typical forms of ARPKD. The PKDH1 gene product, fibrocystin, is a transmembrane protein localized to the cell primary cilia.

The clinical spectrum is variable and correlated to the severity of mutations. Up to 50% of affected neonates will die soon after birth from pulmonary hypoplasia, caused by abdominal distension and enlarged kidneys. Other neonates will survive and during childhood will eventually develop recurrent UTIs, severe hypertension, and fluctuating renal failure. With hypertension control, 50% of the children may reach adulthood without the need for renal replacement therapy.

Congenital hepatic fibrosis is a constant finding and may be the predominant clinical feature. This hepatic disease may either be asymptomatic or cause portal hypertension and bacterial angiocholitis, if intrahepatic ducts are dilated. Liver function tests are usually normal. Ultrasonography of the liver may reveal dilated bile ducts, hepatic cysts, and portal hypertension.

Because of increased use of ultrasonography in the fetus, pediatricians may be confronted with the discovery of bilateral renal cysts. In very rare cases (100 in the literature), ADPKD (PKD1 form or in association with TSC2) may manifest early, leading to ESRD in the very first years of life. The diagnosis of the cystic disease is then based on the result of ultrasound in the parents. The presence of renal cyst in one parent supports ADPKD. In contrast, ARPKD is suggested when both parents have no cysts and when the liver lesion is detected in the proband. High intrafamilial variability in ARPKD disease expression should be underlined; disease expression is often different among siblings. Every older asymptomatic sibling of affected children should be evaluated for hepatic fibrosis [16].

Nephrophthisis (NPHP)

NPHP is a group of autosomal recessive tubulointerstitial nephropathies with multiple small medullary cysts. NPHP is the most common genetic cause of ESRD in children and young adults. 15% of patients have no obvious family history. These apparently sporadic cases are not surprising in an autosomal recessive disorder. 80% of NPHP cases are caused by homozygous deletions of the NPH1 gene, which codes for nephrocystin. At least three other genes (NPH2, 3 and 4) account for the remainder of the cases, and the respective encoded proteins (inversin, nephrocystin 3, nephrocystin 4) may interact in common signaling pathways downstream the primary cilia of the cells [17, 18].

Polyuria, polydipsia, growth retardation, and urinary sodium leak are present in children between 1 and 3 years of age. Proteinuria is a late finding. Renal failure appears before 12 years of age in most cases and uniformly progresses to ESRD before 20, with a mean age of 14 years. At ultrasound examination, kidneys have a normal or slightly reduced size with smooth outline, increased echogenicity, and loss of corticomedullary differentiation. Multiple small or large cysts at the corticomedullary junction are usually seen in advanced renal failure. CT scanning is more sensitive, detecting cysts as small as 5 mm in diameter. Histology shows small cysts (1 – 10 mm) irregularly distributed at the corticomedullary junction and in the medulla, arising from intact distal and collecting tubules. Medullary cysts appear later in the course and are often absent in renal biopsies performed at an early stage. On light microscopy, atrophic tubules alternate with groups of dilated or collapsed tubules. Changes in tubular basement membranes, including homogeneous or multilayered thickening and disintegration, are highly suggestive of NPHP. There is moderate interstitial fibrosis with rare inflammatory cells.

Detection of NPH1 homozygous deletions allows diagnosis for the propositus and siblings, and prenatal diagnosis without the need for renal biopsy. Therapy for NPHP is exclusively symptomatic. The tubular injury does not recur in the transplanted kidney.

Many eye anomalies have been reported in association with NPHP. Senior-Loken syndrome (not linked to NPH1) is defined by the combination of a NPHP phenotype with tapetoretinal degeneration (18% of NPHP cases). Leber's congenital amaurosis is the early-onset form, with children being blind from birth. In the late-onset form, blindness develops subsequently. Cerebral disease, e.g. mental retardation and cerebellar ataxia, various bone anomalies, and hepatic fibrosis have been described in some families [19].

Hereditary Diseases

A classification of hereditary noncystic disease can be found in Table 2.

Alport Syndrome

Alport syndrome is a hereditary hematuric glomerular disease progressing to ESRD in males, often associated with hearing loss and specific ocular changes. The prevalence of Alport syndrome is 1/5,000 and it accounts for 2% of ESRD. The disease is clinically and genetically heterogeneous. Defects in type IV collagen are responsible for the disease. Genes coding for the different chains of this essential component of basement membranes have been cloned, and mutation characterization has made genetic counseling possible (see Table 4).

Table 3. Main renal hereditary diseases (non-cystic).

Predominant glomerular involvement
- Alport syndrome
- Hereditary nephritis with macrothrombocytopenia
- Congenital nephrotic syndrome of Finnish type
- Familial steroid-resistant FGS
- WT1-related glomerulopathies (Denys-Drash syndrome, diffuse mesangial sclerosis, Frasier syndrome)
- Nail-patella syndrome
- Metabolic disorders
  - Fabry disease
  - LCAT deficiency
  - Glycogenosis, type 1
  - Hereditary amylosis
- Primitive glomerulopathies, sometimes familial (IgA, collagen III, fibronectin)

Predominant tubular involvement

Fanconi syndrome
- *Idiopathic*
- *Secondary* (cystinosis, Wilson's disease, Lowe syndrome, galactosemia, tyrosinemia, fructose intolerance, type I glycogenosis, mitochondrial cytopathies, etc.)

Other tubular diseases
- Bartter syndrome
- Gitelman syndrome
- Liddle syndrome
- Pseudohypoaldosteronism, type I
- Pseudohypoaldosteronism, type II
- Nephrogenic diabetes insipidus

Hereditary urolithiasis
- Cystinuria
- Hyperoxaluria, primitive
- Renal tubular acidosis
- ARTPase deficiency
- Dent's disease

Various malformative syndromes with renal involvement
- Branchiaotorenal syndrome
- Bardet-Biedl syndrome

Clinical Symptoms and Course

In 80 – 85% of kindreds, this disorder is inherited as an X-linked trait. Pedigree analysis shows two important clinical characteristics: father-to-son transmission does not occur, and males are severely affected, while females tend to have a benign course. The initial renal manifestations in males may be recurrent episodes of gross hematuria precipitated by upper respiratory infections during childhood and adolescence. Microscopic hematuria begins in the first years of life. Proteinuria develops later and increases with age, sometimes reaching the nephrotic range. Progressive renal failure and hypertension occur with time. ESRD affects virtually all males before age 30 (juvenile form), but in some families is delayed until age 45 – 70 (adult form). The rate of progression to renal failure is quite constant in males within the same family, but some intrakindred variability has been reported in adult forms. Women are heterozygous, and carriers tend to have a benign course, with 90% having microscopic hematuria during pregnancy or familial screening. However, 10% of them will develop late ESRD, sometimes predicted by gross hematuria during childhood, nephrotic syndrome, and diffuse glomerular damage on electron microscopy examination.

Sensorineural hearing loss occurs in more than 50% of affected males and begins around 10 years of age, with bilateral hearing defect involving high tone frequencies (4,000 to 8,000 Hz) detected by audiometry. Often the hearing defect is moderate and nonprogressive in adults. When present, this symptom frequently shares renal involvement in precocity and severity. Women are less frequently affected, and hearing loss may develop later in life. Ocular defects are less common than hearing loss (15 – 30% of patients). Anterior lenticonus (conical protru-

Table 4. Alport syndrome and related diseases.

Clinical definition	Biochemical defect	Genetic defect
X-linked (classical)	5 (IV)	COL 4 A5
X-linked with leiomyomatosis	5 (IV) and 5 (IV)	COL 4 A5 and COL 4 A6
Autosomal recessive	3 (IV) or 4 (IV)	COL 4 A3 or COL 4 A4
Autosomal dominant	3 (IV) or 4 (IV)	COL 4 A3 or COL 4 A4

5 (IV): -5-chain of type IV collagen
COL 4 A5: gene encoding for

sion of the lens into the anterior chamber) usually develops after 20 years of age. It is pathognomonic of Alport syndrome and strongly correlates with severe nephritis, although it has also been described in females with milder disease. It may be accompanied by severe myopia and opacities of the lens. Other ocular lesions have been reported, such as whitish or yellowish perimuscular lesions in the retina or recurrent corneal ulcers.

Diffuse leiomyomatosis involving the esophagus, tracheobronchial tree, and female genitalia have been reported in more than 20 families. Diffuse leiomyomatosis is inherited as an X-linked dominant trait. Affected females have leiomyomatosis and are carriers for hereditary nephritis. Dysphagia, epigastric pain, vomiting, bronchitis, stridor, and cough appear before adolescence, and imaging (MRI or CT scan) helps to confirm the suspected leiomyomatosis.

Autosomal recessive inheritance accounts for 15 – 20% of cases of Alport syndrome. In this setting, Alport syndrome is often juvenile and severe, with constant hearing loss and very frequent ocular lesions. Women are as severely affected as males in the same kindred. Parents without severe nephropathy and parental consanguinity highly suggest recessive transmission. Autosomal dominant Alport syndrome is very rare.

Renal Pathology

When Alport syndrome is suspected, renal biopsy must focus on ultrastructural and immunological analysis of glomerular basement membranes (GBM). The changes on light microscopy or direct routine immunofluorescence provide prognostic clues, but are nonspecific: focal increased glomerular cellularity, glomerulosclerosis, and interstitial infiltrate containing lipid-laden foam cells. The earliest change is thinning of the GBM (which is not pathognomonic). With time, changes become diagnostic for hereditary nephritis, with the development of longitudinal splitting of the GBM on electron microscopy, producing a multilamellated thickened appearance. Cycles of injury-repair of the GBM may be responsible for these changes. In males, the number of glomeruli showing splitting increases with age to reach 90% by age 30.

Immunohistochemistry is a useful adjunctive study, because antibodies directed against the different chains of type IV collagen have become available. It must be remembered that a normal chain expression does not exclude Alport syndrome. Antibody staining will always be absent with large defects (gene deletion), but some point mutations might result in antigenicity normal but

functionally abnormal (IV) chain formation. Thus, antibody staining might be relatively normal, falsely suggesting that the patient does not have hereditary nephritis.

In X-linked Alport syndrome in males, absence of 3, 4 and 5 (IV) in GBM, tubular basement membrane, and Bowman's capsule is diagnostic, while women frequently show mosaic expression of these chains. In the autosomal recessive form, 3, 4, and 5 are not detected in the GBM while 5 is still present in the basement membrane of the collecting duct and skin where 3 and 4 are not normally expressed. Examination of skin biopsies for 5 (IV) expression is an additional tool, because this chain is normally expressed in the epidermal basement membrane. Lack of its expression is diagnostic in a male with suspected Alport syndrome and may preclude the need for renal biopsy. Here again, a normal expression does not exclude the diagnosis. In heterozygous women, the 5 expression pattern may be mosaic, diagnostic of a carrier state, or normal, e.g. non-diagnostic.

Pathogenesis

Type IV collagen is ubiquitously present in basement membranes. Type IV collagen molecules self-associate into polygonal networks and interact with several glycoproteins to form basement membranes. Each type IV collagen molecule is composed of three -chains. Six different -chains (1 – 6) have been identified and their genes recently cloned.

The six type IV collagen genes are arranged in pairs on three different chromosomes: 1- and 2- (IV) chains are encoded by COL4A1 and COL4A2 genes on chromosome 13; 3 and 4 (IV) are encoded by COL4A3 and COL4A4 genes on chromosome 2; 5 and 6 (IV) are encoded by COL4A5 and COL4A6 genes on chromosome X. Expression of the various type IV collagen chains, as determined by antibodies staining, shows that 1 and 2 (IV) are present in all basement membranes, while 3 and 4 have restricted distribution, including basement membranes involved in Alport syndrome (GBM, lens capsule, and cochlea). All basement membranes that express 3 and 4 (IV) also express 5 (IV), and suggest a preferential 3 4 5 network formation.

A mutation affecting one of the chains involved in the putative 3 4 5 network can not only prevent GBM expression of that chain, but also that of the other 2 chains as well. The network is usually absent from Alport patients' basement membranes or sometimes persists with probable defects in structure and function. How the basement membrane defects produce clinical disease remains unclear. High glomerular capillary pressure might directly damage a weakened GBM. Alternatively, defective synthesis of the (IV)-chain may promote the synthesis of other types of collagen, leading to glomerulosclerosis. It is likely that abnormal collagen IV function is also responsible for the extrarenal manifestations in hereditary nephritis.

Not surprisingly, in more than 50% of X-linked Alport syndrome families, mutations (90%) or major rearrangements (10%) of the COL4A5 gene have been identified. These mutations are likely to interfere with the normal folding of the 5-chain into triple helices with other (IV). The variability in clinical course may result, at least in part, from different mutations in the 5 gene. Affected males with a gene deletion may have more severe disease than those with a point mutation. Patients with leiomyomatosis show deletions at the 5' ends of both the COL4A5 and COL4A6 chains (located head-to-head on the X chromosome). In autosomal reces-

Table 5. Genetic counseling in Alport syndrome.

– Identify the mode of inheritance in a given family. X-linked dominant (more than 80% of cases) Autosomal recessive (rarely dominant)
– Characterize the mode of progression in affected males with X-linked disease. Juvenile vs. adult type
– Identify carrier heterozygous females in X-linked disease. Clinical diagnosis (may be uncertain) Molecular diagnosis: identification of the mutation in the family [5 (IV)] or linkage analysis
– Provide information to the patients and families, including risk of progression and transmission to offspring

sive Alport syndrome, mutations of either COL4A3 and/or COL4A4 have been described. In autosomal dominant Alport syndrome, COL4A4 mutations (with a possible dominant negative effect) have been described.

Genetic Counseling

The principal steps are summarized in Table 5 [20].

Differential Diagnosis

Alport syndrome is usually suspected from the family history of renal failure and deafness. In this setting, other major causes of persistent glomerular hematuria are unlikely. In up to 15% of cases, there is no family history of renal disease, and the diagnosis is first suggested by renal biopsy. These patients probably represent new mutations (10 – 15% of cases) in the gene responsible for the basement membrane abnormalities.

Treatment

There is no specific treatment for hereditary nephritis. ACE inhibitors reduce protein excretion in some patients and may slow renal failure in male patients with hypertension and progressive disease. Dialysis or transplantation can be performed in those patients with hereditary nephritis who develop ESRD. Initial disease does not recur in the transplant, but some patients develop anti-GBM antibody disease. These antibodies are directed against the Goodpasture antigen (within the 3-chain). This epitope is recognized as foreign in the graft because it is not expressed in the native kidneys. The incidence of anti-GBM antibody disease in the transplant is not known, because antibody deposition has been found in patients with and without clinical disease. Less than 5% of transplanted patients will develop early clinical disease with crescentic glomerulonephritis and frequent loss of the graft despite plasmapheresis and immunosuppressive treatment. The risk factors for this complication are juvenile renal failure, large gene deletions, and first graft loss due to anti-GBM antibody disease [21].

Hereditary Nephritis with Macrothrombocytopenia

More than 30 families with autosomal dominant transmitted hereditary nephritis, deafness cataract, and hematologic abnormalities have been reported under the terms of either Epstein syndrome or Fechtner syndrome

and were considered to be Alport syndrome variants. Hematologic findings include macrothrombocytopenia (low platelet count and giant platelets) and leukocyte inclusions, known by hematologists under the names of May-Hegglin syndrome or Sebastian syndrome. These four syndromes result from allelic mutations of a common gene, MYH9, which codes for the heavy chain of non-muscle myosin IIA, an enzyme linked to the cytoskeleton [22]. There is considerable intrafamilial phenotypic variability, and in some kindreds, males present with hematologic abnormalities but no renal involvement.

Congenital Nephrotic Syndrome of Finnish Type (CNF)

CNF is the leading cause of congenital nephrotic syndrome. CNF is frequent in Finland, with an incidence of 1 in 8,000 births, but has also been described all-around the world. CNF is inherited as an autosomal recessive trait. Heterozygous individuals do not manifest renal disease. The responsible gene, NPHS1, codes for a novel immunoglobulin-like protein, nephrin, which is responsible for the intercellular adhesive force between podocytes at the glomerular slit diaphragm [23]. Nephrin mutations result in truncated proteins that alter the glomerular filtration barrier and cause the nephrotic syndrome. Two major nephrin mutations (Fin-major and Fin-minor) account for more than 94% of the CNF in the Finnish population (suggesting a founder effect), but are rare in non-Finnish patients.

CNF becomes overt during early fetal life (15 weeks) with fetal proteinuria, high amniotic fluid, and maternal plasma -fetoprotein (AFP) concentration. In at-risk families, these changes used to lead to termination of the pregnancy, but today NPH1 gene analysis is the method of choice to establish a precise prenatal diagnosis.

Most infants with CNF are born prematurely with a low weight for gestational age. Fetal distress is not uncommon. In 50% of cases, edema is discovered during the first week of life. Highly selective proteinuria without hematuria, hypoalbuminemia, normal renal function, and enlarged, hyperechogenic kidneys without normal corticomedullary differentiation are the initial findings. Renal biopsy shows mild mesangial changes of hypercellularity and increased matrix, without any immune deposits on immunofluorescence studies. Over time, progressive glomerulosclerosis, tubulointerstitial changes, and fibrosis develop. As the disease progresses, growth retardation, bacterial infections, thromboembolic complications, and hypothyroidism may occur. ESRD invariably develops before 8 years of age.

CNF is not an immunologic disease and is always resistant to corticosteroids and immunosuppressive drugs. Treatment is conservative and includes albumin infusion, -globulin replacement, nutrition with a high-protein and low-salt diet, tube feeding or parenteral alimentation, vitamin and thyroxine substitution, and prevention of infections and thrombotic complications. The combination of an ACE inhibitor and indomethacin to reduce intraglomerular pressure and lower protein excretion may improve both nutritional status and growth and may obviate the need for bilateral nephrectomy. Dialysis is begun when ESRD is reached. Renal transplantation is considered when a sufficient body weight (8 – 9 kg) is reached. The disease does not recur after transplantation. Interestingly, recent reports suggest that minor mutations of nephrin could be responsible for milder or atypical forms of nephrotic syndrome in children.

Familial steroid-resistant Focal Segmental Glomerulosclerosis (FGS)

NPHS2 gene, which encodes podocin, was found to be mutated in some families with recessive steroid-resistant nephrotic syndrome [24]. In these families, the nephrotic syndrome ranges from early onset (resembling CNF) to a late onset, in the second decade of life, resembling idiopathic FGS. Not surprisingly, podocin mutations were also detected in rare cases of sporadic steroid-resistant nephrotic syndrome [25].

Mutations in ACTN4, encoding -actinin-4, cause autosomal dominant focal segmental glomerulosclerosis [26].

Podocin and -actinin-4 are both synthesized and exclusively expressed by the podocytes. Podocin is an integral membrane protein with a short extracellular domain and may connect the slit diaphragm to podocyte cytoskeleton. -actinin-4 is an actin-filament crosslinking protein. These two proteins may interact with nephrin in a network regulating podocytes plasticity and slit diaphragm permselectivity.

WT1-related Glomerulopathies

WT1, the Wilms' tumor suppressor gene, encodes a transcription factor that regulates the expression of many genes and plays a major role in renal and genital development. WT1 complete deletions are responsible for WAGR syndrome (Wilms' tumor, Aniridia, Genitourinary malformations, Mental retardation); WT1 germline truncations are found in 10% of Wilms' tumors; and finally, WT1 point mutations have been detected in three disorders with predominant glomerular involvement. Most of these WT1 mutations arise de novo and have a dominant effect [27].

Denys-Drash Syndrome

This syndrome is characterized by the combination of diffuse mesangial sclerosis, male pseudohermaphroditism, and Wilms' tumor. Denys-Drash syndrome is usually sporadic, but constitutional mutations in the Wilms' tumor predisposing gene WT1 have been found. The clinical course of the nephropathy is not different from that described above in isolated diffuse mesangial sclerosis (see below). Wilms' tumor (unilateral or bilateral) may be the first clinical manifestation of the syndrome. Male pseudohermaphroditism is characterized by ambiguous genitalia or female phenotype with a 46, XY karyotype.

Isolated Diffuse Mesangial Sclerosis (IDMS)

Diffuse mesangial sclerosis is the leading cause of infantile nephrotic syndrome. Children are usually normal at birth. Proteinuria with an unremarkable urine sediment develops postnatally and increases during the first 2 years of life. In rare cases, however, the nephrotic syndrome may be present at birth or even be suspected in utero because of elevated maternal plasma AFP and enlarged and hyperechogenic fetal kidneys. Most children develop hypertension, and all progress to ESRD before age 3. The mesangial sclerosis is initially characterized by a progressive increase in mesangial fibrillar matrix and cells. Capillary lumens are then reduced, and the glomerular tuft contracts into a sclerotic mass within a dilated urinary space, with thickening of the GBM. Mesangial and perglomerular nonspecific immune deposits (IgM, C3 and C1q) are common. Diffuse mesangial sclerosis is resistant to steroids and immunosuppressive therapy. The nephrotic

syndrome is mild, and supportive treatment is less aggressive than in CNF. Recurrent disease does not develop in the transplanted patient. Extrarenal symptoms have been reported, including mental retardation, microcephaly, muscular dystrophy, and various ocular anomalies. The disease is transmitted as an autosomal recessive trait. WT1 mutations have only been detected in 15% of IDMS cases, suggesting genetic heterogeneity. From a practical point of view, every patient with suspected IMDS should be screened for the Denys-Drash syndrome and would benefit from a karyotype (if phenotypically female) and an ultrasonography to detect potential Wilms' tumor [28].

Frasier Syndrome

This rare syndrome, caused by a specific intronic mutation of the WT1 gene, was initially characterized by male pseudohermaphroditism, the absence of Wilms' tumor, and a slowly progressive glomerulopathy. The proteinuria appears in the first decade and increases with age, resulting in steroid-resistant nephrotic syndrome, and ultimately ESRD by age 6 – 35. Renal histology shows normal glomeruli or FGS. All patients have female external genitalia. Theoretically, this rare diagnosis should be suspected in every young female presenting with a steroid-resistant nephrotic syndrome. However, the search for WT1 intronic mutation is unlikely to be positive, unless the patient has a 46, XY karyotype, or a familial disease. In 46, XX patients, the genital development is normal; in 46, XY patients, the gonads are fibrous, not functional, and should be removed due to the high risk of gonadoblastomas [29].

Nail-Patella Syndrome

The nail-patella syndrome (NPS, also called osteo-onychodysplasia) is a rare autosomal dominant disorder linked to chromosome 9q34. NPS is characterized by bone and nail abnormalities. Renal involvement occurs in 40% of cases. NPS is caused by heterozygous loss of function mutations in LMX1B, a member of the LIM homeodomain protein family [30].

Absence, dysplasia, or hypoplasia of the nails is present at birth in 90% of patients. These abnormalities are bilateral and symmetrical and predominate on the fingernails, particularly the thumb and index fingers. The patella may be absent or hypoplastic, causing lateral slippage during knee flexion and sometimes knee pain or complications of effusion, arthritis or arthrosis. Elbow subluxation and limitation of forearm movement are not infrequent. X-rays reveal radial head and humeral hypoplasia. The pathognomonic radiologic finding of the disease is bilateral iliac horns arising from the anterosuperior iliac crest, observed in 50% of the patients.

Renal disease develops in half of the patients with the nail-patella syndrome, with considerable variation among families and also within single families. Symptoms are proteinuria (possibly nephrotic), hematuria, and hypertension. ESRD develops in approximately 30% of patients, at a mean age of 33 1 8 years. For unknown reasons, some superimposed renal diseases (anti-GBM antibody disease, necrotizing vasculitis, membranous or IgA nephropathy) have been frequently reported.

Light microscopy usually reveals basement membrane thickening and nonspecific focal and segmental glomerulosclerosis. Immunofluorescence microscopy is typically negative. Electron microscopy shows a pathognomonic lesion of the glomerular basement

membrane, consisting of clusters of cross-banded collagen fibrils within the lamina densa. There is no correlation between the severity of the ultrastructural lesions and the clinical manifestations. Not surprisingly, immunohistochemical studies have shown different renal fibrillar collagen expression.

There is no specific therapy for nail-patella syndrome. The lesions do not recur after renal transplantation, and patients do not develop anti-GBM antibodies.

Fabry Disease

Fabry disease is an X-linked lysosomal disorder, characterized by -galactosidase deficiency. Estimates of incidence range from 1 in 40,000 – 60,000 males.

The first symptom is generally acroparesthesia, which is often very painful in children and may be relieved by carbamazepine or diphenylhydantoin. Skin angiokeratoma, corneal deposits, and decreased sweating develop during adolescence in affected hemizygous males. Proteinuria appears between 10 and 25 years of age; progressive renal failure follows, usually reaching end-stage between 35 and 50 years. Patients are at risk of developing other cardiovascular complications, such as ischemic cerebrovascular and coronary accidents or atrioventricular block. All these manifestations, including kidney involvement, are due to glycolipid accumulation in lysosomes, predominantly of vascular cells. Fabry disease is largely under-recognized, and although symptoms in males start during childhood, most cases are not diagnosed until adulthood. Diagnostic clues are familial history, symptoms, measurement of -galactosidase activity in leukocytes, demonstration of typical inclusions on a tissue biopsy, and genetic analysis. Carrier (heterozygous) females occasionally have slight or moderate symptoms, because of random X-chromosomal inactivation. Corneal deposits are found in 80% of them. Gene testing allows identification of the carrier state, whereas biochemical enzyme measurements may be inconclusive in heterozygous females.

Kidney transplantation is an adequate treatment of ESRD in Fabry patients, and the disease does not generally recur. Enzyme replacement therapy using recombinant human -galactosidase is now available, safe, and reverses substrate storage in the lysosomes. The early results of clinical trials also suggest organ function improvement. All males with Fabry disease and all females with substantial disease manifestations should receive this treatment as early as possible [31].

Hereditary Nonlithiasic Renal Diseases with Tubular Involvement

Fanconi Syndrome

This syndrome is characterized by complex dysfunction of proximal tubules, i.e. low molecular weight proteinuria ($_2$-microglobulinuria), hypokalemia, defective transport of bicarbonate (type II renal tubular acidosis), glucose (glucosuria), amino acid (hyperaminoaciduria), urate (hypouricemia, uricosuria), phosphate (hypophosphatemia, hyperphosphaturia, rickets), and citrate (hypercitraturia); and polyuria. When hereditary, the Fanconi syndrome may be idiopathic (autosomal dominant) or secondary to various inherited metabolic diseases: cystinosis, type I glycogenosis, mitochondrial cytopathies, Lowe syndrome, Wilson's disease, galactosemia, tyrosinemia, and fructose intolerance. We will focus mainly on cystinosis, the most frequent cause in children.

Table 6. Main inherited tubular diseases (proximal tubule excepted).

Tubular segment disease	Transmission pattern	Age at onset/ discovery	Phenotype	Mechanism/ gene	Treatment
Bartter syndrome [34]	AR	childhood	hypokalemia, metabolic alkalosis, growth retardation, hypercalciuria, +/– nephrocalcinosis	NaCl reabsorption defect due to various mutations: type I: NKCC transporter, type II: ROMK channel, type III: CLCkb channel	symptomatic, indomethacin, COX-2 inhibitors, ACEI, angiotensin II blockers
Gitelman syndrome [35]	AR	childhood +/–, adulthood +++	hypokalemia, metabolic alkalosis, hypomagnesemia, hypocalciuria, +/– chondrocalcinosis	NaCl reabsorption defect (TSC sodium-chloride cotransport mutations)	symptomatic
Liddle syndrome [44]	AD	childhood ++, adulthood ++	hypertension, hypokalemia, low renin and aldosterone	increased absorption of Na (sodium channel, activating mutation of or subunits)	amiloride (+++), low-salt diet
Pseudohypoaldosteronism, type I [36]	AD, AR	newborn	dehydration, hyponatremia, hyperkalemia, high renin and aldosterone	decreased absorption of Na (sodium channel, inactivating mutations of or subunits)	NaCl
Gordon syndrome (Pseudohypoaldosteronism, type II) [45]	AD	neonates, children	hypertension, hyperkalemia, acidosis hypercalciuria, growth retardation, low renin and aldosterone	WNK4 kinase mutations, sodium and chloride hyperabsorption	thiazide diuretics

Table 6. Continuation

Tubular segment disease	Transmission pattern	Age at onset/ discovery	Phenotype	Mechanism/ gene	Treatment
Nephrogenic diabetes insipidus [46]	XR/AR	newborn	insipid polyuria, ADH resistance	ADH V2 receptor mutation (X-linked), aquaporin 2 mutation (RA)	hydration, thiazide, NSAIDs

AR: autosomal recessive, AD: autosomal dominant, ADH: antidiuretic hormone, NSAID: non-steroid anti-inflammatory drug.

Cystinosis is a metabolic lysosomal storage disease of cystine affecting most of the body cells and is characterized by both renal and extrarenal symptoms. Cystine is derived from protein degradation within the lysosome, then is normally transported through the lysosomal membrane to the cytosol, transformed into cysteine, and finally utilized. Cystinosis involves a defect in the transport system in which the poorly soluble cystine accumulates inside the lysosome and forms crystals. Cystinosis is transmitted as an autosomal recessive trait. The causative gene, CTNS, encodes cystinosin, a lysosomal membrane protein responsible for cystine transport [32].

Three forms of cystinosis have been described: the infantile form found in 1/100,000 to 1/200,000 children, the intermediate (also called adolescent or late-onset) form, and the adult (benign) form.

The first renal symptoms of infantile cystinosis appear before 6 months of age, with varied manifestations of the Fanconi syndrome. The tubular losses gradually decline after age 6, as renal failure progresses. ESRD is typically reached before 12 years of age. Cystine may also accumulate in other tissues both before and after kidney transplantation. Eye involvement consists of photophobia, then retinal depigmentation and visual impairment. Hypothyroidism, portal hypertension, hepatomegaly, splenomegaly, diabetes mellitus, muscle weakness, low testosterone levels, incomplete pubertal development, and central nervous system manifestations of encephalopathy, pyramidal signs and cranial nerve palsies may also occur. The diagnosis of cystinosis can be confirmed by determining the intraleukocytic cystine content. Prenatal diagnosis is available.

The administration of cysteamine should be started as soon as the diagnosis of cystinosis is confirmed. Cysteamine concentrates within the lysosome and forms cysteine and cysteine-cysteamine complexes that are able to leave the lysosome, thus reducing the intracellular cystine content. This treatment has no effect on preexisting fluid and electrolyte losses, but if started early may slow the rate of progression to renal failure, improve growth, and prevent most extrarenal complications. Unfortunately, poor compliance due to numerous side effects limits the benefits of cysteamine. Topical cysteamine prevents corneal crystal deposition and reduces photophobia [33].

Table 7. Clinical factors suggesting hereditary urolithiasis.

- Early onset of urolithiasis
- Bilateral and recurrent urolithiasis
- Associated nephrocalcinosis
- Tubular dysfunction (growth retardation, polyuria, acidosis, etc.)
- Extrarenal symptoms

Other Tubular Disorders

Other inherited tubular disorders caused by mutations in transports, channels, enzymes and receptors are presented in Table 6 [34, 35, 36, 44, 45, 46]. Most of them are diagnosed soon after birth or during childhood, and rapid recognition is essential to provide symptomatic treatment. Others, like Gitelman or Liddle syndrome, are usually diagnosed in adults [36].

Urolithiasis Secondary to Hereditary Diseases

Hereditary urolithiasis (Table 7) accounts for 10 – 40% of all causes of lithiasis in children and up to 15% in adults. The most frequent inborn disorders are cystinuria, distal tubular acidosis, and hyperoxaluria (Table 8) [37, 38, 39]. Stone formation is secondary to an increased urine concentration of substances promoting crystal formation, e.g. cystine, calcium, oxalate or phosphate. The best diagnostic tool is infrared spectrophotometry, which can identify stone composition. Routine and specific biochemical examinations will help confirm the diagnosis. In many cases, an efficient specific preventive treatment is often available. The long-term renal prognosis is related to both the primary disease and therapeutic compliance.

Malformation Syndromes with Renal Involvement

See Table 9 for list.

Congenital Abnormalities of the Kidney and Urinary Tract

For review, see Moffat [40].

Kidney

Anomalies of Number

Bilateral renal agenesis is frequently associated with ureter and bladder development failure, Potter facies, pulmonary hypoplasia, and single umbilical artery. This abnormality is incompatible with life, and infants are stillborn or die soon after birth.

Unilateral agenesis is detected by fetal ultrasound during pregnancy or incidentally during childhood or adulthood. Compensative hypertrophy of the single kidney maintains normal renal function, but the kidney frequently develops focal and segmental glomerulosclerosis. The ureter and hemitrigone are absent on the affected side in most cases, and other organ abnormalities are possible.

Supernumerary kidney is rare and is sometimes bilateral. Ureters may be joined or separated.

Table 8. Hereditary urolithiasis (main causes).

Disease	Trans-mission pattern	Age at onset	Phenotype	Diagnosis	Specific treatment
Cystinuria [37]	AR	childhood +++, adolescence ++, adulthood +/–	fuzzy gray, +/– radiopaque stones	urinalysis: hexagonal cystine crystals; cystine excretion elevated, stone analysis	alkalinization of the urine (pH 7 – 7.5), D-penicilla-mine, tiopronin
Hyperoxaluria, type I [38]	AR	childhood +++, adolescence ++, adulthood +/–	radiopaque calcium stones, nephrocalcinosis, +/– renal failure	oxalate elevated, glycolate elevated, stone or crystal analysis (type 1c, monohydrated calcium oxalate), liver biopsy	vitamin B_6, trans-plantation (kidney, liver, or both)
Renal tubular acidosis, distal (type 1) [39]	AR/AD	childhood	radiopaque calcium stones, nephrocalcinosis, deafness	acidosis (metabolic), hypokalemia, urinary pH > 5 – 5.2	potassium citrate (or potassium or sodium bicarbonate)
APRTase deficiency	AR	variable	radiotransparent stones, +/– renal failure	2,8-dihydro-adenine crystals (stone analysis misleading: uric), enzyme deficiency	allopurinol
Dent's disease (and related diseases) [47]	XR	variable	radiopaque calcium stones, nephrocalcinosis, hypercalciuria, Fanconi syndrome, rickets, renal failure (in men)	CLCN5 mutation	thiazide

Renal Hypoplasia

Renal hypoplasia is defined as congenitally small kidney(s) with normal nephrons. Renal function is normal in proportion to the mass of the kidney. When bilateral, hypoplasia leads to renal failure.

Dysplasia should not be confused with hypoplasia. In addition to small kidney(s), various microscopic abnormalities are found,

Table 9. Various malformation syndromes with renal involvement.

Syndrome	Mode of inheritance	Gene(s)	Extrarenal signs	Renal manifestations
Bardet-Biedl syndrome [32]	AR	4 gene loci (BBS 1 –4)	retinal degeneration, polydactyly, obesity and short stature, mental retardation, hypogonadism	hypertension, tubular dysfunction (diabetes insipidus, acidosis), abnormal calyces, communicating cysts, fetal lobulation, interstitial nephritis, glomerular scarring, renal failure
Bronchiaoto-renal syndrome [48]	AD	EYA1 (8q 13.3)	laterocervical fistulas or cysts, outer, middle and inner ear anomalies	hypoplasia, dysplasia, aplasia (uni- or bilateral), various collecting system anomalies
PAX2 gene mutations syndrome [49]	AD	PAX 2	optic nerve coloboma	renal hypoplasia, vesicoureteral reflux

AR: autosomal recessive, AD: autosomal dominant.

including primitive pelvis, ducts, ductules, tubules, glomeruli, cysts, cartilage deposits, and fibrosis. Urinary tract obstruction, infection, hypertension, and poor renal function are common.

In oligomeganephronia, both kidneys are small and have interstitial fibrosis and a reduced number of nephrons, but markedly enlarged glomeruli and tubules. Symptoms of polyuria, polydipsia, salt loss, metabolic acidosis, and growth retardation appear during childhood. Progressive renal failure is the rule, and ESRD is reached before 16 years of age in most cases.

In Ask-Upmark kidney, one kidney is small and shows a lobulated hypoplastic area with thyroid-like tubules and hyalinized glomeruli, supplied by a narrowed artery. Hypertension is the main symptom and may be cured by partial nephrectomy.

Ectopic Kidney

Pelvic kidney is the most frequent variety of ectopia. It results from failure to ascend and is usually associated with malrotation (anterior pelvis). Ptotic kidney can be excluded by demonstration of a short ureter or a pelvic origin of the renal blood supply. Thoracic location is extremely rare and results from excessive ascent of one kidney. In crossed ectopia, one kidney has crossed the

midline and sometimes joins the opposite kidney. Blood supply and ureteric course are variable; obstruction and infection are not rare.

Horseshoe Kidney

In this condition, the lower poles of both kidneys fuse across the midline. The connection or isthmus runs anterior to the aorta and vena cava. Fusion prevents normal rotation, resulting in anterior pelvis. Ureters emerge anteriorly and obstruction can occur, with stone formation or infection. No therapy is required for uncomplicated horseshoe kidney. In case of obstruction, pyeloplasty or division of the isthmus may be required

Urinary Tract Abnormalities

Ureteric Duplication

In complete typical duplication, one ureter from the upper pelvis is dilated and opens ectopically in the bladder below a normal ureter running from the lower pelvis. Reflux of both poles, obstruction, and infection are frequent. In these cases, surgical reimplantation of the ectopic ureter should be discussed before massive dilatation or serious renal damage occurs. In incomplete duplication, ureters join prior to entry into the bladder. Complications are rare.

Ureteric Ectopia

The ectopic orifice can be located in the urethra, bladder neck, or trigone in both genders; uterus, vestibule, cervix, or vagina in females; and prostatic urethra, seminal vesicles, ejaculatory ducts, or vas deferens in males. Incontinence, UTI, and vaginitis are the main symptoms leading to diagnosis.

Retrocaval Ureter

The right ureter passes posterior to the inferior vena cava. Compression between vena cava and lumbar spine can result in obstruction and hematuria or right-sided symptoms, such as pain, urolithiasis, and infection. First symptoms often appear during adulthood. Intravenous pyelography (IVP) demonstrates a medially displaced right ureter, with a large superior portion. CT scan confirms the abnormality. Treatment consists of resection and anastomosis of the ureter.

Ureterocele

Ureteroceles may be uni- or bilateral and consist of a cystic ballooning of the intramural portion of the ureter commonly associated with duplication, ectopia, ureteric dilatation, and reflux. The intravesical protrusion may cause obstruction, resulting in persistent UTI. As the ureter usually drains a poorly functioning kidney, IVP shows the ureterocele as a radiolucent area in the bladder. Cystoscopy shows ureterocele protrusion into the bladder [41].

Vesicoureteral Reflux and Reflux Nephropathy

See chapter I-13.

Megaureter

Any ureter > 5 – 7 mm is a megaureter. This term should not be used alone, because this condition can be primary (congenital vesicoureteric junction abnormality) or secondary (e.g. high urinary flow, bladder or bladder neck dysfunction, posterior urethral valves, prunebelly syndrome). Congenital megaureters deserve complete evaluation to determine whether they are associated with obstruction and/or reflux, and to determine whether the best treatment is medical surveillance or surgical ureteric reimplantation [42].

Exstrophy of the Bladder

The diagnosis is made at inspection. The anterior abdominal wall and the anterior wall of the bladder are missing. The posterior wall of the bladder is everted and fused to the remaining abdominal wall. Epispadias, rudimentary penis, cleft clitoris, and other extraurinary malformations are frequently associated. Permanent incontinence produces skin lesions; UTIs are frequent, and bladder malignancy is not rare. Surgical treatment is difficult and often disappointing. Multistep reconstruction or urinary diversion with the Bricker procedure is usually considered [40].

Posterior Urethral Valves

In this frequent condition (1 in 5,000 males), the normal ridges running below the verumontanum to the lateral urethral walls become hyperplastic and obstructive with posterior urethra dilatation. Bladder hypertrophy, ureteric dilatation, reflux, dysplasia, or renal failure sometimes occur. Severe forms are diagnosed prenatally in most cases. Milder cases are discovered later in children presenting with UTIs, dysuria, incontinence, growth retardation, or hypertension. Endoscopic resection of the valves is the best treatment, but should be preceded by urinary drainage and antimicrobial therapy [43].

Urinary Tract Infection (UTI)

Claire Pomeroy and James R. Johnson

Urinary tract infections (UTI) are a major cause of morbidity, mortality, and increased health care costs [1 – 3]. They can cause a wide variety of clinical manifestations ranging from asymptomatic bacteriuria to simple cystitis to life-threatening illnesses including sepsis [4]. Recent approaches to UTI treatment have emphasized protocols for management without office visits and short-term antibiotic therapy in women with uncomplicated cystitis, as well as awareness of the impact of emergence of resistant bacteria. To achieve optimal efficacy while limiting costs and the potential for adverse drug effects, the health care provider must tailor therapy with consideration of host status, probable infecting organisms, resistance patterns in the local community, and currently recommended practice guidelines [2, 5, 6].

Asymptomatic Bacteriuria

Bacteriuria unaccompanied by UTI symptoms is present in 1 – 3% of young women but < 0.1% of young men. Increasing percentages of both men and women develop bacteriuria as they age. At least 10% of elderly men and 20% of elderly women have asymptomatic bacteriuria [7]. Bacteriuria is nearly universal in chronically catheterized patients. Under most circumstances, if the patient does not have symptoms of UTI such as dysuria or fever, bacteriuria should not be treated with antibiotics, regardless of the presence or absence of pyuria [2].

Nevertheless, asymptomatic bacteriuria does require treatment in some groups of patients. Specifically, it is important to treat children with asymptomatic bacteriuria to decrease the chances of renal damage and long-term renal insufficiency. Patients scheduled to undergo urinary tract instrumentation or surgery should also be screened, and if found to have asymptomatic bacteriuria, they should be treated with antibiotics to reduce the risk of procedure-induced urosepsis [2]. Up to 20% of pregnant women with asymptomatic bacteriuria may develop pyelonephritis. For this reason, routine screening of urine and treatment of asymptomatic bacteriuria are components of appropriate prenatal care [6, 8, 9]. Asymptomatic bacteriuria in these patient groups should be treated based on the results of susceptibility testing, usually with a 3-day course of trimethoprim-sulfamethoxazole (TMP-SMX), oral fluoroquinolones (avoid in pregnancy and children), amoxicillin, nitrofurantoin, or an oral cephalosporin. Some authors also recommend that other patients at particular risk for severe consequences of infection, such as neutropenic patients, should be treated with antibiotics if they develop asymptomatic bacteriuria.

Early observations associating asymptomatic bacteriuria with increased mortality in the elderly raised concerns that this condition

might contribute to mortality. However, it is now well substantiated that a causal connection cannot be established between asymptomatic bacteriuria and mortality in the elderly [7, 10]. Furthermore, treatment of such patients with antibiotics is quite ineffective in producing lasting urinary tract sterility. In fact, treatment of asymptomatic bacteriuria in the elderly has been shown to be associated with adverse medication effects, selection of resistant organisms, and possibly increased mortality [6].

Nonantibiotic approaches to the prevention of bacteriuria have been attempted, including use of estrogen replacement therapy for elderly women and cranberry juice consumption in the elderly. Oral or topical estrogen replacement therapy in postmenopausal women with recurrent UTI reduces the frequency of bacteriuria, possibly because of the effectiveness of such therapy in restoring a premenopausal vaginal microenvironment and diminishing vaginal colonization with coliform bacilli [11]. Daily consumption of cranberry juice for 6 months significantly decreased the prevalence of bacteriuria among elderly residents of a home for senior citizens [12]. However, most of the episodes of bacteriuria were asymptomatic, so the clinical value of the observed preventive effect could be questioned. Nonetheless, there were trends towards decreased antibiotic use and fewer symptomatic UTI episodes in the treatment group, suggesting that the intervention may have provided a meaningful benefit.

Symptomatic UTI

Symptomatic UTIs range from simple cystitis to pyelonephritis to invasive febrile UTI with bacteremia [3, 13]. UTIs may be further classified as uncomplicated or complicated by the presence of anatomic or functional abnormalities of the urinary tract or by underlying medical illnesses. In practice, it is often difficult to definitively classify patients into one of these categories. The important principles are that it is critical to treat all symptomatic UTIs and that the required intensity and duration of therapy increase in proportion to the severity of the clinical syndrome (Table 1) [3, 6]. The antimicrobial agent and duration of therapy should be selected based on the host status including presence of complicating conditions, the identity and susceptibility pattern of the pathogen (whether directly determined or extrapolated from aggregate statistics), and the agent's cost and potential side effects [13, 14]. Uncomplicated cystitis can usually be treated with a short course of antibiotics, whereas complicated or invasive UTIs often are more difficult to eradicate and require more aggressive antibiotic therapy, as well as evaluation and treatment of underlying urologic abnormalities or medical conditions [6].

Lower UTI – Cystitis

Epidemiology

Acute bacterial cystitis is a commonly encountered health problem, accounting for over 5 million visits to physician offices and over $1 billion in medical costs annually in the United States [2]. Uncomplicated cystitis is defined as an infection of the bladder, usu-

Table 1. Factors Suggestive of Increased Likelihood of Complicated or Invasive UTI

Demographics	Male sex, age < 18 or > 65 years, pregnancy
Symptoms	Duration of > 7 days Rigors, flank pain, fever > 101°F (38.3 °C), or other symptoms suggestive of pyelonephritis or bacteremia
Risk factors	Urinary catheterization or recent urologic surgery/instrumentation Obstruction or anatomic defects of urinary tract; functional defects (neurogenic bladder, reflux) Diabetes, sickle cell anemia, immunosuppression (steroids, chemotherapy, HIV infection) Renal insufficiency, polycystic kidney disease, renal transplantation Recent hospitalization or residence in nursing home
Past history	History of childhood UTI 4 ≥ UTIs in past year or pyelonephritis within past 3 months Failure of antibiotic treatment for UTI in past 1 – 3 months

ally bacterial, in an otherwise healthy young woman with normal urinary tract anatomy and renal function. Nearly one-half of women suffer an episode of cystitis during their lifetime. Risk factors for cystitis include female gender, sexual activity, history of previous UTI, use of spermicide-diaphragm contraception, postmenopausal state, and possibly being a nonsecretor of blood group substances [15]. Vaginal colonization with *Escherichia coli* (which normally is absent from the vagina) is promoted by sexual intercourse and the use of spermicide-diaphragm contraception [16]. Spermicides are more toxic to the normal lactobacillus-based premenopausal vaginal flora than to *E. coli*, facilitating overgrowth by *E. coli* [17]. Similar alterations in vaginal flora are also observed in postmenopausal women due to hypoestrogenism [11] and in patients receiving antibiotics, especially β-lactam agents [16]. Some studies indicate that women of the nonsecretor phenotype have a greater risk of recurrent UTI, a higher prevalence of vaginal colonization with gram-negative bacilli, and increased bacterial adherence to vaginal epithelial cells compared to secretor women, possibly because of the expression by nonsecretors' cells of unique receptor glycolipids for P-fimbriated *E. coli* that are not present in the cells of secretor women [3, 16, 18 – 20].

Pathogenesis and Pathology

The vast majority of bladder infections in women are due to ascent of pathogens from the rectum to the vagina and then into the urethra and bladder [3, 4]. In women with uncomplicated cystitis, infection is most commonly caused by *E. coli* (80%), *Staphylococcus saprophyticus* (10 – 15%), and only rarely by other gram-negative bacteria or other organisms [2, 17]. While complicated UTIs still are most often due to *E. coli* (about 50%), they are more likely than uncomplicated cystitis to

involve infection with other gram-negative bacteria including *Klebsiella, Proteus, Pseudomonas, Serratia,* or *Enterobacter*. In addition, *Enterococcus* may be detected, and *Candida* and other yeasts are encountered with increasing frequency. In general, bacteria must have substantial intrinsic virulence to overcome the normal host's urinary tract defenses and cause infection. In contrast, organisms of lesser intrinsic virulence can infect patients with impaired defenses. However, these infections due to less virulent organisms in compromised hosts may paradoxically be more difficult to treat [6].

Manifestations

The clinical syndrome of cystitis is defined by the presence of symptoms localized to the bladder and urethra including frequency, dysuria, and suprapubic pain, without concomitant evidence of renal or systemic involvement. Dysuria due to acute cystitis must be differentiated from that caused by other inflammatory or infectious conditions, including vaginitis, sexually transmitted diseases, and miscellaneous noninflammatory causes of urethral discomfort.

Diagnosis

Bacterial cystitis traditionally has been defined microbiologically by the presence of $\geq 10^5$ colony-forming (CFU) units of bacteria/mL of urine. However, it is now well recognized that UTIs with lower bacterial counts of $10^2 - 10^4$ CFU/mL are responsible for dysuria and frequency in many women [2]. Although a pretreatment urine culture allows for precise targeting of antimicrobial therapy based on the known urinary organisms and their susceptibility patterns, the predictability of the infecting pathogens in cystitis occurring in healthy young women allows such patients to be treated presumptively without a urine culture when the clinical presentation strongly suggests cystitis. Collection of a urine specimen for a quantitative culture before the institution of therapy for UTI is appropriate for patients with complicating factors and in whom pyelonephritis or bacteremia is suspected, and for those who have failed to respond or responded poorly to empiric therapy. Patients recently treated with antimicrobial agents should also usually have pretreatment urine cultures because they are at greater risk of infection with resistant organisms.

Management

Young women with presumed uncomplicated cystitis can often be managed successfully without a traditional physician office visit, e.g. over the telephone or through a clinic by a physician extender who follows a practice guideline. Patients should be screened for risk factors suggestive of a complicated UTI and for evidence of another condition causing the symptoms, especially sexually transmitted disease. If this evaluation is unremarkable, a presumptive diagnosis of uncomplicated cystitis can be made and an empiric trial of antibiotics recommended.

A variety of nonspecific therapies have been advocated for patients with uncomplicated cystitis [21]. Agents to lower the urinary pH, such as hippuric acid or cranberry juice, are usually not necessary and have not been well documented to be beneficial. As an adjunct to antimicrobial therapy for patients with severe dysuria, treatment with oral phenazopyridine (Pyridium) in doses of 200 mg PO TID can provide symptomatic relief.

Table 2. Treatment Options for Uncomplicated Cystitis

Therapy	Comments
Single Dose	
TMP-SMX 2 double-strength (DS) tabs PO	Single dose therapy less effective than 3-day regimen.
Trimethoprim 400 mg PO	Failure of single doses of fluoroquinolones for cystitis due
Ciprofloxacin 250 mg PO	to *S. saprophyticus* is reported.
(or other fluoroquinolones)	
Three-Day Regimens	
TMP-SMX 1 DS tab PO BID	3-day TMP-SMX regimen is a good strategy for most young women with uncomplicated cystitis.
Trimethoprim 100 mg PO BID	Trimethoprim useful in sulfa-intolerant patients.
Ciprofloxacin 250 mg PO BID	Fluoroquinolones useful for patients with complicated UTI
(or other fluoroquinolones)	or those who fail or who are intolerant of TMP-SMX.
Seven-Day Regimens	
As above but continued for 7 days	Indicated for men, diabetics, pregnant women (avoid fluoroquinolones), children (avoid fluoroquinolones), and the elderly, if symptoms present for 7 days, and for other complicated cystitis.

Antibiotic Choice

The choice of antimicrobial therapy for cystitis depends upon the resistance patterns in the local community as well as the underlying host status (Table 2). Knowledge of the antibiotic-resistant patterns in the community or institution, including in nursing homes, should be used to guide the choice of empiric antibiotic therapy while urine culture results.

TMP-SMX is considered by many experts to be the drug of first choice for uncomplicated cystitis because of the low cost and well-established efficacy. Adverse effects may be less frequent with TMP alone, which is a good choice in patients intolerant of sulfonamides. However, in some locales, resistance to TMP-SMX is increasingly prevalent among *E. coli* and other urinary tract pathogens. In these communities, fluoroquinolones may be the preferred agents for empiric therapy. These drugs' excellent spectrum of activity against gram-negative uropathogens and the infrequency of side effects are advantageous. However, the cost of these agents and concerns about the emergence of resistance have lead many to exclude them from consideration as first-line empiric therapy for uncomplicated cystitis. Because of a high prevalence of resistance among uropathogens and their inferior performance in clinical trials, oral first-generation cephalosporins or ampicillin are not generally considered to be first-line therapy for cystitis. However, in cases with confirmed sensitivity, these agents may be reasonable alternatives if TMP-SMX and fluoroquinolones are contraindicated.

Complicated cystitis can be treated initially with fluoroquinolones, which have emerged as drugs of choice in this setting because of their excellent activity against many gram-negative bacteria and their satisfactory per-

formance in clinical trials when compared with traditional intravenous regimens. Subsequent therapy should be guided by the results of urine culture and susceptibility patterns of the identified pathogen.

Duration of Therapy

It is now well recognized that "short course" therapy is adequate for treatment of most women with uncomplicated cystitis. An empiric 3-day course of TMP-SMX or an oral fluoroquinolone is the currently recommended treatment duration [6, 22]. Three-day treatment courses have been well demonstrated to cost less, have fewer side effects, and have comparable efficacy to traditional therapeutic approaches using 7 to 14 days of antibiotics. Single-dose therapy is the most convenient but is associated with higher failure rates than those observed with multiple dose regimens. Longer regimens such as the traditional 7-day regimen are very effective but produce more side effects and should be reserved for high-risk patients. Treatment for a minimum of 7 – 10 days is recommended for UTIs in men, even in the absence of signs of renal or systemic involvement, due to the increased likelihood of undetected underlying complicating factors and the paucity of studies of short-course (3-day) therapy of UTI in men. Men or women known to have complicated cystitis should be treated with a 7- to 14-day course of antibiotics, and even longer periods of therapy may be necessary in selected subgroups.

Prognosis

Complete recovery from cystitis is the norm. Post-therapy urine cultures have traditionally been recommended to confirm successful eradication of infections in patients with acute UTI. However, this is not often necessary in patients with uncomplicated cystitis [1]. In one study, the incidence of symptomatic UTI following therapy for acute cystitis was not reduced when routine follow-up cultures were used (as compared to performing cultures in symptomatic patients only). Post-therapy cultures need to be obtained in nonpregnant women only when there are persisting symptoms or known complicating factors. In contrast, for children, men, pregnant women, patients with obstructive uropathy, or patients with relapsing infection, a follow-up culture should be obtained as a "test of cure".

One challenge for the physician is determining the indications for urologic studies for patients with UTIs. Traditionally, it has been recommended that men with UTIs should be evaluated for predisposing anatomic abnormalities. However, it is now recognized that young men, especially homosexual men and heterosexual men whose female sex partners have vaginal colonization with uropathogens, may develop cystitis in the absence of abnormalities of the urinary tract. In older men, it is certainly still reasonable to screen for prostate abnormalities or neurogenic bladder. More studies are needed to clarify this issue.

Upper UTI – Pyelonephritis

Epidemiology

Pyelonephritis is infection of the renal pelvis and renal parenchyma. Acute bacterial pyelonephritis is one of the most common serious infections of adult women and can also affect children and adult men. In the United States, more than 100,000 patients are admitted to the hospital for an average of 6 – 7 days because of renal infection. The annual risk for hospitalization for pyelonephritis among adults has been estimated at 1 per 1000

women and 0.3 per 1000 men [23]. Many more patients are treated for pyelonephritis as outpatients [24 – 27]. The ratio of pyelonephritis to cystitis episodes has been estimated at approximately 1 : 20 [28]. Increased risk for pyelonephritis is predicted by many of the same factors as for cystitis. In addition, among children, P_1 blood group phenotype is associated with increased risk of pyelonephritis. Pyelonephritis is also more likely in patients with abnormalities of the urinary tract including neurogenic bladder, posterior urethral valves (in infant boys), congenital vesicoureteral reflux (in girls), chronic urinary catheterization, urolithiasis, and kidney transplantation [29 – 32].

Pathogenesis

In most cases, pyelonephritis arises as an ascending infection wherein bacteria enter the urinary tract via the urethra, establish bladder colonization, and then ascend up the ureters to the kidneys [3, 32]. Usually the pathogens are derived from the host's own intestinal, and in women, vaginal, flora [16, 33]. If the patient is catheterized, the urine can be contaminated from the hands of healthcare workers or other environmental sources [34].

The microbial flora of pyelonephritis is quite similar to that of acute cystitis, with *E. coli* accounting for over 80% of cases and other gram-negative bacilli including *Klebsiella* and *Proteus*, as well as *S. saprophyticus* and *Enterococcus* making up the remainder of cases [32]. The *E. coli* strains that cause pyelonephritis are quite distinct from ordinary intestinal *E. coli* and belong to a limited number of genetic lineages characterized by specific antigens and other properties that promote invasion and inflammation within the upper urinary tract [32, 35]. *E. coli* strains that cause pyelonephritis are likely to express adhesins including P fimbriae, which recognize Gal (α1-4) Gal-containing receptors on host epithelial surfaces via their adhesion molecule, PapG. PapG occurs in 3 known variants. Class II variants are the most common among *E. coli* strains that cause pyelonephritis and bacteremic UTIs, whereas class III variants predominate in cystitis. Other virulence factors of *E. coli* include the cytotoxin alpha hemolysin, the aerobactin iron sequestration system, polysaccharide capsules, lipopolysaccharide, and serum resistance proteins [19, 35].

Host factors also can promote ascending infection. Ascent of bacteria up the ureters is more common in patients with vesicoureteral reflux, whether due to underlying congenital or acquired urological abnormalities or secondary to acute changes in ureteral peristalsis induced by irritation of the ureter by lipopolysaccharide from adherent bacteria [32]. Pathogens can move from the renal pelvis into the collecting ducts and tubules due to intrarenal reflux [32]. Pyelonephritis is promoted during pregnancy by physiologic urethral hypotonia and partial ureteral obstruction.

Pathology

Pathogenic bacteria in the urinary tract adhere to the mucosa and trigger inflammation with production of proinflammatory cytokines and influx of polymorphonuclear leukocytes and other inflammatory cells [20]. Reactive oxygen species, leukotrienes, and prostaglandins act in concert with bacterial cytotoxins to produce tissue damage and renal vasoconstriction [19, 32]. The kidney becomes edematous and infiltrated with leukocytes, tubules may become necrotic, and microscopic and macroscopic abscesses may form.

Clinical Manifestations

Patients with pyelonephritis typically present with progressive flank pain, malaise, fevers, and possibly gastrointestinal symptoms of nausea and vomiting. These symptoms of pyelonephritis may be preceded or accompanied by symptoms of acute cystitis such as dysuria, urinary frequency, and urgency. On physical examination, patients are generally more ill appearing than those with simple cystitis. They are febrile and often are dehydrated and tachycardic. Tenderness over the costovertebral angles can be elicited with palpation or percussion. However, atypical presentation of pyelonephritis is not uncommon [36]. Symptoms may localize to the abdomen, pelvis, or back. Patients with sensory impairment may have minimal local symptoms and present solely with fever or hypotension.

Diagnosis

The clinical diagnosis of pyelonephritis is based on characteristic symptoms and signs and supportive laboratory tests [37]. Urinalysis and urine culture with susceptibility testing should be obtained in all patients with suspected pyelonephritis [2]. A gram stain of the urine is particularly helpful in confirming the presence of bacteria and suggesting a likely bacterial type, distinguishing between gram-positive and gram-negative pathogens. In the absence of prior antimicrobial therapy, the urine culture in most patients with pyelonephritis will have $> 10^5$ CFU of bacteria/mL of urine. Antimicrobial sensitivity testing is important and should be used to tailor antibiotic choices when the results are available. Blood cultures will be positive in a large percentage of patients with acute pyelonephritis. Their use in uncomplicated pyelonephritis is considered optional by some experts because bacteremia is usually adequately treated with the antibiotics chosen for the UTI, and clinical outcome is most often independent of blood culture results.

Imaging studies are not routinely needed for the diagnosis or management of acute pyelonephritis [30, 37, 38]. However, in patients who fail to respond appropriately to therapy, further diagnostic studies and interventions are indicated [38]. Suspicion of obstruction or renal abscess should prompt additional evaluation. If obstruction is suspected, abdominal roentgenograms to screen for urinary calculi may be appropriate, followed by excretory urography if indicated. Computed tomography (CT) scanning may provide the best definition of anatomical abnormalities [39]. Contrast-enhanced CT scan facilitates detection of abscesses and allows their differentiation from surrounding inflamed tissue. Streaky or wedge-shaped hypodense areas that fail to concentrate contrast material normally are indicative of pyelonephritis. Other CT findings in pyelonephritis may include a swollen, enlarged kidney, focal bulges of the kidney, and inflammatory stranding in the perinephric fat. Under the new terminology, these CT findings are now labeled as “acute pyelonephritis” by the radiologist, and modifiers are used to describe the specific observed anatomic abnormalities [40]. The extent and severity of the CT findings have been demonstrated to correlate with risk of bacteremia and other complications, including death. Ultrasound is now recognized as less sensitive than CT for detecting or following pyelonephritis but remains useful for detecting perinephric abscesses or obstruction and hydronephrosis. Single photon emission CT (SPECT) scanning using Tc-99m (dimercaptosuccinic) acid (DMSA) is even more sensitive than CT for detecting inflammation but is less useful in differentiating abscesses from inflamed tis-

Table 3. Treatment Options for Pyelonephritis

Entity	Drug	Duration
Subclinical or mild-moderate pyelonephritis (outpatient)	TMP-SMX 1 DS tab PO BID Ciprofloxacin 500 mg PO BID (or other fluoroquinolones)	14 days
Moderate-severe pyelonephritis (inpatient initially)	*Enterococcus:* IV ampicillin ± gentamicin; Gram-negative bacteria: IV fluoroquinolone, third-generation cephalosporin, aztreonam or gentamicin	IV therapy until clinically stable, then complete 14-day course with oral antibiotics
Complicated pyelonephritis	IV broad spectrum antibiotics, usually to include agents active against *Pseudomonas*, especially if nosocomial or nursing home-acquired infection	IV therapy until stable, followed by oral drugs to complete a minimum of 14 days; longer therapy may be necessary.

sues. Nonenhanced spiral CT may be superior to conventional CT or excretory urography for detecting urolithiasis.

Clinical Management

Severity of illness is the main determinant of the need for hospital admission and parenteral therapy in the patient with pyelonephritis [23, 26, 27]. If a reliable patient is clinically stable and able to take oral medications, a trial of outpatient therapy can be considered and can result in significant cost savings [25]. Parenteral therapy is needed for the patient with nausea and vomiting who is unable to take oral medications. If such a patient is otherwise stable, home intravenous (IV) antibiotic therapy may be an option. For the more seriously ill patient, especially if fever, rigors, or unstable blood pressure suggest sepsis syndrome, hospitalization is required. Acute pyelonephritis in the pregnant woman requires hospitalization because of the high risk of bacteremia and potential for significant morbidity and mortality for both mother and baby [23, 41, 42].

Antibiotic Choice

Antibiotic choices for the treatment of pyelonephritis depend upon the severity of symptoms, the causative organisms, and the presence or absence of complicating factors [37, 43] (Table 3). For mild cases of pyelonephritis, outpatient therapy with oral antibiotics such as TMP-SMX or fluoroquinolones in the same doses prescribed for cystitis but continued for 2 weeks may be sufficient. If hospitalization and parenteral therapy are required, options for treatment of uncomplicated pyelonephritis include IV, fluoroquinolones, aminoglycosides, or third-generation cephalosporin drugs (Table 3). If the in-

itial gram stain of the urine culture suggests the possibility of *Enterococcus*, IV ampicillin with or without gentamicin should be considered. Other possible agents include imipenem or other broad-spectrum antibiotics. The choice of antibiotics should be adjusted as indicated by the infecting organism's susceptibility pattern, when available. For hospitalized patients, parenteral antibiotics should be continued until the patient is stable, after which oral antibiotics can usually be used to complete the treatment [6, 43, 44].

Care must be exercised in the choice of antibiotics for pregnant women [6, 45]. Fluoroquinolones should be avoided in pregnant women (and in children) because of concerns about their effect on cartilage development. Aminoglycosides should be used with caution due to the possibility of fetal cranial nerve VIII damage, and TMP-SMX should be avoided near term to avoid kernicterus in the baby. Tetracyclines are contraindicated in children and pregnant women.

Duration of Therapy

The optimal duration of therapy for pyelonephritis has not been well studied. Although treatment for as long as 6 weeks has traditionally been advocated, > 2 weeks of treatment is usually not necessary for uncomplicated cases [46, 47]. Some studies have explored the possibility of reducing the duration of therapy to ≤ 1 week [30, 44], but concern remains that there may be an increased risk of relapse with such a short course of treatment [43]. Fortunately, the availability of oral fluoroquinolones increases the ease of IV to PO switching and again allows earlier discharge from the hospital. Therapy for > 14 days may be necessary in selected cases of complicated pyelonephritis or in men if prostatic infection is suspected.

Prognosis

With appropriate antimicrobial therapy, the prognosis for patients with pyelonephritis is complete recovery. In patients who fail to respond clinically after 72 hours of therapy with appropriate antibiotics, additional evaluation is indicated. Careful review of antibiotic sensitivity based on culture results should be undertaken [48]. Radiographic imaging to rule out obstruction, anatomic abnormalities, or intrarenal or perinephric abscesses can be considered [38]. Renal ultrasound, CT scans and possibly an intravenous pyelogram (IVP) may be necessary to detect abnormalities requiring surgical intervention.

Careful follow-up of patients with pyelonephritis is important, but the specifics of the required evaluation are unclear. At the least, instructions to return if symptoms recur is critical. The role of follow-up office visits, urinalysis, or urine culture is undefined. Follow-up "test of cure" urine cultures should be done within 1 – 2 weeks of completion of therapy in pregnant women, children, and patients with multiple episodes of pyelonephritis, and should be considered for other patients [49].

Complications

The intense renal inflammation associated with pyelonephritis can have functional consequences. Inflammation-induced tubular dysfunction can result in delayed excretion of contrast dyes and, rarely, overt acute renal failure (ARF) [36]. However, these changes usually are not clinically significant or persisting. Pyelonephritis can be complicated by bacteremia, especially during pregnancy and in older patients or those with obstructed urine flow. Septic shock with disseminated in-

travascular coagulation (DIC), adult respiratory distress syndrome (ARDS), and multiorgan failure can occur [43].

Particularly in hyperglycemic diabetic patients, rapid fermentation of glucose by the bacteria can produce gas within the kidney, causing emphysematous pyelonephritis (if the renal parenchyma is involved), gas abscess, or emphysematous pyelitis (if the renal pelvis or collecting system is involved) [50]. Papillary necrosis can also complicate pyelonephritis, especially among diabetics. In this circumstance, infection causes sloughing of the tissue, which can cause obstruction and worsen infection.

Kidney-associated abscesses may be intrarenal or perinephric [51, 52]. They occur predominantly in compromised hosts, especially in patients with diabetes, recent surgery or instrumentation of the urinary tract, or urinary reflux or obstruction. Those abscesses that develop as a complication of pyelonephritis are usually due to a gram-negative bacteria, especially *Enterobacteriacae*. In contrast, staphylococcal abscesses may occur secondary to bacteremia. Indeed, the isolation of *Staphylococcus aureus* in the urine in a febrile patient without urinary tract instrumentation signals the need for investigation of possible associated bacteremia. *S. aureus* abscesses should be treated with antistaphylococcal penicillin drugs or first-generation cephalosporins, whereas abscesses due to gram-negative bacteria should be treated with agents active against these organisms [51, 53]. Small abscesses may respond to medical management, but especially with larger abscesses, surgical or image guided needle drainage may be necessary [54, 55].

Recurrent UTIs

Recurrent infections pose important challenges to the patient's physician [1, 2, 18, 28, 56]. Differentiation between reinfection and relapse is critical to the correct management of these 2 very different conditions [2]. Reinfection implies newly-introduced infection with a new organism. Although such repeat infections are usually due to *E. coli*, the new organisms are different strains of this species. Risk factors for reinfection include sexual intercourse and use of diaphragm/spermicide as contraception [15, 56]. In contrast, relapse implies recurrent infection caused by the same organism, usually beginning soon after completion of an initial course of therapy, and is attributable to incomplete treatment of the initial episode. Relapse is more likely to occur in complicated UTI and is attributable to a persistent nidus of infection. Functional or anatomic abnormalities, prostatitis, or infected stones should be suspected.

Prevention of reinfection is focused on preventing reintroduction of bacteria into the urinary tract (Table 4). Oral antimicrobial therapeutic regimes have been shown to decrease the likelihood of reinfection and recurrent UTI [1, 2, 6]. For reliable patients, patient-initiated antibiotic therapy immediately after the onset of symptoms can be useful. In women who can accurately identify when they are developing a recurrence, a supply of antibiotics, usually TMP-SMX or a fluoroquinolone kept at home and initiated with onset of symptoms, can be effective. If recurrent UTI episodes are related to sexual intercourse, postcoital antibiotic prophylaxis can be helpful [57]. Because diaphragm/spermicide contraception is associated with high risk of urinary tract infection, alternative contraceptive methods should be considered. Continuous

Table 4. Management of Recurrent Cystitis Due to Reinfection

Post-coital prophylaxis	TMP-SMX 1 single-strength or 1 DS tab PO or Nitrofurantoin 50 – 100 mg PO
Continuous prophylaxis (daily or 3 times per week)	TMP-SMX 1 single-strength tab PO or Trimethoprim 100 mg PO or Nitrofurantoin 50 – 100 mg PO
Patient-initiated therapy	As recommended for single dose or 3-day therapy of cystitis

antibiotic prophylaxis can be used in patients with frequent (> 2 – 3 per year) episodes of UTI. Chronic prophylaxis (daily or thrice weekly) with low doses of TMP-SMX or a fluoroquinolone has been demonstrated to reduce the frequency of recurrences from 2 – 3 episodes per year to about 0.2 episodes per year among women with frequent UTI. Such prophylaxis is often continued for 6 months to a year and then interrupted to see if episodes of UTI recur. If so, prophylaxis can be resumed. Fortunately, emergence of resistant strains has not been a significant problem for women using long-term antibiotic prophylaxis for UTI. Finally, postmenopausal women with recurrent UTI may benefit from topical vaginal estrogen replacement therapy [11].

In contrast to reinfection, relapse of UTIs requires investigation of the underlying cause. A urine culture should be obtained and a full 7- to 14-day course of appropriate antibiotics initiated. Diagnostic studies should be considered to search for an occult source of infection in the kidney, perinephric space, or prostate and for urologic abnormalities including anatomic defects [18]. Renal, urethral, or bladder stones and other causes of obstruction need to be ruled out. Urinary tract stones may occur in patients with chronic infection due to a urease-producing organism such as *Proteus mirabilis*. Removal of calculi via lithotripsy or surgery is often necessary before antibiotics can effectively eradicate infection in patients with urolithiasis.

Catheter-associated UTI

Bacteriuria in patients with indwelling catheters occurs at a rate of 3 – 10% per day of catheterization and is nearly universal in patients with prolonged catheter use [58]. Routine treatment of asymptomatic bacteriuria in catheterized patients does not improve survival and often results in the selection of increasingly resistant microbes. Nevertheless, some bacteriuric patients will go on to develop symptomatic cystitis, pyelonephritis, and even bacteremia. Antibiotic therapy should be reserved for catheterized patients with significant symptoms or signs attributable to UTI [34].

Treatment of symptomatic UTI in the catheterized patient should include attempts to remove the catheter plus administration of appropriate antibiotics. Because catheterized patients often have infections due to bacteria other than *E. coli*, urine cultures are desirable to define the pathogen's identity and sensitivity patterns. Urine samples should be obtained directly from the Foley catheter and not from the drainage bag. Choice of initial empiric treatment should be based on review of the

organisms known to have previously infected the patient and on resistance patterns in the hospital or nursing home. TMP-SMX or fluoroquinolones are often reasonable choices until culture and sensitivity results are available, at which time therapy should be modified as needed. By definition, catheter-related infections are complicated UTIs, and antibiotics should be continued for ≥ 7 days.

Prevention of UTIs in catheterized patients is desirable but difficult [2]. The best preventive method is to avoid unnecessary use of urinary catheters. Use of diapers or pads, external drainage devices, or possibly intermittent catheterization is preferable to chronic catheterization [59]. Clean technique, as opposed to sterile technique, has been shown to be adequate for patients trained in self-administered intermittent catheterization [58]. Antibiotic prophylaxis may be useful for the patient with short-term catheterization [6], but this remains controversial. However, routine antimicrobial prophylaxis should not be used for chronically catheterized patients [2, 60]. This approach serves only to select antibiotic-resistant organisms [58, 60]. If chronic indwelling catheters must be used, meticulous handwashing by all caregivers should be emphasized. The role of local antibiotics and antibiotic impregnated catheters remains incompletely defined [2, 6, 61]. Reflux of urine from the collecting system into the bladder and breaks in the drainage system must be avoided.

The patient with neurogenic bladder and recurrent UTIs poses a particular challenge [62]. Intermittent catheterization or, in men, condom drainage with or without sphincterotomy can be useful. The use of alpha-blockers to control autonomic dysreflexia or of anticholinergic agents to improve incontinence should be considered. Transurethral sphincterotomy and external drainage may be needed to maintain low voiding pressures. Diversion procedures are required for some patients but are becoming less popular because of a variety of complications [62].

UTI in Children

In children, both asymptomatic bacteriuria and symptomatic UTIs should be treated with antibiotics, with drug choice determined by the results of urine culture [29, 31, 63]. Low bacterial counts in urine cultures from infants may reflect infection requiring treatment [64]. Short-course therapy is not appropriate, and antibiotics should be continued for 7 – 14 days. TMP-SMX is often appropriate as empiric therapy, and the acutely ill child with suspected pyelonephritis should receive treatment with parenteral antibiotics pending culture results [65]. Cure should be documented by follow-up urine cultures [29].

In many children, especially infants, UTIs should prompt diagnostic imaging because of the likelihood of discovering anatomic or functional urinary tract abnormalities and the high risk of renal damage from infection [18, 29, 30, 66, 67]. Ultrasonography is a commonly used initial test. A voiding cystourethrogram (VCUG) can be used to look for evidence of reflux in young children and in children with an abnormal ultrasound or a history suggestive of voiding dysfunction [30, 66]. Children found to have reflux should be placed on suppressive antibiotics at least until 5 years of age and have regular urine evaluations for unexplained febrile illnesses, with aggressive treatment of identified UTIs [31]. Surgical interventions are clearly required for obstructive lesions and may be considered in the child with reflux who develops recurrent UTI despite antibiotic therapy [66].

UTI after Renal Transplantation

Renal transplant recipients are at high risk for renal infection, both for mechanical reasons and because of the immunosuppressive therapy used to prevent graft rejection. Continuous prophylactic antibiotic therapy with TMP-SMX is commonly used in this context. Such therapy additionally provides protection against opportunistic infections such as nocardiosis, toxoplasmosis, or *Pneumocystis carinii* pneumonia, for which these patients are at risk. The efficacy of continuous TMP-SMX prophylaxis in preventing UTI and bacteremia in kidney transplant recipients was documented in a recent trial using both a standard dose (160 – 400 mg daily) and a higher dose regimen (320 – 800 mg daily). Emergence of resistance was not observed [6].

Prostatitis

Prostatitis syndromes can be divided into 4 types: acute bacterial prostatitis, chronic bacterial prostatitis, nonbacterial prostatitis, and prostadynia [68, 69]. The diagnostic approach and therapeutic management differs markedly between these 4 conditions [70].

Acute bacterial prostatitis denotes bacterial infection of the prostate and usually manifests with an abrupt onset of symptoms [68]. The patient classically presents with fevers, dysuria, frequency, obstructive voiding symptoms, and extreme perineal pain. The diagnosis of acute bacterial prostatitis is often quite obvious, with extreme tenderness to palpation of the prostate. Indeed, vigorous prostatic massage should not be performed in these patients because of the risk of precipitating bacteremia. To confirm the diagnosis and an etiologic agent of acute prostatitis, a urinalysis and urine culture should be performed. The urine specimen will usually show significant pyuria and may reveal hematuria. Urine culture will be positive. The most common organisms identified are *E. coli* and less frequently *Enterococcus* and other gram-negative bacilli, including *Pseudomonas*.

Treatment of acute bacterial prostatitis consists of empiric antibiotic therapy followed by tailoring of this therapy based on the results of urine culture and sensitivity patterns. Currently, the drug of choice is considered by many to be a fluoroquinolone, but TMP-SMX is also a reasonable choice. If the patient appears seriously ill with a high fever and the possibility of bacteremia is suspected, hospitalization for treatment with broad-spectrum IV antibiotics and supportive care may be needed. On occasion, prostatic edema can be so severe that acute urinary retention can result. In this case, urologic consultation and treatment with suprapubic urinary drainage catheter is needed. When the patient has been stabilized, antibiotic therapy can be given orally. Acute bacterial prostatitis requires prolonged therapy with oral antibiotics. A minimum treatment duration of 30 days, and sometimes 6 weeks to 3 months, may be required.

Chronic bacterial prostatitis is characterized by relapsing urinary tract symptoms and evidence of prostatic infection [68]. The patient may have prostatic, perineal, or suprapubic discomfort, but the symptoms are usually more intermittent and milder than those observed in acute bacterial prostatitis. Prostatic massage may yield secretions that contain > 10 white blood cells per high power field. The presence of white blood cells in the expressed prostatic secretions but not in the pre-massage urine favors the diagnosis of

chronic bacterial prostatitis rather than recurrent cystitis. Most patients with chronic bacterial prostatitis have infection with a gram-negative bacillus, and the recurrent episodes are caused by the same organism. Treatment involves identification of the infecting organism and long-term (1 – 3 months) oral antibiotic therapy with agents such as TMP-SMX or fluoroquinolones. Some patients with chronic bacterial prostatitis may have prostatic calculi that harbor organisms capable of causing recurrent symptomatic episodes. These patients are particularly likely to require long-term antibiotic treatment to eradicate the infecting organism. Occasionally, transurethral resection of the prostatic gland (TURP) to remove prostatic calculi may be necessary.

Nonbacterial prostatitis is infectious prostatitis for which no identifiable bacterial etiology can be found [71]. Prostatic inflammation is evidenced by the presence of > 10 white blood cells per high power field in expressed prostatic secretions. However, in contrast to bacterial prostatitis, routine cultures of expressed prostatic secretions will be negative. Patients present with symptoms including prostatic, perineal, or suprapubic pain that may be indistinguishable from symptoms of chronic bacterial prostatitis. A variety of organisms have been postulated as possible etiologic agents of nonbacterial prostatitis, including *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma*, and *Trichomonas vaginalis* [72]. However, a definite role for any of these agents has not been established [71]. Nevertheless, many experts will give a trial of antibiotic therapy directed towards these unusual organisms in patients who present with nonbacterial prostatitis. Most commonly, a 2- to 4-week trial of doxycycline or tetracycline is attempted. If the patient experiences symptomatic improvement, it is possible that the antibiotic has treated an infecting organism. However, it may be difficult to distinguish between a placebo effect, coincidental improvement, nonspecific anti-inflammatory actions, and true response to the antibiotic. A variety of non-antimicrobial approaches have also been utilized in the treatment of nonbacterial prostatitis. The use of nonsteroidal anti-inflammatory agents, sitz baths, and avoidance of caffeine or alcohol, which can cause bladder irritation, have been advocated. Some patients may respond to treatment with alpha adrenergic blocking agents such as terazocin.

Prostadynia is a condition that can be quite distressing to the patient and difficult to treat [73]. Patients with prostadynia have symptoms similar to prostatitis but no evidence of infection or inflammation upon examination of urine or expressed prostatic secretions. The etiology of prostadynia is unknown. The role that stress or emotional problems play in the etiology of prostadynia remains to be defined. In some patients, urologic evaluation may reveal obstructive voiding physiology, but the vast majority of these patients will have no abnormalities on urological evaluation. Some patients with prostadynia may benefit from treatment with alpha adrenergic blocking agents [74] or muscle relaxants such as diazepam. Stress reduction and attention to underlying emotional problems contribute to the complete care of the patient [75].

Unusual Infections

Candida UTI

Candida UTI now represents the fourth most common cause of nosocomial UTIs (Table 5). The vast majority of candiduria epi-

Table 5. Treatment Options for Candidal UTI

Therapy	Comments
None	Appropriate in most asymptomatic patients without evidence of dissemination.
Fluconazole	Drug of choice for uncomplicated symptomatic cystitis (200 mg PO q day x 7) or ascending pyelonephritis (400 mg PO or IV q day).
Amphotericin B bladder washes (50 mg/L sterile water administered via triple-lumen catheter for 7 – 14 days)	Alternative for use in symptomatic patient requiring chronic Foley catheterization. No advantage over fluconazole in absence of fluconazole resistance.
Parenteral amphotericin B	Remains the drug of choice for disseminated disease in the immuno-compromised patient, but increasing evidence for efficacy of azole drugs.

sodes originate from the lower urinary tract. *Candida* UTIs may manifest as asymptomatic candiduria, cystitis, pyelonephritis, hematogenous renal candidiasis, or fungus balls [76]. When yeast is identified on urine culture, it is often advisable to determine that it is persistent. If a repeat urine specimen confirms the presence of yeast, it is important to consider the possibility of an underlying cause such as catheterization, prolonged antibiotic therapy, immunocompromising medical conditions, or urinary tract anatomic abnormalities.

If the patient with candiduria is asymptomatic, therapy is rarely appropriate. In the patient with a Foley catheter, it is reasonable to attempt at least one trial of changing or removing the catheter. Asymptomatic candiduria is widely overtreated, and treatment of asymptomatic infection is probably only justified before urologic surgery or manipulation and in the patient at high risk for disseminated fungemia such as the neutropenic host or other immunocompromised individual.

Symptomatic *Candida* cystitis usually should be treated with oral azoles [77]. Local bladder irrigation with amphotericin B is an alternative, particularly in the chronically catheterized patient. Ascending candidal pyelonephritis is an uncommon complication of candidal cystitis and usually only occurs in patients with diabetes and/or urinary obstruction. Instead, renal candidiasis is usually due to hematogenous seeding as a manifestation of disseminated fungal infection. Systemic therapy with fluconazole or amphortericin B is required for renal *Candida* infection irrespective of the route of acquisition. Patients with possible disseminated disease may need additional diagnostic or therapeutic interventions, plus a longer duration of treatment.

Viral UTI

In immunocompetent hosts, viral infections usually do not produce symptoms in the uri-

nary tract. However, in immunocompromised patients, significant manifestations such as hematuria, dysuria, and frequency can be associated with viral UTIs. Viral UTIs have been described as acute illnesses including acute hemorrhagic cystitis in children with adenovirus and in bone marrow transplant patients infected with adenovirus or polyoma virus. Viral UTIs can also occur as part of disseminated viral illnesses such as mumps, cytomegalovirus, measles, or varicella virus.

Tuberculous UTI

Tuberculous involvement of the urinary tract is well described. The pathogenesis of genitourinary tuberculosis (TB) is usually thought to involve hematogenous seeding of the renal cortex with progression to the medulla. Patients with renal TB are often asymptomatic but may present with dysuria or hematuria or, less commonly, with constitutional manifestations of disseminated tuberculosis. Evidence of active TB outside of the genitourinary tract is identified in < 10% of patients with renal TB, but evidence of old pulmonary infection can be found in most patients. Patients with genitourinary TB are often identified when "sterile pyuria", i.e. pyuria with negative routine bacterial cultures, is noted. *Mycobacterium tuberculosis* can be grown from the urine in the majority of cases. Genitourinary TB can be complicated by the development of ureteral strictures, hydronephrosis, and renal parenchymal abscesses. The IVP may demonstrate strictures or a beading pattern in the ureters, and ultrasonography may reveal hydronephrosis or an infiltrative process in the renal parenchyma. Treatment of renal TB is the same as that for other forms of TB.

Non-candidal Fungal UTI

Infection of the urinary tract with a variety of fungi, including cryptococcus, blastomycosis, or histoplasmosis, has been described. Treatment with the new azole drugs may be effective, but amphotericin-B therapy is sometimes necessary.

Parasitic UTI

A variety of parasites can also infect the urinary tract including *Schistosoma haematobium, Schistosoma mansoni*, or *Onchocerca volvulus*. Hematuria is suggestive of infection with *S. haematobium*, and the eggs of this trematode, as well the eggs of *S. mansoni*, can be detected in urine samples. Therapy of parasitic infections should be tailored to the specific organism.

The Dysuric Patient

Many conditions may cause the patient to present with dysuria [2]. About one-half of young women with dysuria will have classical bacterial cystitis with > 10^5 CFU of bacteria/mL urine on culture. In the remaining patients who have what has been termed "urethral syndrome", symptoms are due either to bacterial cystourethritis with fewer organisms or to other conditions. Bacterial cystitis must be distinguished from sexually transmitted diseases, vaginitis, and noninfectious etiologies of dysuria. Urethritis may be caused by genital *Herpes simplex* virus, *Chlamydia trachomatis*, gonorrhea, or other sexually transmitted diseases. *Candida* or *Trichimonas* vaginitis often presents with dysuria. Patients with *C. trachomatis*, gonorrhea, *Candida*, or

Trichimonas will respond to appropriate antimicrobial therapy for these conditions. Hypoestrogenism, urethral spasm, or chemical irritation can produce dysuria in the absence of infection. Finally, approximately 10% of patients with dysuria-frequency syndrome have no evidence of infection or any other identifiable cause for their symptoms.

Summary

Optimal management of acute UTI requires delineation of the patient's clinical syndrome and consideration of the underlying host status followed by selection of an antimicrobial agent and duration of therapy appropriate to the clinical situation. The choice of antimicrobial agent should be guided by the susceptibility pattern of the infecting organism and relevant characteristics of the antimicrobial agent, including efficacy, cost, pharmacokinetic properties and adverse effect profile. For women with uncomplicated cystitis, short-course therapy with 3 days of TMP-SMX or a fluoroquinolone is optimal. In other clinical situations, including complicated cystitis, pyelonephritis, prostatitis or bacteremic UTIs, longer courses of therapy are indicated. Pretreatment urine cultures are not necessary in most young women with uncomplicated cystitis but should be used to guide therapy in most other circumstances. Asymptomatic bacteriuria requires treatment only in children, pregnant women, and patients undergoing urinary tract instrumentation likely to be associated with bacteremia. Urologic investigation is warranted in patients not responding to therapy for UTI, when obstruction is suspected, with relapse of infection due to the same strain of bacteria and in children with symptomatic UTI, but not in the vast majority of women with uncomplicated UTI. Unusual organisms may cause UTI and should be considered based on historical or other clinical clues.

Reflux Nephropathy

Billy S. Arant, Jr.

Introduction

The frequent association between chronic atrophic pyelonephritis and vesicoureteral reflux (VUR) was noted just over 25 years ago, and the term reflux nephropathy (RN) was quickly substituted for other words used previously to describe the localized injury and scarring from suppurative inflammation in the renal parenchyma [8]. In the pre-antibiotic era, chronic atrophic pyelonephritis was recognized as a common cause of hypertension and chronic renal insufficiency. In fact, up to 20% of patients at autopsy were found to have pyelonephritis and, when data were available, 45% of them were known to be hypertensive before death [43].

In 1929, an unusual but consistent pathologic finding was observed in kidneys of several patients with severe hypertension [6]. An aglomerular, fibrous band of tissue overlying a calyx gave the appearance of a circumferential groove in the renal parenchyma. These peculiar lesions were considered congenital and, subsequently, were referred to as the Ask-Upmark kidney [33]. Whether the lesions were associated with VUR is unknown because the observations were made before the introduction of radiocontrast cystography. Similar renal lesions in hypertensive children, some of whom were studied for VUR, were often, but not always, associated with VUR and urinary tract infection (UTI). For nearly two decades, these aglomerular lesions were referred to as segmental renal hypoplasia, which implied a localized failure of normal metanephric development. Finally, a series of patients whose kidneys had segmental renal lesions similar to Ask-Upmark kidneys and to segmental renal hypoplasia were observed in serial radiographic and pathologic studies; most of these patients had VUR as well as documented UTI [4]. Careful dissection in some of these kidneys revealed parenchymal lesions in various stages of development – acute inflammatory lesions only days old adjacent to completed aglomerular scars with no evidence of inflammation. It became quite evident that the aglomerular grooves or hypoplastic segments, described previously, were actually atrophic parenchymal scars resulting from localized pyelonephritis in previously normal renal tissue that had contained glomeruli and tubular structures. These lesions could now be referred to, more correctly, as *segmental renal atrophy* [11].

The proposed mechanism for pyelonephritis in humans has been that bacteria, multiplying rapidly in bladder urine, cross an incompetent ureterovesical junction as intravesical pressure increases during micturition. The inoculum reaches the renal pelvis and calyces, enters the papillary collecting tubules in one or more renal pyramids through the ducts of Bellini – intrarenal reflux (IRR) – and causes suppurative inflammation. The resulting injury may heal by scarring, and even a single scar may be associated with severe hyperten-

sion later in life. When scarring is more extensive and both kidneys are damaged, not only hypertension, but also chronic renal insufficiency or end-stage renal disease (ESRD) may develop. Although characteristic radiographic findings and histopathologic features of RN may be observed in kidneys never known to be infected or subjected to VUR, such cases have been considered unusual.

Once the relationship of renal injury to VUR was established, it was reasonable to think that eliminating VUR by surgery could prevent subsequent episodes of pyelonephritis and its clinical consequences. Clinical efforts over more than 30 years produced about 3,000 published reports on VUR and UTI [20]. Most so-called studies were focused on surgical techniques for restoring competence to the ureterovesical junction. When appropriate clinical trials were finally completed, just in the past decade, surgical correction was found to offer no advantage over conservative medical management in preventing renal scarring [13, 37]. Further understanding of the mechanisms whereby VUR injures the kidney acutely and initiates progressive injury without further infection, therefore, must come from future studies, not of the ureterovesical junction, but rather of the human kidney's responses to sterile injury as well as suppurative inflammation both before and after birth.

Incidence

The true incidence of RN is unknown. Perhaps the best evidence for RN being a distinct and, therefore, significant clinical problem is that it accounts for 15 – 25% of patients treated for ESRD in Europe and Australia/New Zealand [19]. There is no reason to think that the prevalence is less among patients with chronic renal insufficiency in North America, where RN has been shown to be a major cause of hypertension and ESRD in children and adolescents (Table 1).

Primary VUR includes only those patients in whom no other anatomic or functional abnormality can be identified and has been demonstrated in < 1% of humans with no prior history of UTI [2]. However, primary VUR will be found in 20 – 50% of children investigated following the first UTI (the highest incidence in the first year of life), 20% at 12 years of age, and only 5% in adults. A long-held notion has been that the incidence of VUR is higher when the voiding cystourethrogram (VCUG) is performed soon after an acute UTI, so the recommendation has been to wait for 4 to 6 weeks after the UTI to order the diagnostic study. Although no report has been made of the incidence of VUR between early and late studies within a single center, the incidence of VUR among children of various ages has not varied when studies at different centers were done either within the first week or more than 3 weeks following UTI [2]. There seems to be no merit in the practice of delaying a diagnostic VCUG once the urine has been rendered sterile, only to "minimize" the number of children with VUR. There may have been a time in the past when the diagnosis of VUR of any grade resulted in an attempt at surgical correction, but this is no longer the case. Today, children with UTI managed conservatively tend to get better clinical supervision, more education about the consequences of UTI and longer periods of follow-up when VUR is identified.

There is no gender difference in the incidence of primary VUR with UTI. The absolute number of girls with VUR is actually greater than the number of boys, but this is related more to the higher incidence of UTI in girls than boys after the first year of life. This

incidence of VUR is similar among white, Hispanic and Asian children with UTI, but VUR is identified less often in black children. Moreover, RN is an unusual cause of hypertension or chronic renal insufficiency among black adolescents and young adults.

Primary VUR will be identified in 27 – 45% of asymptomatic siblings of children with VUR [36]. If one child in a family has renal scarring at the time primary VUR is found, the incidence of VUR in siblings may be even higher. As more genetic studies of families with VUR have been conducted, it would appear that primary VUR, with or without RN, does occur in multiple generations implying vertical transmission suggestive of a pattern of autosomal dominance with variable penetrance. A specific gene locus has not yet been identified. Scarred kidneys may also be associated with secondary VUR from anatomical obstruction as in posterior urethral valves, prune-belly syndrome, ureteropelvic

junction obstruction and urolithiasis, as well as from functional obstruction in a neurogenic bladder or with dysfunctional micturition – none of which are inherited problems.

One of the most common serious bacterial infection in infants and young children presenting with fever is UTI. Some general idea of the prevalence of RN in the general population can be learned from the frequency of a first UTI being, on average, 2.8% in children under five years of age. In the 1990 census there were 18,264,096 of these infants and young children in the United States. Therefore, approximately 511,394 children will have a first UTI by their fifth birthdays, and 30 – 50% or between 150,000 and 250,000 will, if examined, have VUR. The estimates of any degree of renal scarring from VUR and pyelonephritis – one simple scar, perhaps, or multiple scars involving one or both kidneys – have been reported between 12 – 50%, depending upon length of follow-up and methods used to assess renal scarring. The longer the follow-up and the more experienced the investigator, the more often renal scarring will be detected. Also, carefully performed intravenous pyelograms (IVP) and technetium-99m-dimercaptosuccinic acid (DMSA) renal scans found more scars than renal ultrasonography or poorly-done IVP. In a recent study of very young infants with acute pyelonephritis, for example, up to 40% of infants with VUR studied by DMSA scans six months after a UTI had some degree of renal scarring, but not all had VUR [24]. It will be important to follow these patients long-term to record the clinical significance of renal scars detected at this very young age.

If, for example, only 30% of infants and young children under 5 years of age with VUR and UTI develop renal scarring, there should be around 61,367 of them with RN. Assuming no renal scarring ever occurred after 5 years of age and no deaths among children and adolescents with renal scarring, approximately 368,204 people (3.3:1000) currently under 30 years of age in the United States alone should have RN. Only half of children recognized to have acute pyelonephritis, however, will have VUR demonstrated. One study found renal scarring following an episode of acute pyelonephritis in 37% of children without VUR [40]. Until recently, those children with UTI but without VUR have not been subjected routinely to follow-up renal imaging studies. Just how many of them will develop hypertension or renal insufficiency later in life is yet to be determined, but these patients will add to the overall incidence of RN in the general population.

More than half of children with a first UTI, with or without VUR, will experience another UTI within 6 months [31]. With each subsequent infection, the risk of renal injury is increased from 9% after the first UTI to 58% after the fourth [28]. A delay in effective therapy, which is not unusual in an infant or child whose complaints do not suggest UTI, can double the rate of scarring, and, therefore, increase the incidence of RN.

Despite opinions to the contrary, acute renal injury from pyelonephritis definitely causes scarring in children over 5 years of age – even in the absence of detectable VUR [10]. As children grow, VUR tends to resolve gradually in most infants and young children [20], while the incidence of UTI increases to 6 – 8% of school-age girls. Moreover, the rate of VUR resolution in these older children is slower. The consequences of secondary VUR, particularly in decompensated urinary bladders with recurrent UTI, as well as pyelonephritis complicating urolithiasis, only add to the total number of individuals suffering from RN. Perhaps the only reliable statement that could be made about RN to date is that its incidence has been underestimated – especially in the United States.

Etiology

RN has been attributed to pyelonephritis associated with VUR – more specifically IRR – in infants and young children (Figure 1). Few, if any, would argue that suppurative pyelonephritis can cause significant and permanent renal injury. The pathogenesis of renal scarring from VUR-associated pyelonephritis has been produced experimentally in animals either by injecting bacteria into the renal parenchyma or inoculating the bladder with fecal flora after VUR had been created. Shortly thereafter, one or more focal lesions of suppurative inflammation could be demonstrated in the renal parenchyma and, if effective antibiotic therapy was not provided within 5 days, renal scarring developed even though further bacterial growth was eradicated [38]. When treatment was delayed in children with UTI, the incidence of renal scarring was increased 4-fold over those treated promptly [49]. It seems that an inflammatory cascade is initiated by the bacteria within the renal parenchyma, much like that described for endotoxemia, which permits the inflammatory response to continue long after effective antibiotic therapy is introduced [39]. The evolution of the acute inflammatory lesions either to complete resolution or permanent scarring has been demonstrated by serial DMSA renal scintigraphy. Pyelonephritis caused by *P-fimbriated E. coli* seems related more frequently to renal scarring than some other common pathogens. The unique ability of this organism to attach itself to uroepithelium may allow it to cross the ureterovesical junction when VUR is not present and, perhaps, persist in the urinary tract longer than other bacteria.

Figure 1. Intrarenal reflux (arrows) into the collecting ducts which extends into the outer cortex of the upper pole of a young girl's left kidney during voiding cystourethrography. There is no evidence of cortical thinning or scarring.

Whether sterile VUR can cause similar renal injury, however, is still actively debated. There is no doubt that typical atrophic renal scarring can be induced when sterile VUR is produced experimentally in animals, but the intravesical pressure required for scarring exceeds 60 cm water – higher than normal voiding pressures measured in children. Some will argue, therefore, that in the absence of bladder outlet obstruction or a decompensated, noncompliant bladder generating high intravesical pressures, renal injury is never associated with sterile VUR. The greatest argument favoring a role for sterile reflux, however, is the scarring associated with VUR in the fetal urinary tract where the urine is always sterile. The developing kidney of the fetus and young infant appears more easily damaged from VUR than does the kidney of an adult and probably older children as well. As more fetuses with dilated urinary tracts have been identified as having renal scarring associated

with VUR – not obstruction – at birth, it is hard to deny sterile VUR causes renal injury with scarring which is different from dysplasia. Segmental scars have been described in dysplastic kidneys subjected to primary VUR as well as obstructed urinary tracts [4]. When studied postnatally, a kidney with dysplasia will have the same ultrasonographic and, perhaps, DMSA scintigraphic appearance as the scarred kidney; however, an IVP will demonstrate segmental scars and calyceal deformities characteristic of RN even in abnormally small kidneys (Figure 2). Kidneys that are small from dysplasia alone will not excrete the radiographic contrast material, so the kidney will not be visualized by IVP. This limitation to more modern diagnostic imaging studies, now favored widely over IVP, is often overlooked as a means of establishing the diagnosis of RN in small kidneys.

Just what kind of intravesical pressure is "normal" for human infants and children? Before toilet training, intravesical pressures generated in normal bladders during micturition rarely exceed 35 cm water. On the other hand, during or after toilet training, when young children are rewarded for postponing micturition or, on their own, delay bladder emptying to continue playing or engage in other activities, intravesical pressures can easily exceed 35 cm water. Add to this any increase in intra-abdominal pressure that will increase intravesical pressure further, as would occur when the child jumps down steps, lands prone in a fall or coughs vigorously with a respiratory illness, and intravesical may exceed 100 cm water. Moreover, there is little dampening of pressure transmitted from the bladder to the renal pelvis across a refluxing ureterovesical junction. A distinct group of young children, for reasons yet unexplained, suffer from dysfunctional micturition, where there is poor coordination of sphincter relaxation during bladder contraction. Higher than normal intravesical pressures may reach 200 cm water in some children both during and between attempts at micturition. Recurrent UTI, which is typical in children with dysfunctional micturition, adds to the incidence and severity of renal injury. Other symptoms of dysfunctional micturition include infrequent micturition, dysuria in the absence of UTI, diurnal incontinence, nocturnal enuresis and constipation. This condition is complicated by VUR, but when unrecognized and inadequately treated,

Figure 2. Intravenous pyelogram in 3 yo male discovered to have right Grade II vesicoureteral reflux following a first recognized urinary tract infection. There is generalized cortical atrophy (arrows) in the abnormally small right kidney with deformed calyces. Note how well the small kidney excreted the contrast agent that is typical of chronic atrophic pyelonephritis or reflux nephropathy. The left kidney is unusually large because of compensatory hypertrophy, but is otherwise normal.

VUR fails to resolve spontaneously as it does in other children, and anti-reflux surgery often fails.

Statements have been made that only IRR can cause renal injury. When the renal pelvis of either the human or animal kidney was filled with contrast material under pressure, the contrast solution was found not only to enter the papillary collecting ducts but also to traverse the length of the entire nephron reaching Bowman's space. Because IRR is rarely identified or, perhaps, recognized when a voiding study is done, the conclusion stated in many references is that the actual incidence of IRR is low. Again, this problem is relative only to the detection of IRR which, when seen, is a transient phenomenon at peak voiding pressure (Figure 1). The frequency of IRR being identified is directly related to the interest and skill of the observer performing the VCUG. If renal scarring were possible only with IRR, but IRR is never identified – even in repeated studies – then an entirely new, alternate mechanism for the development of segmental renal lesions must be tendered.

Renal scarring is most evident on diagnostic imaging studies in either upper or lower poles. The porcine model of the refluxing kidney was favored by some investigators because, like the human kidney, the pig kidney has compound papillae draining polar pyramids. The assumption was that IRR occurred more easily in these compound papillae; however, scarring occurs frequently in association with simple papillae as well and in the mid-region of kidneys where small scars seem more difficult to detect by IVP or ultrasonography. Another popular hypothesis advanced 20 years ago was the *"Big-Bang theory"* which meant that the kidney was scarred, sometimes irreversibly, after a single episode of infected IRR. For example, one month following a first UTI, the right kidney of a 3-year-old child with mild (Grade I) VUR was normal (Figure

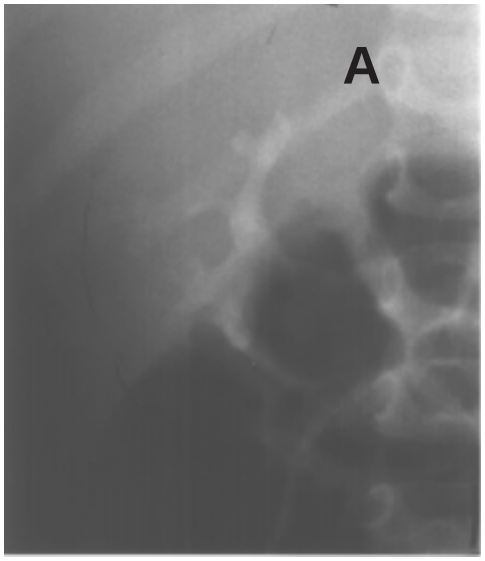

Figure 3a.

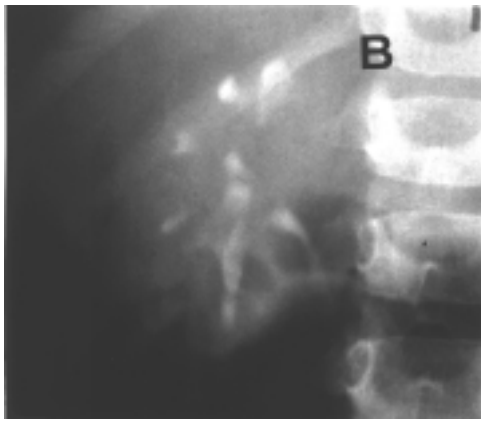

Figure 3b.

Figure 3. The appearance of the right kidney (A) was normal following the first urinary tract infection in a 3 yo female who had right Grade I vesicoureteral reflux. One year later, during which the urine was documented to have remained sterile and the reflux had not worsened, the same kidney (B) is reduced in overall size from 4.5 to 3.0 vertebral bodies due to cortical atrophy. The calyces in all regions exhibit the swallowtail deformity of chronic atrophic pyelonephritis or reflux nephropathy.

3a). One year later, VUR remained mild, compliance with conservative management including antibiotic prophylaxis was good and the urine had been confirmed sterile by culture at regular intervals. The kidney, however, was reduced to approximately half its previous size and exhibited generalized renal scarring with calyceal abnormalities (Figure 3b). On the other hand, new and progressive scarring over several or many years have been reported often in patients subjected to serial IVP during follow-up for VUR [37]. The histopathologic identification of lesions in various stages of development supports the idea that multiple scars may result as well from a *"series of little bangs"* [12]. This latter hypothesis appears to have support from the increase in the incidence of renal scarring with recurrent pyelonephritis [28].

It is widely accepted that the prevalence of renal scarring among all patients with VUR is related directly to the grade of VUR observed during voiding cystourethrography. When VUR is associated with a dilated collecting system (International Grades III – V), renal scarring will be noted in 28 – 50% of kidneys. The number of scarred kidneys associated only with non-dilating VUR (Grades I – II) is usually overlooked because the incidence of scarring is only about 10%. Many seem willing to attribute the renal injury in children with lesser grades of VUR to an earlier time when "VUR must have been more severe" because VUR tends to resolve in most, if not all children, with time and continued growth. When infants and young children with radiographically normal kidneys were followed in serial studies for 5 years after their first recognized UTI, 28% of kidneys subjected to grade III VUR were scarred while only 10% of kidneys with grades 0, I and II VUR had scars [3]. The importance of these observations is not that the incidence of renal scarring was less with mild and moderate VUR, but rather that the total number of scarred kidneys is greater because more patients have mild and moderate VUR than severe VUR. The consequences of renal scarring from any grade of VUR should not be ignored.

Case Presentation

Following her first recognized UTI, a 3-year-old white female was found to have Grade I VUR on the right. Both kidneys were normal by renal ultrasonography. There was no additional UTI, but 5 years later, the patient presented to an emergency department with heart failure. Her blood pressure was 210/160 mm Hg. Once her hypertension was controlled, the heart failure abated. Evaluation revealed Grade I VUR still on the right – no change in 5 years. However, the IVP revealed a single scar in the upper pole of the right kidney.

There has been a long running debate over whether renal scarring from UTI and VUR ever occurs after 5 years of age. In fact, some would argue that all renal injury is initiated by VUR *in utero* and detected only when diagnostic imaging is performed postnatally following the first UTI. Others have claimed that renal scarring never results from VUR and UTI and that so-called scars are actually areas of renal dysplasia. Certainly, most patients with recognized RN have a history of UTI in early childhood. A recent retrospective study could identify few scars by DMSA scintigraphy to develop in children with VUR after 4 years of age [48]. One prospective study in children of all ages found no renal scar to develop beyond 2 years after the last episode of pyelonephritis [13]. On the other hand, 2 other prospective studies noted new scars not only later than 2 years from the last febrile UTI but also to occur in subjects older than 5

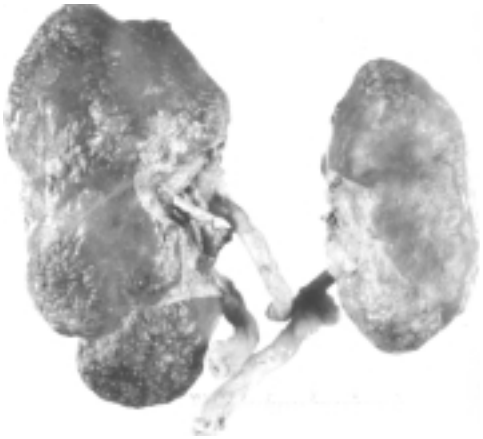

Figure 4. Both kidneys were removed from this 14 yo female before transplantation. Grade III vesicoureteral reflux was demonstrated into both ureters of the duplicated but unobstructed right collecting system as well as the single left ureter. This girl presented at the age of 9 years with hypertensive encephalopathy and had only one recognized prior urinary tract infection. In spite of satisfactory control of her hypertension without ACE inhibition, surgical repair of her reflux, and sterile urine, progressive deterioration in renal function was observed over the next 5 years (see Figure 11, upper panel, square symbols labeled SR).

Figure 5. The left kidney from a 13 yo female who presented with ESRD and no evidence of prior hypertension or urinary tract infection. A thin rim of aglomerular parenchyma was present over each calyx. In the upper pole an unscarred pyramid (arrow) had evidence for compensatory hypertrophy and what was responsible for most of her residual renal function. There was no histopathologic evidence of renal dysplasia.

years of age [3, 37]. Recently, adolescent patients with febrile UTI – a group rarely subjected to diagnostic imaging – were studied by DMSA scintigraphy. The rate of renal scarring was compared in infants (43%) and found actually to be higher in young children (84%) and adolescents (80%) [10].

Pathology

The gross morphologic appearance of kidneys scarred by pyelonephritis associated with VUR is illustrated in Figure 4. The kidney is usually reduced in weight as well as overall dimension if scarring is extensive. When there is only one or, perhaps, 2 segmental scars, however, the kidney may otherwise appear normal. Any irregular contour of the uncut kidney's surface is due to areas of segmental atrophy separated by unscarred parenchyma that has undergone compensatory hypertrophy. When the scarring is mainly in polar regions, the mid-portion of the kidney may have a nearly round appearance because of the compensatory growth in unscarred pyramids. When the kidney is bisected longitudinally through the pelvocalyceal system (Figure 5), scarred areas can be seen to overlie a dilated or deformed calyx. Pelvocalyceal dilatation is not a constant finding in RN. The histopathologic features of RN will be missed if the pathologist, hoping to find renal tissue

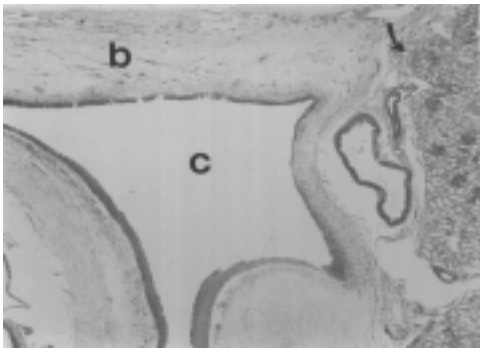

Figure 6. Microscopic examination of the aglomerular fibrous band of tissue (b) overlying a calyx (c). The segment is well demarcated from the normal renal cortex with glomeruli and tubular structures to the right of the calyx (arrow). (PAS stain; 18x magnification).

not yet completely destroyed, examines only sections from the most normal looking areas. To make the diagnosis of RN, a section for microscopic examination should be taken across a scar to include both the adjacent, more normal appearing parenchyma, as well as the underlying calyx.

Microscopically, a completely atrophic scar will be seen as an aglomerular band of tissue overlying a calyx (Figure 6). This band represents once normal renal cortex and medulla injured when IRR, with or without infection, disrupted the collecting duct epithelium and caused local inflammation. The inflammatory response irreversibly damaged either the medullary or papillary collecting ducts associated with those nephrons, the post-glomerular medullary vessels, or both. In time, the segmental injury causes loss of normal histology with the lesions variably containing atrophic tubules, tubular microcysts, sclerotic glomeruli and arcuate vessels separating the atrophic cortex from the atrophic medulla [4, 11]. Depending on the timing of the histologic examination after the injury was initiated, the various phases of acute tubular disruption with mild to marked inflammation – even pus – may be found in proximity to a much older, completely atrophic lesion, especially in a kidney which has been or continues to be injured repeatedly over a period of years. The lesions of RN have been identified even in patients whose VUR was surgically corrected years before the kidney was removed [12]. Other histopathologic features of RN may include renal dysplasia in kidneys subjected to intrauterine VUR or obstruction during metanephric development, but kidneys injured only after birth should not contain dysplasia [4]. When one kidney is scarred in RN, the contralateral kidney, if never subjected to VUR or infection, may exhibit focal glomerulosclerosis [29]. This finding suggests a humoral mechanism by which injury to one kidney can cause changes in the opposite kidney. Based on studies of remnant kidneys focal glomerulosclerosis in RN may be explained better as evidence of glomerular hyperfiltration. A very good candidate for the circulating factor may be angiotensin II (Ang II) produced either after renin is released in increased amounts from the scarred kidney or to increased efferent arteriolar resistance and glomerular filtration by the normal kidney.

Diagnosis

Confirming the clinical diagnosis of RN in any given patient requires a high index of suspicion. Firstly, one must believe that the renal lesions associated with VUR represent a distinct pathologic entity. Distinguishing the problem from other clinical entities, in which a kidney may also be small, requires a certain familiarity with the specific features of RN. A

history of UTI or VUR in a sibling should alert the clinician to the possibility of RN. The medical history of a patient with RN is important, but the physical examination is usually unhelpful unless the patient already has developed complications of renal scarring, particularly hypertension and its clinical consequences. Not all patients presenting with RN will have had a UTI recognized in the past and, if so, will not have had radiographic investigation to document the presence of VUR. This was the case of the 13-year-old white female who presented with ESRD and normal blood pressure; one of her kidneys is pictured in Figure 5. The absence of VUR, particularly in older children with UTI and renal scarring, does not guarantee that VUR was never present because the natural tendency is for VUR to resolve with age [3, 20].

One or more febrile UTIs in infants and young children, with or without VUR, place them at risk of renal injury with subsequent parenchymal scarring. A longer interval between the clinical onset of pyelonephritis to the first dose of an effective antibiotic will increase the chance for renal scarring [49]. With recurrent UTI, the incidence of renal scarring increases from 9% after the first UTI to 58% after the fourth [28]. When VUR is detected, renal scarring can be expected to be present or develop in 50% of children with severe VUR (Grades IV and V), 28% with moderate VUR (Grade III) and in 10% of mild VUR (Grades I and II) [3, 44]. Symptoms of dysfunctional micturition such as diurnal incontinence, infrequent and incomplete micturition and constipation, mostly in females, imply higher intravesical pressures, persistent dilating VUR, recurrent UTI and a greater likelihood of renal scarring.

Voiding Cystourethrography (VCUG)

Clinical recommendations have been made consistently in general pediatrics, pediatric nephrology and urology literature for more than 50 years that each infant or child with a first febrile UTI undergo radiologic investigation to detect an anatomic or functional abnormality which may cause further damage to the urinary tract [34]. In addition, boys at any age and girls under 3 years of age should be studied following the first UTIs whether it is symptomatic or not. More recently, the recommendation has been made to investigate asymptomatic siblings of children with VUR – at least those < 5 years of age – in the hope of detecting VUR before the first UTI can occur [36]. These directions have been followed reluctantly by some and inconsistently by others. The principles of treating cystitis in sexually active women often prevail in managing UTI in children, particularly when the physician is not a pediatrician. There seems to be an aversion by many parents to subject their child to the perceived emotional and physical trauma of bladder catheterization. Substituting renal ultrasonography for the cystogram may identify an upper tract abnormality, like a dilated calyx or advanced cortical atrophy, but will not eliminate the possibility of VUR [14]. When the child's physician is not convinced of its value, the workup is often not pursued.

Until recently, contrast VCUGs were done initially and as frequently as every 6 months during follow-up of a patient with VUR. In the past, when VUR worsened or a renal scar was noted, surgical correction of the VUR was recommended. Upon learning from prospective clinical trials that all grades of VUR either resolved spontaneously or the renal outcome could not be altered appreciably by surgical intervention, whether or not the kidney was

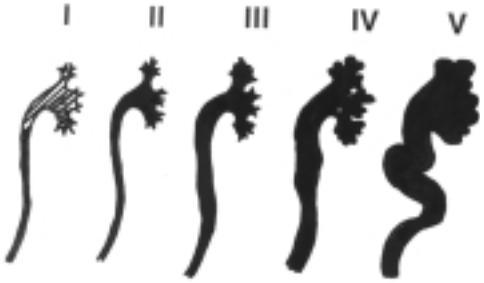

Figure 7. Grading of vesicoureteral reflux according to the classification of the International Reflux Study in Children. The black areas of the collecting system represents contrast material from the bladder, which flows retrograde across the ureterovesical junction during micturition. If the contrast material enters the ureter but does not reach the renal pelvis, Grade I is assigned. When the contrast material fills but does not distend either the ureter, pelvis or calyces, Grade II is assigned. If either the pelvocalyceal system or ureter is distended, reflux is considered Grade III. In Grades IV and V, the ureter becomes progressively more tortuous, the pelvis is more dilated and the calyces are more blunted, losing their papillary impressions.

already scarred, follow-up radiographic studies were ordered less often. A more sensitive test to detect VUR is the radionuclide cystogram, which is recommended for all females, for sibling screening and for follow-up studies. Grading VUR as being more than dilating or non-dilating is not possible with radionuclide cystography, but this does not diminish its clinical value. The contrast VCUG is still recommended for the first study of the male bladder to detect posterior urethral valves. Either type of cystographic study should include observations after the catheter is removed and during micturition when intravesical pressure is highest and the possibility for VUR being detected and graded in a standardized fashion is more likely.

Through the years, there have been 3 or more different grading classifications of VUR. The classification used by the International Reflux Study in Children has now replaced all others and facilitates comparison of data from one study to another (Figure 7). The grading of VUR should be done under standardized conditions. The bladder is gradually filled, but not overdistended, at 70 cm water pressure. If VUR is observed before the bladder is filled with radiocontrast or radionuclide material, the reflux is said to occur when intravesical pressure is low. When VUR is noted only during micturition, the reflux is considered to occur at high intravesical pressure only. The grading of VUR depends on whether the contrast or radionuclide reaches the renal pelvis; if it does not, the VUR is grade I. If the reflux fills but does not distend the ureter or renal pelvis, it is grade II. Grades III, IV and V depend on the extent to which the collecting system is distended by VUR and how tortuous the ureter has become – an effect of dilating VUR and time. An acute distention of the collecting system by an overly aggressive filling of the bladder can cause mild VUR to be assigned a higher grade. A renal ultrasound examination or IVP done before or sometime after the VCUG will, in this case, not show the collecting system to be dilated. When studied subsequently, the VUR may have "improved" or even have resolved if the intravesical pressure remains normal during the procedure. Patients whose collecting systems by IVP or renal ultrasonography are dilated and who exhibit grades III, IV or V VUR usually have long-standing reflux that may have been originally under high pressure. Once the collecting system is damaged, however, the benefit of elastic fibers and smooth muscle layers do not permit its return to its former caliber, and VUR will occur even at low intravesical pressure. The grade of VUR in these ureters is much less likely to improve even after many years of observation.

While great importance has been paid and much time spent on the grading of VUR, it is probably enough to know whether the VUR

Figure 8a.

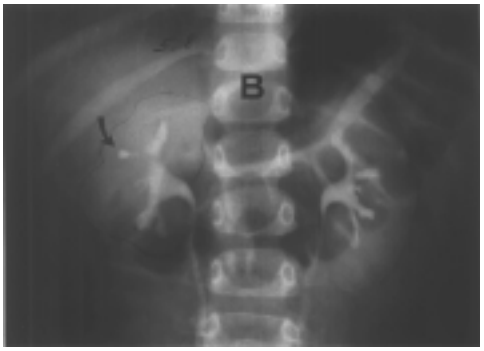

Figure 8b.

Figure 8. Bilateral vesicoureteral reflux, Grade III on the right and Grade IV on the left, noted during a VCUG (A) in a 2 yo female following her second recognized urinary tract infection. The renal ultrasound examination was reported as normal. Because the calyces were deformed on the voiding study, an IVP (B) was performed and revealed cortical atrophy on the right with the very same calyceal deformity (arrows).

caused dilatation of the collecting system or not – a reflection of the intravesical pressure and, perhaps, the pressure exerted at the ducts of Bellini to cause IRR. When VUR causes the entire collecting system to be filled completely (Grade II or higher), the calyceal abnormality associated with scarring is often identified and, if the renal outline is seen well, parenchymal thickness over the calyx can be assessed. These findings, when present, are important and should never be overlooked – the VCUG is not just a VUR detecting study. In Figure 8, the same calyceal deformities and parenchymal thickness over the calyx can be appreciated on both the VCUG (Figure 8a) as well as the IVP (Figure 8b).

Intravenous Pyelography (IVP)

The standard IVP was the diagnostic study done most often in the initial, and usually annual, evaluation of patients with VUR to detect scarring. While imaging studies introduced more recently may be more convenient, as with renal ultrasonography, or more sensitive in detecting renal injury earlier, as claimed for DMSA scintigraphy, IVP remains the best and, sometimes, only test available which depicts the anatomy of the calyces, renal pelvis and ureters. The history of allergic reactions to the contrast material used before the availability in most centers of non-ionic preparations, now used in most centers, has been another excuse used to forego the IVP. The sensitivity of identifying significant renal injury among the various studies depends more on the experience of the technician/observer than on the inherent superiority of the study itself [45]. Although many radiologists have abandoned the practice of bowel preparation before an IVP is done, it is still essential to empty the colon of feces to assure good visualization, especially of the renal parenchyma, but also to see the collecting systems well. Feces in either flexure of the colon may obscure a renal cortical defect or abnormal calyx. To further improve the quality of the imaging, the patient should be hydropenic

(thirsted until the urine specific gravity is > 1.025, or 8 – 12 hours, except in infants), and the volume of contrast material should be injected in age-related doses to get a good nephrogram on a film at 1 – 3 minutes after injection. Subsequent films should be obtained to visualize the contrast-filled pelvocalyceal systems and ureters. The characteristic renal lesion of RN will be thinning of the renal cortex overlying a calyx that may or may not be abnormal. As originally described, the calyx associated with the scar was referred to as a swallowtail deformity [25] (Figure 8). Basically, this calyx has no papillary impression and, when filled by the excreted radiographic contrast material, no longer has its normal appearance, which resembles a white china teacup.

The radiologic diagnosis of a renal scar should be suspected when a calyx is clearly abnormal or deformed either on IVP or VCUG (if VUR is present), when the renal length or parenchymal surface area is > 2 standard deviations (SD) below the recognized mean size for age or height, or when there is a discrepancy between the lengths of the right and left kidneys of > 0.5 cm. A scar may be present when the renal cortex is thin in one area (> 2SD below the mean normal value), usually overlying a calyx which may or may not be deformed [37]. The two-dimensional measurement or planimetric surface area (PSA) of the kidney will give important information for determining whether there has been any reduction of functioning renal parenchyma compared to normal, especially when renal injury has resulted more in poor renal growth rather than discrete segmental scarring [16]. Changes in the combined PSA of both kidneys have been correlated well to changes in glomerular filtration rate (GFR) [1]. There may be little difference between the apparent thickness of the scarred segment and the adjacent normal renal tissue especially in infants whose cortical height may be ≤ 10 mm. When the normal renal parenchyma on either side of the scar grows or undergoes compensatory hypertrophy, the scarred segment – which does not grow – may be noted on the next IVP [42]. Even when done carefully and interpreted by an experienced observer, the IVP may not show convincing evidence of renal scarring for 6 months to 6 years after the diagnosis of VUR was made, especially in infants and young children [4]. Suggestive evidence of renal scarring, which may precede the detection of a definite renal scar, is a discrepancy in size between kidneys. The kidney with scarring may be smaller than normal, while the contralateral kidney, if truly unaffected, will be larger than normal because of compensatory hypertrophy (Figure 2). If the PSA of the two kidneys were combined, the total PSA (scarred + normal large kidneys) may actually be normal, as will overall renal function.

Renal Ultrasonography

The factors of convenience and safety provide the basis for recommending that renal ultrasonography is preferable for diagnostic screening of at least the kidney and upper urinary tract of children with UTI. In fact, the suggestion that the ultrasound exam be the only diagnostic study for a child with febrile UTI has been made, but is not yet widely accepted. The basis for this recommendation has been that when kidneys appear normal following a UTI and the collecting systems are not dilated, then it matters little whether the patient has VUR because management will be directed at preventing further UTI, rather than deciding for or against surgical repair of VUR. There is some merit to this proposal. However, ultrasonography is rela-

tive insensitive at detecting all but severe renal scarring and does not identify VUR unless the collecting system is dilated – even then one study reported the sensitivity to be no more than 25% [14]. Dilated calyces are often mistaken for simple renal cysts (Figure 10a). For those who have relied on knowing whether VUR is present, not knowing about the status of the VUR presents a clinical dilemma.

Case Presentation

A white female had 2 recognized UTIs with fever and several other episodes of unexplained fever treated with antibiotics before her first radiologic investigation at 4 years of age. The renal ultrasound was reported to be normal, and no VUR was detected on a radionuclide VCUG. The patient was treated with antibiotic prophylaxis for one year without breakthrough UTI. Once the treatment was discontinued – the patient had no VUR and the ultrasound was normal – a febrile UTI occurred within 2 months. After appropriate antibiotic treatment for the acute pyelonephritis, prophylaxis was prescribed again for 6 months, and the patient remained free of UTI. After stopping daily antibiotic therapy, the patient had another febrile UTI one month later. Re-evaluation of the patient at 6 years of age revealed both kidneys to be "normal" by ultrasound (Figure 9a) except that the length of the left kidney (6.4 cm), which at 4 years of age had been at the lower limit of normal, had not changed during the 2 years between the studies and was 6.6 cm (> 2SD below the mean normal value for age). The right kidney measured 8.1 cm and had grown normally. A DMSA renal scan was performed to investigate the small left kidney (Figure 9b). Extensive parenchymal scarring of the upper and lower poles of the left kidney was identified. Careful re-evaluation of both renal ultrasound studies revealed no evidence of renal scarring other than the small size of left kidney. Had the variable of renal size been overlooked, which is all too often the case, this patient would have been considered normal and appropriate follow-up for a child with a scarred kidney would not have been planned.

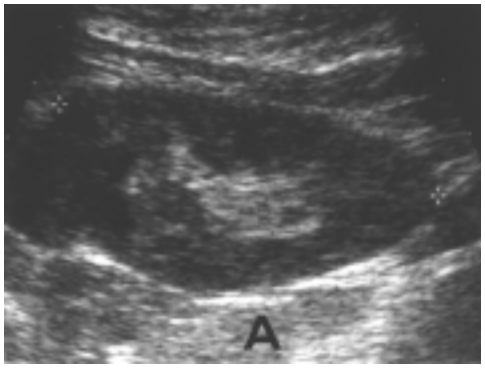

Figure 9a.

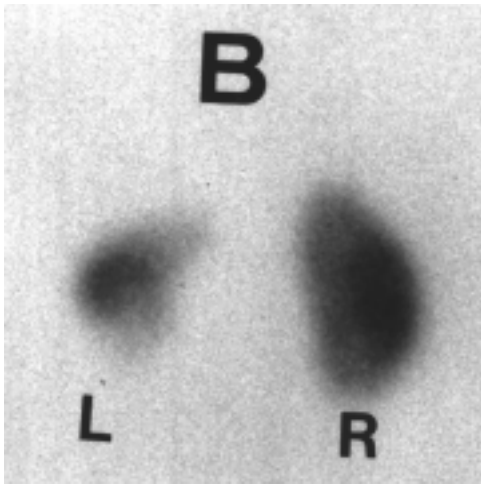

Figure 9b.

Figure 9. Renal ultrasound examination of the left kidney in a 6 yo female with a history of recurrent urinary tract infection. The overall appearance of the image (A) is normal but the length (+) was 6.4 cm (> 2 SD below normal mean length for age). A DMSA renal scan (B) revealed extensive scarring of both upper and lower poles of the left kidney.

Technetium-99m-Dimercaptosuccinic Acid (DMSA) Scintigraphy

The DMSA scan offers less radiation than conventional urography, is much more convenient for the patient, requires no bowel preparation or fluid restriction and has little or no risk of an allergic reaction. The shortcomings of the DMSA renal scan include an inability to estimate renal size or function or to assess calyceal morphology. Moreover, the DMSA scan takes a minimum of 3 hours, is expensive – about twice that of the IVP or renal ultrasound examination – and has what is probably too much interobserver variability. Individual observers may be consistent with their interpretations of DMSA renal scans only about 85% of the time, but the interobserver variability may be even greater. Some clinicians have recommended a DMSA renal scan be performed during an acute episode of UTI to confirm the diagnosis of pyelonephritis. Then, a follow-up DMSA scan at least 3 months later, after acute inflammatory changes have resolved, will confirm the presence of any renal scarring in the areas of inflammation noted on the original study. Managing the costs of such recommendations may prove problematic in the future. Moreover, knowing renal parenchymal inflammation is present in a febrile child with significant bacteriuria will have no impact on clinical decision for treatment. Recently, 40% of infants [24] and 80% of children and adolescents [10] with febrile UTI were found to have renal scarring by DMSA studies done 2 – 6 months later. There are no long-term data on the outcome of scarred kidneys identified so soon after acute injury.

There are now just about as many opinions for how UTI in children should be evaluated as there are physicians treating them. While clinicians more experienced with the management of UTI and VUR in children may have held on for too long to outdated ideas, inexperienced observers – especially non-clinicians who perform meta-analyses on other people's incomplete data – are recommending radical departures from conventional approaches. One such meta-analysis [17] concluded that there was no correlation between diagnostic imaging and clinical outcome in patients with UTI – an obvious notion, just as there would be no expected relationship between bone marrow aspiration and the outcome of patients with leukemia. Because there has been little progress to date in preventing renal scarring associated with UTI and VUR, several reports have recommended little or no investigation be done to detect VUR or renal scarring – just treat the UTI when it occurs. After a careful and extensive review of the medical literature for the past 30 years, the American Urological Association published a report to give clinical guidelines, especially for urologists but for other physicians as well, to standardize the diagnostic approach and clinical management of children found to have VUR following a first UTI [20].

Clinical Outcome

The natural history of acute pyelonephritis can be characterized from clinical descriptions in the pre-antibiotic era as fever and flank pain lasting 4 – 7 days. Subsequently, the patient either died from urosepsis or became entirely asymptomatic. Many of those who apparently recovered from acute pyelonephritis exhibited recurrent bouts of "suppurative nephritis" and died years later, sometimes of heart failure or stroke. When

indirect measurements of arterial blood pressure came to be measured more routinely about 60 years ago, there was a clinical debate over what the upper limits of normal systolic blood pressure should be – 120 or 140 mmHg. The higher limit was accepted. Nevertheless, it became possible in autopsy series to correlate antemortem hypertension with its cardiorenal complications. A direct relationship between pyelonephritis and hypertension was established more clearly when nephrectomy in unilateral renal scarring was followed by an abrupt return of the blood pressure to normal. Of particular interest was the frequent finding of pyelonephritis in patients who had succumbed to cardiovascular disease that likely was secondary to unrecognized or untreated hypertension. Effective pharmacologic control of hypertension and, therefore, prevention of its cardiorenal consequences became possible only in the past 30 years. Recently, the upper limit of normal blood pressure which appears to afford some cardiorenal advantage – 125 mmHg – seems to be closer to the recommendation of the losers in the original debate.

Hypertension

The cause of sustained hypertension in 26% of adolescents at one U.S. center [5] and in 35% of children referred to a single center in the U.K. [18] was renal scarring or RN. Hypertension has been detected in up to 50% of adults with RN [30], depending, again, on how long patients with renal scarring were seen for follow-up evaluations. In one series, hypertension was detected, on average, 8 years after the diagnosis of VUR was made and 2 years after the first renal scar was detected on serial IVP [42]. Another study found hypertension 27 years after the diagnosis of VUR was made [26]. The most common presentation of RN-associated hypertension in women is encephalopathy or heart failure which usually occurs around puberty, when taking birth control pills or during pregnancy: all periods associated with increased estrogen. Estrogen is thought to increase the production of angiotensinogen, at least during pregnancy. Many women are unaware of their RN before their hypertension is identified. For reasons yet unexplained, hypertension from RN is less common in adolescent males. The mechanism for hypertension in older adults with renal scarring, mainly from pyelonephritis associated with urinary tract obstruction or urolithiasis, may be multifactorial and requires a slightly different kind of clinical evaluation and management.

Hypertension in RN is angiotensin mediated and easily controlled in most cases with an ACE inhibitor or AT_1 receptor blocker given once daily. Plasma renin activity (PRA) in the segmental venous drainage of a renal scar has been demonstrated, whereas the PRA from blood sampled only from the main renal vein may be normal, owing to its dilution with blood draining normal areas of the kidney [27]. The resulting increase in angiotensin production raises vascular resistance and pressure in both the systemic and renal circulations. The hypertension may not produce recognizable symptoms often until there is headache, a disturbance in visual acuity, seizure activity, heart failure, or stroke. Retinopathy consisting of arteriolar changes, hemorrhages, cotton wool spots and papilledema will be noted on physical examination in many patients. Moreover, concentric hypertrophy of the left ventricle will be detected by echocardiography. The duration of sustained hypertension required to produce these changes before severe symptoms necessitate a precipitous evaluation is not known, but it is thought to be at least 2 months and

maybe longer. Before the availability of reliable treatment, not every case of severe hypertension in adults was associated with retinopathy for as long as 2 years of more. Unsuspected and uncontrolled hypertension may itself damage the scarred kidney further and accelerate deterioration of renal function as recognized for many years in patients with malignant nephrosclerosis.

Case Presentation

A typical presentation in which the diagnosis of RN was missed initially is illustrated by the following case. A 15-year-old white female was treated by a gynecologist for severe menorrhagia and anemia with blood transfusion and an oral contraceptive agent. The patient's blood pressure was 100/68 mmHg at the outset of treatment. Within a month, the patient began to complain of blurred vision that worsened over several months before she presented to the emergency department with encephalopathy, retinopathy including papilledema and a blood pressure of 260/140 mmHg. A CT scan of the head was reported to be normal. The only biochemical abnormality detected was a serum creatinine concentration of 2.0 mg/dL, which represented an estimated reduction in overall kidney function to < 50% of normal. In an adult critical care setting, the patient's blood pressure was lowered, but not well controlled, first by nitroprusside then by nitroglycerin with the addition of labetalol and clonidine. Nevertheless, the encephalopathy improved. Further evaluation included renal ultrasonography which was interpreted as normal except for a small "cyst" in the outer renal cortex (Figure 10a) No observer appreciated that the length of each kidney (8.3 cm and 8.8 cm) was > 2 SD below the normal mean length for age [22]. Selective renal arteriography revealed no vascular abnormality and was considered normal, except for what appeared to be fetal lobulations bilaterally, (Figure 10b). Because no renal arterial lesion was identified, delayed films were omitted, so the pelvocalyceal systems were never visualized.

Upon discharge from the hospital, the parents consulted yet another physician because the blood pressure was poorly controlled on increasing doses of clonidine and labetalol. The patient's school performance had deteriorated, and she was sleepy during the day despite adequate sleep at night. After reviewing the patient's prior records, the physician noted the small size of both kidneys and ordered an IVP to "complete" the angiographic study and demonstrated conclusively that the "fetal lobulations", which do not have such an exaggerated appearance in the mature kidney, really represented bilateral renal scarring. The segmentations in the renal cortex of both kidneys were immediately above abnormal calyces and the "cyst" noted on the ultrasound examination was, in fact, a dilated calyx (Figure 10c).

The estrogen-containing oral contraceptive agent was discontinued, and an ACE inhibitor was prescribed as monotherapy for severe hypertension. The patient's blood pressure has remained at 110/65 mmHg with enalapril 10 mg daily as the only medication. Within a month, the patient's school performance had returned to its previous superior level. Six months later, the concentric left ventricular hypertrophy had resolved. However, the serum creatinine concentration remained elevated at 1.6 mg/dL, meaning the patient is at high risk to experience further deterioration of renal function.

While all 3 studies either suggested or confirmed the correct diagnosis of RN, neither the internist who admitted the patient for hypertensive encephalopathy nor the various radi-

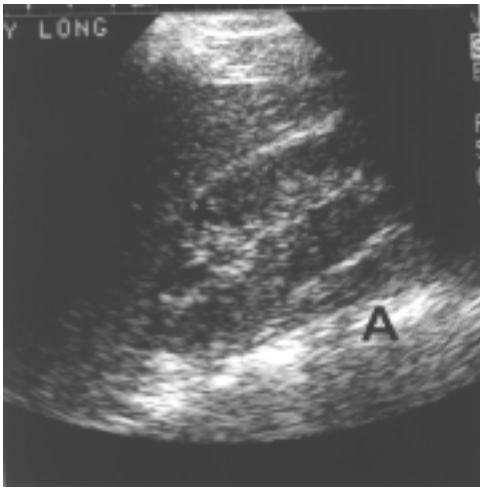

Figure 10a.

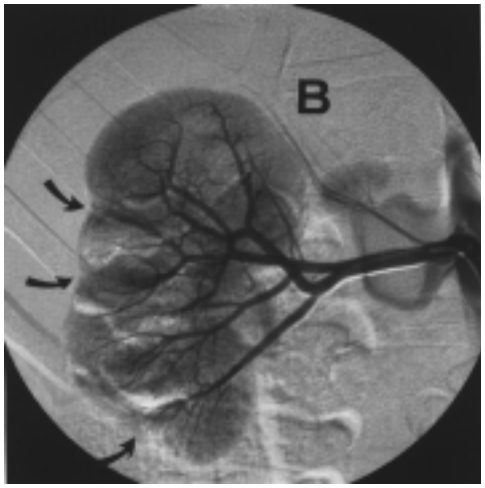

Figure 10b.

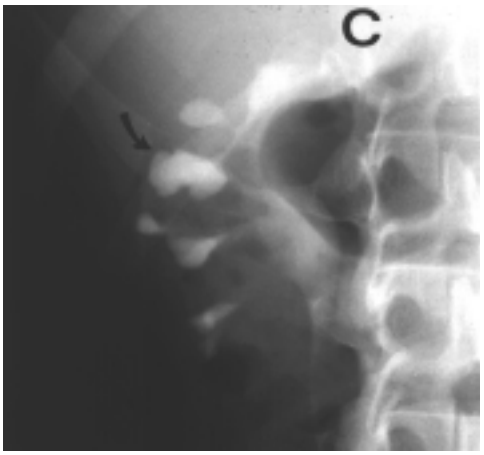

Figure 10c.

Figure 10. A 15 yo female presented with hypertensive encephalopathy. The renal ultrasound examination (A) was read as normal except for a "small cyst" (limits demarcated) in the upper pole of the right kidney. Selective renal angiography (B) was interpreted as normal with bilateral "fetal lobulations" (arrows; right kidney), but the study is characteristic of angiographic findings in reflux nephropathy. An IVP (C) demonstrated segmental cortical atrophy with deformed calyces – reflux nephropathy. The "cyst" noted on the sonogram (arrow) is actually a dilated calyx.

ologists performing the imaging studies appeared to be familiar with the typical presentation and diagnostic features of RN. Unfortunately, this clinical scenario is not uncommon. The absence of a prior history of UTI or recurrent febrile illnesses in the first years of life is not so unusual in patients with RN. Acute UTI at this age is not recalled by the patient and the parents may not recall the past medical history of the child or may not be available to provide such a history in adult patients. However, there is almost no other cause of hypertension with such a dramatic onset of symptoms in adolescent females soon after puberty, after estrogen-containing oral contraceptive agent is prescribed or with pregnancy.

Chronic Renal Insufficiency

Chronic renal insufficiency develops only in patients with RN who have bilateral, severe

renal scarring and may be recognized only when patients are examined for other problems, such as hypertension. The approximately 1% of patients born with a single kidney and those who lose a kidney after birth are at risk of a reduction in GFR with only unilateral renal injury from VUR or UTI. Undetected hypertension may, in fact, cause further injury to a scarred kidney and, itself, account for the development of chronic renal insufficiency – even ESRD. This deterioration in renal function might have been prevented had the hypertension been detected soon after its onset and treated appropriately. It is not unusual for scarred kidneys to exhibit deterioration of overall renal function > 20 years after the last episode of pyelonephritis [26] and after VUR has resolved or corrected surgically. Therefore, RN may be the cause of the large number of adult patients with small kidneys presenting with ESRD without a clinical diagnosis.

The overall prevalence of chronic renal insufficiency in RN is difficult even to estimate, but 24% of adolescents and 17% of adults under 40 years of age presenting for end-stage care in Australia/New Zealand have RN listed as their primary diagnosis [19]. In the United States, there has been less interest in establishing a specific diagnosis of RN in ESRD patients. When patients – hypertensive or not – are found to have small kidneys by renal ultrasound, further efforts at making a diagnosis are usually abandoned. Most native kidneys are no longer removed for hypertension or in preparation for transplantation. Even if they are, the diseased kidneys are usually not examined carefully – just given an arbitrary diagnosis of end-stage kidney. A North American registry of more than 4000 children and adolescents with ESRD listed the prevalence of RN among these patients at only 4 – 5% [24]. However, the diagnosis submitted for these patients was only a clinical impression because, in most of them, no histopathologic confirmation of the diagnosis was required. In this registry, there was a large group of patients with conditions associated with secondary VUR (obstructive uropathy) and hypoplasia/dysplasia, i.e. small kidneys, some of which may indeed have been injured by VUR or UTI. By comparison, in the first 100 patients < 18 years of age who were transplanted in a single center where histopathologic diagnosis was established in every patient (Table 1), the most common cause for ESRD was RN in 38%; 19% had primary VUR with or without UTI and another 19% had secondary VUR. Similar numbers were reported for ESRD in children from France, Germany and New Zealand [2].

Pregnancy

The incidence of UTI, especially pyelonephritis, during pregnancy was greater in women with renal scarring following UTI in childhood [35]. Moreover, blood pressures were higher in pregnant women with renal scarring than in those with unscarred kidneys. An inverse relationship between maternal blood pressure from any cause and fetal weight has been reported [15]. RN is the basis for pregnancy-induced hypertension in many women, but the correct diagnosis, for one reason or another, is not made very often. It is possible that the blood pressure in most women with RN returns to normal following delivery and after estrogen production has diminished, just as it does in toxemia. Some women with RN will remain hypertensive but asymptomatic post-partum, while others will become markedly hypertensive either with estrogen therapy as part of contraception or during a subsequent pregnancy. A most dramatic deterioration of renal function has been

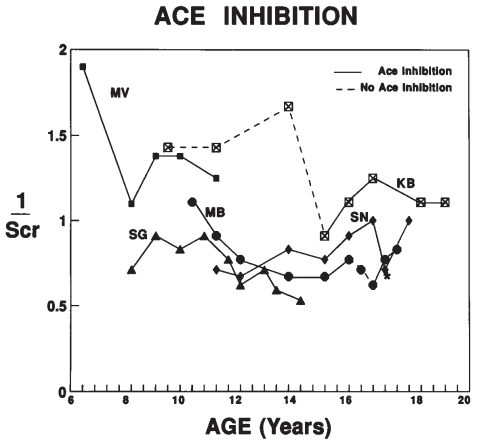

Figure 11. The reciprocal of the serum creatinine concentration (1/Scr) compared to the age of 5 females with bilateral renal scarring, chronic renal insufficiency and hypertension. The broken line (labeled KB) connecting the crossed square symbols represents the treatment period before an ACE inhibitor was available and hypertension was controlled with other drugs. No significant deterioration of renal function over 5 years or more of follow-up observation when hypertension was controlled satisfactorily with an ACE inhibitor.

reported in pregnant women with RN more than 20 years after a febrile UTI [26]. Not only do some of these women become dialysis-dependent during pregnancy, but not all recover following delivery of the fetus and require renal replacement therapy.

Case Presentation

A 16-year-old white female had the diagnosis of RN made when she presented at the age of 11 years with hypertensive encephalopathy (Figure 11, diamond-shaped symbols labeled SN). Renal scarring assessed by IVP was severe bilaterally, and serum creatinine concentration was elevated for age at 1.4 mg/dL (1/serum creatinine = 0.7). The hypertension was managed easily with enalapril 10 mg daily. Over the next 5 years, blood pressure, monitored regularly at home and quarterly by her physician, remained below 110/70 mmHg with no treatment other than enalapril. Renal function improved as evidenced by a gradual decrease in serum creatinine to 1.0 mg/dL even though the patient had increased her lean body mass, completed pubertal development and achieved a normal final adult height by 16 years of age. Despite warnings of the consequences of pregnancy with RN, of hypertension being more difficult to manage when estrogen-containing oral contraceptive agents were taken, and of fetal injury from ACE inhibition therapy, the patient engaged in unprotected sex. After having stable renal function and normal blood pressure for 5 years on the same dose of enalapril, the patient developed a sudden increase in blood pressure to 160/110 mmHg and an increase in serum creatinine to 1.4 mg/dL (decrease in 1/serum creatinine to 0.7). The patient had always been compliant with therapy and even an increase in the enalapril to 20 mg twice daily did not lower the blood pressure. Although denying the possibility of pregnancy, the patient had a positive pregnancy test. By dates and ultrasonography, the pregnancy was estimated at 6 – 8 weeks gestation. The patient chose to abort the fetus and, within 24 hours, her blood pressure was normal. The enalapril dose was reduced again to 10 mg daily and good blood pressure control continued over the next year. Importantly, GFR returned to its antepartum level estimated by a serum creatinine of 1.0 mg/dL. Progesterone-only contraceptive agents were prescribed for the patient without noticeable changes in her blood pressure. The patient was advised that if ever in the future she chose to risk another pregnancy, ACE inhibition therapy must first be discontinued and other antihypertensive agents used to control blood pressure.

ACE inhibitors now carry the warning about their use for treating hypertension, renal disease or heart failure in women of childbearing age. ACE fetopathy has been described as a severe failure of the fetus to develop normally, especially the kidneys, owing, perhaps, to angiotensin being an important growth factor that influences angiogenesis and tissue remodeling. Moreover, the unique hemodynamic changes in the pregnant female, particularly the gradual reduction of blood pressure when PRA and plasma angiotensin levels, indicators of potent vasoconstrictor activity, are increased above normal. When an ACE inhibitor was given during the second and third trimesters of pregnancy, unresponsive hypotension and irreversible renal failure in the newborn infant have been described. Because hypertension in RN is angiotensin-mediated, other antihypertensive agents cannot be expected to give as predictable control of blood pressure as an ACE inhibitor or AT_1 receptor antagonist. Because of the risk of worsened hypertension, ACE fetopathy, and deterioration of GFR – even ESRD – during pregnancy, consideration of a woman with RN becoming pregnant must be a part of the patient's education, but only at the appropriate time when emotional development permits rational decision making.

Progression

There has been no satisfactory explanation to date that characterizes how a kidney, damaged in the past by VUR or pyelonephritis, continues over many years to exhibit parenchymal changes. Newly-identified scars or worsening of established scars usually would suggest further renal injury but not in the absence of VUR, after anatomic or functional obstruction was relieved and when the urine has remained sterile. It is unreasonable to think the progression of renal lesions in RN is due to a prolonged scarring process that takes years to complete – scarring should be completed in months, not years. Acute inflammatory changes in the renal medulla, identical to those associated with IRR and infection, have been identified in scarred kidneys in which VUR had been repaired surgically more than a year before, and the urine was documented to be sterile by frequent cultures for 2 months before nephrectomy [12]. The only difference noted in the lesions found was the paucity of inflammatory cells compared to the ones associated with infection.

One possible explanation for continued scarring in those treated surgically could be that the antireflux procedure itself disturbed ureteral peristalsis. In experimental studies of the canine ureter, re-implantation was associated with reverse peristalsis so that urine flowed retrograde towards the renal pelvis which, instead of VUR, there would be ureteropelvic reflux and, perhaps, IRR. This same phenomenon may occur more proximally when urine from the renal pelvis re-enters the ducts of Bellini, referred to as pyelorenal backflow and observed in micropuncture studies of the rat papilla during progressive saline diuresis. Although most attention to date has been given to the surgical techniques used to correct VUR, no study has been reported on the effect the various procedures have, if any, on normal ureteral physiology.

For lack of a better explanation, and because sterile inflammation has been observed in these kidneys, a immunological mechanism has been proposed as a cause of progressive renal injury. This notion has persisted in spite of the lack of evidence to support it. Perhaps, it is easier to accept at face value because the kidney is injured by so many other immune-mediated diseases. Even a reaction

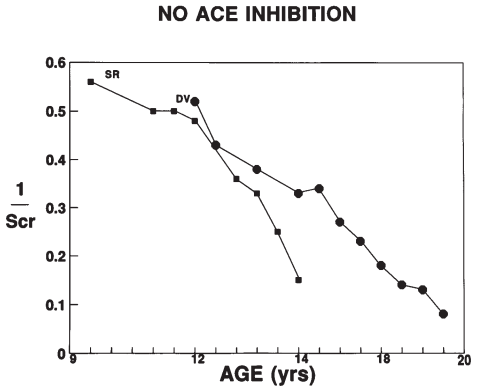

Figure 12. The reciprocal of the serum creatinine concentration (1/Scr) compared to the age of 2 females with bilateral renal scarring, chronic renal insufficiency and hypertension. Progressive deterioration of renal function over 5 – 8 years after VUR corrected, urine remained sterile, and hypertension was controlled satisfactorily with drugs other than an ACE inhibitor.

to Tamm-Horsfall protein has been proposed, but most of these lesions do not contain unusual amounts of PAS positive material.

Consistent blood pressure control at a mean arterial pressure ≤ 100 mmHg, or 125/75 mmHg, is considered essential to slowing the progressive deterioration of renal function in diabetic nephropathy and in primary renal diseases like pyelonephritis. Because many patients with RN are identified because of hypertension, one might argue that the progressive nature of these lesions represent the renal damage caused by uncontrolled hypertension or malignant nephrosclerosis. Media hypertrophy and endothelial proliferation has been identified regularly in the renal vasculature. However, progression has been observed in kidneys never exposed to systemic hypertension as well as those where hypertension has been well-controlled by medication other than ACE inhibitors soon after its onset (Figure 12).

Two findings in kidneys that exhibit deterioration of structure and function may provide evidence for a mechanism to explain the progressive nature of this renal lesion. One finding is compensatory hypertrophy. In RN, the remaining normal parenchyma undergoes marked compensatory changes that may be associated with an actual increase in overall renal dimensions. When this is seen in a child, further normal renal growth may be naively assumed. Compensatory changes allow GFR to remain stable for awhile. By the time GFR has been reduced to 50% of normal, 90% of the functioning renal mass has been destroyed. The other finding is the histopathologic feature of focal glomerulosclerosis – even in unscarred contralateral kidneys – causing some, but not all, to consider this lesion specific for RN. Moderate and heavy proteinuria has been identified in many patients with RN, and is an almost certain sign of eventual ESRD [30]. Most children and adolescents with RN have nothing more than mild proteinuria. Patients with bilateral RN may have increased urinary excretion of microalbumin, retinol-binding protein or N-acetyl-beta-D-glucosaminidase excretion before clinical proteinuria being detected by urinalysis [47]. Whether there is a role for proteinuria to damage renal tubules or cause interstitial inflammation in RN has been mentioned. The glomerular findings described for RN, therefore, appear similar, if not identical, to lesions in remnant kidneys, which may be consequent to hyperfiltration rather than a continuum of injury initiated by IRR in the past. In any event, proteinuria appears to be the hallmark of progressive deterioration of renal function.

ACE inhibition therapy, which does not eliminate intrarenal angiotensin production much more than by half [7], has been shown to reduce proteinuria and to slow the progressive deterioration of renal function in kidneys scarred by pyelonephritis [9]. ACE inhibition

affords a benefit in RN not seen when hypertension is treated successfully with other antihypertensive drugs [23]. Progressive changes in renal function in young hypertensive females with RN are depicted in Figure 12 by serial ratio of 1/serum creatinine over 5 years or longer. Those 2 patients whose blood pressure was controlled effectively with drugs available before the introduction of ACE inhibitors (propranalol and hydralazine) exhibited progressive deterioration of GFR; both were treated first by dialysis, then received a renal allograft. By comparison, the girls treated first with captopril and later with enalapril had their blood pressures controlled as well, but exhibited little change in GFR. The criticism of using 1/serum creatinine in children is acknowledged, but these girls were of similar ages when the diagnosis of RN with hypertension was made. Moreover, all had severe scarring of both kidneys with similar elevations of systolic pressure to > 180 mm Hg and of diastolic pressure to > 120 mm Hg before treatment. This benefit of ACE inhibition may extend as well to normotensive patients with RN and other progressive renal diseases.

The protection afforded the damaged kidney by ACE inhibition is not mediated solely through control of blood pressure [23]. The production of angiotensin in the intrarenal circulation and tubules has been shown to be approximately 1000 fold greater than in the systemic circulation [41]. Similarly, the renal metabolism of angiotensin was demonstrated to be as efficient as its synthesis. A disturbance either in the production of angiotensin or its metabolism could cause localized renal ischemia, perhaps, by intense vasoconstriction of glomerular or post-glomerular blood vessels. angiotensin is also known as a growth factor important in angiogenesis, tissue remodeling after injury and hypertrophy of smooth muscle. Moreover, it may promote fibroblastic activity not only to facilitate the repair of injured tissue but also to cause scarring – even progressive fibrosis. Therefore, many of the consequences attributed once to IRR or infection may, in fact, be explained better by a localized increased production of angiotensin in the repair of damaged tissue. Once initiated, either the further production of angiotensin or a failure of its intrarenal metabolism may promote compensatory responses at first, then cause hyperfiltration and ischemic injury resulting in progressive reduction in renal size – simulating progressive scarring, with gradual deterioration in overall renal function. Perhaps even more aggressive efforts to control angiotensin, say with higher doses of ACE inhibitors and angiotensin receptor blockade, or both may afford even better control of remnant kidneys, not only in RN, but also other renal diseases characterized by progressive deterioration of structure and function.

Dietary protein intake has been shown in renal ablation models and in various renal diseases, both diabetic and non-diabetic, to have an adverse effect on kidney function. While conclusive evidence for any clinical benefit of a protein-restricted diet in retarding or preventing progression altogether of renal disease in humans has not been demonstrated to date, there is enough information to suggest a role for reducing protein intake in most patients with chronic renal disease, even when renal functional impairment is mild or moderate. When combined with other measures such as control of hypertension and inhibition of angiotensin, the ADA recommended normal protein intake each day for adolescents and young adults of 1 g/kg body weight is considerably less than the usual protein intake for most people living in North America, and may be beneficial in overall efforts to preserve renal function.

Strategies for Prevention

RN is one of very few kidney diseases with the immediate potential of not just being modified, but actually prevented. Although there is a potential risk for renal injury from acute pyelonephritis at any age, most scarring which leads to chronic renal insufficiency seems to originate in infancy and early childhood when the kidney appears more vulnerable to insult, when symptoms of UTI may be overlooked or mistaken, and when appropriate treatment may not be instituted promptly. Whether a patient has pyelonephritis or only cystitis at the time of an acute illness is an academic discussion for a later time. Also, the debate about whether to treat asymptomatic bacteriuria should not enter into any decision of a febrile child, especially if the child is known to have VUR.

Firstly, the clinical suspicion of acute pyelonephritis at any age must be confirmed by urine culture; urinalysis never serves more than a screening role either in diagnosis of the first UTI or during follow-up of children with a prior UTI. Even the most experienced clinician – using reagent strips for leukocyte esterase and nitrite, semi-quantitative urine white blood cells estimates, Gram stains of uncentrifuged urine, C-reactive protein measurements or erythrocyte sedimentation rates (ESR) – cannot be relied upon to discern the clinical differences. The urine culture is the gold standard for establishing the diagnosis of UTI regardless of the patient's age. All the other laboratory tests may improve clinical suspicion of UTI before the preliminary results of the urine culture are known, but, in reality, only increase the cost of making the diagnosis. Acute renal inflammatory lesions by DMSA renal scans have been described in some patients thought at first to have only cystitis.

Therapeutic intervention, however, does not have to be delayed for a urine culture report. Antibiotic treatment should be instituted immediately after the clinical diagnosis is suspected and the urine culture obtained. Where patient or parent non-compliance may be anticipated, parenteral antibiotic therapy should be considered. No antibiotic will be effective against every urinary pathogen, therefore the drug initially prescribed may need to be changed when the sensitivities of the organism are known or the urine obtained for culture after 48 hours of treatment is not yet sterile. The duration of treatment is somewhat arbitrary. In the uncomplicated urinary tract, 1 – 3 days of oral or parenteral treatment with an appropriate antibiotic has been shown to be sufficient. Failure of an abbreviated course of antibiotic therapy has been associated with a high incidence of urinary tract abnormality. Seven to 10 days of antibiotic treatment is more conventional, even though there are no studies to confirm any additional benefit. The treatment should continue, at least in a prophylactic regimen, until the decision is made for instrumenting the bladder for VCUG in those children who have not previously undergone radiologic investigation. More importantly, the urine should still be sterile a week after discontinuing treatment of any duration. The goal of the clinical follow-up is to assure, as best one can, that the urine remains sterile. Even under the most compliant circumstances, breakthrough UTI can be expected in a third of patients who have VUR. The best clinical outcomes have been reported in an uncontrolled trial with long-term daily antibiotic prophylaxis where new scars in patients with VUR were detected in only about 2% of patients – these were considered non-compliant with therapy [46]. By comparison, new scars were observed in up to 21% of patients with VUR treated acutely as each new UTI was recognized [32].

There is a clinical notion that has gained popularity in recent years that renal scarring in patients with VUR cannot be prevented. In other words, because most patients with renal scarring already have it when first evaluated for UTI and most of these patients are identified in the first 5 years of life, this pessimistic viewpoint holds that preventing renal damage is not possible. Evidence to the contrary includes new scars observed to develop in older children, adolescents and adults with previously normal kidneys or in locations within the kidney of acute lesions of pyelonephritis identified by DMSA technology that progress to scarring. Finally, in Sweden, where the management of UTI in children has been a priority in a socialized system with good access to medical care and follow-up, the incidence of renal scarring in patients with VUR has been reduced significantly – compared to results reported 25 years ago – to what is probably the lowest reported incidence in the world today, about 10%. This clinical evidence supports experimental observations in which renal scarring in animals was avoided when appropriate antibiotic therapy was initiated within 5 days of pyelonephritis being induced.

Patients at risk of renal scarring must be identified early and, if possible, before the first UTI ever develops. Screening programs are not recommended because the yield of pathology in asymptomatic children is < 0.5%. There are 2 situations in which screening patients at risk of renal scarring has merit. The first is the newborn infant whose dilated urinary tract was noted by fetal ultrasound examination. While the kidney may have sustained injury before birth, it would be secondary to VUR alone because fetal urine is sterile. Most of these infants will develop UTI within the first week of postnatal life, which permits pyelonephritis to develop in kidneys already damaged, perhaps, by VUR or obstruction. Any protection afforded these infants by prophylactic antibiotic treatment from birth seems warranted at least until the urinary tract can be investigated. The other group of children at risk of renal injury from UTI associated with VUR are siblings of patients with VUR. It is generally agreed, at present, that all siblings < 5 years of age should have a screening VCUG performed. This age limit has been set arbitrarily. The incidence of VUR in asymptomatic siblings decreases with age – just as it does in those with UTI – but may still be identified in children older than 5 years. VUR-associated renal injury which is manifested in successive generations may be enough reason to ignore the factor of age to assure each family member at risk is identified and protected as early as possible. Each newborn sibling of patients with VUR should be placed on antibiotic prophylaxis until the VCUG can be scheduled. While this practice may seem overly aggressive to some, it is a very conservative attitude for those who have observed a normal kidney damaged irreversibly by a single episode of pyelonephritis (Figure 3).

There will be no progress in reducing the incidence of RN without education. Clinicians who treat children must understand their unique problems associated with UTI and provide consistent treatment, evaluation and surveillance of patients with UTI through young adult life. Then, treating or consulting physicians must educate the patient or parents as to the importance of being compliant with treatment and the consequences that may be expected to follow even a single episode of UTI in a child. Finally, society, in general, needs to become aware of the morbidity associated with UTI. Because cystitis is common among sexually-active women – who often are mothers, the almost casual approach by physicians to the diagnosis and treatment of their bladder infections, conveys the message

that UTI in their children, their nieces and nephews and their neighbors' children can be treated casually as well.

Conclusion

Even as late as 1950, the only antibacterial agents available to treat acute pyelonephritis were sulfa compounds and streptomycin. Moreover, the treatment of usually severe, sometimes malignant hypertension associated with chronic atrophic pyelonephritis was limited to barbiturates and reserpine as recently as 1965. Therefore, a cardiorenal complication of pyelonephritis proved fatal for many individuals in the past and will continue to do so even today.

Unfortunately, the pendulum may be swinging away from a more aggressive pursuit of UTI, at least in children. The greatest clinical discouragement comes from very little progress being made over the past 30 years in our understanding of the pathophysiologic mechanisms in RN. The bulk of the medical literature to date represents, with few exceptions, case reports and experience with various surgical techniques rather than well designed, controlled clinical trials. The clinician treating the first UTI in a child does not always appreciate the potential risk of the infection, and is not the one who will provide the medical care later in life when the patient develops hypertension, heart disease, stroke or chronic renal insufficiency. In the absence of a much more consistent clinical care path, including long-term outcome measures, renal injury from pyelonephritis is unlikely to be eliminated entirely.

If pyelonephritis can be detected early in its course, treated effectively and further episodes of UTI prevented, the incidence of renal scarring may be reduced significantly. Moreover, if the patient with renal scarring is monitored closely to detect hypertension that is then treated effectively with an effective inhibitor of angiotensin, the complications attributable to systemic hypertension itself can be avoided. Once chronic renal insufficiency has developed, further deterioration of renal function in RN may be modified by dietary protein restriction and by inhibiting angiotensin – even in normotensive patients. Preliminary clinical data provide hope that development of ESRD in patients with RN can be delayed – if not avoided altogether. It is not yet time to accept defeat in our pursuit of understanding the mechanisms of renal injury from VUR-associated pyelonephritis. Too many patients are still at risk.

Urinary Tract Obstruction

Thomas H. Waid

Obstruction of the urinary tract is a condition that physicians in all disciplines frequently encounter. Regardless of the cause, obstruction of urinary outflow leads to renal impairment that is initially reversible if obstruction is alleviated. The tubules are primarily affected; however, with time, progression results in parenchymal atrophy with glomerular sparing until late in the clinical course. Long-standing obstruction affects the kidney grossly as well as microscopically, resulting in dilatation of the pelvis and calices and thinning of the cortex. Whether the obstruction is unilateral or bilateral, acute or chronic, it produces changes in the anatomy and physiology of the kidney involved.

Therapeutic efforts are often aimed solely at relieving the cause of obstruction. Therefore, the sequelae of obstruction and its management may be overlooked. Often a significant salt-and-water diuresis, known as post-obstructive diuresis (POD), results and the physician's thought process must shift from relieving and perhaps treating the obstructing lesion to treating the physiologic derangements associated with the POD.

Nephrologists, urologists, and internists should have a working knowledge of the renal response to obstruction and its alleviation. This chapter encompasses diagnoses, pathophysiology, and treatment of obstruction and management of POD.

Incidence

Impairment of normal urine flow by functional or structural changes in the urinary tract is a common occurrence in all ages. Pyelocaliectasis has been found on autopsy of 3.5% of adults with a 1 : 1 male to female ratio. Additionally, 2% of children display hydronephrosis at autopsy, mostly because of congenital anomalies. After age 60, obstruction occurs more often in males, resulting from benign prostatic hypertrophy and prostatic cancer, whereas middle-aged women develop obstructive uropathy as a result of pelvic cancer or retroperitoneal fibrosis. Currently in the United States, the incidence of patient visits attributed to obstructive uropathy is about 380 out of 100,000 patient visits.

Causes of Partial or Complete Urinary Obstruction

Obstruction of the urinary tract can occur at any level and has many causes [1, 2]. Furthermore, obstruction can be complete, implying obstruction of all functioning nephrons, or partial. In the former scenario, obstruction is

Table 1. Causes of Urinary Tract Obstruction

Kidney
- Urolithiasis – pelvis
- Ureteropelvic junction obstruction
- Papillary necrosis
- Tumor (malignant or benign)
- Intratubular obstruction (crystalline nephropathy)

Ureter
- Tumor (papilloma, transitional cell carcinoma)
- Urolithiasis
- Congenital obstructive megaureter
- Eagle Barrett syndrome (prune belly)
- Ureterocele, orthotopic or ectopic
- Ectopic ureter
- Retrocaval ureter
- Retroperitoneal fibrosis (idiopathic, drugs, irradiation)
- Inflammatory bowel disease
- Metastatic tumor, retroperitoneal adenopathy
- Infection (tuberculosis, *Schistosoma haematobium*, fungus ball)
- Ureteral valve
- Ureteral polyp
- Pelvic lipomatosis
- Lymphocele

Bladder
- Neurogenic bladder (spinal cord defect, trauma, diabetes, multiple sclerosis, Parkinson's disease,
- strokes)
- Bladder neck contracture
- Transitional cell carcinoma
- Hemorrhagic cystitis
- Blood clots
- Infection (pyocystis, schistosomiasis)
- Detrusor, sphincter dyssynergia
- Bladder stones

Urethra
- Stricture
- Detrusor-sphincter dyssynergia
- Trauma/obliteration
- Meatal stenosis
- Posterior and anterior urethral valves
- Prostatic hypertrophy or cancer
- Calculus
- Polyp or urethral carcinoma
- Phymosis, paraphymosis
- Diverticulum

Table 1. Causes of Urinary Tract Obstruction (Part 2)

Extrinsic compression
- Cervical tumor
- Uterine tumor or pregnancy
- Endometrial tumor
- Endometriosis
- Uterine prolapse
- Vaginal distension
- Aneurysms
- Aberrant crossing vessels
- Abscess
- Gartner's duct cyst
- Crohn's disease
- Diverticulitis

bilateral or involves an anatomically or functionally solitary kidney. The causes of complete or partial obstruction are listed in Table 1.

Intratubular obstruction is the result of crystalline nephropathy and cannot be demonstrated radiographically or sonographically. In many cases, such as in tumor lysis syndrome, sulfa drug administration, or ethylene glycol poisoning, there will be crystals in the urinary sediment (uric acid, sulfa, oxalate, etc.) that yield a timely diagnosis. Because the crystal deposits are the result of filtration from the blood and crystallization in the lumen of all nephrons of the kidney, the obstruction is, by definition, bilateral and complete.

Obstruction of the renal calix or pelvis may be unilateral or bilateral, complete or partial. Unilateral obstruction may result in ipsilateral loin pain, microhematuria, gross hematuria, or it may be asymptomatic. However, there will be little or no change in blood urea nitrogen (BUN), creatinine, or electrolytes if the unobstructed kidney is functioning normally. Causes of obstruction in the pelvis or calices include renal stones of any type, including staghorn calculi, renal papilla sloughed during papillary necrosis, and benign and malignant tumors.

Ureteric obstruction can be unilateral or bilateral, partial or complete. Ureteral colic and flank pain result from acute obstruction and may be accompanied by nausea, vomiting, scrotal pain and micturitional urgency; however, chronic indolent obstruction may be asymptomatic.

Malignant tumors such as transitional cell carcinoma, stones, and retroperitoneal lymphadenopathy constitute the more common causes of ureteral obstruction. Ureteric strictures may be caused by multiple stone passage, instrumentation or a previous operation, pelvic irradiation, infections such as renal tuberculosis or *Schistosoma haematobium* infection, and inflammatory bowel disease. Additionally, in cases of inflammatory bowel disease, radiation, and penetrating trauma, a urinary fistula can develop from the ureter or bladder with resorption of urine by the peritoneal membrane and resultant elevation in BUN, creatinine, chloride, and other electrolytes. This urinary resorption may mimic obstruction, although no obstruction exists per se.

Extrinsic causes of ureteral obstruction are best classified by the system of origin. Most extrinsic lesions obstructing the ureters originate in the reproductive system, including pregnancy and cervical, endometrial, and ovarian cancer as well as uterine prolapse and endometriosis. Vascular abnormalities such as aortic or iliac aneurysms or aberrant vessels and retroperitoneal lymphadenopathy from malignancy cause extrinsic obstruction. As previously stated, inflammatory bowel disease, particularly Crohn's disease, can cause strictures and fistulas of the ureters and bladder, respectively. Finally, retroperitoneal fibrosis results in encasement of the ureters, inhibiting peristalsis and causing significant partial obstruction. Patients usually present with vague back pain and an elevated erythrocyte sedimentation rate (ESR), BUN, and creatinine. There may also be a history of methyldopa, methysergide, or beta blocker drug use or retroperitoneal malignancy requiring chemotherapy or irradiation. Unlike other causes of obstruction, hydronephrosis may not be apparent radiographically or sonographically because of fibrous encasement of the upper urinary tract.

Pathophysiology of Obstruction

Obstruction of the urinary tract generally causes dilatation of all portions of the urinary tract proximal to the level of obstruction ascending to the renal parenchyma. The initial response is one of muscular hypertrophy of the proximal ureter and renal pelvis followed by production of collagen and elastic tissue. The latter connective tissue impairs myogenic impulse transmission, thereby disturbing peristalsis [3, 4]. Hydronephrosis causes tubular dilatation and tubule cell atrophy, appearing within 7 days of obstruction in the distal tubule and within 14 days in the proximal tubule. By day 28, approximately 50% of the medulla is lost, and there is obvious cortical atrophy because of the associated loss of proximal tubules. Glomerular changes occur only after 28 days of obstruction. Although there is an eventual reduction of blood flow in hydronephrosis, it appears to be the result of impaired venous drainage and not only to an alteration in arterial flow [5, 6, 7].

When complete obstruction occurs, the urine in the obstructed kidney is not static; rather, there is a turnover of urine in hydronephrosis as most urine extravasates via the calyceal fornix. Urine can exit the renal pelvis by extravasation, pyelolymphatic back-

flow, and pyelovenous backflow while glomerular filtrate replenishes the urine and maintains the hydronephrosis. With lower pressure, the urine exits into the lymphatics; with higher pressure, the renal venous system resorbs the urine [8, 9]. In chronic obstruction of 6 to 34 days' duration, the quantity of urine escaping the renal pelvis ranges from 0.04 to 0.16 mL/min. Glomerular filtration in complete obstruction is 1.2 mL/min after 2 weeks and 0.4 mL/min after 5 weeks [10].

Renal Compensation for Obstruction

When a single kidney fails, regardless of the etiology, there is adaptation within the remaining kidney to restore total renal function toward normalcy. Such adaptation occurs both by hypertrophy and hyperplasia [11]. As a result of unilateral obstruction, there is an ipsilateral and contralateral increase in renal mass in the first week. Thereafter, there is progressive hypertrophy in the nonobstructed kidney while the obstructed kidney slowly atrophies [12, 13]. During this compensatory hypertrophy, the glomeruli increase in size but not in number. Perhaps this is the result of single nephron hyperfiltration.

Upon alleviation of obstruction, the obstructed kidney regains some function, and although compensatory hypertrophy of the contralateral kidney persists, total renal function does not recover to normal by 4 months. The degree of recovery of renal function after relief of obstruction varies with the duration of obstruction and the severity of pyelolymphatic or pyelovenous backflow of urine [14]. Upon releasing total ureteral obstruction of 4 weeks' duration, the glomerular filtration rate (GFR) returns to 35% of normal by 5 months; however, there is no recovery of function after 6 weeks of total ureteral obstruction.

Hydrostatic Pressures in the Ureter, Pelvis, and Renal Tubules During Obstruction

Normally the pressure in the renal pelvis is between 6 and 7 mm Hg, exceeding intraperitoneal pressure and that within the bladder and ureter. The pressure in the normal proximal tubule is 14 mm Hg, and the pressure from glomerular filtration (glomerular capillary pressure [60 mm Hg], less capillary oncotic pressure [25 to 30 mm Hg], less the hydrostatic pressure in Bowman's space [15 mm Hg]) is between 15 and 20 mm Hg [15].

During urinary tract obstruction, renal pelvis and ureteral pressures rise acutely only to decline to 50% of the peak value within 24 hours. Over the next 2 months, the intraureteric pressure steadily decreases to a nadir of 15 mm Hg [14, 16]. This higher ureteral pressure, sometimes measured at 50 – 70 mm Hg during acute obstruction, results from filtration pressure and active muscle contractions in the renal pelvis and ureter [15, 17]. Administration of mannitol or volume expansion with saline can increase ureteral pressures to 100 mm Hg [18, 19]. Proximal tubular pressures may acutely rise to 40 mm Hg; however, within 24 hours the proximal tubular pressure is below normal because of afferent renal arteriolar vasoconstriction [20, 21].

Glomerular Filtration, Renal Blood Flow, and Tubular Function in Acute Obstruction

Glomerular filtration and renal blood flow (RBF) are affected as a consequence of afferent renal arteriolar constriction. As proximal tubular pressure increases, the GFR falls because of afferent renal arteriolar vasoconstriction beginning within 5 hours of the onset of

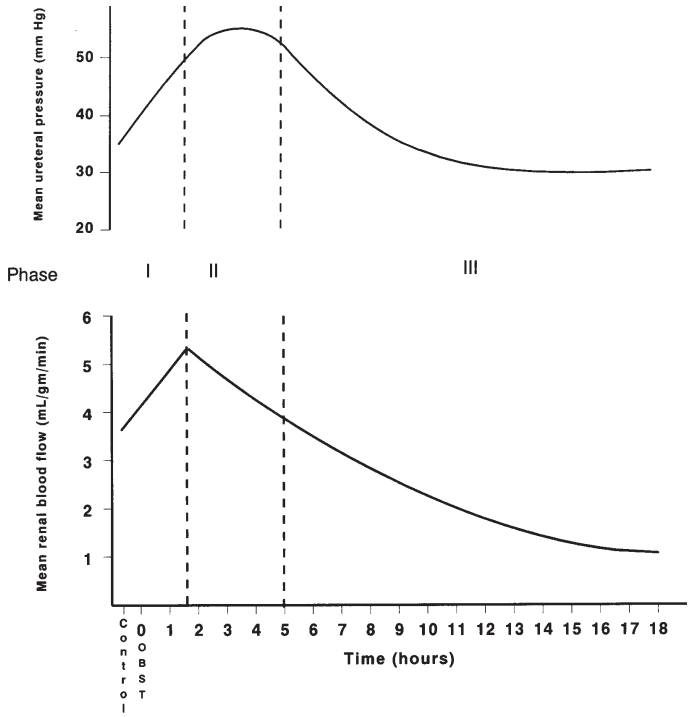

Figure 1. The triphasic response of ureteral pressure and renal blood flow in response to unilateral obstruction. Adapted from [Vaughan ED Jr, Bruce RG, Waid TH, Lucas BA et al 1997 Understanding postobstructive diuresis. Contemp Urol 9: 53-66] with permission.

obstruction. Additionally, as the proximal tubular pressure rises, there is a declining pressure gradient between the glomerulus and the proximal tubule. GFR is 52% of normal 4 hours after the onset of complete obstruction but only 2% of normal after 48 hours [22]. Additionally, during the first 24 hours of obstruction, RBF and ureteral pressure in the ipsilateral kidney display a triphasic relationship (Figure 1) [16, 23]. In the first 90 minutes, there is an increase in RBF and ureteral pressure consistent with preglomerular vasodilatation, a phenomenon that is prostaglandin mediated [24]. The increase in RBF appears to be confined to the cortex with the majority being distributed to the inner cortex [25].

The second phase occurs from 90 minutes to 5 hours after acute obstruction and is the result of preglomerular arteriolar resistance. The mean RBF begins to decline; however, the mean ureteral pressure continues to rise and then plateau. The third phase then ensues from 5 – 18 hours, marked by declines in both ureteral pressure and RBF. The presumed mechanism would appear to be persistent preglomerular vasoconstriction, but the exact mechanism remains unknown [26].

Tubular function is altered in partial acute ureteral obstruction because of a slower rate of tubular fluid flow. As a result, urine volume decreases, osmolality increases, and urinary sodium concentration may be reduced [27]. After complete acute ureteral obstruction, there is a further decline in GFR, and tubular function becomes impaired, which results in a temporary concentrating defect after the release of acute ureteral obstruction [28].

The effects of partial and complete chronic obstruction have also been studied. In chronic partial obstruction, there is a reduction in RBF, GFR, urinary concentrating ability, so-

dium reabsorption, and urinary acidification (hydrogen ion excretion) [27, 29]. Indeed, impairment of urinary acidification is a result of impairment in all aspects of tubular hydrogen ion handling, including ammonia excretion, titratable acidity, and bicarbonate reabsorption [30]. Complete chronic obstruction displays a decline in ureteral pressures after 24 hours, and the decline continues over 6 – 8 weeks. Proximal tubular pressures may normalize or become 30% lower than normal [26, 31]. Because of afferent arteriolar vasoconstriction, RBF progressively declines to 70% of normal at 24 hours and 50%, 30%, and 12% at 3, 6, and 50 days, respectively [16, 23]. The most significant reductions in RBF are seen in the outer renal cortex and the inner medulla [25, 32].

As stated, the rate of glomerular filtration declines progressively in chronic complete obstruction, with fluid exiting the collecting system by pyelolymphatic, pyelovenous, and pyelotubular backflow. The GFR is 0.4 mL/min at 5 weeks of obstruction; however, this is enough to replace the exiting tubular fluid [10]. One week after release of complete obstruction of 2 weeks' duration, the GFR is restored to 15% of normal with the maximum attainable recovery being 46% of normal. No recovery of GFR is ever noted after 6 weeks of chronic obstruction [33].

Complete urinary obstruction impairs all tubular function except urinary dilution, and upon release of obstruction, urinary concentrating ability and sodium conservation are severely impaired. Although urinary concentrating ability can be recovered after release of 2 weeks of complete obstruction, it remains permanently impaired after 4 weeks of obstruction [14]. Other tubular functions are likewise impaired, including glucose transport, potassium excretion, sodium resorption, and urinary acidification. Inability to concentrate urine remains the primary defect [14, 34].

Obstruction and Hypertension

Hypertension may be associated with either unilateral or bilateral obstruction. Acute unilateral obstruction is associated with renin elaboration and renin-dependent hypertension [14, 23]. Chronic unilateral obstruction may be associated with hypertension. However, renin is rarely elevated in bilateral obstruction, and patients usually have volume-dependent hypertension in this setting.

Clinical Presentation and Diagnosis of Obstruction

The clinical manifestations of urinary tract obstruction vary, depending on the location, duration, and degree of obstruction. Patients with complete bilateral obstruction or with an obstructed solitary kidney may present with acute oligoanuric renal failure, whereas partial obstruction of both kidneys or a solitary kidney may result in chronic azotemia with polyuria or urine output alternating from oliguria to polyuria. Pain is more likely to be associated with acute obstruction; however, obstruction may be totally asymptomatic and occur without laboratory findings or clinical manifestations [35].

As stated previously, hypertension may occur as a consequence of obstruction and may be volume or renin dependent. Polycythemia because of erythropoietin secretion has been described; however, in severely azotemic patients a normochromic, normocytic anemia is more commonly seen. Physical examination may uncover a palpable flank mass or bladder, and rectal or pelvic examination may reveal an enlarged prostate gland or gynecologic pathology. In thin patients, bladder masses may

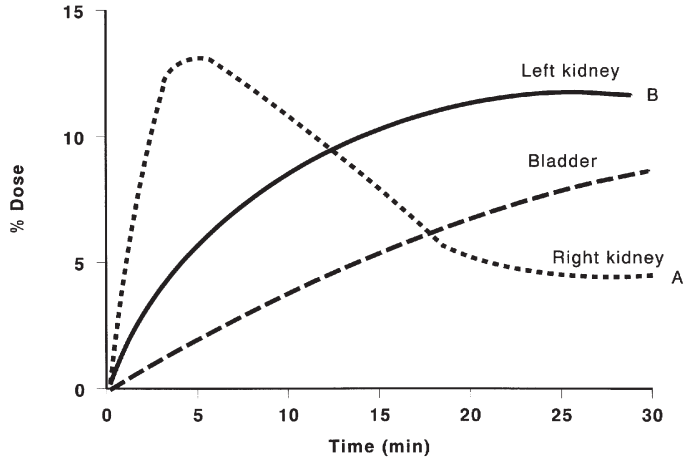

Figure 2. Renogram showing unobstructed pattern in the right kidney (A) and an obstructed pattern in the left kidney (B). Appearance of radionuclide in the bladder is seen in the bladder curve.

be palpated bimanually. Finally, assessment of volume status is very important in determining how to best manage the patient. Complete obstruction usually results in volume expansion, which in severe cases can produce congestive heart failure (CHF) and pulmonary edema. Volume depletion can occur in unilateral obstruction in which the contralateral kidney excretes salt and water in a compensatory fashion.

Laboratory evaluation may or may not be helpful. The diagnosis can be aided by the presence of azotemia, a normal anion gap (8 – 12 mmol/L), hyperchloremic metabolic acidosis with normal potassium, or hyperkalemia. The urinalysis will usually have a pH of > 5.5 on a fresh specimen. The urinary sodium will be ≥ 40 mmol/L and the fractional excretion of filtered sodium (FENa) will be > 1. First voided morning urine will reveal the patient's lack of concentrating ability with a low specific gravity (1.002 to 1.010) and osmolality ≤ 400 mOsm/kg. If renal failure is far advanced, the patient may develop a uremic metabolic acidosis in which the anion gap will be elevated. Urinary sediment can range from bland to active including erythrocytes (due to tumor, BPH, clots, or stones), infection; leukocytes (due to infection, or stones), or crystals (due to stones, infection, or crystalline nephropathy) [35]. Finally, hypernatremia may occur if patients are partially obstructed and sustain severe water losses because of tubular insensitivity to antidiuretic hormone (ADH), i.e. nephrogenic diabetes insipidus.

Ultrasonography remains the most useful test in diagnosing urinary tract obstruction. It is noninvasive, relatively inexpensive, and both sensitive and specific. Sonography will rarely yield a false-positive result because of anatomic variations of the pyelocaliceal system that may be misinterpreted as hydronephrosis. Sonography may provide false-negative results in patients who are both obstructed and volume depleted or in patients obstructed because retroperitoneal fibrosis has encased the entire collecting system. In the latter case, retrograde pyelography with drainage films, placement of ureteral catheters or stents, or placement of percutaneous nephrostomies and antegrade nephrostograms may diagnose and treat the obstruction.

Radioisotope renography can be useful in diagnosing urinary tract obstruction and differentiating between mechanical (anatomic) obstruction and functional (aperistaltic) obstruction (Figure 2). Isotope scanning is unique in the investigation of obstruction be-

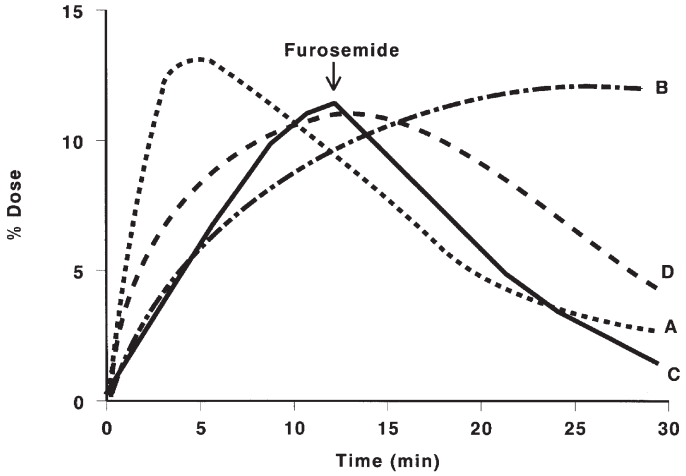

Figure 3. The diuretic renogram. Results are followed on a time activity curve with a normal curve excluding obstruction (A). A rising curve unaffected by diuretic administration indicates obstruction (B). Response to diuretics suggests a dilated collecting system, which is not obstructed (C). A partial diuretic response indicates subtotal obstruction (D).

cause it offers simultaneous quantification of renal function and dynamic analysis of urine flow rates. Urinary tract dilitation without a demonstrable anatomic lesion may occur in ureteric reimplantation, pyeloplasty, ureterolithotomy, pyelolithotomy, primary megaureter or vesicoureteral reflux. If a standard renogram is abnormal with no or sluggish elimination of radionuclide tracer at 10 – 30 min, furosemide is given intravenously (IV) while the study continues. One of 4 responses may occur (Figure 3):

- The renogram is normal, excluding obstruction (A).
- The renogram curve remains obstructive, confirming anatomic obstruction (B).
- The obstructive curve is converted to a nonobstructive curve with rapid and complete elimination of the tracer (C).
- The obstructive curve displays a partial response to diuresis, indicating subtotal or partial obstruction (D).

It must be noted that in patients with abnormal voiding or in patients with free vesicoureteral reflux, the bladder must be drained with a catheter or the test result may suggest mechanical obstruction, when, in fact, it is not present. A repeat scan with a Foley catheter in place is then warranted.

Finally, perfusion-pressure flow studies can be obtained to rule out obstruction. Also known as the Whitaker test, the procedure measures the perfusion pressure of a solution passing antegrade through a percutaneous nephrostomy tube at 10 mL/min. A pressure rise of ≥ 22 cm water indicates obstruction, whereas a rise of < 15 cm of water excludes obstruction. Values ranging between 15 and 22 cm water are said to be equivocal [36, 37]. The major disadvantage of the test is its invasiveness. The results of numerous studies comparing perfusion pressure flow with the less invasive diuretic isotope renography have been variable, with correlations ranging from 53 – 86% [37, 38]. Additionally, studies comparing diuretic renography with renal pelvic morphology appear to correlate well (r = 0.88) [39].

Summary of Physiologic Conditions During and After Release of Obstruction

Changes in renal physiology depend on whether ureteral obstruction is partial or complete. Complete obstruction often results in the uremic state because of retention of waste products normally excreted. Anatomically the tubules look normal in complete obstruction, whereas in partial obstruction, the tubules of the nonobstructed kidney are collapsed and the nephrons are poorly perfused. Pressures are elevated in the proximal and distal tubules in complete obstruction but are lower than normal in the unobstructed units in partial obstruction. Afferent arterial pressure is elevated in complete obstruction and diminished in the unobstructed units in partial obstruction.

RFB and GFR are reduced to one-third of normal in both complete and partial obstruction, in the former by increased proximal tubular pressure and in the latter by afferent arteriole vasoconstriction of the unaffected kidney. When complete obstruction is alleviated, the tubular pressures normalize; however, the GFR diminishes because of afferent arteriolar vasoconstriction. Urine flow may be increased dramatically after the release of complete obstruction, and the excretion of urea, potassium, phosphate, and magnesium is enhanced. A diuresis occurs regardless of fluid balance until the GFR can restore sodium delivery to the tubules and medullary hypertonicity can be regained. The urinary concentrating defect persists for several days beyond the salt-wasting defect, and the ability to conserve urinary sodium should herald the recovery of concentrating ability and attenuation of the diuresis.

After the release of partial obstruction, the affected kidney has a normal urine flow of dilute urine because of reduced GFR and RBF and impaired concentrating ability. The contralateral kidney maintains homeostasis and a POD is often clinically inapparent.

Mechanisms of POD

POD occurs when there is correction of complete bilateral obstruction or complete obstruction of a solitary functioning kidney. During unilateral obstruction, urinary and serum abnormalities are obscured by the unobstructed kidney and POD rarely occurs. First characterized as a syndrome of volume and electrolyte imbalance following relief of obstruction by catheterization, POD involves the production of large volumes of urine immediately after the relief of urinary obstruction [40]. This syndrome occurs when all nephrons are obstructed and patients still have reversible, albeit advanced, renal failure. Three mechanisms are postulated (Figure 4): a defect in urinary concentrating ability, impaired renal sodium reabsorption, and solute diuresis due to retained urea or iatrogenic administration of sodium-containing IV fluids [41].

Upon relief of complete urinary tract obstruction, RBF and GFR initially decrease as a result of the action of renal prostaglandins [42]. Because a defect in urinary concentration and sodium conservation exists, diuresis ensues. When the diuresis is prolonged and severe, significant loss of water, sodium, potassium, and magnesium can result in hypovolemia and electrolyte abnormalities that

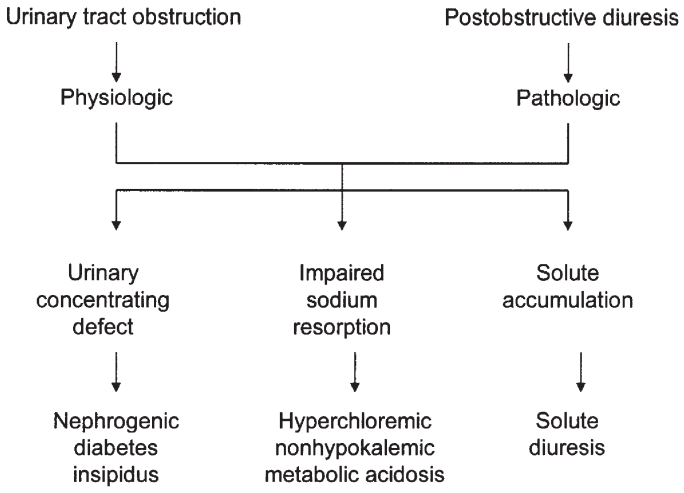

Figure 4. Pathophysiologic alterations in urinary tract obstruction and postobstructive diuresis. These mechanisms are physiologic during obstruction, continue pathologically in the postobstructive period until the hypertonicity of the renal medulla is restored. Solute accumulation and diuresis are pathologic when IV fluids are inappropriately administered. [Bruce RG, Waid TH, Lucas BA 1997 Understanding postobstructive diuresis. Contemp Urol 9:53-66] with permission.

cannot be adequately prevented or restored by oral intake of solute (diet) and water [34].

Patients with prolonged POD are insensitive to the administration of ADH or deoxycorticosterone acetate (DOCA), which explains the 2 patterns of diuresis seen in POD. The more common clinical entity is the diabetes insipidus-like nephropathy, which is usually associated with chronic obstruction and is a self-limiting concentrating defect leading to free water losses. Postobstructive sodium-losing nephropathy is rare but is a more severe and protracted diuresis that occurs in the setting of severe bilateral obstruction and reversible renal failure [43]. The question becomes how and to what degree do urinary concentrating defects and renal sodium loss contribute to pathologic water and electrolyte loss in POD.

As stated earlier, the urinary concentrating defect is the result of altered renal hemodynamics in the early phases of complete obstruction. The GFR initially decreases after obstruction is relieved, and without tubular solute, including sodium and urea, the medullary tonicity cannot be maintained. Until glomerular flow and filtration improve and provide solute to restore the medullary tonicity, hypotonic urine losses will continue. Clinically, this generally results in a water diuresis of 1 – 4 days' duration.

The natriuresis occurring in POD results from increased delivery of sodium to the distal tubule in the face of limited capacity of the distal tubule to resorb the increased sodium load [44]. This state is not unlike that produced by loop diuretics, which, when administered, block chloride and sodium resorption in the loop of Henle, increase delivery to the distal tubule, and thereby create a solute-rich urine. Additionally, disturbances in proximal sodium resorption can occur due to proximal tubular dysfunction and further add to distal tubule solute delivery. The naturesis of POD is therefore not only related to enhanced sodium excretion to relieve volume expansion, but also to a pathologic decrease in tubular sodium reabsorption [44].

Patients with POD have elevated serum levels of atrial natriuretic factor (ANF) [45]. ANF is elevated whenever there is extracellular volume expansion, whether acute or chronic, and has four effects: natriuresis, diuresis, vascular relaxation, and increasing GFR via afferent arteriole dilation and effer-

ent arteriole constriction [46]. ANF has been associated with complete urinary obstruction and to the development and control of POD [47].

Diagnosing and Treating POD

The diagnosis of POD should be considered whenever excessive diuresis occurs after obstruction is alleviated. Recognition of the patients at greatest risk for developing POD is an important first step. Complete urinary tract obstruction is usually the predisposing clinical condition. The clinical situation is often encountered in elderly males with bladder outlet obstruction from prostate disease, who develop reversible renal failure [48]. These patients have, at some time in their clinical course, high pressure chronic retention of urine and elevated serum levels of ANF, conditions which favor the development of POD. Additionally, the patient's volume status is an important indicator of the degree of diuresis. Hypervolemic patients will diurese more vigorously than those who are euvolemic or volume depleted [35].

Once the obstruction has been treated by catheterization, stenting, or percutaneous nephrostomy, treatment of POD must begin. Hourly assessment of the patient's urine flow and oral intake along with assessment of volume status is essential to prevent the patient from becoming volume depleted. Remembering that the recently unobstructed kidney requires time to recover the ability to conserve sodium and to concentrate urine, the clinician may find it useful to categorize these patients into low, moderate, and high risk of developing diuresis [33] (Figure 5).

In the low-risk and moderate-risk patient, the diuresis may not be brisk, and the thirst mechanism will compel the patient to increase oral intake and replace volume. Obviously if the patient is obtunded, then the thirst mechanism is unreliable, and oral intake will be both inadequate and unsafe. If the patient is nauseated and/or vomiting, oral intake is again unreliable, and if there is orthostatic hypotension, tachycardia, or urine volumes > 200 mL/hour, IV replacement is necessary. The high-risk patient will have evidence for volume overload, mental status changes due to uremia or other neurologic conditions, and almost always complete obstruction of both kidneys or a solitary functioning kidney. These patients should receive IV fluid replacement from the onset of POD.

When IV fluid replacement is needed, a solution with a composition similar to that of urine is desirable. A spot urine for sodium, potassium, and chloride is helpful in determining the makeup of this solution. Urine sodium and chloride are usually 70 – 80 mmol/L. Urine potassium is usually 20 – 30 mmol/L. Therefore, replacement of urine with half normal saline or 5% dextrose in half normal saline with 20 – 30 mmol K/L is ideal in this situation. Since patients requiring immediate IV therapy are often volume overloaded, replacement of each mL of urine with one half mL of IV solution will correct the volume expansion while avoiding volume depletion. If the patient is hyponatremic, then normal saline should be used initially at 1/2 mL IV /mL urine. If the patient is volume depleted on physical assessment, the patient should be given IV normal saline at least 1 IV mL urine and additional boluses of normal saline until euvolemic by physical assessment or by central venous pressure monitoring. If the patient is hyperkalemic at the start of IV replacement, monitoring of the serum potassium will be necessary until the patient is

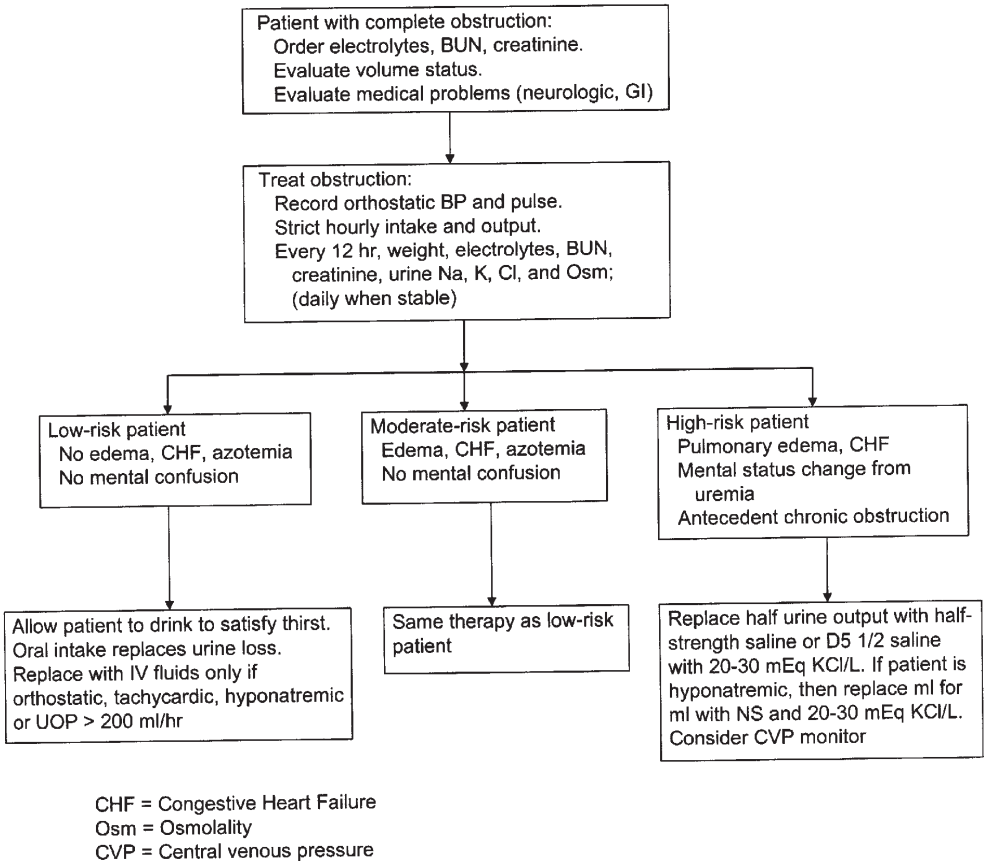

Figure 5. Algorithm for managing postobstructive diuresis. Adapted from [Vaughan ED Jr, Gillenwater JY, Bruce RG, Waid TH, Lucas BA 1997 Understanding postobstructive diuresis. Contemp Urol 9:53-66] with permission. CHF = Congestive Heart Failure, Osm = Osmolality, CVP = Central venous pressure.

normokalemic. Potassium may then be added to the IV urine replacement solution. During the period of recovery of renal function and volume replacement, serum magnesium must be monitored because magnesium wasting can occur in POD. Replacement with magnesium sulfate 0.25 to 0.5 mmol/kg in 4 divided doses daily for the next 24 – 72 hours should be adequate to replace magnesium deficits in these patients [35].

It should be noted that IV fluid replacement is recommended by some authors even in mild cases of POD and in volume overloaded patients [49]. IV fluid administration may result in increased diuresis and natriuresis; however, GFR may recover more quickly. Finally, one must understand that prolonged diuresis can be iatrogenic due to IV volume expansion. When IV fluid replacement is used in patients who are not volume depleted, the clinician should discontinue treatment every 8 – 12 hours. Discontinuation of therapy should produce a slowing of iatrogenic diuresis, whereas POD will continue unabated. One should re-

member that the obstructed kidney has transiently lost its ability to transport chloride and sodium from the lumen of the loop of Henle to the medullary interstitium. The urine concentration of sodium should be high until medullary tonicity is restored, a process requiring urea. If IV fluids are administered too vigorously, the urea concentration will be lowered and the medullary interstitium will be "washed out", delaying the recovery of concentrating ability. In this scenario, the clinician should allow the BUN to rise and follow the urinary sodium. As medullary tonicity rises and the ability to concentrate urine and conserve sodium is restored, the urinary sodium will fall, heralding the slowing of the diuresis within 24 – 48 hours [35].

Summary Points of POD

In summary, it should be remembered that POD stems from the relief of complete urinary obstruction (all functioning nephrons) and is usually, but not always, associated with significantly advanced but reversible renal failure. Urinary concentrating defects begin during the obstructive phase and are not resolved until alleviation of the obstruction and restoration of the hypertonic renal medullary gradient, via the countercurrent exchanger. Natriuresis occurs after the relief of complete obstruction because of defective sodium handling in the proximal and distal tubules. Additionally, the loss of renal medullary function (countercurrent multiplication) presents more sodium and chloride to a relatively nonresorptive distal tubule and collecting duct producing a solute-enriched urine. ANF levels are elevated in volume-expanded states, such as complete urinary tract obstruction, and facilitate a diuresis when the patient is no longer obstructed. An osmotic diuresis from retained urea also occurs.

Although volume overload may be present initially, it can progress to volume depletion when untreated diuresis occurs. In this case, IV fluid administration is needed to prevent prerenal azotemia and possibly shock. However, iatrogenic volume expansion from overzealous administration of IV fluids may prolong the diuretic phase. Advanced but generally reversible renal failure, an acquired distal nonhypokalemic renal tubular acidosis (Type IV RTA) and salt-wasting nephropathy are often present, and other significant electrolyte losses (magnesium, potassium, and chloride) can occur and require replacement. Treatment regimens must be individualized to the patient's volume status, severity of diuresis, mental status, and degree of electrolyte abnormalities. In this regard, vigilant monitoring of the patient's physical status as well as serum and urine chemistries remains the basis of optimum clinical care.

Nephrolithiasis

Gilberto B. González and Charles Y.C. Pak

Introduction

Kidney stones, formed within the upper urinary tract, are concretions of different mineral salts mixed with an organic matrix. Nephrolithiasis has plagued humans since antiquity. The oldest urinary calculi on record actually comes from an Egyptian mummy dated about 4800 BC. A renal colic due to stone was the first renal disease described by Hippocrates. Considered a classic, this description included a differential diagnosis between renal and bladder stones [1]. Galen (AD 130) was the first to associate stones with a metabolic origin [2]. Some of the notable figures in history who suffered from stones include Pliny, Sir Walter Scott, Benjamin Franklin, Napoleon, and Lyndon B. Johnson [3].

During the past 20 years, notable advances have been made in the nephrolithiasis field. Pathophysiologic mechanisms for many causes of stones have been clarified, and specific molecular defects are beginning to be unraveled [4, 5]. It is now possible to diagnose the cause of stone disease in > 95% of patients [6], and new drugs provide improved treatment options [7 – 9]. Facilitated stone removal has become possible with the introduction of the endoscopic approach [10] and extracorporeal shock wave lithotripsy (ESWL) [11].

Despite these advances, only a few practicing physicians avail themselves of new diagnostic methods and preventive treatment modalities in the management of stone disease. Reasons for this lapse are 2 fold. First, the facility with which stones can now be removed has led to a disparagement of the need for medical diagnosis and treatment. Why bother to have tests done and take drugs for a long duration, when one feels well between stone episodes? Instead, all one has to do is to undergo lithotripsy when, once in a while, a stone is formed and causes trouble.

Second, our group advocated a selective treatment approach that necessitated a careful differentiation of various causes of stones and the selection of specific drugs for each cause. The complexity of this process may have led some physicians to forego the medical approach. However, urinary stone risk factors are not modified by urological procedures alone [12], and nephrolithiasis carries a lifetime recurrence rate as high as 80% [13]. Consequently, a medical approach, directed at prevention of recurrent stone formation, is still required. Strict adherence to the selective approach seems impractical except at a large stone research center. In this chapter, a new and simplified approach for the medical management of kidney stones is proposed, which any physician may readily adopt.

Epidemiology

More than 95% of urinary stones encountered in developed countries are localized in

the kidney or upper urinary tract. Bladder stones are found most commonly in men with prostatic diseases and children who live in less-developed countries in Southern Asia and the Middle East. These stones, related to malnutrition or infection, are a different entity from nephrolithiasis and will not be discussed in this chapter. The true incidence of nephrolithiasis is not well known. Most of the studies have underestimated the problem because they relied on data from hospital records. As many as 70% of patients will not require hospitalization [14]. In an attempt to address this issue, Johnson et al. [15], studied the incidence and prevalence rates for symptomatic, noninfected renal stones over a 25-year period in a well-defined population of Rochester, Minnesota. They found an annual age-adjusted incidence rate for males of 123.6 per 100,000 population in 1974, a 57% increase from 1950. The incidence rate for females was stable over the study period at 36.0 per 100,000. The peak incidence occurs between the ages of 15 – 44 years, during the most productive years [14]. Recurrence rates increase with follow-up: 14%, 35%, 52%, and 75% after 1, 5, 10, and 20 years from the first stone episode, respectively [16, 17]. Thus, recurrence is the rule rather the exception.

Based on this and other population studies, it has been estimated for the United States population that 5 – 15% will have symptomatic stone disease by the age of 70, with the prevalence being twice as common in men as in women. Worldwide, the lifetime stone prevalence in men > 60 years of age varies from 1.5% in China, to 5.4% in Japan, around 8% in the United Kingdom, Germany and Sweden, 12% in Canada, and 20% in Saudi Arabia [18]. Obviously, these differences can be explained in part by variations in study design, but they also reflect real changes due to genetic, nutritional, and environmental influences.

Nephrolithiasis leads to considerable morbidity – renal colic, hematuria, and infection (UTI). It accounts for 0.9% of hospital discharges, with a mean duration of hospital stay of 3 days. The total annual cost in the United States, including direct costs from hospitalization and outpatient evaluation, and indirect costs from lost wages, was estimated to be $1.83 billion in 1993 [19]. In addition, loss of kidney function may occur because of complications such as infection and obstruction, and from damage during surgery. Up to 1% of patients in a dialysis program developed end-stage renal disease (ESRD) secondary to stones [20]. Mortality from stone disease is rare and data are not available.

Stone Composition

Mineral salts, mostly in a crystalline form, account for > 95% of the weight of a kidney stone. A heterogeneous material called matrix is found in concentric layers or radial striations throughout the stone and explains the remaining weight.

The composition of the different crystalline components in stones varies from one part of the world to another, depending on specific methods of analysis and prevalence of stone risk factors. Infrared spectroscopy and X-ray diffraction crystallography offer the highest degree of certainty for the correct analysis of the stone [21]. The most recent series of stone composition based on those techniques for some industrialized countries are summarized in Table 1 [21 – 23]. The majority of stones are mixtures of 2 or more components. Calcareous stones, occurring as calcium oxalate alone or in combination with apatite, comprise approximately 75% of all stones. Cal-

Table 1. Frequency of Occurrence of Components in Renal Stones

Stone type	Mineral name	Mandel 1989 USA (10,163)	Leusmann 1990 Germany (5,035)	Daudon 1995 France (10,438)
I) Calcareous stones

Miscellaneous		2.3	2.1	2.4

Numbers indicate the percentage occurrence of the most common stone type in the series. In parentheses is indicated the number of stones.

cium oxalate crystals are found in monohydrate and dihydrate forms, which have different lattice structures and microscopic appearances. Only 5% of stones are principally made of calcium phosphate salts such as apatite or brushite. Noncalcareous stones account for no more than 20% of stones. Struvite stones comprise 5 – 10% of stones; they are often called infection stones because they develop from infection of the urinary tract with urea-splitting organisms. Pure struvite stones are rare; they typically occur as mixtures with carbonate apatite or other calcium salts. Uric acid, the major end product of purine metabolism, accounts for 5 – 10% of stones in Europe and United States. However, endemic regions exist in the Mediterranean countries and in the Near East, where up to one third of all stones are composed of uric acid [24]. Cystine stones, comprising about 1%, are diagnostic of cystinuria, an inherited disorder of dibasic amino acid transport. The miscellaneous group (approximately 2%) includes rare forms of stones such as 2,8-dihydroxyadenine and xanthine (due to inborn errors of metabolism), triamterene or silica (from drug treatments), or matrix calculi (which contain mostly organic molecules and occur in association with chronic UTI) [25, 26].

Stone matrix is composed of about 64% protein, 12% organic ash, 10% bound water, 9% nonamino sugars, and 5% glucosamine. These organic materials might not only derive from substances normally present in urine, but may also be produced by epithelial cells from the trauma induced by an enlarging stone [27].

Pathogenesis

Nephrolithiasis is a heterogeneous disorder; stone composition and the underlying

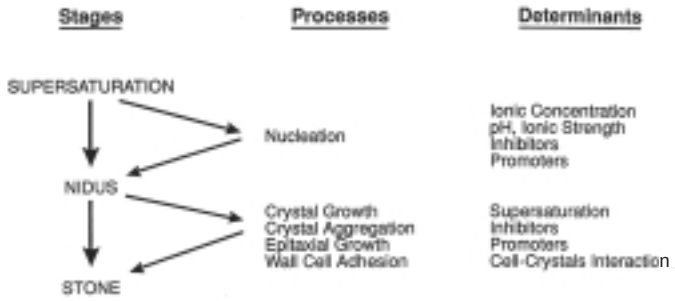

Figure 1. Pathogenesis of stone formation. (Adapted from Pak CYC 1993 Urolithiasis. In: Schrier RW, Gottschalk CW (eds): Diseases of the Kidney (Fifth Ed). Little, Brown and Company, Boston, figure 25-1, p 73, with permission).

mechanisms responsible for stone formation are diverse. Three principal theories of stone formation have been invoked. The precipitation-crystallization theory considers stone formation to be a physicochemical process of precipitation of stone-forming salts from a supersaturated urinary environment [28]. The inhibitor theory holds that a deficiency in urine of substances that physicochemically prevent crystallization leads to stone formation [29]. In the matrix theory, the stone is believed to form in an organic matrix, analogous to the mineralization of the bone [30]. While none of these theories is exclusive of the others, the precipitation-crystallization theory has the most experimental support.

A current scheme for stone formation considers the process to begin by nucleation of a crystal nidus from a supersaturated urinary environment, followed by transformation of the nidus into a stone through crystal growth, epitaxial growth, and crystal aggregation (Figure 1) [31]. This scheme is consistent with all three classic theories, because stones could form without or within an organic matrix and because lack of inhibitors could facilitate the process.

By whatever mechanism, the necessary condition that must occur for stones to form in human urine is nucleation, defined as the beginning of a crystalline solid phase. Homogeneous nucleation refers to the process of spontaneous crystal formation that occurs for any stone-forming salt when its urinary saturation exceeds the limit of metastability. However, in a complex solution such as urine, many foreign surfaces are constantly present cell debris, epithelial membranes, another crystal species (e.g.), and crystals may nucleate on such foreign surfaces in a phenomenon known as heterogeneous nucleation. Because it is not necessary to reach a critical cluster size for nucleation, it is more likely that heterogeneous nucleation occurs at lower levels of metastability [27]. This process may also be the basis for the formation of stones of mixed composition. Examples of heterogeneous nucleation are nucleation of calcium oxalate by seeds of calcium phosphate or by uric acid. The urinary environment of patients with stones is typically supersaturated with respect to stone constituents and possesses a reduced limit of metastability. Thus, the nucleation process is facilitated in the stone-forming urinary environment. This increased propensity for nucleation is reflected, for instance, by the reduced amount of soluble oxalate or calcium required to elicit spontaneous precipitation of calcium oxalate and calcium phosphate in urine of stone-forming patients [32, 33].

Once a crystal nidus has been formed, other events must occur to allow this nidus to become large enough to get lodged in the urinary tract. In principle, the retention of particles within the renal tubule can occur through several mechanisms: by the addition of new

crystals of the same chemical composition to the nucleus (crystal growth); by agglomeration of preformed crystals into large clusters (crystal aggregation); or by epitaxial growth, the process whereby material of one crystal type is precipitated upon the surface of another whose lattice dimensions are almost identical. Alternatively, the stone-forming crystals may react with components of the renal tubular cell, become attached, and grow [27, 34].

Supersaturation of crystalloids can result from the following processes:

- An increase in free ion concentrations, through too little urine output (a concentrated urine), an absolute increase in the amount of a stone-forming constituent excreted in urine (such as calcium, oxalate, uric acid or cystine), or a reduction in natural ligands (such as citrate, which forms a soluble complex with calcium).
- An alteration in the urine pH, because low urinary pH (< 5.5) increases urinary saturation of uric acid, whereas high urinary pH raises that of calcium phosphate and magnesium ammonium phosphate.
- A change in the ionic strength, which alters the ionic activity of stone-forming constituents [34].

Several methods for assessing supersaturation levels in urine have been reported [27, 35]. The urinary activity product provides the best estimate for the state of saturation with respect to stone-forming ions. It is calculated for any given salt, such as calcium oxalate, by estimating ionic activities with a computer program. When the activity product, e.g. $[Ca^{2+}] \times [Ox^{2-}]$, is divided by the corresponding thermodynamic solubility product (solubility product of calcium oxalate in artificial solutions), a relative saturation ratio is derived [35]. A value > 1 represents urinary supersaturation, whereas a value < 1 indicates undersaturation.

Despite the importance of supersaturation in stone formation, the urinary environment of normal subjects without stones is often supersaturated with respect to calcium oxalate, the most common stone salt. To explain lack of stone formation, studies during the past 40 years have sought the presence of inhibitors that retard crystallization processes, particularly of calcium oxalate. These substances have been defined as molecules that raise the metastable limit (so that nucleation would be initiated at a higher supersaturation), inhibit secondary nucleations, or reduce the growth rate and aggregation of crystal nuclei [36]. The mechanism of action appears to be the adsorption of the inhibitors to specific growth sites on the crystal surfaces, which are thought to be dislocations in the crystal lattice. This adsorption prevents the further deposition of crystal lattice ions and prevents the crystals from "sticking" together in an aggregation process [34]. A list of proposed inhibitors is shown in Table 2. Macromolecular inhibitors have been isolated from

Table 2. Urinary Crystallization Inhibitors

the soluble part of the organic matrix of kidney stones or in the urine. Small molecules (citrate and pyrophosphate) play a prominent role in the inhibition of crystal growth of calcium phosphate [37], whereas larger molecules [36] (glycopeptides and glycosaminoglycans) are believed to play a prominent role in the inhibition of calcium oxalate crystallization. Urinary excretion of some of these inhibitors, e.g. citrate [38] and glycosaminoglycans [39], has been reported to be reduced in some patients with stones. In other studies, Tamm-Horsfall protein and nephrocalcin have been reported to be structurally and functionally abnormal in recurrent calcium oxalate stone formers. However, the role of these organic macromolecules in the pathogenesis of nephrolithiasis has not been well established. Finally, epithelial cell injury and the response of renal cells to crystals might be relevant to the effective growth of renal calculi [40, 41].

Other factors, such as anatomical abnormalities, predispose to stone formation. Nephrolithiasis may be found in association with ectopic, polycystic, or horseshoe kidney, or with stenosis at all levels of the urinary tract. In these conditions, it is generally accepted that secondary urinary stasis predisposes to infection stones or exaggerates stone disease. Medullary sponge kidney is often associated with calcareous renal calculi. There is no convincing evidence that this structural abnormality causes stone formation, because patients with medullary sponge kidney and stones have the same spectrum of biochemical abnormalities as the overall population of stone formers without tubular ectasia [26].

In summary, the pathogenesis of nephrolithiasis is multifactorial and involves alteration in physicochemical and biological mechanisms that regulate the solubility of the urine. Not all aspects of stone formation are well understood, and the exact site in the kidney at which initial steps in stone formation take place is unknown. However, from a clinical point of view, abnormalities or risk factors that predispose to stone formation can be identified in most patients with stones from analysis of their urine.

Urinary Risk Factors for Nephrolithiasis

The frequency and pathogenetic significance of most important urinary risk factors for renal stones are described in Table 3. Data from 1,270 patients with recurrent nephrolithiasis studied during the last 20 years under the same ambulatory protocol were considered in estimating the relative frequency of various risk factors [6]. No abnormality was found in only 4% of patients. Several independent disturbances may, in fact, coexist in a given patient. The co-occurrence of various derangements could be explained by (1) superimposition of a dietary or environmental aberration on an underlying metabolic abnormality, (2) coexistence of separate metabolic abnormalities in the same patient (e.g. distal renal tubular acidosis (RTA) causing hypercalciuria and hypocitraturia), and (3) primary metabolic abnormality causing other derangements (e.g. increased intestinal calcium absorption, leaving less calcium remaining in the gut to bind oxalate, thus resulting in hyperoxaluria).

Hypercalciuria

Hypercalciuria is the most common underlying abnormality, encountered in approxi-

Table 3. Incidence and Pathogenetic Significance of Risk Factors for Nephrolithiasis

Risk factor	Incidence (%)*	Effect in Urine
Hypercalciuria	61	Increased saturation of calcium oxalate and calcium phosphate Reduced inhibitor activity against crystallization of calcium salts by binding negatively charged inhibitors (citrate, chondroitin sulfate) and inactivating them
Hyperuricosuria	36	Increased saturation of monosodium urate Facilitated calcium oxalate crystallization by heterogeneous nucleation or binding macromolecular inhibitor
Hypocitraturia	31	Increased saturation of calcium salts via reduced calcium binding Reduced inhibitor activity against spontaneous nucleation and agglomeration of calcium oxalate,crystal growth of calcium phosphate and heterogeneous nucleation of calcium oxalate by monosodium urate.
Low urine volume	15	Increased saturation of stone-forming salts
Low urinary pH (pH < 5.5)	10	Low uric acid solubility
Hyperoxaluria	8	Increased saturation of calcium oxalate
Hypomagnesiuria	7	Increased saturation of calcium oxalate from reduced binding of oxalate
High urinary pH (pH > 7.0) (struvite stones)	6	Increased saturation of calcium phosphate Increased saturation of struvite (if ammonium ion concentration is high)
Cystinuria	1	Increased saturation of urine

*Represents percentages of patients among 1,270 stone formers studied in Dallas who had each risk factor, either singly or concurrently.

mately 60% of patients with stones. It is usually defined in adults on an unrestricted diet (about 1 g of calcium intake) as urinary calcium excretion in 24 hours > 250 mg in women and 300 mg in men, or 4 mg/kg body weight in patients of either sex [42]. When calcium intake is restricted for one week to 400 mg/day and sodium intake to 100 mEq/day, the upper limit of normal for urinary calcium excretion is 200 mg/day [43].

The association of hypercalciuria with nephrolithiasis was first recognized by Flocks [44]. A pathogenetic role for hypercalciuria in stone formation is supported by several lines of evidence. First, the urinary saturation of calcium oxalate and calcium phosphate has been shown to correlate directly with urinary calcium concentration. Moreover, the urinary environment of patients with hypercalciuric nephrolithiasis was typically supersaturated

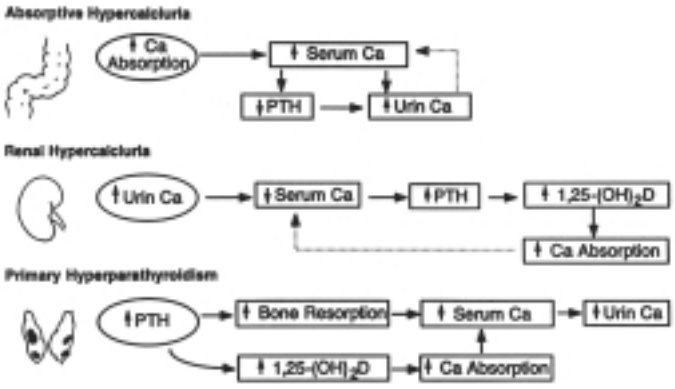

Figure 2. Schemes for the major forms of hypercalciuria. (From Pak CYC 1990 Hypercalciuric calcium nephrolithiasis. In: Resnick MI, Pak CYC. (eds): Urolithiasis.: WB Saunders, Philadelphia, figure 3-5, p 44, with permission.)

with respect to these salts [33]. It was initially suggested that hyperoxaluria was more effective than hypercalciuria in augmenting the urinary saturation of stone-forming calcium salts [45]. However, a reexamination of the problem disclosed an equivalent action of calcium and oxalate. Within the range of concentrations encountered in urine, the rise in calcium concentration was as effective as the increase in oxalate concentration in raising the urinary saturation of calcium oxalate [43]. Indeed, correction of hypercalciuria with the administration of thiazides [46] or sodium cellulose phosphate [47] has effectively reduced stone formation in hypercalciuric patients. Second, hypercalciuria may reduce the inhibitor activity in urine by binding negatively-charged inhibitors and inactivating them. Thus, Zerwekh and colleagues reported that the inhibition of spontaneous nucleation of calcium oxalate exhibited by citrate and chondroitin sulfate was reduced by calcium [48]. Lastly, failure of medical therapy in some patients with calcium nephrolithiasis has been associated with persistent hypercalciuria [49].

Most patients with hypercalciuric nephrolithiasis are normocalcemic and have no obvious cause for increased calcium excretion. The term idiopathic hypercalciuria was used by Albright et al. to denote this entity [50]. Pak, et al. broadly categorized hypercalciuria of nephrolithiasis into 3 types (Figure 2) [43].

Absorptive hypercalciuria (AH), the most common stone-forming entity [6], is characterized by a primary enhancement of intestinal calcium absorption. Following oral calcium ingestion, there is a transient hypercalcemic response which leads to hypercalciuria by enhancement of renal filtered load of calcium and suppressed secretion of parathyroid hormone (PTH), a hormone known to increase renal reabsorption of calcium. AH appears to be inherited as an autosomal dominant trait [51]. Our group in Dallas have devoted considerable effort to delineating the pathophysiology of this disturbance. Although increased circulating calcitriol concentrations have been reported for AH patients and could explain the elevated intestinal calcium absorption, we have not observed frank elevations in serum calcitriol in the majority of our patients [52]. This observation suggests that vitamin D-independent processes or increased intestinal sensitivity to the action of vitamin D might be operative in a majority of the AH patients.

When patients with AH are challenged with a short course of ketoconazole, an inhibitor of steroid synthesis, the ensuing reduction in

calcitriol synthesis produces a decline in intestinal calcium absorption and in urinary calcium in some, but not all, patients [53]. This finding suggests some dependency or sensitivity of the gut to the prevailing concentration of 1,25-$(OH)_2D_3$. Furthermore, we previously reported increased vitamin D receptor (VDR) numbers in activated lymphocytes from some patients with AH who had normal circulating 1,25-$(OH)_2D_3$ levels [54]. These observations, as well as a report of increased intestinal VDR concentration in the genetic hypercalciuric rat [55], an animal model with a phenotype similar to that of the human disease, all prompted a detailed examination of VDR expression in patients with AH. However, extensive molecular biological studies have so far failed to support a pathophysiological importance of vitamin D. Thus, no alteration was found in the VDR cDNA coding region from patients with AH [56]. The gene for VDR or 1-α-hydroxylase of vitamin D was not linked to the inheritance pattern of AH from linkage analysis [57]. Again, there was neither an increase in VDR levels in skin fibroblasts, a recognized vitamin D-responsive cell, nor increased sensitivity to upregulation of VDR numbers by 1,25-$(OH)_2D_3$ in patients with AH [58]. These studies do not preclude a role of VDR concentration in intestinal tissue from patients with AH, where prolongation of the protein's half-life may promote increases in intestinal calcium absorption, hypercalciuria, and nephrolithiasis. Moreover, there may be involvement of other vitamin D responsiveness genes.

Renal hypercalciuria and primary hyperparathyroidism each account for no more than 2% of patients with renal stone disease [6]. In renal hypercalciuria, there is a primary renal leak of calcium, with a transient hypocalcemia. This stimulates parathyroid function, and the excess of PTH leads to calcium mobilization from bone and increased intestinal calcium absorption via 1,25-$(OH)_2D_3$. The cause for the renal leak of calcium is not known. The restoration of normal serum PTH, 1,25-$(OH)_2D_3$ and intestinal calcium absorption upon correction of renal calcium leak by thiazide supports the proposed pathogenetic scheme [59]. Resorptive hypercalciuria is most commonly due to primary hyperparathyroidism. The excessive secretion of PTH stimulates bone resorption, increasing serum calcium and renal filtered load of calcium. Furthermore, PTH-induced renal synthesis of 1,25-$(OH)_2D_3$ leads to enhanced intestinal calcium absorption, leading to further increase in serum calcium and filtered renal calcium load.

Some hypercalciuric patients cannot be categorized into these major variants. Many of them present with fasting hypercalciuria with normal parathyroid function. This presentation may reflect abnormal renal clearance of absorbed calcium in patients with absorptive hypercalciuria. However, recent studies suggest that in some of these cases, hypercalciuria may be partly skeletal in origin because of cytokine-induced bone resorption [60].

Hyperuricosuria

The association of hyperuricosuria with uric acid stone formation is universally recognized [61]. However, it is less commonly realized that hyperuricosuria is also associated with the formation of calcium oxalate stones, even in the absence of hypercalciuria or hyperoxaluria. This association was first noted by Coe et al. who reported that these patients respond favorably to treatment with allopurinol [62].

Figure 3 explains calcium stone formation in the setting of hyperuricosuria, although this scheme has not been clearly validated [63] (Figure 3). Hyperuricosuria, in the setting of

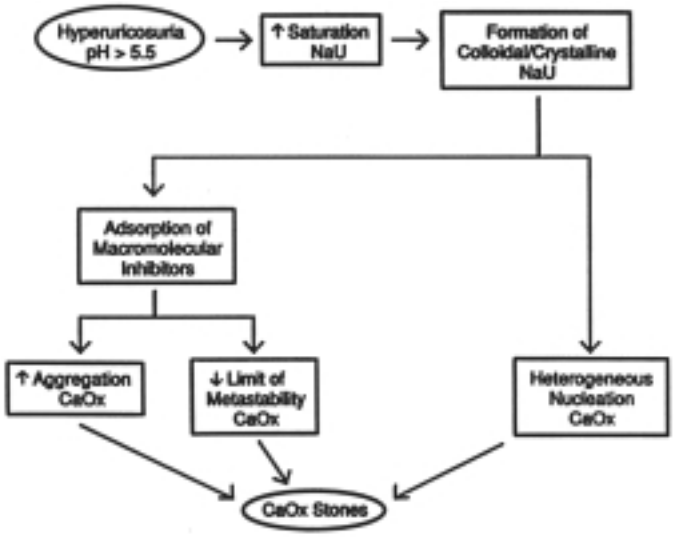

Figure 3. Scheme for calcium oxalate stone formation from hyperuricosuria. NaU = monosodium urate; CaOx = calcium oxalate. (From Pak CYC 1990 Hyperuricosuric calcium nephrolithiasis . In: Resnick MI, Pak CYC. (eds): Urolithiasis.: WB Saunders, Philadelphia, figure 5-1, p. 80, with permission.)

normal pH at which adequate dissociation of uric acid occurs, produces urinary supersaturation of monosodium urate. The resulting formation of colloidal or crystalline monosodium urate causes formation of calcium oxalate stones by heterogeneous nucleation [64, 65], or by adsorption of macromolecular inhibitors [66].

The usual upper limits for normal uric acid excretion are 750 mg/day in women and 800 mg/day in men. However, urine specimens with normal pH of 6.4 were invariably supersaturated when the content of the total dissolved urate exceeded 300 mg/L [63]. Thus, a more functional definition of 600 mg/day for normal upper limit of uric acid excretion is employed in our laboratory at Dallas, assuming a desired urine volume of 2 L/day. Depending on the definition used for hyperuricosuria, it is present in 20 – 40% of the stone-forming population.

The most frequent cause for hyperuricosuria is a purine-rich diet (red meat, poultry and fish). Recurrent stone formation can be ameliorated by dietary purine deprivation [63]. In a minority of patients, hyperuricosuria results from urate overproduction (e.g. myeloproliferative disorders) or uricosuric drugs (e.g. high doses of aspirin).

Hypocitraturia

Citric acid is a tricarboxylic acid with pKa's of 2.9, 4.3, and 5.6. Therefore, in plasma, citrate exists predominantly as a trivalent anion, citrate^{-}. Intracellular citrate is a key component of the tricarboxylic acid cycle (Krebs' cycle), in which ATP is produced from glucose and other fuels [67]. Citrate represents the most abundant of the organic anions and acids present in the urine and plays an important role as an inhibitor of the crystallization of calcium salts.

The physicochemical action of citrate is summarized in Figure 4. Citrate probably acts chiefly through the formation of a complex with calcium, causing a reduction in the ionic calcium concentration and the urinary saturation of calcium oxalate and calcium phos-

Figure 4. Scheme for the inhibitor activity of citrate. (From Pak CYC 1990 Hypocitraturic calcium nephrolithiasis In: Resnick MI, Pak CYC. (eds): Urolithiasis.: WB Saunders, Philadelphia, figure 6-1, p.91, with permission.)

phate [68]. In addition, citrate directly inhibits agglomeration of calcium oxalate [69] and spontaneous nucleation of calcium oxalate [70], and may also impair urate-induced crystallization of calcium oxalate [71]. The loss of inhibitor activity of citrate leads to increased saturation, enhanced heterogeneous nucleation, and facilitated crystal growth and aggregation of calcium oxalate (Table 3).

The principal cause for hypocitraturia in nephrolithiasis is acidosis or acid retention (Table 4). Acidosis reduces urinary citrate both by enhancing renal tubular reabsorption and by impairing peritubular uptake and synthesis of citrate. Renal citrate lyase activity is increased by chronic acidosis, leading to reduced intracellular citrate and enhanced tubular reabsorption [67].

Distal acidification defect (type I) is the only form of renal tubular acidosis (RTA) associated with nephrolithiasis. Acidosis is characteristic of distal RTA (due to an inability to excrete acid) and is characterized by systemic metabolic acidosis or defective urinary acidification following an ammonium chloride load, and urinary pH > 6.5 in the absence of UTI. The acidosis is a hypokalemic, hyperchloremic, nonanion gap metabolic acidosis. In the complete form, metabolic acidosis is present before an ammonium chloride load is given. In the incomplete form, urinary acidification following ammonium chloride load is impaired, despite normal serum electrolytes before the load. Chronic diarrheal states are associated with acidosis secondary to intestinal alkali and potassium loss. The degrees of hypocitraturia are generally proportional to the severity of intestinal fluid loss. Hypokalemia, itself a result of intracellular acidosis, may in turn cause hypocitraturia (e.g. during thiazide treatment).

Other causes of acidosis-induced hypocitraturia are strenuous physical exercise (from lactate accumulation), high sodium intake (from bicarbonaturia), and a high meat diet (from increased acid ash content). Hypocitraturia is also found in UTI, probably from the degradation of citrate in urine by bacterial enzymes and bacterial consumption of citrate. In a significant number of cases, there is no apparent cause of hypocitraturia; dietary acid excess may be responsible. Our own studies do not support existence of primary citrate malabsorption. Citrate absorption from the gastrointestinal tract was directly measured by using the intestinal washout technique. In both normal subjects and in patients with stones, citrate absorption was very efficient, with nearly 100% absorption in 3 hours [72 – 74].

Hypocitraturia has been variously reported in 19 – 63% of patients with nephrolithiasis [75]. This variation reflects different normal ranges for urinary citrate established by various laboratories. In the laboratory at Dallas, hypocitraturia is defined by citrate < 320 mg/day for adult men and women [76]. This value of 320 mg/day was derived from a large number of normal subjects in this laboratory. Among stone-forming patients, no significant difference in urinary citrate was found between men and women. In distal RTA, urinary citrate is invariably < 320 mg/day [77]. Finally, this limit provides a good empirical definition of hypocitraturia, because patients with urinary citrate below this level often show a clinical response to potassium citrate therapy that is superior to the response in patients with citrate > 320 mg/day [78]. Using this definition, hypocitraturia was found in 31% of our population of stone-forming patients [6].

Low Urine Volume

Low urine output represents one of the major risk factors, predisposing to all forms of stone disease. It may be the result of an inadequate fluid intake or elevated extrarenal loss of fluid (e.g. chronic diarrhea or excessive sweating in hot climates) [79 – 81]. Failure to increase urine volume has been identified as a predictor of relapse of calcium nephrolithiasis during treatment [49]. Low urine output increased the urinary saturation of all stone-forming salts by increasing the concentration of constituents of the stone. Conversely, urinary dilution was found to reduce the propensity for the crystallization of calcium salts in urine by lowering the urinary saturation of brushite and calcium oxalate, and by increasing the minimum supersaturation needed to elicit spontaneous nucleation of calcium oxalate [80]. With a stringent definition of 1 L/day as the low normal limit of urine volume, 15% of patients had this risk factor [6]. Had we used a higher figure of 2 L/day, indicative of desired urine volume [80], a much higher percentage of patients would have had low urine volume.

Low Urinary pH

The principal determinant of uric acid crystallization is its relative insolubility in the acidic urinary environment. Thus, the solubility of uric acid is pH dependent (Figure 5). Below a pH of 5.5 (the pKa of uric acid), most of the uric acid remains in an undissociated form, possessing a low aqueous solubility of < 100 mg/L [63]. This unusually acid environment leads to the development of uric acid stones. Once a uric acid stone is formed, it could induce formation of calcium oxalate stones by the same mechanisms already mentioned for monosodium urate (see *Hyperuri-*

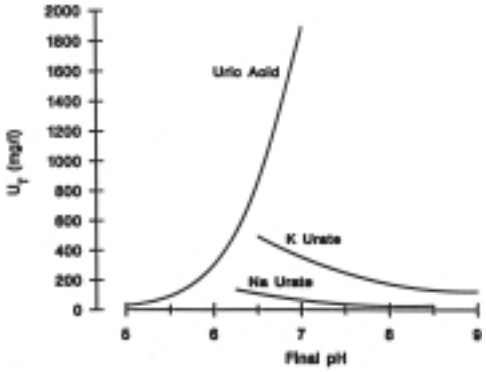

Figure 5. Uric acid solubility and transformation to urate salts. (From Pak CYC 1990 Uric acid nephrolithiasis. In: Resnick MI, Pak CYC. (eds): Urolithiasis.: WB Saunders, Philadelphia, figure 7-1, p 106, with permission.)

cosuria). Secondly, the urinary saturation of uric acid increases proportionately with the rise in total uric acid concentration. With a rise in pH, more uric acid becomes dissociated into an anionic form, approaching 100% at pH 6.5. Thus, the propensity for uric acid crystallization is low at higher urinary pH [63].

Low urinary pH could result from environmental or nutritional aberrations, such as dehydration, strenuous physical exercise, and consumption of a diet rich in animal proteins [82]. Undue urinary acidity may be due to metabolic disturbances as well, such as chronic diarrhea [83] or, most often, gouty diathesis [84, 85].

The term gouty diathesis represents the formation of uric acid and/or calcium stones in patients with primary or latent gout. Stones may precede articular manifestations of primary gout in up to 40% of those patients. The 2 types of gouty diathesis, presenting with uric acid stones or calcium stones, share similar clinical and biochemical features characteristic of primary gout. Thus, a substantial percent of gouty diathesis patients have gouty arthritis, hyperuricemia, hypertriglyceridemia, and high renal tubular reabsorption of urate, in addition to a low urinary pH (< 5.5) unaccounted for by dietary acid excess or intestinal alkali loss [84]. The underlying mechanism in gouty diathesis responsible for undue urinary acidity is still unknown. Some patients have decreased ammonium excretion even with normal glomerular filtration rate (GFR), however, the cause for this defective urinary ammonium excretion is unclear [86]. Since there is a reciprocal increase in urinary titratable acidity, no systemic acidosis occurs [87, 88]. Gouty diathesis was found in 10% of recurrent stone-formers [6].

Hyperoxaluria

Oxalate is a useless end product of metabolism and is excreted primarily in the urine. It is clinically relevant to renal stone formation because of the low solubility of its calcium salt (calcium oxalate) [89]. Both in patients with recurrent calcium nephrolithiasis and in normal subjects, urinary saturation of calcium oxalate is directly correlated with urinary oxalate concentration. As mentioned previously, a rise in oxalate concentration is equally effective as a rise in calcium concentration in augmenting the saturation of calcium oxalate [68].

Normally, about 10% of urinary oxalate is derived from diet, 25 – 30% comes from direct metabolic conversion of ascorbic acid and tryptophan, and 60% is attributable to oxidation of glyoxalate. Two major pathways for glyoxalate degradation are its transamination to alanine and glycine. This last step requires pyridoxine (vitamin B_6) as a cofactor (Figure 6) [90].

Hyperoxaluria, defined as a daily urinary oxalate excretion > 44 mg, is found in around 10% of recurrent stone formers [6]. It results from 2 main mechanisms: either intestinal

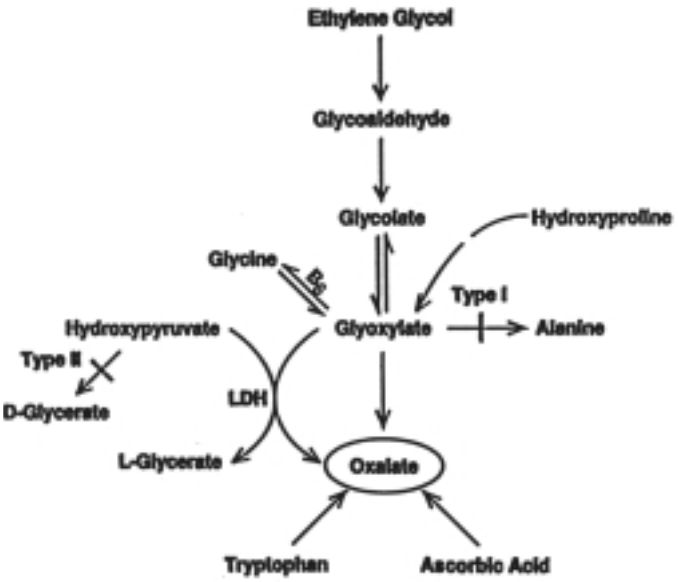

Figure 6. Biosynthetic pathway for oxalate. (From Pak CYC 1990 Hyperoxaluric calcium nephrolithiasis. In: Resnick MI, Pak CYC. (eds): Urolithiasis.: WB Saunders, Philadelphia, figure 4-2, p 68, with permission.)

Table 5. Causes of Hyperoxaluria

2. Ethylene glycol and methoxyflurane

hyperabsorption of oxalate or, less frequently, from increased synthesis of oxalate (Table 5).

In general, only 2 – 5% of oxalate from food is normally absorbed. Foods of high oxalate content are leafy green vegetables, nuts and peanut butter, brewed tea, and chocolate. Slight to moderate hyperoxaluria could develop from an excessive intake of oxalate-rich foods. In such cases, urinary oxalate is normal after one week on a diet poor in oxalate [6, 89]. Enteric hyperoxaluria is defined as hyperoxaluria occurring in patients with ileal disease (Crohn's disease, ulcerative colitis, jejunoileal bypass or intestinal resection) or fat malabsorption (pancreatic insufficiency, celiac sprue or bacterial overgrowth) [83, 90]. Two mechanisms have been implicated. First, the intestinal mucosa may become more permeable to oxalate from the direct action of nonabsorbed bile salts and fatty acids. Second, the nonabsorbed bile salts and fatty acids may complex divalent cations, reducing the amount of free calcium and magnesium in the intestinal lumen. Fewer divalent cations would be available to bind oxalate, leaving an enlarged pool of absorbable oxalate. An intact colon is essential for the development of hyperoxaluria, because it is the principal site of oxalate absorption. The occasional mild hyperoxaluria found in patients with absorptive

hypercalciuria or low calcium intake may occur in a similar fashion from the reduced complexation of oxalate by calcium.

Hyperoxaluria due to increased oxalate synthesis occurs less frequently. Primary hyperoxaluria is an inherited abnormality of oxalate metabolism. Patients with this condition excrete more than 80 mg/day of urinary oxalate. Two types have been well characterized (Figure 5). In type 1, the more common, there is a deficiency of the enzyme alanine:glyoxylate aminotransferase, whereas in type 2 the enzyme D-glyceric dehydrogenase is deficient. The typical sequelae of primary hyperoxaluria are early nephrolithiasis, nephrocalcinosis, systemic oxalosis, and renal failure leading to death [91]. Preliminary data suggest that pyridoxine deficiency may induce hyperoxaluria in some patients; thus, pyridoxine supplementation might be useful in some cases.

Vitamin C in doses > 500 – 1000 mg/day may induce a rise in urinary oxalate by serving as a substrate for oxalate synthesis. A similar mechanism is seen in those rare cases of severe hyperoxaluria (often associated with renal failure) induced by ethylene glycol or methoxyflurane [89].

Hypomagnesiuria

Magnesium inhibits stone formation by binding oxalate, thus reducing the saturation of calcium oxalate. Moreover, it has a modest inhibitory effect on the crystal growth of calcium oxalate [92, 93]. Thus, calcium oxalate crystallization could be enhanced in the setting of hypomagnesiuria. Hypomagnesiuria occurs in chronic diarrheal syndrome from malabsorption of magnesium, thus increasing the risk for nephrolithiasis in patients with bowel disease [94]. In the absence of intestinal disease, hypomagnesiuria, defined as urinary magnesium excretion < 50 mg/day, was present in 7% of patients with stones in the series at Dallas [6]. This entity (termed hypomagnesiuric calcium nephrolithiasis) is probably dietary in origin. Most patients give a history of avoidance of magnesium-rich food [95], and magnesium metabolism has been reported to be normal in patients with calcium nephrolithiasis [96]. Most of the hypomagnesiuric patients also have hypocitraturia.

High Urinary pH

– *Calcium phosphate stones*. Urinary pH has a pronounced effect on the supersaturation of calcium phosphate salts by influencing the dissociation of phosphate to form HPO_4^{2-} (a component of brushite stones) and PO_4^{3-} (a component of apatite) [97]. Thus, at pH < 6.9, brushite ($CaHPO_4 \cdot 2H_2O$) is the predominant phase of calcium phosphate salts, whereas a higher pH favors the formation of apatite ($Ca_5(PO_4)_3(OH)$) [98]. This relationship explains at least some of the mechanisms for the occurrence of calcium phosphate stones in patients with distal RTA [99, 100] or infection.

– *Infection stones*. These stones occur in urine infected with urea-splitting organisms and are composed of a combination of struvite ($MgNH_4PO4 \cdot 6H_2O$) and carbonate-apatite ($Ca_{10}(PO_4)_6CO_3$). Figure 7 illustrates the pathogenesis of infection stones. The action of urease within the urinary tract produces high levels of ammonium, carbonate, and urinary pH > 7.2. The resulting alkalinity of urine increases the amount of trivalent phosphate, as already mentioned. Thus, the urinary environment becomes supersaturated with struvite and carbonate apatite, leading to the crystallization of

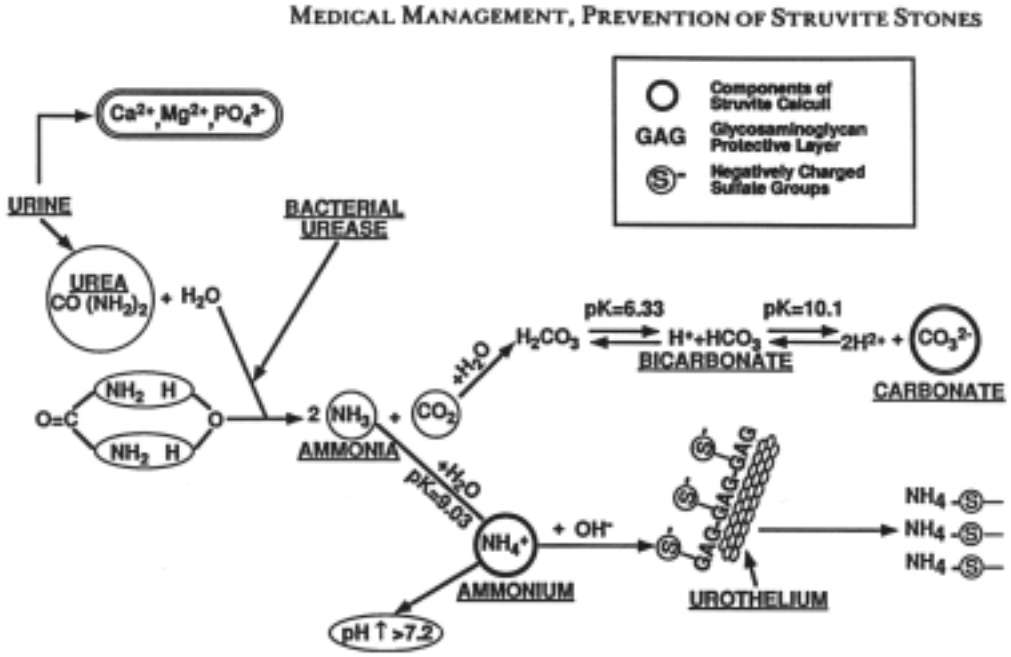

Figure 7. Pathogenesis of stone infection. (From Wong HY, Riedl CR, Griffith DP 1996 Medical management and prevention of struvite stones. (In: Coe FL, Favus MJ, Pak CYC, Parks JH, Preminger GL (eds.): Kidney Stones: Medical and Surgical Management, Lippincott-Raven Publishers, Philadelphia, figure 1, p 943, with permission).

these stone constituents. Moreover, propagation of struvite crystals is enhanced by its adhesion to the sulfate groups of the glycosaminoglycan layer protecting the urothelium. Both factors combined can lead to rapid development of large stones [101]. The experimental evidence suggests that infection stones can be formed only in the presence of urea and urea-splitting organisms. Thus, a high urinary pH alone in the absence of other factors would promote the crystallization of calcium phosphate, but not struvite [102]. Infection stones account for 6% in the series at Dallas [6]. *Proteus* species are responsible for the majority of infection that cause these stones in all age ranges. Other common organisms that produce urease are *Haemophilus influenzae, Staphylococcus aureus, Yersinia enterocolitica,* and *Ureaplasma urealyticum* (this last requires special culture techniques for its detection). *Escherichia coli* does not produce urease and therefore is not responsible for the formation of infection stones [103].

Cystinuria

Cystinuria is an autosomal recessive disease characterized by increased urinary excretion of the dibasic amino acids cystine, arginine, lysine, and ornithine. Only cystine is insoluble enough to precipitate in physiological settings. Thus, the most important pheno-

Table 6. Role of Urinary Risk Factors in the Different Types of Renal Stones

Urinary risk factor	Calcium Oxalate	Calcium Phosphate	Uric Acid	Infection Stones	Cystine
Hypercalciuria	√	√			
Hyperuricosuria	√		√		
Hypocitraturia	√	√			
Low urine volume	√	√	√	√	√
Low urinary pH			√		
Hyperoxaluria	√				
Hypomagnesiuria	√				
High urinary pH		√		√	
Cystinuria					√

√ = risk factor

typic expression of cystinuria is the predisposition toward cystine stones (1% of renal stones) [104].

The main determinant of cystine crystallization is urinary supersaturation. It has also been recognized that the solubility of cystine is pH dependent, with the lowest solubility at the low range of urinary pH, gradually increasing with a rise in pH to 7.5, and rapidly increasing above a pH of 7.5 [105]. There is no inhibitor of cystine crystallization. In the homozygous state (cystine excretion greater than 250 mg/g creatinine in a 24-hour urine collection), cystine stones invariably develop because the solubility limit for cystine is often exceeded [104].

The solute carrier family 3, member 1 (SLC3A1) gene, located on chromosome 2, codes for a protein involved in renal cystine transport. In a recent review, 9 polymorphisms and 21 different mutations were reported in the SLC3A1 gene. Most of them were base substitutions, while others were deletions. Some mutations have been found in a single individual patient, while others have been found in more than individual. Transfection studies indicate that these mutations are responsible for cystinuria. However, some cases of cystinuria are not related to defects in SLC3A1; thus, other genes might also be involved [4].

Table 6 summarizes the role of urinary risk factors in the different types of renal stones.

Medical Management

The primary objective of medical management is the prevention of recurrent stone formation. The medical approach may be fully justified because of the high rate of recurrence characterizing most forms of stone disease. Moreover, medical evaluation may disclose underlying diseases with extrarenal manifestations, such as bone disease in primary hyperparathyroidism or intestinal malabsorption syndrome in enteric hyperoxaluria.

In the past, a selective treatment approach was advocated by Pak and colleagues [51].

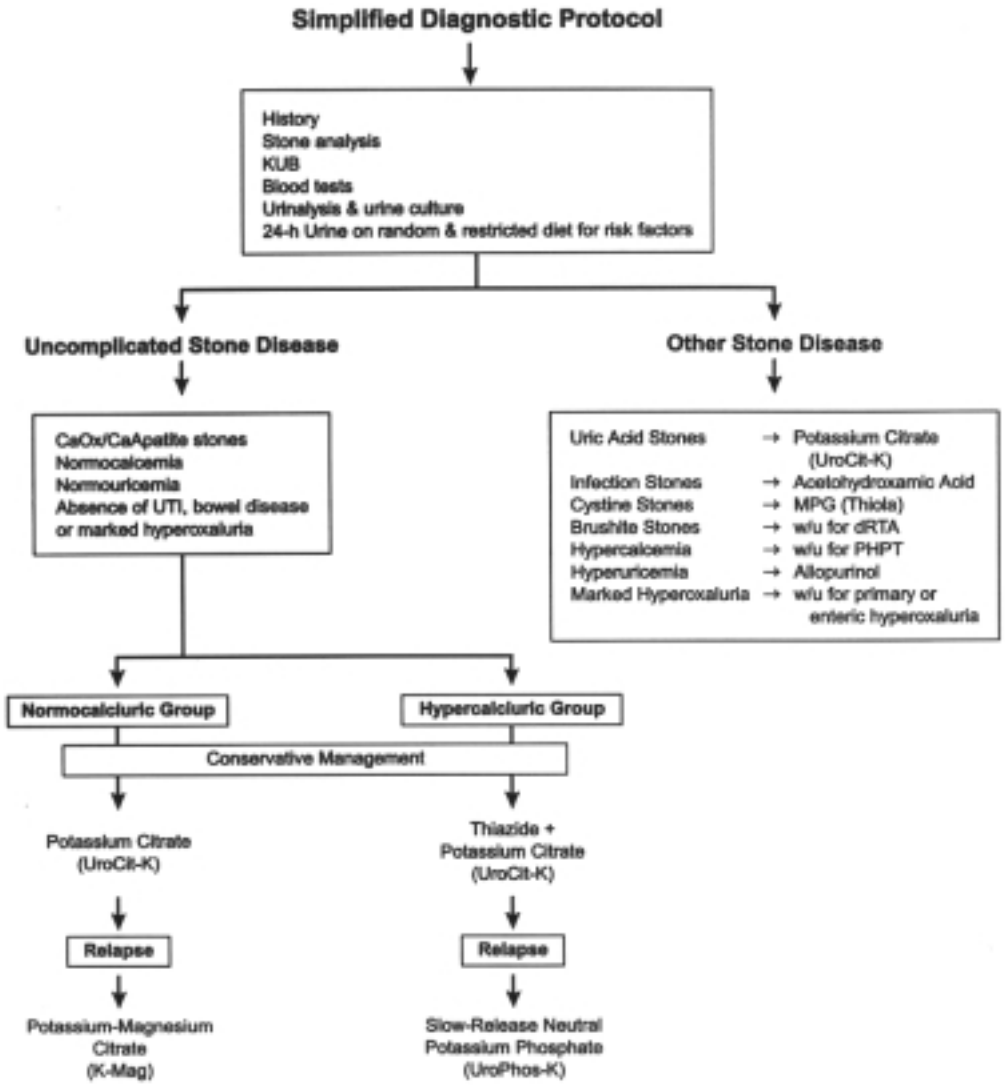

Figure 8. Algorithm for simplified approach to the medical management of nephrolithiasis.

This approach recognized heterogeneity in the pathophysiology of stone disease. After a detailed diagnostic protocol, a specific drug was selected for each cause, based on its ability to correct underlying metabolic derangements. Unfortunately, this approach seems to be too cumbersome for ready adoption for some practicing physicians. In a recent survey of 10 stone research centers from different parts of world, medical drug treatment was used sparingly and nonselectively [106]. Thus, a simplified program for the management of stones which any physician anywhere may readily adopt is described here, in lieu of a selective approach which could be used in large stone research centers.

Table 7. Stone-provoking Medications

Medications	Stone Type	Mechanism
Acetazolamide	CaP, CaOx	Hypercalciuria, Hypocitraturia, High urinary pH
Allopurinol	Xanthine	Enhanced excretion of xanthine
Ca supplements	CaOx, CaP	Hypercalciuria
Ca channel blockers	CaOx, CaP	Hypercalciuria
Loop diuretics	CaOx, CaP	Hypercalciuria
P-binding antacids	CaOx	Hypercalciuria
Silica (Antacids)	Silica	Urinary excretion of silica
Theophylline	CaOx, CaP	Hypercalciuria
Triamterene	Triamterene	Urinary excretion of triamterene
Uricosuric agents	CaOx, UA	Hyperuricosuria
Vitamin C	CaOx	Hyperoxaluria
Vitamin D	CaOx	Hypercalciuria

CaOx: calcium oxalate; CaP: calcium phosphate; UA: Uric Acid

A summary of the simplified program for medical management of nephrolithiasis is shown in Figure 8. This approach was designed to achieve 3 important purposes in medical management of nephrolithiasis.

Separation of Uncomplicated Stone Disease from Other Stone Disease

History

A careful history should be taken during the evaluation of the stone-forming patient, because it may provide clues about the severity, underlying causes and extrarenal manifestations of stone disease. It should focus on: (1) chronology of stone events, such as age of first stone passage and dates of further episodes, number and type of stones passed, spontaneous passage vs. need for surgical intervention; (2) family history of stones or personal history for bone or gastrointestinal disease, gout, chronic urinary tract infection (UTI), or nephrocalcinosis; (3) stone-provoking medications; and (4) nutritional habits [107, 108].

Patients with early onset of nephrolithiasis may suffer from inherited metabolic disorders (e. g. primary hyperoxalurias, xanthinuria, cystinuria) or have a higher risk for calcium stone recurrence. Patients with multiple stones or a family history of stones are also at increased risk of recurrence. A list of the most common medications that could cause or exacerbate stone disease is shown in Table 7. A careful history should also be taken for past medical treatments of stone disease. Their failure may indicate inaccuracy of the original diagnosis or a need for more specific therapy. Nutritional history should be taken, directing particular attention to dietary aberrations implicated in stone formation, such as low fluid intake, high calcium intake, high oxalate diet, sodium excess, animal protein excess, and low citrus fruit intake. The pathogenetic role of some of these factors will be briefly reviewed.

A recent epidemiological study disclosed that, among healthy subjects without stones, high calcium intake may reduce the risk of stone formation [109], attributed to the binding of oxalate by calcium in the intestinal tract. Unfortunately, the concurrent higher intake of potassium (citrus fruits), magnesium, phosphate, and fluids by the high calcium intake group could have clouded interpretation of the results. Moreover, these results may not be extrapolated to stone formers or hypercalciurics, since these two groups were not studied. Physiologically, high calcium intake or calcium supplementation may not confer an increased risk of stone formation in healthy subjects because of the operation of the intestinal adaptation process [110]. During high calcium intake, the fraction of calcium absorbed is decreased because of parathyroid suppression and reduced calcitriol synthesis. In healthy subjects, urinary calcium rose substantially after one month of calcium supplementation, but it decreased toward the pretreatment range during continued treatment for 2 more months [111]. In patients with absorptive hypercalciuria, the intestinal adaptation process may not operate because of the primary enhancement of intestinal calcium absorption [43]. Thus, a high calcium intake provoked a marked increase in urinary calcium that was considerably above the normal range and was apparently sustained. In contrast to healthy subjects, patients with absorptive hypercalciuria may be at increased risk of stone formation from high calcium intake.

The metabolic effect of sodium load has been examined by providing 250 mEq of sodium daily over a basal metabolic diet. As reported previously, urinary calcium increased significantly. In addition, urinary pH increased modestly and urinary citrate decreased significantly. These effects have been ascribed to bicarbonaturia from sodium-induced volume expansion. Commensurate with these changes, sodium load increased the propensity for the crystallization of stone-forming calcium salts [112].

Animal proteins are rich in sulfur-containing amino acids. When they are metabolized, sulfate is released. Thus, a high consumption of animal protein represents an acid load, which could reduce urinary citrate and pH. In addition, urinary calcium may increase because of higher bone resorption and renal calcium leak induced by the transient metabolic acidosis. Uric acid also will increase with an ingestion of all meat products (beef, poultry and fish) since they are rich in purines [113, 114].

Citrus fruits are rich in citric acid and potassium, particularly the former. Their intake is associated with a rise in urinary pH and citrate and occasionally by a fall in urinary calcium. Citrus fruits contain a modest amount of calcium (100 mg/L), vitamin C (< 500 mg/L) and oxalate (0 – 21 mg/L). The amount of these nutrients in fruit juices is probably insufficient to affect stone disease adversely. Thus, the net effect of citrus fruits is beneficial. Conversely, a low intake of citrus fruits may contribute to hypocitraturia, and may enhance the risk for stone formation [108, 115].

The role of a low fluid intake and high oxalate diet was already discussed in the section on urinary risk factors.

Stone Analysis

The diagnosis of different causes of nephrolithiasis is no longer made solely on the basis of stone composition. There is increasing reliance on underlying physiological derangements. However, stone analysis is still important and should be obtained in every stone-forming patient if a sample is available.

The disclosure of cystine, or struvite or carbonate apatite, is diagnostic of cystinuria or infection with urea-splitting organisms, respectively. The presence of 2,8-dihydroxyadenine, triamterene, silica, or xanthine indicates 2,8-dihydroxyadeninuria, treatment with triamterene or magnesium trisilicate, or xanthinuria. In these conditions, the crystallographic identification is critical for the diagnosis; laboratory and clinical data provide supporting evidence. For the remaining stones (80 – 85% of all stones), which are associated with or formed from a variety of metabolic or environmental disturbances, stone composition is helpful but not conclusive for diagnosis of the underlying disease.

Radiologic Appearance (Kidneys, Ureter and Bladder)

Most stones can be detected by radiograph of the kidneys, ureter, and bladder (KUB) alone. Radiopaque stones include those containing calcium oxalate, calcium phosphate, and infection stones (due to their component of carbonate apatite). Cystine stones are also radiopaque, though less dense. Radiolucent stones include those composed solely of uric acid, 2,8-dihydroxyadenine, triamterene, xanthine and silica. Uric acid may have a faint radiopacity because of the incorporation of calcium salts. The morphologic appearance of radiopaque stones may provide clues to their mineral composition or to the underlying process. Cystine stones are moderately dense and have a homogeneous appearance. Struvite stones are more dense but also tend to have a rounded appearance. Cystine and infection stones may reach staghorn size. Calcium oxalate stones often have a dense, spiculated appearance.

Cortical nephrocalcinosis suggests the diagnosis of primary hyperoxaluria. Medullary nephrocalcinosis is encountered in distal RTA and primary hyperparathyroidism.

Other imaging modalities such as intravenous urography (IVP) or ultrasonography are useful in detecting radiolucent stones, anatomic abnormalities (e.g. medullary sponge kidney), or complications produced by a stone (e.g. obstruction) [116].

Blood Tests

A multichannel screen of venous blood should be performed to identify primary hyperparathyroidism (high serum calcium concentration), gouty diathesis (hyperuricemia), complete distal RTA (hypokalemia, low CO_2, and hyperchloridemia), or hypophosphatemic absorptive hypercalciuria (hypophosphatemia due to phosphate renal leak). In addition, serum creatinine and BUN are helpful to assess renal function.

Urinalysis and Urine Culture

A fresh spot urine sample should be cultured for urea-splitting organisms (suggestive of infection stones) and examined for pH (with an electrode pH). Low urinary pH (< 5.5) suggests gouty diathesis and high pH (> 7.5) is compatible with infection stones. A qualitative cystine test should be performed on the urine sample, using the cyanide-nitroprusside test, in which a purple-red color after addition of sodium cyanide and sodium nitroprusside suggests that cystine excretion exceeds 75 mg/L [117]. A false-positive test may be obtained in patients with homocystinuria and acetonuria. Follow-up quantitative analysis showing 24-hour urinary cystine > 250 mg/g creatinine confirms diagnosis. Identification of a particular crystal type in the urinary sediment is compatible with, but not

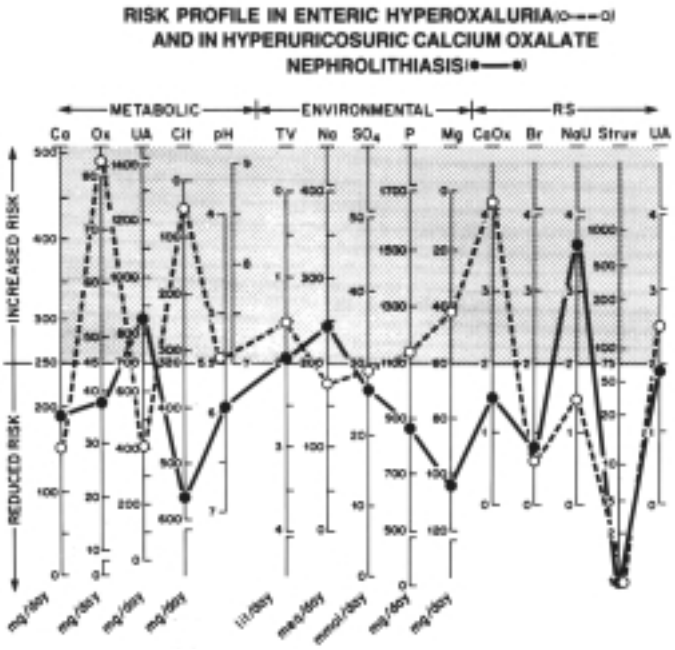

Figure 9. Graphic display of urinary risk factors in patients with enteric hyperoxaluria and with hyperuricosuric calcium oxalate nephrolithiasis. From [Pak CYC, Skurla C, Harvey J 1985 Graphic display of urinary risk factors for renal stone formation. J Urol *134:* 869], figure 3).

diagnostic of, that type of nephrolithiasis. Thus, crystalluria itself is not a pathologic finding.

24-hour Urine for Urinary Risk Factors

This simplified approach takes advantage of commercially-available stone risk analysis. The technique was first developed in our laboratory at Dallas [118]. A 24-hour urine collection kit, containing a volume marker and appropriate preservatives, is provided by the physician to the patient. After obtaining a 24-hour urine sample while the patient is kept on random diet and fluid intake, 2 30 mL aliquots are sent via regular mail to a central laboratory. The laboratory then calculates the total volume from the dilution of the volume marker and analyzes urinary constituents. Risk factors are categorized into 3 groups: metabolic risk factors (calcium, oxalate, uric acid, citrate, and pH), environmental risk factors (total volume, sodium, sulfate, phosphorus, and magnesium), and physicochemical risk factors (saturation of urine with respect to stone-forming constituents calculated from metabolic and environmental factors). Results are displayed graphically or in a tabular format.

A sample stone risk profile as originally reported in 1985 is shown in Figure 9. To provide a visual display of all available data in a single report, each risk factor is assigned a vertical line with linear or logarithmic scales. A horizontal line intersecting each vertical scale at the approximate midpoint represents the upper or lower normal limit. The direction of increasing values is appropriately adjusted, so that values below the horizontal line represent normal values (reduced risk)

Table 8. Dietary Modifications for Diagnostic Assessment

Finding in 24-h urine (on random diet)		*Modification (1 week)*
Total volume	< 2 L/day	Increase fluid ingestion
Sodium	> 200 mEq/day	Sodium restriction
Oxalate	> 45 mg/day	Oxalate restriction
Calcium	> 250 mg/day	Calcium restriction (moderate)
Sulfate	> 30 mg/day	Restriction of animal proteins
Uric acid	> 600 mg/day	Restriction of animal proteins

and those above the line represent abnormal values (increased risk). In this case, samples of two patients are displayed. A patient with small bowel disease (dotted line) had hyperoxaluria (from increased oxalate absorption), hypocitraturia and low urinary pH (from acquired metabolic acidosis), low urine volume (from diarrhea), and low urinary magnesium (from malabsorption). As a consequence, urinary saturation of calcium oxalate and uric acid was higher than normal, accounting for the susceptibility of patients with ileal disease to form stones of calcium oxalate and uric acid. The other patient (continuous line) had hyperuricosuria as the sole metabolic abnormality. Urinary sodium was high from dietary salt abuse. There was relative supersaturation of monosodium urate. The first case is a typical patient with enteric hyperoxaluria, whereas the latter is a patient with hyperuricosuric calcium oxalate nephrolithiasis.

The accuracy of urine collection could be assessed from urinary creatinine values and body weight. In a carefully studied population on a metabolic dietary regimen in whom the accuracy of urine collection was ensured, the mean urinary creatinine in men was 22.1 ± 4.7 mg/kg, whereas it was 17.2 ± 3.8 mg/kg in women. Thus, a value substantially below these figures would indicate undercollection, and a value far exceeding these numbers would suggest overcollection [108].

After obtaining a full stone risk analysis in a urine sample collected on random diet, the next step is to impose a short-term dietary modification (minimum one week) (Table 8) [119]. Fluid intake should be increased at least to ten 10-ounces glasses per day if urine volume is < 2 liters on the stone risk analysis. Salty foods and table salt should be avoided if urinary sodium > 200 mEq/day. Oxalate restriction should be imposed (avoidance of nuts, spinach, chocolate, tea, and vitamin C). Calcium intake should be restricted (avoidance of dairy products and spinach, for diagnostic purpose only) if there is hypercalciuria. Servings of meat products should be limited when there is hyperuricosuria, or if urine sulfate is high.

The last step in this simplified diagnostic protocol for nephrolithiasis is to obtain a 24-hour urine collection while the patient is on a temporary dietary modification. A limited analysis could be performed, involving 7 constituents: calcium, oxalate, uric acid, citrate, pH, total volume, and sodium. The differences in values between the full and the abbreviated analysis (random and modified diet) represent changes imposed by dietary influences.

The work-up described above should allow differentiation of most causes of stones (absorptive hypercalciuria, renal hypercalciuria, hyperuricosuric calcium oxalate nephrolithiasis, hypocitraturic calcium oxalate nephrolithiasis). However, for the simplified ap-

proach to the medical management of nephrolithiasis to be described, only the following differentiations are necessary. First, separate uncomplicated stone disease from other stone disease (Figure 8). The former, constituting the majority of patients with stones, is characterized by calcium oxalate or calcium apatite stones, normal serum calcium and uric acid, and the absence of chronic UTI, bowel disease, or marked hyperoxaluria. Other stone disease would comprise patients with primary gout with hyperuricemia, infection stones, cystinuria, distal RTA, primary hyperparathyroidism, and primary or enteric hyperoxaluria.

Categorization of Uncomplicated Stone Disease

Once patients with uncomplicated stone disease have been identified, an additional diagnostic separation is necessary in this group for purposes of medical treatment. From the 24-hour urine calcium obtained previously, uncomplicated calcium stone disease is separated into normocalciuric and hypercalciuric subgroups (Figure 8). The normocalciuric subgroup would be composed of hyperuricosuric calcium oxalate nephrolithiasis, hypocitraturic calcium oxalate nephrolithiasis, gouty diathesis, and hypomagnesiuric calcium oxalate nephrolithiasis, all presenting with normal urinary calcium. The hypercalciuric subgroup comprises absorptive and renal hypercalciuria, and dietary hypercalciuria.

Most practicing physicians should be able to identify the groups without difficulty.

A Simple Approach to Medical Treatment

Conservative Management

All patients with nephrolithiasis should be offered a conservative treatment program, similar to dietary modifications imposed for diagnostic purposes (Table 8).

Fluid intake should be sufficient to assure a urine level ≥ 2 L/day [80]. Adequate hydration in the absence of any other treatment has been recently proved to decrease stone formation by as much as 55% during a 5-year follow-up [79]. The type of liquid is generally of less concern than the volume; exceptions include the avoidance of tea in hyperoxaluria and excessive milk in absorptive hypercalciuria. Fluids are most valuable if they are distributed throughout the day. Patients also should be encouraged to measure the urine volume regularly (once every 2 – 3 months) to ensure its adequacy.

Traditionally, calcium restriction has been the mainstay of stone prevention. However, this measure may be ineffective in normocalciuric patients and may cause negative calcium balance and bone loss. Our practice is to recommend a moderate restriction of dietary calcium (limit dairy products to one serving/day) only in hypercalciuric patients with normal bone density, and not to restrict calcium in others.

Other dietary modifications have already been explained. Conservative management alone may be necessary in patients with mild disease, those with a single episode, or those without metabolic disturbance. Conservative management should always accompany specific drug therapies in patients with more severe recurrent disease, since it will improve the control of stone risk factors and may allow the use of a lower dose of recommended drugs. In severe stone disease or recurrences

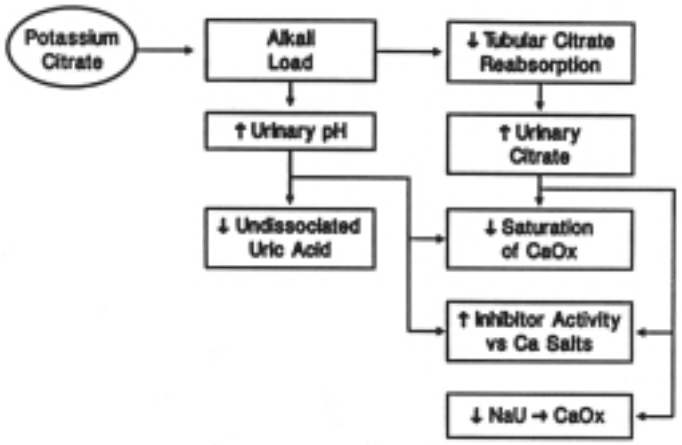

Figure 10. Physicochemical action of potassium citrate. (From Pak CYC 1990 Hypocitraturic calcium nephrolithiasis. In: Resnick MI, Pak CYC. (eds): Urolithiasis, WB Saunders, Philadelphia, figure 6 – 4, p 98, with permission).

despite conservative management, drug treatment is indicated.

Treatment of Uncomplicated Stone Disease

The simplified approach advocates the use of only 2 drugs as initial options in uncomplicated calcium stone disease (Figure 8). The normocalciuric subgroup would be prescribed potassium citrate (Urocit-K) alone. The hypercalciuric subgroup would be given thiazide and potassium citrate.

The rationale for potassium citrate in uncomplicated normocalciuric stone disease is shown in Figure 10. Potassium citrate increases citrate excretion by providing an alkali load [74, 75]. The induced rise in urinary citrate should inhibit the crystallization of calcium oxalate and calcium phosphate, not only in hypocitraturia, but also in the presence of other derangements such as hyperuricosuria. In addition, potassium citrate raises urinary pH, reducing the propensity for uric acid stone formation. The complication of calcium stone should be inhibited as well from the impaired urate-induced calcium oxalate crystallization. A placebo-controlled randomized trial has validated the efficacy of potassium citrate in uncomplicated stone disease with normocalciuria [120]. Among patients treated with potassium citrate, 72% had no further stone formation during a follow-up of 3 years, compared with 20% in the placebo group. Moreover, for those in the treatment group who still formed stones, the stones developed at a lower rate than before treatment.

Potassium citrate (Urocit-K) is available as wax matrix tablets, containing 5 or 10 mEq of citrate per tablet. It is also available as a liquid, powder or syrup combining potassium citrate and citric acid (PolyCitra-K); the powder and syrup are mixed with water before ingestion. The wax matrix tablet formulation has been shown to produce less variability in the level of urinary citrate throughout the day [121]. The customary dose of potassium citrate is 20 mEq twice daily; the dose should be adjusted based on urinary citrate [74, 75]. Contraindications for its use are hyperkalemia or predisposing conditions to hyperkalemia (type IV RTA, concomitant use of potassium-sparing diuretics, adrenal insufficiency), renal failure

(GFR < 40 mL/min), active peptic ulcer disease, UTI or obstruction.

The rationale for the combined use of thiazide with potassium citrate in hypercalciuric patients with uncomplicated stone disease is based on following considerations. Thiazides are unique among diuretics in reducing urinary calcium excretion. Thiazides act directly on the distal convoluted tubule to augment calcium reabsorption, and indirectly at the proximal convoluted tubule secondary to volume depletion [122]. They are widely used in the management of hypercalciuric nephrolithiasis [123]. However, thiazide-induced hypokalemia may lead to intracellular acidosis, which provokes hypocitraturia and may thereby attenuate the beneficial hypocalciuric effect of therapy on renal stone formation [123, 124]. Potassium chloride supplementation may prevent hypokalemia and hypocitraturia. In the management of stone disease, potassium citrate is preferable because it can not only avert hypokalemia, but also raise urinary citrate, an important inhibitor of stone formation [124, 125]. Amiloride has been shown to potentiate the hypocalciuric effect of thiazides while reducing the associated hypokalemia; however, amiloride has no effect on urinary citrate [126]. Therefore, the combination of a thiazide and potassium citrate is preferred.

The recommended doses of thiazides in an average adult patient are trichlormethiazide 4 mg daily, chlorthalidone 50 mg daily, hydrochlorothiazide 25 mg twice daily, or bendroflumethiazide 2.5 mg twice daily. Long-acting agents are preferable, since compliance may be better. Potassium citrate should be added in doses of 15 – 20 mEq twice daily to prevent thiazide-induced hypokalemia and hypocitraturia. A modest sodium restriction is advisable in conjunction with thiazide therapy because excessive sodium intake attenuates the hypocalciuric effect of the drug [127].

Future Treatment of Uncomplicated Stone Disease After Relapse

Some patients may be intolerant of, or may not respond to potassium citrate therapy. Moreover, potassium citrate does not correct magnesium loss in long-term thiazide therapy or hypomagnesiuria that is encountered in 7% of patients with recurrent calcium nephrolithiasis [6]. Potassium-magnesium citrate (K_4MgCit_2 or K-Mag), a new drug under development by the Dallas group, may overcome these problems. Compared to Urocit-K at the same dose of potassium, K-Mag causes a more prominent rise in urinary citrate and pH [128] and a greater inhibition of the propensity for the crystallization of uric acid and calcium oxalate [129]. A recent placebo-controlled, randomized trial indicated that K-Mag is highly efficacious in inhibiting calcium stone formation during a 3-year follow-up. The relative risk of stone-free rate (K-Mag/placebo) was 0.15 (95% confidence interval, 0.05 to 0.44) [7]. Finally, in a randomized, controlled comparison of gastrointestinal tolerance of K-Magvs.Urocit-K, the former drug appeared to be better tolerated [130].

Thiazide may not be effective in all patients with hypercalciuric nephrolithiasis. There may be an attenuation or loss of hypocalciuric action after ≥ 2 years of thiazide treatment because of its inability to correct the underlying intestinal hyperabsorption of calcium [131]. Thiazide may cause hypokalemia, volume depletion, impotence, hyperuricosuria, and hyperuricemia.

Slow-release neutral potassium phosphate (UroPhos-K), a new drug being developed by our group at Dallas, may obviate the problem of thiazide therapy in the future. Its slow release minimizes gastrointestinal side effects, unlike conventional phosphate preparations. It causes a small sustained rise in serum phosphate and a slight parathyroid stimula-

tion within the normal range. Thus, there is suppression of calcitriol synthesis. Calcium absorption is reduced about 50% by inhibition of calcitriol synthesis as well as from the binding of calcium by phosphate in the intestinal tract. Moreover, UroPhos-K increases urinary citrate (from the alkali load) and pyrophosphate (from the rise in orthophosphate excretion), 2 important inhibitors of calcium stone formation, and inhibits crystal agglomeration of calcium oxalate [132].

UroPhos-K treatment in patients with absorptive hypercalciuria produced a substantial decline in the urinary saturation of calcium oxalate at 3-month follow-up [132]. The saturation for calcium phosphate did not change, because the rise in urinary phosphorus was compensated for by a decline in urinary calcium. Unlike thiazide, the hypocalciuric effect remained over 4 years of treatment. This effect is probably a combination of reduced intestinal calcium absorption, reduced skeletal calcium mobilization, and a possible augmented renal calcium reabsorption [133].

Thus, K-Mag and UroPhos-K promise to be useful alternatives or potentially superior agents to be used in lieu of thiazide and potassium citrate, especially in relapse.

Treatment of Other Stone Disease

Treatment of conditions other than uncomplicated calcium stone disease is well established (Figure 8).

If uric acid stones are found, gouty diathesis or conditions causing undue urinary acidity should be suspected. Potassium citrate is the treatment of choice for gouty diathesis. A dosage of 30 – 60 mEq/day in divided doses raises the low urinary pH (< 5.5) to the desired range of 6.0 – 7.0 [134]. Although sodium alkali is as effective as potassium citrate for prevention of uric acid stone formation by increasing urinary pH, it may induce the formation of calcium stones by its hypercalciuric action [135].

The mainstay of managing infection stones is surgical removal of the stone and eradication of urea-splitting organisms. Antibiotics are given before and after surgery to reduce recurrence. Acetohydroxamic acid, a urease inhibitor, reduces urinary saturation of struvite by preventing the formation of ammonium and hydroxyl ions. It may prevent stone growth and sometimes cause dissolution of existing stones. Unfortunately, its use is associated with significant side effects (hemolytic anemia, thrombophlebitis, and neurological disorders) [101].

In patients with cystine calculi and moderate cystinuria (250 – 500 mg/day), high fluid intake and potassium citrate (30 – 60 mEq/day in divided doses) is recommended to maintain urinary pH at a high normal range of 6.5 – 7.0. When further therapy is necessary, the addition of sulfur-chelating agents such as alpha-mercaptopropionylglycine (MPG or Thiola) or penicillamine will reduce cystine excretion. These agents act by complexing cysteine, the monomeric form of cystine. Both drugs are associated with frequent and sometimes severe side effects, including nephrotic syndrome, dermatitis, and pancytopenia. Penicillamine is administered in a daily dose of 1 – 2 g in 3 or 4 divided doses. Thiola (800 – 2000 mg/day in 3 or 4 divided doses) is preferred, because it has a lower toxicity profile than penicillamine [104].

Patients with brushite stone have a high recurrence rate. Distal RTA or primary hyperparathyroidism, the most frequent secondary causes, should be ruled out [100, 136]. If there is no evident secondary causes, these patients may be treated according to the guidelines for uncomplicated stone disease.

If hypercalcemia is found, work-up for primary hyperparathyroidism should be under-

taken. Parathyroidectomy is the optimal treatment for the nephrolithiasis associated with primary hyperparathyroidism. A medical approach with phosphates or estrogens (in postmenopausal women) should be used only when parathyroid surgery cannot be undertaken [137].

Allopurinol treatment should be considered for anyone with hyperuricemia because of the risk of gouty arthritis. It is administered at a dosage of 300 mg/day. Side effects are rare and include a skin rash and a reversible elevation of liver enzymes. In the event of a rash, the drug should be discontinued immediately because it may progress to Stevens-Johnson syndrome.

Finally, the finding of marked hyperoxaluria mandates a search for primary or enteric hyperoxaluria. The established treatment regimen for primary hyperoxaluria is orthophosphate, 1.5 – 2.5 g of phosphorus per day in 3 or 4 divided doses, and pyridoxine 100 mg twice a day. Orthophosphate reduces urinary calcium and augments urinary pyrophosphate. If given in a neutral form, it increases citrate excretion. Thus, the urinary saturation of calcium oxalate is reduced, and the inhibitor activity against calcium oxalate crystallization may be augmented. Pyridoxine may reduce urinary oxalate excretion by reduction of endogenous oxalate synthesis in some patients. Potassium citrate may be a useful therapeutic option in lieu of orthophosphate. Patients should be maintained on these programs as long as complications are controlled and renal function remains stable. If this is not the case, then planning for renal and/or liver transplant is necessary [89, 91].

Specific therapies to correct fat malabsorption such as a gluten-free diet (celiac sprue), pancreatic enzyme replacement (pancreatic insufficiency), or the use of antibiotics (bacterial overgrowth) may be required in some cases of enteric hyperoxaluria. In patients with significant fat malabsorption, a low-fat diet with medium-chain fatty acid supplementation should be instituted to minimize steatorrhea. Medical therapy to prevent stones in this condition is directed at decreasing oxalate absorption and correcting associated metabolic complications. Calcium citrate (400 mg of calcium with meals) may be useful to decrease urinary oxalate by binding oxalate in the intestinal tract. It may raise urinary citrate and pH by providing an alkali load. Careful monitoring of urinary calcium and oxalate should be routine. Magnesium supplements act via an identical mechanism: binding free oxalate in urine. Cholestiramine does not cause a sustained reduction in oxalate excretion. Low urinary pH and hypocitraturia can be treated with potassium citrate 40 – 60 mEq/day in divided doses. Severe cases may require larger doses up to 120 mEq/day. K-Mag, which provides citrate as well as magnesium, should be the logical therapeutic option in enteric hyperoxaluria to correct associated metabolic disturbances [89, 138].

Conclusion

This chapter presents a simplified approach to stone disease. First, obtain a full analysis of urine for stone risk factors to identify environmental or metabolic disturbances. Second, obtain an abbreviated stone risk profile after a dietary modification. Differentiate between patients with uncomplicated calcium stone disease and patients with other stone disease. In the former group, separate patients into hypercalciuric and normocalciuric subgroups. In those with normal urinary calcium, apply potassium citrate therapy. In those with hypercalciuria, treat with thiazide and potassium citrate. For those with multiple relapses, new drugs are under development, particularly potassium-magnesium citrate and slow-release neutral potassium phosphate.

Evaluating Solid and Cystic Lesions of the Kidney

Thomas H. Waid

The presentation of cystic and solid renal lesions differs today from that of 25 years ago. The classic triad of renal cell carcinoma (RCC), flank pain, hematuria, and palpable mass represents a minority of presentations, albeit microscopic hematuria remains an almost universal, often early sign. Because of advances in computerized tomographic imaging technology, detection of incidental tumors serendipitously discovered during screening or other diagnostic examinations is increasing. The paradigm of diagnosis based on clinical presentation followed by excretory urogram (intravenous pyelogram (IVP)) to demonstrate a mass, ultrasound to differentiate solid from cystic lesions and then cyst puncture or angiography has succumbed to computed tomography (CT) and magnetic resonance imaging (MRI). Arteriography, cyst aspiration for cytology and fine needle aspiration biopsy (FNA) are rarely necessary and diagnostic percutaneous renal biopsy almost never needed.

The purpose of this chapter is to characterize the renal mass lesions, cystic and solid, benign and malignant, encountered by the nephrologist and internist and to act as a guide for evaluation of the lesions and possible referral to a urologist for further evaluation and/or operation.

Systematic Evaluation of Renal Mass Lesions

Patients presenting with complaints of gross hematuria, flank pain, or fullness, or those who have persistent microscopic hematuria warrant an evaluation for mass lesions of the urinary tract, particularly if smokers. In the past, renal masses remained undetected until they grew to be quite large, producing local symptoms. However, the routine use of ultrasonography and CT allows earlier detection.

Excretory Urography (Intravenous Pyelography)

When a patient presents with clinical symptoms, intravenous excretory urography, despite its lack of sensitivity and specificity, remains the initial study of choice. It is an anatomic as well as a physiologic study with a time-honored role in evaluating hematuria; however, small masses, solid or cystic, may be missed. The urogram can establish the presence of a mass; it cannot indicate what the nature of the mass might be. Radiographic signs such as distortion, elongation, and amputation of the calices can occur with renal

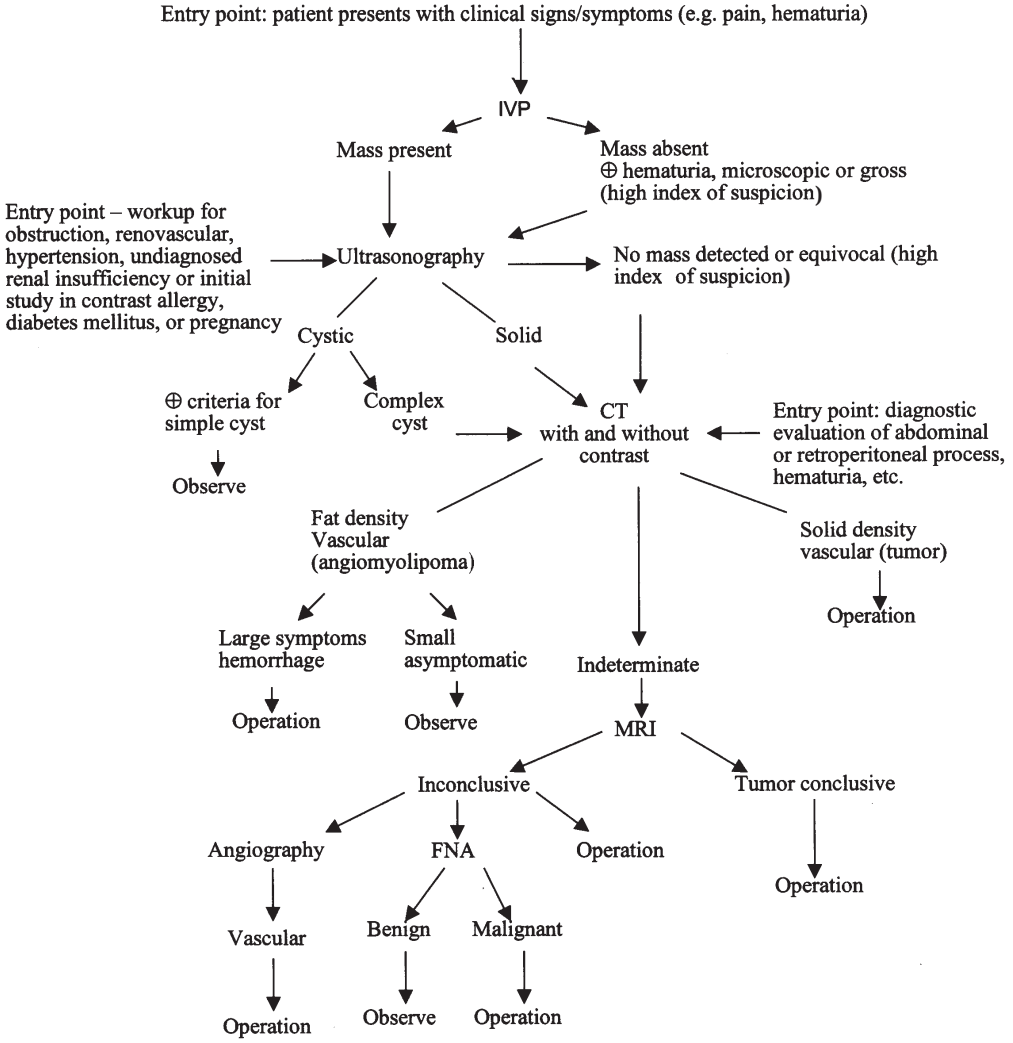

Figure 1. Algorithm for evaluating renal masses with 3 entry points: 1) IVP (urography) for clinical signs and symptoms; 2) sonography for evaluation of other clinical conditions or if the patient is contrast allergic, diabetic or pregnant; 3) CT for evaluation of other abdominal or retroperitoneal processes or hematuria. Entry point: patient presents with clinical signs/symptoms (e.g. pain, hematuria).

tumors or cysts. The deformity of the calices, infundibula, and pelvis can be identical, except that cysts do not commonly amputate the calices, whereas tumors do [1]. Both cysts and tumors can likewise distort the kidney capsule, giving it an irregular outline on urographic imaging; however, so can an area of compensatory hypertrophy [1]. Truly, excretory urography continues to occupy an important role in initial screening, despite the availability of newer imaging techniques. Additionally, solid and cystic renal masses may be discovered when ultrasonography or CT has been employed in other diagnostic en-

deavors. This may change the starting point of the algorithm and excretory urography may be unnecessary. A systematic diagnostic approach to the renal mass lesion is seen in Figure 1.

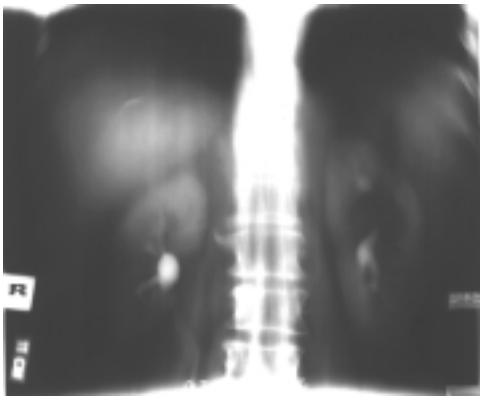

Figure 2a. Benign simple renal cyst. a) 71 yo white female with squamous cell carcinoma of the rectum. An IVP was performed to locate the ureters before surgery. It displayed a normal right kidney and a lucent filling defect in the left kidney with pressure deformation of the collecting system. b) Ultrasound reveals a sharply demarcated, echo-free mass located in the upper pole of the left kidney. The walls are thin. There are no calcifications or internal echoes, and enhanced sound transmission through the cyst is evident.

Ultrasonography

Ultrasonography is the study most widely used to determine whether a mass lesion demonstrated on excretory urography is solid or cystic. It may also be used as an initial screening technique in patients with chronic renal failure, diabetes mellitus (DM), pregnancy, or contrast allergy [2]. If a mass fulfills all the strict criteria for a simple cyst, such as a round or oval shape with through transmission without acoustic shadows off of any internal echoes and a strong posterior wall, there is no need for further workup in the otherwise asymptomatic patient (Figure 2a, b). Failure to fulfill these criteria warrants further evaluation by CT. Percutaneous cyst puncture and aspiration cytology have largely been abandoned because the results were frequently nondiagnostic except in simple benign cysts, which can be classified sonographically or by CT [3]. Finally, masses seen on urography may not be detected by ultrasound if they are isoechoic with the renal parenchyma. Examples are fetal lobulation and a hypertrophied column of Bertin. Whereas radionuclide scanning was used in the past for imaging these structures, contrast-enhanced CT is now the preferred test.

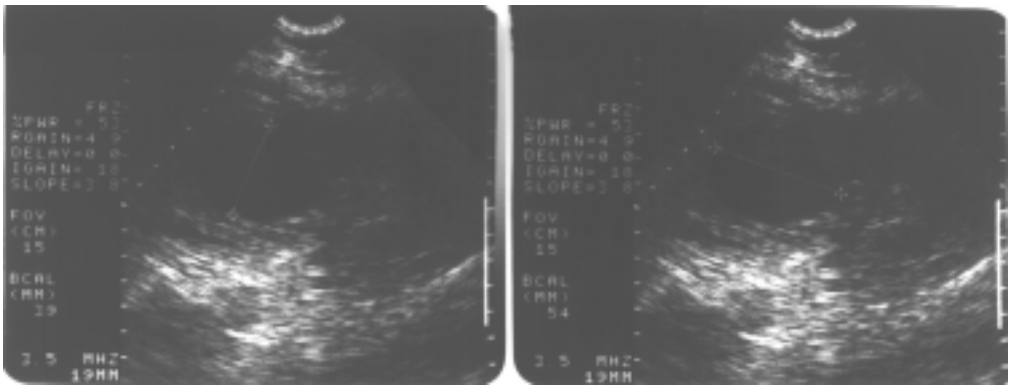

Figure 2b. Benign simple renal cyst. b) Ultrasound reveals a sharply demarcated, echo-free mass located in the upper pole of the left kidney. The walls are thin. There are no calcifications, or internal echoes, and enhanced sound transmission through the cyst is evident.

Computed Tomography (CT)

Presently, CT scanning has assumed the preeminent role in imaging renal masses and complex cysts. CT scanning, with and without oral and intravenous contrast, is more sensitive in detecting small renal masses, the presence of fat within tumors, the overall density of the mass, and the extent, if any, of retroperitoneal involvement. As stated above, CT scanning has essentially eliminated cyst puncture and aspiration cytology and has all but eliminated arteriography, with a few notable exceptions. The limitations of CT are few, but it is important to remember that differentiation of atypical angiomyolipomas, complex cystic masses, and inflammatory or infectious masses from malignant solid tumors may not be possible. Under these circumstances, further imaging with MRI, arteriography, or FNA cytology may be indicated, albeit rarely.

Magnetic Resonance Imaging (MRI)

MRI as an imaging tool offers some advantages over CT and is especially useful when the use of intravenous contrast is contraindicated. MRI is useful in evaluating vascular and adjacent organ invasion. Enhancement with gadolinium contrast allows detection of renal masses of < 3 cm in size. Because of its expense, it remains an adjunct to CT.

Arteriography

Arteriography remains as a useful test in the evaluation of indeterminate renal masses. It is useful when nephron-sparing surgery is being considered, because it best defines the blood supply to the tumor and normal parenchyma. Digital subtraction angiography in combination with CT has been advocated as a suitable replacement for the more invasive and risky arteriogram, and appears to provide acceptable anatomic definition [4].

Solid and Cystic Masses

Whenever a renal mass is encountered on an excretory urogram or incidentally during sonography or CT, the immediate question is whether it is solid or cystic. Both types of lesions may be benign or malignant. Some may be characterized radiographically and need only be followed at specified intervals, whereas others require further evaluation and/or surgical removal.

Solid renal mass lesions that are evident on urography, sonography, and CT are generally upper urinary tract and retroperitoneal neoplasms. They may be benign or malignant and are listed in Table 1. Individual lesions and their evaluation will be discussed below. It is critical that the solid mass be characterized as malignant or benign; modern diagnostic technology has decreased to < 10% the number of masses remaining indeterminant before definitive therapy. Multiple solid tumors may be associated with multiple renal cysts in three conditions: chronic renal failure with or without dialysis, von Hippel-Lindau syndrome (vHL), and tuberous sclerosis (TS).

Cystic lesions of the kidney remain both a commonly encountered and complicated condition. Benign renal cysts still account for 55% of renal masses first seen on excretory urography, and can be defined by ultrasonography or CT [5]. Although modern imaging techniques usually allow diagnosis, the morphology can be quite confusing, and complicated cystic lesions can present dilemmas in

Table 1. Classification of Urinary Tract and Retroperitoneal Neoplasms

Renal - Primary Benign	*Retroperitoneal*
Adenoma	Lipoma benign
Angiomyolipoma-hamartoma	Lymphoma → malignant
Fibroma	
Hemangioma	Sarcoma → malignant
Juxtaglomerular tumor	
Leiomyoma	
Lipoma	
Oncocytoma	
Renal – Primary Malignant	*Renal – Secondary Malignant*
Renal cell carcinoma – hypernephroma	Retroperitoneal sarcoma
Urothelial carcinoma	Carcinoma – spread from following:
Transitional cell	Pancreas, colon (direct spread);
Squamous cell	lung, breast, GI tract (hematogenous spread)
Adenocarcinoma	
Sarcoma	
Adult Wilms' tumor	Lymphoma, leukemia and myeloma (plasmacytoma)

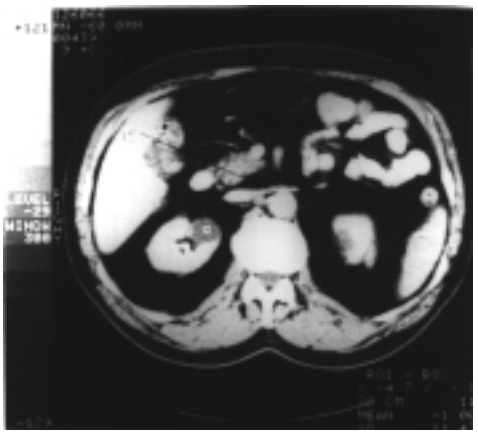

Figure 3. Benign renal cyst. The patient, a 50 yo white male, presented with hematuria and no other symptoms. CT shows an oval-shaped cystic structure. The kidney is not enlarged, and there is no distortion of the renal outline. The density of the mass is uniform with homogenicity of contents and overall less dense than the renal parenchyma. The incidence of simple cysts is high, occurring in > 50% of adults over 50 yo.

diagnosis and management. Fortunately, the work of Bosniak has provided some clarification and classification of cystic lesions [3, 6 – 8]. The Bosniak classification, first proposed in 1986, places cystic renal lesions into 4 categories (Table 2). As previously described, a round or ovoid lesion with through sonography without internal echoes and strong acoustic shadows off the back wall requires no further evaluation. However, more complex lesions require CT. Most category I, minimally complicated category II, obvious category III, and category IV lesions can be diagnosed with enhanced scans. There are some complicated category II lesions and equivocal category III lesions that still present a diagnostic dilemma, especially when surgical exploration is being contemplated [6]. Examples of benign cysts are seen in Figure 2a and b and Figure 3. A more complicated cyst is seen in Figure 4.

The technique of CT scanning is also important, especially when renal cysts are dis-

Table 2. Bosniak Classification of Cystic Lesions of the Kidney

- Category I: Benign – do not require operation
  Simple, uncomplicated, benign cysts
  Round or ovoid with thin walls
  No internal septae or calcification
  Fluid in cysts with attenuation of clear fluid
- Category II: Benign but not simple – do not require operation, but may require 6 month follow-up
  Slightly more complicated cysts
  One or more septae in cyst
  Thin areas of calcification in cyst wall or septae
  Fluid in cyst with higher attenuation than clear fluid
- Category III: Some characteristics of cystic neoplasms – operation required
  More complicated cyst with thickened wall or septae
  Thickened areas of calcification
- Category IV: Clearly malignant lesions – operation required
  In addition to Category III criteria, these lesions have solid elements that enhance with contrast material

covered during abdominal scanning using intravenous and/or oral contrast where preliminary unenhanced scans are not available for comparison. In such a situation, scanning following bolus contrast administration is not done and the tubular nephrogram phase is missed. Additionally, thin (5 mm) sections, often needed for high resolution of more complicated cysts, are often unavailable. In such cases, if the original study is inadequate, it needs to be repeated, both unenhanced and enhanced, with attention to the tubular nephrogram phase and with thin sections through the renal parenchyma. One should not attempt to classify cysts with inadequately performed examinations [9, 10].

In a recent presentation by Levy et al. at the Radiological Society of North American, December 1996, the Bosniak classification was reported to display a diagnostic accuracy of 100% in 88 patients with cystic renal lesions. All category I and category II lesions were benign; all category IV lesions were malignant, as were 46% of the category III lesions. Obviously, the classification can be very operator dependent, and the area of greatest diagnostic uncertainty arises between catego-

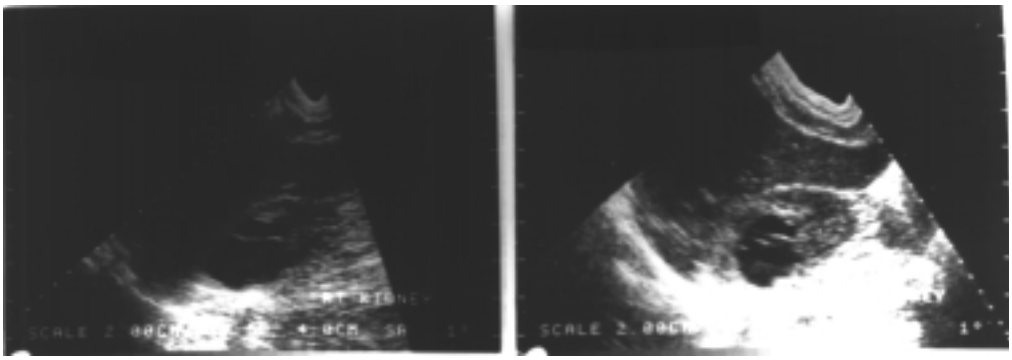

Figure 4. Multilocular cyst. This is a 34 yo white male with a 2 day history of right flank pain radiating to his right testicle. Evaluation for a kidney stone began due to his history and the presence of microscopic hematuria. An IVP revealed irregular calcified densities in the right pelvis and a 3 cm radiolucent area in the midportion of the right kidney. Ultrasound revealed a multilocular cyst with internal septae. CT was recommended and the patient was followed every 6 months.

ries II and III. Operator experience, CT technique, and use of other imaging studies such as MRI are all important in rendering a diagnosis, and clinical criteria may often be the deciding factor [11]. Clinical information such as patient age, history of infection, heart disease, hematuria, and lesion size are not only important in diagnosis, but also deciding between observation or exploration.

Acquired Renal Cystic Disease

Nephrologists should be especially aware of acquired renal cystic disease (ARCD) in their dialysis population. Approximately 45% of patients acquire multiple renal cortical cysts, with a 9% incidence of renal tumor development – 2500 times greater than the normal population. These patients may present with gross or new-onset microscopic hematuria. An enhanced CT scan should be done [12]. Rarely, the patients develop tumor-associated secondary erthyrocytosis, which may be masked by erythropoietin therapy. CT reveals contrast-enhancing solid renal masses among renal cysts. These masses may be single or multiple, unilateral or bilateral. There is a 6% rate of metastases in ARCD patients with renal tumors (0.54% of all patients with ARCD). The rate of tumor development correlates directly with the duration of chronic hemodialysis, with patients of < 3 years duration having a 43.5% incidence, increasing to 79.3% in those patients dialyzed > 3. Patients with chronic renal failure who do not require dialysis also have an increased propensity for developing renal cysts, as do patients on peritoneal dialysis. The latter patients do not seem to be predisposed to tumor formation [13]. Surgical resection of these masses is required, and since these tumors tend to be multiple and bilateral, native nephrectomy of both kidneys is recommended.

Benign Renal Tumors

Benign tumors of the kidney are common. Because they are usually asymptomatic, they are detected incidentally or at autopsy (Table 1). Abdominal sonography and tomography have uncovered these otherwise “silent” lesions which must be differentiated from malignant renal masses.

Adenoma

Renal cortical adenomas are the most common solid renal parenchymal lesions [14]. Adenomas are usually < 1 cm in size and are located exclusively in the cortex [15]. The etiology of the adenoma is unclear, although there is an association with smoking, dialysis, and arteriolar nephrosclerosis, as well as trisomy 7 and 17 and deletion of the Y chromosome [16, 17]. Adenomas are rarely symptomatic and paraneoplastic syndromes are not encountered. However, controversy persists in the literature as to the true clinical nature of these neoplasms. Indeed, there are suggestions that adenomas are not histologically distinguishable from carcinomas [18]. These tumors occur in the same 2:1 male:female ratio and are rarely found adjacent to a renal cancer, except in patients with acquired renal cystic disease or vHL. Because they are histologically indistinguishable from larger carcinomas, urologic oncologists recommend removal. Urologic referral of the patient with a small solid mass lesion thought to be adenomatous is important, because it is not possible to differentiate adenomas from carcinomas preoperatively based on size, symptoms, or radiographic imaging. These lesions should be considered malignant until proven otherwise.

Angiomyolipoma-Hamartoma

This benign tumorous lesion is a hamartoma of the renal parenchyma. It is unencapsulated and characterized by three histologic components: mature fat cells, smooth muscle, and abnormal vessels. The tumor may extend into the collecting system or perirenal fat, but there is no distant metastasis [19]. Hemorrhage and necrosis are common, and, very rarely, malignant degeneration of angiomyolipoma into a sarcoma with distant metastasis has been reported [20]. Finally, RCC and hamartoma may coexist in the same kidney.

Tuberous sclerosis (TS), an autosomal dominant condition affecting 1/150,000 live births, is associated in > 80% of patients with renal hamartomas. Brain gliosis, mental retardation, seizures, adenoma sebaceum of the face, submucosal fibromas, and hamartomas of the retina, lungs, liver, pancreas, bone, and kidney characterize the syndrome [22]. In these patients, the tumors are usually bilateral, small, and asymptomatic. Eighty percent of patients with renal hamartomas do not have TS. In these patients, usually women in the fourth to sixth decades, the lesions are larger, commonly unilateral, and present with symptoms caused by spontaneous rupture and retroperitoneal hemorrhage. Flank and abdominal pain occur in 50% of patients, combined with a palpable mass and hematuria. The diagnosis of hamartomas relies on the algorithm previously outlined. Intravenous urography with nephrotomography displays a solid mass in which malignancy cannot be established. Ultrasonography reveals high-intensity internal echoes suggesting fat (Figure 5). CT reveals the fat content (which has a negative density of -20 to -80 Hounsfield units), which is pathognomonic for hamartoma when it is observed in the kidney [23] (Figure 3a, b; Figure 6). Additionally, MRI may be used to aid in an equivocal diagnosis because of the high signal intensity of fat on T1-weighted images. Because all of the above diagnostic modalities rely on the proportion of fat within the tumor, rarely a small number of cases will remain uncertain. Only then should FNA biopsy be considered [24].

Figure 5. Hamartoma (angiomyolipoma). 68 yo white female referred for microscopic hematuria and proteinuria. History and physical exam were unremarkable. The urinalysis disclosed 2+ proteinuria and 5 – 10 RBC/HPF. IVP was read as being normal; however, abdominal ultrasound revealed a 2x2 cm echogenic focus with smooth margins and increased through transmission. Subsequent CT revealed an irregular 2x2 cm low-density lesion in the mid to lower pole of the left kidney without cystic features. MRI confirmed a 2 cm lesion with the intensity of fat on all pulse sequences.

The treatment of renal hamartomas depends on the size of the lesion. Asymptomatic tumors < 4 cm in size are followed by yearly sonograms. If the tumors are > 4 cm but asymptomatic, the elective follow-up may still be done yearly or semiannually. Fifty percent of these tumors will expand, requiring embolization or nephron-sparing surgery to prevent loss of renal parenchyma [25]. Finally, larger angiomyolipomas can hemorrhage into the kidney and/or retroperitoneum with life-threatening sequelae. In such cases, radical nephrectomy is the treatment of choice, although partial nephrectomy may be considered if the patient is known to have an angiomyolipoma preoperatively.

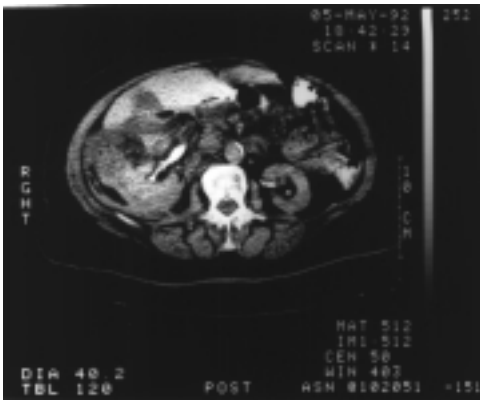

Figure 6. Hamartoma (angiomyolipoma). 70 yo white female with acute onset of right flank pain and hypotension. Emergent CT revealed a high density collection in the right perinephric space extending into the anterior and posterior pararenal spaces consistent with acute hemorrhage. There is fat density at the epicenter of the hemorrhage. This patient then had angiography, which revealed a large feeding vessel to a hypervascular mass but without the arteriovenous shunting seen in RCC. Because of the acute hemorrhage and hemodynamic instability, an operation was performed.

Oncocytoma

This benign renal tumor was not identified until recently [26]. Oncocytomas account for 5 – 7% of all renal tumors, or about 750 cases yearly. Asymptomatic in nature and usually discovered incidentally, these tumors affect patients in the fifth decade, and there is a 2:1 male:female predominance. In the latter 2 aspects, oncocytomas are similar to RCC. Unlike RCC, there are few distinguishable clinical signs and symptoms. Fewer than 20% of patients develop hematuria and the paraneoplastic syndrome is absent. Unlike the hamartoma, there are no characteristic features on urography, sonography, or CT.

These tumors are usually solitary and unilateral, although bilateral and multilateral cases have been reported. Histologically, oncocytes are large, well-differentiated cells with intensely eosinophilic cytoplasm packed with mitochondria. They rarely display mitosis or invade adjacent structures, and although, the exact cellular origin is unknown, they resemble proximal tubular cells [27]. Oncocytomas containing only pure oncocytoma cells (grade I) are benign with no metastasis, and no deaths due to tumor have been reported. Metastases and death have been reported in 15% of patient with so-called grade II tumors, which likely represents mixed tumors with elements of renal adenocarcinoma present. Because pure oncocytomas can neither be characterized radiographically nor can RCC be eliminated by FNA, radical nephrectomy remains the treatment of choice [28, 29].

Other Benign Renal Tumors

The remainder of the benign renal tumors – fibromas, lipomas, leiomyomas, hemangiomas, and juxtaglomerular cell tumors – are rare. Fibromas vary in size, exist mainly in females, arise mainly in the medulla, and therefore constitute the most common benign tumor of mesenchymal origin. Most of these tumors are small, totally asymptomatic, and found at autopsy [30]. Lipomas are usually found in middle-aged females. They arise form the kidney capsule and are composed of mature adipocytes [31]. When the tumor is large, the diagnosis may be made by CT due to the attenuation of fat. Hemangiomas are uncommon, but may be responsible for hematuria of an undetermined cause. They are usually < 2 cm in diameter, and occasionally multiple and bilateral. Diagnosis is not confirmed by sonography or by CT, but angiography is helpful in this regard [32].

Leiomyomas tend to be < 1 cm in size and arise from the kidney capsule or renal vessels. The lesions rarely require treatment despite the common occurrence of multiple tumors.

They usually occur in young white females, and hematuria and suggestion of a flank mass are the most common clinical presentations [33]. Radiographic techniques cannot provide a definitive diagnosis. If an operation is needed, radical nephrectomy is the procedure of choice, unless an intraoperative diagnosis can confirm the benign process and allow a renal-sparing operation.

Juxtaglomerular cell tumors are rare benign renal tumors with < 40 cases reported. Because they secrete renin, the patient presents with severe systolic and diastolic hypertension, hypokalemia, metabolic alkalosis, and elevated plasma renin and aldosterone activity. Patients are usually young, 70% being < 25 years of age, and two-thirds are female [34]. CT is the most helpful imaging method, with angiography being useful as a means of excluding renovascular hypertension. Total or partial nephrectomy is curative. As with other mass lesions, the latter can be accomplished only when the benign nature of the mass can be established preoperatively or intraoperatively.

Primary Malignant Renal Tumors

The primary malignant tumors include renal cell carcinomas, transitional cell carcinoma of the renal pelvis and collecting system, and more rarely squamous cell and adenocarcinoma of the urothelium, sarcoma and adult Wilms tumor. RCC accounts for about 90% of primary renal tumors and transitional cell carcinoma for another 8%. The rest share the remaining 2% of primary renal malignancies. These tumors present as solid masses or as enhancing elements within cystic lesions, and the treatment is surgical removal. Detailed discussion of the etiologies and pathogenesis of each lesion is beyond the scope of this text. In classifying each tumor, however, pertinent discussion of the clinical presentation, radiologic evaluation, diagnosis, and treatment will be presented.

Renal Cell Carcinoma (RCC)

Accounting for about 90% of all upper urinary tract malignancies and 2 – 3% of all adult malignancies (excluding skin cancer), RCC represents the ninth most common malignancy in white men and the thirteenth most common in women. The majority of patients are diagnosed in the sixth to seventh decades.

Both hereditary and sporadic forms of RCC exist. Familial nonpapillary RCC is associated with a chromosomal translocation that is inherited in an autosomal dominant fashion [35]. RCC is seen in 45% of patients with vHL, an autosomal dominant disease [35]. A third form of familial RCC, known as hereditary familial papillary RCC, has been described [37]. This disease is often bilateral and multifocal, and occurs in younger patients.

The etiology of RCC is unknown, but it appears to be associated with cigarette smoking, and the risk increases proportionately to the duration and number of cigarettes smoked. Additional risk factors for RCC include obesity, especially in women, and diuretic use, which imparts a 3-fold increased risk [40, 41]. Occupational exposure to asbestos may increase the risk of RCC, and leather workers and paperboard printing workers likewise are at increased risk [42 – 44].

Presentation and Diagnosis

RCC can present in a variety of ways. The classic triad of flank pain, hematuria, and a palpable mass is exhibited < 10% of the time, and with current imaging studies, many tu-

mors are being discovered incidentally. Hematuria remains a reliable presenting sign; 60% of patients will display gross or microscopic total painless hematuria. The development of flank pain or presence of a palpable mass suggests the presence of a tumor in an advanced stage. Additionally, the presence of a new variocele, usually on the left, suggests vena cava thrombus. Urine cytology is of little benefit in diagnosing RCC.

RCC may have protean manifestations and paraneoplastic syndromes unrelated to metastases occur in 10 – 40% of patients. Fever occurs in 20% of patients, while hypertension and anemia occurs in 20 – 40% of patients. Secondary erythrocytosis and hypercalcemia occur in 3 – 5% of patients with RCC [46 – 49]. Hepatic dysfunction occurs in 10 – 15% of patients. The alkaline phosphatase is elevated in 15% of patients, as is the prothrombin time and the α2-globulin. This paraneoplastic syndrome, unrelated to metastases, has been named Stauffer's syndrome and portends a poor prognosis [50].

The diagnosis of RCC relies on the algorithm shown in Figure 1. Patients presenting with hematuria, microscopic or gross, with or without constitutional or paraneoplastic syndrome, should undergo excretory urography with nephrotomography. A mass on this study dictates ultrasonography to determine whether it is cystic or solid. Simple cysts by ultrasound criteria terminate the workup (Figure 7a, b). Complex or indeterminant cysts or solid masses require CT, and so it is for RCC. CT has replaced angiography of solid lesions seen on ultrasonography. Rarely, angiography is needed to demonstrate the arterial supply of a tumor. In these cases, the angiogram demonstrates neovascularity, arteriovenous fistulae, and venous pooling in 85 – 90% of the tumors. These tumors likewise enhance with CT contrast infusion. Hypovascular RCCs constitute 10% of tumors and neither displays the above angiographic findings, nor enhances with CT contrast (Figure 8).

Figure 7a. RCC. White 59 yo white male presenting with gross and microscopic hematuria and right flank discomfort. a) IVP revealed distortion of the calices in the mid portion of the right kidney with a filling defect in the right renal pelvis. Ultrasound showed a solid mass.

The current accuracy of CT is approximately 95% when the typical features of RCC are present [52]. Usually, the mass is isodense or hypodense when compared to the renal parenchyma (15 – 40 Hounsfield units), enhances less than the normal parenchyma with contrast infusion, but may initially appear hyperdense due to its significant vascularity [53]. Invasion of the mass into the surrounding normal parenchyma and central calcification with soft tissue extending beyond the calcification are also highly suggestive of RCC.

When CT cannot be used in patients (e.g. contrast allergy or renal failure) or when CT findings are equivocal, MRI can be used to diagnose RCC with up to 95% accuracy [54].

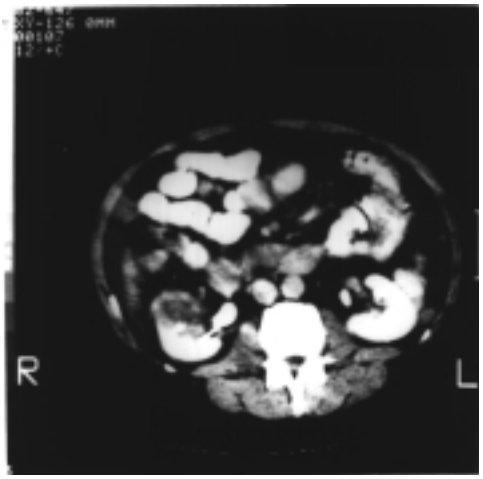

Figure 7b. RCC. White 59 yo white male presenting with gross and microscopic hematuria and right flank discomfort. B) CT confirmed a contrast-enhancing mass in the right kidney without retroperitoneal extension or involvement of the inferior vena cava.

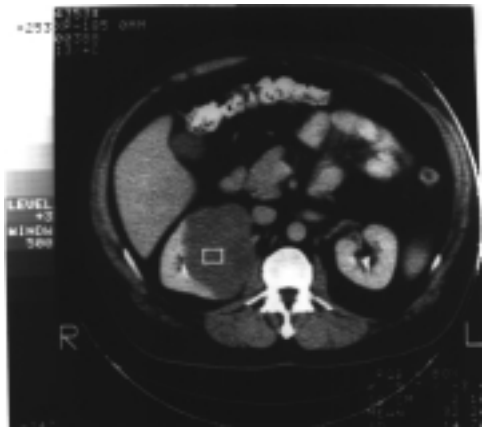

Figure 8. RCC (nonenhancing). A 57 yo white male admitted for evaluation of painless gross hematuria. No other symptoms were reported, and the physical examination was unremarkable. IVP revealed a large 10x12 cm mass in the medial upper pole of the right kidney. Ultrasound revealed an echogenic solid mass. CT revealed a nonenhancing low-density mass measuring 10x12 cm in the upper pole of the right kidney distorting the architecture of the parenchyma and calices. There is no involvement of the inferior vena cava and no adenopathy. In this case, an arteriogram was done confirming a hypovascular to avascular renal mass that distorted the normal renal vasculature. Removal of the mass was indicated.

On T1-weighted images, RCC imparts a signal intensity midway between that of cortex and medulla, and most RCC are hyperintense on T2-weighted images. Currently, MRI serves as a useful adjunct to CT.

Only in rare instances can a diagnosis not be made by imaging techniques. In these cases, FNA can be attempted [53]. If the mass is solid and there is a suspicion of malignancy, then proceeding to surgical exploration or nephrectomy, even without FNA, is warranted.

Renal Urothelial Cancer – Transitional Cell Carcinoma of the Collecting System and Pelvis

Transitional cell carcinoma of the upper tract accounts for about 7% of upper tract tumors, but for only 5% of all transitional cell urothelial tumors. The peak incidence is in the sixth to seventh decade with a 3:1 male-female predominance. Bilateral presentation occurs in 2 – 4% of patients. In patients with Balkan and analgesic abuse nephropathy, the male-female ratio is more equal and the incidence of bilateral presentation is higher.

The etiology of upper tract urothelial cancer is unknown, but several risk factors have been identified. Cigarette smoking, caffeine ingestion, exposure to chemicals used in the tile and rubber industries, chronic urinary infection, analgesic abuse, and Balkan nephropathy have been implicated in urothelial cancer [56, 57].

Patients present with microscopic or gross hematuria 75 – 95% of the time and with total hematuria on the 3 glass test, not unlike RCC

[58]. Flank pain may occur in 30 – 40% of patients, but a palpable flank mass occurs only in < 15% of patients. Constitutional symptoms (fever, anorexia) are late events in 7 – 10% of patients and suggest disseminated disease.

Evaluation often begins with excretory urography workup for hematuria. An abnormal filling defect intrinsic to the collecting system is present in 50 – 75% of studies where urothelial cancer is involved. Complete obstruction of the renal pelvis resulting in nonvisualization occurs in 10% of the urograms. Other causes of filling defects include nonopaque renal calculi, blood clots, sloughed papilla, fungus balls, or a hemangioma. Ultrasonography is helpful in differentiating a stone from a tumor but has no further value.

CT is a useful diagnostic test in urothelial tumor and is used to delineate pelvic filling defects when the mass is large (Figure 9a). In comparison to normal parenchyma, urothelial tumors appear hypodense upon contrast administration. This also aids in differentiation from RCC [59, 60]. MRI is of undetermined value in the evaluation of urothelial tumors. Angiography may differentiate RCC from urothelial carcinoma (the latter will not have the hypervascularity of the former) but is more invasive and expensive than CT (Figure 9b). The treatment of choice is nephroureterectomy, because a urothelial tumor must be considered a tumor of the entire urothelium.

Figure 9a. Urothelial cancer (transitional cell). A 78 yo white male with painless gross hematuria, no history of trauma, and an unremarkable physical examination. a) CT of the abdomen shows right-sided hydronephrosis with high attenuation in the collecting system, probably representing hemorrhage. From this study, a mass could not be excluded.

Other Primary Malignant Tumors

Primary renal sarcomas and adult Wilms tumor account for only 2 – 3% of primary renal malignancies. There are no significant distinguishing features to differentiate them from RCC, and surgical removal is always indicated. Sarcomas are thought to arise from the renal capsule or renal vasculature. Leiomyosarcoma is the most common, constituting 60% of renal sarcomas with liposarcomas accounting for another 20% [61, 62]. Malignant fibrous histiocytomas (fibrosarcomas) rarely arise in the kidney and cannot be preoperatively differentiated from RCC. Finally, hemangiopericytoma, originating from pericytes which envelope capillaries and aid in blood flow, accounts for 20 reported cases [63].

Renal sarcomas often grow to be quite large and present with symptoms not unlike other renal tumors, including flank pain or abdominal pain, hematuria, and a palpable mass. Radical nephrectomy is indicated in all sarcomas and the prognosis is generally poor, especially for malignant fibrous histiocytoma [61].

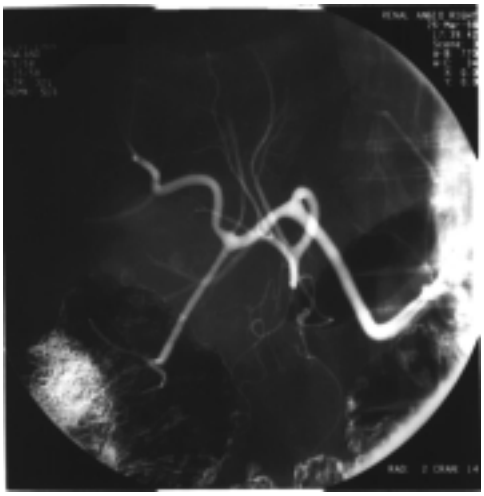

Figure 9b. Urothelial cancer (transitional cell). A 78 yo white male with painless gross hematuria, no history of trauma, and an unremarkable physical examination. b) A right renal arteriogram was performed showing fine neovascularity in the region of the right uretero pelvic junction with splaying of the segmental renal arterial branches. There are no underlying arteriovenous malformations as with renal cell carcinoma.

Primary Retroperitoneal Tumors

Benign retroperitoneal tumors account for only about 20% of retroperitoneal masses. For the most part, they are the benign counterparts of more malignant processes and include lipomas and leiomyomas. The majority of retroperitoneal masses are malignant with 80 – 90% being lymphomas and sarcomas. The most common sarcoma arising from the retroperitoneum is liposarcoma followed by fibrosarcoma and leiomyosarcoma [64]. As with sarcomas of the kidney, retroperitoneal sarcomas do not produce symptoms until they are large, at which time abdominal pain and a palpable mass may be evident. The patient may have the constitutional symptoms of fever, weight loss, and malaise. CT is the most valuable imaging study, and radical resection with wide margins is the treatment of choice for sarcomas, whereas lymphomas are best treated with chemotherapy and/or radiotherapy.

Renal Masses Due to Infection: Xanthogranulomatous Pyelonephritis and Malakoplakia

Xanthogranulomatous pyelonephritis is a specific presentation of chronic recurrent bacterial pyelonephritis. It occurs mostly in the elderly, with 70% of the 300 cases reported occurring in women [66]. Its presentation may be similar to malignant renal tumors, in that there may be recurrent flank pain, constitutional symptoms such as fever, weight loss, malaise, fatigue, hematuria, and anemia. Hepatic enzyme elevation occurs in 15 – 25% of patients [67]. Pyuria exists in 75% of patients, and urine cultures are positive for *Proteus mirabilis* in 66% of patients, *E. coli* and *Klebsiella sp* in 33% of patients, and *Staphylococcus aureus* in the remaining few. Multiple pathogens can be present in about one-fourth of the patients, albeit some patients present with culture-negative urine despite ongoing disease activity [67, 68]. Patients have a history of recurrent urinary tract infections (UTI) often complicated by struvite calculi and/or obstruction. Intravenous urography may show a mass with calcific densities present. The mass may be cavitary, have a cystic appearance, and must be differentiated from a malignant tumor. Notably, urography may reveal a nonfunctioning kidney in 80% of patients [67]. Sonography reveals a solid or sometimes cystic structure with distorted architecture, with or without obstruction, frequent echogenic shadows characteristic of stones, and echogenic amorphous material with some attenuation of sound distally. CT reveals an enlarged kidney with distorted architecture, low density due to the fat content,

the presence of stones, and poor to absent enhancement. Differentiation cannot be made from RCC, and MRI is of little added value. The treatment should be surgical removal, at which time a pathologic diagnosis can be made. Fortunately, the disease rarely involves both kidneys.

Malakoplakia is a rare granulomatous disease of uncertain etiology that occurs in the same clinical setting as Xanthogranulomatous pyelonephritis. Over 200 cases have been reported. Unlike patients with xanthogranulomatous pyelonephritis, patients with malakoplakia usually have positive cultures for E. coli rather than Proteus mirabilis, and the disease is bilateral in 50% of patients [69]. Fever and flank pain are present in upper tract malakoplakia, and a palpable mass may be present [70]. Excretory urography reveals enlarged kidneys with distorted architecture and multiple filling defects. CT is relatively unhelpful in rendering a specific diagnosis, and exploration or removal of the lesion imparts both diagnosis and treatment.

Summary

In conclusion, greater than 90% of renal masses can be diagnosed by radiographic techniques using the algorithm developed over the last 25 years and discussed in this chapter. FNA biopsy is rarely needed, but may be used if the diagnosis is unclear and a renal sparing operation rather than radical nephrectomy is being considered. Simple cysts (Bosniak class I) can be reliably diagnosed by ultrasonic and CT imaging and should be left alone. More complicated class II lesions and some class III lesions should be followed, or in the latter case explored or removed, because almost 50% are malignant. Patients with cysts with contrast-enhancing elements (class IV) and solid tumors should undergo an operative procedure, unless the mass is a lymphoma or can be proven to be benign radiographically, as is the case with a renal hamartoma (angiomyolipoma).

Acute Renal Failure

Sean Leavey and David Humes

Introduction

Acute renal failure (ARF) is a common clinical syndrome characterized by an abrupt deterioration in kidney function resulting in abnormalities in volume-regulatory, metabolic-regulatory, excretory, and endocrine functions. At presentation, ARF is roughly evenly divided between patients who are oliguric (produce < 400 mL/day urine output) and those who are nonoliguric (produce > 400 mL/day urine output). Most clinicians would accept a rise in the serum creatinine concentration of > 0.5 mg/dL/day and a rise in the blood urea nitrogen (BUN) level of > 10 mg/dL/day over several days as diagnostic of ARF. Many definitions can and have been proposed for ARF. In one review of 28 different studies, no two used the same diagnostic criteria [47]. It is not clear, in fact, whether an optimal definition exists. The syndrome of ARF has multiple causes, diverse manifestations, and a clinical presentation covering a continuum from mild to life-threatening disease. A patient may progress from normal renal function to dialysis-dependent ARF within a few days.

ARF may evolve from diminished renal blood flow (RBF), termed prerenal functional ARF; from an acute severe parenchymal insult, termed intranenal structural ARF; or from obstruction to urine flow termed postrenal obstructive ARF. Intrarenal ARF is further characterized according to the site of injury as a primarily vascular, glomerular, tubular, or interstitial process. The relative contributions of different etiologies to the development of ARF vary between community-based and hospital-based populations; and within the hospital, between medical intensive care unit, surgical intensive care unit, and nonintensive care unit populations. Prerenal azotemia, for instance, accounts for some 70% of community-acquired and 40% of hospital-acquired ARF. Intrarenal causes account for at least 50% of hospital-acquired ARF but are less common in community-acquired cases.

ARF is present on admission to hospital in 1% of cases and further complicates up to 5% of admissions. The mean age of affected individuals has increased such that 36% of patients in one recent hospital survey were > 70 years old at presentation [37]. Despite decades of improvements in the provision of intensive care and specifically in the provision of renal replacement therapy, the morbidity and mortality associated with ARF remains extremely high. The percentage of patients with ARF requiring dialytic intervention ranges from 20 – 60%. Of those requiring dialysis who survive, 12 – 33% have been reported to require long-term renal replacement. The mortality in dialysis-requiring ARF is generally reported to be ≥ 50%, while the mortality in those admitted to the hospital with prerenal azotemia is approximately 7%. For example, a recent cohort analytic study reported mortality rates of 62%, 31%, and 7% in matched groups who developed dialysis-requiring, nondialysis-requiring, or no ARF, following a contrast procedure [36]. A mortality rate of 63.7% was noted in those with

dialysis-requiring ARF vs. 4.3% in those without ARF in a prospective cohort study of 43,642 patients after open cardiac surgery [7].

The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) reported a median duration of survival for a group of 490 seriously ill patients with dialysis-requiring ARF of only 32 days [28]. Only 27% of patients in this report were alive after 6 months, but of those who survived 62% rated their quality of life as good. The overall estimated cost (in 1994 US dollars) per quality-adjusted life year saved by initiating dialysis and continuing aggressive care in this group of patients was $128,200. When the patients were stratified into prognostic categories, the estimated cost per quality-adjusted life year saved was $274,100 vs. $61,900 for those in the worst and best prognostic categories, respectively.

ARF is a serious, common, complicated, and costly medical illness.

Approach to the Differential Diagnosis of ARF

General Comments

There is often more than one contributing etiologic factor in an ARF presentation, and a broad consideration of all possible causes is necessary. The time-honored approach to establishing a diagnosis in renal disease rests on 1) localizing the predominant site(s) of renal injury and 2) establishing the temporal course of the event(s) leading to the presentation. If the process is localized to prerenal or postrenal sites, the treatment required is restoration of normal perfusion or relief of obstruction, and, notwithstanding the recognition that there are many causes of pre- and postrenal ARF, the specific diagnosis is often easily made. In intrarenal ARF (be it primarily due to vascular, glomerular, tubular, or interstitial processes), specific treatments are less readily available and recovery of renal function in those who survive is slower and less certain.

An elevation in BUN and creatinine may be acute, acute on chronic, or chronic. In a patient with recently measured and available BUN and creatinine levels, determining which is the case may be easy, e.g. a patient who develops ARF as an iatrogenic complication during a hospital admission. However, the distinction must be made in all cases because a delay in the diagnosis and treatment of acute (or acute on chronic) renal failure may allow a prerenal syndrome to progress to established acute tubular necrosis (ATN), a potentially treatable intrinsic renal process such as renal vasculitis to progress to ESRD, or a potentially life-threatening metabolic complication to develop in any patient with deteriorating renal function. Features that suggest chronicity are summarized in Table 1. Most of these are nonspecific. If doubt exists as to the nature of the temporal onset of the renal failure, then it should be treated as acute until proven otherwise.

Prerenal Functional Azotemia

Prerenal azotemia results from a persistent, significant decline in renal blood flow (RBF) that overcomes autoregulatory mechanisms producing a reduction in glomerular filtration rate (GFR) and hence a rise in BUN and serum creatinine concentrations. Implicit in the functional component of the definition is that complete reversibility of prerenal ARF occurs with restoration of RBF. Often more than one

Table 1. Factors Suggestive of Chronicity*

History
- Prior diagnosis of renal impairment
- Remote / Prolonged history of proteinuria or hematuria
- Family history of hereditary renal disease (i.e. ADPKD)
- Long history of systemic illness
- Long duration/evolution of presenting symptoms

Physical Examination
- Ballotable polycystic kidneys

Urinalysis
- Broad casts

Laboratory Tests
- Anemia of chronic disease
- Percent carbamylated hemoglobin

Radiology
- Small kidneys

*Unless there is clear historical evidence indicating chronic renal failure or bilateral small scarred kidneys renal failure should be treated as acute until proven otherwise.

etiologic factor will be present. The causes of prerenal azotemia are listed in Table 2. Medications that interfere with autoregulatory mechanisms in the kidney are included in the list. A nonlinear relationship exists between serum creatinine concentration and GFR. As a result, individuals with chronic renal insufficiency exposed to prerenal insults are susceptible to more dramatic increases in BUN and serum creatinine concentrations. In chronic renal failure, prerenal effects are common and should be considered before activity or progression of the primary renal disease is invoked to explain a rise in BUN and creatinine.

A careful history for gastrointestinal, skin, and renal salt and water losses, or for bleeding is important. The symptoms of thirst or orthostatic dizziness may be important diagnostic clues. A complete history of drug ingestion, including prescription and nonprescription medications, is often instructive. Symptoms indicating other underlying etiologies may be apparent in the presenting complaint and should be sought in a thorough systems review. Physical exam needs to be complete. The history may direct a search for signs of chronic liver disease, congestive heart failure (CHF) or other specific etiologies. An assessment of intravascular volume status is always necessary. This should include a search for orthostatic hypotension and tachycardia and assessment of jugular venous pressure, skin turgor, and moistness of mucous membranes. (Table 3).

Jugular venous pressure can be measured with the patient reclined at any angle, as the vertical distance separating two imaginary horizontal lines that correspond respectively to the level of the manubriosternal angle and top of the neck vein pulsation (assuming the top of the venous pulsation in the neck is visible). In the envolemic state, when the head of a patient's bed is elevated to a 45° angle, neck vein pulsation is just visible at the root of the neck. Likewise, in this position an external jugular vein allowed to fill from above by occlusive external compression at the root of the neck will empty briskly with release of occlusive pressure. However, when intravascular volume is low, even with the patient lying perfectly flat, neck vein pulsation may be absent, and an external jugular vein allowed to fill from above by external compression will continue to empty briskly when the compression is removed.

Postrenal Obstructive ARF (Chapter I-14)

Common causes of ARF from obstruction include benign prostatic hypertrophy or prostatic carcinoma in men leading to obstruction of the bladder outlet; carcinoma of the uterine cervix in women leading to either obstruction

Table 2. Etiology of Acute Renal Failure

ARF → Anuric:

*Always consider possibility of multiple coexisting etiologies

of the bladder outlet or ureter bilaterally; and a blocked Foley catheter in hospitalized patients. Other pelvic or retroperitoneal tumors may also cause obstruction. A blood clot, stone, or tumor within the lumen of the lower urinary tract in the bladder, ureter bilaterally, or single ureter in the case of a transplanted or a solitary native kidney, can produce a similar result. Neurogenic bladder is also a common finding, especially in diabetic patients. Drugs with anticholinergic side effects or the postoperative state may precipitate urinary retention in predisposed individuals. Intrarenal obstruction due to precipitation of crystals within the tubules is rare. It is considered here in the differential diagnosis, although this

6. Decide on probable cause / causes & 7. Order confirmatory tests as indicated					

syndrome is not truly postrenal. Causes of intrarenal obstruction include acute uric acid nephropathy, ethylene glycol toxicity complicated by calcium oxalate precipitation, and drugs such as methotrexate, acyclovir, and sulfonamides.

A detailed history, including a drug history, may suggest obstructive ARF. Complete anuria in ARF is rare and generally narrows the differential diagnosis to an obstructive etiology, renovascular occlusive etiology, severe acute glomerulonephritis, or a catastrophic ischemic event such as acute major bleeding – as described in obstetric cases of acute cortical necrosis (Table 2). However, the urine output is a poor indicator of underlying obstructive problems because polyuria, alternating oliguria and polyuria, anuria, or an

apparently normal urine output may all be seen. Specific symptom complexes may point to prostatic disease, bladder outlet obstruction, or stone disease. The physical exam should assess for a distended bladder, a pelvic mass, and an enlarged prostate. When bladder distension is suspected, measurement of a postvoid residual volume by straight catheterization is diagnostically helpful.

Intrarenal Structural ARF

The causes of intrarenal ARF (Table 2) are grouped into categories based on localization of the dominant injury. Tubular pathology defining the clinical syndrome of ATN accounts for the majority of the cases of intrarenal ARF. ATN is the result of either ischemic or nephrotoxic tubular injury. Ischemic ATN and prerenal azotemia are at opposite poles of a continuum of renal injury resulting from hypoperfusion. A prerenal azotemic state left untreated may progress towards established ATN. Toxic and drug-related causes of ATN are listed separately (Table 6). Acute tubulointerstitial nephritis may account for approximately 10% of cases of intrarenal ARF, and may be idiopathic or more often secondary to drugs, toxins, autoimmune, idiopathic, or infective processes. Among the vascular causes, atheroembolic disease is suggested to be underrecognized as a factor in ARF presentations [41]. It may occur spontaneously or as a complication of cardiac catheterization, vascular, and cardiac surgical procedures (Part I, Chapter 6). Glomerular diseases account for about 5% of intrarenal ARF and include, in addition to vasculitic syndromes, all other causes of rapidly progressive glomerulonephritis (RPGN).

A history of systemic disease, fever, chills, IV drug use, arthralgia, skin rash, recent infection, sinusitis, hemoptysis, hematuria, or recent drug exposure may point towards glomerular or interstitial pathologies. Recent exposure to exogenous toxins or a history of immobilization, seizure, skeletal muscle injury, or ethanol intoxication may point towards a nephrotoxic etiology. Clues from the physical examination may include acrocyanosis, digital infarction, livedo reticulosis or funduscopic evidence of cholesterol emboli in atheroembolic disease; skin rash or palpable purpura in vasculitis; petechia and nonpalpable purpura in hemolytic-uremic syndrome/thrombotic thrombocytopenic purpura (HUS/TTP); sclerodactylia in systemic sclerosis; a new murmur, fever, splinter hemorrhages, Osler's nodes, Janeway lesions, or Roth spots in infective endocarditis; a maculopapular erythematous rash in allergic interstitial nephritis; and muscle tenderness in rhabdomyolysis.

Urinalysis and Diagnostic Indices in the Differential Diagnosis of ARF

Urinalysis should be performed in all cases and should include, at the very least, reagent strip testing and microscopy of a freshly-spun sediment. Measurement of urinary biochemical indices may provide additional information. Urinalysis data are interpreted in the context of the clinical situation in which they are obtained. Specifically, the urinalysis is used to aid localization of and differentiation between likely causes of ARF (Table 3). In essence, one interrogates the ability of the glomeruli and tubules to elaborate urine appropriately. From this, one attempts to derive an indication of nephron structural and functional integrity.

Red cells, not normally present in the urine, can enter the urinary tract anywhere from the glomerulus to the tip of the urethra. In prerenal disease, they are unexpected unless sec-

ondary to traumatic catheterization. In postrenal disease, they may reflect underlying pathology in the lower urinary tract. If present in the form of casts, however, they are indicative of intrarenal disease and almost always a glomerulopathy. The presence of detectable heme pigment in the absence of microscopic hematuria points towards a rhabdomyolytic or hemoglobinuric pigment-induced ARF.

White cells also may arise from anywhere along the urinary tract, from the glomerulus to the tip of the urethra. The common thought to consider them only indicative of a lower UTI (a common etiology of leukocyturia) needs to be guarded against in ARF patients. Intrarenal inflammation or infection also need to be considered. Again, the presence of white cell casts or white cells in the company of granular casts or significant proteinuria heralds an intrarenal cause. Possibilities include interstitial nephritis, acute glomerulonephritis, and pyelonephritis.

Tubular epithelial cells (present < 1 per several high-powered fields in normal urine) are frequently seen in intrarenal ARF. Intact cells may be seen free or within tubular epithelial cell casts or degraded as constituents of the granular casts. Muddy-brown granular casts are particularly classical for acute tubular necrosis.

Large quantities of protein are indicative of intrarenal disease, while trace to 1+ proteinuria may be present in the concentrated urine of prerenal azotemia or sometimes in postrenal azotemia. Quantitatively, in an adult > 2g of proteinuria in 24 hours, or a urine protein to creatinine ratio > 2, is suggestive of underlying glomerular disease (nephrotic range proteinuria > 3.5g/1.72m^2/day is pathognomonic of glomerular disease). Tubular disease typically is associated with < 2g (urine protein to creatinine ratio < 2) per 24 hours of proteinuria. Qualitatively, glomerular and tubular proteinuria are distinguished based on size and charge characteristics by urine protein electrophoresis. Leakage of larger molecular weight proteins is associated with glomerular disease. The predominantly positively-charged immunoglobulin light chains responsible for nephrotoxic ATN in multiple myeloma are characteristically missed by reagent tests, which preferentially detect anionic (negatively-charged) proteins. Gram quantities of Bence-Jones proteinuria may be present with a negative urine dipstick for protein and must always be sought for directly in adult patients with unexplained renal failure.

Diagnostic indices reflecting the tubular capacity to handle solutes and water help differentiate prerenal azotemia from ischemic ATN. The context in which the measurements are taken determines the expected results. In general, if a state of absolute or relative decreased effective arterial volume is present, then, in the absence of pharmacologic inhibition, healthy kidney tubules should maximally reabsorb solutes and water. Whereas in prerenal azotemia this should be possible, in ATN maximal reabsorptive capacities are reduced. Diagnostic indices provide corroborative evidence for suspected diagnoses. It should be recognized, however, that they may be misleading, if interpreted in isolation, without regard for the entire clinical context.

The reabsorption of water is dependent on tubular integrity, antidiuretic hormone (ADH), and the maintenance of the medullary hypertonicity concentration gradient. In respect of ADH secretion, protection of volume will take precedence over protection of osmolality. A concentrated urine with an increased urine osmolality and an increased urine creatinine to plasma creatinine ratio is expected in prerenal disease vs. ATN. As shown in Figure 1, the absolute discriminating value of these 2 indices of water reabsorption with respect to prerenal azotemia in ATN is poor, with considerable overlap.

Overlap between diagnostic indices in prerenal azotemia and ATN exists when solute reabsorption in the form of urea nitrogen is considered. As opposed to creatinine, urea nitrogen is significantly reabsorbed by healthy tubules, and more avidly so when the kidney is underperfused. The BUN to serum creatinine ratio describes this difference. Attempts to separate prerenal disease and ATN based on this ratio have suggested that a BUN to serum creatinine ratio > 20:1 is indicative of prerenal disease. However, BUN concentrations and creatinine concentrations are both subject to many influences independent of the state of renal perfusion and tubular integrity.

Urine sodium concentration is also frequently measured in an effort to differentiate between prerenal azotemia and ischemic ATN. A urine sodium < 20 mM is suggestive of prerenal disease, while one > 40 mM is suggestive of ATN. Overlap persists between these 2 syndromes in terms of urine sodium concentration, and additional factors can impact urine sodium concentrations (Table 3). Perhaps the most frequently used diagnostic index is the fractional excretion of sodium (FE_{Na}). It is derived from the urine-to-plasma sodium ratio divided by the urine-to-plasma creatinine ratio, multiplied by 100, and is expressed as a percentage (Figure 1). It is therefore an integrated index describing the extraction of sodium and water from the glomerular filtrate. FE_{NA} is the most sensitive index to differentiate pre- vs. intrarenal disease: an FE_{Na} < 1% suggests prerenal disease, while an FE_{Na} > 1% suggests ATN. However, nonazotemic patients in sodium balance will often have an FE_{Na} of < 1%, because the amount of sodium reabsorbed to maintain homeostasis (in those on a normal salt diet) is typically > 99% of the sodium filtered. Similarly, an FE_{Na} of < 1% in ARF has been described in intrarenal and postrenal disease and an elevated FE_{Na} is occasionally seen with prerenal disease [61] (Table 3).

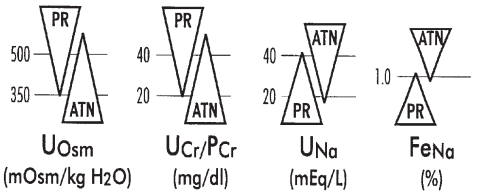

Figure 1. Diagnostic indices in acute renal failure. The horizontal axis displays four laboratory tests and the units used to differentiate functional prerenal (PR) azotemia from acute tubular necrosis (ATN). The vertical axis depicts values that define the nondiagnostic zones of overlap between the designated values and diagnostic areas of nonoverlap above and below the designated values. The derived urinary index, the fractional excretion of sodium (FE_{Na}), has essentially no nondiagnostic overlap zone (exceptions discussed in text). The fraction of the filtered sodium FE_{Na} can be calculated from a urine specimen:

$$FE_{Na}(\%) = \frac{\text{quantity of sodium excreted}}{\text{quantity of sodium filtered}} \times 100$$

Because the quantity of sodium excreted is equal to the product of the urine sodium concentration (U_{Na}) and the urine volume (V); the quantity of sodium filtered is equal to the product of the plasma sodium concentration (P_{Na}) and the GFR (or creatinine clearance, $C_{Cr} = U_{Cr} \times V/P_{Cr}$):

$$FE_{Na}(\%) = \frac{U_{Na} \times V}{P_{Na} \times (U_{Cr} V / P_{Cr})} \times 100 = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100$$

[Kelley WN (ed) 1997 Internal Medicine. Lippincott-Raven, Philadelphia, 934]

Confirmatory Tests in the Differential Diagnosis of ARF

Specific additional tests useful in the differential diagnosis of ARF are shown in Table 4. Among these, renal ultrasound is often used to evaluate for a postrenal cause of ARF. It is usually diagnostic in this setting, although bilateral pelvicaliectasis may not have had time to develop in acute obstruction, and in rare conditions the lower urinary tract is encased and nondistensible, as can occur in retroperitoneal fibrosis. Ultrasound also confirms the presence of two kidneys and pro-

Table 4. Specific / Confirmatory Tests in the Approach to the Differential Diagnosis of ARF

Prerenal ARF
Response to restoration of intravascular volume
or reduction/cessation of drug-related factor
Investigation of underlying disease state
e.g. liver evaluation, cardiac evaluation,
ACTH stimulation fest
Intrarenal ARF
Ischemic ATN: Workup of unexplained hypotension as indicated
Drug-related ATN: Monitoring serum drug levels
Multiple myeloma: serum protein electrophoresis and urine immunoelectrophoresis, skeletal survey, bone marrow aspirate, +/- kidney biopsy
Rhabdomyolysis: CK and aldolase concentrations
Hemolysis: haptoglobin, free serum and urine hemoglobin estimation, LDH level, direct antiglobulin test
Acute tubulointerstitial nephritis: Serum and urine eosinophils, kidney biopsy
Atheroembolic Disease: LDH, C3/CH50 complement, absolute eosinophil count
Thrombotic microangiopathy: stool cultures for VTEC, LDH, platelet count, reticulcyte count, haptoglobin
Vasculitis and/or glomerulonephritis: quantitation of urinary protein excretion, ANCA, ANA, anti-GBM antibody, C3, C4 and total complements, ASO titer, hepatitic serologies, kidney biopsy
Postrenal ARF
Renal ultrasound
Other noninvasive / invasive procedures as required
Measurement of post-void residual volume

ACTH: adrenocorticotropic hormone, ANCA: antineutrophil cytoplasmic autoantibody, ANA: antinuclear antibody, CK: creatine kinase, LDH: lactate dehydrogenase, VTEC: verotoxigenic E. coli, GBM: glomerular basement, ASO: antistreptolysin O

vides a measure of renal size, useful in the distinction between chronic and acute disease (Table 1). Doppler ultrasound provides information regarding perfusion and resistive indices. The resistive index is derived from dividing the peak systolic excursion on Doppler waveform analysis by the peak systolic minus the peak diastolic excursion. In a nonspecific manner, the resistive index approaches unity with various pathological conditions that perturb diastolic arterial flow to a greater extent than systolic arterial flow. In general, interstitial swelling or obstruction may produce such an effect. In studies of normal kidneys, the probability that a single measurement of the resistive index is > 0.7 was estimated to be 6%, while the probability that an average of 3 readings is > 0.7 was estimated to be 3% [32]. Therefore, a resistive index > 0.7 should raise suspicions for an underlying abnormality.

Summary

Table 3 details a stepwise approach to the evaluation of ARF. ARF is a complex disorder and several contributing factors may play a role in the same case. A careful history and physical examination will generate a list of plausible causes, and is complemented by a skillful interpretation of urinalysis and appropriate laboratory and radiologic investiga-

tions. This approach will lead to the correct diagnoses in most cases. If the case does not fit comfortably into the categories of prerenal and postrenal disease or ATN, then resolution of the diagnostic dilemma will generally require a renal biopsy. Failure to do this could lead to missing treatable diseases [51].

Pathophysiological Mechanisms in ARF

This section deals specifically with pathologic mechanisms that relate to the development of ischemic or nephrotoxic ATN. Significant progress has been made in unraveling the multiple, synergistic, and interdependent mechanisms involved in generating ATN. The term ATN is somewhat a misnomer because renal failure in this syndrome produces typically only patchy segmental necrosis in the tubules, *but* it appropriately directs attention on tubular injury as the focal point for understanding the pathogenesis. The clinical course of ATN can be considered in terms of 3 phases: an initiation phase, a maintenance phase (where the triggering factors of ARF have ceased to exist, but the renal failure continues), and a recovery phase. In the clinical setting, these phases may overlap, although ongoing triggering events may hamper ongoing recovery. These events will be discussed separately.

Initiation Phase – Hemodynamic Alterations [45]

Any cause of a significant decline in absolute or relative effective arterial blood volume results in a decrease in perfusion of vital organs and a fall in mean arterial pressure. Both central and peripheral baroreceptors are activated to initiate neurohumoral compensatory mechanisms, including an increase in cardiac contractility and venous and arteriolar vasoconstriction, to improve the perfusion of vital organs and maintain blood pressure. A variety of vasoactive substances are released locally and systematically to promote arteriolar contraction, primarily in the renal, splanchnic, and musculocutaneous circulatory beds. In the kidney alterations in levels of angiotensin II (Ang II), endothelin, sympathetic amines and endothelial-derived relaxant factor are important. Initially, in response to a global reduction in RBF, preferential vasoconstriction of efferent postglomerular arterioles attempts to maintain glomerular perfusion pressure and GFR. Sustained significant reductions in RBF override this mechanism, however, and result in substantial declines in GFR. Contraction of glomerular mesangial cells in response to mediators of vasoconstriction may also contribute to the decrease in GFR by reducing the surface area for filtration.

Initiation Phase – Medullary Hypoxemia [4]

Normal renal physiology requires generation and maintenance of a medullary hypertonicity gradient. It is achieved via a countercurrent system of blood vessels and tubules in the renal medulla. As a direct consequence of countercurrent transport, oxygen levels in the medullary interstitium are decidedly low. Active transport processes in the straight segment of the proximal tubule (S3) and in the medullary thick ascending limb of the loop of Henle therefore take place in a zone of relative regional hypoperfusion and relative hypoxia – the outer medulla. The ATP-dependent ac-

tive transport processes dictate the demand for, while perfusion and blood oxygen content dictate the supply of, oxygen in a delicately balanced system. As RBF decreases, medullary hypoxemia can rapidly ensue. A variety of agents attempt to regulate oxygen homeostasis in these circumstances, including vasodilatory prostaglandins, nitric oxide, dopamine, and adenosine. A redistribution of blood flow may help, both by reducing GFR and therefore tubular workload, and by increasing oxygen delivery to the tubules. Some mediators may also directly inhibit transport processes and in this way further reduce tubular workload. However, as adaptive responses are overwhelmed, tubular injury inevitably ensues.

Initiation Phase – Tubular Injury

Nephrotoxic or ischemic insults can cause tubular injury. Insults may occur separately or in various combinations, e.g. the shocked patient on aminoglycoside antibiotics or the dehydrated patient with myeloma who receives an injection of radiocontrast. Nephrons are typically injured focally and segmentally. The injury may be lethal, resulting in necrosis or apoptosis, or it may be sublethal, resulting in structural and functional alterations that fall short of cell death. Overlap in the nephron segments affected by ischemia and nephrotoxins is possible, as is synergy in mediating damage, e.g. decreased RBF may lead to ischemic tubular injury in S3 segments, while also enhancing absorptive concentration of nephrotoxic antibiotics throughout the proximal convoluted tubule.

Initiation Phase – Consequences of Tubular Injury [38]

Tubular injury leads to an ATP-depleted state in tubular cells. Disruption of normal cytoskeleton, cell-cell contact at tight junctions, and loss of cell polarity with redistribution of Na-K-ATPase and other important proteins follows. At a biochemical level, cytosolic calcium levels rise and a variety of enzymes are abnormally activated. Ultrastructurally, cells appear swollen and microvilli are shed into the tubular lumen. Congestion of medullary capillaries is also a characteristic finding. Such alterations in the tubulointerstitial compartment leave it no longer adapted to water and solute transport or oxygen delivery, thus aggravating local ischemia and tubular injury. Some cells may suffer apoptosis or necrosis. A mixture of viable and nonviable cells is shed into the tubular lumen.

Accumulation of intraluminal debris and Tamm-Horsfall protein leads to intratubular obstruction. Impedance of urine flow in turn increases intraluminal and Bowman's capsular hydrostatic pressures, thus reducing GFR. In addition, transtubular backleak of filtrate occurs secondary to loss of cell-cell contact and sloughing of tubular cells. Hemodynamic alterations, intratubular obstruction, and transtubular backleak combine to produce the decline in GFR (Figure 2).

Maintenance Phase

The maintenance phase of ATN is characterized by persistence of renal failure, with GFR sometimes staying at its nadir for several weeks. Mechanisms thought to be responsible for sustained renal failure include toxic effects of reactive oxygen species generated as part of a reperfusion injury; persistent maladaptive

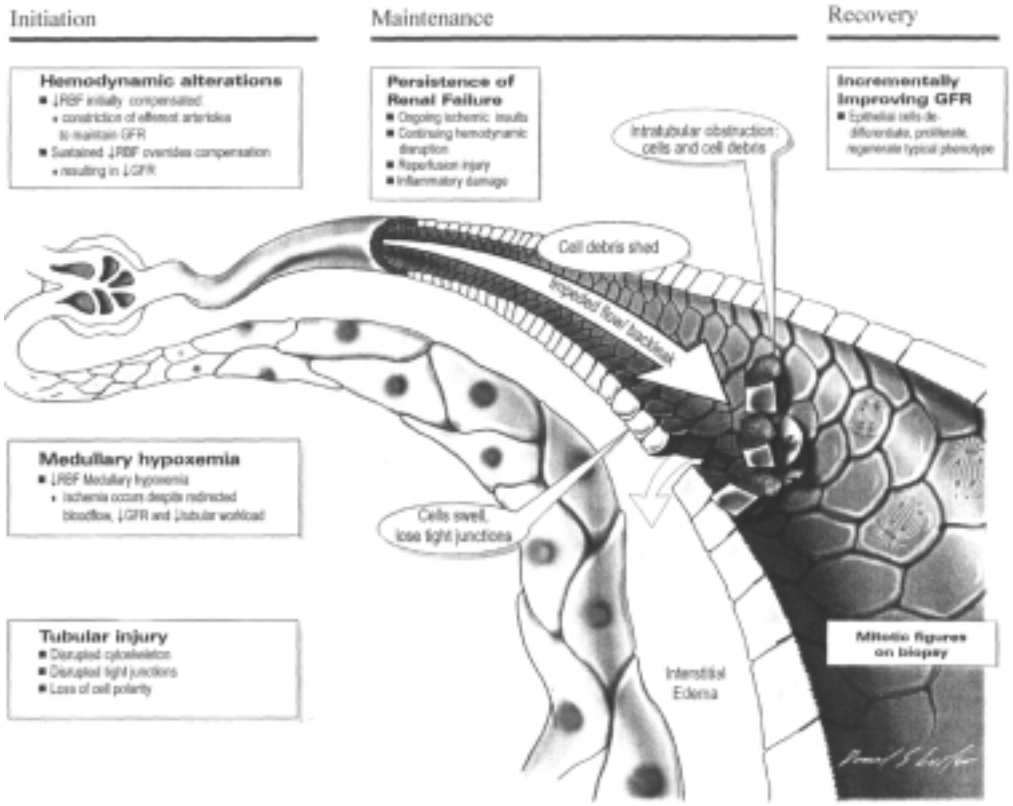

Figure 2. Mechanisms of reduced GFR in acute tubular necrosis.

intrarenal hemodynamic alterations; chemotaxis and adherence of neutrophils and platelets to intercellular adhesion molecules that have been unregulated on altered endothelial tissue; release by the leukocytic infiltrate of a mixture of damaging inflammatory mediators, proteases, elastases and other enzymes. Prolongation of ATN may also result from ongoing ischemic insults in dialysis-requiring ARF, due to inter- or intradialytic hypotensive episodes, combined with continued autoregulatory failure to maintain perfusion. The role of membrane biocompatibility in initiating inflammatory events that prolong ARF has received much attention recently. Finally, ongoing difficulties in maintaining adequate oxygen supply and in avoiding nephrotoxic exposures often complicate the course of a critically ill patient with ATN.

Recovery Phase

The recovery phase of ATN is characterized clinically by a diuresis followed by incremental improvements in GFR. At a cellular level, it is thought that some tubular epithelial cells dedifferentiate and recapitulate many of the processes involved in normal epithelial development in order to regenerate functionally intact tubules. Other cells may repair their cytoskeleton, cell-cell and cell-matrix interac-

tions and recover a normal functional phenotype. Mitotic figures are characteristically seen in biopsies at this time. The role of growth factors such as epidermal growth factor (EGF), hepatocyte growth factor (HGF), and insulin-like growth factor-1 (IGF-1) in regulating these processes is being investigated [35].

Management of ARF

The following discussion of management in ARF is broadly evidence based. However, it should be recognized that only a few studies in the clinical trial literature relating to management of ARF have prospectively randomized "like subjects" into control and study groups or been sufficiently powered to avoid missing clinically significant effects of the treatments being investigated. In this interpretation of current practices, areas of controversy are highlighted. Specific management strategies for vascular, glomerular, and interstitial processes giving rise to ARF are not discussed.

Principles of Management in Prerenal ARF

Treatment of prerenal ARF is directed towards restoring RBF and tissue oxygenation to normal as early as possible. For most patients restoration of renal perfusion is gratifyingly easy and rapidly effective. It is always necessary to address the underlying cause. Withdrawal of an NSAID or temporary withdrawal and reduction of diuretic dose may help in both the recovery and prevention of further prerenal insult. Avoidance of unnecessary exposure to other nephrotoxic agents, such as radiocontrast dye, while in a prerenal and, therefore, primed state for nephrotoxicity, is vitally important.

When volume depletion is the cause of prerenal azotemia, infusion of blood or saline is indicated, depending on the clinical circumstance. In edematous states complicating heart failure or liver failure, intravascular volume may also be low despite increases in total body salt and water. In general, volume expansion can be guided by careful serial clinical evaluations of volume status. However, in the critically ill patient with hypotension of unclear etiology, more precise definition of cardiac filling pressures and cardiac output may be required. In these cases, *right heart catheterization* is often employed to guide therapeutic decision making. Although the efficacy and safety of right heart catheterization has been demonstrated in certain subgroups of patients, a large observational study has recently questioned its safety for a significant proportion of critically ill patients in whom it is used [13]. As a result, there is a growing consensus (see comments published in JAMA regarding paper by Connors [13]) that the role of right heart catheterization needs to be studied by randomized clinical trials in those broad groups of patients for whom controversy surrounds its risks and benefits. In the interim, many believe the procedure to be a crucial diagnostic tool which, in the hands of operators experienced in its use and interpretation, can provide valuable information in the care of seriously ill patients.

Prevention or Reduction of Tubular Cell Injury

Given the high morbidity and mortality associated with ARF, prevention is crucial.

Strategies include maintaining an adequate intravascular volume; avoiding nephrotoxic exposure; saline expansion prior to, during, and after radiocontrast exposure in at-risk patients; titrating drug dosages to the level of renal function; understanding the vagaries involved in estimating GFR from serum chemistries in the elderly, the poorly nourished, and those whose blood chemistries are not in steady-state; and monitoring drug levels.

Restoration of RBF with early and active volume replacement may reduce renal tubular cell injury in the initiation phases of ischemic ATN. In nephrotoxic ATN, a forced saline diuresis may reduce the absorptive concentration of nephrotoxins in the tubular cells and renal interstitium, partly abrogating injury. This type of approach must always be tempered to the clinical situation with great care to avoid volume overloading critically ill patients or those with tenuous cardiac status.

Pharmacologic interventions with proven success in the prophylaxis of ARF are few. *Allopurinol* is beneficial as a pretreatment to chemotherapy in the prophylaxis of acute uric acid nephropathy following tumor lysis. *Mannitol* administered prior to clamp removal and reperfusion has been shown to be beneficial in improving postoperative graft function in kidney transplantation [62].

The prophylactic value of mannitol in other clinical settings is unproved. In fact, mannitol has been associated itself with causing ARF. *Furosemide* is also of doubtful prophylactic value, and its use may even negatively influence outcomes, as appears to be the case following radiocontrast exposure [58]. The strategies employed to reduce tubular cell injury in early and established ARF are similar to those used for primary prevention. No beneficial role has been demonstrated for either mannitol or furosemide in affecting the course or outcome of established disease. While uncontrolled data suggested a higher survival rate in patients who had an initial increase in urine output in response to furosemide, this observation was not upheld in controlled studies [11].

A controversial pharmacologic intervention in ARF is the use of *"renal-dose"/"low-dose"* dopamine to prevent the development of, or lessen the severity of, early or established ATN. To determine the utility of "low-dose" dopamine in preventing ATN, it has been estimated [17] that if the incidence of new onset renal failure in a study were 20%, then 400 patients would be needed for the study to have 80% power to detect a 10% risk reduction at the 0.05 level of statistical significance. Based on this observation, no study has ever conclusively addressed the primary preventative value of dopamine in ARF. The current evidence, such as it is, however, provides no substance to the claim that dopamine has a role in the prophylaxis of ARF in high-risk patients.

In those with early or established disease, good evidence for an effect is also lacking. In a small controlled study in ARF, it has been suggested that dopamine and furosemide were superior to furosemide alone [39]. However, this observation is hardly generalizable. A thorough review of papers in this area concluded that low-dose dopamine was apparently ineffective in humans in preventing ARF or improving outcomes in early or established ARF [17]. A post-hoc analysis of the Auriculin study group, which attempted to control for confounding factors and bias, also suggested that the use of low-dose dopamine confers no benefit in ARF [8]. As with primary prevention, however, a definitive clinical trial has not been done.

Dopamine is associated with documented significant complications, including tachyarrhythmias and myocardial ischemia. Experimental data indicate an implied risk also exists for selective mucosal ischemia in the gut, with

potential for enhanced bacterial translocation and subsequent systemic sepsis [56]. Use of *"low-dose" dopamine* has, up until recently, been very prevalent. This usage has been partly driven by the lack of other effective therapies and by a wealth of experimental evidence in animals suggesting that "low-dose" dopamine has beneficial effects on a variety of the factors involved in maintaining oxygen homeostasis in the renal outer medullary nephron segments. Justification of use of "low-dose" dopamine in patients, however, awaits a randomized, prospective, placebo-controlled clinical trial demonstrating both its safety and efficacy. The use of dopamine in pressor doses, with a view to protecting blood pressure and vital organ perfusion, remains clearly necessary and justified in some critically ill patients.

Atrial natriuretic peptide (ANP) is yet another agent of interest in early and established ATN. Through a series of mechanisms on transport processes and vascular smooth muscle tone, it has the potential to enhance GFR while sparing workload and oxygen demand in critically ischemic tubular segments. A recent well-designed prospective, randomized trial has reported on this agent in 504 critically ill patients with ATN [1]. Disappointingly, as compared with placebo, anaritide (a synthetic form of ANP) had no significant effect overall on the key outcome measures of need for dialysis, the rate of dialysis-free survival 21 days after treatment, and overall mortality. In the anaritide group, however, the subgroup of patients with oliguria had a reduced need for dialysis during the first 14 days and greater dialysis-free survival at 21 days. This type of subgroup analysis is hypothesis generating but does not constitute proof of benefit. In the case of anaritide, a follow-up randomized study in oliguric ARF has been terminated early because of failure to detect any benefit [3]. It remains to be seen whether specific patient groups or clinical settings can be identified in which this new drug will confer benefit.

Calcium channel blockers have been used with some success in ameliorating renal insufficiency in the short term after renal transplantation [11]. Whether this reflects a salutary effect on renal tubular cells of a decrease in cytosolic free calcium concentration, or is mediated by effects on renal perfusion or immune mechanisms is unclear. In transplantation, calcium channel blockers appear to be effective in reducing cyclosporine toxicity via the presumptive inhibition of cyclosporine-dependent vasoconstriction. It has also been suggested that inhibition of contrast-induced vasoconstriction by calcium channel blockers might be renoprotective. However, calcium channel blockers are potentially hypotensive agents. In general, they are neither routinely used nor believed to have a major role in the prevention or treatment of ATN.

General Supportive Therapy

From a *volume* standpoint, it is necessary to restrict salt and water intake in euvolemic patients with oliguric ATN to approximately 2 g and 1 L per day, respectively. This greatly limits space for alimentation or intravenous medications. It is particularly suited to situations in which rapid functional recovery and diuresis is anticipated. In the early stages of oliguric ATN, 1 – 2 high-dose intravenous therapies (80 – 400 mg) of furosemide may induce diuresis following adequate volume replacement. The goal of this therapy is to assist in volume management of the patient, not to favorably influence the course of the disease. In nonoliguric ARF, more liberal fluid intake replacing urine output and insensible losses to maintain a euvolemic state is advised.

The general inability of the kidney in ATN to handle excess free water and elaborate a hypotonic urine underlies the propensity in ATN toward development of *hyponatremia*. Avoiding excess intake of fluids low in effective osmolytes, such as water, dextrose, and hypotonic saline solutions, can prevent this. *Hypernatremia* is a less common development, which, in the absence of administration of hypertonic saline solutions, almost always implies a combined salt and water deficit that needs to be corrected.

Hyperkalemia often accompanies ARF and may be more exaggerated in settings of tissue breakdown, such as in rhabdomyolysis. ECG changes, e.g. QRS widening, p wave flattening and/or arrhythmias, are signs to provide intravenous calcium as a stabilizer to the myocardium. Insulin and dextrose infusions, intravenous bicarbonate, and, in selected patients, nebulized beta-agonists can be used to promote a shift of potassium into the intracellular compartment. Anion exchange resins and/or loop diuretics and/or dialysis serve to remove potassium from the body. Avoidance of drugs, such as ACE inhibitors, potassium-sparing diuretics, potassium supplements and beta-blockers together with dietary potassium restriction may help prevent hyperkalemia. *Hypokalemia* is less commonly seen in ATN but should be corrected carefully as it is independently arrhythmogenic, enhances the arrhythmogenicity of other drugs, e.g. digoxin, and may enhance the nephrotoxicity of aminoglycoside antibiotics.

Hyperphosphatemia is a frequent finding managed by dietary restriction and orally administered phosphate binders. Infrequently, hyperphosphatemia is severe enough to raise the calcium-phosphate product to a point where dialysis is required to prevent metastatic calcification. Magnesium-containing antacids are best avoided in ATN to prevent *hypermagnesemia*. Homeostatic alterations in the humoral control of calcium balance, i.e. low 1-25 dihydroxy-vitamin D_3 levels, PTH resistance, sometimes together with tissue uptake of ionized free calcium, as in pancreatitis or evolving rhabdomyolysis, may precipitate symptomatic *hypocalcemia* requiring the administration of intravenous calcium. *Hyperuricemia*, while generally present, is rarely of a degree requiring treatment. Levels greater than 15 mg/mL, however, raise the possibility of acute uric acid nephropathy and require treatment with allopurinol.

Finally, the accumulation of fixed acids and nitrogenous waste products from protein catabolism contribute to the development of an anion gap *acidosis* and other features of *uremia*. Complex acid-base perturbations may accompany the critically ill patient. Mixed disorders with retention of volatile and fixed acids and/or increased gastrointestinal bicarbonate losses can complicate respiratory and renal impairment in a surgical or medical patient and be particularly severe. Such disorders require careful monitoring and aggressive management. Ventilation and/or dialysis offer rapidly effective ways to raise pH in a patient with combined respiratory and metabolic acidosis. In the uncomplicated patient with ARF, short-term restriction of dietary protein intake to approximately 0.6 g/kg/day can retard the accumulation of protein catabolites. This is a very undesirable approach in the hypercatabolic patient in whom protein catabolic rates may exceed 200 g of protein / day.

Nutritional Support

Malnutrition is common in ARF. A hypercatabolic state results from: mediators of the systemic inflammatory response syndrome; metabolic and hormonal derangements, such as metabolic acidosis, insulin resistance, and

hyperparathyroidism; medications; and aggravating effects of uremic toxins. Compounding this, both inadequate nutritional supplementation and impaired utilization of nutrients can lead to profound protein-energy malnutrition [30].

Although nutritional supplementation is proposed to reduce morbidity and mortality, a beneficial effect in ARF has never been conclusively demonstrated. Nonetheless, attempting to supply adequate caloric and protein support to critically ill patients appears intuitively the correct approach. Enteral supplementation is preferable to parenteral treatment whenever possible. Provision of nutritional support can give rise to complications, including infections, volume overload, hyperglycemia, hypertriglyceridemia, hypokalemia and increases in uremic end products of protein metabolism. In oliguric ARF, nutritional support often requires support with complementary renal replacement therapy.

Prescriptions can be based on Harris-Benedict and Long equations [59]. Caloric requirements of 30 – 35 kCal/kg/day and protein requirements of 1.5 g/kg/day are not unusual. Protein is generally provided as mixed essential and nonessential amino acids, and lipids are used to supply 30 – 40% of total daily calories. In studies where the normalized protein catabolic rate (nPCR) has been measured, it has been noted to frequently exceed 1.5 g/kg/day and to vary intra-individually from day to day. Nutritional prescriptions based on equations that predict protein requirements may fall short of providing sufficient protein. Aggressive hyperalimentation with amino acids in a setting complicated by decreased utilization may, on the other hand, simply fuel urea nitrogen generation. Is it possible in profoundly hypercatabolic patients to individualize nutritional prescriptions and successfully override utilization difficulties such that a net even or positive nitrogen balance is obtained? Would it be beneficial to do this? Should nutritional supplementation be titrated to the protein catabolic rate calculated from urea nitrogen generation or total nitrogen appearance? Would this provide for better outcomes? What is the role of recombinant human growth hormone or insulin-like growth factor-1(IGF-1) in promoting an anabolic state and better overall outcomes in ARF? Answers to these questions are not readily available.

Renal Replacement Therapy (RRT)

Traditional indications for initiation of renal replacement therapy (RRT) in ARF include volume overload, hyperkalemia, severe metabolic acidosis, uremic complications such as pericarditis and encephalopathy, or simply treatment of a rapidly rising BUN and serum creatinine. It is often better to start RRT preemptively to make room for the obligate volume intakes incumbent in providing nutritional, antimicrobial, and pressor support to the critically ill patient than to await volume overload. Although peritoneal dialysis is still used and is an acceptable treatment in certain circumstances, most patients with ARF receive either intermittent hemodialysis (IHD) or one of the forms of continuous renal replacement therapy (CRRT) discussed later in detail. (Chapter II-1c).

For IHD, short femoral vein catheters are the least optimal access because they are accompanied by high recirculation rates and reduced clearances. Internal jugular vein catheters are preferred because they spare subclavian vein cannulation, thus avoiding the complication of subclavian vein stenosis, which can preclude future successful upper extremity vascular access. However, in the critically ill patient access comes at a pre-

mium, and one often must take what is available.

The value of *early* initiation of dialysis in ARF or *intensive* dialysis in ARF merits discussion. Current practice is to initiate hemodialysis at BUN levels ≤ 100 mg/dL. This is based on a series of historically controlled retrospective studies, over 2 – 4 decades ago, which suggested but did not prove in a statistically significant manner that early initiation of hemodialysis is better. For instance, in one series of 500 patients [33], the overall mortality decreased from 42 – 27% when patients dialyzed prior to 1968, with an average BUN of 164 mg/dL at initiation of dialysis, were compared to those dialyzed after 1968, when the average BUN at initiation of dialysis was 93 mg/dL. Similarly it was reported that mortality decreased from 77 – 51% when dialysis was begun at a BUN of 150 mg/dL rather than 200 mg/dL in patients with ARF [20].

In a prospective evaluation of different intensities of dialysis in the treatment of ARF in Vietnam War casualties [12], patients paired based on similar injuries were maintained with predialysis serum creatinine levels of 5 mg/dL or 10 mg/dL, respectively. Statistically significant differences were not present in the 18 patients. However, the mortality rate observed was 36% in the more intensively dialyzed group versus 80% in the other patients. Subsequently [24], no advantage for intensive dialysis was detected in a group of 34 patients, paired by ARF etiology, initiated on dialysis when serum creatinine increased to > 7.5 mg/dL and dialyzed to maintain predialysis serum creatinine of either ≤ 5 mg/dL or between 9 – 11 mg/dL.

Limitations of these studies need to be emphasized in terms of design and application to the type of ARF population managed in intensive care unit settings today. Current data on the value of earlier initiation or more intensive dialysis in critically ill patients are urgently needed. This is highlighted by a recent retrospective analysis in 842 patients with dialysis-requiring ARF, in which, adjusting for the Cleveland Clinic Foundation ARF scoring system (an index of severity), survival correlated positively with delivered dialysis dose across a broad range of severity scores [48].

Using models developed from calculating total nitrogen appearance (generation) over a 5 day period in a group of patients receiving CRRT, it has been predicted that some 50% of hypercatabolic ARF patients would require at least 6 intermittent hemodialysis treatments per week to maintain a peak predialysis BUN < 100mg/dL [9]. Large patients (> 90 kg) would predictably fail to achieve this target even with daily dialysis. In contrast, any number of the available modifications of CRRT can easily provide for this intensity of dialysis.

Choices between CRRT and IHD are generally made based on the hemodynamic stability of the patients, volume control issues, and local availability of resources and trained staff. In general in intensive care unit (ICU) patients with ARF, there is a group whose prognosis is so bleak that differences in the relative efficacies of currently available treatment modalities within the group may be small. Likewise in ARF that is uncomplicated, nonoliguric, and secondary to a single insult in an otherwise healthy patient, the prognosis may be equally good regardless of the dialytic modality chosen. However, there is a large intermediate group for whom differential cost-effectiveness data relating to CRRT vs. IHD is clearly needed.

Increased dialysis membrane biocompatibility in intermittent hemodialysis has been associated with improved recovery of renal function and a trend toward increased patient survival [27]. A second prospective study also found a lower survival rate in patients dia-

lyzed with nonbiocompatible cuprophane membranes [55]. Finally, a retrospective, nonrandomized analysis implicated membrane biocompatibility in outcomes in ARF [43]. However, a third prospective study did not confirm a difference in either the rate of recovery of renal failure or patient survival based on membrane biocompatibility [34]. This was a smaller study, and there were possible confounding differences between the 2 dialysis membrane groups in terms of the proportions of patients with diagnoses of ischemic ATN and nephrotoxic ATN.

Accelerating Renal Recovery

Specific treatments targeted at renal regeneration and enhancing recovery from ARF remain to be established into clinical practice. Among the general interventions, it is clear that ongoing exposure to triggering factors may prolong the maintenance phase of ATN. Avoidance of nephrotoxic insults and maintenance of euvolemia and organ perfusion are critical. Avoidance of dialysis membranes with poor biocompatibility profiles and/or hypotension during dialysis treatments may be important.

Managing Complications of ARF

Infectious complications account for a large proportion of the mortality in dialysis-requiring ARF. The patients are immunocompromised (by uremia and other comorbid conditions), hospitalized and have numerous assaults on normal mucocutaneous barriers. Careful attention to aseptic care techniques, surveillance for infectious complications, and early and aggressive management form the best lines of defense.

Bleeding is also a common problem. Qualitative and quantitative defects in circulating procoagulants and platelets may complicate the uremic syndrome and predispose to bleeding. Stress and hematologic complications of multiple organ system dysfunction contribute. Strategies to control and treat bleeding are as for any critically ill patient with the following added observations: 1 – 2 doses of intravenous desmopressin (DDAVP) 0.3 μg/kg may enhance clotting through the release of endothelial cell stores of von Willebrand factor; conjugated estrogens (0.4 mg/kg daily) have a slower but sustained procoagulant effect; aggressive dialysis without heparin can partly ameliorate the anticoagulant action of uremic serum; maintaining a hematocrit > 30% enhances clotting ability; and cryoprecipitate may also promote clotting in the uremic patient.

ARF – Specific Syndromes

Hepatorenal syndrome refers to a type of functional ARF, in the setting of hepatobiliary disease, that is characterized by a relatively hyperosmolar urine and a urine sodium concentration < 10 mM. Hepatorenal syndrome is a diagnosis of exclusion. Specifically there is a requirement to outrule prerenal, renal and postrenal etiologies. It occurs most often secondary to alcohol-induced hepatic cirrhosis but occasionally complicates the course of fulminant acute viral hepatitis, biliary tract obstruction or surgery, hepatic malignancies, and partial hepatic resections. Severe hepatic failure with ascites, jaundice, and encephalopathy usually accompanies this syndrome. The prognosis of hepatorenal syndrome is poor, with a mortality of 80 – 95%.

Survival is generally dependent on effective liver regeneration or liver transplantation. When liver function is restored by liver regeneration, liver transplantation, or by renal transplantation into a recipient with normal liver function, RBF and GFR return to acceptable levels.

Patients with advanced liver disease have an impaired capacity to generate urea and also have reduced generation of creatinine as a consequence of asthenia. Thus, in patients with liver disease significant renal impairment may be present with only borderline elevations in BUN and creatinine. The classic pattern of hepatorenal syndrome is that of an acute oliguric form with rapid onset and progressive renal failure. It is unclear, however, whether renal function is initially normal in such classic presentations. A commonly seen clinical presentation is the patient with advanced liver disease whose renal failure progresses more slowly over weeks or months, but otherwise fits the description of hepatorenal syndrome.

Hepatorenal syndrome is characterized by avid tubular reabsorption of salt and a FE_{Na} < 1%; by an intact urinary concentrating ability and a urine osmolality that exceeds the serum osmolality; by a bland urine sediment without increased cells or formed elements, and with no more than 1+ proteinuria. Other causes of prerenal disease can produce the same clinical picture. Differentiating between these often rests on a careful volume challenge with colloid and saline. Sometimes central venous pressure monitoring will be required to prevent volume overloading the patient. If tense ascites is present, the simultaneous relief of this by large volume or total paracentesis while infusing colloid is sometimes useful. Prerenal azotemia will respond to such maneuvers with a rapid recovery of function, whereas hepatorenal syndrome typically responds less favorably.

Glomerular pathology was universally present in a prospective series of 18 consecutive recipients undergoing native kidney biopsies at the time of liver transplantation for end-stage liver disease [16]. Abnormalities included minor changes, glomerulosclerosis, membranoproliferative glomerulonephritis, and IgA nephropathy. The significance of cirrhosis-associated glomerular pathology is unknown, and it is rare for glomerular disease to be a dominant feature of renal failure syndromes in advanced liver disease. In hepatitis C-infected patients, the presence of glomerular proteinuria or red cell casts may be indicative of an underlying membranoproliferative glomerulonephritis (MPGN).

The finding of granular and tubular epithelial cell casts in urine microscopy is not uncommon in patients with renal failure and liver disease. By clinical definition, these patients do not have hepatorenal syndrome but rather evidence of structural tubular damage, indicating ATN. The etiology of ATN in this setting may be nephrotoxic or a continuum of prolonged renal hypoperfusion resulting in ischemic renal injury consequent on the same pathophysiologic processes that lead to the hepatorenal syndrome. Initially the FE_{Na} may be < 1% when ATN complicates liver failure but increases to levels > 1% with time.

Hepatorenal syndrome is a multifactorial process. Hemodynamic changes with widespread peripheral arterial vasodilation, increases in arteriovenous shunting, and increased vascular capacitance accompany hepatic failure. Activation of the sympathetic nervous system and renin-angiotensin system is well documented. Evidence has accumulated implicating alterations in vasoactive substances, including nitrous oxide, endothelin and vasodilator and vasoconstrictor prostaglandins, both systemic and intrarenal, in advanced liver disease. The result is intense renal arterial and arteriolar vasoconstriction

with decreased RBF and GFR and a state of functional renal failure.

Continued preferential accumulation of ascitic fluid can be understood as a sequela of splanchnic vasodilation, portal hypertension, and low plasma oncotic pressures shifting Starling's forces to promote localization of free fluid in the peritoneal space. Refractory ascites in selected patients may provide an indication for transjugular intrahepatic portosystemic shunts, peritoneovenous shunts, or liver transplantation. Unfortunately, neither of the first 2 options appears to prolong survival in patients with advanced liver disease and refractory ascites [53, 60]. Both can be associated with serious complications. The decision to aggressively manage the patient with hepatorenal syndrome (including the provision of renal replacement) hinges on whether liver regeneration or liver transplantation is anticipated for a given patient. Short of one or the other of these outcomes, renal replacement may only prolong the dying process.

When candidates with hepatorenal syndrome are transplanted, increased hospital morbidity and length of stay, but comparable patient survival at one year and acceptable actuarial patient survival at 5 years (60% vs. 68%, $P < 0.03$ for patients with and without hepatorenal syndrome, respectively) has been described [26]. Recovery of dialysis independence was usual, and the incidence of ESRD after liver transplantation in patients who had hepatorenal syndrome was 7%, compared with 2% in patients who did not have hepatorenal syndrome.

Pigment-related Nephrotoxicity

Rhabdomyolysis is a syndrome characterized by muscle fiber dissolution and release of intracellular contents into the extracellular space and circulation. The occurrence of myoglobinuric ARF is common. It has been studied since the classic descriptions of the "crush syndrome" complicating the London bombing raids during World War II [6]. Hemoglobin, likewise a heme pigment, is also capable of precipitating ARF.

Muscles make up approximately 40% of body tissue and contain large quantities of myoglobin. A classification of the causes of rhabdomyolysis is listed in Table 5. Muscle hyperthermia accompanying strenuous physical exertion, convulsions, septic rigors, or malignant hyperthermia may precipitate rhabdomyolysis. Ischemic injury below a major arterial occlusion; inflammatory disorders such as polymyositis, and various hereditary and infectious muscle disorders have also been implicated. Many medications may mediate muscle injury, including cyclosporine

and HMG-CoA inhibitors increasingly used in combination in transplant patients. Alcohol can be implicated in the generation of traumatic and nontraumatic rhabdomyolysis. The latter is often due to hypophosphatemia during calorie refeeding, and is preventable with careful monitoring and phosphate supplementation. Hypokalemia is also described as causative for rhabdomyolysis.

Among the many etiologies of hemolysis/hemoglobinemia, those most likely to contribute to ARF combine rapid and extensive hemolysis with situations in which decreased renal perfusion may simultaneously coexist, e.g. disseminated intravascular coagulation (DIC), incompatible blood transfusions, and infectious causes of hemolysis such as malarial or clostridial infections. Hemoglobinuria appears to result in ATN only when associated with other systemic abnormalities, especially dehydration, shock, and acidosis.

Cellular ATP depletion, intracellular calcium overload, and myocytolysis characterize the events at a muscle cell level in rhabdomyolysis. Severe local capillary leakiness can lead to rapid widespread third spacing of fluid in the muscular interstitial spaces. The pathomechanisms of heme pigment-related ATN are shared by myoglobin and hemoglobin. Both pigments are filtered at the glomerulus, although hemoglobin much less freely than myoglobin because of its larger size (molecular weight 68 vs. 17 KD) and because of the presence of a hemoglobin-binding protein, haptoglobin, in the plasma. Intrarenal vasoconstriction is common as a consequence of uncorrected volume depletion due to third spacing of fluid. This vasoconstriction leads early on to a low FE_{Na} and a concentrated and acidic urine. In turn, this favors the precipitation of heme pigments and Tamm-Horsfall protein in the distal nephron with consequent intratubular obstruction. Delayed urine transit and reduced GFR prolong the exposure of proximal tubular cells to heme pigments and maximize pigment uptake by endocytotic absorption in the proximal tubule. Proximal tubular heme loading leads to cell injury by complex mechanisms in which ischemia, ATP depletion, and oxidant stress induced by intracellular release of catalytic iron molecules are all thought to play a role [63].

Because myoglobin is so much more freely filterable, the urine but not the plasma is pigmented in myoglobin-associated ATN, while both urine and plasma are pigmented in hemoglobinuric states. Heme-positive urine and the absence of red blood cells on sediment microscopy are characteristic findings. A definitive diagnosis can be made by demonstrating myoglobin or hemoglobin directly in the urine by counterimmunoelectrophoresis. In rhabdomyolysis, the diverse nature of the intracellular contents released into the circulation is reflected by marked elevations in plasma levels of creatine phosphokinase, phosphate, uric acid, potassium, and creatinine. The elevation in creatinine is more rapid than in other types of ARF, reflecting both muscle release and reduced plasma clearance. Thus, the BUN:creatinine ratio is typically < 10. Severe hyperkalemia may be seen. The release of intracellular potassium and phosphorous can obscure the pathogenic role that low levels of these electrolytes may play in the etiology of the condition. Symptomatic hypocalcemia due to high phosphorous levels and deposition in muscle beds is common. In the recovery phase of myoglobinuric ARF, hypercalcemia may be seen as a consequence, in part, of calcium mobilization from skeletal muscle.

The prevention of rhabdomyolytic-induced ATN rests on early and aggressive volume replacement, enhancing the rapid clearance of heme pigments, and providing protection to proximal tubular cells. Retrospective analyses provide overwhelming support for aggressive

volume replacement. When urine output allows, it has been recommended that after resuscitation at least a 12 L mannitol-alkaline diuresis be provided in the first 24 hours [2]. To provide for this, large volumes of fluid may be required early on to replace the third-spaced volume loss. Alkalinization is recommended to produce a urine pH > 6.5. This prophylactic measure aims to reduce Tamm-Horsfall-heme pigment precipitation, which occurs more readily in an acid urine – although it may simply exert its protective effect through a saline diuresis. Mannitol probably exerts its protective beneficial effect as a proximal tubular diuretic rather than the theoretical suggestions that it has a beneficial vasodilatory effect or hydroxyl radical scavenging effect. The emphasis is on maintaining a volume-replete state and a solute diuresis with an alkaline urine. If mannitol is used, monitoring is mandatory to avoid an excessively hyperosmolar state. The amount of bicarbonate required to produce an alkaline urine varies widely. We prefer to administer the bicarbonate as part of an isotonic solution (0.45% saline solution with 75 mmol $NaHCO_3$), because bolus doses of hypertonic bicarbonate predispose to hypernatremia. Once renal failure is established, these interventions are of no benefit, and the principles of management are the same as for any form of ATN. Avoidance of volume overload then becomes mandatory, and it should be remembered that pigment-induced ARF may often be accompanied by severe hyperkalemia, hyperphosphatemia, and hypocalcemia, which can necessitate early dialysis.

Radiocontrast Procedures and ARF

ARF after radiocontrast-related procedures is a common problem in the inpatient setting.

The importance of ARF after radiocontrast procedures in an in-patient hospital population was recently emphasized in a well-controlled retrospective cohort analytic study [36]. In this analysis, the development of renal failure after a radiocontrast procedure was strongly and independently correlated to mortality risk in a multivariate analytic model developed and validated for the cohort being studied. Over 16,248 patients were screened to identify 183 index subjects who developed ARF (1.1% of those undergoing radiocontrast-related investigations). The overall mortality rate was 34% vs. 7% in those who did or did not develop ARF, respectively. The study did not firmly establish contrast nephropathy as the underlying etiology of ARF in all the observed cases. However, the results do pertain to an at-risk inpatient population undergoing contrast procedures and, as such, are important.

Atheroembolic disease complicating angiographic procedures is discussed elsewhere. This next section focuses on the outcome and clinical significance of classic cases of contrast nephropathy. The classic presentation of contrast nephropathy is that of deteriorating renal function occurring within 1 – 2 days, peaking within 3 – 5 days, and resolving within 7 – 10 days of radiocontrast exposure. Most cases are nonoliguric and do not require dialysis. The urine sediment early in contrast nephropathy may be bland, and urinary indices suggest prerenal injury (low FE_{Na}). Later, tubular epithelial cells and granular and tubular epithelial cell casts are seen, indicating tubular injury. The mechanisms of contrast nephropathy are thought to involve a reduction in RBF, an imbalance between tubular workload and oxygen supply, and a direct tubular toxicity of the contrast agent.

Contrast nephropathy occurs in only approximately 3% of patients without identifiable risk factors in most large prospective

population studies. With appropriate controls, the true incidence of ARF in low-risk patients (nonazotemic, nondiabetic) is even less: 2.1% and 1.3% in those exposed and not exposed, respectively, to contrast media [14]. Preexisting chronic renal impairment, diabetes, and multiple myeloma are the comorbid risk factors most often cited as predisposing to contrast nephropathy. Whether preexisting renal insufficiency truly increases the incidence of contrast nephropathy or simply increases the sensitivity of detecting renal injury as a result of the exponential relationship between creatinine and GFR is debatable. It is clear, however, that contrast nephropathy is more of a problem in those with impaired baseline kidney function. For example, the implications of a 10 mL/min decrease in GFR are different for the patient with a baseline GFR of 20 mL/min, compared to a patient with a baseline GFR of 120 mL/min. The incidence of contrast nephropathy appears directly proportional to the degree of chronic renal insufficiency. Moore et al. report an incidence of 4.7%, 14.3%, and 20%, respectively, for those with baseline creatinine levels in the ranges of 1.5 – 1.9, 2.0 – 2.4, and 2.5 – 2.9 mg/dL, respectively [44].

Having diabetes and chronic renal insufficiency seems to further predispose to more clinically serious contrast nephropathy. Risk is again proportional to baseline GFR, and of those with severe chronic renal impairment 50 – 90% may develop contrast nephropathy. For some, the ARF will be irreversible. In contrast to azotemic diabetics, diabetics with normal renal function are not at a significantly increased risk for contrast nephropathy, according to recent studies. Likewise, multiple myeloma in the absence of other predisposing risk factors (e.g. volume depletion, renal insufficiency) does not absolutely mitigate against contrast exposure [42]. It is wise, however, to be careful with all diabetics and patients with multiple myeloma, regardless of baseline serum creatinine levels. Any prerenal state, whether or not functionally significant prerenal azotemia has been documented, should be considered an at-risk state for contrast-induced renal injury. To better appreciate the procedural risk, it is prudent to recommend a recent serum creatinine precontrast exposure for all inpatients and for outpatients who are elderly, diabetic, hypertensive, or predisposed to decreased renal perfusion.

Prophylaxis of contrast nephropathy is important. Indications for contrast-related procedures need to be clearly defined, especially for high-risk patients. Measures should be taken to correct predisposing factors such as volume depletion. Optimal prophylaxis includes avoidance of concomitant nephrotoxic exposures and ensuring a euvolemic state. Maintaining a saline hydration, with 0.45% saline solution, 1 mL/kg body weight/hr, commenced 12 hours before and maintained for 12 hours after contrast exposure is indicated for at-risk patients. In a randomized,

prospective study, saline alone provided better protection against acute contrast-induced decreases in renal function than saline combined with either mannitol or furosemide [58]. The prophylactic usefulness of other agents in high-risk patients remains uncertain. However, the volume of contrast to which the high-risk patient is exposed should be minimized [40]. Likewise, low-osmolality contrast media has been shown in a large, prospective, randomized trial to reduce the incidence of contrast nephropathy in azotemic patients with and without diabetes [54].

Drug-related ARF

See table 6 for summary.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs can lead to decrements in GFR and elevations in BUN and serum creatinine when used in clinical circumstances characterized by prostanoid-dependent RBF. The pathomechanism is clearly hemodynamic. NSAIDs do not exert this effect in euvolemic individuals with normal renal function because in this state, maintenance of RBF and GFR is independent of prostaglandins.

A decline in absolute or relative effective arterial blood volume results in compensatory humoral mechanisms to maintain blood pressure. As in most hormonal systems, these vasoconstrictor hormones participate in a negative feedback loop by promoting the renal production of vasodilatory substances, primarily prostaglandins. Intrarenal prostaglandins work both to modulate vasoconstriction by lessening preglomerular vascular tone, thus preserving GFR, and to preserve medullary oxygen hemostasis by preferentially increasing medullary regional perfusion. NSAIDs inhibit the cyclooxygenase (COX) I and II isoenzymes that metabolize arachidonic acid substrate in a rate-limiting step in prostaglandin synthesis. In states of diminished effective arterial blood volume, they inhibit the protective effects of prostanoid on RBF. The consequence is ARF with rising BUN and creatinine levels, sodium and water retention, and frequent hyperkalemia. Onset is typically within 24 hours of taking a dose. The effect occurs with all commonly used anti-inflammatory drugs at therapeutically prescribed doses. Low-dose aspirin for platelet inhibition does not produce the effect. Sulindac is an NSAID which the kidney can rapidly metabolize and inactivate. However, acute hemodynamic renal failure has also been described with this drug. In addition to leading to ARF, NSAIDs produce other nephrotoxic effects including an allergic interstitial nephritis (of slow onset) and nephrotic syndrome secondary to minimal change disease (MCD) or membranous glomerulonephritis. In the future, selective Cox II inhibitors will be available and may mediate anti-inflammatory effects at doses that minimally alter intrarenal hemodynamics [23].

Angiotensin-converting Enzyme (ACE) Inhibitors

In discussing drug-induced hemodynamic ARF, it is necessary to comment on ACE inhibitors and angiotensin II (Ang II) receptor blockers. These 2 classes of drugs are associated with predictable declines in GFR in patients with chronic renal insufficiency or humoral-dependent RBF, especially in patients

with bilateral renal artery stenosis. In these circumstances autoregulatory mechanisms protect GFR by preferential Ang II-mediated postglomerular arteriolar constriction. Loss of this increased efferent arteriolar tone follows introduction of any of the drugs belonging to these 2 classes of agents. The decline in GFR is generally acceptable as a hemodynamic and reversible consequence. Indeed, it is desirable in order to slow subsequent progressive declines in GFR in macroproteinuric renal diseases and diabetes. However, severe baseline renal failure and hyperkalemia are limiting factors to the use of these agents. Very rarely, ARF may result from ACE-associated renal infarction. This occurs in patients with severe baseline renovascular disease in whom abrupt hypotensive effects of drug administration drop the perfusion pressure across a tight renal artery stenosis and precipitate complete renovascular occlusion. Although rare, this occurrence dictates caution in using these agents in patients with suspected severe renal artery stenosis.

Antibiotics

Aminoglycosides have a major role in the treatment of gram-negative microbial infections. They are small molecules (approximately 500 KD), negatively charged, minimally protein-bound in plasma, and excreted unchanged in the urine. Their plasma clearance roughly equals GFR. After filtration in the kidney, reuptake of a small percentage of aminoglycosides in the proximal tubule is mediated via the process of adsorptive pinocytosis. Once intracellular, the pinocytosed vesicle fuses with lysosomes and localizes the aminoglycosides to this organelle. The intracellular half-life of an aminoglycoside is up to 4 – 5 days in the renal cortex vs. a plasma half-life that is measured in hours. Accumulation of high concentrations of the drug occurs in proximal tubular cells.

The nephrotoxicity that complicates some 10 – 20% of courses of aminoglycoside antibiotics is the result of this accumulation. The aminoglycosides interfere with lysosomal phospholipids leading to a so-called "phospholipidosis" characterized in part by intracellular accumulation of myeloid bodies that contain aggregates of undigested phospholipid membranes damaged by the aminoglycosides. Other drugs may cause phospholipidosis without causing renal failure. At what point and through what additional mechanisms aminoglycosides mediate their nephrotoxicity needs further clarification.

The consequences of aminoglycoside toxicity are proximal tubular cell injury with enzymuria and the shedding of microvilli and cells into the tubular lumen. Intraluminal obstruction and transtubular back leak are important pathophysiologic mechanisms. Serum creatinine and BUN levels characteristically rise 7 – 10 days into a course of aminoglycoside treatment. In uncomplicated cases where aminoglycosides represent the sole insult to the kidneys, cessation of the antibiotic typically is followed by a course of nonoliguric ARF, not requiring dialysis intervention, with a gradual recovery of renal function over a couple of weeks. However, a more common situation is the additional contribution of aminoglycosides to renal failure in combination with other renal insults, including ischemia, contrast agent and sepsis. The relative contribution of aminoglycosides in this setting is more difficult to establish.

While the therapeutic indications for aminoglycosides have been clearly established over time, the avoidance of nephrotoxicity remains a challenge. Advanced age, preexisting renal disease, liver disease, long or repeated courses of antibiotic, volume depletion and/or a prerenal state, hypokalemia, hypo-

magnesemia, and concurrent exposure to additional nephrotoxic agents predispose to aminoglycoside nephrotoxicity. Avoidance of some of these predisposing factors, such as volume depletion, is possible. Consideration may be given to shorter courses when antibiotic sensitivities are available to guide treatment.

Dosimetry pertaining to aminoglycosides is another area of active research. The bactericidal effect of aminoglycosides correlates with the peak blood level achieved, while the nephrotoxic side effect correlates with trough blood levels. As 100% of the drugs are renally cleared, preexisting or developing renal failure during a course of aminoglycosides will lead to increasing plasma trough levels unless the dosage interval is appropriately lengthened to allow for clearance. The widespread use of measuring serum concentrations of aminoglycosides has been disappointing in terms of its impact on the incidence of nephrotoxicity. This is not to say that measurement of levels and avoidance of high trough levels should be ignored, but rather emphasizes that nephrotoxicity may occur even when levels are maintained in the appropriate range.

Daily dosing of aminoglycosides in patients with normal renal function was introduced a number of years ago to exploit several known properties of this class of drugs, namely that bactericidal effect correlates with peak drug levels, that a post-antibiotic effect is present suppressing bacterial growth at levels below the minimal inhibitory concentration (MIC), that the length of the post-antibiotic effect increases with higher peak levels of the drug, and that adsorptive pinocytosis in the proximal tubule is a saturable process. It was hoped that once-daily dosing would enhance or sustain efficacy while reducing the incidence of nephrotoxicity. Recommendations have been published for high-dose, extended-interval aminoglycoside regimens including dose adjustment guidelines for those with creatinine clearances in the range of 20 mL/min to normal [46, 50]. At present there is moderate to strong evidence of probable clinical benefit for daily dosing in gram-negative infections; moderate evidence of a limited benefit or no difference in gram-positive infections; little or no evidence for benefit in pediatric, geriatric, pregnant, obese, burn, or cystic fibrosis patients, or in those with creatinine clearances < 20 mL/min; and indications that high-dose extended interval regimens may be inappropriate for enterococcal infections [22]. The application of computer-generated alert systems may also have a role in reducing the incidence or severity of drug-related nephrotoxicity [52].

Amphotericin B Nephrotoxicity

Amphotericin B, a polyene antibiotic, presently remains the most effective agent for the treatment of deep-seated and disseminated fungal infections. Amphotericin B interacts with lipid sterols present in the outer membranes of susceptible microorganisms. Fungi contain ergosterol as part of their membranes, hence their sensitivity to polyenes such as amphotericin B. In contrast, bacteria do not have lipid sterols in their membranes and are resistant to the effects of this class of drug.

The renal toxicity of amphotericin B is characterized by distal renal tubular acidosis (RTA), hypokalemia, an ADH-resistant urinary concentration defect, reduced GFR, and occasional symptomatic hypomagnesemia and salt wasting. The integration of amphotericin B with cell membranes in the distal nephron leads to formation of pores of sufficient size to allow abnormal solute trafficking. The distal RTA is believed to be secondary to an increased passive permeability of the luminal membrane and back diffusion of hydrogen

ion, rather than an active transport failure. Likewise, potassium wasting, which may be profound, occurs in the context of increased membrane permeability in the distal nephron and passive flux along a favorable electrochemical gradient. Increased aldosterone-dependent potassium-sodium exchange is not involved. Although the hypokalemia may aggravate or cause a nephrogenic diabetes insipidus, membrane effects increasing the permeability of the medullary collecting ducts to urea may partly efface the medullary hypertonicity gradient and account for some of the failure to elaborate a concentrated urine. Hypomagnesemia occurring as a result of amphotericin B toxicity may contribute to exaggerated hypokalemia that is resistant to aggressive correction until the magnesium has first been replaced.

In contrast, acute rises in serum potassium levels have been described following the rapid infusion of amphotericin B in anephric patients [15]. This may occur because of leakage of potassium from the intracellular compartment unopposed by exaggerated urinary losses. The patient with established renal failure receiving amphotericin B needs to be carefully monitored for this complication.

Pathologic mechanisms by which amphotericin B precipitates ARF include both a renal vascular effect producing ischemia and direct tubular toxicity. Greater levels of toxin in the kidney caused by longer courses of treatment and/or larger doses overwhelm the ability of the cell to repair membrane defects. The renal toxicity is clearly dose dependent. While GFR can return to normal after discontinuation of the drug, a fraction of patients have irreversible damage. Chronic renal failure was observed in 44% of patients receiving a total dose of > 4 g and in 17% of patients receiving < 4 g total dose [5].

Preventive strategies include salt loading and avoidance of concomitant volume depletion and additional nephrotoxic insults. Protective roles for alkalinization, aminophylline administration and calcium channel blockers remain unproved. A small prospective study showed no beneficial effect of mannitol, while a case control study reported a 12.5 fold greater risk of nephrotoxicity with prophylactic use of furosemide. The place of liposomal and other lipid-based formulations of amphotericin B requires continued investigation. An advantage proposed for these formulations is a reduction in nephrotoxicity based on characteristics that favor selective drug delivery to the reticuloendothelial system, macrophages, and sites of infection. These formulations also decrease the systemic side effects that often accompany the infusion of free amphotericin B.

Miscellaneous Antibiotics

Other antibiotics implicated in the generation of ATN include the beta-lactam group of antibiotics, i.e. penicillins, cephalosporins, and imipenum. Except for cephaloridine, nephrotoxicity is a rare side effect of these drugs. The mechanism of injury may be via lipid peroxidation in the case of cephaloridine, or mitochondrial injury in the case of the other antibiotics. Selectivity for the proximal tubule is a result of dependence on the organic amino acid transport system. The administration of imipenum with cilastin serves to reduce its toxicity, because cilastin inhibits enzymatic cleavage of imipenum by brush border dehyropeptidases in the proximal tubule. The nephrotoxicity of current vancomycin preparations is much less than before, and synergistic nephrotoxicity between these preparations and aminoglycosides has not been convincingly demonstrated. Tetracyclines may worsen azotemia via an antianabolic effect leading to an elevation in BUN, but not

serum creatinine, in patients with preexisting azotemia. Accumulating levels of tetracycline may also produce a toxic tubular cell injury in patients with liver disease. Acute allergic interstitial nephritis complicating antibiotic usage is not discussed here.

Antineoplastic Drugs and Heavy Metals

A variety of heavy metals have been shown to produce ARF with proximal tubular cell necrosis. Salts of mercury, arsenic, chromium, uranium, bismuth, silver, and platinum are potent nephrotoxins. Exposure is usually occupational with the exception of the platinum salts, which are used therapeutically.

Cisplatin, which describes the organic compound cisdiaminodichloroplatinum, is a chemotherapeutic agent. Its nephrotoxic effect is dose limiting. Interventions that decrease nephrotoxicity are potentially beneficial in terms of facilitating larger doses and greater efficacy. After a single dose of cisplatin, mild reductions in GFR may be seen in up to 25% of patients. Repeated doses may give rise to nephrotoxicity in up to 75% of patients. While the acute effects are generally reversible, permanent irreversible damage may follow repeated exposure. The reduction in GFR is generally delayed 1 – 2 weeks after dosage. The mechanism is understood to depend on uptake and slow transformation of cisplatin in proximal tubular cells. Aquation of the cis chloride sites of cisplatin in the relatively "low chloride" intracellular environment is thought to produce toxic-charged species. The typical histologic features are injury in the tubulointerstitial compartment. Particularly susceptible are the S_3 segments of the proximal tubule, and less so the distal tubule and collecting duct.

Enzymuria, rarely measured in clinical practice, may be the earliest indication of tubular injury. Following on this, urinalysis findings of tubular proteinuria and granular and tubular epithelial cell casts are seen. Hypomagnesemia complicates 50% of cases. Urinary magnesium wasting may contribute to secondary hypokalemia and hypocalcemia. This defect typically resolves within a few weeks of the last cisplatin dose, but has been observed to persist for several years.

Prevention of cisplatin nephrotoxicity is approached by employing an aggressive saline diuresis and also by avoidance of concurrent exposure to other nephrotoxic drugs, such as aminoglycosides. In general, a euvolemic state is required, after which a bolus dose of saline of approximately 500 mL and infusion of as much as 150 – 250 mL per hour thereafter is initiated before, continued throughout, and for 4 – 6 hours after cisplatin has been infused. Normal saline or hypotonic half-normal saline has been used with or without mannitol. It has been observed that larger doses of cisplatin remain nephrotoxic despite these measures, but can be tolerated when administered in hypertonic (3%) saline solutions. This raises the possibility that optimal protection requires not just hydration with increased urine flow and reduced contact between tubular cells and the drug, but an additional chloriuresis and hyperchloremic state. Continued investigation of other agents that might reduce nephrotoxicity is worthwhile. With careful application of a prophylactic hydration protocol, renal toxicity is no longer per se a treatment limiting complication of cisplatin chemotherapy. Other chemotherapeutic platinum analogues have been developed, including carboplatin and ormaplatin. Renal dysfunction has been described with both, and hydration is important when using these drugs.

Other Antineoplastic Drugs

The alkylating agent *ifosfamide*, unlike its parent compound cyclophosphamide, is associated with nephrotoxicity. It also shares with cyclophosphamide the property of urotoxicity. Mesna, a synthetic sulfhydryl compound, protects against the urotoxicity of the acrolein and chloroacetalalahyde metabolites of ifosfamide, but it does not protect against the renal parenchymal insult [57]. Ifosfamide nephrotoxicity is characterized by proximal tubule cell injury and Fanconi's syndrome with proximal RTA, phosphaturia, glycosuria, uricosuria and aminoaciduria. Aggressive supplementation of electrolytes may be necessary, and in children a propensity to hypophosphatemic rickets has been described. While GFR is generally only mildly reduced, severe ARF may also occur. Preexisting chronic renal insufficiency or prior cisplatin exposure may be a predisposing factor to ifosfamide-induced renal injury. General preventive measures are advisable. Experimental data has suggested glycine, via a membrane protective effect, is worth investigating as an agent with potential clinical applications.

Recombinant *interleukin-2* is employed as an immunomodulatory agent in various drug protocols for patients with metastatic adenocarcinoma. A lymphokine normally produced by activated T-cells, it is sometimes given in combination with lymphokine-activated killer cells. A predictable septic shock-like syndrome often follows its administration, with decreased systemic vascular resistance, increased cardiac output, capillary leakiness, and a transient requirement for crystalloid, colloid, and/or pressors to maintain perfusion pressure. Weight gains of 10 – 15% of body weight are not unusual. The renal lesion most commonly seen is a prerenal functional azotemia with characteristic urinary indices and rapid reversibility with restoration of RBF. Ischemic ATN may complicate its use. Rare cases of allergic interstitial nephritis and even RPGN have been described.

Nitrosureas associated with renal toxicity include streptozotocin, semustine, and lomustine. Of these, streptozotocin is the most likely to manifest acute toxicity. Fanconi's syndrome, mild reductions in GFR, and severe acute "nephrotoxic" ATN have all been described.

Mitomycin-C is notorious for the propensity for recipients to develop HUS as a delayed and dose-related complication of this drug. HUS is considered elsewhere in this text.

The drug *mithramycin-C* used occasionally to treat hypercalcemia of malignancy is associated with ARF when used as an antineoplastic agent. ARF, however, is rare when single doses are used to treat hypercalcemia, although it has been reported.

Gallium nitrate, another agent used to treat hypercalcemia of malignancy, may lead to ARF as a result of intratubular precipitation of calcium-gallium-phosphate salts. This was a major side-effect of short infusions of this drug in initial studies. Continuous infusions (200 mg/m^2 for 5 days) have been administered without severe nephrotoxicity.

A similar mechanism of intrarenal obstructive ARF is described with large doses of *methotrexate*. Intraluminal precipitation of the metabolite 7-hydroxy-methotrexate and methotrexate is favored by a concentrated acidic urine. Preventive strategies employing hydration, alkalinization, and folinic acid (to prevent systemic toxicity) generally work well. Low-dose chronic use of methotrexate is generally well tolerated. However, renal impairment can lead to significant drug accumulation and systemic toxicity.

Mannitol

Mannitol is the polyol of the sugar mannose. Administered intravenously, it is inert, remains in the extracellular compartment, and is freely filtered by the kidney. It is used clinically for its osmotic properties to reduce intracranial pressure and intraocular pressure, and occasionally for its diuretic properties. It has been used as prophylaxis for nephrotoxic ATN, although an incremental benefit of mannitol over and above that gained from solute diuresis is unproved. When mannitol infusion exceeds its rate of clearance, the drug accumulates in the extracellular space. The osmotic effects are exaggerated beyond the therapeutic targets of lessening intracerebral pressure to include excessive cellular dehydration and altered mental status, extracellular volume expansion with congestive heart failure (CHF) and pulmonary edema, and metabolic abnormalities such as hyponatremia, hyperkalemia, and metabolic acidosis. Less recognized is the potential for mannitol to paradoxically precipitate ARF [18].

Observations have connected hemodynamic effects of mannitol at high and low doses with worsening medullary hypoxemia. Therefore, injury is most likely secondary to ischemia. A dose of 0.25 mg/kg every 4 hours used to lower intracranial pressure appears to be therapeutically effective, and higher doses have been shown to portend a poor prognosis. The osmotic gradient between the extracellular and intracellular compartment attributable to mannitol determines the fluid shift. It is recommended that during mannitol use, the osmolal gap rather than the serum osmolality be monitored. This is because a serum osmolality of 310 mOsm/kg in the setting of a sodium of 140 mM indicates a very different mannitol concentration in the extracellular fluid than the same serum osmolality in the setting of a sodium of 120 mM. ARF has been observed with peak osmolal gaps of 74 ± 39, and 107 ± 17 mEq/kg. The osmolal gap should be prevented from reaching these high levels by decreasing or holding mannitol doses while following renal function closely. ARF-complicating mannitol infusion reverses rapidly when the drug is discontinued.

Immunosuppressive Drugs

Nephrotoxic effects of immunosuppressive drugs are discussed in detail elsewhere in this text. Briefly, both cyclosporine and tacrolimus (FK506), commonly used immunosuppressants, can contribute to acute elevations in BUN and serum creatinine in a number of ways. First, both produce dose-dependent intrarenal preglomerular vasoconstriction with a reduction in glomerular hydrostatic pressure and GFR. This effect occurs within the therapeutic dose range used for transplantation. Second, nephrotoxic effects on both microvasculature and tubules are described. Early posttransplantation endothelial injury can initiate a thrombotic microangiopathic syndrome with ARF. This is fortunately uncommon. Acute tubular toxicity early post-transplant is also a dose-related adverse effect. Both cyclosporine and FK506 produce a chronic arteriolopathy and chronic toxicity with irreversible kidney damage that is discussed in detail elsewhere (Chapter III-4).

ARF in Bone Marrow Transplantation

Up to 40 – 50% of patients receiving a bone marrow transplant may develop some degree of ARF. Often dialysis is required, and the mortality rate is as high as 80 – 90%. A variety of etiologic factors, singly or in combination, may play a role. Included are volume deple-

tion; exposure to nephrotoxic antineoplastic, antibiotic, or immunosuppressive drugs; and an acute uric acid nephropathy complicating cytoreduction therapy. Additional etiologies include a syndrome of functional renal failure, hepatorenal syndrome-like in its presentation, that accompanies veno-occlusive disease of the liver. It is primarily a hemodynamic renal failure that occurs coincident with veno-occlusive disease during the first 2 – 3 weeks after transplantation. The outcome of the ARF is dependent on the outcome of the veno-occlusive disease. In the past, myohemoglobinuric ARF was seen to complicate marrow transplantation. This was usually the result of red cell lysis and hyperthermia complicating the use of dimethyl-sulfoxide as a cryoprotectant. Autologous and allogenic marrow is now red cell depleted, and patient management is specifically designed to avoid volume depletion. As a result, pigment nephropathy is now rare. Tumor infiltration is a recognized but exceedingly rare cause of ARF. For instance, although autopsy studies report a prevalence of 63 – 90% renal infiltration in chronic lymphocytic leukemia (CLL), reports of impaired renal function are uncommon.

Tumor Lysis Syndrome

Tumor lysis syndrome is characterized by ARF complicating the release of large quantities of intracellular molecules by necrotic tumor cells. It occurs most often in non-Hodgkin's lymphoma and acute lymphocytic leukemia (ALL). These are tumors with large bulk and very rapid growth phases. The syndrome can occur without treatment as tumors outgrow their blood supply, or it may complicate glucocorticoid or cytoreductive therapies. Characteristic metabolic abnormalities are hyperuricemia, hyperphosphatemia, hyperkalemia, hypocalcemia, and acute, typically oliguric renal failure. Volume depletion often plays a predisposing role. Renal failure is due to intraluminal precipitation of crystals of uric acid and, to a lesser extent, calcium phosphate. This occurs in the distal nephron leading to intraluminal obstruction. Precipitates and sludging are also seen in the medullary microvasculature.

Hydration, high-dose allopurinol, and alkalinization attenuate the occurrence and severity of this syndrome. Prevention is not absolute. Alkalinization to reduce uric acid precipitation should be titrated to achieve a urine pH of 7.0. If the urine pH rises above 7.0, alkali should be held because an alkaline urine favors calcium phosphate precipitation. Due to the scale of release of potassium and phosphorous from intracellular stores, early and intensive dialysis is frequently needed to prevent life-threatening hyperkalemia and extensive metastatic calcification. Early dialytic support can be life saving. Renal function typically recovers well in patients who survive.

Future Directions

A recent publication resulting from an NIH consensus conference, organized to discuss future directions for research in ARF, included recommendations for establishment of a multicenter database to be developed to facilitate outcomes research in ARF; an emphasis on prospectively validating risk stratification measures in ARF to be employed in the design of new randomized clinical trials; new clinical trials in ARF to investigate the roles of low-dose dopamine, hemodynamic monitoring, nutritional supplementation, di-

alysis modalities, dialysis delivery/intensity, and new adjunctive agents developing out of basic science research; and enhanced support of basic research addressing the cellular and molecular basis of renal tubular injury, changes in cell differentiation, cell repair, cell death, and organ recovery [19]. These various goals address urgent needs of physicians, patients, and families when approaching difficult decisions in the management of patients with ARF.

Exciting new treatments need to be investigated. Experimental data are accumulating to suggest exogenous administration of epidermal growth factor (EGF), hepatocyte growth factor (HGF), or insulin-like growth factor-I (IGF-1) might be beneficial in ARF syndromes [35]. Effects of growth factors are likely to be directly exerted on tubular cells. IGF-1 is also anabolic and modulates blood flow to increase RBF and GFR. In a double-blind, placebo controlled, prospective, randomized study of patients undergoing suprarenal aortic or renal artery surgery, the administration of IGF-l was found to be feasible and associated with a smaller postoperative decline in renal function [21]. However, no cases of established ARF were documented in the study, and the use of IGF-l did not significantly impinge on the outcomes or hospital course. IGF-l has also been safely administered to patients with chronic renal failure, where it augments RBF and GFR. The therapeutic value of arginine-lysine-aspartate (RGD) peptides is also worth investigating [25]. These peptides bind up B1 integrins on tubular cells, thus preventing the cells from binding to each other. They may also ameliorate aggregation of intraluminal debris and cells, thus preventing luminal obstruction in ATN. Antibodies against the cell adhesion molecule ICAM-l or against other inflammatory mediators may reduce the inflammatory component of the ischemic-reperfusion injury in the maintenance phase of ATN [31]. Enhanced blood flow to hypoxic tubules with newer vasoactive agents, such as those modulating endothelin-mediated vasoconstriction, may also have value in human ARF.

Advances in supportive therapies for dialysis-requiring ARF must focus on clarifying the respective roles of continuous and intermittent treatment modalities. Since outcomes in ESRD are inversely related to the dialysis dose delivered, intensive dialysis needs to be pursued with further evaluation of its role in ARF. It will be necessary to modify quantification techniques of the delivered dialysis dose in ARF to account for the confounding factors posed by the non-steady state metabolic characteristics, variable volumes of solute distribution, and impaired tissue perfusion that exist in this population of patients. Prescriptions may need to be related to urea generation as a marker of catabolic rate, and delivered dose may require dialysate-side quantification of solute clearance [9].

Improvements in dialysis and hemofiltration, however, only replace the filtrate function of the kidneys. Renal tubules also have important reabsorptive, homeostatic, metabolic, and endocrine functions. Replacement of these lost functions through cell therapy or tissue engineering in patients with ATN could be helpful in providing more complete support during the maintenance phase of ATN, and might enhance a speedier recovery and improve overall prognosis. Cell therapy is an evolving strategy that uses cells as vehicles for delivery of drugs by taking advantage of their synthetic and metabolic properties. A “bioartificial” renal-tubule device that uses epithelial progenitor cells is currently being tested in preclinical trials [29]. Its potential additive benefits in treating syndromes of ARF are also worthy of continued investigation, as it provides a unique and novel supportive strategy.

Conclusion

ARF is a serious, common, complicated and costly medical illness. Other comorbid conditions may accompany ARF, often as a presentation of multiple organ dysfunction. Management of these issues is outside the scope of this chapter. The precise contribution of ARF to these other serious comorbid conditions is sometimes difficult to determine. The dictum that people *die with* and not *of* ARF, however, suggests that if only we could manage all the other combined problems better, our current sophistication in terms of renal replacement therapy is good enough to ensure survival. However, it has been suggested that renal failure per se affects mortality rates [36] and that improving biocompatibility of dialysis treatments enhances survival [27]. It is thus more likely that the high mortality rate in ARF is determined by complicated interdependent relationships among all the existing comorbid conditions, including ARF itself.

Much progress needs to be made in both the prevention and treatment of patients with ARF. We believe that interventions which improve the treatment of ARF or shorten its duration will translate into lives saved.

Clinical Manifestations of Chronic Renal Insufficiency

Paolo Fanti

Introduction

Progression to end-stage renal disease (ESRD) is characterized by the disruption of a number of biological functions, including fluid and electrolyte balance, intermediate metabolism, and endocrine, neurological, hematological, cardiovascular, gastrointestinal, cutaneous and ophthalmologic functions. This brings about a large and characteristic cohort of clinical manifestations that constitute the uremic syndrome. Uremia starts to declare itself to patient and physician when renal function drifts below 30%. However, individual manifestations do not appear simultaneously, but rather depend on the degree of loss of glomerular filtration rate (GFR); on the concomitance or pre-existence of other pathologies such as diabetes mellitus (DM), coronary artery disease (CAD), and peripheral vascular disease (PVD); and on the individual predisposition of a patient. The following review of the clinical manifestations and management of the uremic syndrome is limited to the period preceding the institution of renal replacement therapy (RRT).

Water and Electrolyte Balance

Water Balance

Progressive loss of the structural integrity of the nephrons and anatomical derangement of the renal medulla causes loss of renal responsiveness to anti-diuretic hormone (ADH). This, along with the increased single-nephron GFR and the increased filtered load of solutes such as urea, impairs the renal concentrating and diluting functions. Under these conditions, the urine approaches isosthenuria, i.e. urine osmolality equal to that of serum, and the solute excretion becomes the main determinant of water excretion. The practical consequence of this phenomenon is that patients with advanced renal insufficiency are at risk of developing either dehydration and hypernatremia, or water intoxication and hyponatremia, when water intake is less or more, respectively, than mandated by the solute load.

Sodium (Na^+) Balance

Na^+ load per nephron increases as renal function is progressively lost, and both humoral and renal tubule adaptative mechanisms are activated to decrease tubular Na^+ reabsorption and to maintain Na^+ balance. In

advanced renal insufficiency, excessive Na^+ intake tends to cause Na^+ retention and volume overload because of the preexisting maximal or close-to-maximal depression of renal tubule reabsorption. Conversely, the ability to lower Na^+ excretion during Na^+ restriction is hindered by the increased osmotic diuresis per nephron. Thus, patients with advanced renal insufficiency tend to develop volume overload or volume depletion, respectively, when the dietary Na^+ intake is excessively large or small.

Potassium (K^+) Balance

As is the case with Na^+, the K^+ load per nephron increases in advanced renal failure. Differently from Na^+, however, K^+ balance is maintained primarily by changes in tubular secretion rate. This is accomplished primarily by activation of the renin-angiotensin system and consequent increased distal tubular K^+ excretion. Large intestine excretion of K^+ is also responsive to this hormonal system, and it contributes some to the maintenance of K^+ homeostasis in chronic renal failure (CRF). The importance of the renin-angiotensin-aldosterone axis in the maintenance of K^+ balance is underscored by the observation that CRF patients with anatomic damage of the juxtaglomerular apparatus and with hyporeninemic hypoaldosteronism frequently experience hyperkalemia. Even when this hormonal system is normally functional, patients with CRF usually do not tolerate excessive dietary K^+ intake or the use of β-adrenergic receptor agonists, nonselective beta blockers (which impair K^+ entry into cells), nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and K^+-sparing diuretics (which impair tubular K^+ excretion).

Intermediate Metabolism

Protein Metabolism and Calorie Requirement

The minimum daily protein requirement of moderately active healthy adults in energy balance is commonly set at 0.6 g/kg/day of high biological value proteins. In Western postindustrial societies, the average protein intake is higher than 1 g/kg/day and includes a large proportion of high biological value proteins. Healthy individuals tolerate this excess of proteins relatively well due to biochemical pathways that dispose of surplus amino acids. Conversely, patients with advanced renal insufficiency cope poorly with excessive protein intake. Inability to dispose of the degradation products derived from excess protein intake leads to accumulation of: (1) nitrogen moieties that contribute to uremic symptoms, (2) titratable acid leading to metabolic acidosis, (3) phosphates with secondary hyperparathyroidism, and (4) Na^+ with volume expansion and arterial hypertension. An increased renal load of osmotically active moieties and phosphates is also believed to accelerate the progressive loss of renal function. Additionally, recent observations indicate that unrestricted protein intake is harmful for patients with the nephrotic syndrome, as it seems to worsen these individuals' proteinuria and hypoalbuminemia.

For these reasons, protein-restricted diets have been utilized for > 3 decades in the management of patients with CRF [1, 2]. The soundness and safety of this practice has been corroborated over the years by a large body of clinical observations and experimental studies which show:

– protein-restricted diets do indeed prevent or ameliorate many symptoms and com-

plications of CRF and they might slow the progressive loss of renal function;
- the rates of amino acid metabolism and the energy expenditure of nonacidotic patients with CRF are not different from those of healthy controls, both at rest and during exercise [3, 4]; and
- normal subjects and patients with CRF are equally able to achieve neutral nitrogen balance when fed low amounts of high biological value proteins (0.6 g/kg body weight/day), as long as they are provided with adequate amounts of energy (≥ 35 kcal/kg/day) [5].

Despite these findings, most studies of patients on dialysis indicate that these individuals are malnourished [6, 7] and that malnutrition often antedates the dialysis therapy [8]. This is of major concern since malnutrition at the onset of ESRD is a potent predictor of increased morbidity and mortality, as shown in studies with up to 5 years of follow-up [9, 10]. Protein and/or energy intake below the thresholds given above are important contributing factors [11], because it is known that patients with GFR below 25% tend to suffer from anorexia [12]. In addition, It is believed that accelerated protein catabolism may be as important in promoting malnutrition. Conditions that promote protein degradation during advanced renal insufficiency include
- inadequate energy intake in concomitance with a protein-restricted diet, because patients with CRF are unable to adapt to low protein diets when the caloric intake is < 35 kcal/kg/day;
- metabolic acidosis, which starts to develop with a GFR < 40 mL/min [13];
- depressed anabolic effect of insulin on muscle protein synthesis; and
- chronic inflammatory conditions with increased pro-inflammatory cytokine activity.

Treatment

Protein restriction should be implemented in those patients who are motivated and capable of following the rather stringent rules of this diet. The goals of nutritional therapy are to prescribe a diet sufficient to prevent malnutrition, to diminish the accumulation of nitrogenous waste and metabolic disturbances characteristic of uremia, and to slow the progression of renal failure. Protein intake is determined based on the degree of renal insufficiency, the presence of progressive renal failure, the level of proteinuria, the presence of diabetic nephropathy, and the concomitant use of glucocorticoids.

Lipid Metabolism

Abnormal serum lipid and lipoprotein concentrations are present early in patients with CRF and are only marginally affected by the degree of renal failure and by the use of dialysis. This metabolic abnormality is a likely important contributor to the high incidence of atherosclerosis and cardiovascular disease in the CRF population. Although total cholesterol is frequently normal, the serum concentrations of low-density lipoproteins (LDL) and high-density lipoproteins (HDL) cholesterol tend to be high and low, respectively. Triglyceride levels are often elevated, due to low lipoprotein lipase activity and impaired conversion of very-low density lipoproteins (VLDL) to LDL. Low activities of lipoprotein lipase, hepatic triglyceride lipase and lecithin cholesterol acyltransferase result in accumulation of intermediate density lipoproteins (IDL) and reduction of HDL. Factors such as insulin resistance or deficiency, hyperparathyroidism, carnitine deficiency, and altered

lipoprotein content of the VLDLs have been proposed as contributors to the decreased lipase activity. Recently, several groups have reported the frequent occurrence of high levels of lipoprotein(a) (Lp(a)) and of oxidized lipid moieties in the circulation of patients with ESRD [14 – 16] and CRF [17]. The observation that both Lp(a) and oxidized lipids contribute to cardiovascular disease in subjects with normal renal function justifies the recent interest in the possible role of these factors in the progression of atherosclerosis in renal patients. Interestingly, high blood levels of both Lp(a) and oxidized lipids are favored by increased oxidative stress and chronic inflammation, conditions that frequently occur in CRF patients.

Treatment

Because accelerated atherosclerosis and cardiovascular disease are the leading cause of morbidity and mortality in patients with CRF, prophylactic treatment of these conditions should be considered in patients with chronic renal insufficiency. Unfortunately, very limited information is currently available on the effectiveness of long-term lipid reduction therapy in this patient population, and most of the practices in this area are based on clinical trials in populations without renal disease. In general, these patients should be instructed to follow the American Heart Association step 1 diet, which provides < 30% of total calories from fat and < 10% of total calories from saturated fat. Also, all patients are urged to achieve desirable body weight and to maintain cardiovascular fitness with daily exercise. Pharmacological intervention with β-hydroxy-β-methyl glutaryl coenzyme A (HMG-CoA) has been proposed for individuals with LDL persistently > 140 mg/dL [18]. Gemfibrozil can also be used with pronounced lowering effects on the triglycerides and some modest effect on LDLs [19]. The practice of prescribing antioxidants such as high dose α-tochopherol is gaining popularity to reduce oxidative stress and ameliorate the chronic inflammation seen in these patients. However, high-dose ascorbic acid (vitamin C) should be avoided because of the tendency of this moiety to be converted to oxalic acid, resulting in oxalosis.

Carbohydrate Metabolism

Moderate and advanced renal insufficiency is associated with glucose intolerance, caused in part by acquired resistance of the target organs to the insulin action. In these patients, normal binding of insulin to its receptor is not followed by adequate activation of the postreceptor pathways that mediate this hormone's cellular actions. An additional cause of glucose intolerance in renal insufficiency is the abnormal pancreatic release of insulin in response to glucose. Secondary hyperparathyroidism contributes to the latter abnormality because PTH increases intracellular levels of calcium. These metabolic aberrances may require the institution of exogenous insulin therapy in patients with noninsulin-dependent (Type II) DM who develop moderate renal insufficiency. Paradoxically, the insulin requirement of diabetics with renal insufficiency tends to decrease as the renal function falls below 20%, due to reduced renal degradation of proinsulin, C-peptide, and both endogenous and exogenous insulin, resulting in higher blood levels of these peptides.

Immunity, Inflammation and Oxidative Stress

Both humoral [20, 21] and cellular immunity [22] are compromised as renal function is progressively lost [23]. This acquired immunodeficiency state contributes to increased infection risk [24], anergy, poor response to vaccines, and decreased autoimmune disease activity. Paradoxically, this immunodeficiency state is associated with sustained activation of several cell types that participate in the host defense, including the monocytic cell line [25]. Activated monocytes and macrophages are integral elements of the smoldering multifactorial inflammatory state that is often detected in renal failure patients. This develops early in the course of renal failure and is characterized by the presence of high circulating levels of C-reactive protein (CRP) [26, 27], lipopolysaccharide binding protein [28], interleukins IL-1β and IL-6, and tumor necrosis factor-α (TNF) [29, 30], as well as the presence of cytokine-specific inhibitors, including interleukin-1 receptor antagonist (IL-1Ra) and tumor necrosis factor soluble receptors (TNFsRs) [31]. This chronic inflammatory state is intimately linked to increased monocytic and neutrophilic production of reactive oxygen species. Since both exogenous and endogenous antioxidants such as α-tocopherol [32, 33], ascorbic acid [34], superoxide dismutase [35], and the glutathion system [36] are decreased in CRF, the high production of reactive oxygen species results in oxidative damage and further stimulates inflammation [37 – 39]. Indeed, markers of lipid and protein oxidation are elevated in advanced chronic renal insufficiency [40 – 42]. During the last decade, evidence has accumulated to suggest that inflammation and oxidative stress contribute substantially to the high morbidity and mortality of renal failure patients by promoting anorexia, wasting, malnutrition [43, 44], accelerated atherosclerosis [45] and premature cardiovascular disease [46].

Treatment

Prospective studies demonstrating the safety, efficacy, and cost effectiveness of measures aimed at identifying and treating inflammation and oxidative stress in the renal failure population are lacking. Based on the currently available evidence, the measurement of CRP seems a reasonable test to survey patients with chronic renal disease for signs of chronic inflammation and oxidative stress. High levels should prompt a search for potentially correctable causes, such as infections, drug allergies, autoimmune disease, and cancer. Also, a therapeutic trial with antioxidants may be considered. Alpha-tocopherol is a good candidate since it is a potent dietary antioxidant, its level is low in renal failure patients, and it does not present any specific toxicity for the renal failure population. Ascorbic acid has a synergistic effect with α-tocopherol in its antioxidant activity. However, prudence should be exercised, since it is converted to oxalic acid and may cause oxalosis.

Endocrine Systems

Divalent Ion, Parathyroid Hormone (PTH) and Vitamin D Metabolism

Early signs of altered mineral homeostasis can be detected in most patients with 50% reduction of GFR, although the laboratory

and clinical signs become obvious in all patients when the GFR is < 25 – 30%. During progressive loss of renal mass, the remaining functional tissue adapts by decreasing tubular reabsorption of ultrafiltered phosphorus (Pi), leading to increased single-nephron excretion of this ion. In advanced renal failure, the fractional excretion (FE) of Pi can be as high as 90% [47, 48]. This compensatory mechanism allows maintenance of adequate renal Pi clearance until the GFR is < 20 – 25 mL/min, at which point the residual renal mass is often unable to handle the normal dietary intake of Pi and hyperphosphatemia develops. Serum calcium (Ca) declines progressively in moderate and advanced renal insufficiency, due in part to the formation of Ca-Pi products (see above), but mostly because of progressive development of calcitriol deficiency and of target-organ resistance to this hormone, leading to inadequate intestinal absorption of Ca. The calcitriol deficiency is caused primarily by the progressive loss of renal mass, which is essential for the production of calcitriol, and also by the inhibitory effect of hyperphosphatemia on the renal production of this hormone. Hyperphosphatemia, hypocalcemia and calcitriol deficiency are stimuli to the production of PTH, and they all contribute to the development of secondary hyperparathyroidism. The clinical consequences of these divalent ion and hormonal abnormalities are secondary hyperparathyroidism, renal osteodystrophy, and soft tissue calcifications [49]. Hypocalcemia develops slowly and it becomes symptomatic (muscle twitching or frank tetany) almost exclusively associated with an abrupt rise of systemic pH, which in turn causes a fall in ionized Ca. Soft tissue calcifications usually occur when the Ca-Pi product (both expressed in mg/dL) exceeds 70 and they affect primarily the blood vessels, skin, cornea, and periarticular tissues. Pseudo/gout, i.e. intraarticular deposition of Ca pyrophosphate crystals, with clinical manifestations indistinguishable from those of gout, can occur in patients with advanced renal insufficiency. High blood levels of PTH and skin deposition of Ca-Pi products are important contributors to the development of pruritus. Prior to the diagnosis of ESRD, renal osteodystrophy is most often asymptomatic, although the most severe cases of secondary hyperparathyroidism are associated with early onset of bone pain and skeletal deformities. Additionally, patients with severe secondary hyperparathyroidism have a high rate of bone turnover with excess release of Pi from bone, which can contribute substantially to the maintenance of hyperphosphatemia.

Treatment

In patients with moderate to severe renal insufficiency, serum Pi should be maintained at 4.0 – 5.5 mg/dL. Reductions of Pi intake to 10 mg/kg/day, which is implemented primarily to slow the progression of the renal failure, contribute to the control of hyperphosphatemia. Small amounts of Pi binders are often required once the GFR is below 25%. Ca acetate and Ca carbonate are the most popular choices [50]; aluminum-containing Pi binders should be avoided even at this stage of renal disease. Organic polymer-based phosphate binders have been tested successfully, and they were recently introduced to the market [51]. Serum Ca levels should be maintained in the normal range. Intake of Ca-containing Pi binders with meals inevitably results in intestinal absorption of small amounts of Ca. Serum Ca levels > 10.0 mg/dL should be avoided to prevent further deterioration of renal function. When serum Ca is low and Pi is normal, Ca salts can be given between meals to increase Ca absorption without interfering with the absorption of dietary Pi. Cir-

culating intact PTH should be checked once yearly to rule out the presence of advanced secondary hyperparathyroidism. If PTH is > 3-fold above the upper limit of normal, therapy with calcitriol should be started at the low dose of 0.125 μg/day. This calcitriol dose is effective at reducing circulating PTH without causing deleterious effects such as hypercalciuria, hypercalcemia or loss of renal function [52, 53]. Hypercalcemia is a rare event in the predialysis population, and it should be avoided to prevent further renal damage.

Reproductive System

Dysfunction of the hypothalamic-pituitary-gonadal axis becomes clinically apparent with a GFR < 20 mL/min. Men and women are affected alike, although the deficiency is more obvious in men. In both genders, sexual desire and activity are inversely proportional to the severity of uremia [54]. Indifference to sexual activity can develop with advanced renal failure. In women, menstrual irregularities consistently follow the deterioration of the renal function. Oligomenorrhea occurs with GFR < 15 ml/min and amenorrhea occurs once the GFR is below 5 ml/min. In men, decreased libido and performance develop as the renal function deteriorates and impotence is present in as many as 56% of men with ESRD [55]. The testicles are soft and atrophic, and spermatogenesis is impaired or absent. Gynecomastia occurs more often after dialysis is started. Adolescents suffer from delayed puberty with retardation of skeletal growth. The pathogenesis of these abnormalities seems to be related to direct or indirect effects of uremia on both the hypothalamic-pituitary system and on the gonads. The roles of anemia, zinc deficiency and secondary hyperparathyroidism have been reported. Relatively frequent issues that come up in young women with renal disease are the counseling and management of pregnancy. Pregnancy outcome is 90% successful in women with a serum creatinine < 1.5 mg/dL [56, 57]. When the serum creatinine is > 1.5 mg/dL, the therapeutic abortion rate is 13 – 24% [58, 59], and 56 – 63% of deliveries are preterm, mostly due to worsening renal function, hypertension, abruptio placentae, and fetal distress [60, 61]. Fetal survival ranges from 60 – 92% with highest frequencies in the most recent reports [62]. The presence of maternal hypertension seems to substantially affect the fetal outcome, since preterm birth and growth retardation are more common in hypertensive than normotensive women [63]. Recent progress in medical and pharmacologic management of mother and fetus may continue to improve the fetal outcome in women with chronic renal insufficiency and hypertension.

Growth Hormone System

Growth hormone and the radioimmunoassayable levels of the insulin-like growth factors (IGFs) are elevated in renal failure. However, the bioassayable levels of the IGFs are low due to the presence in the uremic serum of low-molecular-weight inhibitors of the IGFs. This accounts for the stunted growth of children with renal insufficiency, which responds favorably to exogenous administration of recombinant human growth hormone.

Thyroid Hormone

Total thyroxine (T4), free thyroxine index (FTI), total triiodothyronine (T3) and free triiodothyronine index tend to be low in renal

failure while the reverse T3 level is normal. Despite these hormonal abnormalities, the thyroid-stimulating hormone (TSH) and the basal metabolic rate are normal.

Hematology

Hematopoietic System

The hemoglobin concentration in azotemia has roughly the same prognostic significance as the creatinine level [64]. In over 90% of the patients with CRF, the hematocrit (HCT) starts to fall when the creatinine clearance reaches 30 – 35 mL/min. Exceptions are patients with polycystic kidney disease (PKD), acquired multicystic disease, hypertensive nephrosclerosis, and some diabetics who can maintain normal HCTs well into end-stage renal disease (ESRD). The anemia is usually normochromic and normocytic. The most important factor by far in the development of anemia is the decreased production of erythropoietin, which normally regulates the bone marrow erythrocyte production. Other factors include:

- resistance to erythropoietin due to deficiency of iron or folic acid; reticuloendothelial blockade from infections, cancer and inflammatory states [65 – 68]; myelofibrosis; aluminum intoxication [69]; bone marrow fibrosis secondary to severe hyperparathyroidism [70, 71];
- shortened erythrocyte life span [72] and possibly neocytolysis [73]; and
- occult bleeding.

Anemia has a profound effect on these patients' general well being and on the performance of their cardiovascular and central nervous systems. Anemia results in progressive reduction of activity and energy level and of exercise tolerance [74]. This is associated with left ventricular dilatation and diastolic dysfunction [75]. Additionally, anemia causes deterioration of the cognitive function and contributes to the neurobehavioral syndrome of uremia that is characterized by confusion, inability to concentrate, decreased mental alertness and impaired memory [76, 77]. The association between anemia, intractable pruritus, and high circulating histamine concentration was reported in a subset of CRF patients [78]. Anemia has also been implicated in the impairment of sexual function that is common in patients with CRF [79].

Treatment

The mainstay of anemia management is the systemic administration of recombinant human erythropoietin (rHu-Epo) with concomitant adequate support of iron stores. RHu-Epo is started when the HCT drops below 30%. A starting dose of 100 – 150 U/kg 3 times/week achieves HCTs > 35% within 4 weeks. The dose is subsequently adjusted to approximately 25 U/kg once weekly, based on individual response [80]. Initiation of rHu-Epo therapy must be preceded by assessment of iron stores. Iron should be replaced to maintain the transferrin saturation > 16% and ferritin > 80 µg/L. In resistant cases, occult blood loss, hemolysis, inflammation, infection, malignancy, aluminum toxicity, vitamin B12 and folate deficiency, myelofibrosis, red cell enzyme defect and hemoglobinopathies should be considered and corrected [81]. Nephrectomy of failed allografts, empiric treatment with broad spectrum antibiotics, and a cycle of steroids may be considered [82].

Coagulation System

The bleeding tendency is characterized by prolonged bleeding time, and it is rarely of clinical consequence before the GFR falls below 15%. The pathogenesis relates to dysfunction of platelet aggregability, but also to abnormal function of the vascular endothelial wall, to aberrant interaction of platelets and endothelium and to the anemia. Treatment of the bleeding diathesis is required before surgical procedures and during active bleeding. Correction of concomitant anemia with transfusions or rHu-EPO injections are often effective at shortening the bleeding time. 1-deamino-8-D-arginine (DDAVP), either 0.3 μg/kg intravenously (IV) or 3 mg/kg intranasally, restores hemostasis within 30 – 120 minutes and for as long as 8 hours, although repeated administration quickly results in tachyphylaxis. Transfusions of cryoprecipitate are effective for 12 – 18 hours from the time of infusion, but they carry a risk of transmitting viral infections. Conjugated estrogens (0.6 mg/kg/day for 5 days) correct hemostasis one day after administration and last for up to 2 weeks.

Cardiovascular System

Systemic Hypertension

Hypertension is the initial cause of renal disease in approximately 3% of Caucasians and 16% of African-Americans with CRF [83]. Conversely, hypertension develops in virtually all cases of CRF secondary to glomerular and renal small vessel disease, and in 40 – 70% of the cases secondary to tubulointerstitial disease. Hypertension is one of the earliest manifestations of chronic renal insufficiency, since it is diagnosed even with minimal loss of renal function and can precede the onset of most signs and symptoms of uremia by many years. Hypertension of renal disease accelerates the progression of the already present renal damage and the development of congestive heart failure (CHF), CAD, and cerebrovascular disease. The major factors involved in the pathogenesis and maintenance of hypertension in CRF are salt and water retention, enhanced activity of the renin-angiotensin system, and increased sympathetic tone. Other possible contributors are the decreased production of the endothelium-relaxing factor nitric oxide and the presence in the circulation of inhibitors of the Na-K-ATPase pump.

Treatment

Treatment of hypertension is essential in CRF, because it slows down the progression of the renal damage and decreases morbidity and mortality. The definition of satisfactory blood pressure control in renal failure is not well established, although the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure (JNC VI) recommends controlling the blood pressure to 130/85 mmHg (mean arterial pressure (MAP) 100 mmHg) in individuals without proteinuria and to 125/75 (MAP 92 mmHg) in individuals with > 1 g/day of proteinuria [84]. The management of the hypertension of CRF presents 3 major challenges:

- hypertension is often severe and difficult to control, thus requiring the use of ≥ 2 medications;
- the choice of the antihypertensive agents must take into account the coexistence of several medical conditions that can be

exacerbated by antihypertensive therapy, including DM, dyslipidemias, LVH, and accelerated atherosclerosis; and

– the pharmacology of many antihypertensive agents is altered in renal failure, often leading to special posology requirements, to altered type and frequency of side effects as compared to the normal renal function population, and in some instances to outright contraindication of their use.

Nonpharmacologic intervention should include restriction of sodium chloride intake to < 6 g/day (100 mmol of elemental Na^+), daily moderate exercise, and weight reduction. Pharmacologic intervention often starts with a diuretic which, for GFR < 50%, should always be a loop diuretic. For these levels of compromise in renal function, the thiazides should be used only as an adjunct to loop diuretics in the rare cases of resistance to loop diuretics. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II (Ang II) receptor blockers have been shown to have renal protective effects. When tolerated, they can be either added to the diuretic or used as first-line agent. When ACE inhibitors and Ang II receptor blockers are not tolerated, the calcium channel blockers are a good alternative. The nondihydropyridine calcium channel blockers (verapamil and diltiazem) seem to have renal protective effects of somewhat lesser magnitude than the ACE inhibitors, although not all studies have reported this effect. Conversely, the dihydropyridine calcium channel blockers (nifedipine, amlodipine, felodipine, isradipine, and nicardipine) appear to be neutral in terms of renal-protective effects. Beta-blockers are a good alternative to ACE inhibitors, Ang II receptor blockers, and calcium channel blockers. The selection of a beta-blocker should try to match the pharmacologic features of the individual drug with each patient's special needs. Beta-blockers with intrinsic sympathetic activity (Table 1) can be prescribed in the attempt to minimize unwanted effects on lipid metabolism and exercise tolerance. Beta-blockers with poor lipid solubility can be chosen to minimize diffusion in the nervous system and the occurrence of central nervous system (CNS) side effects. β_1-selective blockers should be prescribed when the presence of CAD is documented or strongly suspected. Beta-blockers with extensive hepatic elimination can be used when toxicity due to excess accumulation is a concern. Central alpha agonists (clonidine) and peripheral alpha-adrenergic receptor blockers (terazosin and doxazosin) are effective third-choice antihypertensives. Minoxidil and hydralazine are potent peripheral vasodilators that are often effective in cases of tenaciously resistant hypertension.

Cardiac Function

Congestive heart failure (CHF) is often present in patients with advanced renal insufficiency. Ischemic heart disease, hypertrophic and/or dilated cardiomyopathy are frequently present and should be managed with the same diagnostic and therapeutic principles that apply to cardiac patients with normal renal function. Manifestations of CRF that often participate in the development and/or exacerbation of CHF are hypertension, anemia, fluid overload, and electrolyte abnormalities including hyperkalemia, hypocalcemia, and acidosis. These should be carefully looked for and aggressively treated and prevented. Uremia per se is believed to affect myocardial contractility, the most convincing evidence coming from the incidental observation of improved cardiac function after renal transplantation and from animal studies [85]. Disturbances of

Table 1. Pharmacological Properties of Beta-blockers. Modified from [88]

Drug	Trade name	β_1-Selectivity	Intrinsic Symp. Activity	d Blockade	Lipid Solubility	Renal Elimination	Dose
Acebutolol	Sectral	+	+	–	++	0	200 – 800 qd
Atenolol	Tenormin	++	–	–	–	100	12.5 – 25 qd
Betaxolol	Kerlone	++	0	–	–	0	5 – 20 qd
Bisoprolol	Zebeta	++	0	–	++	50	2.5 – 5 qd
Carteolol	Cartrol	0	+	–	–	100	1.25 – 2.5 qd
Carvedilol	Coreg	–	0	+	++	10	12.5 – 50 bid

qd = daily, bid= twice daily

the cardiac rhythm are relatively frequent in renal insufficiency and are mostly related to electrolyte imbalance (hyperkalemia, hypermagnesemia, hypocalcemia, acidosis) or to drug toxicity (digoxin, procainamide, renally-excreted β-blockers). Pericarditis used to occur in about half of the patients who died from uremia before the advent of dialysis. Currently, this condition is much less frequent and is almost always detected once ESRD is reached. Uremic pericarditis in advanced renal insufficiency is a fibrinous inflammatory process. Onset of pericarditis is in itself an indication for initiation of chronic RRT.

Neurologic System

Peripheral Neuropathy

Peripheral neuropathy develops early in chronic renal insufficiency, and abnormalities of the nerve conduction velocity test are often detected much earlier than the onset of symptoms. The onset of symptoms is insidious but very frequently present once the GFR is < 30 mL/min. Peripheral neuropathy is symmetrical, insidious in onset, and slowly progressive. It begins distally and spreads proximally, with the lower extremities being affected first. It is sensorimotor, with the sensory involvement preceding the motor involvement. It is indistinguishable from diabetic neuropathy

and the 2 very often overlap. Loss of 2-point discrimination, vibratory perception, and paresthesias are common. When the GFR is < 15 mL/min, the restless-leg syndrome can occur, with sensations of crawling, prickling and pruritus that worsen with rest and in the evening and improve with movement. The burning-feet syndrome is less frequent and characterized by tenderness and sensation of swelling of the lower extremities. The motor deficit occurs later and is characterized by loss of deep tendon reflexes, weakness of dorsiflexion of the feet, limb weakness, and unsteady gait. The neurological deficit is only partially reversed by RRT, with Wallerian degeneration and neuron loss accounting for the irreversible component of the syndrome. Presence of severe peripheral neuropathy is an indication for initiation of RRT, since procrastination can result in irreversible damage. Low dose tricyclics (e.g. amytriptiline) are moderately effective. The author has had favorable anecdotal experience prescribing the anticonvulsant gabapentin for treatment of symptoms related to peripheral neuropathy [86, 87].

Autonomic Dysfunction

The most frequent and troublesome manifestation is gastroparesis, which overlaps with diabetic gastroparesis. Other manifestations are orthostatic hypotension, impaired sweating and abnormal response to the Valsalva maneuver.

Uremic Encephalopathy

Patients with GFR < 20 mL/min can develop symptoms of reduced general cerebral activity with disturbances of mentation and cognition. These symptoms are more frequent and pronounced in the elderly, especially if uremia is superimposed on preexisting organic damage of the brain. Frequent initial symptoms are apathy, fatigue, confusion, narrowed attention span, impaired memory, and somnolence. The normal sleep pattern is often affected with altered day-night rhythm. More advanced symptoms, that usually occur with GFR < 10 mL/min, are disorientation, irritability, inappropriate behavior, hallucinations, delusion, anxiety, lethargy, stupor, and coma. The latter more advanced symptoms are almost never experienced nowadays, because of intervention with RRT.
