There is substantial overlap between factors that regulate endothelial COX-2 and mediators of cardiovascular disease, including shear stress (Healy et al. 2005), hypoxia (Schmedtje et al. 1997), thrombin (Syeda et al. 2006), and pathophysiologically elevated levels of angiotensin II (Zerrouk et al. 1998) and aldosterone (Xavier et al. 2011). Increased vascular oxidant stress, which is associated with each of these, may be one converging mechanism by which agents these affect COX-2 regulation of platelets. Under pathological conditions, vascular endothelial cells and platelets synthesize elevated levels of the reactive oxygen species (ROS) superoxide anion ($O_2^{-\cdot}$), H_2O_2, and hydroxyl anion ($^{\cdot}OH$), which in the setting of thrombosis are likely derived mainly from NAD(P)H oxidase (NOX) or xanthine oxidase enzyme activation (Marcus et al. 1977). Additional triggers of ROS release in platelets include their stimulation by collagen or eNOS uncoupling (Essex 2009; Pignatelli et al. 1998). Platelet-released $O_2^{-\cdot}$, in turn, is associated with increased availability of ADP, activation of thrombin receptor-activating peptide that inhibits thrombus dissolution, and scavenging of $NO^{\cdot}$ by $O_2^{-\cdot}$ which generates $ONOO^-$ (Essex 2009). Endothelial H_2O_2 generation stimulated by the inflammatory cytokine TNF-α increases endothelial COX-2 expression and COX-2-dependent increases in TXA_2 levels (Eligini et al. 2005) (see discussion on overlap between COX-1 and COX-2 signaling, later).

Strategies that attenuate ROS accumulation in endothelial cells or platelets may reverse this prothrombotic tendency. Pignatelli and colleagues observed an inverse, dose-dependent effect of catalase (which reduces H_2O_2 to water) on TXA_2 synthesis, platelet membrane arachidonic acid release, and inositol triphosphate (IP3) formation (Pignatelli et al. 1998). More recently, the plant derivative and antioxidant catechol (benzenediol) (1–10 μM) was demonstrated to attenuate rabbit platelet COX-2 activity and TXA_2-induced platelet activation, which correlated positively with inhibition of platelet-derived ROS accumulation (Chang et al. 2014). Others propose transcription and activation of NF-κB, a redox-sensitive transcription factor present in various vascular cells involved in thrombosis, as a unifying mechanism involved in COX-2 regulation (Schmedtje et al. 1997).

Generally, prostanoids have a short half-life (e.g., 3 s for PGI_2) and, thus, do not have sustained bioactivity in the circulation. However, PG stability is sufficient to enable physical interaction with the IP after release from the vessel wall. Stimulation of the IP by PGI_2 promotes coupling of the heterodimeric G protein subunit $G\alpha_s$, resulting in activation of adenylyl cyclase (AC) 3, AC6, and AC 17 (Dittrich et al. 2008) in platelets (Kobayashi et al. 2000). Activation of

protein kinase A (PKA) by AC-derived cAMP occurs in human platelets through dissociation of the PKA regulatory and catalytic subunits RIα, RIβ, RIIβ, Cα, and Cβ (Smolenski 2012; Rowley et al. 2011) and confers on platelets a multitude of downstream effects including inhibition of adhesion, aggregation, and granule release.

A number of PKA substrates involved in mediating platelet bioactivity have been studied. For example, phosphorylation of the small G-protein Rap1B at Ser7 or Ser179 (Subramanian et al. 2013) by PKA deactivates Rap1B and inhibits platelet aggregation. Compared to wild-type mice, *rap1b*$^{-/-}$ mice have a four-fold increase in bleeding time attributable to decreased platelet aggregation, exhibit impaired platelet reactivity in response to ADP and epinephrine (Chrzanowska-Wodnicka et al. 2005), and express an abnormal response to mechanotransduction in the endothelium (Lakshmikanthan et al. 2015).

Phosphorylation of the myosin light chain (MLC) component of the actomyosin complex is another critical target of PGI_2-PKA signaling. Although platelet activation through Ca^{2+} release is an important mechanism underlying TXA_2-mediated MLC kinase (MLCK) and MLC_{20} phosphorylation (Offermanns 2006; Wikstrom et al. 2008), PGI_2 attenuates platelet activation/aggregation through Ca^{2+}-independent mechanisms, including via RhoA. In particular, stimulation of the IP subunit $G\alpha_{13}$ is linked to Rho-specific guanine nucleotide factor activation (Hart et al. 1998), which, in turn, inactivates myosin phosphatase, MLC, and the negative regulator of MLC CPI-17 (Wikstrom et al. 2008). Collectively, these changes decrease cellular Ca^{2+} stores and limit MLCK binding of calmodulin, resulting in attenuated platelet contraction and induced platelet disaggregation (Body 1996). Alternatively, PGI_2 has been shown to induce phosphorylation of the platelet inositol 1,4,5-triphosphate ($InsP_3$) receptor in saponin-permeabilized platelets in vitro and human platelets ex vivo, which abolishes the Ca^{2+} releasing activity of $InsP_3$ (Tohmatsu et al. 1989). However, this effect does not appear to be contingent on de novo $InsP_3$-mediated Ca^{2+} release, as PGI_2-induced inhibition of $InsP_3$ (and subsequent depletion of Ca^{2+}) is observed after $InsP_3$ stimulation with thrombin (Cavallini et al. 1996).

Upregulation of PGI_2 may also target vasodilator-stimulated phosphoprotein (VASP), which is a member of the proline-rich protein family and serves as a major receptor for cAMP and cGMP in various mammalian cell types (Lincoln and Cornwell 1993; Aszodi et al. 1999). Compared to normal platelets, transgenically modified VASP$^{-/-}$ platelets demonstrate a decrease in time necessary for collagen-induced aggregation (50 % maximum aggregatory response: 106 ± 4 vs. 89 ± 4 s, $P < 0.003$), which parallels differences in aggregation inhibition induced by low cGMP concentrations (77.8 vs. 21.6 %, $P < 0.002$). Posttranslational modifications of VASP by PKA include its phosphorylation at Ser157, Ser239, and Thr278, which is used to assess VASP activity experimentally. For example, multidrug resistance protein-4 (MRP4), which regulates cyclic nucleotides by promoting their extracellular transit, was recently demonstrated to prolong bleeding time and decrease platelet aggregation in response to vascular injury through its redistribution of cAMP to dense granules and upregulation of phosphorylated VASP (Decouture et al. 2015).

It is important to note that cross-talk is observed between signaling pathways that mediate the effects of TXA_2 and PGI_2, despite the opposing functions of these prostaglandins. For example, Cheng and colleagues observed that the platelet-stimulating effects of TXA_2 are inhibited by PGI_2-IP signaling. The fact that TXA_2 receptor knockout mice are prone to bleeding (Thomas et al. 1998) is likely attributed to the effect of PGI_2-IP on platelet–endothelial interactions through MLC, $InsP_3$, and VASP (Cheng et al. 2002). Furthermore, it is hypothesized that a thrombotic tendency occurs under conditions in which COX-1 activity is not offset by the antiplatelet/vasodilatory effects of COX-2 in the vascular endothelium (Pratico and Dogne 2005). This hypothesis, which is supported by some mechanistic data (Grosser et al. 2006), emerged largely based on a number of clinical studies involving the use of selective COX-2 inhibitors for the treatment of rheumatological disease. Data from these trials indicated a signal toward increased risk of cardiovascular thrombotic events in patients treated with selective COX-2 inhibitors. In one meta-analysis (Kearney et al. 2006) of 31,129 patients, for example, selective COX-2 inhibitor celecoxib use was associated with a 50 % increase in the relative risk of myocardial infarction (0.6 %/year) compared to nonselective COX-1/-2 inhibitors, prompting a black box warning for the use of celecoxib with respect to cardiovascular disease event risk. More recent data, however, suggest that celecoxib at moderate doses is non-inferior to naproxen and ibuprofen with respect to safety (Nissen et al. 2016).

EctoADPase/CD39

Ecto-nucleoside triphosphate diphosphohydrolases (ENTPDases) comprise a family of endothelial cell membrane glycoproteins that use Ca^{2+} or Mg^{2+} as cofactors to hydrolyze proinflammatory/thrombotic extracellular 5′-di- and triphosphatases (i.e., nucleotides). Among this protein class, CD39 (NTPDase1; also denoted apyrase, ecto-ATPase, ecto-ADPase, nucleotide phosphohydrolase, or ATP pyrophosphohydrolase) is the principal vascular ENTPDase, although it has also been identified in human placenta, lung, skeletal muscle, kidney, and heart tissues (Kaczmarek et al. 1996). Endothelial CD39 has no direct physical interaction with platelets but mediates platelet

aggregation by metabolizing ADP and inhibiting ADP-dependent platelet activation (Marcus et al. 1997). This effect was observed initially by Marcus and colleagues, who demonstrated that platelet reactivity could be reversed within 60 s in CD39-trasfected COS cells stimulated with 10 μM ADP (Marcus et al. 1997). In Chinese hamster ovary cells, the Km of soluble CD39 for ADP and ATP are 5.9 μM and 2.1 μM, respectively, while the catalytic efficiency (k_{cat}/K_m) is 1.2×10^8 min^{-1} M^{-1} for both ADP and ATP (Gayle et al. 1998). These binding kinetics, which favor association of CD39 with ADP, may account for autonomous endothelial regulation of platelet bioactivity even under conditions in which $NO^{\cdot}$ or PGI_2 are diminished. Indeed, recombinant endothelial CD39 blocks ADP-induced platelet aggregation in vitro and inhibits collagen-induced platelet reactivity.

There are also accumulating data to support the importance of CD39 in the pathogenesis of thrombotic vascular disease clinically. In patients with angiographically proven epicardial coronary artery disease (CAD), the ratio of plasma ectonucleotidase ADPase-to-ATPase activity is decreased compared to controls (El-Omar et al. 2005), indicating that endogenous CD39 is impaired in CAD patients and that CD39 may hold promise as a potential treatment target to decrease clinical events in patients with atherosclerotic disease. The HMG-CoA-reductase inhibitors simvastatin or cerivastatin have also been shown to improve the metabolism of exogenous ADP and attenuate platelet activation fully despite treatment with thrombin in vitro (Kaneider et al. 2002), while exercise is linked to increased endogenous CD39 expression and decreased platelet aggregation in patients (Coppola et al. 2005).

S-Nitrosylation

Early observations indicating that the half-life of $NO^{\cdot}$ in plasma is substantially longer than in aqueous solution (6 vs. 0.1 s) suggested the existence of $NO^{\cdot}$ molecular adducts that protect $NO^{\cdot}$ metabolism in vivo (Keaney et al. 1993). Subsequently, it was determined that $NO^{\cdot}$ may react with transition metals (Cu^{+}, Cu^{2+}, Fe^{2+}), other free radicals, or molecular oxygen to generate various nitrogen oxide species (N_2O_3 or $ONOO^{-}$), and that the reactive nitrogen derivative of $NO^{\cdot}$ forms a covalent bond with the sulfhydryl group of cysteine to generate *S*-nitrosothiols (RSNOs) (Fig. 3) *S*-nitroso-glutathione reductase (GSNOR) and

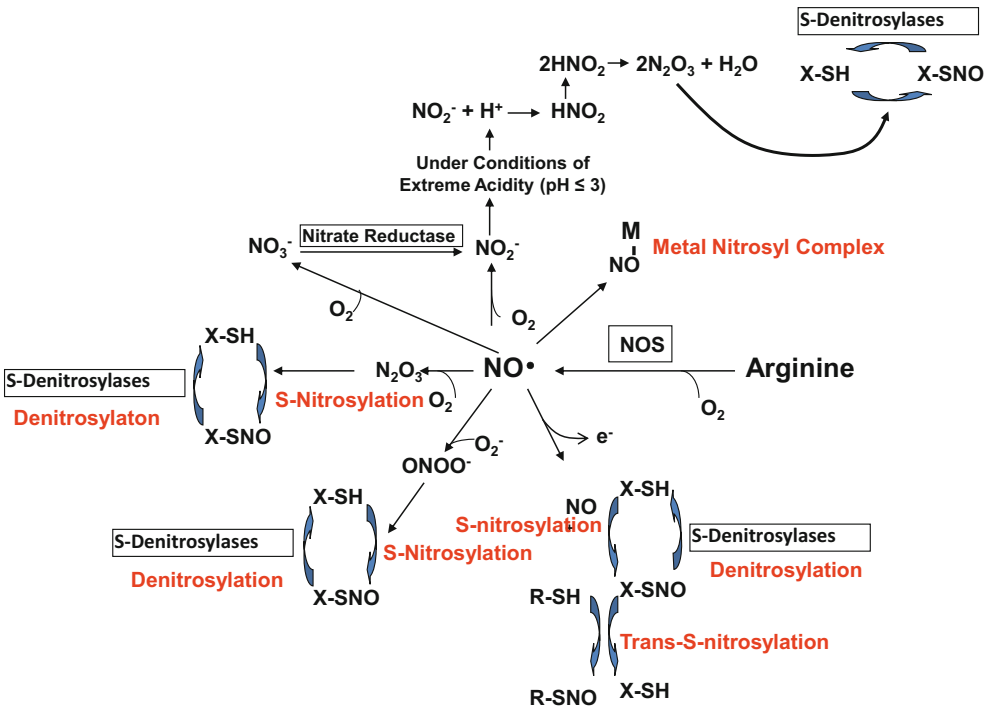

Fig. 3 *S*-Nitrosylation reactions. Nitric oxide ($NO^{\cdot}$) synthesized from L-arginine by nitric oxide synthase (NOS) may bind to transitional metals (NO-M), undergo oxidation in the presence of molecular oxygen (O_2), or interact with superoxide anion ($O_2^{\cdot-}$) to form peroxynitrite ($ONOO^{-}$). In the presence of O_2, $NO^{\cdot}$ may be converted to nitrosonium (NO^{+}), an electrophile that interacts with nucleophilic thiols to form *S*-nitrosothiols (SNO). Additionally, under conditions of extreme acidity (pH $\leq$ 3), protonation of $NO^{\cdot}$ yields the formation of nitrous acid (HNO_2), which is a reactant for the synthesis of the nitrosylating agent nitrogen trioxide (N_2O_3). *S*-Nitrosothiol denitrosylation may occur enzymatically or through nonenzymatic exchange with free thiols. *Adapted from* Maron BA, et al. Antioxid Redox Signal 2013;18(3):270–287

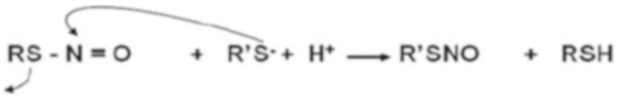
thioredoxin reductase (TrxR) are two key denitrosylating enzymes that induce NO· release from SNOs. The mechanism by which this occurs involves a series of intermediate reactions including, in the case of TrxR, nucleophilic attack of the target cysteine by the N-terminal Cys thiolate ($R'S^-$) of TrxR, the formation of an intermolecular disulfide bond, and subsequent liberation of HNO and NO· [reviewed in detail in (Maron et al. 2013)].

S-nitroso-human serum albumin (SNO-SA), *S*-nitrosocysteine, and *S*-nitrosohemoglobin are three principal RSNOs discovered in plasma that protect NO· from oxidation and allow for paracrine effects of NO· on targets distal to the site of NO· synthesis. *S*-nitrosoglutathione (GSNO) is the most abundant intracellular RSNO and has been implicated in platelet synthesis and bioactivity. Megakaryocyte-derived platelet generation is sevenfold greater in the presence of GSNO as compared to thrombopoietin (Battinelli et al. 2001), while GSNO fully inhibits platelet aggregation (Liu et al. 1998) and is associated with impaired platelet adhesion to collagen in vitro (Irwin et al. 2009).

Protein disulfide isomerase (PDI) is believed to facilitate intracellular NO· entry into platelets through trans-*S*-nitrosylation (Maron et al. 2013; Zai et al. 1999). In trans-*S*-nitrosylation, the nitrogen of an *S*-nitrosothiol is the substrate for nucleophilic attack by the thiolate ($R'S^-$) of R'SH according to the following equation (Maron et al. 2013):



Trans-*S*-nitrosylation of GSNO and *S*-nitrosocysteine suppress thrombosis by virtue of cGMP-mediated inhibition of platelet aggregation, granule secretion, and fibrinogen binding (Gordge and Xiao 2010; Mendelsohn et al. 1990). Importantly, GSNO appears to promote these effects without affecting vascular tone, indicating selective delivery of NO· to platelets. In fact, although detectable levels of PDI have been reported for smooth muscle cells and endothelial cells (Xiao and Gordge 2011), expression and provoked activity of PDI is substantially greater on the cell membrane surface of platelets where its activation hinges on conformational changes to platelet glycoprotein GP1bα (Hogg et al. 1997). Furthermore, GSNO-mediated delivery of NO· is greater in platelets than in vascular cells and can be inhibited to a greater extent in the presence of the thiol isomerase inhibitor phenylarsine oxide (Xiao and Gordge 2011). Another protein involved in hemostasis that is the target of *S*-nitrosylation is tissue plasminogen activator (t-PA): SNO-t-PA at Cys83 increases fibrinogen-stimulated t-PA activity by 4.4-fold as well as rate and extent of platelet inhibition by 50 % over unmodified t-PA (Stamler et al. 1992).

Using RSNO-based technology has emerged as an attractive approach to manipulating the platelet–vascular interaction for therapeutic purposes. Yang and colleagues reported on a NO-catalytic bioactive coating developed through covalent binding of 3,3'-dipropionic acid diselenide, (SeDPA). They demonstrated that the addition of GSNO sustained inhibition of collagen-stimulated platelet activation and adhesion to vascular smooth muscle cells for 30 days in vitro (Yang et al. 2015). Other systems have been tested in preclinical scenarios, including polythiolated S-NO-bovine serum albumin (Marks et al. 1995) and the polymeric delivery of pH-activated spermine/NO· for sustained NO· release. In one study using the rat ileofemoral balloon model of vascular injury, vessels injected with spermine/NO· engineered for drug delivery over 14 days demonstrated a decrease in neointimal proliferation and an increase in cGMP levels by 69 % and 64 % at study completion, respectively, compared to control. Similar beneficial effects of spermine/NO· have also been reported in experiments on injured cerebral (Scheckenbach et al. 2006) and pulmonary vascular beds (De Witt et al. 2001).

Special Considerations in the Pulmonary Vasculature

A number of important differences distinguish the pulmonary from systemic circulations with respect to vascular wall regulation of platelet function. The parallel circuitry of the pulmonary vascular system produces a high-flow and low resistance circulation, and, therefore, pulmonary artery atherosclerotic vascular injury is uncommon in the absence of *severe* pulmonary hypertension (Maron and Loscalzo 2013). Nonetheless, vascular inflammation, endothelial dysfunction, vascular endothelial and smooth muscle cell apoptosis resistance, and abnormal fibrillar collagen deposition underlie the plexogenic vasculopathy of pulmonary arterial hypertension (PAH), which is also characterized by platelet-rich thrombi in distal pulmonary arterioles. In addition to PAH, chronic thromboembolic pulmonary hypertension (CTEPH) is an important clinical phenotype that generally occurs after luminal pulmonary embolism but is characterized by in situ thrombosis of large and segmental pulmonary arteries and small-vessel arteriopathy in the setting of sustained platelet overactivation (Lang and Madani 2014).

In PAH or CTEPH patients, increased thrombus susceptibility is associated with a decrease in pulmonary endothelial NO·, which, in turn, appears to be a consequence of decreased eNOS expression (Giaid and Saleh 1995); altered levels of key substrates required for NOS-dependent NO· synthesis, such as L-arginine; eNOS uncoupling due to depletion of the eNOS cofactor tetrahydrobiopterin (BH_4) (Xu et al. 2004); and/or oxidation of NO· in the setting of increased vascular ROS accumulation (Maron et al. 2013). Monogenetic causes of PAH, including inherited (loss of

function) BMPR-2 mutations, are also associated with diminished eNOS activity through inhibition of normal BMP2- and BMP4-mediated signal transduction (Klinger et al. 2013). Gangopahyay and colleagues demonstrated that in cultured pulmonary artery endothelial cells (PAECs), the BMPR-2 ligands BMP2 and BMP4 promote PKA-dependent phosphorylation and activation of eNOS. In that study, molecular inhibition of BMPR-2 in cultured PAECs uncoupled BMP2/4-eNOS signaling, while BMP2/4 failed to stimulate eNOS in PAECs isolated from patients with BMPR-2-dependent PAH (Gangopahyay et al. 2011).

Although a genetic predisposition to hypercoagulability has been proposed to account for CTEPH incidence, polymorphisms in thrombogenic genes, such as Factor V Leiden (G20210A), plasminogen activator inhibitor-1 4G/5G, tissue plasminogen activator C7351T, Factor XIII G100T, or fibrinogen Bβ G455A, are identified in only a minority of patients (Suntharalingam et al. 2008). Furthermore, no significant differences are observed between platelet-poor and platelet-rich plasma from CTEPH patients with respect to levels of tissue-type plasminogen activator (t-PA) and type 1 plasminogen activator inhibitor (PAI-1), and CTEPH patients do not differ significantly from healthy controls with respect to activity levels of these prothrombotic mediators (Olman et al. 1992). From these collective observations, increased attention has turned toward impaired vascular suppression of platelet activation in the phase following initial pulmonary embolism as a critical determinate of disease progression.

Compared to sex-matched healthy controls, postendarterectomy thrombus specimens or plasma from CTEPH patients express increased levels of key inflammatory cytokines, including interleukin (IL)-6, IL-8, IL-10, monocyte chemoattractant protein-1, and interferon-γ-induced protein-10 (Zabini et al. 2014), suggesting a persistent inflammatory milieu underlying the platelet–endothelial interface in CTEPH patients. In turn, increased pulmonary vascular inflammation is linked to dysregulated angiogenesis and impaired endogenous thrombolysis. In an experimental model of pulmonary venous thromboembolism, for example, delayed thrombus resolution is observed in mice expressing an endothelial cell-specific deletion of the endothelial growth factor receptor 2 (VEGF-2R)/kinase insert domain protein receptor deletion (Alias et al. 2014). Others have observed an increase in the abundance of collagen-secreting cells from endarterectomy samples and contend that this potentiates endothelial injury and propagates thrombosis formation in situ (Yao et al. 2009). Recently, it has also been proposed that endothelial injury in CTEPH occurs due to an increase in vasa vasorum density, which serves as a reservoir for migrating endothelial cells, proliferation, and recanalization of thrombus (Kimura et al. 2001). These changes are maladaptive, however, and are linked mechanistically to a prothrombotic vascular surface, possibly related to the upregulation of angiostatic and platelet-activating factors, including increased PF4 and collagen type I (Zabini et al. 2012).

In animal models of pulmonary venothromboemoblism and in CTEPH patients, hypoxia and mediators of inflammation (particularly IL-6) diminish pulmonary endothelial cGMP bioavailability due, in part, to increased phosphodiesterase-mediated hydrolysis of cGMP to its inactive metabolite 5'-GMP (Evgenov et al. 2004). Diminished cGMP, in turn, disrupts the cellular $[Ca^{2+}]_0$ -to- $[Ca^{2+}]_i$ gradient and increases $[Ca^{2+}]_i$ that impairs endothelial barrier function and promotes vascular injury, edema, and thrombogenicity (Moore et al. 1998). Hypoxia also increases pulmonary artery endothelial vWF expression through inhibition of the nuclear repressor nuclear factor-IB association with the vWF promoter (Mojiri et al. 2013), and appears to suppress leukotriene metabolism in PAH in vivo. Hypoxia-PAH rats express increased platelet $\alpha_{IIb}\beta_3$, as well as endothelial expression of P-selectin and platelet factor-4 (PF4), which, collectively, are prevented by treatment with the 15-lipoxygenase inhibitor nordihydroguaiaretic acid (NDGA) (Shen et al. 2015) or the COX-2 inhibitor diethylcarbamazine (Al-Husseini et al. 2015). These findings are consistent with work demonstrating that overexpression of 5-lipoxygenase results in abnormal endothelial cell proliferation (Zhang et al. 2002; Walker et al. 2002).

Biosynthetics in Platelet–Vascular Wall Interactions

There has been substantial progress in the development of biosynthetics and novel platforms in silico for clarifying the physical and molecular factors underlying platelet–endothelial interactions. This includes the emergence of micro/nanostructure- and nitinol-based surfaces to study platelet-vascular function ex vivo and in vivo (Huh et al. 2010; Nozaki et al. 2015), the development of $NO^{\cdot}$-releasing stent prototypes (Yang et al. 2015), and synthetic vascular grafts engineered to improve endothelial cell binding that reduce thrombotic potential (Solouk et al. 2015).

Although a number of vascular stent coatings have been tested or are approved for use in clinical practice, including diamond-like carbon, titanium-nitride-oxide, and plasma-activated coatings among others (Ma et al. 2007), endothelialization extent and rate associated with these synthetics remain suboptimal and are believed to cause some forms of stent failure observed clinically. Use of novel surface modifications that leverage enhanced hydrophilicity, such as SiCOH, n-butyl methacrylate, and phosphorylcholine (Zhang et al. 2014), as well as apyrase (ADPase) and other biomolecules that inhibit platelets

directly, frames the next generation of biosynthetic stents with increased antithrombogenic potential (Zhang et al. 2014). Modification of surfaces with pendant tags that attract endothelial cells as a method to promote endothelial cell adherence has also gained attention recently. A polycarbonate urethane surface coated with polyethylene glycol, pentafluorophenyl methacrylate polymer, and Cys-Ala-Gly peptide tagged with allyl amine molecules, for example, has been shown to generate a hydrophilic surface favorable for promoting adhesion of functional endothelial cells and inhibiting platelet adhesion when exposed to platelet-rich plasma ex vivo (Khan et al. 2015).

To offset the limitations of studying vascular function under traditional, static conditions, some investigators have turned to three-dimensional models that aim to recapitulate physiologic conditions in silico. Huh and colleagues developed a human lung-on-a-chip microdevice, which affords dynamic study of the alveolar–capillary interface under dynamic conditions, including contemporaneous analysis of blood flow and mechanical changes associated with ventilation (Huh et al. 2010). This model has been used to test the effect of prothrombin, IL-2, and fibrinogen on endothelial fibrin formation in the setting of pulmonary edema-associated alveolar injury. Their findings, which demonstrate that even physiological mechanical force potentiates the hazardous effect of IL-2 on fibrin clot formation, provide proof-of-concept for the study of an integrative physiological system, and have important implications for analyzing endothelial–platelet interactions in understudied forms of thrombotic disease.

Conclusions

Suppression of platelet activation is a cornerstone feature of normal endothelial function and is critical for maintaining blood flow. Endothelial synthesis of $NO^{\cdot}$ induced by blood flow, endogenous release of PGI_2 in response to oxidant stress or inflammation, and endothelial CD39 that inhibits ADP-induced platelet activation are key mechanisms that define vascular regulation of thrombosis. Differences between the systemic and pulmonary vascular circuits in flow rate and design inform platelet pathobiology and the attendant clinical pathophenotypes that are commonly observed in each circulation. Gains in biosynthetic technology and the development of dynamic models that allow for studying the interaction between vascular cell types, blood flow, and vascular injury on an organ level are anticipated to further our understanding of the blood vessel–platelet relationship. One important outstanding goal in endothelial–platelet biology is the generation of novel device therapies that treat vascular dysfunction effectively in patients but with hemorrhagic risk.

Take Home Messages

1. Nitric oxide, thromboxane, and prostaglandins are important endogenous regulators of platelet bioactivity.
2. Increased vascular oxidant stress is associated with a prothrombotic phenotype.
3. Platelet aggregation can be inhibited indirectly through metabolism of ADP by ENTPDases.
4. In the pulmonary circulation, hypoxia and inflammation stimulate platelet–vascular interactions.
5. Biosynthetic systems are increasingly used to study the properties of platelet adherence to the blood vessel wall.

Platelet–Leukocyte Interactions

Virgilio Evangelista, Licia Totani, Angelo A. Manfredi, and Norma Maugeri

Abstract

The current vision of the mechanisms involved in the hemostasis, inflammation, and innate immunity is based on the intricate interplay between platelets and leukocytes. However, were necessary about three decades to abate the paradigm in which leukocytes are involved only in the immune response and platelets only in the hemostasis. In this chapter, we try to illustrate the clinical and experimental evidences of the wealthy cross-talk between platelets and leukocytes that support real insight into the function of these cells.

Introduction

The cross-talk between platelets and leukocytes is a hallmark of thrombotic and inflammatory processes. Platelets perform diverse immune-related functions such as interacting with neutrophils (Zarbock et al. 2007) and monocytes (van Gils et al. 2009). The interaction depends on direct contact via specific adhesive ligand–receptor couples and through the generation of soluble active moieties (Semple et al. 2011). Platelets, whose primary function is the surveillance of vascular integrity and the initiation of a hemostatic plug in the case of vessel damage, also rely on the interaction with leukocytes to guard vessels against infective agents. These homeostatic interactions may, however, also contribute to tissue damage in a wide variety of acute and chronic inflammatory diseases. The cross-talk between platelets and leukocytes may result in reciprocal activation and inhibition which is likely to fine tune the eventual outcome of the inflammatory process, determining health or disease.

This chapter illustrates the basic molecular mechanisms that underlie platelet–leukocyte communication, the pro-/antithrombotic and inflammatory interactions, the clinical features associated with the cross-talk between platelets and leukocytes, and the experimental evidence that support novel pharmacological approaches targeting platelet–leukocyte interactions.

Cross-Talk Between Platelets and Leukocytes

In physiological conditions, flowing leukocytes reach sites of injury and infection via a well-regulated multistep process. They initially tether to and roll along the vessel wall. This is followed by the firm adhesion to activated endothelial cells and eventual diapedesis. These events involve various interacting ligand–receptor pairs in an adhesion cascade. The activated endothelial cells express P- and E-selectins, both recognized by leukocytes via the constitutively expressed counter-receptors, P-selectin glycoprotein ligand 1 (PSGL-1) and E-selectin ligand 1 (ESL-1) (Hidalgo

et al. 2009; Maugeri and Manfredi 2015; Maugeri et al. 2012a, 2014a; Sreeramkumar et al. 2014; Nacher and Hidalgo 2011; Campana et al. 2014).

Moreover, leukocytes can be recruited at the site of endothelial injury and transmigrate through compromised vessels by the interaction with adherent platelets. The first evidence of platelet–leukocyte interaction during hemostasis was provided by Giulio Bizzozero in 1882 (Mazzarello et al. 2001). More than 100 years were required to confirm Bizzozero's observations: adherent platelets at the site of a damaged vessel wall promoting leukocyte rolling, arrest, and transmigration across platelet thrombi through the sequential action of P-selectin and the ß2-integrins (Manfredi et al. 2015; Ramirez et al. 2014). Conversely, leukocytes aggregated with activated platelets promote thrombus formation (Evangelista et al. 2007; Furie and Furie 2008).

Adhesive Receptors

Adhesion of platelets and leukocytes depends essentially on selectins and integrins. P-selectin expressed on activated platelets is recognized by PSGL-1 on the surface of resting leukocytes. After ligation, PSGL-1 triggers activation-dependent conformational changes of the β2 integrins, mainly CD11b/CD18 (formally αMβ2 and also called Mac-1), which mediates firm adhesion of the neutrophils and monocytes (Gardiner et al. 2001; Gawaz et al. 1998; Nacher and Hidalgo 2011; McEver and Cummings 1997; Totani and Evangelista 2010).

P-selectin—formally CD62P—originally described as GMP-140 (granule membrane protein 140 kDa) (Johnston et al. 1989) and as PADGEM (platelet activation-dependent granule external membrane protein) (Larsen et al. 1989; Hamburger and McEver 1990) is a type-I membrane protein containing an N-terminal C-type lectin domain, an epidermal growth factor (EGF)-like motif, a series of short consensus repeats, a transmembrane domain, and a cytoplasmic domain. P-selectin is stored as an integral protein of the membrane of α-granules in platelets and Weibel–Palade bodies in endothelial cells (Furie and Furie 1995). Upon cellular activation, fusion of the granules with the external membrane exposes P-selectin at the cell surface (McEver and Cummings 1997).

PSGL-1 (Sako et al. 1993; McEver and Cummings 1997), constitutively expressed on the surface of neutrophils, monocytes, dendritic cells, and subclasses of lymphocytes is an homodimeric mucin molecule bearing multiple *O*-glycans on serine and threonine residues, which displays high affinity for P-selectin. The physiologic role of P-selectin/PSGL1 axis is the recruitment of leukocytes to reach inflamed tissues (Fig. 1). Indeed, the rapid association/dissociation rates for P-selectin/PSGL-1 interactions are fundamental for initial tethering and rolling of leukocytes on P-selectin surfaces (offered by the activated endothelium or activated adherent platelets) under conditions of flow (Varki 1997; McEver and Cummings 1997; Yang et al. 1999).

As a consequence, leukocytes reach sites of injury and infection (Rouhiainen et al. 2000; Maugeri et al. 2014a; Campana et al. 2014). After having tethered to and rolled, they firmly adhere to activated endothelial cells and eventually diapedese. Mac-1 and LFA-1 (formally αLβ2 and also called CD11a/CD18) mainly mediate firm adhesion of neutrophils and monocytes to activated platelets. Activated Mac-1 recognizes at least three counter-receptors exposed on the platelet surface: fibrinogen bound to the platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) (Weber and Springer 1997), GPIbα (Simon et al. 2000a), and the junctional adhesion molecule-3 (JAM-3) (Santoso et al. 2002). Intercellular adhesion molecule-2 (ICAM-2), a member of the immunoglobulin (Ig) superfamily of adhesion molecules constitutively expressed by platelets, is probably the principal LFA-1 ligand expressed on the platelet surface (Diacovo et al. 1994).

While P-selectin/PSGL-1 interaction is critical for activated platelet/leukocyte adhesion (Evangelista et al. 2003; Manfredi et al. 2010; Totani and Evangelista 2010), resting platelets can also interact with activated leukocytes through the contact of platelet glycoprotein GPIbα with the activated Mac-1 (Simon et al. 2000a). Platelet glycoprotein GPIbα is the counter-receptor of the A1 domain of VWF, which is exposed by subendothelium after vascular injury (Ruggeri 2003; Colombatti and Bonaldo 1991). The GPIbα leucine-rich repeat and COOH-terminal flanking regions bind to the I domain present on Mac-1 (Colombatti and Bonaldo 1991; Simon et al. 2000a) that is homologous to the VWF A1 domain (Li et al. 1998; Simon et al. 2000a). This interaction offers an additional mechanism through which platelets adherent to, and become immobilized on, compromised vessel walls to support firm adhesion and, eventually, transmigration of neutrophils through the injured vessel wall (Simon et al. 2000a) (Fig. 1).

GPIbα also serves as a counter-receptor for P-selectin expressed on activated endothelium. This interaction represents another important role of platelet adhesion, where the same receptor (GPIb–IX–V) can support platelet adhesion to endothelial cells under the appropriate conditions of endothelial activation and to the subendothelial matrix when the endothelial cells have been removed by injury. Indeed, platelets rolled on activated

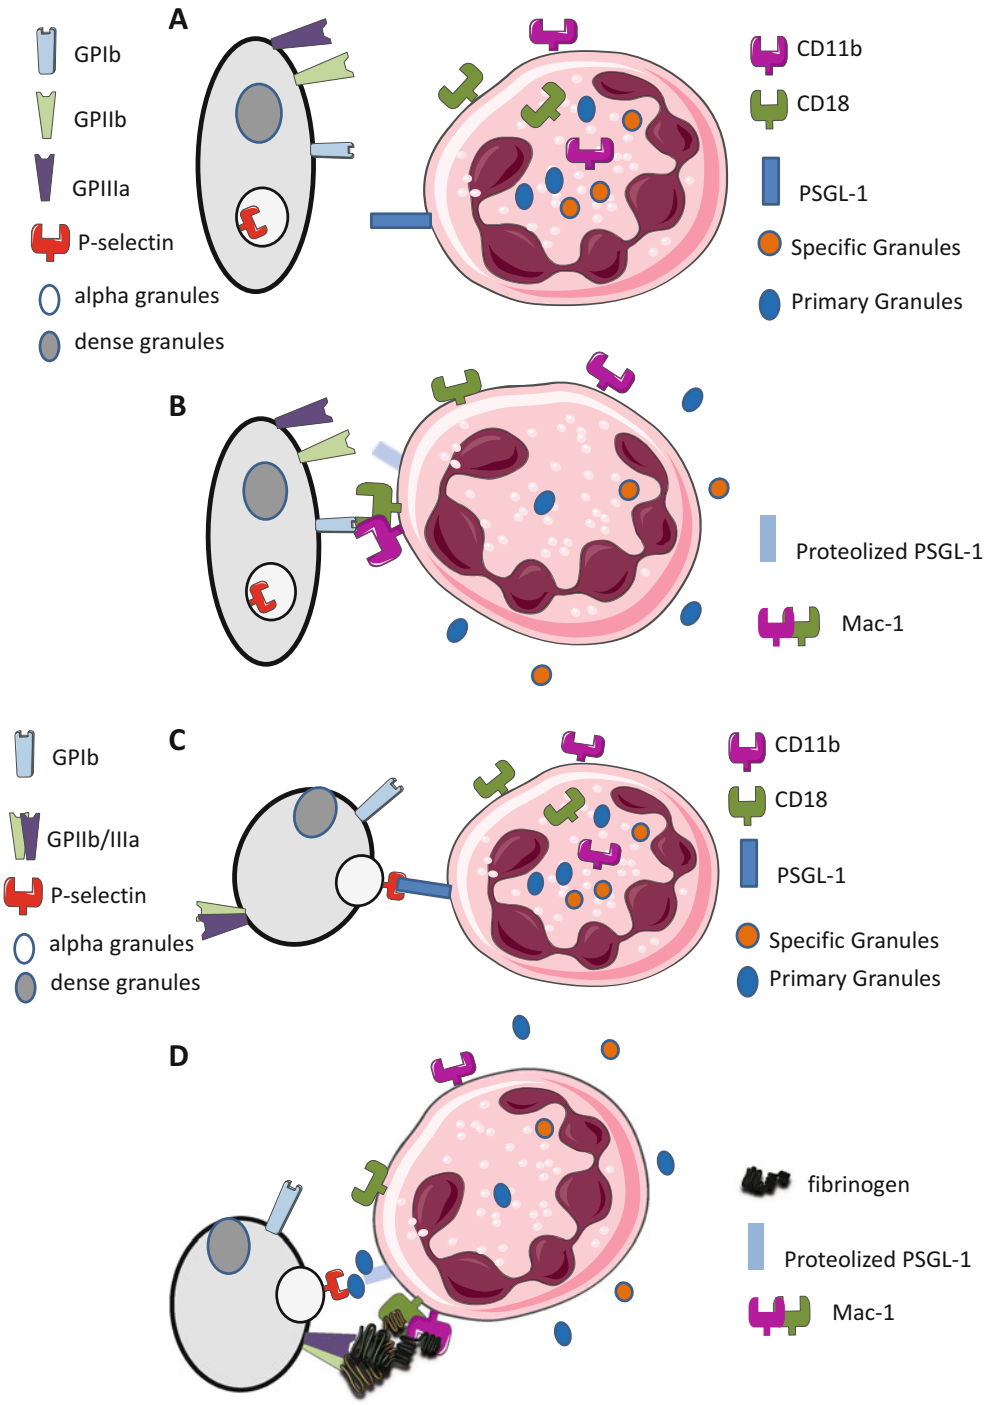

Fig. 1 Adhesive interactions between platelets and neutrophils. (**a**) Resting platelets do not interact with resting neutrophils. (**b**) Platelet GPIb recognizes the I domain expressed by activated Mac-1 (activated neutrophils). (**c**) Activated platelets express P-selectin that is recognized by neutrophils PSGL-1. (**d**) The P-selectin/PSGL-1 cross-talk induces neutrophil degranulation, degrades PSGL-1 (by the proteases derived from primary granules), and upregulates Mac-1. In this condition, Mac-1 recognized the fibrinogen bound to the platelet GPIIb–IIIa to promote the firm adhesion

endothelium, a phenomenon exquisitely dependent on both P-selectin and GPIbα (Romo et al. 1999). Unlike the P-selectin interaction with PSGL-1, the interaction with GPIbα required neither calcium nor carbohydrate core-2-branching or α(1,3)-fucosylation. Thus, injured vessel wall offers two different mechanisms to platelet interaction through GP Ib–IX–V complex: platelet attachment to both subendothelium (via vWF) and activated endothelium (via P-selectin) (Romo et al. 1999).

Soluble Mediators

Released from Platelets

Together with the hemostatic factors, platelets contain and release, upon activation, an array of mitogenic and angiogenic factors and various bioactive molecules such as platelet factor-4 (PF-4, CXCL4), β-thromboglobulin, (β–TF, CXCL7) which is converted to the CXC chemokine NAP-2 (CXCL7) by neutrophil cathepsin G, ENA-78 (CXCL5), and

Table 1 Soluble molecules released by platelets that can modify leukocyte responses

Mediator	Function	Target
CXCL1 (GROα)	Chemokine	Neutrophils
CXCL4 (PF4)	Chemokine	Neutrophils
CXCL7 (NAP2)	Chemokine	Neutrophils
CCL2 (MCP1)	Chemokine	Monocytes
CCL3 (MIP1α)	Chemokine	Eosinophils, basophils, monocytes, NK lymphocytes, dendritic cells
CCL5 (RANTES)	Chemokine	Eosinophils, basophils, monocytes, NK, dendritic cells, T lymphocytes
CCL7 (MCP3)	Chemokine	Basophils, monocytes, NK lymphocytes, dendritic cells
CCL17 (TARC)	Chemokine	T lymphocytes
CD40L	Costimulatory molecule	Monocytes, B lymphocytes, endothelial cells, dendritic cells
TREM1 ligand	Costimulatory molecule	Monocytes, neutrophils, dendritic cells
TGFβ1	Growth factor	Monocytes, neutrophils, T and B lymphocytes
PDGF	Growth factor	Monocytes macrophages, T lymphocytes
HMGB1	Chemokine	Neutrophils, monocytes, macrophages, dendritic cells

GROα (CXCL1). They also release CC chemokines including RANTES (CCL5), MCP-1 (CCL2), MIP-1α (CCL3), TARC (CCL17) and a number of miscellaneous signals with immunoregulatory properties such as the CD40L, triggering receptor expressed on myeloid cell-1 (TREM-1) ligand, transforming growth factor (TGF) β1, and the prototypical Damage-Associated Molecular Patterns (DAMPs), and high mobility group box 1 (HMGB1) (Rouhiainen et al. 2000) (Maugeri et al. 2014a, b, c; Baldini et al. 2012, 2014; Campana et al. 2014; Manfredi et al. 2015; Ramirez et al. 2014). These signals are in resting platelets stored in alpha granules or in other still uncharacterized cytoplasmic compartments (Table 1).

CXCL4 and CXCL7 are among the most abundant proteins contained in platelet α-granules. There is evidence that CXCL4 induces neutrophil activation, causing β2-integrin-mediated adhesion to endothelial cells and exocytosis (Kasper et al. 2004, 2006). CXCL4 also induces monocyte phagocytosis and respiratory burst (Pervushina et al. 2004). CXCL4 seems to contribute to leukocyte activation by the interaction with other chemokines, thus finely tuning the bioactivity of different chemokines (Proudfoot et al. 2003).

The platelet chemokine CXCL7 derives from the pro-platelet basic protein present in megakaryocytes. As the result of proteolytic modifications (Walz and Baggiolini 1990; Walz et al. 1990) it is transformed in connective tissue-activating peptide-III (CTAP-IIIβ–TG and neutrophil activating peptide-2 (NAP-2). The neutrophil CXC receptor 1 and 2 are potential receptors for NAP-2 and stimulate chemotaxis (Walz et al. 1989).

CCL5 (RANTES) (Klinger et al. 1995) promotes leukocyte migration (Kameyoshi et al. 1992; von Hundelshausen et al. 2001; Gilat et al. 1994) via the adherent activated platelets to reach the surrounding tissues. This mechanism might account for the role of platelet-derived CCL5 in the progression of atherosclerosis in experimental murine models (Huo et al. 2003; Schober et al. 2002; von Hundelshausen et al. 2005). Consistent with this concept, treatment with specific blocking peptides against CCL5–CXCL4 heterodimers attenuate monocyte recruitment and reduce development of atherosclerotic lesions in mice (Koenen et al. 2009). Other bioactive molecules such as CCL2 (monocyte chemotactic protein-, MCP-1) (Gosling et al. 1999; Boring et al. 1998; Dawson et al. 1999), CCL3 (macrophage inflammatory protein [MIP]-1α) (Klinger et al. 1995), and CCL17 (thymus and activation-regulated chemokine [TARC]) (Fujisawa et al. 2002) also contribute to the development and stabilization of atherosclerotic lesions (Gu et al. 1998; Gawaz et al. 1998).

Platelets contain and release CD154 (known as CD40L), an inflammatory molecule that reacts with the CD40 present on monocytes, dendritic cells, and vascular endothelium (Grewal and Flavell 1998; Schonbeck and Libby 2001). CD154 induces the expression of tissue factor by endothelial cells (Henn et al. 1998) and monocytes (Sanguigni et al. 2005) and has been proposed as a key player in the development and progression of cardiovascular disease (Lutgens and Daemen 2002).

TGFβ is present in large amounts in platelet α granules, and platelet storage seems to be important for maintaining circulating levels of this potent immunoregulatory factor (Assoian et al. 1983). Whether TGFβ directly contributes to platelet–leukocyte interactions is not known, although limited data suggests that TGFβ may play a role in the prolongation of neutrophil survival sustained by activated platelets (Brunetti et al. 2000).

High mobility group box 1 (HMGB1) is a nuclear molecule highly conserved and abundantly expressed in human tissues. In contrast with most of the nuclear protein, HMGB1 transits continuously from the nucleus to the cytoplasm. In eukaryotic cells, HMGB1 is excreted from the cytoplasm in the presence of environmental inflammatory signals (Bianchi and Manfredi 2014; Lu et al. 2014). In the

extracellular milieu, HMGB1 acts as a potent inducer of the production of cytokines, the attraction of leukocytes, prompting, depending on the microenvironmental conditions, angiogenesis, and fibrosis. Although platelets are anucleated fragments derived from megakaryocytes, they contain substantial amounts of HMGB1 (Rouhiainen et al. 2000; Maugeri et al. 2012b, 2014a, c). In resting platelets, HMGB1 is mainly associated with cytoplasmic molecules, whereas upon activation HMGB1 is translocated to the platelet surface and released to the extracellular environment either as a soluble moiety or associated to the membrane of platelet-derived microparticles (Maugeri et al. 2012b, 2014c). Platelet-derived HMGB1 acts as a potent leukocyte agonist (Maugeri et al. 2014a, c; Vogel et al. 2015).

Complete platelet activation results in the release of the content of dense granules essentially ADP, ATP, and inorganic polyphosphate (Morrissey and Smith 2015). All these molecules modulate neutrophil and monocyte activity by acting through leukocyte purinergic receptors (Di Virgilio et al. 2001). Indeed, platelet-derived adenosine nucleotides enhance the oxygen respiratory burst in neutrophils which is mediated by (Ward et al. 1988) and upregulated by the β2 integrins on the neutrophil surface (Maugeri et al. 2009c).

Released from Neutrophils: Cathepsin G

Neutrophils contain four different granules (Table 2), primary (azurophilic granules), secondary (specific granules), tertiary (gelatinase granules), and quaternary (secretory granules) (Borregaard et al. 2007). Granule contents are usually sequentially released starting from secretory granules, followed by gelatinase granules, specific granules, and finally azurophilic granules (Pham 2006). At present four molecules released from activated neutrophils have been demonstrated to be able to modify the platelet response: proteinase 3 (Renesto et al. 1994, 1997), elastase (Selak 1992, 1994b; Si-Tahar et al. 1997; Renesto et al. 1993), cathepsin G (Selak et al. 1988; Selak 1994a; Maugeri et al. 1994; Cerletti et al. 1995; Molino et al. 1992, 1993, 1995; Si-Tahar et al. 1996), and pentraxin-3 (Maugeri et al. 2011b). While proteinase 3, elastase, and cathepsin G are potent platelets agonists, pentraxin-3 may inhibit P-selectin binding and reduce neutrophil responses. On the contrary pentraxin-3 may directly stimulate tissue factor expression in monocytes (Napoleone et al. 2002, 2004).

Prothrombotic and Proinflammatory Interactions

As described earlier, experimental models indicate that the recognition of P-selectin by PSGL-1 induces the leukocyte β2 integrin transactivation (Evangelista et al. 2007; Piccardoni et al. 2001, 2004), the release of neutrophil granule contents (Maugeri et al. 2005, 2007, 2009c, 2011b, 2012c), and the de novo synthesis and expression of preformed functional tissue factor in monocytes (Celi et al. 1994; Lorenzet et al. 1998; Cerletti et al. 2010) and neutrophils (Maugeri et al. 2006a, 2007; Maugeri and Manfredi 2015). Likewise, platelet–leukocyte heterotypic aggregates that characterize thrombotic, inflammatory, neoplastic, and autoimmune diseases were associated with the presence of tissue factor on the surface of neutrophils and monocytes (Maugeri and Manfredi 2015; Ritis et al. 2006; Ramirez et al. 2014; Baldini et al. 2014; Brambilla et al. 2008).

The adhesive interaction between P-selectin and PSGL1 also promotes arachidonic acid and eicosanoid exchange between platelets and neutrophils resulting in the transcellular synthesis of bioactive eicosanoids that modify

Table 2 Neutrophil granules content

Azurophilic granules (primary granules)	Specific granules (secondary granules)	Gelatinase granules (tertiary granules)	Secretory granules (quaternary granules)
Myeloperoxidase	Lactoferrin	Gelatinase	Complement receptor 1
Neutrophil elastase	Cathelicidin	Leukolysin	Complement receptor 3 (CD11bCD18)
Cathepsin G	Lysozyme	Lyzozyme	Formyl peptide receptor
Proteinase 3	Collagenase	Natural-resistance-associated-macrophage protein 1	CD14
Azurocidin	Complement receptor 3 (CD11bCD18)	Complement receptor 3 (CD11bCD18)	CD16
Bacterial permeability-increasing protein	Formyl peptide receptor	Acetyltransferase	Alkaline phosphatase
Defensins	Leukolysin		
	Cytochrome b558		
	Neutrophil gelatinase-associated lipacalin		
	Pentraxin-3		

platelet, leukocyte, and endothelial barrier function. Moreover, mainly through the release of HMGB-1, activated platelets promote NETs formation.

These prothrombotic and proinflammatory mechanisms, together with the capacity of neutrophils to downregulate some platelet functions, are described later.

Neutrophils Stimulate Platelets

The first evidence of the capacity of neutrophils to induce platelet aggregation through released cathepsin G was provided by Chignard (Selak et al. 1988). After this pioneering observation, the protease-activated receptor-4 (PAR-4) was suggested to be the main surface receptor transducing cathepsin-G-induced platelet activation (Sambrano et al. 2000).

Moreover, additional studies reported that cathepsin G also cleaves the main thrombin receptor (PAR-1) in human platelets, at the site Phe55-Trp56, thus deleting the tethered ligand domain and desensitizing platelets to thrombin (Molino et al. 1995), and cleaving GPIb (Pidard et al. 1994; Molino et al. 1993) and GPIX (Molino et al. 1993), thus reducing the ability of platelets to interact with vWF.

Through these mechanisms cathepsin G induces calcium mobilization and transduces signals by a pathway different from, but as effective as, that of thrombin (Molino et al. 1993). Platelet activation induced by cathepsin G, causes the rearrangement of the cytoskeleton (LaRosa et al. 1994a, b), and the release of both alpha and dense platelets granules (Si-Tahar et al. 1996), resulting in the expression of P-selectin on the platelet surface (Maugeri et al. 1994). Thus, when neutrophils release cathepsin G, neighboring platelets become activated and tightly adhere to neutrophils. Tight contact, in turn, is necessary for the transfer of metabolites during the transcellular metabolism of arachidonic acid and creates the microenvironment that protects cathepsin G and elastase (Evangelista et al. 1991, 1993) from the action of antiproteases present in plasma (Fig. 2). Elastase, also released from azurophilic granules upon neutrophil activation, acts in concert with cathepsin G (Selak 1992, 1994b; Si-Tahar et al. 1997; Renesto et al. 1993).

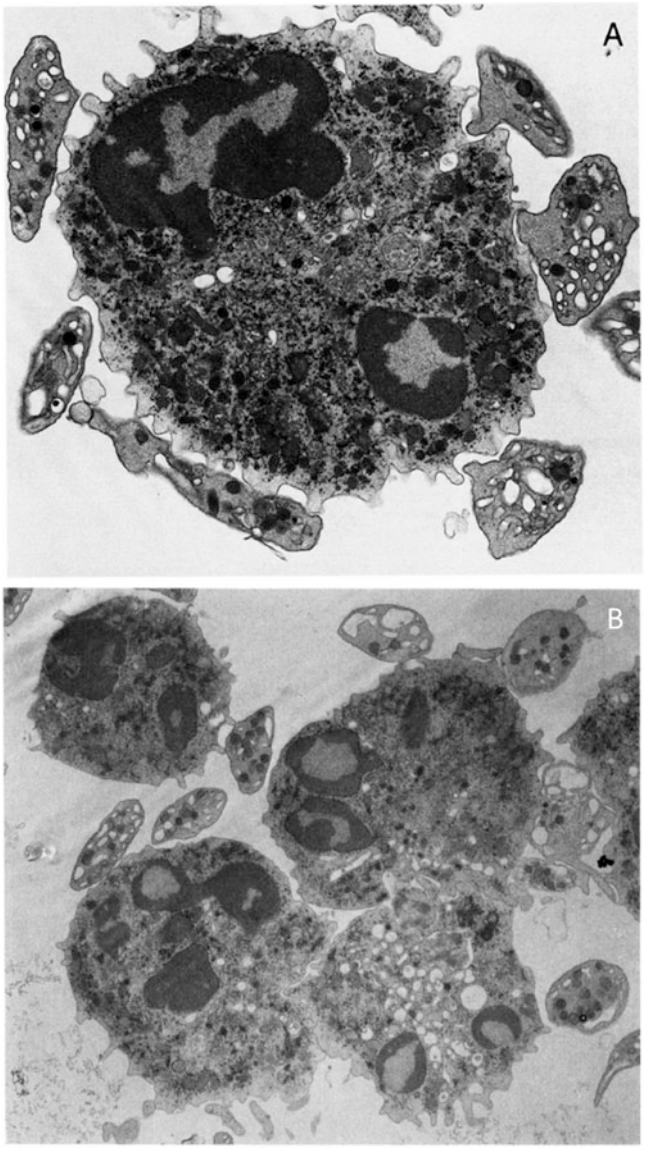

Fig. 2 The close contact between platelets and neutrophils creates a microenvironment that prevent the effect of plasma antiproteases. Electron microscopies of (**a**) platelets and neutrophils clumps and (**b**) platelet–neutrophils heterotypic aggregates. Panel **a**[113] and Panel **b**[112] were originally published in Evangelista et al., the American Society of Hematology

Platelets Stimulate Neutrophils

Mac-1 Transactivation

In neutrophils, the key molecular events which are induced by engagement of PSGL-1 by P-selectin that lead to β2 integrin activation include Src-family-kinase (SFK)-dependent phosphorylation of Nef-associated factor 1 (Naf-1), which is constitutively associated with the cytoplasmic domain of PSGL-1. The phosphorylated Naf-1 recruits phosphoinositide (PI)-3-OH kinase p85-p110δ, which then mediates Mac-1 activation. Mac-1 then initiates a SFK-mediated, outside-in signal that leads to phosphorylation of the proline-rich tyrosine kinase-2 (Pyk2), which stabilizes the integrin–ligand interaction and this forms neutrophil–platelet adhesion (Piccardoni et al. 2001, 2004; Evangelista et al. 2007) (Fig. 3).

Platelet-derived HMGB1, as well as platelet-derived microparticles bearing HMGB1, are able to upregulate and transactivate β2 integrins (Maugeri et al. 2014c). This

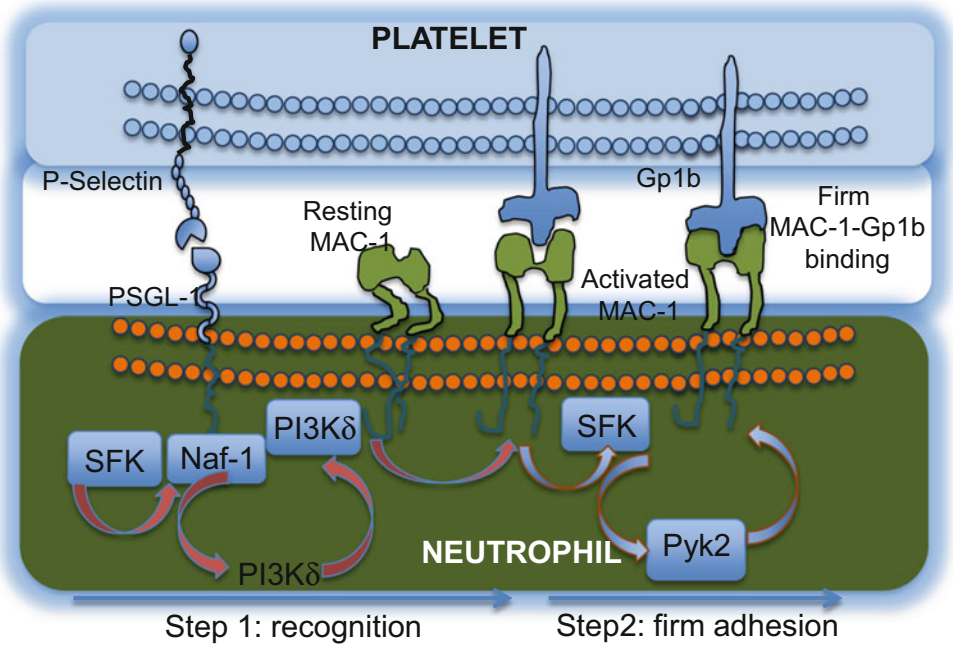

Fig. 3 Two-step model of platelet–neutrophil adhesion. P-selectin expression on the surface of activated platelets and its binding to neutrophil PSGL-1 triggers a dynamic cascade of signaling events and receptor–ligand pairs assembly that causes shear-resistant adhesion of neutrophils to platelets. In this model, the binding of P-selectin to PSGL-1 results in a SFK-dependent phosphorylation of Nef-associated factor 1 (Naf-1), which is constitutively associated to the cytoplasmic domain of PSGL-1. Phosphorylated Naf-1 recruits and activates phosphoinositide-3-kinase (PI3K)d which in turn mediates Mac-1 activation (Evangelista et al. 2007). Studies using a combination of pharmacological and genetic tools showed that the Src-family kinase (SFK) members Hck, Fgr, and Lyn also mediate signals downstream Mac-1 that are essential to stabilize Mac-1-ligand binding. These signals are required for Mac-1-dependent neutrophil recruitment by activated platelets along damaged arteries and for the subsequent development of intimal hyperplasia (Evangelista et al. 2007). In these studies, Pyk2 emerged as a novel potential regulator of αMβ2 downstream SFK. Thus, SFK may influence multiple steps in the signaling cascade leading to firm platelet–neutrophil interaction

pathway was shown to be regulated by the environmental conditions and specifically by the redox balance. Indeed HMGB1 oxidation, mediated by ROS formation by P-selectin-activated neutrophils, appears to amplify the ability of the moiety to functionally activate the leukocytes, possibly enforcing a self-sustaining positive feed-forward loop (Fig. 4).

Tissue Factor Expression

The first evidence of the involvement of P-selectin in thrombus formation was provided by Palabrica et al. (Palabrica et al. 1992) by using a dacron graft implanted within an artero-venous shunt in baboons. This study showed that P-selectin-mediated fibrin deposition in the growing thrombus mainly depended on the recruitment of granulocytes and of monocytes (Palabrica et al. 1992). In murine models, Furie et al. suggested that the process also requires the expression of tissue factor by the cells involved in the thrombus formation process (Furie and Furie 2008). In vitro observations reveal that P-selectin induces the de novo expression of procoagulant tissue factor in monocytes (Celi et al. 1994; Lorenzet et al. 1998) and neutrophils (Maugeri et al. 2006a; Maugeri and Manfredi 2015) and the release of the preformed molecule in a concentration-dependent manner.

Induction of Inflammatory Gene Expression

The interaction with platelets triggers delayed responses in leukocytes, which include gene expression and synthesis of inflammatory mediators. Delayed responses require the concerted actions of outside-in signaling that is transmitted by adhesive receptors (mainly PSGL-1 and β2-integrins) and of signals transduced by chemokine or cytokine receptors (Weyrich et al. 1995, 1996; Gawaz et al. 1998; Dixon et al. 2006). P-selectin and RANTES induce nuclear translocation of NF-kB, gene expression, and synthesis of MCP-1 and interleukin-8 (IL-8) in monocytes (Weyrich et al. 1996). The sustained adhesion of activated platelets induces cyclooxygenase (COX)-2 expression in monocytes through a mechanism that requires (i) the activation of PSGL1 due to platelet P-selectin (Weyrich et al. 1996) and (ii) the action of IL-1β released by activated platelets. Both agonists induce the activation and translocation of NF-kB and transcription of the COX-2 gene, and the translocation of COX-2 protein

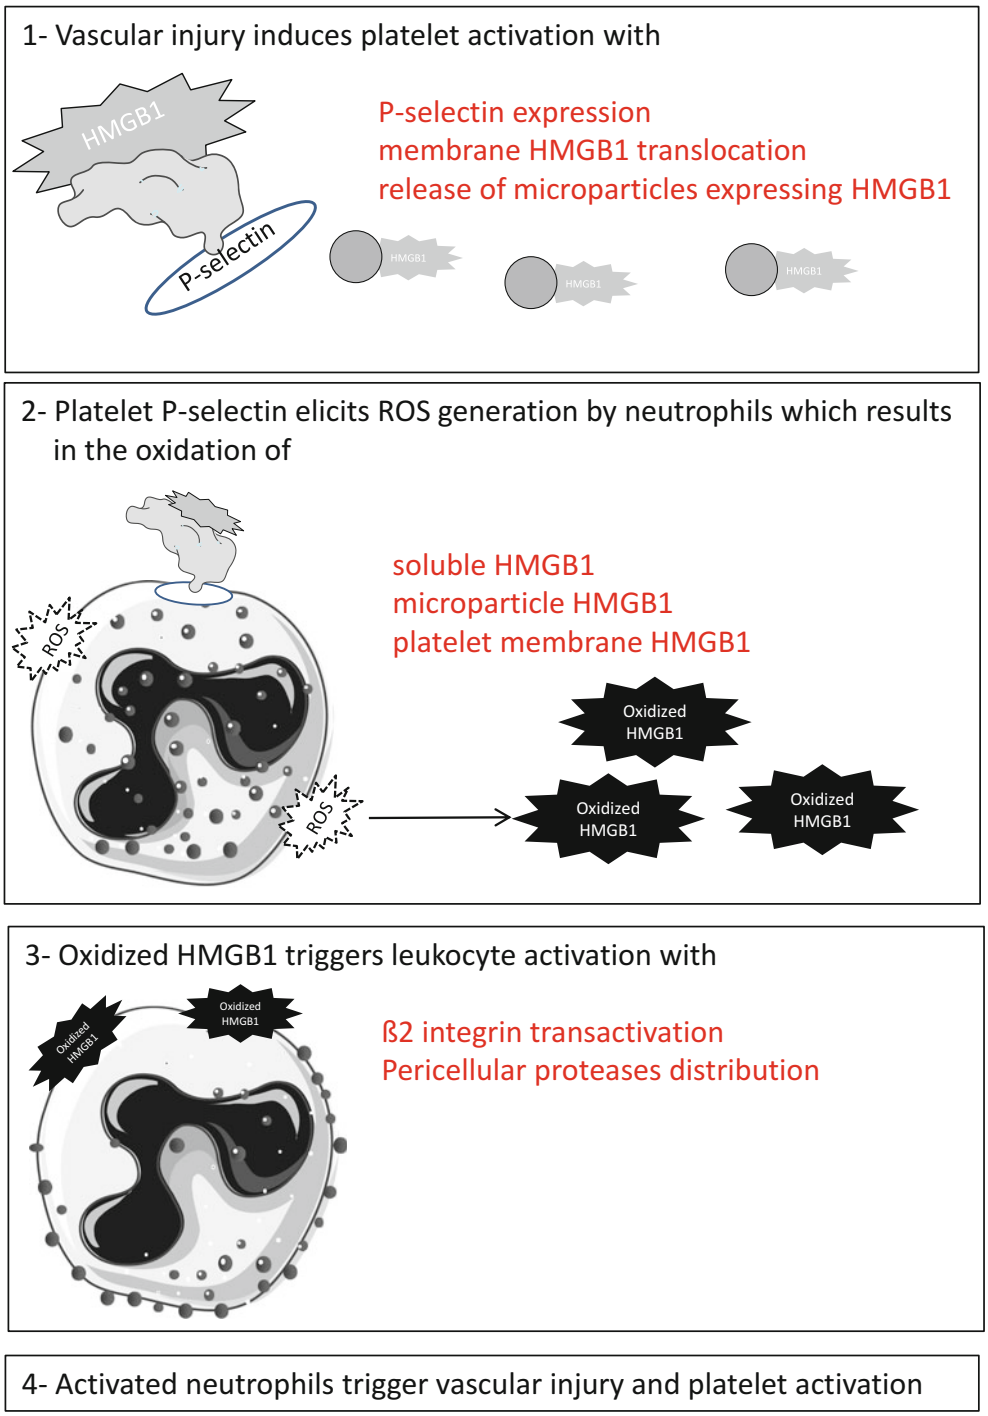

Fig. 4 Platelet–neutrophil cross-talk, role of HMGB1, and microparticles. Platelet P-selectin induces the neutrophil ROS formation and releases microparticles HMGB1^{+}. Oxidized HMGB1 promotes the pericellular distribution of granules and the transactivation of ß2 integrins

(Dixon et al. 2006). P-selectin/PSGL1 also promotes the tissue factor gene expression in monocytes (Di Santo et al. 2011) and neutrophils (Maugeri et al. 2006a).

Induction of ROS and Granule Secretion in Neutrophils

P-selectin expressed on activated platelets, as well as soluble P-selectin, induces the generation of ROS in intact neutrophils (Vanichakarn et al. 2008). The process of ROS generation requires leukocyte β2 integrins and platelet P-selectin and is sensitive to $P2Y_{12}$ antagonism, supporting a role for released ADP as discussed earlier (de Gaetano et al. 1999; Evangelista et al. 2005). The ROS produced by neutrophils can in turn enhance platelet activation and elicit the release of soluble CD40L (Vanichakarn et al. 2008). The generation of ROS by monocytes is also influenced by platelet-derived PF4/CXCL4, which serves as a potent inducer (Pervushina et al. 2004).

Transcellular Metabolism of Arachidonic Acid

Platelet–leukocyte interactions include cooperation in the arachidonic acid (AA) metabolism which has been defined as "transcellular metabolism" (Marcus 1986; Folco and Murphy 2006). Cytosolic phospholipase A2α translocates to the membrane and releases AA when cells are activated. AA becomes available to the enzymes involved in its metabolism: cyclooxygenases (COXs) and lypooxygenase-5 or -12 (5-LOx and 12-LOx, respectively) (Clark et al. 1995; Maclouf et al. 1998). 5-LOx and 15-LOx are expressed in neutrophils and monocytes while 12-LOx is expressed in platelets. 5-LOx is a cytosolic enzyme which translocates to the perinuclear membrane upon activation (Woods et al. 1993; Radmark et al. 2007). 5-LOx initially oxidizes free AA to 5-hydroperoxyeicosatetraenoic acid (5-HETE) and then in a second reaction dehydrates this intermediate to generate leukotriene (LT)A4 (Marcus et al. 1982) or lipoxins (LX) due to the action of 15-LOx (Serhan 1991). LTA4 is then further metabolized either to LTB4, by the action of cytosolic LTA4 hydrolase, or to LTC4 by LTC4 synthase, a nuclear envelop enzyme that conjugates LTA4 with glutathione essentially offered by platelets and endothelial cells (Maclouf et al. 1998). The final products of the 5-LOx pathway, LTB4 and peptido-LTs (LTC4, LTD4 and LTE4), play a fundamental role in inflammation because of their neutrophil activating effects (particularly in the case of LTB4) or ability to elicit smooth muscle cell contraction and edema (Peters-Golden and Henderson 2007). Intermediate compounds, mainly prostaglandin (PG)H2 and LTA4, are only partially metabolized intracellularly; a large proportion of intermediate metabolites exit from the cell to undergo nonenzymatic oxidation or to be taken up by adjacent cells (Borgeat and Samuelsson 1979).

At sites of inflammation where many cell types, platelets, and neutrophils, in particular, interact closely, the released AA and its metabolites can be exchanged. In this process, the donor cell provides intermediate metabolites that are transformed by the enzymatic machinery of the acceptor cell in a final active metabolite that none of the interacting cells would be able to produce alone (Marcus 1990). Platelets and neutrophils participate in this transcellular biosynthetic process in a bidirectional way. In fact activated platelets use AA released from adherent activated neutrophils to increase the production of TxA2. Furthermore, activated platelets provide free arachidonic acid to increase LTB4 production by the adherent neutrophils (Marcus et al. 1982; Palmantier and Borgeat 1991; Maugeri et al. 1992, 1994). Moreover, platelets utilize LTA4 from activated neutrophils to synthesize LTC4 (Maclouf and Murphy 1988; Maugeri et al. 1994). P-selectin-mediated membrane-to-membrane contacts facilitate the exchange of intermediate metabolites between neutrophils and platelets and promote transcellular synthesis of TxA2, LTB4, and LTC4 (Maugeri et al. 1992, 1994) (Fig. 5).

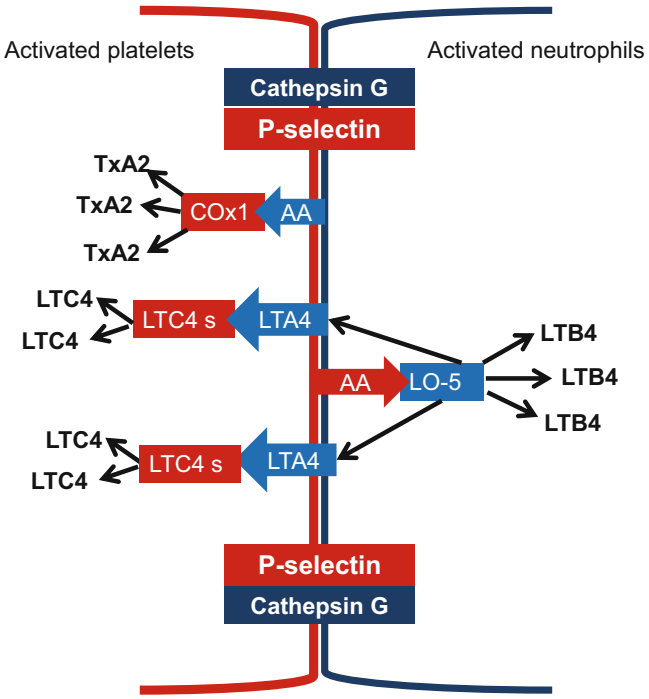

Fig. 5 Platelet–neutrophil cross-talk: transcellular metabolism of arachidonic acid

Platelet–leukocyte transcellular metabolism also leads to the generation of LX, an important class of anti-inflammatory mediators (Serhan et al. 2008), which have been implicated in the physiological termination of inflammatory responses. These metabolites arise from the combined action of 5-LOx and 12-LOx/15-LOx. Early studies demonstrated that coincubation of platelets and neutrophils in the presence of calcium ionophore generates LXA_4 as a consequence of the metabolic action of platelet 12-LOx on neutrophil-derived LTA_4 (Fiore and Serhan 1990; Serhan and Sheppard 1990; Romano and Serhan 1992).

Neutrophil Extracellular Traps

The discovery in 2004 of neutrophil extracellular traps (NETs) has modified the general vision of neutrophil biology and of key mechanisms of innate immunity. NETs are chromatin fibers decorated by neutrophil microbicide proteins, which are biologically active. NET generation thus represents a novel mechanism by which neutrophils kill microbes. More recently, the formation of NETs was observed in many sterile inflammatory disorders, including autoimmune (Radic and Marion 2013) and thrombotic diseases (Pfeiler et al. 2014) (Martinod and Wagner 2014).

NETs are apparently generated when neutrophils fail to engulf the pathogen because they are immobilized, adherent,

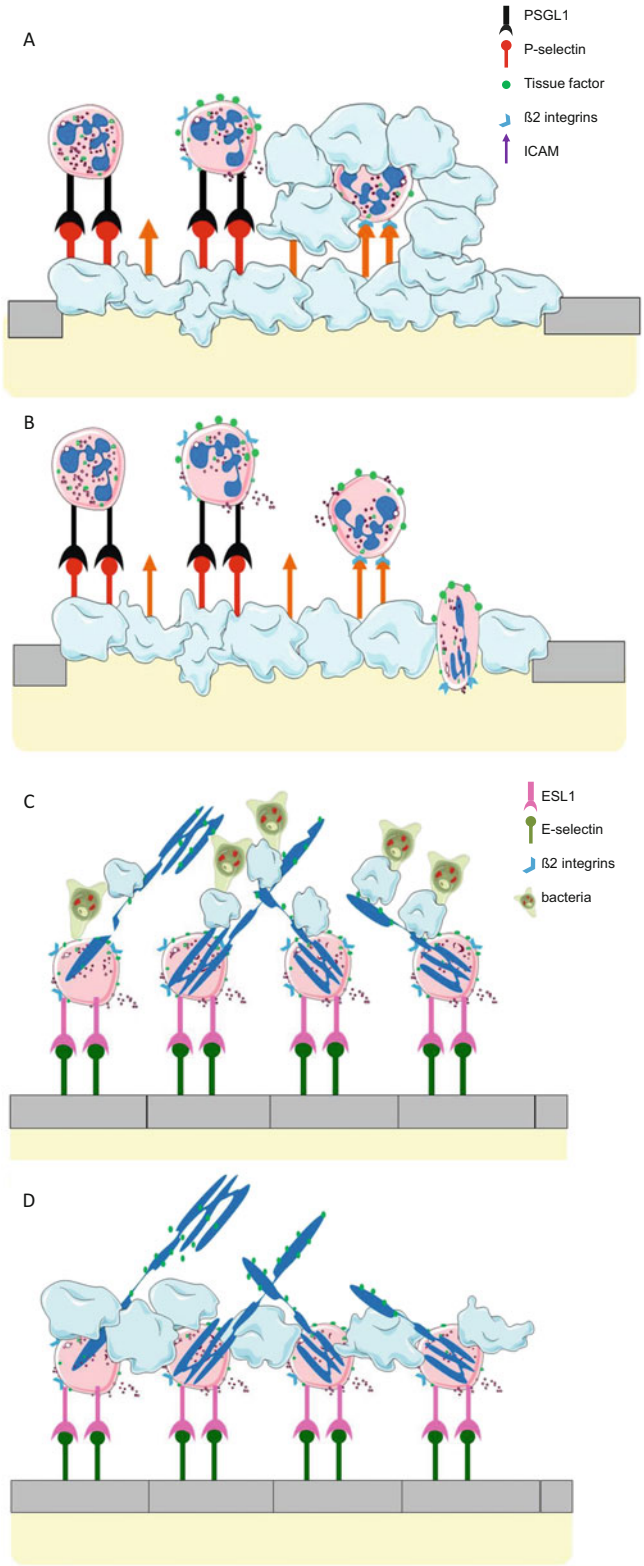

Fig. 6 Heterotypic interactions. Panel **a**: A modern vision of Bizzozero's observations: neutrophil PSGL1 recognizes P-selectin expressed by the activated platelets that adhere to denudated endothelium. The interaction induces neutrophil activation, tissue factor expression release of granular content, and the upregulation of ß2 integrins. The latter interacts with platelet integrins eliciting the formation of an heterotypic thrombi. Panel **b**: activated platelets, that have adhered to the subcellular matrix exposed as a consequence of vascular injury, express P-selectin and platelet integrins. The interaction with neutrophil PSGL1 induces neutrophil activation, tissue factor expression, release of granular content, and the asymmetrical (polarized) upregulation of ß2 integrins, resulting in the formation of heterotypic mural thrombi and/or the leukocyte transmigration. Panel **c**: model of platelet involvement in the NETs during infection. Activated endothelial cells express E-selectin, which is recognized by neutrophil ESL-1, resulting in the symmetrical (not polarized) upregulation of ß2 integrins. Platelets recognize bacteria and become activated and elicit the NETs formation increasing the capture of microbes. Panel **d**: Model of NETs formation in sterile conditions. Persistently activated endothelial cells express E-selectin, which is recognized by neutrophil ESL-1, resulting in the symmetrical (not polarized) upregulation of ß2 integrins. Leukocytes firmly adhere to endothelial cells. Activated platelets present HMGB1 and P-selectin to adherent neutrophils that induce the release of NETs that express tissue factor

or near to apoptosis (Manfredi et al. 2015; Yipp and Kubes 2013; Clark et al. 2007). Their generation depends on the fusion of primary granules to the nuclear membrane, the formation of myeloperoxidase– and elastase–DNA complexes (Papayannopoulos and Zychlinsky 2009; Papayannopoulos et al. 2010), and the citrullination of histones by peptidylarginine deiminase 4 (PAD4) (Leshner et al. 2012; Neeli et al. 2008).

As described earlier, neutrophils reach sites of injury and infection via a multistep process. The persistent endothelial activation induces the expression of E-selectin which is recognized by neutrophils through the constitutively expressed counter-receptor ESL-1 (Munoz-Caro et al. 2015; Hidalgo et al. 2009).

Intravascular generation of NETs may trigger thrombosis as the recognition of E-selectin, expressed on activated endothelial cells, by neutrophils through ESL-1 (Munoz-Caro et al. 2015; Hidalgo et al. 2009) (Fig. 6) initiates heterotypic interaction between neutrophils and endothelial cells resulting in a polarized distribution of integrins by which adherent neutrophils capture circulating platelets. In this multicellular context, signals of thrombo-inflammation and immune-thrombosis are thus integrated and may lead to the release of NETs (Maugeri et al. 2014a; Clark et al. 2007; von Bruhl et al. 2012).

The first evidence of the capacity of platelets to induce NETs was offered by Clark and collaborators (Clark et al.

2007) who demonstrated that platelets respond to gram-negative bacteria via activation of TLR4 receptors. In fact, in this model, neutrophils in the absence of adherent platelets do not respond to LPS (Clark et al. 2007; Maugeri et al. 2014a), but recognize platelets activated by gram-negative bacteria in the microcirculation. Neutrophil activation induced by LPS-stimulated platelets results in NET generation, thrombosis, and organ damage (Urban and Zychlinsky 2007). More recently, the development and use of surrogate animal models of venous thrombosis have demonstrated that monocytes, neutrophils, and platelets cooperate together to initiate and propagate venous thrombosis (von Bruhl et al. 2012), and that NETs are required for thrombus growth and stabilization. Other studies have shown that the infusion of NETs resulted in thromboembolism due to platelet activation, thrombin formation, and fibrin deposition (Fuchs et al. 2010).

A major mechanism by which platelets induce NETs formation is via HMGB1 (Maugeri et al. 2014a) (Fig. 7). The interaction of adherent neutrophils with activated platelets, or their challenge with supernatants obtained from activated platelets, induces NETs formation in static and flowing conditions, in the presence or absence of plasma and independently of the platelet agonist. All neutrophil responses associated to NETs formation induced by activated platelets or recombinant HMGB1 abated in the presence of competitive antagonists of HMGB1 or by using *Hmgb1*$^{-/-}$ platelets (Maugeri et al. 2014a; Vogel et al. 2015).

RAGE (Receptor for Advanced Glycation End products) is the receptor for HMGB1 that has been more clearly associated to NETs formation upon recognition of platelet-derived signals. The stimulation of RAGE by specific agonists (SA100 proteins, glycated albumin) induce NETs, and neutrophils from *Rage*$^{-/-}$ mice do not respond to activated platelets or to recombinant HMGB1 (Maugeri et al. 2014a; Vogel et al. 2015). In contrast, neutrophils from *MyD88*$^{-/-}$ mice (Maugeri et al. 2014a; Vogel et al. 2015) respond normally to platelets, confirming that neutrophil TLR signaling is not directly involved in platelet-induced NETs formation (Clark et al. 2007). Neutrophil exposed to recombinant HMGB1, as well as to activated platelets, activates the autophagy flux. As a consequence they maintain their mitochondrial potential, form autophagosomes and survive for longer time spans (Maugeri et al. 2014a). Recently, in vivo experiments by Vogel and collaborators (Vogel et al. 2015) further supported the contention that HMGB1-positive platelets are detectable along the NETs of coronary thrombi, and that deletion of platelet HMGB1 reduces/prevents thrombosis (Vogel et al. 2015).

Antithrombotic and Anti-inflammatory Interactions

Neutrophil Released Products That Downregulate Platelet Response

As described earlier, cathepsin G released from activated neutrophils may degrade platelet receptors by proteolysis. The degradation of GPIIbGPIIIa reduces platelet aggregation by preventing fibrinogen binding (Molino et al. 1993). Similarly proteolytic cleavage of GPIbα, GPIX and the (reversible) redistribution of GPV on the platelet surface induced by cathepsin G result in a reduction of the platelet capacity to respond to ristocetin and to bind von Willebrand factor, with a general impairment of their hemostatic and thrombotic capacity (Molino et al. 1993; LaRosa et al. 1994a). The pretreatment of platelets with cathepsin G also reduces their capacity to adhere to collagen and respond to thrombin and TxA2 (Kinlough-Rathbone et al. 1999). Finally, cathepsin G or neutrophil elastase cleaves PSGL1 indicating an autocrine mechanism for the downregulation of neutrophil adhesion-activated platelets (Gardiner et al. 2001).

Pentraxin 3

The presence of PTX3 associated to a substantial fraction of circulating platelets was observed 12 h after an acute myocardial infarction. In vitro observations confirm that PTX3 binds to activated platelets and reduces their ability to (1) form heterotypic aggregates with neutrophils and monocytes; (2) activate neutrophils, as evaluated by assessing the upregulation of Mac-1; (3) aggregate with other platelets; and (4) bind to fibrinogen. These results indicate that PTX3 released from activated neutrophils dampens platelet proinflammatory and prothrombotic actions (Baldini et al. 2012). PTX3 also binds to endothelial P-selectin and can attenuate neutrophil recruitment at sites of inflammation (Deban et al. 2010)

Clearance of Activated Platelets

Anionic phospholipids that represent a well-characterized phagocytic tag (or ‘eat me’ signal) are expressed together with P-selectin by activated platelets. The two signals may act in concert to promote capture of platelets by polarized clusters of neutrophil β2 integrins in vitro and in vivo. Neutrophils phagocytose activated platelets in circulation (Maugeri et al. 2009c, 2014b; Manfredi et al. 2010) and

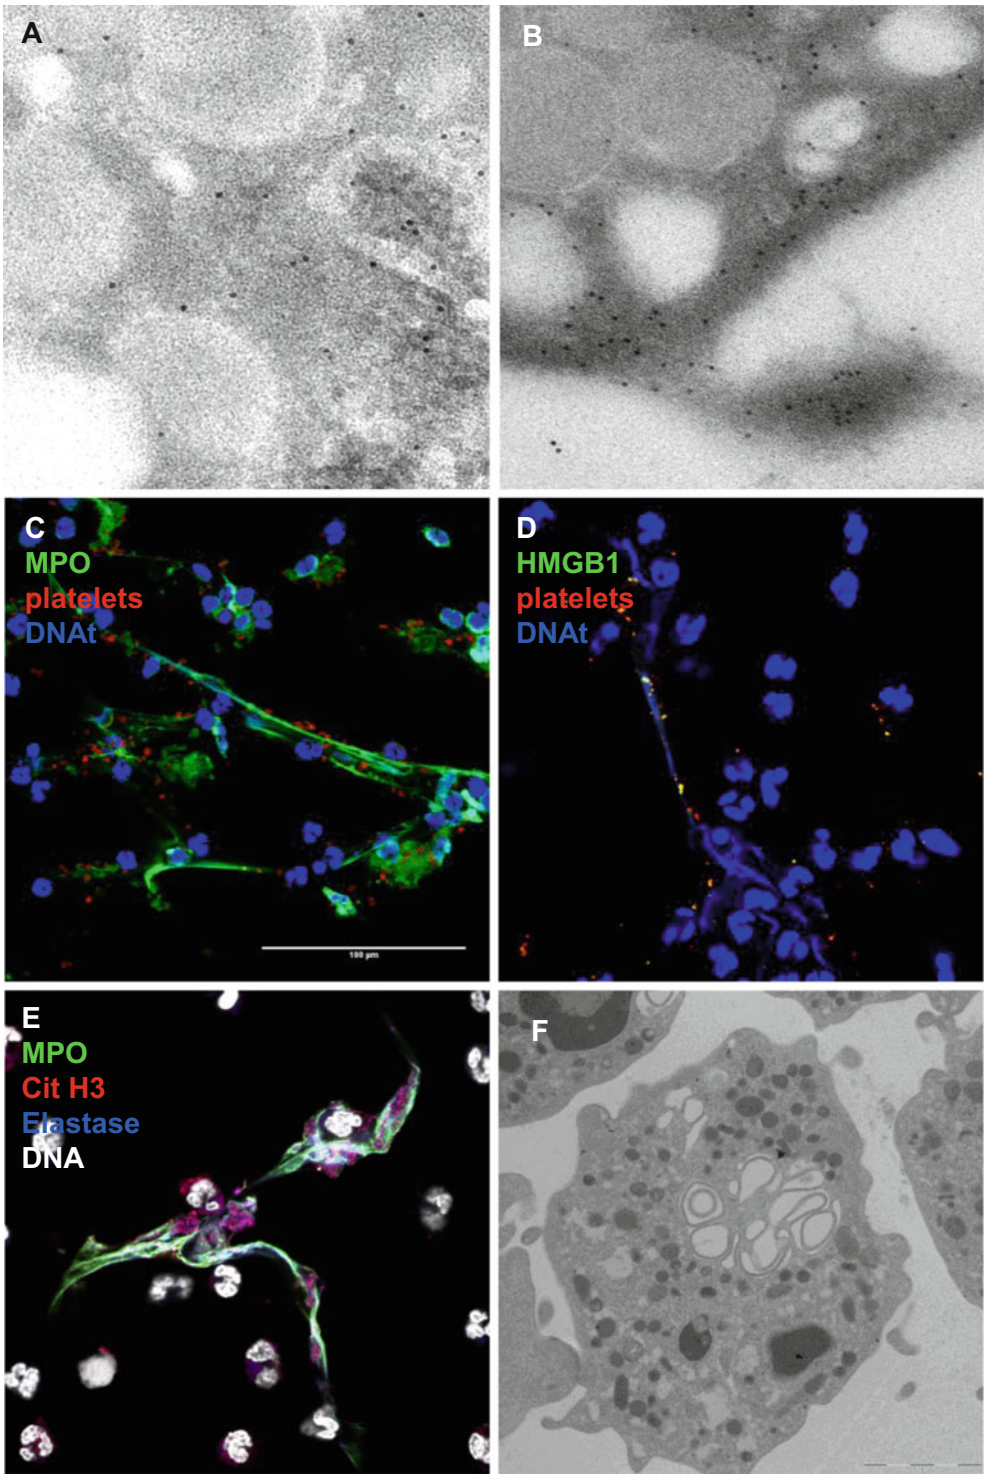

Fig. 7 Resting platelets content HMGB1 within cytoplasmic compartment. (**a**) HMGB1 expressed on activated platelets induce the NETs formation and neutrophil autophagy. Resting platelets content HMGB1 within cytoplasmic compartment (**a**) and is translocated to platelet surface when activated (**b**). (**c**) Adherent neutrophils challenged with autologous activated platelets (*red color*) generate NETs. NETs can be easily identified by the DNA lattices (*blue color*) decorated with MPO (*green color*). (**d**) Activated platelets (*red*) along NETs express HMGB1 (*green*). (**e**) Recombinant HMGB1 induce the NETs formation. NETs are characterized by the DNA (*white*) extrusion, the presence of citrullinated histone H3 (*red*), and the presence of MPO (*green*) and elastase (*blue*) along the DNA lattices. (**f**) Electron microscopy of neutrophils stimulated with HMGB1 illustrates the presence of autophagosomes. **Panels a–c,** and **f** were originally published by Maugeri et al. (2014a)

this clearance mechanism depends on the activation state of platelets, since their internalization requires the recognition of anionic phospholipids on platelets. This mechanism could play both an antithrombotic and anti-inflammatory action, since (i) it eliminates activated platelets that expose anionic phospholipids and tissue factor; (ii) render phagocytosing neutrophils into an unresponsive/anergic state that limits their reactivity to inflammatory stimuli. Accordingly, neutrophils from patients with Essential Thrombocythemia and Polycythemia Vera with thromboembolic events are apparently less effective at phagocytosing activated platelets in vivo (Maugeri et al. 2011a) (Fig. 8).

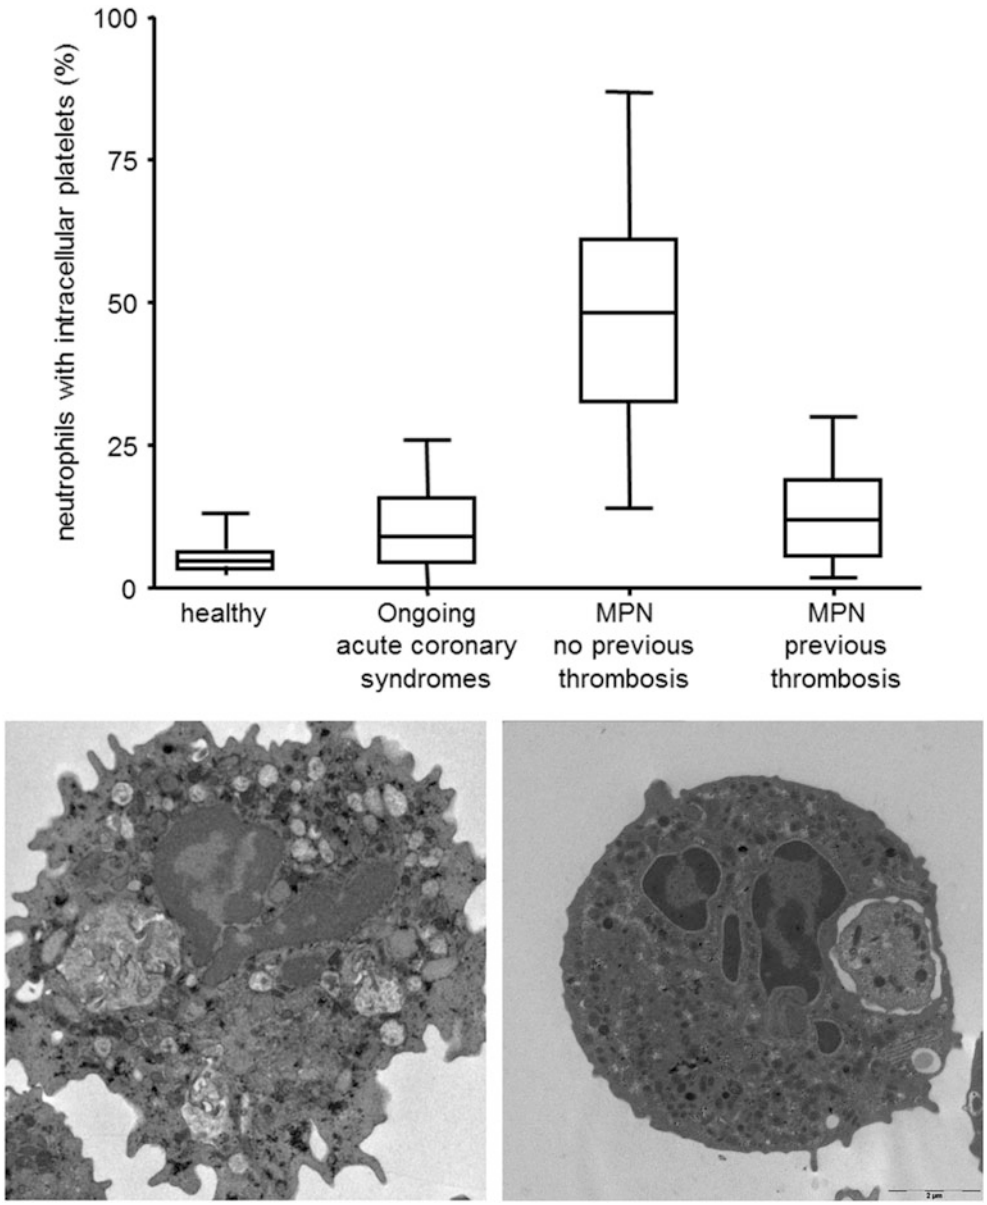

Fig. 8 Impaired clearance of activated platelets by neutrophils in patients with thromboembolic events. (**a**) The amount of neutrophils with intracellular platelets was determined in healthy donors, patients with acute myocardial infarction within 6 h from symptoms onset, patients with myeloproliferative neoplasms (MPN) with or without history of thrombotic events. Results of the plot were published by (Maugeri et al. 2009c, 2011a). (**b** and **c**) Representative electron microscopies illustrating the presence of intracellular platelets in neutrophils of patients with acute myocardial infarction and polycythemia vera, respectively, Images were originally published by (Maugeri et al. 2009c, 2011a)

CD39 Ecto-apyrase

Endothelial cells and leukocytes express the CD39 ecto-apyrase, which rapidly metabolizes ATP and ADP, thus reducing the nucleotide availability in the microenvironment and thus activation of purinergic receptors. As a consequence, the activity of CD39 also controls the migratory and inflammatory properties of neutrophils (Fung et al. 2009; Kukulski et al. 2011). Since platelets are a major source of agonistic nucleotides, these mechanisms may limit the activation of platelet and neutrophil activation in injured vessels and ischemic tissues (Fung et al. 2009; Hyman et al. 2009).

Pathological Features of Platelet and Leukocyte Interactions

Vascular Remodeling Responses

Platelets mediate leukocyte recruitment, primarily neutrophils and then monocytes, in the setting of endothelial injury, such as that occurs after angioplasty and stent deployment (Palmerini et al. 2002; Roque et al. 2000; Simon et al. 2000b; Smyth et al. 2001). Recruitment of inflammatory cells mediates the vascular response to injury

and neointimal formation (Roque et al. 2000; Simon et al. 2000b; Smyth et al. 2001). Platelet P-selectin is required for leukocyte recruitment and subsequent intimal hyperplasia (Wang et al. 2005a). P-selectin directly mediates platelet–leukocyte interactions and is required for the deposition of RANTES along the vessel wall, which also contributes to monocyte recruitment and the development of intimal hyperplasia (Schober et al. 2002). Moreover, in agreement with the concept that platelet-mediated leukocyte recruitment required coordinated actions of adhesive receptors, in vivo experiments in the mouse demonstrated that integrin αMβ2 and its main ligand on the platelet surface, GPIbα, are both essential for the recruitment of leukocytes at the site of vascular injury and for the subsequent development of intimal hyperplasia (Simon et al. 2000a, b; Wang et al. 2005b).

Atherosclerosis and Acute Coronary Syndromes

Studies in animal models support the contribution of activated platelets in the formation and progression of atherosclerotic plaques (Burger and Wagner 2003) through mechanisms that require expression of both P-selectin (Huo et al. 2003) and CD40L (Lievens et al. 2010), although there is conflicting evidence about the requirement for CD40L on bone marrow-derived cells in atherosclerosis (Bavendiek et al. 2005). Moreover, treatment with antibodies that inhibit platelet adhesive molecules mediating the interaction with leukocytes such as GPIbα (Massberg et al. 2002) or GPVI (Bultmann et al. 2010) and defects in platelet secretion (King et al. 2009) reduce atherosclerosis in mice (Schulz and Massberg 2017).

In hypercholesterolemic animals, activated platelets and platelet–leukocyte aggregates adhere to the endothelium at sites that are prone to plaque formation and deliver RANTES and PF-4. These signals in turn amplify the recruitment of monocytes and accelerate atherosclerosis (Huo et al. 2003). In humans, the increased fraction of circulating platelet–leukocyte heterotypic aggregates is considered as a hallmark of acute coronary syndromes (Maugeri et al. 2009c, 2011b, 2012c, 2014a; Furman et al. 2001; Michelson et al. 2001). Additionally, neutrophil infiltration at the culprit lesions in patients who have died following acute myocardial infarction suggests that platelet–neutrophil interactions occur at the site of ruptured plaques (Naruko et al. 2002).

The role of procoagulant tissue factor in coronary artery disease and acute coronary syndromes is well established. The exposure of tissue factor by the vessel wall at the site of endothelial injury plays a major role in the initiation phase, whereas blood-borne tissue factor would be involved more in the propagation phase of thrombus formation and coronary artery disease (Camera et al. 2012, 2015). Furthermore, the presence of tissue factor in circulating leukocytes and platelet–leukocyte heterotypic aggregates has been documented in patients with unstable angina and acute myocardial infarction (Brambilla et al. 2008).

The interaction of platelets and neutrophils in acute myocardial infarction seems to be unique in terms of the ability of activated platelets to induce neutrophil degranulation (Maugeri et al. 2011b, 2012c). Indeed, three subpopulations of circulating neutrophils have been described in patients during the very early phase of acute myocardial infarction: (1) newly formed neutrophils (expressing increased amounts of MPO), (2) neutrophils with low MPO content, and (3) neutrophils with complete MPO depletion. This three-modal pattern of MPO expression is specific of the first hours of an acute myocardial infarction and disappears 24–48 h after the onset of symptoms. MPO could not be detected in patients with unstable or chronic stable angina, and in patients with systemic inflammation due to either noninfectious (acute bone fracture), infectious (sepsis), or autoimmune diseases (small and large vessel systemic vasculitis, rheumatoid arthritis). In patients with an acute myocardial infarction, MPO depletion was associated with platelet activation, indicated by P-selectin expression, activation and transactivation of leukocyte β2-integrins, as well as the formation of platelet–neutrophil and –monocyte aggregates (Fig. 9). Likewise, the injection of activated platelets in mice produced P-selectin dependent complete MPO depletion in about 50 % of circulating neutrophils (Maugeri et al. 2012c).

The analysis of the composition of coronary thrombi obtained from patients with segment T elevation myocardial infarction reveals that neutrophils are the most abundant cell within the thrombi, having close engagement with activated platelets, the presence of HMGB1-positive platelets along the NETs (Maugeri et al. 2014a), and the TF associated to NETs structures in the culprit artery (Stakos et al. 2015) (Fig. 10).

Systemic Autoimmune Diseases

Vasculitides The clinical variability of vasculitides is characterized by a variety of pathophysiological causes that can be associated with established extravascular diseases, e.g., systemic autoimmune diseases, or occur as primary conditions and share clinical pathological features with other pathologies characterized by a prevalent vessel inflammation such as atherosclerosis, systemic sclerosis (SSc), and thrombotic microangiopathies (Ramirez et al.

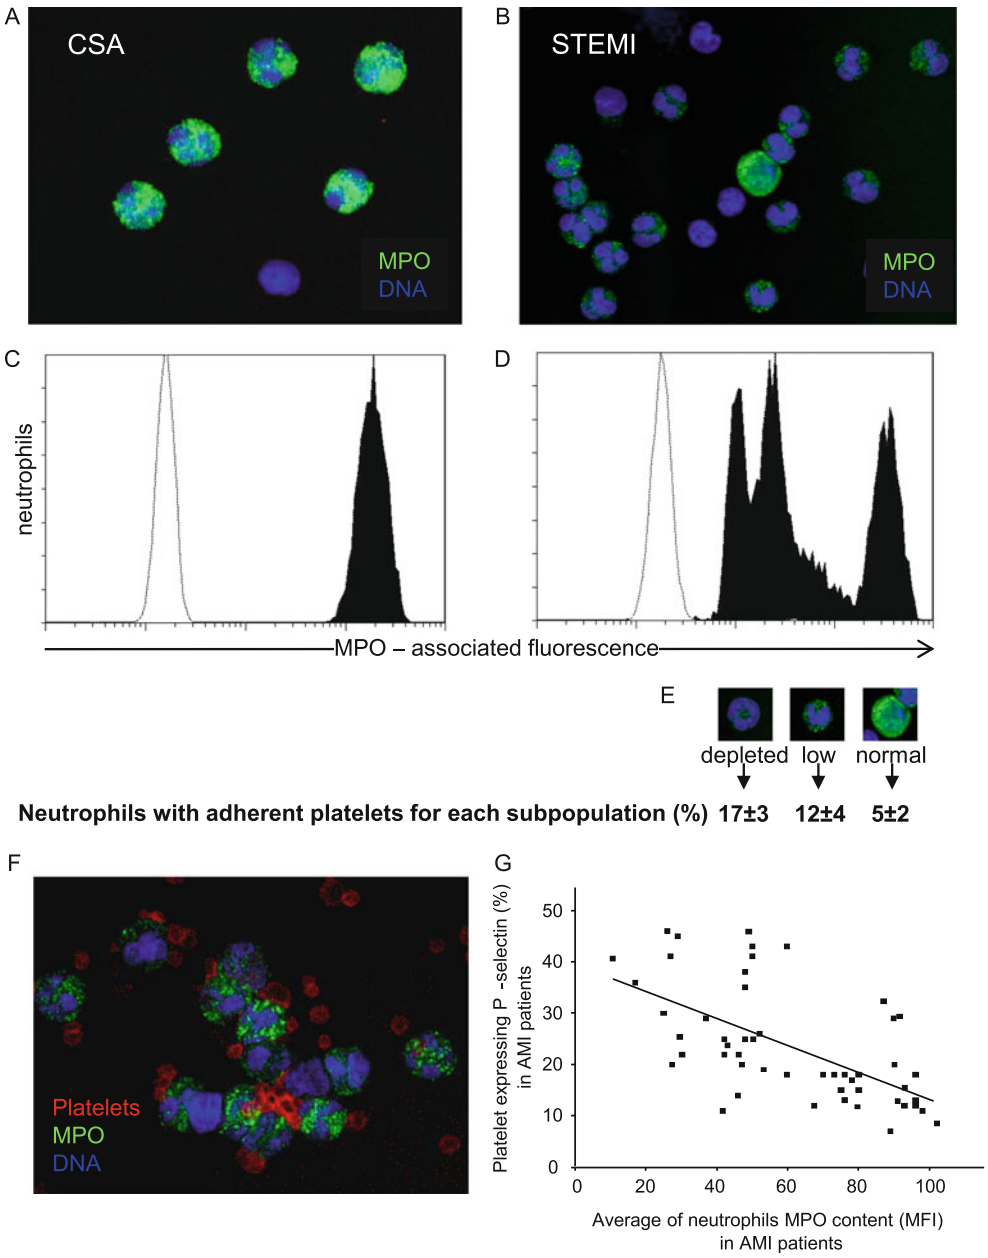

Fig. 9 Heterogeneity of myeloperoxidase content in circulating neutrophils from patients with acute myocardial infarction is associated to platelet adhesion and activation. Images were originally published by (Maugeri et al. 2012c)

2014; Baldini et al. 2014). Inflammation is, in most cases, self-sustaining with heterogeneous clinical manifestations, depending on the size of the vessels and the anatomical regions that are preferentially involved.

Large vessel vasculitides: An inflammatory process entirely developing inside the vessel wall characterizes large vessel vasculitis (Takayasu arteritis, giant cell arteritis or GCA) (Maugeri et al. 2009b; Grayson et al. 2012). GCA is the most common vasculitis affecting large vessels in the elderly. The onset is characterized by the arterial wall inflammation that leads to eventual occlusion of the vessel lumen and consequent ischemia. Thrombocytosis, activation of circulating platelets, platelet–leukocyte aggregates, and the expression of TF by circulating leukocytes are characteristics of GCA (Foroozan et al. 2002; Kale and Eggenberger 2010; Maugeri et al. 2009a, 2012c).

Small vessel vasculitides, also known as antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitis (AAV), are characterized by the high prevalence of venous thromboembolism (Xu et al. 2015), platelet, and leukocyte activation (Maugeri et al. 2012c). Antibodies against neutrophil cytoplasmic antigens induce the generation of NETs, de novo synthesis of C-reactive protein (Xu et al. 2015; Peng et al. 2014; Radford et al. 2000). Circulating neutrophils in AAV express proteinase 3 on their surface which induces platelets activation (Peng et al. 2014).

In Behcet's disease, a rare, chronic multisystemic vasculitis, the occurrence of platelet–leukocyte interactions has

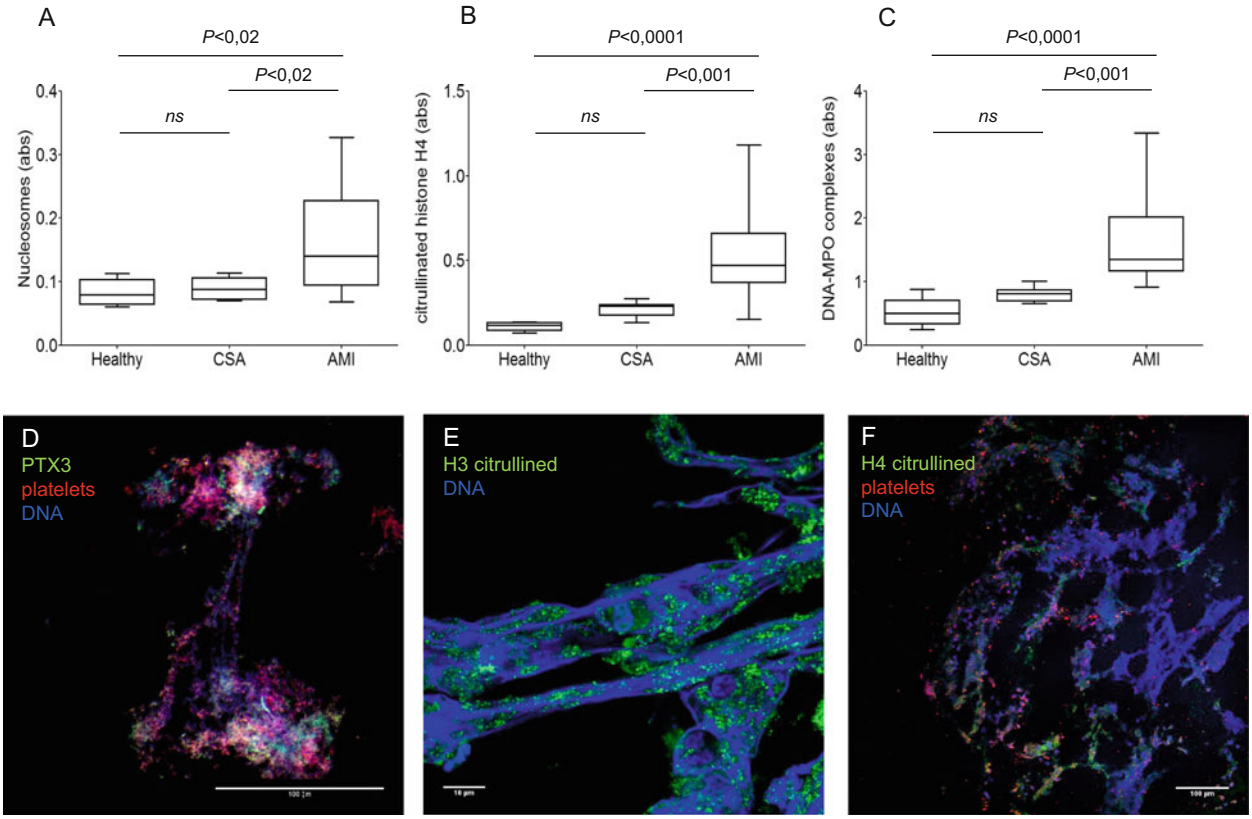

Fig. 10 NETs characterizes acute myocardial infarction. Increased plasmatic markers of NETs in patients with STEMI respect to healthy donors and patients with chronic stable angina. Results and images adapted from (Maugeri et al. 2014a)

been linked to vascular inflammation. In these patients, the presence of heterotypic aggregates, activated platelets, and platelet-derived microparticles appear to be associated with disease progression (Macey et al. 2011).

Rheumatoid Arthritis (RA) Platelets play a major role in RA since the presence of activated platelets and platelet-derived microparticles accumulate in the blood and the synovial fluid of patients with RA (Yaron and Djaldetti 1978; Knijff-Dutmer et al. 2002). Biologically active inflammatory microparticles are released as a consequence of platelet activation due to exposure to collagen and accumulate in the joints inducing the activation of fibroblastoid synoviocytes, which in turn secrete chemokines and cytokines that sustain synovitis and bone erosion (Boilard et al. 2010). These events might be important in the natural history of the disease, since the depletion of platelets reduces the severity of experimental murine arthritis (Boilard et al. 2010). Platelet-derived prostaglandins and serotonin contribute to the persistent inflammation and vascular permeability that characterizes RA synovial vessels (Boilard et al. 2012; Gasparyan et al. 2014). Thus, platelet activation is an early and possibly integral component of the vascular inflammation that is an hallmark of RA and may be a mechanism contributing to the increased cardiovascular risk in these patients. The platelet activation observed in RA extends to the formation of heterotypic aggregates with leukocytes, the consequent neutrophils and monocyte activation, and neutrophil degranulation (Maugeri et al. 2012c; Weissmann et al. 1982; Weissmann and Korchak 1984; Palmer et al. 1986; Bunescu et al. 2004; Manfredi et al. 2016).

Systemic Sclerosis (SSc) Oxidative stress is a critical player in the natural history of SSc, an inflammatory systemic disease associated with fibrosis, autoimmunity, and extensive vessel remodeling while the etiology of SSc is still unknown, platelets play a crucial role in SSc (Ramirez et al. 2012) since they show a unique biological behavior and represent a consistent circulating source of bioactive compounds that contribute to the development of many clinical features of the disease, such as formation of ROS, fibrosis, and impaired vascular tone (Ramirez et al. 2012).

At variance with the above-described mechanisms of platelet–leukocyte interaction observed in autoimmune-

inflammatory diseases, the effect of activated platelets on leukocytes seems to be exclusively dependent on platelet-derived microparticles bearing HMGB1 and on the oxidation state of HMGB1 (Maugeri et al. 2014c). Neutrophils and monocytes of patients with SSc show a dramatic decrease of PSGL1 and CD15 expression; in contrast, β2 integrins appear to be in a persistent activated state but without bound fibrinogen. Both, the loss of P-selectin receptors and the absence of fibrinogen on its receptors (β2 integrins) could be due to proteolytic cleavage mediated by released proteases (Maugeri et al. 2014c). The oxidation of HMGB1 amplifies its ability to activate neutrophils, as detected assessing the redistribution of primary granules molecules and the transactivation of the β2 integrins. In the context of platelet–leukocyte interactions, high amount of ROS can be generated by both activated platelets and by neutrophils triggered by P-selectin. In this context, oxidized extracellular HMGB1, soluble or associated to platelet membrane or to platelet-derived microparticles, further increased leukocyte activation. Leukocyte activation abated in the presence of inhibitors of HMGB1 or of catalase, which catalyzes the dismutation of hydrogen peroxide into water and molecular oxygen. The redistribution of the content of primary granules and the activation of β2 integrins appear to be a hallmark of circulating neutrophils in SSc patients; in these patients, membrane HMGB1 is significantly higher in a subset of patients with pulmonary hypertension or with diffuse SSc. $HMGB1^{+}$ microparticles purified from SSc patients, but not $HMGB1^{-}$ microparticles purified from control subjects, activated in vitro healthy neutrophils and HMGB1 inhibitors reversed the effects of microparticles (Maugeri et al. 2014c) (Fig. 11).

Inflammatory Lung Diseases

A large variety of observational studies in patients and experimental studies in animal models have established a key role of platelet–leukocyte interactions in inflammatory lung disease. These studies emphasize the role of platelet–leukocyte interaction in the pathogenesis of clinical conditions characterized by acute lung injury (ALI) (Bozza et al. 2009) such as acute respiratory distress syndrome (ARDS) (Matthay and Zemans 2011) and transfusion-related lung injury (TRALI) (Caudrillier and Looney 2012).

Early studies showed the presence of platelets often associated with neutrophils and monocytes in lung vessels of histological samples from subjects with ALI/ARDS (Heffner et al. 1987) and suggested that platelets were required for complement-induced ALI in mice (Tvedten et al. 1985). More recently, taking advantage of novel pharmacological and genetic approaches, researchers have demonstrated that platelet–leukocyte interactions play a pathogenic role in ALI syndromes and identified mechanisms and mediators as potential targets for novel pharmacological strategies.

Using a murine model of acute lung injury, triggered by aspiration of hydrochloric acid (HCL), as a surrogate for human ALI/ARDS, Zarbock et al. (Zarbock et al. 2006) demonstrated that platelet depletion or administration of an anti-P-selectin antibody reduced neutrophil and protein accumulation in the airways, improved gas exchange, and increased animal survival. The use of chimeric mice indicated that platelet, but not endothelial, P-selectin was responsible for neutrophil recruitment and tissue injury (Zarbock et al. 2006). In vitro experiments identified thromboxane A2, which is released during platelet–neutrophil interactions, and signaling through thromboxane receptors, as a central mechanism stimulating ICAM-1 expression by endothelial cells, and contribute to neutrophil recruitment in the lungs (Zarbock et al. 2006). Overall these results were consistent with other studies in models of ALI indicating that treatment with anti-P-selectin antibody or genetic deletion of P-selectin protects animals from inflammatory lung damage (Kuebler 2006).

TRALI is the major cause of transfusion-related mortality, mainly mediated by passive infusion of human leucocyte antigen (HLA) and/or human neutrophil antigen (HNA) antibodies present in blood products. Although the pathophysiology of TRALI is still being defined, MHC antibody-based experimental TRALI models have revealed that platelets are recruited in the lung microvasculature and contribute to lung injury mainly through their interactions with neutrophils (Looney et al. 2009)

Using an elegant in vivo multichannel fluorescent imaging of the systemic circulation, Hidalgo et al. described the dynamics of heterotypic interactions of neutrophils with platelets in a two-event model of TRALI. In this model, the transfused antibody binds to endothelial MHC I antigen and mediates the capture of neutrophils via FcγR. In this context, E-selectin–ESL-1 engagement induces activation and polarization of the activated β_2 integrin Mac-1 at the neutrophil leading edge. In this position, Mac-1 mediates the capture of circulating platelets. The latter in turn triggers the generation of ROS leading to endothelial damage and microvascular occlusion (Hidalgo et al. 2009). In association with cell adhesion molecules, platelet-derived products, such as lysophosphatidylcholines (LysoPCs) which are released by aged PLTs during storage enhances neutrophil priming activity in vitro and triggers lung inflammation in healthy rats. By this mechanism, aged platelets contribute to pulmonary and systemic coagulopathy, in a "2-hit" TRALI model (Vlaar et al. 2010).

In a similar model, in vivo treatment with anti-P-selectin antibody reduced pulmonary edema, pulmonary and systemic inflammation, MPO activity, as well as pulmonary

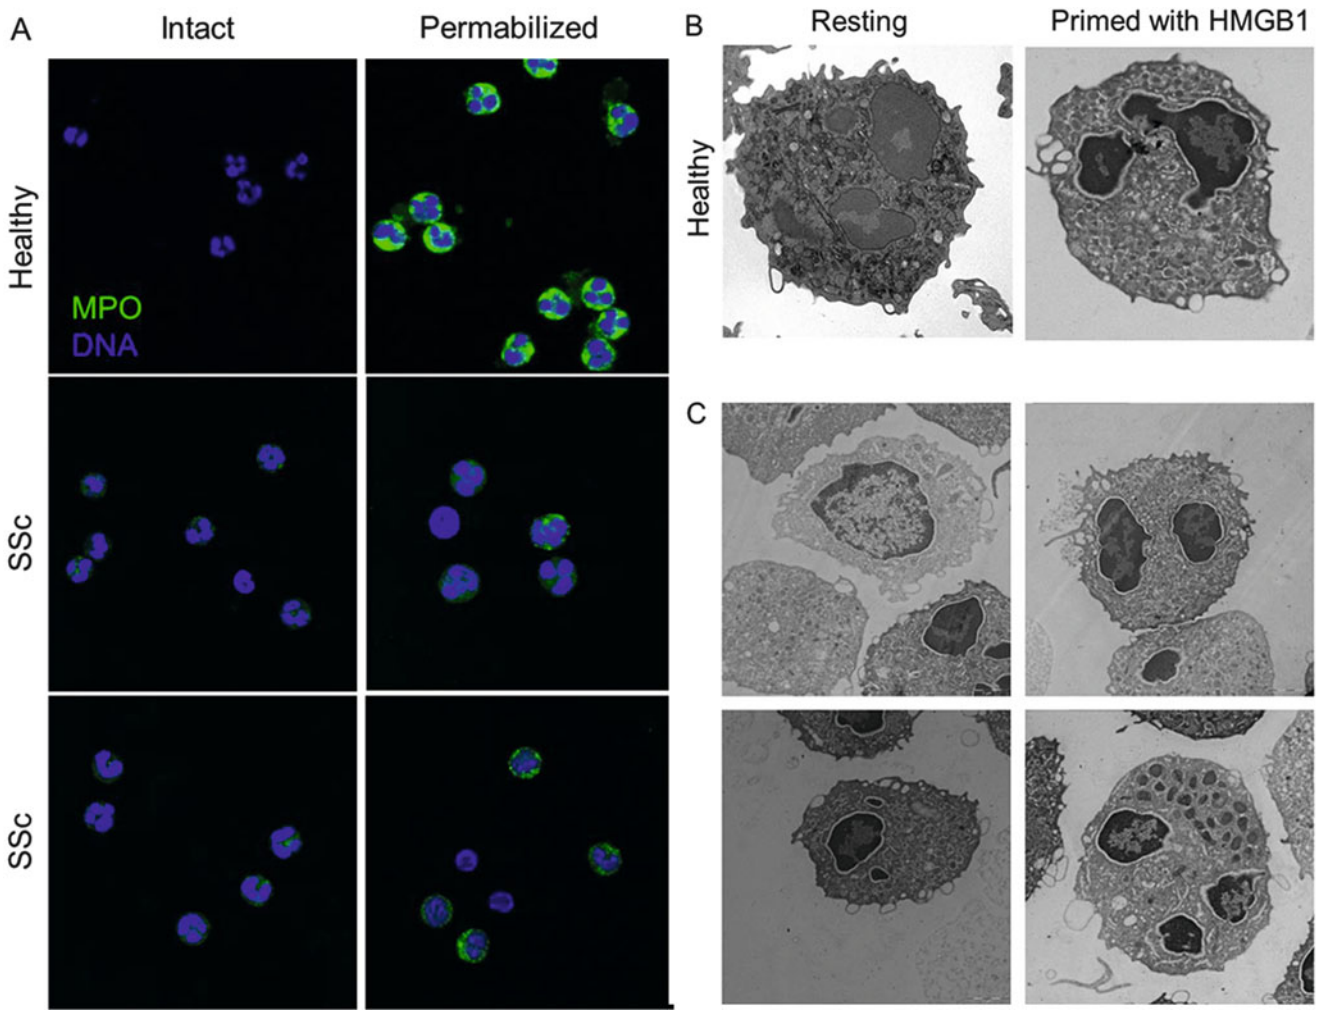

Fig. 11 MPO redistribution of circulating leukocytes of SSc patients. Representative images of neutrophils from the blood of patients with SSc and healthy controls. (**a**) The expression of MPO (*green*) in the blood neutrophils of patients with SSc and of matched controls has been analyzed by confocal microscopy before and after permeabilization of the plasma membrane, to allow the access of the mAb. Hoechst (*blue*) was used for counterstaining nuclei. MPO intracellular expression is substantially lower in SSc patients and appear to cluster at the plasma membrane of intact, nonpermeabilized neutrophils; (**b** and **c**) representative images by electron microscopy of neutrophils from a healthy control, in the absence or where indicated in the presence of recombinant HMGB1 (see Methods) (**b**) or of untreated neutrophils from four SSc patients (**c**). An extensive remodeling of intracellular granules, most of which acquire a pericellular distribution, characterizes SSc neutrophils and healthy neutrophils treated with HMGB1. Images were previously published by (Maugeri et al. 2014c)

and systemic coagulation, supporting the notion that P-selectin may play a key role in mediating TRALI (Tong et al. 2015).

Emerging evidence also indicates that NETs play important roles in inflammatory processes. Recent studies report that in a neutrophil- and platelet-dependent mouse model of ventilator-induced lung injury, NETs were found in the lung microvasculature, and circulating NET components were increased in the plasma. Pharmacological disruption of NETs, as well as the use elastase$^{-/-}$ mice, demonstrated that NETs directly influenced the severity of ALI (Rossaint et al. 2014).

Similarly to ALI, platelet–leukocyte interactions may play a role in allergic inflammation of the airways. In animal models of allergic asthma, platelet depletion reduced eosinophil and lymphocyte accumulation in the lungs after exposure of animals to specific allergens. Injection of wild-type, but not P-selectin-deficient platelets, restored leukocyte recruitment in the airways (Pitchford et al. 2005) (see also Momi et al. (2017)).

In addition to ALI and asthma, emerging hypotheses suggest that platelets may assist the recruitment of leukocytes into lung tissue in cystic fibrosis (CF) (O'Sullivan and Michelson 2006), a genetic disease in which mutations in

the gene of the CF transmembrane conductance regulator (CFTR) result in reduced secretion of Cl^- and HCO_3^- ions, thickened mucosal secretions, and chronic infections of the airways. An excessive and persistent accumulation of neutrophils, and tissue damage characterize the airways of patients with CF. These patients show increased levels of neutrophil–platelet and monocyte–platelet aggregates in their circulating blood, and increased Mac-1 expression on their neutrophils and monocytes (O'Sullivan and Michelson 2006; Mattoscio et al. 2010). Interestingly, in vitro blockade of CFTR in platelets and neutrophils from healthy subjects results in reduced generation of LX A4 by platelet–neutrophil coincubation and prolonged neutrophil survival (Mattoscio et al. 2010), suggesting that dysfunctional platelet–neutrophil interactions may contribute to the persistence of lung inflammation in CF. In animal models, LPS challenge of mice carrying the F508del (a common type of CFTR mutation) mutation induced more severe thrombocytopenia and had increased levels of plasma TXB2 (confirming the activating effect of LPS on platelets Maugeri et al. 2014a; Clark et al. 2007) that coincided with neutrophilic lung inflammation, relative to wild-type mice. Inhibition of platelets or depletion of neutrophils diminished LPS-induced lung inflammation in these F508del mice. In contrast, reconstitution of normal mice with F508del bone marrow or neutrophils resulted in a worse thrombocytopenia. Blockade of PSGL-1, in F508del mice reduced alveolar neutrophil transmigration after LPS challenge suggesting that F508del platelets and their interaction with neutrophils may contribute to the development of lung disease (Zhao et al. 2013).

Inflammatory Bowel Disease

Patients with inflammatory bowel disease (IBD) have an increased risk of microvascular thrombosis and thromboembolism (Yoshida and Granger 2009). Analysis of surrogate markers indicated the presence of thrombocytosis, platelet activation, and circulating platelet–leukocyte heterotypic aggregates in patients with IBD (Pamuk et al. 2006). This evidence can be recapitulated in the dextran sodium sulfate (DSS) and T-cell transfer models of murine colonic inflammation (Yan et al. 2013; Deban et al. 2008). The use of these animal models highlighted a key role for platelet–leukocyte–endothelial cell interactions in the pathogenesis of IBD (Gironella et al. 2002; Vowinkel et al. 2007). Intravital microscopy of colonic venules in mice subjected to experimental colitis has demonstrated that leukocytes that adhere to the vessel walls recruit the circulating platelets. The use of neutralizing monoclonal antibodies or the induction of colitis in P-selectin$^{-/-}$ mice indicated that P-selectin and PSGL-1 mediate the accumulation of platelets and leukocytes, and the extent of their accumulation correlates with disease severity (Gironella et al. 2002). In addition to P-selectin-PSGL-1 pair, CD40L appears to mediate platelet–leukocyte interaction in experimental colitis. Genetic deletion or pharmacological inhibition of CD40–CD40L pathway reduces platelet and leukocyte accumulation in the colonic microvasculature and attenuate the disease (Vowinkel et al. 2007). Thus, platelet and leukocyte recruitment in the microvasculature of the colon mucosa are codependent and might be responsible for microthrombosis, fibrin deposition, focal arteritis, and microinfarctions that have been observed in biopsies of patients with IBD.

Hypercoagulability and the prothrombotic state of the inflamed mucosal microvasculature are also sustained by increased expression of the procoagulant tissue factor. In a mouse model of colitis, a blockade of tissue factor using monoclonal antibodies prevented platelet and leukocyte recruitment and reduced tissue injury and microthrombosis (Anthoni et al. 2007).

In addition to contributing to thrombotic and inflammatory reactions at the intravascular side of the intestinal microcirculation, platelets migrate across the mucosal epithelium together with neutrophils. Interestingly, transmigrated platelets release large amounts of ATP, which is metabolized to adenosine by ectonucleotidases expressed on the apical surface of intestinal epithelial cells. Adenosine, in turn, induces chloride secretion and concomitant water movement into the intestinal lumen. In this way, transmigrated platelets can influence important functions at the luminal surface of the gastrointestinal epithelium.

Final Remarks

The molecular mechanisms and mediators of platelet–leukocyte cross-talk have been extensively investigated and there are consistent observations indicating that many of these can be considered potential targets for pharmacological intervention. For instance platelet-derived chemokines may be targeted to halt the progression of atherosclerosis, as demonstrated in hypercholesterolemic mice (Evangelista et al. 2007). Interference with P-selectin or PSGL-1, the main receptor pair mediating platelet–leukocyte adhesion successfully treated deep vein thrombosis in nonhuman primates (Myers et al. 2007). Finally, genetic and pharmacological targeting of the intracellular pathways that mediate Mac-1 activation has drawn attention to SFK- and PI(3)K-mediated pathways as novel targets for pharmacological control of thrombosis-related inflammation and vascular response to injury (Evangelista et al. 2007).

The important P-selectin/PSGL-1 axis could be disrupted by hydroxyurea. Indeed, hydroxyurea reduces thrombotic

complications in patients with myeloproliferative neoplasms and effectively prevents neutrophil tissue factor upregulation both in vitro and in vivo (Maugeri et al. 2006b, 2011a). A statistically significant reduction of the fraction of circulating neutrophils expressing tissue factor and of the neutrophil intracellular content was observed after hydroxyurea treatment of patients (Maugeri et al. 2006b, 2011a). Other P-selectin-dependent facets of neutrophil activation (neutrophil degranulation, upregulation of ß2 integrins) are also attenuated after treatment with hydroxyurea (Maugeri et al. 2006b, 2011a) reinforcing the likely mechanism of this drug.

In neutrophils, following binding to P-selectin, a phosphodiesterase type 4-sensitive cAMP pool negatively regulates SFK activity through the upregulation of COOH-terminal-Src-Kinase (CSK) and serves as an intrinsic "check" to inhibit platelet-mediated neutrophil recruitment at the site of endothelial damage. Thus, PDE4 inhibitors may represent a novel therapeutic strategy to counteract the detrimental consequences of platelet—neutrophil interactions in the context of vascular disease and atherothrombosis (Totani et al. 2014, 2015).

Heparin seems to be the most versatile drug to block the interactions between platelets and leukocytes. Independently of it anticoagulant effect, unfractionated heparin completely prevents the action of cathepsin G on platelets, including platelet aggregation, serotonin release, and TxA2 production. This effect seems to be dependent on the electrostatic interactions between the cationic cathepsin G and the anionic heparin that block the protease activity of cathepsin G (Evangelista et al. 1992; Ferrer-Lopez et al. 1992). Low molecular weight heparins (LMWH) also interfere with the formation of heterotypic aggregates of platelets and leukocytes, blocking the capacity of P-selectin to induce neutrophil degranulation and surface expression of TF (Maugeri et al. 2005, 2007). Furthermore, neutrophils treated with LMWH lose the capacity to respond to formylated peptide fMLP (Maugeri et al. 2005) in terms of degranulation and TF expression. LMWH also prevent platelet activation and P-selectin expression independently of the platelet stimuli used (Maugeri et al. 2007). In terms of NETs production, heparins prevent the neutrophil adhesion to activated endothelium since they interfere with P- and E-selectins (Wang et al. 2002), degrade NETs scaffolds (Fuchs et al. 2010, 2012), prevent the capacity of platelets to induce NETs (by blocking HMGB1) (Maugeri et al. 2014a), and inhibit MPO binding to DNA, thus restricting NETs formation (Parker et al. 2012). Heparin also prevents the effect of NETs on the fibrotic activity of differentiated lung fibroblasts (Chrysanthopoulou et al. 2014), influencing acute lung injury (Tong et al. 2014; Luan et al. 2014) and the binding of von Willebrand factor to neutrophils during thrombus formation (Grassle et al. 2014).

The studies cited in this chapter support the concept that platelet–leukocyte interactions represent a fundamental physiological process that bridges thrombosis and inflammation. Beyond atherosclerosis and thrombosis, a complex, bidirectional, functional cross-talk between platelets and leukocytes, mediated by specific adhesive molecules, soluble mediators, and membrane receptors plays a pivotal role in the pathogenesis of a variety of diseases, which supports the view that platelets are active components of the immune system and that activated leukocytes should be considered as thrombotic cells. In contrast, under healthy conditions platelet–leukocyte interactions seem to contribute to the resolution of inflammation and to the maintenance of vessel integrity (Maugeri et al. 2012a; Ramirez et al. 2014; Manfredi et al. 2010), and to the fine regulation of the amount of activated platelets present in the circulation (Maugeri et al. 2009c, 2011a; Manfredi et al. 2010).

Take-Home Message

Platelet–neutrophil interactions	
Prothrombotic and proinflammatory	Antithrombotic and anti-inflammatory
Neutrophils activate platelets by the release of cathepsin G and elastase	Cathepsin G and elastase proteolysis platelet glycoproteins and downregulate platelet function
Platelet activation results in the P-selectin and HMGB1 expression	Neutrophils phagocytose activated platelets by a mechanism dependent on P-selectin and Mac-1
Platelet P-selectin activate leukocytes and induce Mac activation, release of neutrophil granule content, the expression of tissue factor and ROS formation	Neutrophils with intracellular platelets are unable to react to inflammatory stimuli
HMGB1 expressed by activated platelets induce Mac-1 activation, pericellular granules distribution, and release of NETs	Pentraxin-3 released by activated neutrophils inhibits platelet function and the formation of heterotypic aggregates with leukocytes
NETs activate platelets

The Role of Platelets in Lymphangiogenesis and Neoangiogenesis

Katsue Suzuki-Inoue and Toshiaki Shirai

Abstract

During the developmental stages, when the primary lymph sac arises from the cardinal vein, podoplanin in lymphatic endothelial cells (LECs) activates platelets by binding to CLEC-2, which facilitates blood/lymphatic vessel separation. One of the mechanisms for this process is that granule contents from activated platelets inhibit the migration and proliferation of LECs, thereby facilitating separation of the vessels. Angiogenesis consists of several steps, including activation of endothelial cells (ECs), migration to the site of the vessel branch, proliferation, and formation of tube-like structures. Granule contents released from activated platelets, including VEGF and FGF, are required for EC proliferation. On the other hand, direct contact between platelets and ECs via platelet membrane proteins, including GPIbα and $\alpha_{IIb}\beta_3$, prompts angiogenesis by stabilizing developing vessels. Platelets also play a crucial role in maintaining the vascular integrity of high endothelial venules in lymph nodes and inflammatory vessels via the podoplanin receptor CLEC-2 and the collagen receptor glycoprotein VI. Platelets also regulate cerebrovascular patterning and integrity during development via CLEC-2 and podoplanin in neuroepithelial cells. Thus, platelets play a role, not only in thrombosis and hemostasis, but also in lymphangiogenesis, angiogenesis, and maintenance of vascular integrity.

The Role of Platelets in Blood/Lymphatic Vessel Separation During Development

It has long been recognized that platelets affect vascular endothelium stability, contributing to new vessel development (Gimbrone et al. 1969). However, only recently it has been shown that platelets play a role in lymphangiogenesis. Since 2010, several studies have revealed that platelets are involved in lymphangiogenesis, which was quite surprising. In this section, how platelets regulate proper lymphangiogenesis during development will be described starting with basic information about lymphangiogenesis.

Development of the Lymphatic Vasculature

The lymphatic vessels arise after the cardiovascular system has been established. Lymphatic vessel development starts at around embryonic day (E) 9.5–10.5 in mice. At this stage, distinct subpopulations of vascular endothelial cells in the lateral parts of the cardinal veins commit to the lymphatic lineage (Fig. 1a). Then, endothelial cells committed to lymphatic endothelial cells (LECs) sprout laterally and migrate toward vascular endothelial growth factor (VEGF)-C to form primordial lymphatic vasculature, called lymph sacs (Fig. 1b) (reviewed in (Tammela and Alitalo 2010)). LECs begin to express the membrane protein podoplanin, which is a ligand for C-type lectin-like receptor 2 (CLEC-2) in platelets. The interaction between podoplanin in LECs and CLEC-2 in platelets helps to separate the blood and lymphatic vascular systems (Fig. 1c) (for details, see later). The

peripheral lymphatic vessels are then generated by centrifugal sprouting of lymphatic vessels from the lymph sacs, followed by merging of the separate lymphatic capillary networks, followed by remodeling and maturing of the primitive lymphatic capillary plexus (Fig. 1d).

C-Type Lectin-Like Receptor 2 (CLEC-2)

Identification of a C-type lectin family member, CLEC-2, on the surface of platelets revealed an unexpected role of platelets in lymphangiogenesis. CLEC-2 has been identified as a receptor for the platelet-activating snake venom rhodocytin, also known as aggretin (Suzuki-Inoue et al. 2006, 2011). CLEC-2 induces powerful platelet activation through the tyrosine kinase-dependent pathway, which closely resembles platelet activation mediated through the collagen receptor glycoprotein (GPVI/FcRγ-chain. CLEC-2 has a single YxxL motif in its cytoplasmic tail that resembles ITAM (tyrosine-based activation motif, YxxL-(X)10-12-YxxL), which has 2 YxxL motifs. ITAM is a signaling motif found in immune receptors such as the T-cell receptor and the platelet collagen receptor GPVI/FcR-γ-chain complex. Crosslinking of CLEC-2 or GPVI leads to tyrosine phosphorylation of hemi-ITAM or ITAM by the Src family kinases. This leads to binding of the tandem SH2 domain of the tyrosine kinase Syk to the phosphorylated (hemi-)ITAM. Subsequent activation of Syk initiates downstream signaling events that culminate in tyrosine phosphorylation of LAT and SLP-76 and activation of effecter

enzymes, including Btk and phospholipase Cγ2 (PLCγ2), resulting in platelet activation/aggregation (Suzuki-Inoue et al. 2006, 2011; Fuller et al. 2007; Navarro-Nunez et al. 2013; Watson et al. 2005).

Podoplanin

The membrane protein podoplanin has been identified as an internal ligand for CLEC-2 (Suzuki-Inoue et al. 2007; Christou et al. 2008). Podoplanin is a sialoglycoprotein expressed in certain types of tumor cells and various types of normal tissues, including LECs, type I alveolar cells, and kidney podocytes, after which podoplanin is named (reviewed in (Tsuruo and Fujita 2008)). Podoplanin is expressed in LECs, but not in vascular endothelial cells, and hence, it is used as a marker for LECs. Podoplanin expressed on the surface of tumor cells induces platelet aggregation by binding to CLEC-2 and facilitates hematogenous tumor metastasis (Tsuruo and Fujita 2008; Kato et al. 2008). Under physiological conditions, CLEC-2 in platelets cannot interact with podoplanin in LECs. However, as described earlier, the cluster of endothelial cells in the cardinal vein is committed to the lymphatic phenotype and sprout to form the primary lymphatic sacs during organ development (Fig. 1) (reviewed in (Tammela and Alitalo 2010)). At this stage, CLEC-2 in platelets can interact with podoplanin in LECs.

CLEC-2 in Platelets Facilitates Blood/Lymphatic Vessel Separation by Binding to Podoplanin in LECs

CLEC-2-deficient mice die at the embryonic/neonatal stages associated with disorganized and blood-filled lymphatic vessels and develop severe edema due to abnormal blood/lymphatic vessel separation (Bertozzi et al. 2010; Suzuki-Inoue et al. 2010). Platelet/megakaryocyte-specific CLEC-2-deficient mice also have blood-filled lymphatics (Finney et al. 2011; Osada et al. 2012), suggesting that CLEC-2 in platelets is required for blood/lymphatic vessel separation. Podoplanin deficiency and endothelial cell *O*-glycan deficiency also cause blood/lymphatic misconnections (Fu et al. 2008), and it has been shown that sialic acid on *O*-glycans of podoplanin is essential for binding to CLEC-2 (Suzuki-Inoue et al. 2007). These findings suggest that interaction between CLEC-2 in platelets and podoplanin in LECs is important for normal lymphatic vessel development.

Proposed Mechanisms for Blood/Lymphatic Vessel Separation by CLEC-2 in Platelets

The "Platelet Granule Contents" Theory

Mice deficient in the signaling molecules downstream of CLEC-2, Syk, SLP-76, and PLCγ2 have blood/lymphatic vessel misconnections (Ichise et al. 2009; Abtahian et al. 2003). Inhibition of platelet activation by treating pregnant wild-type mice with aspirin resulted in half of the embryos exhibiting blood/lymphatic misconnections (Uhrin et al. 2010). These findings suggest that platelet activation is required for blood/lymphatic vessel separation. Platelet activation results in granule release and platelet aggregation. Platelet granules contain many angiogenetic factors and growth factors, as well as extracellular matrix, implying that these factors could contribute to blood/lymphatic separation. Alternatively, platelet aggregates accumulate at the separation zone of lymph sacs and cardinal veins, which helps the physical process of separation. In fact, Uhrin et al. and Bertozzi et al. reported that platelet aggregates accumulate at the separation zone of podoplanin-positive lymph sacs and cardinal veins in wild-type embryos, but not in podoplanin-deficient or SLP-76-deficient embryos (Uhrin et al. 2010; Bertozzi et al. 2010). However, mice deficient in integrin αIIbβ3, which is necessary for platelet aggregation, but not for granule release, do not show the nonseparation phenotype (Bertozzi et al. 2010), suggesting a role of granule release. Moreover, supernatants from activated platelets and their main component, TGF-β, inhibit the migration and proliferation of LECs (Osada et al. 2012). In addition to TGF-β, platelets contain some proteins that reportedly inhibit the proliferation or migration of LECs (Table 1) (Oka et al. 2008; Shao and Xie 2005; Shao and Chi 2005). Osada et al. proposed the following mechanisms (Fig. 2a): during the developmental stages, primary lymph sacs derive from the cardinal vein. In the connection between the lymph sac and vein, podoplanin in LECs activates platelets by binding to CLEC-2. The released TGF-β family members inhibit LEC migration, proliferation, and tube formation. This results in the elimination of LECs close to activated platelets, which facilitates blood/lymphatic vessel separation. However, patients who lack platelet dense or α-granules do not exhibit defective blood/lymphatic vessel separation (Michelson 2012). Further studies are therefore necessary to clarify this mechanism.

The "CLEC-2-Mediated Podoplanin Clustering" Theory

Pollitt et al. proposed another mechanism (Pollitt et al. 2014) (Fig. 2b) in which CLEC-2 forms a central cluster upon engagement with podoplanin. Clustering of CLEC-2, in

Heparinase (Brill et al. 2004; Vlodavsky et al. 1992)	Angiostatin (Shao and Chi 2005)

turn, induces clustering of podoplanin. CLEC-2 clustering is dependent on Syk and Src kinases, both of which are signaling molecules downstream of CLEC-2 in platelets. Clustering of podoplanin leads to functional effects including inhibition of migration in LECs by podoplanin-mediated signaling though ezrin/radixin/moesin family proteins and regulation of the actin cytoskeleton. In support of this theory, Osada et al. also reported that recombinant CLEC-2 alone inhibits LEC migration without platelet releasates, although it does not inhibit LEC proliferation (Osada et al. 2012). These findings account for the similar lymphatic phenotype of CLEC-2- and Syk-deficient mice.

The "Prevention of Backflow at the Lymph-Venous (LV) Junction" Theory

The vascular networks connect at the LV junction, where lymph drains into the blood and an LV valve (LVV) prevents the backflow of blood into lymphatic vessels. Hess et al. reported that loss of CLEC-2 resulted in backfilling of the lymphatic network with blood from the thoracic duct in both neonatal and mature mice, even when LVVs are intact (Hess et al. 2014). Interaction between platelet CLEC-2 and podoplanin at LVVs results in the formation of platelet thrombi. Fibrin-containing platelet thrombi were observed at the LVV and in the terminal thoracic duct in wild-type mice but not CLEC-2 deficient mice. It is plausible therefore that hemostasis via CLEC-2 functions with the LVV to safeguard the lymphatic vascular network throughout life (Fig. 2c).

These three mechanisms may not be exclusive of each other, and all three mechanisms may exist in vivo.

The Role of Platelets in Angiogenesis

For successful angiogenesis, endothelial cells need to complete several steps: activation, migration to the site of the vessel branch, proliferation, and formation of tube-like structures that are used in the new vessels (Jain 2003; Klement et al. 2013). Soluble factors, including VEGF and FGF, released from activated platelets, but not contact between platelets and endothelial cells, are required for the proliferation of endothelial cells (Pintucci et al. 2002). On the other hand, whole platelets, but not releasates from platelets, can induce tube formation by endothelial cells (Pipili-Synetos et al. 1998), suggesting that direct contact between platelets and endothelial cells is required for this process. Thus, both soluble factors and direct contact via membrane proteins on the surface of both types of cells are required for the different steps of angiogenesis.

Contributions of Soluble Factors Stored in Platelets to Angiogenesis

Platelets contain a number of angiogenesis activators and inhibitors (Table 1) (Klement et al. 2013). These factors are released upon platelet activation and delivered to the site of neoangiogenesis directly or as intraparticle cytokines contained in platelet-derived microparticles (Brill et al. 2005). Brill et al. reported the proangiogenic effects of platelet-derived microparticles in vitro (using the rat aortic ring model or the cell invasion test) and in vivo (using agarose bead transplantation or artificial cardiac ischemia in Sabra rats). They proved that these effects are mediated by intraparticle cytokines, i.e., VEGF, βFGF, and PDGF, using appropriate blocking antibodies (Brill et al. 2005). It has previously been reported that pro- and antiangiogenic proteins are separated in distinct subpopulations of α-granules in platelets and megakaryocytes (Italiano et al. 2008; Chatterjee et al. 2011). Human platelets express two types of thrombin receptors, proteinase-activated receptor 1 (PAR1, high affinity) and PAR4 (low affinity). Treatment of human platelets with a selective PAR4 agonist results in the release of granules containing antiangiogenic protein,

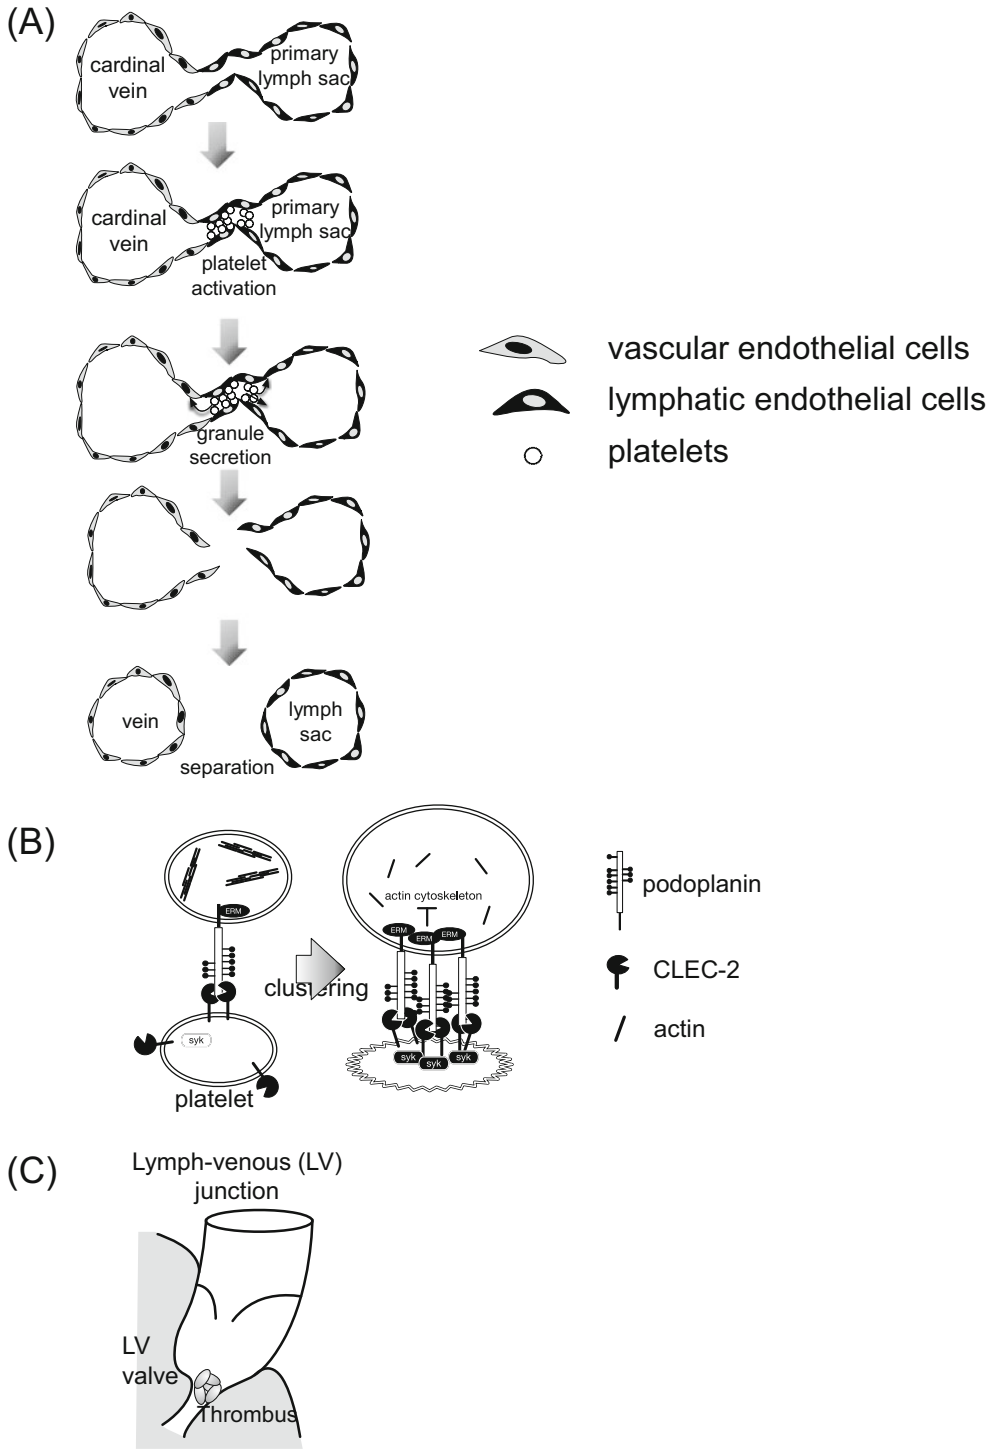

Fig. 2 Proposed mechanisms of blood/lymphatic vessel separation by platelet CLEC-2. (**a**) The "platelet granule contents" theory: during the developmental stages, primary lymph sacs arise from the cardinal vein. In the connection between the lymph sac and vein, podoplanin in lymphatic endothelial cells (LECs) activates platelets by binding to CLEC-2. The released TGF-β family members inhibit LEC migration, proliferation, and tube formation. This results in the elimination of LECs close to activated platelets, which facilitates blood/lymphatic vessel separation. (**b**) The "CLEC-2-mediated podoplanin clustering" theory: CLEC-2 forms a central cluster upon engagement with podoplanin. Clustering of CLEC-2, in turn, induces clustering of podoplanin. CLEC-2 clustering is dependent on Syk and Src kinases, both of which are signaling molecules downstream of CLEC-2 in platelets. Clustering of podoplanin leads to functional effects including inhibition of migration in the LECs by podoplanin-mediated signaling though ezrin/radixin/moesin family proteins and regulation of the actin cytoskeleton. (**c**) The "prevention of backflow at the lymph-venous (LV) junction" theory: the vascular networks connect at the LV junction, where lymph drains into the blood and an LV valve (LVV) prevents the backflow of blood into lymphatic vessels. Interaction between platelet CLEC-2 and podoplanin at LVVs results in the formation of platelet thrombi at LVVs, which prevents backfilling of the lymphatic network with blood from the thoracic duct

but not granules containing proangiogenic protein, whereas the selective PAR1 agonist liberated proangiogenic granules, but not antiangiogenic granules (Italiano et al. 2008; Chatterjee et al. 2011; Ma et al. 2005). In the case of early injury, when there is only a small amount of thrombin, the high-affinity thrombin receptor (PAR1) is engaged, and proangiogenic proteins are released. In later stages of injury, when a high thrombin state occurs because the majority of the clot is crosslinked by factor XIII, the low-affinity thrombin receptor (PAR4) is activated, and antiangiogenic proteins are released, leading to the maturation and stabilization of the vasculature (Italiano et al. 2008). In contrast, oncogenic induction of the stroma and inflammatory cells leads to continuous release of proangiogenic proteins. A lack

of antiangiogenic proteins, which leads to the maturation and stabilization of the vasculature, results in an immature and a highly unstable tumor vasculature (Klement et al. 2013). In addition, it has been reported that stimulation with ADP or a breast cancer cell line, MCF-7, results in the release of proangiogenic VEGF from platelets, whereas stimulation with thromboxane A2 results in the release of antiangiogenic endostatin. These reports suggest that angiogenesis is tightly regulated by various G protein-coupled receptor-mediated signals depending on the physiological/pathological environment. However, the concept that pro-/antiangiogenic proteins are separated in distinct subpopulations of α-granules and released upon PAR1/PAR4 stimulation has been recently challenged by evidence obtained from quantitative immunofluorescence assays and micro-ELISA arrays to quantify the release of distinct α-granule cargo molecules (Kamykowski et al. 2011; Jonnalagadda et al. 2012; Etulain et al. 2015). Further investigations are required to reveal the mechanism of regulation for pro-/antiangiogenic factor release and determine the in vivo conditions under which the selective stimulation of various platelet receptors may occur.

In addition to endothelial cell proliferation and migration, the angiogenic process requires bone marrow-derived cell (BMDC) recruitment to sites of neovascularization. Jin et al. reported that hypoxia-induced thrombopoietin induces the release of SDF-1 from platelets and that released SDF-1 recruits nonendothelial CXCR4+ VEGFR1+ hematopoietic progenitors, which enhances neovascularization (Feng et al. 2011). Feng et al. also reported that secretion of platelet α-granules, but neither dense granule secretion, nor platelet aggregation, is crucial for BMDC homing and subsequent angiogenesis using hypoxia-induced angiogenesis models (Feng et al. 2011).

Thus, platelet granule contents contribute to angiogenesis by increasing the proliferation and migration of endothelial cells and by recruiting bone marrow-derived hemangiocytes, mainly through the secretion of α-granule contents.

Contributions of Platelet Membrane Proteins to Angiogenesis

Kisucka et al. showed that mice lacking extracellular GPIbα, but not the mouse model of platelet storage pool deficiency ($Lyst^{bg}$), experienced a significant reduction in corneal neovascularization and developed hemorrhages at sites of angiogenesis using the cornea micropocket assay and the Matrigel model (Kisucka et al. 2006). These findings suggest that adhesive interactions between platelets and angiogenic vessels, but not dense-granule contents, stabilize developing blood vessels, thereby supporting neoangiogenesis. GPIbα is the receptor for von Willebrand factor as well as other adhesive and procoagulant proteins. Platelet–vessel wall interactions may involve platelet adhesion to the extracellular matrix and/or intact activated endothelium. However, both P-selectin-/- mice and VWF-/- mice exhibit normal angiogenesis without hemorrhages, suggesting that GPIbα ligands other than VWF and P-selectin are responsible for the stabilization of developing vessels. Rhee et al. reported that a highly specific antagonist of integrin $\alpha_{IIb}\beta_3$, which is a fibrinogen and VWF receptor on the surface of platelets, resulted in an approximate 35–50 % reduction in retinal neovascularization, and that platelet remnants and microvesicles were found at sites of angiogenic sprouts. Thus, platelet adhesive receptors, including GPIbα and αIIbβ3, contribute to the stabilization of developing vessels, thereby facilitating neoangiogenesis.

The Role of Platelets in Maintaining the Integrity of High Endothelial Venules in Lymph Nodes

Circulating lymphocytes continuously enter lymph nodes for immune surveillance through specialized blood vessels called high endothelial venules (HEVs). This process increases markedly during immune responses, but no bleeding from HEVs occurs during this process. Herzog et al. identified the mechanism, in which HEVs permit lymphocyte transmigration while maintaining vascular integrity (Herzog et al. 2013). Podoplanin expressed on fibroblastic reticular cells, which surround HEVs, stimulates platelets by binding to its receptor, CLEC-2. Sphingosine-1-phosphate released from activated platelets promotes VE-cadherin expression on HEVs, which is essential for overall vascular integrity. Mice deficient in CLEC-2, podoplanin, or sphingosine-1-phosphate exhibit spontaneous bleeding in mucosal lymph nodes and bleeding in the draining peripheral lymph nodes after immunization. Thus, platelet activation via CLEC-2 is necessary for maintenance of HEV integrity during immune responses (Fig. 3A).

The Role of Platelets in Maintaining the Integrity of Vessels During Inflammation

Platelets have been long known to maintain the integrity of the vasculature (Danielli 1940). Danielli et al. showed that edema in perfused frog hind legs was reduced when platelets were added to the perfusate medium, suggesting that platelets contribute to the maintenance of vascular integrity. Petechial hemorrhage is sometimes observed in severe thrombocytopenia even without traumatic injury. However, the role of platelets in the maintenance of vascular integrity is particularly important during inflammation, when

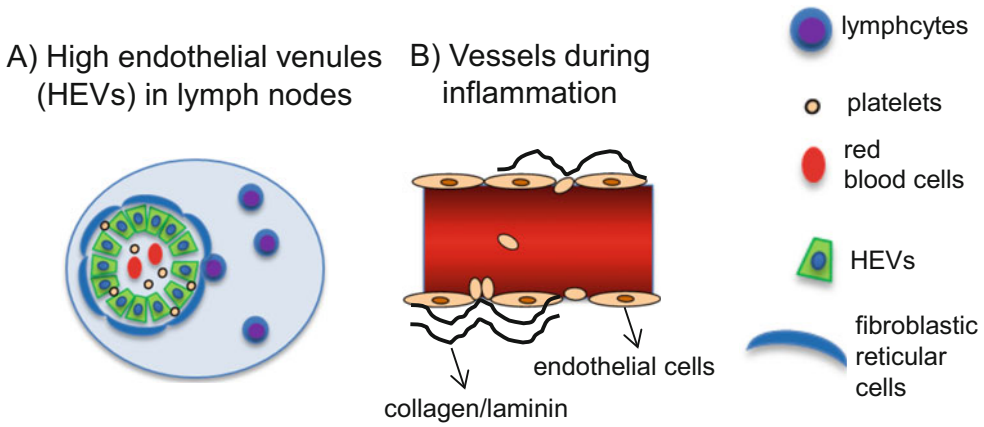

Fig. 3 Maintenance of vascular integrity by platelets. (**a**) Maintenance of the integrity of high endothelial venules in lymph nodes: podoplanin expressed on fibroblastic reticular cells, which surround HEVs, stimulates leaking platelets by binding to CLEC-2. Sphingosine-1-phosphate released from activated platelets promotes the expression of VE-cadherin on HEVs, which is essential for vascular integrity. (**b**) Maintenance of the integrity of inflammatory vessels: during inflammation, inflammatory cytokines enhance vascular permeability, and platelets leak from vessels during inflammation when vascular permeability is increased. GPVI signaling is activated at sites of inflammation by collagen and/or laminin, the two physiological ligands for GPVI found in the vessel wall. Platelet CLEC-2 may interact with podoplanin on the surface of infiltrating macrophages or an as yet unidentified ligand expressed in tissues around vessels

inflammatory cytokines enhance vascular permeability. Goerge et al. showed that acute severe thrombocytopenia in mice does not lead to hemorrhage unless the animals are challenged with an inflammatory insult (Goerge et al. 2008). They also showed that thrombocytopenia resulted in hemorrhage only at the site of inflammation and that GPIb-V-IX and integrin αIIbβ3, which are necessary receptors for platelet aggregation/agglutination, were not required for the maintenance of vascular integrity. These findings suggest that platelets do not maintain vascular integrity by forming a hemostatic plug, and exactly how platelets maintain vascular integrity during inflammation is unclear. Several studies proposed that granule contents released from activated platelets may prevent hemorrhage by strengthening endothelial barrier function or inhibiting inflammation (Boulaftali et al. 2014). A number of candidates for granule contents that regulate angiogenesis have been proposed, including ADP, serpins (protease nexin-1 and plasminogen activator inhibitor I), metalloproteinases, reactive oxygen scavengers, TREM-like transcript-1 shed from the surfaces of platelets, and sphingosine-1 phosphate (McGarrity et al. 1988a, b; Booth et al. 1988; Boulaftali et al. 2010; Villeneuve et al. 2009; Washington et al. 2009; Fong et al. 2011; Yatomi et al. 1997). However, how platelets are activated and release granule contents following vascular injury and the extent of the contribution of these factors to the maintenance of vascular integrity during inflammation are not known.

An elegant study by Boulaftali et al. proved that ITAM signaling, but not G protein-coupled receptor GPCR signaling, is critical for the prevention of inflammation-induced hemorrhage (Boulaftali et al. 2013). In their study, thrombocytopenia was induced by injection of antibodies that recognize the human interleukin-4 (IL-4) receptor into transgenic mice whose platelets express a chimeric protein consisting of the extracellular domain of the human IL-4 receptor and intracellular domain of murine GPIbα. These thrombocytopenic mice were transfused with wild-type platelets, platelets deficient in surface receptors, or antiplatelet drug-treated platelets, which are not destroyed by the circulating antihuman IL-4 receptor antibodies. Inflammation-induced hemorrhage in thrombocytopenic mice was rescued by transfusion of wild-type platelets, thrombin receptor-deficient platelets, or aspirin/clopidogrel-treated platelets, but not by transfusion of platelets deficient in CLEC-2, GPVI, or SLP-76 (a signaling molecule downstream of CLEC-2 and GPVI). These results indicate that the control of vascular integrity is a major function of immune-type receptors on platelets. On the other hand, signaling from GPCR, including thrombin receptors, thromboxane A2 receptors, and ADP receptors, is not necessary for controlling vascular integrity, whereas it is quite important for hemostasis. It has been reported that bleeding time is significantly prolonged in humans or mice with platelets deficient in signaling from GPCR (Mielke 1982; Bird et al. 2011; Fabre et al. 1999; Hamilton et al. 2004). On the other hand, GPVI/FcRγ-chain-deficient mice or CLEC-2-deficient mice do not show significant prolongation of bleeding time (Suzuki-Inoue et al. 2010; Bender et al. 2013; Hughes et al. 2010), suggesting that signaling from ITAM receptors is not required for hemostasis but is required for maintenance of vascular integrity.

As for the mechanism, it is assumed that platelets leak from vessels during inflammation when vascular permeability is increased and that GPVI signaling is likely activated at sites of inflammation by collagen and/or laminin, the two physiological ligands for GPVI found in the vessel wall

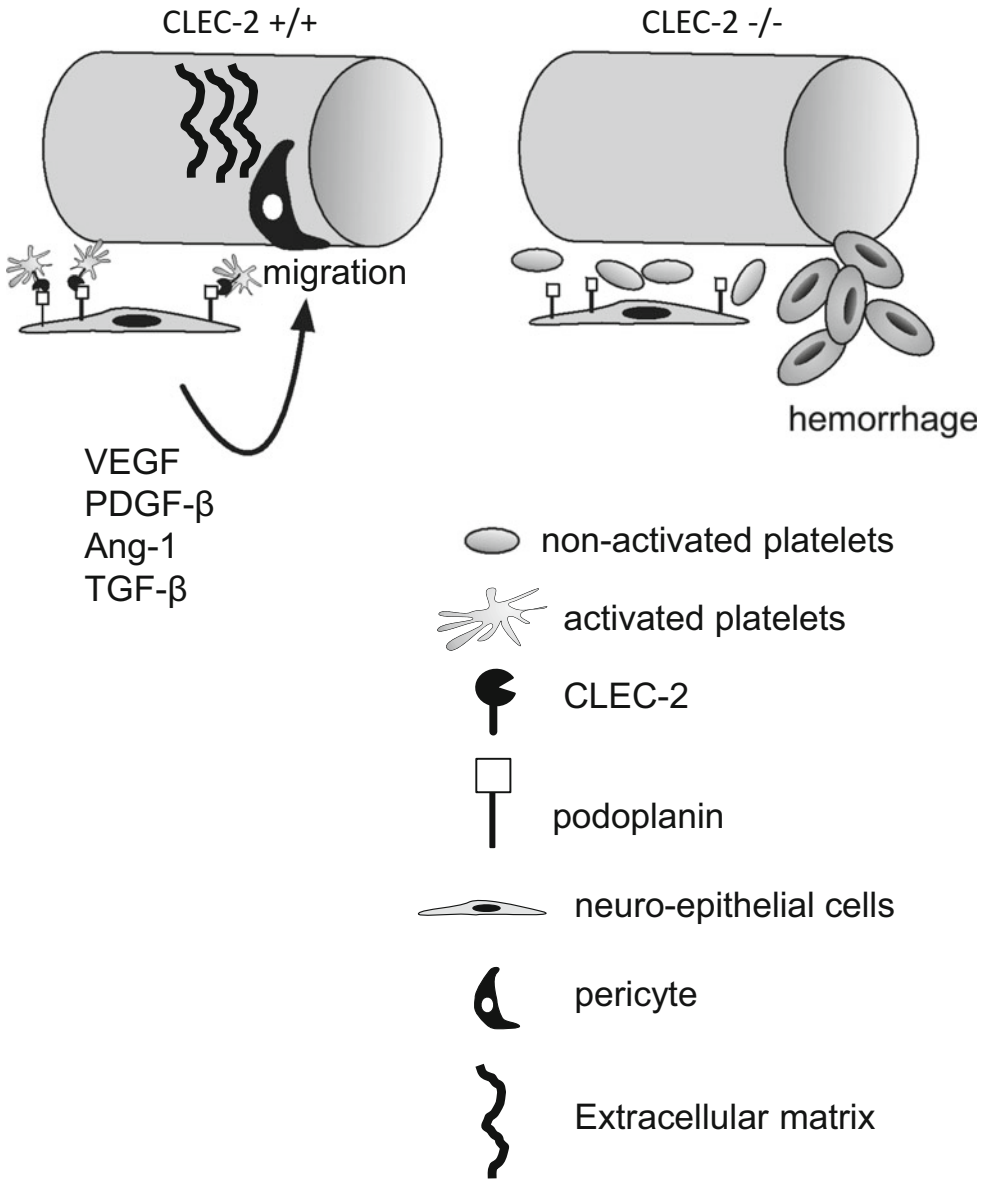

Fig. 4 Cerebrovascular patterning and maintenance of integrity by platelets during development. In CLEC-2+/+ mice, podoplanin on the neuroepithelial cells surrounding cerebral vessels interacts with CLEC-2 on the surface of leaking platelets, mediating platelet adhesion, aggregation, and secretion. Platelet granule contents recruit pericytes, and the recruited pericytes produce extracellular matrix to guide the maturation and integrity of the developing vasculature and prevent hemorrhage. In CLEC-2-/- mice, platelets are not activated by neuroepithelial cells, resulting in the absence of pericytes and extracellular matrix. As a result, cerebral vessels are tortuous and aberrantly patterned at E10.5 in CLEC-2-deficient mice, preceding the formation of large brain hemorrhages

(Ozaki et al. 2009; Inoue et al. 2006). How platelets are activated through CLEC-2 at the site of inflammation is difficult to explain, but Boulaftali et al. speculate that podoplanin on the surface of infiltrating macrophages, or an as yet unidentified ligand expressed in tissues around vessels or in the vessel wall, stimulates platelets via CLEC-2. Alternatively, podoplanin expression may be induced in the tissue around the vessels by inflammatory cytokines (Fig. 4). However, it is unclear whether this is due to the formation of an integrin αIIbβ3-independent hemostatic plug or modulation of endothelial function. Further studies are required to clarify the mechanism.

The Role of Platelets in Cerebrovascular Patterning and Integrity During Development

CLEC-2 in platelets plays a crucial role not only in neoangiogenesis and maintenance of vascular development in adults, but also in cerebrovascular patterning during development. Mice with a constitutive or platelet-specific deletion of CLEC-2 exhibit hemorrhaging in the brain at mid-gestation. Lowe et al. reported that cerebral vessels were tortuous and aberrantly patterned at E10.5 in podoplanin- and CLEC-2-deficient mice, preceding the formation of large brain

hemorrhages. They proposed that podoplanin on the neuroepithelium, which surrounds cerebral vessels, interacts with CLEC-2 on leaking platelets, mediating platelet adhesion, aggregation, and secretion. Platelet granule contents recruit pericytes, and the recruited pericytes produce extracellular matrix to guide the maturation and integrity of the developing vasculature and prevent hemorrhage (Fig. 4) (Lowe et al. 2015). Thrombocytopenia is the most common risk factor for intraventricular hemorrhage (IVH) in premature infants (Ballabh 2010). It was recently reported that platelet infusions in high-risk preterm infants enhance hemostasis and reduce the risk of IVH (Coen 2013). The observations by Lowe et al. may provide a potential explanation for IVH in premature infants and therapeutic insights (Lowe et al. 2015).

Take Home Messages

- Platelets facilitate blood/lymphatic vessel separation during development through the association between CLEC-2 on platelets and podoplanin on lymphatic endothelial cells.
- Angiogenesis activators and inhibitors contained in platelet alpha granules are released upon platelet activation and delivered to the site of neoangiogenesis.
- Platelets maintain the integrity of high endothelial venules (HEVs) in lymph nodes through the association between CLEC-2 on platelets leaking from HEVs and podoplanin on fibroblastic reticular cells.
- Platelets maintain the vessel integrity during inflammation, for which the ITAM-containing receptors, GPVI and CLEC-2 are
- Platelets facilitate proper cerebrovascular patterning during development through the association between CLEC-2 on platelets and podoplanin on the neuroepithelium.

Platelets and Coagulation

Johan W.M. Heemskerk, Judith M.E.M. Cosemans, and Paola E.J. van der Meijden

Abstract

Platelet activation and blood coagulation are reciprocal processes, both contributing to hemostasis and thrombosis in an interactive way. Exposed collagen, von Willebrand factor (VWF), and other components of the subendothelial matrix initiate platelet adhesion, whereas exposed tissue factor simultaneously triggers the coagulation cascade. During the various phases of the coagulation process, activated platelets support and steer coagulation by at least four mechanisms, namely, by (1) exposing the procoagulant phospholipid phosphatidylserine (PS) at their outer surface; (2) releasing coagulation factors like factors V and XIII, as well as anticoagulant factors like tissue factor pathway inhibitor; (3) providing a scaffold for the formation of fibrin fibers; and (4) stimulating retraction of the fibrin clot. In this chapter, we describe these roles of platelets in detail, also focusing on the receptors and signaling pathways involved and on the distinct (anti)coagulant pathways.

Platelets in the Stages of Coagulation

Traditionally, hemostasis and, by implication, also arterial thrombosis are considered as a two-stage processes of platelet plug formation (primary hemostasis) or platelet thrombus formation followed by fibrin clot generation (secondary hemostasis). However, in the last decades, it has become clear that platelet activation and blood coagulation are highly reciprocal processes, each contributing to hemostasis and thrombosis in an interactive way. The initiation of platelet adhesion is considered to start by exposed vascular collagen, von Willebrand factor (VWF), and other components of the subendothelial matrix, while exposed tissue factor (TF) simultaneously triggers the coagulation cascade.

This insight of continued interactions between platelets and coagulation activation has led to new concepts of cell-controlled coagulation with separate roles for TF-bearing cells and platelets (Mackman 2008; Jackson 2011; Versteeg et al. 2013). Herein, the coagulation process takes place in various phases (Mackman 2008): (1) an initiation phase of TF expression and generation of small amounts of activated factor (F)VII, FIX, and FX; (2) an amplification phase in which platelets and VWF (bearing FVIII) take care of increased procoagulant activity, resulting in the activation of FX (via activated FVIII and FIX) and the activation of prothrombin (via activated FV and FX); (3) feeding back of the formed thrombin, e.g., to activate FXI; (4) a propagation phase where massive quantities of thrombin and fibrin are formed; (5) and the extension phase where continued thrombin activity ensures platelet activation, clot remodeling and fibrinolysis, and wound healing.

During the various phases of the coagulation process, activated platelets can support and steer the coagulation process by at least four mechanisms (Heemskerk et al. 2013; De Witt et al. 2014a), namely, by (1) exposing the procoagulant phospholipid phosphatidylserine (PS) at their outer surface; (2) releasing coagulation factors like FV and FXIII, as well as anticoagulant factors like tissue factor pathway inhibitor (TPFI); (3) providing a scaffold for the formation of fibrin fibers; and (4) stimulating retraction of

the fibrin clot. Below we describe these coagulant roles of platelets in more detail.

Mechanisms of Platelet PS Exposure

Negatively charged phospholipid membranes, in particular with surface-exposed phosphatidylserine, appear upon platelet activation (via elevated cytosolic Ca^{2+}), during apoptosis (Ca^{2+} independently via caspases), or upon cell injury/necrosis (causing lysis) (Jackson and Schoenwaelder 2010). As reviewed in detail elsewhere (Heemskerk et al. 2013), combinations of strong platelet agonists, such as collagen/thrombin or Ca^{2+} ionophores, cause a prolonged elevation in cytosolic Ca^{2+} level, which is a direct prerequisite for PS exposure. Predominant pathways responsible for this are signaling via the glycoprotein VI-Fc receptor γ-chain (GPVI-FcRγ) complex, phospholipase Cγ, and phosphatidylinositol 3-kinase (PI3K) isoforms (Heemskerk et al. 2013; Munnix et al. 2009). For the sustained Ca^{2+} response, mobilization of Ca^{2+} from various sources is required, i.e. Ca^{2+} release from the endoplasmic reticulum, entry of extracellular Ca^{2+} via the Orai1 channel and the STIM1 sensor, and Ca^{2+} liberation from the mitochondria. The Ca^{2+}-dependent scrambling of membrane phospholipids, required for PS exposure, is mediated by the Ca^{2+}-dependent ion channel protein anoctamin-6 (see below). Platelets from a patient with Scott syndrome, lacking this protein, are greatly impaired in agonist-induced PS exposure, but have only a minor defect in apoptosis-induced PS exposure (Van Kruchten et al. 2013).

The PS-exposing platelet membranes of activated platelets form high-affinity binding sites for vitamin K-dependent coagulation and anticoagulation factors, i.e., prothrombin, FVII, FIX, FX, protein C, S, and Z (Zwaal and Schroit 1997; Monroe et al. 2002). Gamma-carboxyglutamate (Gla) domains, which are present in all vitamin K-dependent proteins, mediate their binding to PS membranes in a Ca^{2+}-dependent manner. As a consequence, the PS-exposing platelets—as well as PS-exposing platelet-derived microparticles—serve as assembly sites for components of the tenase complex (FVIIIa and FIXa, activating FX) and the prothrombinase complex (FVa and FXa, activating prothrombin). Studies with isolated coagulation factors have shown that PS-containing membranes enhance the activities of both the tenase and prothrombinase complexes by up to 1000-fold in comparison to absence of phospholipids (Bevers et al. 1991; Heemskerk et al. 2002). Clearly, in hemostasis also PS-exposing membranes from other (damaged) cell types can supply such a procoagulant surface and thus support thrombin generation. Recent work supports this for a damaged/activated endothelium (Ivanciu et al. 2014).

Mechanisms of Platelet Retraction and Clot Contraction

Classically, clot retraction is regarded as a platelet response induced by $\alpha_{IIb}\beta_3$ outside-in signaling, thus implying dependency of (thrombin-induced) $\alpha_{IIb}\beta_3$ activation and binding of fibrin(ogen) to platelets (Shattil et al. 2010). The outside-in signaling process leads to actin and myosin cytoskeleton rearrangements, which are needed for the generation of contraction forces that directly transmit to the fibrin clot, causing it to condense (Martin et al. 2010; Schoenwaelder et al. 2010). Mechanistic studies also point to roles of Rho and Src family kinases in the contraction of platelets present in an aggregate or thrombus, which precede the actin-dependent process and can even occur in the absence of thrombin or a fibrin clot (Ono et al. 2008; Auger and Watson 2008). As reviewed elsewhere, multiple studies with genetically modified mice indicate that defective integrin activation almost invariably is accompanied by an impairment of clot retraction (De Witt et al. 2014a).

The cytoskeletal rearrangements required for platelet contraction and clot retraction appear to be hampered in PS-exposing platelets, most likely due to calpain-mediated degradation of the actin cytoskeleton (Mattheij et al. 2013). This can explain why PS-exposing platelets do not contribute to clot retraction.

Mechanisms of Platelet-Dependent Thrombin and Fibrin Generation

As detailed below, PS exposure is both required and sufficient for massive generation of active FXa and thrombin at the platelet surface, e.g., as exemplified in thrombin generation experiments (Vanschoonbeek et al. 2004). Such PS-exposing platelets also produce fibrin fibers at their surface (Cosemans et al. 2011) where, strikingly, the fibrin acts as a main sink of (proteolytically active) thrombin, likely contributing to the further growth of these fibers (Berny et al. 2010). This can provide a mechanism for the earlier recognized positive feedback loops of thrombin, fibrin, and platelet activation (Béguin and Kumar 1997). In line with this observation, patients with complete fibrinogen deficiency can develop thrombosis, which can originate in both the arterial or venous territories (Girolami et al. 2012). A reasonable explanation for this thrombotic tendency is that the formed thrombin in these patients is more active, since it cannot be sequestered by binding to fibrin (De Bosch et al. 2002).

Especially in vivo studies have pointed to a different way of regulation of platelet-dependent coagulation at high, arterial and low, venous flow conditions. At high wall shear rates, where platelet deposition is enforced by interaction

of glycoprotein(GP)Ib-V-IX with VWF, the formation of a platelet-rich (white) thrombus predominates, whereas in regions of low shear flow, more fibrin fibers are formed (Jackson 2011). Also the roles of platelet receptors for collagen (GPVI) and ADP ($P2Y_{12}$) increase at higher shear rates (Nergiz-Unal et al. 2010). The limited evidence so far indicates that the role of thrombin receptors (PARs) in platelet activation decreases at high shear conditions (Lee et al. 2012). Recent in vitro findings indicate that the diminished formation of thrombin and fibrin at higher shear rate can be explained by thrombin dilution during the blood flow, which implies that also at high shear rates thrombin generation is a limiting factor in thrombus formation (Okorie et al. 2008; Berny et al. 2010). Since signaling via both GPVI and PARs can lead to PS exposure, it is understandable that this platelet response is relatively independent of the shear flow conditions (Munnix et al. 2005).

Neither thrombin nor fibrin appears to be uniformly distributed in an arterial thrombus. In vivo studies in the arterial circulation point to a thrombus core with densely packed platelets, in which thrombin is retained, that is surrounded by layers of platelets with reduced activation (Welsh et al. 2012; Stalker et al. 2014). The PS-exposing platelets appear as separate patches in such thrombi (Munnix et al. 2007). Interestingly, it appears that fibrin initially accumulates at the thrombus base and, at later time points, depending on the "coagulant force", gradually builds up within and outside the thrombus (Furie and Furie 2005; Swieringa et al. 2016). In mouse laser injury models, where typically vascular TF becomes exposed, also the injured vascular membranes contribute to the prothrombinase activity (Ivanciu et al. 2014).

Roles of ITAM and hem-ITAM Receptors

Platelet receptors signaling via protein tyrosine kinases are intricately involved in coagulation stimulation. In particular, this holds for receptors acting through the so-called ITAM motif (two adjacent YxxL sequences) or hem-ITAM motif (one YxxL sequence), both of which rely on tyrosine phosphorylation in order to transmit signals. Such receptors are the immunoglobulin receptor GPVI, the FcRIIA receptor, and the C-type lectin receptor CLEC-2.

For long, *GPVI* has been known as the central signaling receptor for collagen (Nieswandt and Watson 2003). However, evidence is accumulating that it can also recognize laminin (Schaff et al. 2013) and fibrin fibers (Mammadova-Bach et al. 2015; Alshehri et al. 2015), thus placing GPVI at a central position in the interactions between platelet and coagulation activities. Deficiency in GPVI leads to an impairment not only of collagen-induced platelet adhesion and aggregation but also of PS exposure (Heemskerk et al. 1997b). On the other hand, GPVI deficiency is accompanied by only a mild bleeding phenotype (Moroi et al. 1989), which may point to functional redundancy of GPVI with other platelet receptors (Shida et al. 2014).

GPVI in association with the FcR γ-chain signals via a signalosome containing several protein tyrosine kinases (Src family and Syk kinases). This results in phospholipase Cγ activation, followed by a prolonged elevation in cytosolic Ca^{2+} (Watson et al. 2005). Analysis of mice lacking GPVI or other proteins of the GPVI signalosome indicates that the assembly of multiple tyrosine kinase-linked proteins is essential for high shear thrombus formation and Ca^{2+}-dependent PS exposure on a collagen surface (Munnix et al. 2005; Nieswandt et al. 2001; De Witt et al. 2014a). Since GPVI is only a low-affinity receptor for collagen, platelet-collagen adhesion needs to be enhanced by co-receptors like integrin $\alpha_2\beta_1$ and GPIb-V-IX (Siljander et al. 2004).

Negative feedback between coagulation and platelet activation takes place via shedding of GPVI on activated platelets by the extracellular proteases ADAM-10 and ADAM-17, which abrogates GPVI-induced responses (Bender et al. 2010). Interestingly, at least part of this proteolytic cleavage is regulated in a not well-understood way by FXa, but not by thrombin (Al-Tamimi et al. 2011).

Clustering of the platelet hem-ITAM receptor, *CLEC-2*, similarly occurs via the Syk tyrosine kinase route (Watson et al. 2010). Platelet stimulation via CLEC-2 relies in part on ADP- and thromboxane A_2-dependent signaling pathways (Pollitt et al. 2010). Known ligands for CLEC-2 are podoplanin, which however is not present in the vasculature, and the snake venom protein rhodocytin. In spite of unclear knowledge of the ligand in vivo, mouse studies have shown that CLEC-2 is an essential platelet-activating receptor in hemostasis and thrombosis (May et al. 2009). In agreement with this notion, platelet interaction with immobilized CLEC-2 ligands leads to full thrombus formation and substantial PS exposure, in a way resembling platelet activation via GPVI (De Witt et al. 2014b).

The immunoglobulin receptor *FcγRIIA*, activated by clustering with IgG immunoglobulins, also evokes Syk-dependent signaling pathways in human platelets, again enforced by autocrine stimulation (Lhermusier et al. 2011). This can lead to thrombocytopenia; to which extent platelet procoagulant activity is increased is still unclear.

Roles of Other Platelet Adhesive Receptors

Interaction of the *GPIb-V-IX* receptor with VWF is one of the first steps in shear-dependent platelet adhesion and, as such, a requirement for the procoagulant role of platelets under high shear conditions. GPIb-V-IX with ~25,000 copies present on platelets induces by itself only weak intracellular signals,

activating Src-related protein kinases, phosphoinositide 3-kinases (PI3K), and small GTPases. These events cause only small Ca^{2+} fluxes, limited integrin $\alpha_{IIb}\beta_3$ activation, and platelet spreading (Canobbio et al. 2004). However, under coagulant conditions, there is evidence that the GPIb-V-IX complex, by interaction with VWF, enhances platelet PS exposure and thereby the formation of thrombin (Béguin et al. 1999; Weiss 2009). Furthermore, GPIb-V-IX appears to have a broader role than only serving as VWF receptor. It binds thrombin with high affinity, which supports activation of the thrombin receptors PAR1 and PAR4 (De Candia et al. 2001). In addition, GPIbα has been proposed to interact with several coagulation factors, such as FVII, FXI, FXII, and high molecular weight kininogen, although the functional consequences of these interactions are unclear (Heemskerk et al. 2013). One can conclude that it is this combination of properties that makes GPIb-V-IX such a crucial receptor in thrombus formation (Bergmeier et al. 2008).

Integrin $\alpha_{IIb}\beta_3$ (*GPIIb/IIIa*) is the most abundant platelet membrane glycoprotein with ~80,000 copies per platelet, and additional copies present in the open canicular system and α-granules. Integrin outside-in signaling, via Src and Syk tyrosine kinases, regulates the spreading of platelets over a fibrinogen surface and mediates the retraction of a platelet-fibrin clot (De Witt et al. 2014a). As a persistent process, signaling via activated integrin $\alpha_{IIb}\beta_3$ (outside-in signaling) is implicated in the coagulation process in various ways. Outside-in signaling, via prolongation of intracellular Ca^{2+} rises, contributes to agonist-induced PS exposure (Van der Meijden et al. 2012). This pathway is however restricted by a negative feedback mechanism, because PS-exposing platelets with high Ca^{2+} levels gradually close their integrins which abrogates the outside-in signaling (Cosemans et al. 2008). The underlying mechanism of this signaling inactivation is calpain-mediated cleavage of multiple integrin-associated proteins including Src and talin (Mattheij et al. 2013).

As an adhesive collagen receptor, *integrin $\alpha_2\beta_1$* sustains and enforces human platelet adhesion to collagen/VWF under high shear conditions via GPIb-V-IX and GPVI (Siljander et al. 2004; Ruggeri 2002). Since platelets in contact with immobilized $\alpha_2\beta_1$-binding peptides are hardly activated, the integrin may primarily support platelet activation via the other collagen receptor, GPVI (Munnix et al. 2008). In a similar way, the laminin receptor integrin $\alpha_6\beta_1$ may also support platelet activation and PS exposure under flow conditions (De Witt et al. 2014b).

The glycoprotein *CD36* (*GPVI*, *GPIIIb*) is abundantly expressed on platelets (10,000–25,000 copies). On platelets it may have different roles, but especially acts as a receptor for thrombospondin-1 and oxidized low-density lipoproteins (Nergiz-Unal et al. 2011; Podrez et al. 2007). CD36 has a limited contribution to platelet procoagulant activity, especially under low shear conditions of thrombus formation (De Witt et al. 2014b). The underlying signaling pathway likely is by enforcing protein tyrosine kinase activation and subsequent Ca^{2+} rises (Nergiz-Unal et al. 2011).

Roles of Receptors for Soluble Agonists (Thrombin, ADP)

As a Gla-domain coagulation factor, prothrombin binds to the membrane of PS-exposing platelets (Versteeg et al. 2013). However, once cleaved by the prothrombinase complex (FXa, FVa), the formed α-thrombin interacts with PAR receptors with high affinity and massively translocates to fibrin fibers (Berny et al. 2010). The conventional concept is that fibrin-bound thrombin is protected from inactivation by antithrombin and the heparin-antithrombin complex (Weitz et al. 1990), but as a result this sequestering will locally confine the thrombin to the direct environment of the clot. Thrombin is a key protease in the coagulation cascade and is hence required for fibrin formation. It is a moderately strong platelet agonist, which enforces PS exposure in combination with other agonists such as GPVI ligands (Mattheij et al. 2016).

The Gq-protein-coupled receptors for thrombin on platelets, i.e., the protease-activated receptors *PAR1* and *PAR4* in human platelets and *PAR3* and *PAR4* in mouse platelets, accomplish full integrin activation and secretion (Offermanns 2006). Thrombin-induced activation of human platelets is dependent on PAR1, since this receptor displays a higher affinity to thrombin than PAR4. The latter is considered to enhance the action of PAR1, e.g., at higher thrombin concentrations (Coughlin 2005; Andersen et al. 1999). Signaling via the Gq protein and phospholipase Cβ, thrombin elicits oscillatory rises in cytosolic Ca^{2+} (Heemskerk et al. 1997a), thus explaining why thrombin possesses limited PS exposure and procoagulant activity on its own. However, thrombin by itself via the PAR receptors greatly enforces the PS exposure induced by collagen receptors (Heemskerk et al. 2002). The likely mechanism for this is potentiation of the GPVI-induced Ca^{2+} signal (Keuren et al. 2005). Strikingly, the limited PS exposure induced by even high thrombin concentrations is less dependent on Ca^{2+} entry via STIM1 and Orai1 (Gilio et al. 2010), but rather relies on receptor-operated Ca^{2+} entry via TRPC channels (Harper et al. 2013). Next to PAR1, also PAR4 has a potentiating role in thrombin-induced procoagulant activity (Dorsam et al. 2004). In mouse platelets, both PAR3 and PAR4 appear to be required for the thrombin effect on PS exposure (Coughlin 2000).

There is limited evidence that the PARs, especially PAR1, can be cleaved by other proteases than thrombin, such as ADAM-17 and matrix metalloproteinase-1 (Andrews et al. 2007; Trivedi et al. 2009), activated

protein C, and neutrophil-derived cathepsin G and the fibrinolysis protease plasmin cleaving PAR4 (Quinton et al. 2004; Sambrano et al. 2000). The relevance of these alternative pathways of thrombin receptor cleavage for platelet procoagulant activity remains to be determined.

The platelet dense granules contain high concentrations of the adenosine nucleotides *ADP* and *ATP*. Once secreted, ADP enhances platelet activation via interaction with the purinergic receptors *P2Y$_1$* and *P2Y$_{12}$*. Similarly to the PARs, the $P2Y_1$ receptor couples to Gq leading to oscillatory Ca^{2+} mobilization through phospholipase Cβ stimulation (Heemskerk et al. 2001). The $P2Y_{12}$ receptor signals via a Gi-coupled pathway that lowers cyclic AMP and stimulates the PI3K route (Versteeg et al. 2013). In addition to a role in (sustaining) platelet aggregation, ADP appeared to potentiate tissue factor-triggered thrombin generation, which effect was assigned to stimulation of the $P2Y_{12}$ and not the $P2Y_1$ receptors (Dorsam et al. 2004; Van der Meijden et al. 2005). Signaling via $P2Y_{12}$ receptors prolongs the platelet Ca^{2+} rises as a consequence of (1) enhanced Ca^{2+} mobilization by the 1,4,5-triphosphate receptors due to inhibition of protein kinase A and (2) prolonged activation of PI3K (Van der Meijden et al. 2008). There is also evidence that $P2Y_{12}$ regulates the $P2Y_1$-induced Ca^{2+} responses via inhibition of adenylate cyclase and activation of PI3K (Hardy et al. 2004). In line with these signaling schemes, inhibition of the $P2Y_{12}$ receptors in patients taking clopidogrel significantly suppressed PS exposure of the platelets in coagulating plasma (Van der Meijden et al. 2005). Similarly, the active metabolite of prasugrel (another $P2Y_{12}$ receptor antagonist) also impairs collagen-induced and $P2Y_{12}$-dependent Ca^{2+} rises, PS exposure, and thrombin generation in coagulant whole blood (Frelinger et al. 2008; Judge et al. 2008).

Thromboxane A$_2$ is a well-known autocrine mediator for platelet activation and aggregation. It interacts with the *TP* receptors which, like the PARs, are coupled to Gq but to a lower extent (Offermanns 2006). Stimulation of TP receptors leads to limited Ca^{2+} mobilization and is therefore hardly effective in mediating platelet PS exposure (Swieringa et al. 2014). In agreement with this, it appeared that blockage of thromboxane A_2 formation by aspirin treatment only slightly affects thrombin generation in platelet-rich plasma (Vanschoonbeek et al. 2004). In platelets adhering to collagen, aspirin decreased PS exposure if used in combination with ADP receptor blockers (Lecut et al. 2004).

Roles of Contact-Dependent Signaling Receptors

Platelets also communicate via homotypic receptors, which have collectively been termed as contact-dependent signaling receptors. From studies with genetically modified mice, it has been deduced that such homotypic interactions contribute in a balanced (positive and negative) way to platelet clot retraction (De Witt et al. 2014a). Thus, the *connexins* 37 and 40, implicated in gap junction formation, have a stimulatory effect on platelet-dependent clot retraction (Vaiyapuri et al. 2012, 2013). Connexins also contribute to other activation processes, such as platelet aggregation, integrin activation, Ca^{2+} signaling, and α-granule secretion (Vaiyapuri et al. 2012).

Similarly, the *tetraspanin members* 32 (TSSC6) and CD151 enhance clot retraction (Goschnick et al. 2006; Lau et al. 2004). Interestingly, in CD151 knockout mice, blockage of the $P2Y_{12}$ receptors was found to lead to an extra defect in clot retraction, suggesting that CD151 and $P2Y_{12}$ have a complementary role in modulating integrin $\alpha_{IIb}\beta_3$ outside-in signaling (Makkawi et al. 2015). More research will be needed to elucidate the action mechanisms of tetraspanins in platelet-based coagulation.

Junctional adhesion molecule (*JAM*)*-A* acts as negative regulator of integrin $\alpha_{IIb}\beta_3$ outside-in activation and clot retraction (Naik et al. 2012). The proposed mechanism is suppression by JAM-A of integrin outside-in signaling through downstream protein kinases such as Src, Syk and focal adhesion kinase (Obergfell et al. 2002), and via phosphatases like PTPN1 (Karshovska et al. 2015).

In some instances, contact signaling receptors seem to act differently on integrin outside-in signaling and on clot retraction. In platelets lacking *endothelial cell-specific adhesion molecule* (*ESAM*), the spreading on immobilized fibrinogen (reflecting outside-in signaling) was found to be unaffected, while fibrin clot retraction was delayed (Stalker et al. 2009). Another intriguing membrane protein in terms of platelet function is *PECAM-1*. Platelets from mice lacking PECAM-1 have been reported as no more than slightly impaired in agonist-induced responses, with unchanged clot retraction (Dhanjal et al. 2007). This contrasts to a detected inhibitory role of human PECAM-1 in platelet integrin activation (Jones et al. 2014). The reason for this discrepancy is unclear.

Roles of Inhibitory Platelet Receptors

Endothelium-derived prostaglandin I_2 (prostacyclin) binds to platelets via the Gs-coupled *IP* receptors. Activation of IP receptors leads to raised intracellular cyclic AMP levels, strongly antagonizing most platelet activation processes, including PS exposure (Swieringa et al. 2014; Heemskerk et al. 1997b). Prostaglandin E_1, also raising cyclic AMP, has equal anticoagulant effects (Kuijpers et al. 2005). Similarly, the platelet inhibitory pathway induced by nitric oxide and guanylate cyclase suppresses agonist-induced PS exposure (Rukoyatkina et al. 2011). In general, the tight control of

collagen-/thrombin-induced PS exposure by multiple cyclic AMP-/GMP-inhibiting and Ca^{2+}-stimulating signaling pathways underlines the physiological importance of this platelet response (Heemskerk et al. 2013), rather than suggesting it is a nonspecific injury- or necrosis-related event (Jackson and Schoenwaelder 2010).

Prostaglandin E_2 which is produced by endothelial cells, macrophages, and platelets exerts opposing effects in comparison to prostaglandin E_1. At low concentrations, prostaglandin E_2 binds to the platelet *EP3* receptors and via Gi-dependent signaling enhances platelet responses induced by other platelet agonists (Petrucci et al. 2011; Friedman et al. 2015). At higher concentrations, it binds to *EP4* receptors, transmitting cyclic AMP-dependent and AMP-independent effects (Friedman et al. 2015).

Syndromes with Altered Platelet-Dependent Coagulation

Impaired hemostasis in patients with several well-known platelet function defects (Nurden and Nurden 2014), such as Glanzmann's thrombasthenia, is frequently accompanied by dysfunctional platelet procoagulant activity. In addition, two platelet disorders have been described that directly concern abnormalities in platelet-dependent coagulation. The Scott syndrome, a rare bleeding disorder, is characterized by mutations in the gene *ANO6* (or TMEM16F, OMIM:608663), encoding for the transmembrane ion channel protein anoctamin-6 (Suzuki et al. 2010). Platelets from Scott patients as well as from mice lacking anoctamin-6 are greatly impaired in collagen-/thrombin-induced PS exposure, swelling to rounded structures (balloons), and inactivation of integrin $\alpha_{IIb}\beta_3$ (Agbani et al. 2015; Mattheij et al. 2016b). Interestingly, the anoctamin-6 protein is also known as a Ca^{2+}-dependent ion channel conducting Cl^- and cations; it now appears that this channel also carries the negatively charged phospholipid PS (Kmit et al. 2013). Given that fact that collagen-induced PS exposure (in contrast to Ca^{2+} ionophore-induced PS exposure) is not entirely canceled in Scott platelets or mouse platelets with a complete deficiency in anoctamin-6 (Mattheij et al. 2016b), it is likely that another phospholipid scramblase activity exists.

On the contrary, an increased Ca^{2+}-dependent PS exposure has been observed in platelets from other patients with a bleeding tendency. This so-called Stormorken syndrome (or York syndrome, OMIM:185070) has been associated with a dominant mutation in the STIM1 gene, resulting in uncontrolled Ca^{2+} entry via the Orai1/STIM1 pathway (Misceo et al. 2014). In line with the increased PS exposure, the platelets from such patients are reduced in integrin $\alpha_{IIb}\beta_3$-dependent signaling events, including clot contraction.

Extrinsic Coagulation Pathway (TF, FVII)

The key trigger of the extrinsic coagulation pathway, tissue factor (TF), is a membrane protein highly expressed on cells that are not in normal contact with the bloodstream but, at a very limited amount, on blood cells. The procoagulant role of TF is highly dependent on the presence of neighboring procoagulant phospholipid membranes (Versteeg et al. 2013).

Evidence for the presence of residual TF on platelets came from the finding that TF-containing membrane vesicles can associate with activated platelets (Giesen et al. 1999). Later findings indicated that platelet activation increases the expression of (platelet-derived) TF in a form, capable to trigger thrombin generation (Müller et al. 2003). Increased TF levels on platelets coincided with the expression of P-selectin. Especially under pathological conditions, mRNA levels of TF seem to increase (Müller et al. 2003), and this mRNA is translated to active protein upon platelet stimulation (Schwertz et al. 2006; Panes et al. 2007). Since also human megakaryocytes contain TF mRNA, it is considered unlikely that the platelet mRNA is derived from other cells via a transfer mechanism (Müller et al. 2003; Schwertz et al. 2006). Recent work using in vitro cultured megakaryoblasts shows that functionally active TF is present in a subset of the shed proplatelets (Brambilla et al. 2015). The relative role of the platelet-derived TF in triggering coagulation is still unclear, especially because platelets contain and release high amounts of tissue factor pathway inhibitor (TFPI) (Maroney et al. 2011), which will effectively block any nearby surface-expressed TF.

Platelet granules contain protein disulfide isomerases, which have been implicated in the conversion (decryption) of TF into its active conformation (Versteeg et al. 2013). Secreted protein disulfide isomerases have different roles on platelets, which may or may not be linked to the decryption of TF: activation of integrin $\alpha_{IIb}\beta_3$ (Lahav et al. 2003) and platelet adhesion and fibrin formation under flow conditions (Cho et al. 2008; Jasuja et al. 2012). In agreement with this, it was observed that impaired protein disulfide isomerase secretion in Hermansky-Pudlak syndrome suppresses thrombus formation and contributes to a bleeding phenotype (Sharda et al. 2015).

The primary role of TF in coagulation is to bind FVII (a) for achieving full activation into FVIIa (Versteeg et al. 2013). Interestingly, also other binding sites of FVII(a) have been reported for platelets. These include PS-exposing membranes, which bind via its Gla-domain, and GPIbα which can capture recombinant FVIIa in platelets stimulated with collagen/thrombin and then support TF-independent thrombin generation (Weeterings et al. 2008). Furthermore, an active variant of FVIIa has been described, which displays enhanced platelet binding characteristics via the

Gla-domain and as yet undisclosed proteins (Hoffman et al. 2011). Due to its binding to platelets, recombinant FVIIa may be a suitable prohemostatic drug in patients with Glanzmann's thrombasthenia or in patients using anti-$\alpha_{IIb}\beta_3$ medication (Lisman et al. 2003).

Intrinsic Coagulation Pathway (FXI, FXII, Polyphosphates)

The intrinsic coagulation factors, *FXII* and *FXI*, play a consolidating role in platelet-dependent thrombus formation and particularly in thrombus stabilization. This has been established for in vivo mouse experiments after damage of healthy vessels (Kleinschnitz et al. 2006; Cheng et al. 2010; Revenko et al. 2011) or damage of atherosclerotic vessels (Kuijpers et al. 2014; Van Montfoort et al. 2014). Such in vivo studies collectively indicate that FXII promotes thrombus formation largely or exclusively via activation of FXI. An emerging concept is that FXII locally triggers the formation of thrombin and fibrin to stabilize specific regions in a platelet thrombus distant from the vascular-exposed TF (Kuijpers et al. 2014). Recent studies support this idea, as anti-FXII(a) antibodies were found to suppress fibrin formation in an ex vivo blood perfusion system (Larsson et al. 2014).

Although there is no strong evidence for the presence of specific binding FXII sites on platelets, a platelet-dependent role in the activation of FXII has been suspected for long. A recent postulation is that platelet-derived *polyphosphates* catalyze the FXII (auto)activation (Müller et al. 2009). However, some authors argue that, for FXII activation, polyphosphates are required with a longer-chain length than that present in platelets (i.e., 60–100 phosphates/molecule) (Smith et al. 2010; Choi et al. 2011). The shorter-chain polyphosphates seem rather to function in accelerating FV and FXI activation by thrombin and in consolidating the fibrin clot. During thrombus formation, also collagen fibers (Van der Meijden et al. 2009) and neutrophil extracellular traps (Von Brühl et al. 2012) are reported triggers of FXII activation and thus for the intrinsic coagulation pathway.

The binding of FXI to platelets has been a matter of confusion. An earlier report suggests that FXI binds via GPIbα (Baglia et al. 2004), but functional studies did finally not lead to publications. Other studies with human and mouse platelets proposed the platelet apolipoprotein E receptor 2 (ApoER2, LRP8) as a binding receptor for FXI (White-Adams et al. 2009). Detailed microscopic analysis confirmed that FXIIa does not bind to PS-exposing platelets in a thrombus, but to collagen and patches of fibrin (Kuijpers et al. 2014). This fits with the idea that fibrin acts as a scaffold for several coagulation factors (Berny et al. 2010).

Common Coagulation Pathway to Thrombin Generation

In spite of a long search, specific protein-type receptors on platelets for the vitamin K-dependent factors *FIX* and *FX* have not been identified (Heemskerk et al. 2002; Monroe et al. 2002). For instance, platelets, unlike other cell types, do not express the PAR2 receptor for FXa (Daubie et al. 2006). Investigations by fluorescence microscopy have shown that the binding of FIXa and FXa (similarly to prothrombin) is confined to PS-exposing platelets in a thrombus (Berny et al. 2010; Swieringa et al. 2015). One study proposes protein disulfide isomerases contribute to the binding of coagulation factors to thrombin-stimulated platelets and thereby stimulate the platelet-dependent thrombin generation (Jurk et al. 2011).

In platelets, *FV* is stored in the α-granules, where it comprises about 20 % of the total blood pool of FV. Megakaryocytes take up plasma FV through endocytosis (Bouchard et al. 2005). Given the high FV storage in platelets, it is likely that the secreted protein significantly contributes to the prothrombinase activity at the platelet surface (Weiss et al. 2001). It is reported by one group that platelet-derived FVa is more resistant to protease *in*activation than the FVa in plasma (Gould et al. 2004), but this finding needs confirmation. Activated FV binds to PS-exposing membranes via the C2 domain, where it assembles with FXa to form local prothrombinase complexes (Majumder et al. 2008; Berny et al. 2010). Using flow cytometry, a subpopulation of thrombin-activated platelets can be identified that is positive for both FVa and FXa binding. However, also another subpopulation was detected with intermediate FVa binding and no FXa binding, thus pointing to a second type of interaction (Fager et al. 2010). This agrees with the observation that FVa can bind in a transglutaminase-dependent way to the membrane of coated platelets (Alberio et al. 2000) and may point to a gradual accumulation of FVa at the surface of activated platelets.

Factor VIII is one of the lowest expressed coagulation factors in blood plasma, which is kept in the blood by binding to circulating VWF. Although FVIII does not possess a Gla-domain, it can bind to PS-exposing platelets via the C2 domain, likely in a similar manner as FV (Heemskerk et al. 2013). Once activated, FVIIIa interacts with *FIXa* on the surface of PS-exposing platelets to form the tenase complex catalyzing FXa generation. Microscopic observation and binding studies indicate that both FIXa and FXa are localized on PS-exposing platelets, while FVIIIa is detected there at a very limited amount (London et al. 2006; Swieringa et al. 2015). The majority of FVIII in a thrombus, instead, was found to co-localize with VWF that is present at

collagen and fibrin fibers. Current understanding is that once the light chain of VWF-bound FVIII is cleaved, the FVIIIa dissociates from VWF and then interacts with FIXa present on PS-exposing platelets (Swieringa et al. 2015).

Even at high TF concentrations, both FVIII and FIX are limiting factors for thrombin and fibrin formation at a thrombus independently of the flow conditions and, remarkably, also for platelet PS exposure (Swieringa et al. 2015). This points to a potent positive feedback loop of FVIIIa-/FIXa-mediated generation of FXa and thrombin, leading to enhanced thrombin-dependent PS exposure. By binding to VFW, FVIII can indirectly interact with GPIb-V-IX on platelets. However, in kinetic studies of fibrin formation, a role for VWF-bound FVIII could not be detected in platelet-dependent fibrin formation (Cosemans et al. 2011). On the other hand, it was shown that functionally active VWF readily incorporates into the fibrin network in a thrombin-dependent way (Miszta et al. 2014).

Both in vivo and in vitro studies have convincingly shown that locally generated thrombin and fibrin have a strong potentiating effect on arterial thrombus formation, thus pointing to positive feedback loops of, e.g., collagen-initiated platelet aggregation and thrombin-/fibrin-dependent consolidation and growth of the platelet aggregates (Munnix et al. 2005; Furie and Furie 2005; Dubois et al. 2007; Kuijpers et al. 2008; Stalker et al. 2014). This also explains why pharmacological inhibition of thrombin or FXa can suppress the thrombus-forming process in human and mouse blood (Kalia et al. 2008; Swieringa et al. 2015; Fukuda et al. 2011).

Coated Platelets, FXIII, and Fibrin Formation

The transglutaminase FXIII, once activated by thrombin, can cross-link multiple proteins by forming glutamyl-lysine bridges such as present in fibrin polymers and other fibrillar proteins. Active FXIII is a prerequisite for platelet clot retraction (Kasahara et al. 2010). Experiments with immobilized FXIIIa have shown that it binds to platelets via the integrins $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ (Magwenzi et al. 2011). Platelets themselves contain and secrete high levels of the catalytic subunit of FXIII (Burkhart et al. 2012), likely serving to ensure a locally high transglutaminase activity within the thrombus with activated platelets. The secretion mechanism of FXIII is not yet fully understood (Mitchell et al. 2014). In the formation of so-called coated platelets (previously COAT platelets), the transglutaminase FXIII has been implicated in the chemical cross-linking of secretory proteins derived from α-granules at the platelet surface (Dale et al. 2002). Coated platelets are invariably considered as platelets that are formed after combined stimulation of the collagen and thrombin receptors, but are often confused with PS-exposing platelets (Mattheij et al. 2016a). The original description of coated platelets refers to the formation of a covalent coat of transglutaminase-dependent serotonin conjugations of multiple secreted proteins (thrombospondin, fibrinogen, fibronectin, VWF, FV, and TFPI) at the platelet surface (Szasz and Dale 2002; Maroney et al. 2007). Tissue-type transglutaminase expressed by platelets may contribute, along with FXIII, in this cross-linking of granular proteins (Jobe et al. 2005).

Considering that coated platelets also expose PS (Alberio et al. 2000), the question arises whether the two platelet populations are identical. Dual labeling studies of thrombi with annexin A5 to probe exposed PS and a serotonin label to probe the cross-linking indicated partial but not complete overlap of the two platelet populations (Munnix et al. 2007). However, stimulation of washed platelets with a Ca^{2+} ionophore in the absence of thrombin results in PS-exposing platelets without a coat of activated FV (Alberio et al. 2000) and without high fibrin(ogen) (Jobe et al. 2005). Recently, it could be elucidated that the transglutaminase-dependent coat formation occurs secondarily to PS exposure (Mattheij et al. 2016a). The emerging concept now is that thrombin-induced FXIII activation is needed to cross-link multiple proteins to the platelet surface, among which fibrin fibers. Coated platelets therefore appear to be in control of the platelet-dependent formation of fibrin fibers, requiring both transglutaminase and integrin $\alpha_{IIb}\beta_3$ interactions (Mattheij et al. 2016a). Functionally active FXIII on the surface of PS-exposing platelets can also have an antifibrinolytic effect by incorporating α_2-antiplasmin to the fibrin coat (Mitchell et al. 2014).

The platelet- and plasma-derived FXIII pools are both essential for clot stabilization, in particular by cross-linking the single fibrin strands, which consist of high molecular weight α-fibrin polymers, which upon formation of γ-γ dimers provide strength to the fibrin network (Reed et al. 1992).

Anticoagulation Factors

The coagulation process is confined in time and place by activity of several *anti*coagulation factors, which act at different levels of the coagulation cascade. Best studied is the protein C/protein S anticoagulant system and furthermore tissue factor pathway inhibitor (TFPI) and antithrombin, which all attack and inhibit the active site of specific coagulation factors. Limited knowledge is present of other serine protease inhibitors (serpins), such as protease nexin-1.

Protein C and protein S Since the 1980s, it is known that activated protein C (APC) inactivates FVIIIa and FVa, thus suppressing the activity of the tenase and prothrombinase complexes, respectively. Protein C needs to be activated by thrombin, a process that normally occurs on endothelial cells in the vessel wall expressing thrombomodulin and the EPCR protein C receptor (Versteeg et al. 2013). The activated protein C (APC) associates with its cofactor, protein S, and then binds via Gla-domains to PS-exposing membranes to form a complex that cleaves and thereby inactivates nearby FVa and FVIIIa. Mechanistic evidence mostly comes from plasma experiments with purified phospholipid membranes. How potent the suppression of the APC/protein S complex is in platelet-dependent thrombin generation under physiological conditions still needs to be sorted out. On the other hand, it is known that a mutation in FV, designated as FV^{Leiden}, removing the APC cleavage site, results in a significantly increased risk of venous thromboembolism (Bertina et al. 1994). However, in agreement with in vivo mouse experiments of arterial thrombus formation (Kuijpers et al. 2008), this mutation does not appear to be predictive for arterial thrombosis. This may suggest that the protein C/protein S system is most effective at low shear flow conditions or stasis as present in the venous system.

TFPI is a Kunitz-type protease inhibitor that limits coagulation initiation. It is present in plasma, abundantly stored in platelets, and expressed on vascular cells (Versteeg et al. 2013). Most active is the isoform TFPIα, which contains all three Kunitz domains. Circulating at a low concentration, its level is markedly increased by secretion from platelets. The second isoform, TFPIβ, is anchored on endothelial cells and needs to be cleaved for appearance in the circulation (Girard et al. 2012). TFPI suppresses coagulation through the inhibition of TF/FVIIa as well as FXa, in the latter case in a protein S-dependent way (Hackeng et al. 2006). Since protein S can bind to PS-exposing platelets, it is likely that the protein S-TFPI complex shuts down the thrombin-generating activity of FXa on procoagulant platelets. In agreement with this notion, it has recently been demonstrated that TFPIα can inhibit prothrombinase activity (Wood et al. 2013).

Antithrombin and other serpins Antithrombin (previously antithrombin III), which belongs to the class of serpins with limited expression in platelets (Burkhart et al. 2014), is a main inhibitor of thrombin activity and generation in plasma. Its importance can be derived from the fact that it turns off three proteases, namely, FIXa, FXa, and thrombin (Versteeg et al. 2013). The activity of antithrombin is greatly enhanced by heparins (note that short-chain heparins only enhance the inactivation of FXa by antithrombin) (Li et al. 2004). There is no strong evidence yet that antithrombin massively binds to the thrombus site.

Other serpins identified in platelets are antitrypsin, with an unclear function in coagulation, and protease nexin-1 (Burkhart et al. 2014). The latter inhibits fibrinolysis by suppressing the cleavage of plasminogen and of fibrin degradation (Boulaftali et al. 2011).

Fibrinolysis Control

Platelets regulate fibrinolysis by releasing fibrinolytic and antifibrinolytic factors, including plasminogen, plasminogen activator inhibitor-1 (PAI-1), thrombin activatable fibrinolysis inhibitor (TAFI), and α_2-antiplasmin. These factors are contained in the platelet α-granules and are liberated upon activation, for instance, with thrombin (Mosnier et al. 2003; Coppinger et al. 2004). After the early evidence that fibrin formation at the platelet surface enhances the binding of plasminogen (Miles and Plow 1985), multiple receptors for plasminogen have been proposed (Miles et al. 2012). Plasminogen bound to platelets promotes fibrinolysis, is more susceptible for cleavage into plasmin (Dejouvencel et al. 2010), and is protected from the inactivation by α_2-antiplasmin (Hall et al. 1991). Recent work demonstrates two populations of platelets with bound plasminogen, i.e., platelets that bind plasminogen directly and PS-exposing platelets that bind plasminogen indirectly via platelet-bound fibrin. The latter platelet population displays enhanced capacity to generate plasmin. Strikingly, on PS-exposing platelets, plasminogen co-localizes with PAI-1, indicating that local plasminogen cleavage must exceed the inhibitory effect of PAI-1 in order to effectuate fibrinolytic activity (Whyte et al. 2015).

Novel Concept of Platelet-Controlled Coagulation

Summarizing the findings of particularly recent work, earlier models of cell-controlled coagulation (Monroe and Hoffman 2006; Versteeg et al. 2013) can now be transformed to a concept that is even more interactive than those previously considered. Initial triggering of the extrinsic coagulation system occurs by de-encrypted vascular TF (with PS-exposing membranes nearby), generating first amounts

of FVIIa, FXa, and thrombin (Fig. 1a). The thrombin activates multiple coagulation factors, among which FV and FVIII. Initiation of the intrinsic coagulation system can start by FXII binding and activation at collagen fibers or other negatively charged surfaces, with ensuing FXI activation. In a shear-dependent way, platelet will adhere to VWF/collagen (also laminin and other subendothelial matrix proteins) via GPVI and co-receptors. This same set of triggers appears to be active after injury of a healthy vessel or upon rupturing of an atherosclerotic plaque (Mastenbroek et al. 2015). Platelets experiencing a high cytosolic Ca^{2+} will expose PS, swell (balloon), and expand their procoagulant surface, whereas the majority of platelets with active integrins—forming the inner shell of a thrombus—remain aggregated and contract. Platelet secretion of multiple coagulation factors (e.g., fibrinogen, prothrombin, FV, FXIII,

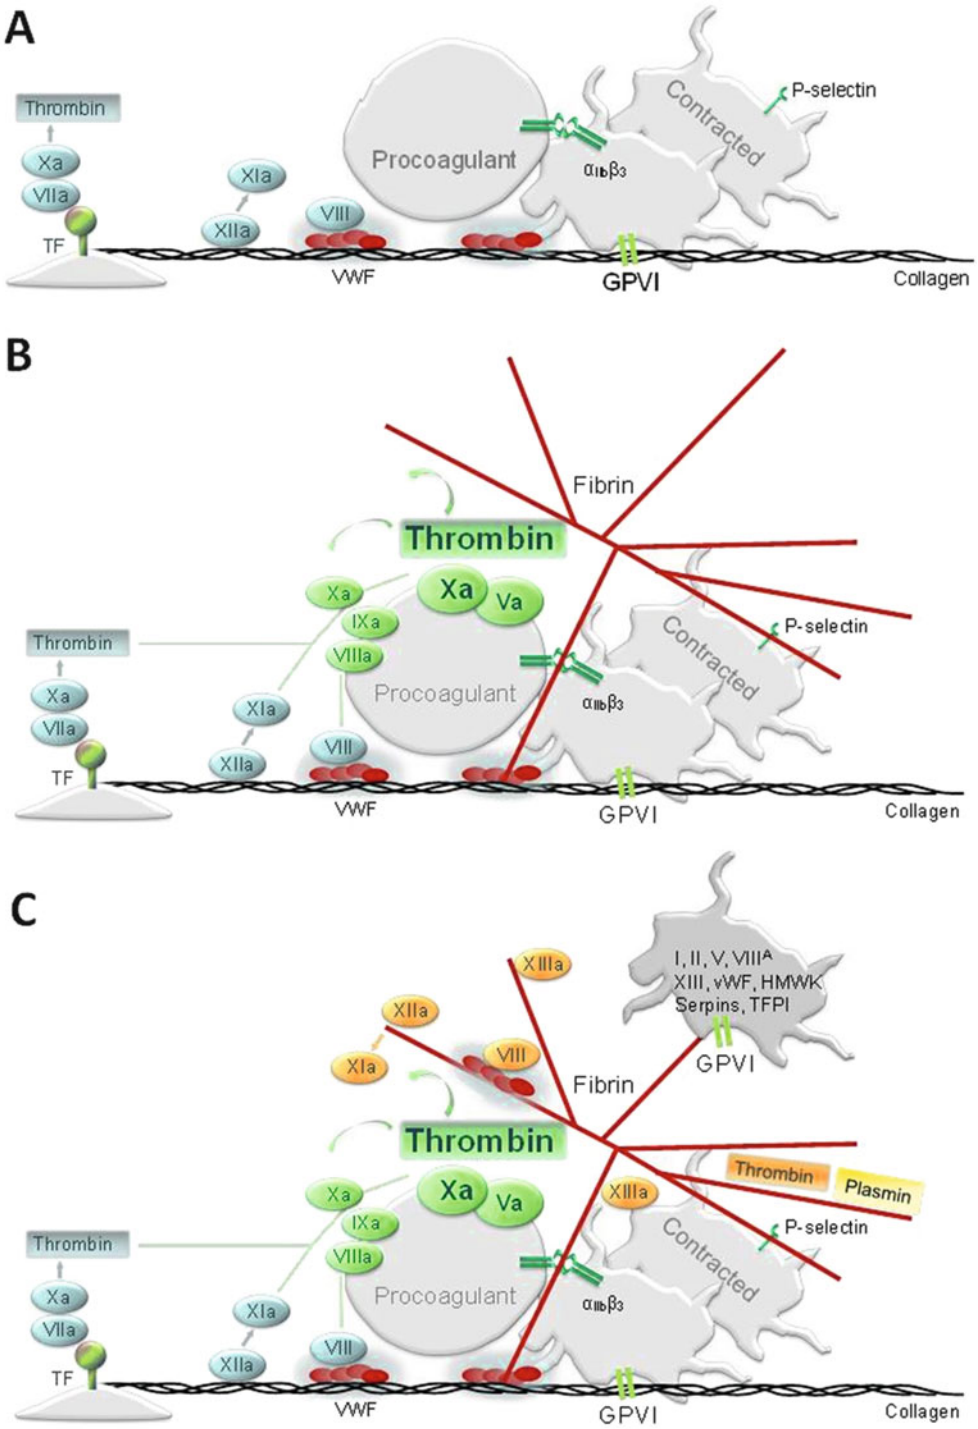

Fig. 1 Concept of staged interactions of platelet activation and coagulation in thrombus formation. (**a**) Initial activation of the extrinsic (TF) and intrinsic (FXII) coagulation pathways leading to traces of thrombin and FIXa, together with shear-dependent adhesion and activation of platelets via collagen/VWF and other adhesive proteins. (**b**) Increased generation of FXa and thrombin via procoagulant, PS-exposing membranes, leading to the formation of fibrin within a thrombus and depending on the flow conditions extending outside of the thrombus. (**c**) Fibrin fibers act as a scaffold for further platelet activation (via GPVI), coagulation factor binding (thrombin, VWF/FVIII, FXII, FXIII) further enhancing the thrombus-forming and clotting process

VWF, high molecular weight kininogen) (Burkhart et al. 2012) ensures that sufficient clotting capacity is present to start a next level of increased generation of thrombin and fibrin.

In the later stages (Fig. 1b), larger amounts of FXa and thrombin are generated via the tenase and prothrombinase complexes, respectively. FVIII bound to VWF is cleaved and will reach the sites of FX activation. Fibrin fibers are formed, heterogeneously, within and outside the platelet thrombus, but this is not an end stage, as this can act as the beginning of a new cycle of platelet activation (via GPVI), coagulation factor binding (thrombin, VWF/FVIII, FXII, FXIII), which further enhances the thrombus-forming and clotting process. Anticoagulants (protein C/S, antithrombin, TFPI), inhibiting especially FXa and thrombin, stop and confine the clotting process.

Take Home Messages

- Platelets direct and steer the coagulation process in various ways.
- Platelets interfere with the intrinsic, extrinsic, and common coagulation pathways as well as with anticoagulation processes.
- Interactions between platelets and coagulation pathways continue until later stages of fibrin thrombus formation.

Platelets and Fibrinolysis

Mario Colucci, Nicola Semeraro, and Fabrizio Semeraro

Abstract

Platelets contain and/or bind an array of fibrinolytic components and related proteins, whereby they can both down- and upregulate the fibrinolytic process. The generally accepted role of platelets is to confer resistance to fibrinolysis in order to prevent untimely removal of the hemostatic plug. This task is accomplished mainly, but not exclusively, through clot retraction, release of huge amounts of plasminogen activator inhibitor 1, and enhancement of thrombin generation, which in turn activates a number of antifibrinolytic pathways. Recent findings, however, suggest that the profibrinolytic properties of platelets also participate in the modulation of fibrinolysis, probably at later stages when the process enters the lytic phase. Moreover, in a reciprocal fashion, the activation of fibrinolysis could have profound and paradoxical effects on platelet function. This chapter outlines current knowledge on the complex cross-talk between platelets and fibrinolysis and its implications for physiological and pathological hemostasis.

Introduction

Platelets have been known for more than 50 years to take part in the modulation of fibrinolysis. Since publication of the first papers on the subject, it has been clear that the effects of platelets on fibrinolysis are complex and that platelets are able to both down- and upregulate fibrinolysis (Johnson and Schneider 1953; Stefanini and Murphy 1956; Greig and Cornelius 1961; Reid and Silver 1964). Since then, our knowledge of the biology of the fibrinolytic system, its regulatory mechanisms, and its multiple interactions with platelets and other intravascular and extravascular cells has dramatically improved. Available evidence now indicates that platelets contain and/or bind an array of fibrinolytic components and related proteins, whereby they exert both antifibrinolytic and profibrinolytic effects. In a reciprocal fashion, activation of fibrinolysis can have profound effects on platelet function (Coller 1990; Pasche and Loscalzo 1991). How these manifold phenomena influence the fibrinolytic process during physiological hemostasis and thrombosis is still debated and a matter of active investigation. From literature data, it appears that platelets are major players in conferring fibrinolytic resistance to blood clots or thrombi, particularly platelet-rich arterial thrombi. However, there is increasing awareness that thrombi formed in vivo contain different platelet populations, which could play different roles at different times (Heemskerk et al. 2013; Ivanciu and Stalker 2015), suggesting that the profibrinolytic properties of platelets also participate in the modulation of fibrinolysis.

This chapter outlines current knowledge on the anti- and profibrinolytic properties of platelets, how they affect fibrin removal during hemostasis and thrombosis, and how fibrinolytic enzymes modify platelet function. Before considering these aspects, we briefly review the intravascular fibrinolytic system and its main regulatory mechanisms.

The Fibrinolytic System and Its Regulation

Within the vascular system, fibrinolysis fulfils two major functions: (1) it removes the provisional matrix created by the hemostatic process following vascular injury and (2) prevents or limits fibrin deposition at sites of aberrant clotting activation, thereby preserving vascular integrity.

The central reaction of the fibrinolytic process is activation of plasminogen to form plasmin, a trypsin-like protease that degrades the fibrin network into soluble fragments (fibrin degradation products; FDP) (reviewed by Collen 1999). Plasminogen activation is catalyzed by two distinct enzymes, tissue plasminogen activator (t-PA) and urokinase-type PA (u-PA). The fibrinolytic enzymes are controlled by specific inhibitors, namely plasminogen activator inhibitor-1 (PAI-1), which inactivates the plasminogen activators, and α_2-antiplasmin (α_2-AP), a fast-acting plasmin inhibitor. PAI-2 is another inhibitor of plasminogen activators, but it is undetectable in plasma, except during pregnancy and in some pathological conditions (Medcalf and Stasinopoulos 2005).

The t-PA-mediated pathway is primarily involved in intravascular fibrinolysis, whereas the u-PA pathway mainly participates in phenomena such as cell migration and tissue remodeling (Murphy et al. 1992). The activation of plasminogen is a localized phenomenon and takes place on fibrin and cell surfaces through binding to specific receptors for plasminogen activators and plasminogen (Miles and Parmer 2013). The contact system of coagulation has also been implicated in fibrinolysis through direct activation of plasminogen by factor XIIa, which is structurally related to t-PA and u-PA (Goldsmith et al. 1978; Tans and Rosing 1987), and through the kallikrein-mediated conversion of the inactive single-chain u-PA (scu-PA) to the active two-chain form (Ichinose et al. 1986).

Regulation of the fibrinolytic process is complex and involves several mechanisms, which include activation of zymogens, specific inhibition of active enzymes, regulation of circulating levels of fibrinolytic factors, and interaction with fibrin and cell surfaces. The process is modulated by numerous factors in addition to the main components of the fibrinolytic system, some of which are relevant to the present chapter and are discussed in later sections. Here, we describe the main regulatory mechanisms, namely the balance between t-PA and PAI-1, interaction with fibrin, and coagulation–fibrinolysis cross-talk.

The serine protease t-PA is primarily involved in the dissolution of fibrin in the circulation, and thus its availability in free form is of utmost importance for efficient fibrinolysis. Circulating t-PA is released by the endothelium as an enzymatically active single-chain molecule, in contrast to the single-chain precursor form of most serine proteases (Rijken and Lijnen 2009). Cleavage by plasmin converts single-chain t-PA into a two-chain form, whose functional properties do not differ substantially from its precursor. The plasma concentration of t-PA is in the picomolar range, with significant circadian variations (Angleton et al. 1989). PAI-1 derives from different sources, including liver, endothelial cells, macrophages, and adipocytes (reviewed by Dellas and Loskutoff 2005). It is contained in platelets in considerable amounts, as discussed below. The origin of circulating PAI-1 remains to be fully defined and could vary depending on the health status (e.g., body weight) and type of disease (Tjärnlund-Wolf et al. 2012). PAI-1 is a very fast inhibitor of t-PA, the second-order rate constant of the reaction being in the order of 10^7 M^{-1} s^{-1}. The normal plasma concentration of PAI-1 is in the picomolar range, but is generally higher than that of t-PA, meaning that most circulating t-PA is in complex with PAI-1. The half-life of both t-PA and PAI-1 is about 5 min, which implies a continuous release of these proteins into the circulation to maintain their plasma concentrations. In striking contrast with these two factors, plasminogen and α_2-AP (both of liver origin) are present in plasma in much higher concentrations (micromolar range) and have plasma half-lives of the order of days. Thus, t-PA and PAI-1 represent the dynamic part of the system and any modification in the synthesis and release of t-PA and/or PAI-1 results in a sudden change in fibrinolytic capacity. The rate of synthesis and/or release of t-PA by endothelial cells is increased by a number of substances, including thrombin, histamine, tumor necrosis factor α (TNF-α), and norepinephrine, and by stress conditions such as venous occlusion and exercise (reviewed by Oliver et al. 2005). The regulation of PAI-1 is achieved primarily by alterations in the rate of gene expression. Inducers of PAI-1 synthesis include TNF-α, interleukin 1 (IL-1), transforming growth factor β (TGF-β), thrombin, insulin, angiotensin II, and corticosteroids (Dellas and Loskutoff 2005).

Fibrin has a central and very important role in the regulation of fibrinolysis. First of all, fibrin is a cofactor for t-PA-mediated plasminogen activation. In solution, in the absence of fibrin or fibrin-derived products, t-PA is a poor activator of plasminogen and no appreciable plasmin is formed in the circulation, even when the levels of free t-PA increase manyfold following strenuous exercise or venous occlusion. When a clot is formed, both t-PA and plasminogen bind to fibrin, forming a ternary complex that dramatically reduces the Km for plasminogen activation so that plasmin is efficiently generated at its site of action. Binding of t-PA to fibrin is mediated by the finger domain and the second kringle domain, whereas binding of plasminogen is mediated by the lysine binding sites located in the kringle domains, which are also essential for the interaction of plasmin with α_2-AP (Rijken and Lijnen 2009). During fibrin degradation by plasmin, new binding sites are exposed, identified as C-terminal lysines, which enhance the

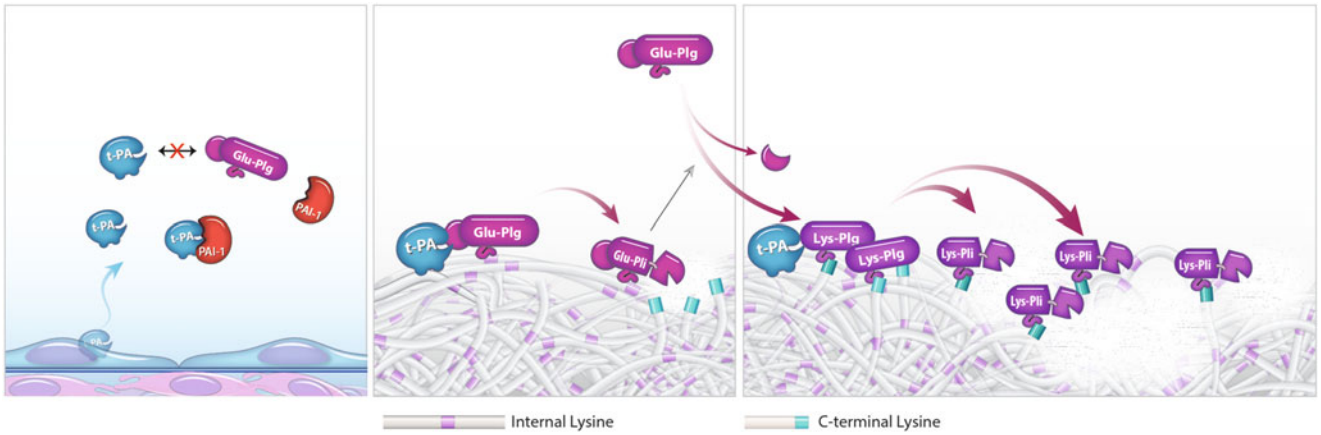

Fig. 1 Role of fibrin as cofactor in tissue-type plasminogen activator (t-PA)-mediated plasminogen activation. The t-PA released from endothelial cells is an inefficient activator of plasminogen (Plg) in solution and is quickly inhibited by plasminogen activator inhibitor 1 (PAI-1) (*left*). In the presence of a fibrin clot, both t-PA and plasminogen bind to fibrin forming a ternary complex in which the activity of t-PA towards plasminogen is highly augmented and the first molecules of plasmin (Pli) are generated (*middle*). After this initial slow phase, plasmin upregulates its own production in two ways (*right*): (1) by degrading fibrin, it exposes new binding sites (C-terminal lysines), which dramatically increase the accumulation of plasminogen on fibrin; and (2) it converts Glu-plasminogen to Lys-plasminogen, a more readily activatable form of plasminogen

accumulation of plasminogen on the clot surface up to 30-fold and increase the lysis rate. Moreover, native plasminogen, which has N-terminal glutamic acid (Glu-plasminogen), is converted by limited plasmic digestion to Lys-plasminogen. This has a more open conformation and is therefore a better substrate for plasminogen activators, further enhancing plasmin generation and fibrin degradation (Fig. 1). Another important consequence of the binding of fibrinolytic enzymes to fibrin is that they are protected from their respective inhibitors. Indeed, fibrin-bound t-PA is neutralized more slowly by PAI-1 (Kruithof et al. 1984; Chmielewska et al. 1988; Thelwell and Longstaff 2007) and the rate of plasmin inhibition by α_2-AP is 100- to 1000-fold lower if the enzyme is bound to fibrin (Rijken and Lijnen 2009). In addition, t-PA (either plasma-derived or released locally) could accumulate on fibrin and reach concentrations severalfold higher than the circulating levels (Tran-Thang et al. 1984).

Fibrin also modulates the function of fibrinolytic inhibitors. PAI-1 binds reversibly to fibrin and maintains its inhibitory activity (Wagner et al. 1989; Reilly and Hutzelmann 1992; Podor et al. 2000) and α_2-AP is crosslinked to fibrin by factor XIIIa (FXIIIa) (Sakata and Aoki 1980). Compelling evidence indicates that fibrin-bound inhibitors play a major role in restraining the lytic process through inhibition of target enzymes within the clot (Sakata and Aoki 1982; Reed et al. 1990; Podor et al. 2000). These multiple interactions emphasize the multifaceted role of fibrin, which can both down- and upregulate its own degradation. These opposite functions are important for fine-tuning the fibrinolytic process and are likely to take place at different moments in order to impede untimely removal of the hemostatic plug.

The extent and the dynamics of clotting activation have a great impact on the fibrinolytic process (reviewed by Nesheim 2003; Wolberg 2007). Thrombin generation, in particular, contributes to fibrinolytic resistance through different mechanisms, which are discussed in more detail in later sections. Suffice to say here that these mechanisms include (1) a direct effect of thrombin concentration on fibrin structure, which in turn determines clot stability and resistance to proteolytic degradation (Blombäck et al. 1994); (2) activation of FXIII, a transglutaminase that introduces covalent bonds into fibrin and crosslinks several proteins to fibrin, including α_2-AP, which is one of the most important fibrin-associated fibrinolysis inhibitors (Muszbek et al. 2011); and (3) activation of TAFI (thrombin-activatable fibrinolysis inhibitor), a carboxypeptidase that inhibits plasminogen activation on the fibrin surface (Wang et al. 1998). The close functional link between coagulation and fibrinolysis has important implications and suggests that fibrinolytic alterations could be much more frequent than previously thought. Numerous studies indicate that conditions of hypo- or hypercoagulation are accompanied by decreased or increased fibrinolytic resistance, respectively. A typical example is hemophilia (A or B), which is characterized by the formation of clots that are highly susceptible to fibrinolysis (Broze and Higuchi 1996; Mosnier et al. 2001). The phenomenon can be corrected by replenishing the missing factor or supplementing plasma with supraphysiological levels of antifibrinolytic factors (e.g., TAFI or FXIII) (Broze and Higuchi 1996; Mosnier et al. 2001; Rea et al. 2014). Similar fibrinolytic changes have been detected in patients under anticoagulant treatment (Incampo et al. 2013), even though not all anticoagulant drugs are equally effective as profibrinolytic agents at clinically relevant

concentrations (Semeraro et al. 2016). On the other hand, patients with heightened thrombin generation, such as carriers of thrombophilic mutations (Colucci et al. 2004; Ammollo et al. 2014) or prothrombotic factors (Colucci et al. 2003), display increased in vitro fibrinolytic resistance, which correlates fairly well with thrombin generation capacity. This concept can be extended to many conditions associated with increased risk of thrombosis, where the fibrinolysis impairment caused by aberrant thrombin formation could contribute to the thrombotic tendency.

The importance of fibrinolysis in physiological hemostasis is underscored by the clinical phenotype of subjects lacking factors involved in regulation of the fibrinolytic process. Patients with congenital deficiency in α_2-AP, PAI-1, or FXIII exhibit a tendency to moderate to severe bleeding characterized by delayed hemorrhage after trauma or surgical procedures (Carpenter and Mathew 2008; Mehta and Shapiro 2008; Biswas et al. 2014), which typically reflects the premature lysis of highly susceptible hemostatic plugs. Conversely, disturbance of fibrinolysis regulation leading to increased fibrinolytic resistance could result in predisposition to thrombosis. Indeed, clinical studies have documented increased levels of PAI-1 in association with arterial thrombosis (Hamsten et al. 1985) and microvascular occlusion in disseminated intravascular coagulation (Hack 2001). Moreover, elevated TAFI levels have been suggested to represent a risk factor for venous thromboembolism and ischemic stroke (Heylen et al. 2011). Augmented risk of venous and arterial thrombosis has also been found in subjects with overall hypofibrinolysis (Lisman et al. 2005; Guimaraes et al. 2009), as assessed by global in vitro assays that depict the complex interplay between fibrinolytic and coagulation pathways. The pivotal role of fibrinolysis is further highlighted by the widespread use of antifibrinolytic drugs such as the lysine analogs ε-aminocaproic acid (EACA) and tranexamic acid, and the serine protease inhibitor aprotinin (whose use is limited because of safety concerns) (De Hert et al. 2015) to reduce bleeding and transfusion needs in hemorrhagic surgical and medical conditions such as cardiac surgery, liver transplantation, hemophilia (Sindet-Pedersen and Stenbjerg 1986; Casati et al. 1999; Hvas et al. 2007; Molenaar et al. 2007), and, of particular relevance in the context of this chapter, thrombocytopenia (Kalmadi et al. 2006).

Platelet Antifibrinolytic Properties

The main features of fibrinolytic inhibitors and antifibrinolytic functions associated with platelets are summarized in Table 1.

Table 1 Main characteristics of platelet-associated fibrinolytic inhibitors

Platelet factor or function	Localization	Main function(s)	Concentration relative to the plasma pool (%)	Additional information
Clot retraction	Mediated by motility proteins and $\alpha_{IIb}\beta_3$	Decreases clot permeability, alters fibrin structure, reduces t-PA binding to fibrin, increases resistance to plasmin	–	Major mechanism of fibrinolytic resistance
PAI-1	α-Granules	Binds fibrin through vitronectin Fast inhibitor of t-PA	900	Largely inactive Major mechanism of fibrinolytic resistance
TAFI	α-Granules	TAFIa removes plasminogen binding sites from fibrin	0.1	Besides releasing TAFI, platelets enhance TAFI activation by promoting thrombin formation
FXIII	Cytoplasm	Fibrin crosslinking Crosslinking of α_2-AP and other factors to fibrin	50	Consists of A subunits only (FXIII-A_2) Protease-independent activation
PolyP	Dense granules	Clotting activation Alteration of fibrin structure	Undetectable in plasma	Enhances thrombin-mediated activation of TAFI
α_2-AP	α-Granules	Fast inhibitor of plasmin	0.05	Fibrin crosslinked α_2-AP plays a major role in fibrinolytic resistance
PN-1	α-Granules Platelet surface	Inhibits fibrin-bound t-PA and fibrin-bound plasmin	Undetectable in plasma	Complementary role with PAI-1 and α_2-AP
TFPI-2	Probably α-granules	Inhibits plasmin	Very low plasma levels	Inhibits the contact pathway
Zinc	Cytoplasm α-granules	Inhibits plasminogen activation and plasmin activity	Variable (≈50)	Most plasma zinc is bound to proteins
Platelet-derived phospholipids	Membranes	Diffusion barrier; reduces the binding of fibrinolytic enzymes to fibrin, increases resistance to plasmin	–	Loss of platelet phospholipids after strong activation or death

PAI-1 plasminogen activator inhibitor 1, *TAFI* thrombin activatable fibrinolysis inhibitor, *FXIII* factor XIII, *PolyP* polyphosphate, *α_2-AP* α_2-antiplasmin, *PN-1* protease nexin 1, *TFPI-2* tissue factor pathway inhibitor 2

Clot Retraction and Clot Structure

Platelets contract the blood clot through the action of cytoplasmic motility proteins, such that fluid is expelled. This process is called clot contraction or retraction and is believed to reinforce hemostasis by forming a seal, and restores blood flow by decreasing the area obstructed by intravascular clots (Carr 2003; Muthard and Diamond 2012). Clot retraction is dependent on fibrin(ogen) binding to active $\alpha_{IIb}\beta_3$ integrin (glycoprotein IIb/IIIa; GPIIb/IIIa) on the platelet surface and transmits the contractile forces generated in the platelet actin–myosin cytoskeleton to connecting fibrin fibers around platelets (Schoenwaelder et al. 2010), thereby transforming a diffuse fibrin network into a small and dense platelet–fibrin clot. The process results in clot stiffening, which is dependent both on direct reinforcement by platelets and on strain stiffening of fibrin fibers under tension as a result of platelet contraction (Lam et al. 2011).

Clot retraction is an important mechanism through which platelets reduce the lysability of clots. If platelet-rich clots are formed in the presence of inhibitors of platelet contraction (e.g., cytochalasin D) or antagonists of the $\alpha_{IIb}\beta_3$ receptor (monoclonal antibodies or the ligand-mimetic peptide D-RGDW), clot retraction is prevented and fibrinolysis is markedly hastened (Kunitada et al. 1992; Collet et al. 2002; Carrieri et al. 2011). In contrast to these findings, a few studies have reported accelerated fibrinolysis associated with clot retraction (Carroll et al. 1981, 1982; Hoki et al. 2009). The latter studies, however, were performed in rather unphysiological conditions, such as with extensive dilution of blood or platelet-rich plasma or use of the euglobulin fraction instead of plasma. The mechanisms behind fibrinolytic resistance induced by clot retraction are complex and not fully understood. Clot compression causes the extrusion of serum from the clot, thereby reducing the amount of plasminogen available within the fibrin mesh, a phenomenon that can be reproduced by mechanical compression of a plasma clot devoid of platelets (Sabovic et al. 1989). In addition, the low permeability of the retracted clot hinders the transport of proteins from the outside. Another important consequence of clot retraction is the reduction in t-PA binding to fibrin, which, as noted above, is an essential step for efficient fibrinolysis. Kunitada et al. (1992) reported that platelet-rich plasma clots bound some 60 % less t-PA than platelet-poor plasma clots. Importantly, the reduction in t-PA binding was observed over a wide range of t-PA concentrations, including pharmacological concetrations, and was paralleled by a reduction in clot lysis. By contrast, t-PA binding to the platelet-rich clot is not impaired if clot retraction is prevented by either cytochalasin D or anti-$\alpha_{IIb}\beta_3$ antibody (Kunitada et al. 1992). Microscopic examination revealed that platelet-rich clots are heterogeneous structures with branching fibers alternating with dense platelet-rich areas, which are made of highly compacted fibrin fibers retracted by the platelet contractile force (Collet et al. 2001). The reduction in t-PA binding and the resistance to lysis is seen around these platelet-rich areas (Collet et al. 2002), probably because of the limited access of t-PA to the compact fibrin network surrounding platelet aggregates. In addition, the stretching of fibrin fibers attached to contracted platelets might contribute to fibrinolytic resistance, as suggested by Varjú et al. (2011), who showed that mechanical stretching of fibrin impaired plasminogen activation and made the denser fibrin network less sensitive to plasmin. A schematic representation of the changes induced by clot retraction is illustrated in Fig. 2.

Concerning in vivo evidence, studies in animal models showed that integrin $\alpha_{IIb}\beta_3$ inhibitors accelerate thrombolysis and prevent reocclusion in experimentally produced coronary thromboses treated with recombinant t-PA (alteplase) (Jang et al. 1989; Yasuda et al. 1988, 1990; Kohmura et al. 1993). Moreover, a number of studies in patients with acute myocardial infarction or ischemic stroke showed that the combination of fibrinolytic agents with anti-$\alpha_{IIb}\beta_3$ accelerated recanalization and reduced reocclusion (Antman et al. 1999; Ouriel et al. 2004; Seitz et al. 2004; Straub et al. 2004; Adams et al. 2008). Furthermore, patients with Glanzmann thrombasthenia (GT), whose platelets lack $\alpha_{IIb}\beta_3$ integrin and do not support clot retraction, display great susceptibility to t-PA in an in vitro thromboelastographic model of clot lysis (Shenkman et al. 2012). However, whether and to what extent the reduced fibrinolytic resistance contributes to bleeding in GT is difficult to establish. For these patients, the clinical manifestations (typically, mucocutaneous hemorrhages with early onset after trauma), suggest that the impairment of platelet plug formation caused by the absence or dysfunction of $\alpha_{IIb}\beta_3$ is the main cause of bleeding. Nevertheless, the successful use of antifibrinolytic agents, either alone or in combination with platelet concentrates or recombinant factor VIIa, for the treatment of non-surgical and surgical bleeding in GT (reviewed by Poon et al. 2016) offers some hints about the possible importance of accelerated fibrinolysis in this disease.

In addition to clot retraction, platelets can influence clot architecture by virtue of their procoagulant function, as the concentration of thrombin at the time of fibrin assembly has a great impact on clot structure (Blombäck et al. 1994). Activated platelets play a major role in the propagation phase of coagulation by providing the most efficient surface for the assembly of coagulation factor complexes that lead to thrombin generation (Monroe et al. 2002). Fibrin clots formed in the presence of low thrombin consist of thick fibers and are highly susceptible to fibrinolysis; by contrast, clots generated in the presence of high thrombin concentrations are made up of thinner,

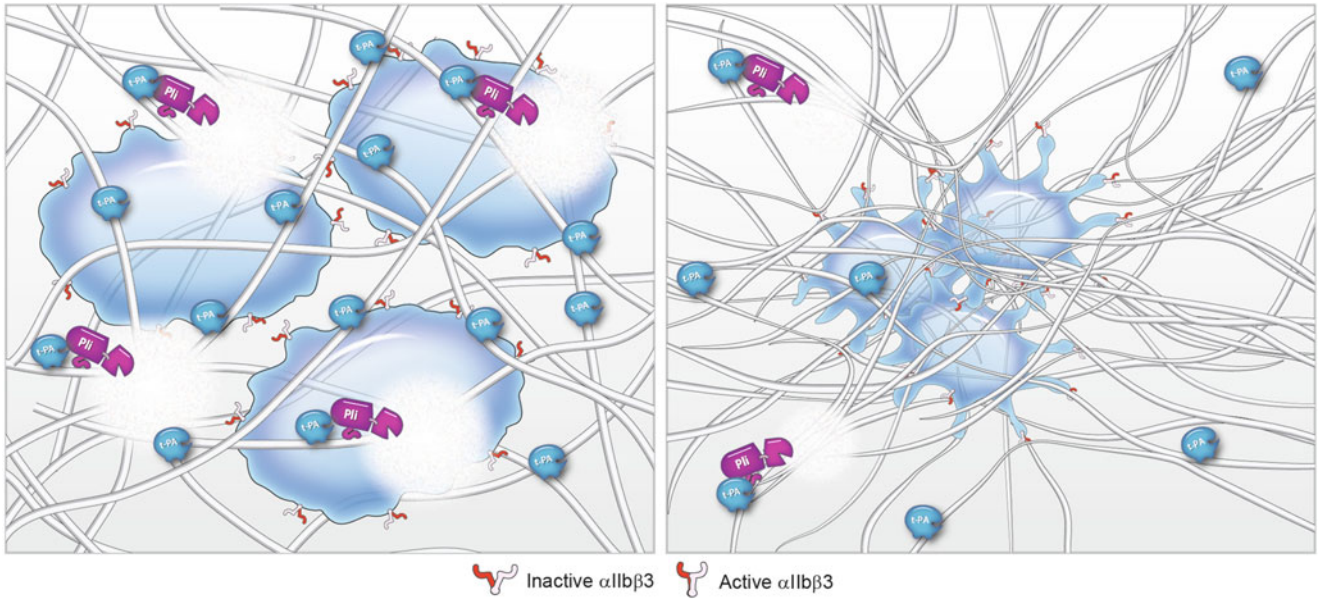

Fig. 2 Fibrinolytic resistance induced by platelet-mediated clot retraction. In the absence of clot retraction (e.g., in platelet-poor areas or when platelet contraction is prevented by platelet inhibitors), fibrin fibers are randomly oriented and organized in a homogeneous network; thus, t-PA-mediated activation of plasminogen on the fibrin surface and consequent fibrin breakdown can proceed at high speed (*left*). Areas enriched in aggregated and contracting platelets are made of fibrin fibers, which are highly compacted and stress-stiffened by the platelet contractile force. In these areas, diffusion of fibrinolytic enzymes, their binding to fibrin, activation of plasminogen, and the susceptibility to plasmin are reduced so that fibrinolysis is greatly impaired (*right*)

more tightly packed fibrin filaments that are resistant to lysis. In analogy with stretched fibrin, thin fibrin fibers support a slower rate of t-PA-mediated plasmin generation than thick fibers, reducing the overall fibrinolytic activity of the system. Moreover, clots with thin fibrin fibers are more resistant to plasmin degradation than clots with thick fibers (Wolberg 2007).

Thrombin-mediated improvement of fibrin structure might be predominant in thrombus areas occupied by procoagulant, non-contracting platelets, which form a distinct platelet population characterized by surface-exposed phosphatidylserine (PS) (Heemskerk et al. 2013). The importance of procoagulant platelet phospholipids in the formation of fibrinolysis-resistant fibrin gel structure has been documented in vitro in platelet-rich plasma clots from both normal subjects and patients with GT (He et al. 2005). On theoretical grounds, the formation of clots with inadequate structure can occur in patients with Scott syndrome, a rare bleeding disorder characterized by a defect in membrane lipid scrambling (Zwaal et al. 2004). The platelets of these patients are unable to expose the procoagulant phospholipids (particularly PS) on the outer membrane upon activation, and thus do not support tenase and prothrombinase assembly and, in turn, thrombin generation. To date, however, there is no formal evidence that platelets carrying this defect do not support the formation of a lysis-resistant fibrin clot.

Plasminogen Activator Inhibitor 1

Plasminogen activator inhibitor 1 (PAI-1) is a member of the SERPIN superfamily and is the principal inhibitor of the plasminogen activators t-PA and u-PA. It binds irreversibly to target enzymes, giving rise to an inactive complex (reviewed by Dellas and Loskutoff 2005). Because of a conformational flexibility, PAI-1 is unstable and spontaneously converts to an inactive (latent) form with a half-life of 1–2 h at 37 °C. Latent PAI-1 can be reactivated in vitro by denaturants such as sodium dodecyl sulfate, guanidine HCl, or urea and by negatively charged phospholipids (Lambers et al. 1987), a finding that led to the hypothesis that latent PAI-1 could be reactivated on the surface of activated platelets. It is unknown, however, whether reactivation of PAI-1 takes place in vivo. Another important feature of PAI-1 is that it binds fibrin without losing its capacity to neutralize t-PA (Wagner et al. 1989). Even though PAI-1 can directly associate with fibrin through low-affinity binding sites, the physiologically relevant PAI-1–fibrin interaction is mediated by vitronectin, which serves as an intermolecular bridge to support high-affinity binding of PAI-1 to fibrin. Furthermore, vitronectin-mediated binding to fibrin stabilizes PAI-1 and enhances its inhibitory effect on t-PA-induced clot lysis (Podor et al. 2000).

In blood, two different pools of PAI-1 exist, plasma and platelet pools. Platelet PAI-1 derives from endogenous

synthesis in megakaryocytes (Alessi et al. 1994; Hill et al. 1996) and is stored in α-granules, from where it can be released after platelet activation with thrombin (Erickson et al. 1984). Platelet PAI-1 accounts for more than 90 % of total PAI-1 in blood (Booth et al. 1988); however, because of thermal instability, a large proportion of PAI-1 is in the inactive latent form. In earlier studies, it was estimated that more than 90 % of platelet PAI-1 was in an inactive conformation (Kruithof et al. 1987; Booth et al. 1988). However, using an approach that minimizes the in vitro inactivation of PAI-1, it was recently found that more than 50 % of PAI-1 in platelets is in the active form (Brogren et al. 2011). This high percentage of active inhibitor can be explained by the ability of platelets to synthesize PAI-1 (Brogren et al. 2004) and to stabilize it through packaging with other α-granule proteins in a calcium-dependent manner (Lang and Schleef 1996). Whatever the specific activity of platelet PAI-1, platelets represent a huge reservoir of PAI-1, independent of the plasma pool. It has been calculated that the local concentration of PAI-1 at sites of platelet aggregates is more than three orders of magnitude greater than the plasma concentration (Kruithof et al. 1987; Biemond et al. 1995).

The role of platelet PAI-1 in conveying fibrinolytic resistance to clots or thrombi has been extensively investigated. In vitro, in the absence of plasma, the release of PAI-1 from stimulated platelets or the addition of a platelet lysate greatly delays fibrinolysis induced by exogenous t-PA or u-PA (Levi et al. 1992; Braaten et al. 1993; Robbie et al. 1993) but not by a PAI-1-resistant plasminogen activator (Fay et al. 1994). Under similar conditions, PAI-1-deficient platelets exhibit a diminished capacity to inhibit clot lysis (Fay et al. 1994). In the presence of plasma, the effect of platelet PAI-1 is greatly influenced by the experimental conditions. The antifibrinolytic effect of platelet PAI-1 is negligible at the normal circulating ratio of plasma to platelets; it becomes significant only when the platelet concentration is increased about 20-fold (Robbie et al. 1993). In model thrombi generated under flow conditions (Chandler loop) (Chandler 1958), platelet PAI-1 is one of the main determinants of fibrinolytic resistance (Torr-Brown and Sobel 1993; Stringer et al. 1994; Mutch et al. 2007). Chandler thrombi consist of a platelet-rich "head" and an erythrocyte-rich "tail," resembling the polarized cell distribution of arterial thrombi (Robbie et al. 1997). The head contains larger amounts of PAI-1 than the tail and is more resistant to lysis (Stringer et al. 1994). Depending on the model used, platelet-mediated fibrinolytic resistance is abolished or greatly reduced by neutralizing anti-PAI-1 antibodies (Braaten et al. 1993; Torr-Brown and Sobel 1993; Stringer et al. 1994; Mutch et al. 2007) or when a PAI-1-resistant plasminogen activator is used as thrombolytic agent (Fay et al. 1994).

In vivo experiments in animal models provide compelling evidence that PAI-1 can influence thrombus formation and growth, reocclusion, and response to thrombolytic therapy (Reilly et al. 1991a, b; Biemond et al. 1995; Friederich et al. 1997; Farrehi et al. 1998; Zhu et al. 1999). However, the role of PAI-1 in each of these phenomena cannot be generalized and depends on specific conditions, such as thrombus localization and composition, thrombotic challenge, and animal species. Platelet PAI-1 is believed to be principally involved in arterial thrombosis, because of the high platelet content of such thrombi. However, the precise contribution of platelet PAI-1 in conferring fibrinolytic resistance in vivo is difficult to define and is largely inferred from indirect evidence. Jang et al. (1989) showed that platelet-rich thrombi are more resistant to t-PA treatment than erythrocyte-rich thrombi formed in the very same femoral artery of rabbits. That platelet PAI-1 is, at least partly, responsible for the thrombolytic resistance of platelet-rich thrombi is suggested by the finding that, in a murine model of carotid artery thrombosis, reperfusion after t-PA infusion occured in PAI-deficient mice but not in wild-type animals (Zhu et al. 1999). Notably, the levels of circulating free t-PA after the thrombolytic treatment were similarly high in PAI-$1^{-/-}$ and PAI-$1^{+/+}$ mice, indicating that an important contribution of plasma PAI-1 to fibrinolytic resistance is unlikely. By contrast, neutralization of PAI-1 by a monoclonal antibody did not improve t-PA-mediated thrombolysis of erythrocyte-rich jugular vein thrombi (Biemond et al. 1995), suggesting that only platelet-rich thrombi contain enough PAI-1 to inhibit pharmacological concentrations of t-PA. In a carotid artery thrombosis model in mice, Farrehi et al. (1998) showed that residual thrombi, harvested 24 h after vessel injury, were smaller in PAI-$1^{-/-}$ mice than in wild-type mice, suggesting that platelet PAI-1 also influences spontaneous thrombolysis.

Additional support for the importance of platelet PAI-1 in fibrinolytic resistance comes from immunohistochemical analysis of human thrombi, which, in line with in vitro findings, showed that arterial thrombi contain greater amounts of PAI-1 than venous thrombi (Potter van Loon et al. 1992, Robbie et al. 1996). PAI-1 was localized in platelet-rich areas in association with fibrin strands (Robbie et al. 1997) and was shown to correlate inversely with ex vivo spontaneous lysis (Potter van Loon et al. 1992). Conceivably, thrombus PAI-1 derives from the platelets recruited during thrombus formation. However, some might have been taken up from plasma or derive from the vessel wall, because both endothelial and smooth muscle cells are able to synthesize PAI-1 (Dellas and Loskutoff 2005). Moreover, platelet-derived products (e.g., TGF-β) might stimulate PAI-1 synthesis by vascular cells, as suggested by in vitro and in vivo studies (Fujii and Sobel 1990; Slivka and Loskutoff 1991).

Studies in humans have focused mainly on hereditary PAI-1 deficiency and on acquired PAI-1 changes associated

with diverse pathological conditions. PAI-1 deficiency is very rare and only a few cases have been described so far (Schleef et al. 1989; Diéval et al. 1991; Lee et al. 1993; Fay et al. 1992; 1997; Iwaki et al. 2011). In two of these studies, the mutated PAI-1 gene was characterized and shown to harbor a frame-shift mutation that results in a new stop codon (Fay et al. 1997; Iwaki et al. 2011). Homozygous carriers of this null mutation had no detectable PAI-1 in plasma nor in platelets and had a life-long history of delayed, sometimes life-threatening, bleeding in response to trauma or surgery, which could be efficiently treated with antifibrinolytic drugs such as tranexamic acid and EACA (Fay et al. 1997). Another patient with very low PAI-1 in plasma and platelets was described by Schleef et al. (1989). This patient too had life-long bleeding problems, often requiring multiple transfusions with packed red blood cells. Two other studies reported patients with low plasma levels of PAI-1 but normal or nearly normal platelet PAI-1 (Diéval et al. 1991; Lee et al. 1993). These patients experienced recurrent bleeding episodes after trauma or surgery, which, however, tended to stop spontaneously and did not require transfusions (Diéval et al. 1991). Although the small number of known cases of PAI-1 deficiency calls for caution, it is tempting to speculate that the absence of both platelet and plasma PAI-1 is associated with more severe bleeding than the lack of plasma PAI-1 only.

Low levels of intraplatelet PAI-1 are encountered in patients with Gray platelet syndrome (GPS) (Booth et al. 1988; Vermylen et al. 1991), an inherited mild-to-moderate bleeding disorder characterized by lack of platelet α-granules and their content (Nurden and Nurden 2014). However, considering the huge number of biologically active proteins stored in α-granules, it is difficult to establish the relationship between deficiency of platelet PAI-1 and bleeding in GPS. Moreover, no study has tested whether GPS platelets differ from normal platelets in in vitro models of clot lysis.

Increased levels of PAI-1 have been reported in patients with venous and arterial thrombosis and with a number of other conditions associated with increased thrombotic risk, such as sepsis, obesity, metabolic syndrome, and diabetes (Alessi and Juhan-Vague 2006; Semeraro et al. 2012; Van De Craen et al. 2012). In the vast majority of these studies, however, only plasma PAI-1 levels and PAI-1 gene polymorphism were examined. The few reports on platelet PAI-1 in disease states indicate that the platelet pool varies independently from the plasma pool, and that platelet PAI-1 concentrations fall within the normal range in several pathological conditions in which plasma PAI-1 is generally increased (Simpson et al. 1990, 1997). Not surprisingly, the platelet pool of PAI-1 is markedly increased in patients with polycythemia vera (PV) and essential thrombocythemia (ET). In such patients, blood PAI-1 content correlates with the platelet number and with fibrinolytic resistance (Bazzan et al. 1993; Pósán et al. 1998). Interestingly, the blood of patients with PV or ET releases more PAI-1 than control blood when exposed to mild mechanical stress (Pósán et al. 1998). Moreover, patients with ET and thrombotic complications were reported to have greater amounts of intraplatelet PAI-1 than ET patients with no history of thrombosis (Bazzan et al. 1993). In septic patients, circulating PAI-1 can reach extraordinarily high levels (Colucci et al. 1985; Levi 2008; Semeraro et al. 2012) and lead to a strong and sustained suppression of fibrinolysis. In these patients, PAI-1 increase has been shown to be strongly associated with disseminated intravascular coagulation (DIC) and poor outcome (Pralong et al. 1989; Mesters et al. 1996; Lorente et al. 2014). Because platelets are extensively activated during sepsis and/or DIC, it might be surmised that platelet-derived PAI-1 contributes to fibrinolytic shutdown. It should be pointed out, however, that very high levels of PAI-1 can be detected in patients with severe sepsis, even in the absence of platelet consumption (Semeraro et al. 2015), suggesting that other cellular types are the principal source of circulating PAI-1 in this condition.

Taken together, the evidence strongly suggests that platelet PAI-1 is a major determinant of fibrinolytic resistance (Fig. 3) and probably plays a role in arterial thrombosis and in hemostasis, where it helps protect the plug from premature lysis.

Thrombin-Activatable Fibrinolysis Inhibitor

Thrombin-activatable fibrinolysis inhibitor (TAFI), also known as plasma procarboxypeptidase B (proCPB) or procarboxypeptidase U (proCPU), is an important modulator of fibrinolysis (reviewed by Bajzar 2000; Foley et al. 2013). In the active form (TAFIa), it removes the C-terminal lysine residues from partially degraded fibrin, thereby reducing the binding of plasminogen to fibrin and thus efficiently inhibiting plasmin formation. TAFIa inhibits clot lysis with a threshold mechanism so that fibrinolysis is halted as long as TAFIa levels are at or above the threshold level (Leurs et al. 2004; Walker and Bajzar 2004). The threshold concentration of TAFIa, in turn, depends on the local fibrinolytic pressure; the higher the levels of plasminogen activator (s) (i.e., the higher the plasmin generation capacity), the higher the concentration of TAFIa needed to arrest clot lysis (Leurs et al. 2004; Walker and Bajzar 2004). At physiologically relevant t-PA concentrations, the amount of TAFIa capable of inhibiting the fibrinolytic process has been calculated to be less than 1 % of total TAFI (Walker and Bajzar 2004). The zymogen TAFI is activated through proteolytic cleavage by thrombin and plasmin. Thrombin is

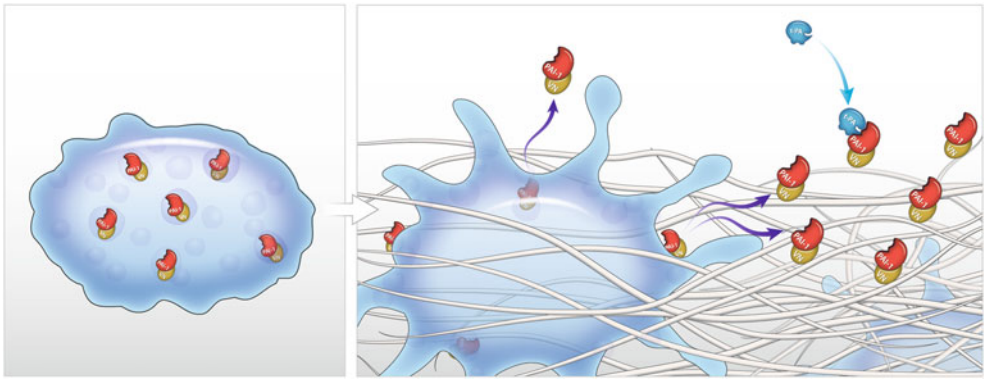

Fig. 3 The antifibrinolytic activity of platelet plasminogen activator inhibitor 1 (PAI-1). Resting platelets contain high amounts of PAI-1 stored in the α-granules in association with vitronectin (VN) (*left*). Upon activation, platelets release the PAI-1-vitronectin complex, which localizes and concentrates on the clot surface, through high-affinity vitronectin-mediated binding to fibrin, where it rapidly inhibits t-PA and prevents premature degradation of the clot (*right*)

a weak activator of TAFI but, when bound to thrombomodulin (TM), displays a 1000-fold higher catalytic efficiency (Bajzar et al. 1996a), which suggests that the thrombin–TM complex is the physiological activator of TAFI. It should be noted, however, that TM is localized on the endothelial surface, which means that at the site of vascular injury, within a nascent plug or thrombus, there is practically no TM apart from the small amount derived from circulating soluble TM (Ishii et al. 1990). Antifibrinolytic amounts of TAFIa can still be produced as a result of generation of huge amounts of thrombin within a forming clot (Mann 2003). Plasmin is a better activator of TAFI than thrombin, and its catalytic activity is further enhanced by binding to glycosaminoglycans (Foley et al. 2013). However, the role of plasmin as TAFI activator, within the frame of intravascular fibrinolysis regulation, is debated (Binette et al. 2007; Vercauteren et al. 2011; Semeraro et al. 2013).

Circulating TAFI derives mainly from the liver and its plasma concentration is approximately 10 μg/mL, with large interindividual variability (Gils et al. 2003). TAFI is also present in the α-granules of platelets, probably originating from endogenous synthesis in megakaryocytes (Mosnier et al. 2003). It is released on activation of platelets by thrombin and other agonists, and displays enzymatic characteristics similar to plasma TAFI. The concentration of platelet TAFI is low and accounts for only 0.1 % of plasma TAFI. However, at sites of platelet accumulation, the release of α-granule content from activated platelets might increase the local concentration of TAFI and enhance the antifibrinolytic effect. It has been calculated that the intraplatelet concentration of TAFI is comparable to that of plasma TAFI (Mosnier et al. 2003), and it is known that even a small increase in TAFI concentration can result in a reduction of clot lysis velocity (Bajzar et al. 1996b; Mosnier et al. 1998). Formal experimental evidence that platelet TAFI can add to plasma TAFI in the inhibition of clot lysis has recently been provided in an in vitro study (Schadinger et al. 2010).

In addition to TAFI release, platelets can potentiate TAFI-dependent inhibition of fibrinolysis through enhancement of thrombin-mediated TAFI activation (Fig. 4). Inside the hemostatic plug or a thrombus, particularly at arterial level, platelet-driven thrombin generation can reach levels that activate significant amounts of TAFI, even in the absence of TM. In an in vitro model of whole blood clot lysis, platelets enhanced thrombin-mediated TAFI activation in a concentration-dependent manner, leading to formation of highly resistant clots, independently of clot retraction (Carrieri et al. 2011). Interestingly, when blood was challenged with a low concentration of tissue factor, the TAFI-mediated antifibrinolytic effect of platelets was partly dependent on factor XI, but not on factor XII (Carrieri et al. 2011), lending further support to the purported role of thrombin-mediated factor XI activation in the generation of the "late" thrombin burst required for efficient TAFI activation (von dem Borne et al. 1995, 1997).

In several animal models of venous and arterial thrombosis, TAFI deficiency or the administration of TAFI inhibitors resulted in significant increase in thrombus lysis following treatment with fibrinolytic agents (reviewed by Morser et al. 2010; Colucci and Semeraro 2012), underscoring the role of TAFI activation in fibrinolytic resistance in vivo. Even though the role of platelets was not investigated in these studies, it is conceivable that, at least in arterial thrombi, activated platelets contribute to thrombus resistance through TAFI release and activation.

Factor XIII

Factor XIII (FXIII) is a pro-transglutaminase that, upon activation, introduces covalent ε(γ-glutamyl)lysyl bonds

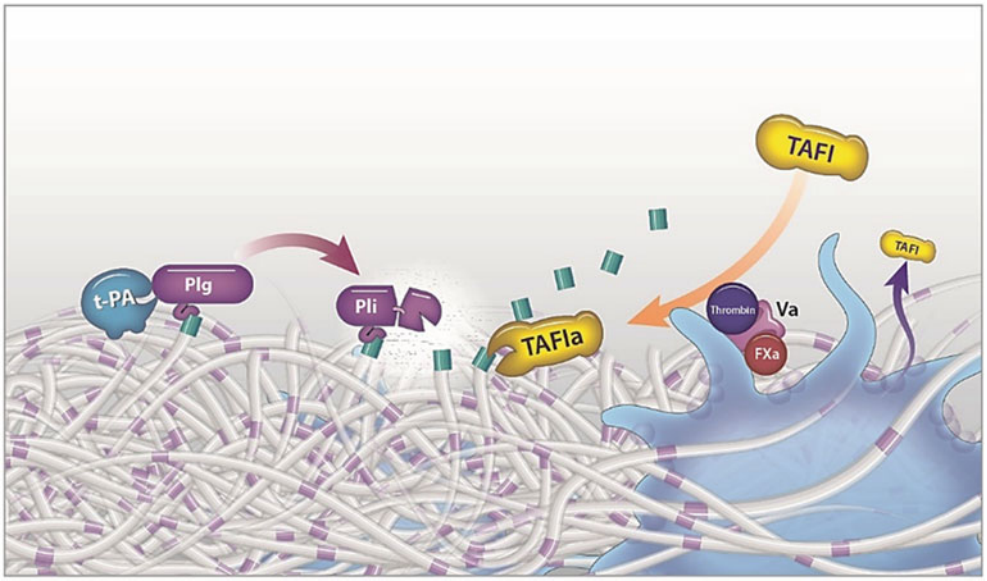

Fig. 4 Thrombin activatable fibrinolysis inhibitor (TAFI)-dependent antifibrinolytic effects of platelets. At the site of clot formation, stimulated platelets secrete TAFI from their α-granules, thereby increasing the local concentration of the inhibitor. Moreover, activated platelets promote the assembly of the prothrombinase complex through the exposure of procoagulant phospholipids and factor Va, thus enhancing thrombin generation. In turn, thrombin activates TAFI, which downregulates fibrinolysis by removing C-terminal lysine residues from fibrin and preventing the binding of plasminogen

between donor and acceptor polypeptides (reviewed by Muszbek et al. 2011). FXIII exists in two molecular forms that follow distinct activation routes and are localized in different compartments. Plasma FXIII (pFXIII) is a heterotetramer of two catalytic A and two carrier/inhibitory B subunits (FXIII-A_2B_2). Its activation requires both cleavage of the activation peptide by proteases (mainly thrombin) and calcium-dependent detachment of the B subunits. Cellular FXIII lacks the regulatory B component and consists of two A subunits only (FXIII-A_2), which assume an active configuration in the presence of increased levels of cytosolic calcium (Muszbek et al. 2011). Plasma FXIII is deemed extremely important in regulation of the fibrinolytic process. It stabilizes the fibrin clot and inhibits fibrinolysis by forming fibrin γ-chain dimers and α-chain polymers of high molecular weight, which are intrinsically more lysis resistant and support reduced binding of plasminogen. Moreover, crosslinking of plasma proteins, above all α_2-AP, but also TAFI and PAI-2, to fibrin further slows fibrin removal (Muszbek et al. 2011). Major sources of cellular FXIII are monocytes/macrophages and platelets, which contain about 60 ± 10 fg FXIII/cell (≈3 % of total platelet proteins) (Katona et al. 2001), making up to 50 % of the total blood FXIII activity (McDonagh et al. 1969). Platelet FXIII derives from megakaryocytes (Adany and Bardos 2003) and represents the only platelet transglutaminase activity (Mitchell et al. 2014). It is converted to the active form by raised calcium levels during platelet activation (Muszbek et al. 1995), although calpain- and platelet acid protease-dependent activation of cytosolic platelet FXIII have also been identified (Ando et al. 1987; Lynch and Pfueller 1988). Moreover, thrombin can accelerate activation of platelet FXIII in the extracellular environment (Muszbek et al. 1993). Most platelet FXIII is stored in the cytosolic fraction (Lopaciuk et al. 1976), and only minute amounts of FXIII endocytosed from plasma are contained in the α-granules (Marx et al. 1993), although pFXIII uptake has not been consistently described (McDonagh et al. 1969; Mitchell et al. 2014). It is not clear whether and how FXIII is released from platelets. It has been recently reported that ADP-activated and aggregated platelets can release FXIII from α-granules (Marx et al. 1993; Kreutz et al. 2015), but other works failed to identify FXIII in the platelet releasate (Joist and Niewiarowski 1973; Lopaciuk et al. 1976). It has been proposed that platelet FXIII is not released into the extracellular milieu, but is exposed on the surface of activated platelets (Kreager et al. 1988), with local distribution on the caps of PS-positive platelets and wider localization on PS-negative cells (Mitchell et al. 2014). However, no consensus exists because activation with thrombin-receptor activating peptide (TRAP-6) produced less than 5 % FXIII-A_2^+ platelets (Nagy et al. 2009) compared with more than 50 % positive platelets after activation with thrombin or dual agonists (TRAP-6/thrombin and collagen) (Mitchell et al. 2014). Probably the nature of the stimulus makes the difference, because dual stimulation with thrombin and collagen generates coated platelets, a subpopulation enriched in procoagulant proteins localized on the surface

through a platelet FXIII-dependent crosslinking process (Dale et al. 2002). Another potential mechanism for release of cytosolic FXIII is through microvesiculation of platelets activated with strong agonists (Holme et al. 1993).

Compared with pFXIII, the role of platelet FXIII in fibrinolysis regulation is more controversial. There is wide consensus that platelet FXIII-A_2 can catalyze crosslinking of fibrin chains and α_2-AP, as demonstrated in purified systems and in FXIII-deficient plasma (Reed et al. 1992; Hevessy et al. 1996), but its relative contribution in the presence of pFXIII is debated. Accelerated α_2-AP-fibrin crosslinking has been reported in platelet-rich plasma compared with platelet-poor plasma (Reed et al. 1992). Furthermore, extensive fibrin α-chain crosslinking has been found to correlate positively with platelet count, similar to the correlation with raised pFXIII concentration (Francis and Marder 1987). However, Hevessy et al. (1996) reported a negligible increase in crosslinking upon addition of normal platelets to normal plasma, raising concerns about the real contribution of platelet FXIII to fibrin stabilization. The difficulty in ascertaining the role of platelet FXIII is further amplified by the fact that platelets can influence FXIII activity independently of their own FXIII content. Indeed, activated platelets can provide a catalytic surface on which pFXIII crosslinking activity, especially on the α-chain and α_2-AP, is enhanced (Hevessy et al. 1996), which supports the antifibrinolytic activity of supplemental pFXIII (Dirkmann et al. 2012). Furthermore, stimulated platelets can bind activated pFXIII through plasmin-sensitive binding sites, probably active $\alpha_{IIb}\beta_3$ (Kreager et al. 1988; Cox and Devine 1994). It has been recently reported that the zymogen form of pFXIII can indirectly interact with the surface of activated platelets via the γ′-chain of $\alpha_{IIb}\beta_3$ receptor-bound fibrinogen (Nagy et al. 2009). In so doing, platelets can convey and concentrate both zymogen and active pFXIII to the site of clot formation. Recently, the role of platelet FXIII in fibrinolysis was studied under dynamic conditions (Mitchell et al. 2014), and platelets were found to increase the fibrinolytic resistance of FXIII-deficient plasma clots in a FXIII- and α_2-AP-dependent manner (Fig. 5). However, platelet FXIII contribution was no longer observed at pFXIII levels above 20 %. It is thus possible that platelet FXIII helps to stabilize the clots when pFXIII is lacking or diminished, as occurs in congenital deficiencies or during surgical and medical conditions associated with an acquired decrease in pFXIII levels (Tosetto et al. 1993). Data from humans congenitally deficient in FXIII, although scarce because of the rarity of the disease, seem to support such a theory because patients deficient in FXIII-B and characterized by low levels of pFXIII but normal cellular FXIII-A_2 experience milder bleeding symptoms than those with FXIII-A deficiency (Saito et al. 1990).

From a different perspective, platelet function, and particularly clot retraction, can be influenced by FXIII. Recently, it has been described that FXIII-A knockout mice exhibit greatly impaired retraction, which is not fully reversed by exogenous FXIII, indicating that it requires both extracellular and platelet FXIII activity (Kasahara et al. 2010). Indeed, extracellular proteins (fibrin and $\alpha_{IIb}\beta_3$) and intraplatelet cytoskeletal molecules (actin and myosin) are crosslinked by FXIII (Cohen et al. 1981), which is required for translocation of the retraction machinery to the sphingomyelin-rich rafts on the membrane of activated platelets (Kasahara et al. 2013). However, studies from FXIII-deficient patients have provided extremely conflicting results, as FXIII was found to inhibit, not affect, or even enhance clot retraction, probably because of differences between species and the use of diverse experimental conditions (Muszbek et al. 2011).

Polyphosphate

Polyphosphate (polyP) is a linear, negatively charged polymer of a few to several hundred inorganic orthophosphate residues and is abundantly distributed in the granules of human platelets (Ruiz et al. 2004) and mast cells (Moreno-Sanchez et al. 2012). Platelet-dense granules store millimolar concentrations of polyP, and lower amounts have also been detected in α-granules, colocalized with von Willebrand factor (Montilla et al. 2012). Platelet polyP is rather homogeneous and contains 60–100 phosphate residues (Müller et al. 2009). Stimulation with thrombin, ADP, or collagen results in platelet secretion of polyP in the extracellular milieu (Müller et al. 2009), reaching blood concentrations of 1–3 μM and, allegedly, even higher levels in platelet-rich thrombi (Ruiz et al. 2004). PolyP is deemed antifibrinolytic, based on multiple actions on both the coagulation and fibrinolytic systems. In plasma clot lysis assays, low micromolar concentrations of synthetic polyP delay t-PA- or u-PA-mediated fibrinolysis in a dose- and chain length-dependent manner. Maximum lysis time prolongation is achieved by polyP containing more than 45 units, representing the size of platelet polyP (Smith et al. 2006). The antifibrinolytic effect of polyP seems to be mediated by plasma TAFI because it is abolished by TAFIa inhibitors and disappears in TAFI-deficient plasma. Because polyP accelerates thrombin generation (Morrissey and Smith 2015), enhanced TAFI activation has been hypothesized. PolyP can also impair fibrinolysis by influencing the fibrin clot structure, although contrasting effects have been described. PolyP was found to either increase the turbidity of fibrin clots, by raising the fiber mass-to-length ratio (Smith and Morrissey 2008), or reduce it, giving rise to clots consisting of normal fibers organized

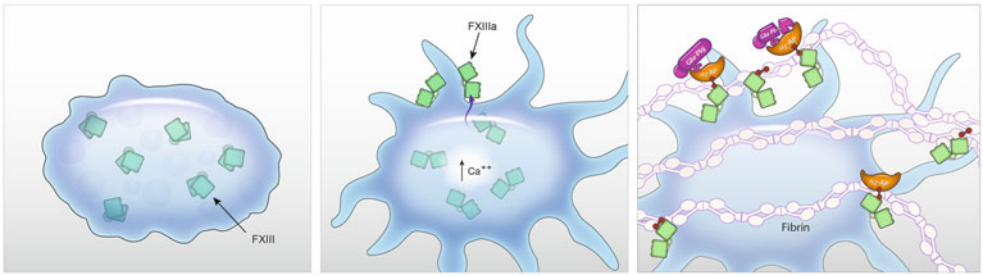

Fig. 5 Factor XIII (FXIII)-mediated antifibrinolytic activity of platelets. Resting platelets contain high amounts of inactive FXIII in their cytoplasm (*left*). Increased levels of cytosolic calcium consequent to platelet stimulation lead to conversion of FXIII into the active configuration (FXIIIa), which then translocates to the platelet surface (*middle*). Exposed FXIIIa forms fibrin γ-chain dimers and α-chain polymers, which are more lysis-resistant, and crosslinks α_2-antiplasmin (α_2-AP) to fibrin, which inhibits plasmin activity on the clot surface and competes with fibrin for plasminogen binding (*right*)

in dense knot-like regions and with ample pores (Mutch et al. 2010). In both cases, polyP downregulates fibrinolysis, probably through interfering with the binding of fibrinolytic proteins to fibrin. Recently, it was found that whole blood clots formed on thrombogenic surfaces under flow conditions are composed of thinner fibers, demonstrate increased clot retraction, and dissolve faster in the presence of the specific polyP inhibitor PPXbd, thus providing further evidence for and additional mechanistic insight into the antifibrinolytic activity of platelet polyP (Zhu et al. 2015).

No specific deficiency in polyP has been described in humans. However, very low polyP levels characterize several hereditary hemorrhagic diseases known as platelet dense granule storage pool deficiencies (e.g., Hermansky–Pudlak and Chediak–Higashi syndromes) (Hernández-Ruiz et al. 2009). In these human models of polyP deficiency, exogenous polyP can restore the platelet procoagulant potential (Müller et al. 2009), suggesting that defective polyP-mediated hemostatic mechanisms (e.g., protection of clots against fibrinolysis) could exacerbate the bleeding risk.

α_2-Antiplasmin

α_2-Antiplasmin (α_2-AP), also known as α_2-plasmin inhibitor, is the main physiological inhibitor of plasmin. It is a SERPIN of liver origin and circulates in blood at a concentration of 1 μM (reviewed by Rijken and Lijnen 2009). The inhibition of plasmin by α_2-AP is very rapid (second-order rate constant of 2×10^7–4×10^7 M^{-1} s^{-1}) and requires interaction of the inhibitor with both the active site and the high-affinity lysine binding sites of plasmin. During clot formation, α_2-AP is crosslinked to the fibrin α-chain by activated FXIII (Sakata and Aoki 1980). Several lines of evidence indicate that fibrin-bound α_2-AP plays a major role in regulating clot lysis (Sakata and Aoki 1982; Reed et al. 1990), unbound α_2-AP serving as inhibitor of plasmin generated in solution or released from the clot.

Platelet α_2-AP is stored in the α-granules (Plow and Collen 1981; Gogstad et al. 1983; Plow et al. 1989) and represents ≈0.05 % of the total inhibitor level in blood. To date there is no formal evidence that platelet α_2-AP makes any significant contribution to fibrinolytic resistance. Immunohistochemical studies, showing that the concentration of α_2-AP in human thrombi is approximately 25 % of that in plasma and that there is no difference between arterial and venous thrombi (Robbie et al. 1996), indicate that platelets add little to α_2-AP accumulation within thrombi.

Protease Nexin-1

Protease nexin-1 (PN-1), a member of the SERPIN superfamily, also known as serpin E2, is produced by many cell types and found in many organs. PN-1 inhibits a broad spectrum of serine proteases and has major pleiotropic functions. In vitro, PN-1 has been shown to inhibit several activated clotting factors as well as the fibrinolytic enzymes t-PA, u-PA, and plasmin. Heparin enhances the PN-1-mediated inhibition of many of its target proteases, including thrombin and FXIa, but has no significant effect on t-PA, u-PA, or plasmin inhibition by PN-1 (reviewed by Bouton et al. 2012).

PN-1 is barely detectable in plasma (Baker and Gronke 1986) but is present in platelets and monocytes (Mansilla et al. 2008). Most platelet PN-1 is stored in α-granules, only a small fraction being present on the surface of resting platelets (Boulaftali et al. 2010). In vitro, platelet-rich plasma clots display greater spontaneous as well as t-PA-induced lysis when formed in the presence of a neutralizing anti-PN-1 antibody or when prepared from PN-1-deficient mice (Boulaftali et al. 2011). Importantly, the antifibrinolytic effect of platelet PN-1 adds to that of PAI-1, because a more pronounced enhancement of lysis is seen upon neutralization of both inhibitors. Moreover, in a mouse model of $FeCl_3$-induced venular thrombosis, it was

reported that t-PA-induced thrombolysis was faster and led to a higher incidence of recanalization in PN-$1^{-/-}$ than in PN-$1^{+/+}$ mice (Boulaftali et al. 2011). An important feature of PN-1 is that it is able to inhibit fibrin-bound t-PA and fibrin-bound plasmin, suggesting that PN-1 plays a complementary role with PAI-1 and α_2-AP, which are much less efficient at inhibiting fibrin-bound enzymes.

Tissue Factor Pathway Inhibitor-2

Tissue factor pathway inhibitor-2 (TFPI-2), a homolog of TFPI-1, is a matrix-associated Kunitz-type serine proteinase inhibitor, previously designated as placental protein 5. TFPI-2 inhibits a broad spectrum of serine proteinases and is thought to play a role in the regulation of extracellular matrix digestion and remodeling (reviewed by Chand et al. 2005). With respect to the coagulation–fibrinolysis system, TFPI-2 has been shown to inhibit plasma kallikrein, FXIa, and plasmin (Petersen et al. 1996). In healthy subjects, the plasma levels of TFPI-2 are very low and unlikely to influence clotting or fibrinolysis. Platelets, by contrast, contain significant amounts of TFPI-2, probably derived from megakaryocytes (Vadivel et al. 2014). TFPI-2 is probably stored in the α-granules and released upon platelet stimulation. In an in vitro model of clot lysis, the release of TFPI-2 from activated platelets was shown to contribute significantly to fibrinolytic resistance, accounting for about 40 % of platelet-mediated clot lysis inhibition (Vadivel et al. 2014).

Zinc

Zinc is the second most abundant transition metal in blood and is considered an important mediator of hemostasis and thrombosis (reviewed by Vu et al. 2013). It binds numerous plasma proteins, thereby modulating their structure and function, and has been shown to influence platelet aggregation, coagulation, and fibrinolysis. Zinc has been reported to inhibit the enzymatic activity of t-PA and plasmin (Henderson et al. 2015) and to alter fibrin structure, giving rise to coarse clots composed of thicker fibers (Marx et al. 1987). The zinc concentration in plasma is 10–20 μM, but most of it is bound to albumin and other plasma proteins so that the free zinc concentration is 0.5–1 μM (Foote and Delves 1984). Platelets accumulate zinc in their cytoplasm and α-granules, such that the intracellular concentration of zinc is 30- to 60-fold higher than in plasma (Marx et al. 1993). Recently, it was reported that zinc ions delay the lysis of plasma clots, in a concentration-dependent manner, by decreasing t-PA-mediated plasminogen activation and plasmin-induced fibrin degradation (Henderson et al. 2015). On the basis of these findings, it can be hypothesized that the local surge in zinc levels at sites of platelet deposition and activation represents an additional mechanism of fibrinolytic resistance. To date, however, direct support for such a hypothesis is lacking.

Platelet-Derived Phospholipids

Platelet-derived phospholipids have been shown to inhibit fibrinolysis through different mechanisms. When incorporated into the clot, they form a diffusion barrier that decreases the penetration of t-PA and plasmin into the fibrin mesh; moreover, they compete with fibrin for the binding of fibrinolytic enzymes, thereby reducing plasminogen activation. In addition, phospholipids impair the protection of plasmin on the fibrin surface (Váradi et al. 2004) and make fibrin less susceptible to plasmin degradation (Günther et al. 1994). These antifibrinolytic effects can be largely reproduced with preparations of phospholipid vesicles consisting of phosphatidylserine and phosphatidylcholine (Váradi et al. 2004), which are the same phospholipids that promote tenase and prothrombinase assembly. These combined mechanisms result in marked inhibition of clot lysis, even in the presence of pharmacological concentrations of t-PA, and might play a role in thrombolysis resistance. In fact, strong activation or death leads to progressive loss of the platelet phospholipid content (Skarlatos et al. 1993), which could then accumulate within thrombi, as demonstrated by histochemical studies of human arterial thrombi (Váradi et al. 2004).

Platelets contain other factors capable of downregulating fibrinolysis, namely C1-inhibitor, which inhibits the plasminogen activators t-PA and u-PA (Huisman et al. 1995; Pannell et al. 2007), and histidine-rich glycoprotein, which acts as a competitive inhibitor of plasminogen (Lijnen et al. 1980). However, there is no evidence that the small platelet pool of these two proteins contributes to fibrinolytic resistance.

Platelet Profibrinolytic Properties

Plasminogen and Its Receptor(s)

Platelets have long been known to contain and/or express several profibrinolytic proteins, namely u-PA, t-PA, and plasminogen (Jeanneau and Sultan 1988; Brisson-Jeanneau et al. 1990; Wang et al. 1994; Coppinger et al. 2004; Maynard et al. 2007; Veljkovic et al. 2009). Plasminogen, in particular, is contained in platelet α-granules (Maynard et al. 2007) and is released upon thrombin stimulation (Coppinger et al. 2004). One of the most important functions

of platelets in mediating fibrinolysis is to provide a surface on which localized fibrinolytic activity can be generated. Platelets, like many other cell types, express specific receptors that bind plasminogen and enhance its activation (Miles and Plow 1985; Adelman et al. 1988; Loscalzo et al. 1995). The plasminogen-binding capacity of platelets is high and increases severalfold following stimulation by thrombin (Miles and Plow 1985). The interaction of plasminogen with platelets is mediated by the lysine binding sites located in the kringle domains of plasminogen and the C-terminal lysine residues on the platelet surface, and can be inhibited by the lysine analog EACA and by carboxypeptidase B (Miles and Plow 1985; Miles et al. 1988; Adelman et al. 1988; Horne III et al. 2005). The exact nature of the protein(s) exposing C-terminal lysines on the platelet surface has not been conclusively established. Available studies indicate that plasminogen interaction with platelets involves the integrin $\alpha_{IIb}\beta_3$ and point to surface-bound fibrin(ogen) (via $\alpha_{IIb}\beta_3$) as the main plasminogen binding site (Miles and Plow 1985; Miles et al. 1986; Adelman et al. 1988). In thrombin-stimulated platelets, fibrin associated with the platelet surface is probably the prominent site of plasminogen binding through the increased exposure of C-terminal lysines (Miles and Plow 1985; Miles et al. 1986), although the possibility that thrombin exposes C-terminal lysines in a protein other than fibrin cannot be excluded (Horne III et al. 2005). In the case of platelet agonists other than thrombin, which have been shown to increase plasminogen interaction with platelets by some investigators (Adelman et al. 1988) but not by others (Miles and Plow 1985; Miles et al. 1986), $\alpha_{IIb}\beta_3$-bound fibrinogen appears to play a major role. Concerning unstimulated platelets, it is possible that plasminogen interacts directly with $\alpha_{IIb}\beta_3$, as originally reported by Miles et al. (1986). Whether platelet $\alpha_{IIb}\beta_3$ undergoes proteolysis or some other change to reveal C-terminal lysine residues remains unclear (Miles and Parmer 2013). Whatever the binding mechanism, when in association with the platelet surface, plasminogen assumes an open conformation that is more readily cleaved to plasmin by plasminogen activators (Miles and Parmer 2013). Moreover, cell-associated plasmin is considerably protected from inhibition by α_2-AP (Hall et al. 1991), suggesting that platelets provide an efficient profibrinolytic surface. The possible relevance of these mechanisms is suggested by recent findings in models that better mimic physiological conditions. Whyte et al. (2015), using an in vitro model of thrombus formation under physiological flow rates, showed that plasminogen accumulates within the platelet-rich thrombus and supports t-PA- or u-PA-induced thrombolysis in a flow-dependent fashion. Plasminogen binds to platelets mainly in a fibrin (ogen)-dependent manner, particularly on PS-expressing platelets, where it localizes on protruding caps displaying greater plasmin generation capacity. These in vitro findings were largely confirmed in vivo in a mice model of laser-induced mesenteric vein thrombosis (Brzoska et al. 2015). In fact, the authors found that plasminogen accumulates in a time-dependent manner in the center of the microthrombus, which coincides with the localization of strongly activated PS-exposing platelets and fibrin. Plasminogen accumulation is dependent on lysine binding sites and requires plasmin formation. Interestingly, both in vitro and in vivo studies provide evidence suggesting that spontaneous plasminogen activation takes place within the thrombus, even though it does not result in detectable thrombolysis during the observation period.

Plasminogen Activators and Their Receptors

Both u-PA and t-PA are involved in platelet-mediated fibrinolysis. Platelets, besides containing t-PA (Jeanneau and Sultan 1988; Brisson-Jeanneau et al. 1990; Wang et al. 1994), have been shown to express specific binding sites for t-PA (Vaughan et al. 1989) and, importantly, platelet-bound t-PA manifests enhanced catalytic activity (Deguchi et al. 1985; Ouimet et al. 1994; Loscalzo et al. 1995). Although neither the nature of the platelet receptor nor the structure(s) in the t-PA molecule that are responsible for binding to platelets have been identified, the co-localization of plasminogen and its activator on the platelet surface boosts plasmin formation and thereby promotes pericellular fibrinolysis.

It has long been known that u-PA is associated with normal platelets and their external membranes; it is estimated that about 20 % of the u-PA intrinsic to blood is tightly associated with platelets. Platelet uptake of scu-PA from the ambient plasma has also been demonstrated (Park et al. 1989; Gurewich et al. 1993, 1995). Platelets are able to bind scu-PA through a still-unidentified surface receptor that is different from the classical u-PA receptor (u-PAR) expressed by other cells (Vaughan et al. 1990; Jiang et al. 1996). Platelet-bound scu-PA can be activated by pre(kallikrein) co-localized on the cell surface (Gurewich et al. 1993; Loza et al. 1994) or by platelet-bound plasmin (ogen) (Baeten et al. 2010). The latter mechanism provides a plausible explanation for the interesting observation that platelets enhance clot lysis by scu-PA, but not by u-PA or a mutated scu-PA that cannot be activated to u-PA (Baeten et al. 2010). In thrombin-activated platelets, a complex mechanism has been described whereby thrombin inactivates scu-PA, which is then reactivated by a platelet protease, suggested to be cathepsin C (Nauland and Rijken 1994; Lenich et al. 1997).

Platelet profibrinolytic activity mediated by u-PA is believed to play a major role in a rare bleeding disorder named Quebec platelet disorder (QPD) (reviewed by

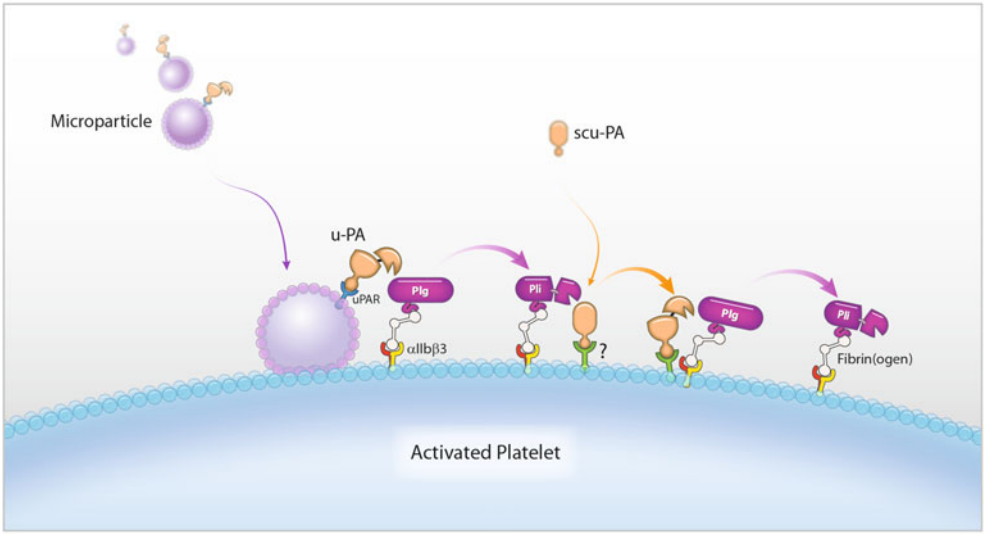

Fig. 6 Main profibrinolytic properties of platelets. Platelets provide a suitable surface for the localization, assembly, and activation of fibrinolytic enzymes. Indeed, plasminogen binds to the platelet surface through the $\alpha_{IIb}\beta_3$-fibrin(ogen) complex and assumes a conformation that is more readily converted to plasmin by plasminogen activators. u-PA expressed on circulating microparticles can activate plasminogen on the platelet surface. Plasmin, in turn, generates additional u-PA activity by cleaving scu-PA, which is bound to platelets by not yet identified receptors. Plasminogen can also be activated by surface-bound t-PA (not shown)

Blavignac et al. 2011). QPD is an autosomal dominant platelet disease with unusual clinical features; it is associated with moderate to severe delayed bleeding, which can be controlled with fibrinolytic inhibitors such as tranexamic acid. The hallmark feature of this disease is the exceedingly high content of u-PA in megakaryocytes and platelets, combined with normal levels of plasma and urinary u-PA. The u-PA content in QPD platelets has been estimated to be more than 100-fold higher than in normal platelets. The enzyme is present in the free form and in complex with PAI-1, suggesting that QPD platelets co-store u-PA with PAI-1 in α-granules (Kahr et al. 2001). The presence of active u-PA is thought to arise from the co-localization of scu-PA and plasminogen within α-granules, which leads to plasmin generation, as indicated by the presence of plasmin–antiplasmin complexes in QPD platelets (Sheth et al. 2003). Intracellular plasmin, in turn, appears to be responsible for the degradation of α-granule storage proteins, including factor V and fibrinogen. Although the bleeding diathesis of QPD patients involves several pathogenetic mechanisms, it is conceivable that the local release of active u-PA into the clot leads to premature lysis of the hemostatic plug (Diamandis et al. 2006; Blavignac et al. 2011).

Other Profibrinolytic Properties

There are other reported mechanisms whereby platelets exert profibrinolytic effects. Dejouvencel et al. (2010), showed that platelet-bound plasminogen is converted to plasmin by u-PA expressed on microparticles derived from monocytes or endothelial cells. This u-PA-driven cross-talk mechanism generates plasmin in situ with higher efficiency than plasminogen activation by u-PA expressed on the same cell surface, thus highlighting its potential relevance in fibrinolysis and matrix proteolysis induced by inflammatory cells or cell-derived microparticles. Moreover, platelets have been shown to upregulate u-PA synthesis by endothelial cells in vitro, an effect that has been attributed to platelet-bound u-PA following its interaction with u-PAR on endothelial cells (Camoin-Jau et al. 2002). Furthermore, platelets can hasten fibrinolysis by indirect mechanisms through the release of platelet factor 4 (PF4) and, paradoxically, polyP. Indeed, as shown by Mosnier (2011), PF4 modulates the substrate specificity of the thrombin–TM complex by inhibiting TAFI activation but not protein C activation, thereby preventing generation of the antifibrinolytic activity of TAFIa. PolyP may drive fibrinolysis by providing a surface for activation of the contact system (Müller et al. 2009). A schematic representation of the main profibrinolytic properties of platelets is shown in Fig. 6.

Effects of Fibrinolysis on Platelets

Plasmin has been extensively investigated in vitro and shown to exert complex and paradoxical effects on platelets, being able to both activate and inhibit platelet functions (reviewed by Coller 1990; Pasche and Loscalzo 1991).

Several variables influence the platelet response to plasmin, including plasmin concentration, temperature, exposure time, and platelet environment. According to numerous reports, high concentrations of plasmin trigger platelet aggregation, calcium mobilization, protein phosphorylation, and activation of protein kinase C and phospholipase C (Schafer et al. 1986; Coller 1990; Pasche and Loscalzo 1991; Loscalzo et al. 1995; Rabhi-Sabile and Pidard 1995; Rabhi-Sabile et al. 1998). As to the mechanism(s) of platelet stimulation, plasmin was shown to activate the protease-activated receptor 4 (PAR-4), but not PAR-1 (Quinton et al. 2004), as previously suggested (Kuliopulos et al. 1999). Moreover, plasmin-induced ADP release might further enhance platelet aggregation by high-dose plasmin (Ishii-Watabe et al. 2000).

In contrast with these findings, exposure to low plasmin concentrations was found to decrease platelet activation in response to several agonists (Coller 1990; Loscalzo et al. 1995; Kinlough-Rathbone et al. 1997). Some investigators have related this effect to plasmin-induced stimulation of adenylate cyclase activity (Adnot et al. 1987) and others to impairment of arachidonic acid metabolism (Schafer and Adelman 1985). Moreover, plasmin was shown to synergize with prostaglandin I_2 (PGI_2) in inhibiting thrombin- and ADP-induced platelet activation (Schafer et al. 1987), a finding of potential importance for the control of platelet accrual at sites of vascular injury, where the release of t-PA and PGI_2 by adjacent endothelial cells is generally increased. Considering the broad specificity of plasmin, it is not surprising that plasmin-induced proteolysis of platelet receptors such as $\alpha_{IIb}\beta_3$ and GPIb has long been considered a major mechanism of platelet dysfunction. The degradation of platelet surface glycoproteins has been documented with both washed platelets (Schafer and Adelman 1985; Coller 1990; Winters et al. 1990; Pasche and Loscalzo 1991; Pasche et al. 1994; Loscalzo et al. 1995) and platelet-rich plasma and is associated with impaired responses to specific platelet agonists (Adelman et al. 1985; Pasche et al. 1994). In addition to these mechanisms, inactivation of the PAR-1 thrombin receptor by plasmin (Kimura et al. 1996) and the generation of fibrin(ogen) degradation products (Torr et al. 1990; Hoffmann and Janssen 1992; Gouin et al. 1992; Huang et al. 1998) have also been suggested to play a role in platelet dysfunction.

Other important factors influencing the platelet response to plasmin in vitro are temperature and exposure time. Lowering the temperature to 22 °C dramatically increases the sensitivity of platelets to plasmin so that low plasmin concentrations result in platelet activation, and very low plasmin doses potentiate the platelet response to other agonists (Lu et al. 1991). Likewise, prolonged (>60 min) exposure of platelets to low doses of plasmin leads to platelet aggregation and enhanced expression of procoagulant activity (Ervin and Peerschke 2001). The influence of temperature on the platelet response to plasmin could be of clinical relevance during open-heart cardiopulmonary bypass surgery (CPB), when blood temperature is reduced. Patients undergoing CPB may experience marked blood loss and prolonged bleeding, which has been attributed to complex hemostatic defects including heightened fibrinolytic activity and platelet activation/consumption (Tanaka et al. 1987; Paparella et al. 2004). It is plausible, therefore, that temperature-dependent, plasmin-induced platelet activation contributes to thrombocytopenia and blood loss during CPB. Consistent with this hypothesis, antifibrinolytic agents have been shown to reduce blood loss in patients undergoing CPB (Koster et al. 2015).

Modulation of platelet function by plasmin could be particularly relevant during thrombolytic therapy. Theoretically, both plasmin-induced platelet activation and platelet dysfunction might occur in vivo in patients undergoing therapeutic thrombolysis. Fibrinolysis-induced platelet activation could represent a potential mechanism for late reperfusion or early reocclusion after initial successful thrombolysis (Leopold and Loscalzo 1995), as also suggested by the observation that the offending thrombus in reoccluded vessels is composed primarily of platelets with very little fibrin (Eccleston and Topel 1995). On the other hand, plasmin-induced platelet dysfunction might contribute to the hemorrhagic complications known to be associated with thrombolytic therapy. Literature data demonstrate that the plasma concentration of platelet-derived substances is often elevated after thrombolysis (Coller 1990; Pasche and Loscalzo 1991; Rasminis et al. 1992; Salvoni et al. 1994; Frandsen et al. 1996). However, there is no consensus about the dynamics of ex vivo platelet status during thrombolytic treatment, with evidence of both platelet activation and inhibition (Coller 1990; Bertolino et al. 1992; Karlberg et al. 1993; Bihour et al. 1995; Lu et al. 1995). Such discrepancies could be related to several factors such as the type of thrombolytic agent, the techniques used to assess platelet function, and the timing of blood sampling. Clinical trials comparing different thrombolytic agents at specified times after thrombolysis have provided a better picture of platelet changes. Early after starting thrombolysis (1–3 h), a reduction in agonist-induced platelet aggregation was found (Moser et al. 1999), the effect being stronger with streptokinase and reteplase (a mutant of t-PA with prolonged half-life) than with alteplase. Analysis of platelet surface receptors (3–6 h) revealed a decrease in $\alpha_{IIb}\beta_3$, P-selectin, and platelet endothelial cell adhesion molecule-1 (PECAM-1), probably reflecting plasmin-induced cleavage (Gurbel et al. 1998; Moser et al. 1999). In contrast, at later intervals (>12 h with peak at 24 h), a marked increase in specific receptor expression was found, which was most pronounced for PECAM-1, very late antigen-2 (integrin $\alpha_2\beta_1$, GPIa/IIa),

and $\alpha_{IIb}\beta_3$. Again, this effect was stronger with reteplase than with alteplase and was associated with an increased aggregation response (Gurbel et al. 1998). A similar effect was reported by Bihour et al. (1995) within the first 72 h after treatment with reteplase, albeit in a small group of patients. Serebruany et al. (2003) compared the effect on platelets of alteplase and tenecteplase (a triple-point mutant of t-PA with longer half-life, enhanced fibrin specificity, and resistance to PAI-1). In vitro, both drugs caused significant inhibition of conventional and whole blood aggregation and decreased the expression of $\alpha_{IIb}\beta_3$, PECAM-1, vitronectin receptor, and the formation of platelet–monocyte aggregates, with tenecteplase exhibiting a stronger antiplatelet activity than alteplase. In patients undergoing thrombolytic therapy, a significant decrease in plasma levels of platelet-released biomarkers was observed in the first 3 h after thrombolysis, which was more marked with tenecteplase than with alteplase. It was suggested that tenecteplase exhibits significantly more powerful antiplatelet properties than alteplase (Serebruany et al. 2003), although ex vivo data on the expression of platelet receptors are lacking. Unfortunately, longer time intervals after thrombolysis (12–24 h) were not investigated in this study and thus it remains unknown whether tenecteplase has the same platelet activating properties as reteplase. The precise mechanisms underlying the platelet changes caused by thrombolytic agents in vivo as well as their impact on clinical manifestations associated with thrombolysis (bleeding, late reperfusion, early reocclusion) remain uncertain. Nevertheless, whatever the mechanism, understanding the temporal relation of phasic changes of platelet function to the administration of fibrinolytic therapy still represents an important task, particularly when considering the concomitant use of antiplatelet drugs to enhance reperfusion.

Putting All Together

It is widely acknowledged that platelets make clots resistant to fibrinolysis. In fact, both in vitro and in vivo studies indicate that platelet-rich thrombi are more resistant than platelet-poor thrombi to both pharmacological thrombolysis and endogenous fibrinolysis. This body of evidence could lead to the conclusion that the antifibrinolytic activities of platelets prevail over the profibrinolytic ones. However, any assumption about the role of platelets based on a mere balance between pro- and antifibrinolytic properties might be flawed. Thanks to recent developments in intravital microscopy imaging approaches, we have learned that platelet activation and function within a thrombus in vivo is heterogeneous both in space and time (Ivanciu and Stalker 2015) and that different platelet populations could play different roles at different times. In order to be effective, the hemostatic plug must form as quickly as possible and must survive long enough to permit the healing process. This implies that the fibrinolytic process must be kept in check for quite a long period to avoid untimely removal of the hemostatic plug, and be activated at the proper time. Platelets are likely to participate in the regulation of fibrin removal by virtue of their multiple pro- and antifibrinolytic properties. Based on current in vitro and in vivo evidence, and on recent findings on the spatiotemporal regulation of platelet and coagulation activation (Ivanciu and Stalker 2015), one can envision the following scenario for how platelets regulate fibrinolysis. Following vascular damage, platelets and fibrin accumulate at the site of injury rapidly and simultaneously (Falati et al. 2002). As the aggregate grows, platelets become activated in a graded fashion extending from the injury site, probably because gradients of platelet agonists are established within the evolving platelet mass. In the in vivo formed thrombus, two main regions can be identified on the basis of platelet activation state, platelet packing density, porosity, thrombin activity, and fibrin deposition: the inner core and the outer shell. The inner core is localized adjacent to the injury site and consists of fully activated, densely packed platelets. High thrombin activity and fibrin deposition characterize this area. Here, fibrinolytic resistance is largely dependent on clot retraction, release of PAI-1 and other antifibrinolytic factors, and enhancement of thrombin formation, with the consequent activation of TAFI and FXIIIa-mediated crosslinking of α_2-AP to fibrin. In addition, dense platelet packing creates sheltered microenvironments between platelets, which, on the one hand, are important harbors for platelet releasates, and, on the other hand, greatly reduce the transport of plasma solutes into the spaces between platelets. The outer shell surrounds the inner core and consists of loosely packed, partially activated platelets, which retain their α-granules, generate little thrombin activity and promote little, if any, fibrin formation. Conceivably, this region displays low fibrinolytic resistance and is susceptible to disaggregation by shear stress forces. A third distinct population of activated platelets is found close to collagen fibers and as patches around the thrombus (Heemskerk et al. 2013). These platelets are characterized by surface-exposed PS, rounded structure, raised cytosolic Ca^{2+}, and the ability to bind coagulation factors (Munnix et al. 2007; Berny et al. 2010). They support thrombin generation and fibrin formation but, at variance with fully activated platelets within the inner core, are unlikely to induce clot retraction because they do not exhibit activated $\alpha_{IIb}\beta_3$ (Kulkarni and Jackson 2004; Munnix et al. 2009). Thus, in these specific areas, fibrinolytic resistance is mainly dependent on thrombin formation and release of intraplatelet inhibitors.

In physiological hemostasis, the mechanisms leading to fibrinolytic resistance are limited in time because thrombin generation and the related antifibrinolytic effects gradually

decay as a result of the action of natural inhibitors. Moreover, the fibrinolytic inhibitors accumulated within the clot, chiefly PAI-1 and crosslinked α_2-AP, become progressively saturated by the continuous influx of plasminogen activators released by endothelial cells or delivered by circulating microparticles (Dejouvencel et al. 2010; Lacroix et al. 2012) and by the generation of plasmin. This leads to a switch from an anti- to a profibrinolytic state and the true lytic phase may eventually take place. Platelets might also participate in this lytic phase, allegedly through plasminogen binding and enhancement of plasmin generation. As shown by in vivo studies, plasminogen binding commences early after vessel injury, is highest within the platelet-rich inner core of the nascent thrombus, and is associated with plasmin formation (Brzoska et al. 2015). However, plasmin generation does not lead to detectable thrombus lysis in the early phases (Brzoska et al. 2015), supporting the idea that at this stage there is an excess of inhibitors within the thrombus. With time, the continuous binding and activation of plasminogen can overcome the inhibitors and initiate the lytic phase. In addition, as already pointed out, platelets can further modulate fibrinolysis through cross-talk with other blood and vascular cells and cell-derived microparticles. It is noteworthy that, in a model of arterial thrombosis, fibrin degradation coincides with leukocyte binding to the thrombi via interaction of leukocyte P-selectin glycoprotein ligand-1 with P-selectin on the surface of activated platelets (Bai et al. 2009). Better knowledge of the complex spatiotemporal regulation of endogenous fibrinolysis and pharmacological thrombolysis by platelets has important pathophysiological implications and should help improve therapeutic strategies for disease states encompassing bleeding and thrombotic disorders.

Take Home Messages

1. Platelets have the potential to both down- and upregulate the fibrinolytic process
2. Antifibrinolytic effects of platelets are mediated mainly by:
   a. Clot retraction, which makes the fibrin mesh stiffer and more resistant to lysis
   b. Release of several inhibitors of fibrinolysis, including huge amounts of plasminogen activator inhibitor-1 (PAI-1)
   c. Enhancement of thrombin formation, which in turn modifies the fibrin structure to make the clot denser and more resistant to fibrinolysis. Thrombin, moreover, activates two important enzyme precursors, namely factor XIII and thrombin-activatable fibrinolysis inhibitor (TAFI), which stabilize the clot and inhibit plasmin generation on the fibrin surface
3. Platelet profibrinolytic activities include:
   a. Release of plasminogen activators
   b. Binding of plasminogen and enhancement of plasminogen activation
4. In the hemostatic process, the antifibrinolytic activities of platelets contribute to protection of the hemostatic plug from premature lysis. At later stages, platelets might hasten fibrinolysis through enhancement of plasminogen activation
5. In thrombotic diseases, particularly arterial thrombosis, platelets increase resistance to fibrinolysis/thrombolysis, thus favoring thrombus persistence

Platelets and Immunity

Ingrid Slaba and Paul Kubes

Abstract

Over the last several decades, a new paradigm of platelet function has evolved. Platelets, long forgotten hemostatic cells, were demonstrated to be versatile immune effector cells engaged in every compartment of the immune system. Platelets express multiple immune receptors, such as toll-like receptors, allowing them to sense both pathogen- and danger-associated signals. Upon activation, platelets release a large array of biologically active molecules, like cytokines, chemokines, and growth factors, many of which are delivered in platelet-derived microparticles. Rich platelet transcriptome allows for signal-dependent translation and protein synthesis, and platelets are considered the main source of circulating microRNA. Platelets avidly interact with immune cells, endothelial cells, neutrophils, and monocytes in particular. Platelets were shown to propagate and modulate the inflammatory response of other immune cells in sterile inflammatory diseases, such as atherosclerosis and metabolic diseases, acute lung injury, ischemia reperfusion, and autoimmune diseases. Platelets are directed to the sites of infection and directly interact with pathogens. They contribute to elimination of pathogens by phagocytosis, release of microbicidal peptides, and signaling to other immune cells. Their interaction with neutrophils triggers release of neutrophil extracellular traps, a potent mechanism to entrap bacteria in flowing blood. Platelets were recently shown to be involved in adaptive immunity and possibly link innate and adaptive responses together. Fast flowing in the bloodstream, readily available for cellular interactions, able to sense signals from pathogens and damaged tissue, and packed with multiple immune mediators, platelets arise as immune sentinels forming an integral part of our immune system.

List of Symbols, Abbreviations, and Nomenclature

ADP	Adenosine diphosphate
AGEs	Advanced glycation end products
ALI	Acute lung injury
ATP	Adenosine triphosphate
C1	C1 esterase inhibitor
CCL2	Chemokine (C–C motif) ligand 2, or monocyte chemotactic protein 1 (MCP-1)
CCL3	Chemokine (C-C motif) ligand 3, or macrophage inhibitory protein 1 alpha (MIP-1α)

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_34

CCL5	Chemokine (C-C motif) ligand 5, or regulated on activation, normal T cell expressed and secreted (RANTES)
CCL7	Chemokine (C-C motif) ligand 7, or monocyte chemotactic protein 3 (MCP-3)
CCL17	Chemokine (C-C motif) ligand 17, or thymus- and activation-regulated chemokine (TARC)
CCR1	C–C chemokine receptor type 1, or CD191
CCR3	C–C chemokine receptor type 3, or CD193
CCR4	C–C chemokine receptor type 4, or CD194
CD11a/CD18	Lymphocyte function-associated antigen 1, or LFA-1
CD11b/CD18	Macrophage antigen 1, or Mac-1
CD14	Cluster of differentiation 14
CD154	Cluster of differentiation 154, or CD40L
CD31	Cluster of differentiation 31, or PECAM-1
CD36	Cluster of differentiation 36
CD40	Cluster of differentiation 40
CD40L	Cluster of differentiation 40 ligand; or CD154
CD41	Cluster of differentiation 41
CD8+	T cells expressing cluster of differentiation 8 on their surface
circRNA	Circular ribonucleic acid
CLEC-2	C-type lectin-like receptor 2
CXCL1	Chemokine (C-X-C motif) ligand 1, or GRO1 oncogene, GROα, KC, neutrophil-activating protein 3 (NAP-3), melanoma growth stimulating activity, alpha (MGSA-α)
CXCL4	Chemokine (C-X-C motif) ligand 4, or platelet factor 4 (PF4)
CXCL5	Chemokine (C-X-C motif) ligand 5, or ENA-78
CXCL7	Chemokine (C-X-C motif) ligand 7, or beta thromboglobulin 1 (βTG1), pro-platelet basic protein (PPBP)
CXCL8	Chemokine (C-X-C motif) ligand 8, interleukin 8 (IL-8)
CXCL16	Chemokine (C-X-C motif) ligand 16
CXCR4	C-X-C chemokine receptor type 4, or CD184
DAMPs	Damage-associated molecular patterns
DC(s)	Dendritic cell(s)
DNA	Deoxyribonucleic acid
EAE	Experimental autoimmune encephalitis
EMCV	Encephalomyocarditis virus
ENA-78	Epithelial-derived neutrophil-activating peptide 78, or CXCL5
Factor V, VII, XI, XIII	Coagulation factors V, VII, XI, XIII
FcγRIIA	Immunoglobulin receptor Fc gamma IIA, or CD32
FoxP3	Forkhead box P3, or scurfin
FPR	Formyl peptide receptor
FPR1	*N*-formyl peptide receptor 1
FPR-L1	*N*-formyl peptide receptor like 1
GPIb	Glycoprotein Ib
GPIb-V-IX	Membrane glycoprotein Ib, V and IX complex
GPIbα	Glycoprotein Ib alpha
GPIIb	Glycoprotein IIb, or integrin αIIb
GPIIbIIIa	Glycoprotein IIbIIIa
GPVI	Glycoprotein VI
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HIV	Human immunodeficiency virus
HMGB-1	High-mobility group box 1
HSPs	Heat shock proteins
ICAM-1	Intercellular adhesion molecule 1
ICAM-2	Intercellular adhesion molecule 2, or CD102
IFNα	Interferon alpha
IgG	Immunoglobulin G
IgM	Immunoglobulin M
IL-1β	Interleukin-1 beta
IL-1R	Interleukin-1 receptor
IL-1α	Interleukin-1 alpha
IL-6	Interleukin 6
IL-8	Interleukin 8, or CXCL8
IL-10	Interleukin 10
IL-12p70	Interleukin 12, or cytotoxic lymphocyte maturation factor (CLMF)
JAM-3	Junctional adhesion molecule 3
JAM-C	Junctional adhesion molecule C
LFA-1	Lymphocyte function-associated antigen 1; or CD11a/CD18
LCMV	Lymphocytic choriomeningitis virus
LPS	Lipopolysaccharide
Mac-1	Macrophage antigen 1, or CD11b/CD18
MD2	Lymphocyte antigen 96
MCP-1	Monocyte chemotactic protein 1, or chemokine (C-C motif) ligand 2 (CCL2)
MCP-3	Monocyte chemotactic protein 3, or chemokine (C-C motif) ligand 7 (CCL7)
MHC	Major histocompatibility complex
MIP-1α	Macrophage inhibitory protein 1 alpha, or chemokine (C-C motif) ligand 3 (CCL3)

mRNA	Messenger ribonucleic acid
miRNA	Micro ribonucleic acid
MS	Multiple sclerosis
MyD88	Myeloid differentiation primary response gene 88
NET(s)	Neutrophil extracellular trap(s)
NFkB	Nuclear factor kappa B
NK cells	Natural killer cells
OLT	Orthotopic liver transplantation
P2Y12	Platelet adenosine diphosphate (ADP) receptor 12
PAF	Platelet-activating factor
PAMPs	Pathogen-associated molecular patterns
PAI-1	Plasminogen activator inhibitor 1
PDGF	Platelet-derived growth factor
PECAM-1	Platelet-endothelial cell adhesion molecule 1
PF4	Platelet factor 4, or CXCL4
PPARγ	Peroxisome proliferator-activated receptor gamma
pre-mRNA	Pre-messenger ribonucleic acid
PRRs	Pathogen recognition receptors
PSGL-1	P-selectin glycoprotein ligand 1
RA	Rheumatoid arthritis
RAGE	Receptor for advanced glycation end products
RANTES	Regulated on activation, normal T cell expressed and secreted, or CCL5
RES	Reticuloendothelial system
RNA	Ribonucleic acid
ROS	Reactive oxygen species
SLE	Systemic lupus erythematosus
SSRI	Selective serotonin reuptake inhibitors
TF	Tissue factor
TFPI	Tissue factor pathway inhibitor
TGF-β	Transforming growth factor beta
TLR1	Toll-like receptor 1
TLR2	Toll-like receptor 2
TLR3	Toll-like receptor 3
TLR4	Toll-like receptor 4
TLR5	Toll-like receptor 5
TLR6	Toll-like receptor 6
TLR7	Toll-like receptor 7
TLR9	Toll-like receptor 9
TLR(s)	Toll-like receptor(s)
TNF	Tumor necrosis factor
TNFα	Tumor necrosis factor alpha
tRNA	Transfer ribonucleic acid
T_{reg}	T regulatory cells
TSP-1	Thrombospondin-1
TXA_2	Thromboxane A2
VASP	Vasodilator-stimulated phosphoprotein
VCAM-1	Vascular cell adhesion molecule 1; or CD106
VEGF	Vascular endothelial growth factor
vWf	Von Willebrand factor
α2β1	Integrin α2β1, or GPIa/IIa
α5β1	Integrin α5β1
α6β1	Integrin α6β1
αIIβ3	Intergrin αIIβ3, or glycoprotein IIb/IIIa, GPIIbIIIa
αvβ3	Integrin αvβ3, or CD51/CD61
βTG	Beta thromboglobulin, or CXCL7

Introduction

The role of platelets as principal cells of thrombosis and hemostasis has been studied for several decades and is quite well understood. However, there is increasing evidence that platelets are active players in many other physiological functions, including inflammation, infection, wound healing, maintenance of endothelial barrier function, angiogenesis, and tumor metastasis (Gay and Felding-Habermann 2011; Nachman and Rafii 2008; Nurden 2011; Sabrkhany et al. 2011; Semple et al. 2011; Smyth et al. 2009; Yeaman 2010).

The role of platelets in immunity, infection, and inflammation is now being studied intensively, and results of this research are substantially changing our understanding of platelet functions. The ability of the platelet to adhere, form aggregates, and release mediators creates the perfect opportunity for platelets to be actively involved in the inflammatory response. Also, platelets are abundant in the bloodstream and readily available for activation and adhesive cellular interactions. Platelets were shown to become activated by various inflammatory mediators, be the source of chemokines and cytokines, express adhesion molecules, recruit immune cells to sites of vascular injury and inflammation, and directly kill bacteria and parasite-infected cells (Andonegui et al. 2005; Bombeli et al. 1998; Faull et al. 1994; McMorran et al. 2012; Semple et al. 2011; Smyth et al. 2009; Yeaman 2010; Zarbock et al. 2007). Platelets binding to adherent and activated neutrophils induce neutrophil extracellular trap (NET) formation to ensnare bacteria in septic blood. NETs consist of chromatin, histones, and elastase, and besides their powerful protection against pathogens, they also might cause injury to the host (Clark et al. 2007; McDonald et al. 2012). Interestingly, NETs were documented also in sterile conditions, like thrombosis (Fuchs et al. 2010, 2012). It is becoming evident that platelets are not only passive bystanders but more essential players in the inflammatory response. Current knowledge about the role of platelets in inflammation, infection, and immunity has been summarized by numerous recent

comprehensive reviews (Klinger and Jelkmann 2002; Weyrich et al. 2003; Weyrich and Zimmerman 2004; Elzey et al. 2005; Gawaz et al. 2005; Fitzgerald et al. 2006; Zarbock et al. 2007; Menezes et al. 2009; Smyth et al. 2009; Leslie 2010; Semple and Freedman 2010; Yeaman 2010; Nurden 2011; Semple et al. 2011; Huang and Chang 2012; Li et al. 2012; Projahn and Koenen 2012; Vieira-de-Abreu et al. 2012; Engelmann and Massberg 2013; Garraud et al. 2013; Ioannou et al. 2013; Jenne et al. 2013a; Mantovani and Garlanda 2013; Rondina et al. 2013; Verschoor and Langer 2013; Herter et al. 2014; Morrell et al. 2014; Rondina and Garraud 2014; Speth et al. 2014; Weyrich 2014; Yeaman 2014; Chabert et al. 2015; Garraud and Cognasse 2015; Hamzeh-Cognasse et al. 2015; Jenne and Kubes 2015; Lam et al. 2015; Thomas and Storey 2015).

Platelet contribution to immunity has been evaluated both in innate and adaptive responses. In sterile inflammation, platelets were studied in models of non-evolutionary, iatrogenic, or lifestyle-induced sterile injury, wherein dysregulated inflammation leads to inappropriate injury. This includes conditions like atherosclerosis, ischemia/reperfusion as happens in myocardial infarction, bowel ischemia, acute liver injury, or post liver transplantation, acute lung injury, fatty liver disease, and autoimmune diseases (Esch et al. 2010; Habets et al. 2013; Kohler et al. 2011a, b; Langer et al. 2012; Lievens and von Hundelshausen 2011; Salter et al. 2001; Zaldivar et al. 2010; Zarbock and Ley 2009). All of these conditions are caused by bad diet, clinical interventions, or toxicity and are not related to healthy repair. Under these dysregulated conditions, blocking either neutrophils or platelets leads to an improved outcome (Kohler et al. 2011a; Liu et al. 2011; Rossaint et al. 2014; Salter et al. 2001; Zarbock et al. 2006). Platelets also contribute to pathogenesis of autoimmune diseases, like rheumatoid arthritis, systemic lupus erythematosus, and multiple sclerosis, wherein dysregulated immunity is again a key feature (Boilard et al. 2010, 2012; Langer et al. 2012). Recent discoveries about platelet involvement in adaptive immune responses suggest that platelets might link innate and adaptive responses (Elzey et al. 2005; Morrell et al. 2014).

Although very poorly understood, platelet-neutrophil interactions in traumatic injury seem to be essential for successful healing (Slaba et al. 2015). In bacterial, viral, and parasitic infections, platelets have been shown to be an indispensable part of host defense. They contribute to elimination of pathogens by signaling to other immune cells as well as by direct platelet-derived defensive mechanisms, including direct bacterial killing (Jenne and Kubes 2015; Klinger and Jelkmann 2002; Yeaman 2010). It is becoming evident that platelets are not only linking hemostasis and thrombosis with inflammation and wound healing (Gawaz and Vogel 2013; Nurden 2011; Zarbock et al. 2007), but they are also involved in immune responses very broadly. Platelets may very likely be the most versatile effector cells in the immune continuum (Vieira-de-Abreu et al. 2012).

Sensing Inflammatory Stimuli

Pathogen Recognition Receptors Expressed by Platelets

In infection and sterile inflammation pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) are sensed by immune cells via pathogen recognition receptors (PRRs) (Kono and Rock 2008). Sensing these stimuli is the first step of the immune response during inflammation. Platelets express several types of PRRs—toll-like receptors (TLRs) 1, 2, 3, 4, 5, 6, 7, 9, CD14, CD40, and formyl peptide receptor (FPR) (Semple and Freedman 2010). TLRs represent a key family of inflammatory receptors binding a wide variety of ligands from both pathogens and damaged tissue. The discovery of TLRs on platelets represents an important milestone in understanding the role of platelets in inflammation and immunity. Messenger ribonucleic acid (mRNA) and protein levels of TLRs, as well as functional responses of platelets to TLR ligands, have been reported (Anabel et al. 2014; Andonegui et al. 2005; Aslam et al. 2006; Cognasse et al. 2005, 2008, 2015; Shiraki et al. 2004; Stahl et al. 2006; Ward et al. 2005; Zhang et al. 2009). Expression of TLRs on the platelet surface is mainly constitutive, although some TLRs, like TLR2 and 9, are upregulated upon platelet activation (Aslam et al. 2006). TLR4 has been the most studied toll-like receptor on platelets. Andonequi et al. first demonstrated that platelet TLR4 contributed to neutrophil-dependent platelet sequestration to the lung vasculature in response to lipopolysaccharide (LPS) (Andonegui et al. 2005). Their findings were extended by Aslam et al., who showed that platelet binding to LPS via TLR leads to thrombocytopenia and tumor necrosis factor alpha (TNFα) production (Aslam et al. 2006). In fact, platelets were shown to express all components of the LPS receptor signaling pathway, including TLR4, CD14, MD2, and MyD88. Although some investigators have reported that LPS leads to P-selectin expression, platelet aggregation, and mediator secretion (Zhang et al. 2009), others have found that LPS induces a different platelet phenotype. For example, engagement of platelet TLR4 was shown to cause platelet binding to neutrophils, without platelet aggregation, with subsequent release of NETs—a robust mechanism to ensnare bacteria in septic blood (Clark et al. 2007; Ma and Kubes 2008). Numerous groups have shown that exposure of platelets to pathogens or engagement of PRRs on the platelet surface has

many functional consequences including increase in intracellular calcium, platelet adhesion to collagen, platelet aggregation, glycoprotein IIb/IIIa (GPIIbIIIa) expression, and cytokine release (Aslam et al. 2006; Blair et al. 2009; Clawson and White 1971; Cognasse et al. 2008; Matera et al. 1992; Zhang et al. 2009; Zhu et al. 2012). Interestingly, platelets were shown to discriminate between various external signals through a single type of PRR and adjust their response by releasing different cytokines (Berthet et al. 2012). Besides TLR and LPS receptor signaling, thrombin-activated platelets were demonstrated to express functional FPR on their surface, and binding of *N*-formylated peptides mobilized calcium pools and induces platelet chemotaxis (Czapiga et al. 2005). However, it is important to recognize that a lot of studies use supraphysiological concentrations of stimuli raising issues of relevance.

Release of Inflammatory Mediators

Secretion of inflammatory mediators is an important mechanism by which platelets deliver signals to leukocytes, monocytes, endothelial cells, and other target cells. Platelet granules store over 1000 proteins, peptides, biologically active lipids, and eicosanoids, which are translocated to the platelet membrane and released upon platelet activation (Zufferey et al. 2012). Many of these substances are pro-inflammatory and contribute to intercellular signaling and inflammatory response at the local and systemic level (Weyrich and Zimmerman 2004). The capacity of the platelets to synthesize lipid mediators such as thromboxane A_2 (TXA_2) and platelet-activating factor (PAF) has been known for many years. However, the signal-dependent translation of interleukin-1 beta (IL-1β) by platelets has only recently been discovered (Freedman 2008; Lindemann et al. 2001; Weyrich et al. 2009; Weyrich and Zimmerman 2004).

Platelet Secretome

Platelets contain several types of granules with a number of important molecules released upon activation (Jurk and Kehrel 2005; Rendu and Brohard-Bohn 2001). Platelet dense bodies (δ-granules) contain strong amplifiers of platelet hemostatic response such as the nucleotides, adenosine triphosphate (ATP) and adenosine diphosphate (ADP), amines, bivalent cations, histamine, and serotonin, the latter two also being involved in monocyte and T cell signaling (Dale et al. 2002; Gachet 2001; Leon-Ponte et al. 2007; Nesbitt et al. 2003; Soga et al. 2007a, b). Platelet α-granules contain adhesion molecules such as von Willebrand factor (vWf), thrombospondin-1 (TSP-1), vitronectin, fibronectin, platelet-endothelial adhesion molecule-1 (PECAM-1, CD31) and GPIIbIIIa, mitogenic factors (platelet-derived growth factor (PDGF)), vascular endothelial growth factor (VEGF), transforming growth factor beta (TGF-β)), coagulation factors (V, VII, XI, XIII, fibrinogen, plasminogen, protein S), protease inhibitors (C1, plasminogen activator inhibitor 1 (PAI-1), tissue factor pathway inhibitor (TFPI)), and chemokines (CCL3, 5, 7, 17 and CXCL1, 4, 5, 7, 8) (Blair and Flaumenhaft 2009). Recently, key proteins of the major histocompatibility complex class I (MHC class I) antigen-presenting pathway, such as β2-microglobulin, 26S protease regulatory subunit 10B from the proteasome, and proteins 1 and 2 from the transporter associated with antigen processing, were identified in α-granules (Zufferey et al. 2014). Platelet α-granules are diversified into distinct populations which allows differential release of active molecules in response to various stimuli (Italiano et al. 2008; Sehgal and Storrie 2007). Molecules in α-granules are either soluble or membrane bound being exposed on the platelet membrane after exocytosis. Many of the α-granule proteins are also constitutively expressed on platelet membranes, including GPIIbIIIa, glycoprotein VI (GPVI), PECAM, and glycoprotein Ib-V-IX complex (GPIb-V-IX). Others, such as P-selectin, are exclusively expressed in α-granules, being exposed on the platelet surface only after platelet activation (Maynard et al. 2007). Platelet lysosomes contain proteases, glycosidases, and cationic proteins with bactericidal activity (Rendu and Brohard-Bohn 2001). Recent work suggests that at least some of the platelet proteins are systematically stored and organized within the granules in the form of sub-granule vesicles or microparticles, each microparticle containing one specific protein (Zhang and Yang 2012).

Upon activation, platelets secrete a number of potent procoagulant, pro-inflammatory, and mitogenic substances which modulate functions of other platelets, leukocytes, and endothelial cells: chemokines, cytokines (IL-1β, CD40L, β-thromboglobulin (βTG)), growth factors, and coagulation factors. These mediators participate in cell survival, proliferation, coagulation and fibrinolysis, chemotaxis, and cell adhesion (Zarbock et al. 2007). Platelet mediators secreted in soluble form act mainly in a paracrine or in an endocrine manner. However, some of the mediators act in a juxtacrine manner—retained on the platelet membrane bound to receptor and available for intercellular signaling (Vieira-de-Abreu et al. 2012).

CXC chemokines secreted by platelets are represented by platelet factor 4 (PF4, CXCL4), βTG (CXCL7), and interleukin 8 (IL-8, CXCL8). CXC chemokines induce chemotaxis of neutrophils, although more importantly, when secreted from platelets immobilized to the vessel wall, together with rapidly synthesized PAF, they trigger activation of rolling neutrophils and their firm adhesion to

endothelial cells via β_2 integrins (Brandt et al. 2000; McIntyre et al. 2003). PF4 and βTG are recognized by CXC receptors 1 and 2 on neutrophils, and they might provide both stimulatory and inhibitory effects (Boehlen and Clemetson 2001; Brandt et al. 2000; Elstad et al. 1995; McIntyre et al. 2003).

CC chemokines enhance paracrine activation of platelets and increase activation of neutrophils (Brandt et al. 2000; Cheng et al. 2001). CCL5 (regulated on activation, normal T cell expressed and secreted, RANTES, or fractalkine) not only activates platelets but also directly targets many other inflammatory cells—neutrophils, monocytes, eosinophils, basophils, natural killer (NK) cells, T lymphocytes, and dendritic cells (DCs). RANTES secreted and deposited by adherent platelets or platelets associated with monocytes in heterotypic aggregates promotes adhesion of monocytes to the endothelium, their activation, and chemokine and cytokine secretion (Schober et al. 2002; Weyrich et al. 1995, 1996). Macrophage inflammatory protein 1 alpha (MIP-1α, CCL3) which targets multiple immune cells—monocytes, eosinophils, basophils, NK cells, CD8+ T lymphocytes, and DC subsets—induces chemotaxis. It can also release histamine from basophils. Monocyte chemotactic protein 3 (MCP-3, CCL7) has similarly diverse effects (Baggiolini and Dahinden 1994; Taub et al. 1993; Weyrich et al. 1996; Weyrich and Zimmerman 2004). Interestingly, platelets display CXC and CC chemokine receptors (CXCR4, CCR1, CCR3, CCR4) on their surface which might suggest autocrine and/or bidirectional paracrine signaling (Boehlen and Clemetson 2001). A comprehensive and updated overview of platelet chemokines was recently published by Karshovska et al. (2013).

Platelet-associated cytokine CD40L (CD154) is a transmembrane protein of the tumor necrosis factor (TNF) family, recognized by CD40 receptor on B lymphocytes, monocytes, endothelial cells, and platelets. CD40L-CD40 complex is recognized as a major mechanism in immune regulation (Blumberg et al. 2009; Henn et al. 1998). Platelet-derived CD40L induces chemokine secretion and upregulation of adhesion molecules on endothelial cells, mediates immunoglobulin M (IgM) to immunoglobulin G (IgG) isotype switch in B cells and DC maturation, and augments T cell responses (Elzey et al. 2003; Henn et al. 1998). Some authors have also suggested reciprocal intercellular signaling of platelets and other cells expressing components of the CD40L-CD40 system (Danese et al. 2004).

The above highlights the huge diversity of the platelet secretome. Although all these factors are made by platelets, whether they are the primary source of these cytokines in blood in the context of inflammation remains controversial. However, unexpectedly high local concentrations of some of the chemokines surrounding activated and aggregated platelets suggest that platelets might be the primary source of these chemokines (Boehlen and Clemetson 2001). Under certain circumstances such as in patients with immune thrombocytopenia, platelets might be the principle source of released cytokines (Andersson et al. 2000; Semple et al. 2011; Stasi et al. 2008).

Platelet Transcriptome

In addition to secretion of the granule content, activated platelets have also synthetic capacities. The ability of activated platelets to synthesize lipid mediators such as TXA_2 and PAF is well known (Weyrich and Zimmerman 2004). However, their capacity to synthesize proteins was not recognized until recently (Weyrich et al. 2009). IL-1β, one of the most important regulators of inflammatory responses, is produced by activated platelets in a process described as a signal-dependent translation (Lindemann et al. 2001; Weyrich et al. 2003). IL-1β pre-messenger RNA (pre-mRNA) is incorporated into proplatelets by megakaryocytes during thrombopoiesis together with functional spliceosome (Denis et al. 2005). Upon platelet activation by platelet agonists, LPS, or engagement of platelet integrins, Fc receptors or TLR4, pre-mRNA is spliced into the mature IL-1β transcript and translated into the protein. IL-1β is secreted by platelets in both a paracrine and juxtacrine manner, incorporated into the fibrin mesh or shed in the form of IL-1β positive microparticles (Brown and McIntyre 2011; Denis et al. 2005; Lindemann et al. 2001; Qian et al. 2008; Shashkin et al. 2008). Synthesis and secretion of IL-1β by platelets was shown to be abolished by inhibition of $\alpha_{IIb}\beta_3$ integrin (GPIIbIIIa) suggesting direct linkage between hemostasis and inflammation (Lindemann et al. 2001). The presence of regulatory mechanisms of IL-1β secretion by platelets suggests that platelets are an important source of this cytokine (Denis et al. 2005; Lindemann et al. 2001).

Receptors for IL-1β are present on a large number of immune cells which makes secretion of IL-1β by platelets potentially a very important mechanism for the inflammatory response. The principal target cells for platelet-derived IL-1β are endothelial cells. IL-1β induces secretion of chemokines (CXCL8, CCL2), cytokines (IL-6, IL-8, epithelial neutrophil-activating protein 78 (ENA-78)), and endothelial adhesion molecules (E-selectin, vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule 1 (ICAM-1), integrin $\alpha_v\beta_3$) leading to amplification and propagation of the inflammatory response by recruitment and activation of neutrophils and monocytes (Gawaz et al. 2000; Hawrylowicz et al. 1991). IL-1β represents a major danger signal for dendritic cells inducing their maturation and activation. Thus, local release of IL-1β by

platelets might represent an important signal to dendritic cells linking innate and adaptive immune responses (Gallucci and Matzinger 2001). It has recently been shown that platelets express interleukin-1 receptor 1 (IL-1R1) on which IL-1β acts as an agonist promoting its own synthesis through an autocrine stimulatory loop. Interestingly, this IL-1β autocrine loop was required to amplify platelet activation induced by LPS (Brown et al. 2013).

Recently, the platelet transcriptome has been under intensive investigation. Platelets were shown to contain a wide array of RNAs: messenger RNA (mRNA), transfer RNA (tRNA), microRNA (miRNA), long noncoding RNA, and, more recently, circular RNA (circRNA) (Alhasan et al. 2016; Bray et al. 2013; Edelstein et al. 2013). Surprisingly, this rich platelet transcriptome was found to have only a weak correlation with the platelet proteome (Londin et al. 2014). Platelet miRNA was proposed to be a regulatory mechanism of platelet mRNA and protein expression levels and the main source of circulating miRNA. Thus, circulating miRNA originating from platelets may serve as a biomarker of platelet function. Moreover, circulating miRNA may play an important role in modulating the function of other cells, particularly immune cells (Lindsay and Edelstein 2016; McManus and Freedman 2015). CircRNA was proposed to be a degradation product of the platelet transcriptome, although biological effects outside of platelets cannot be excluded (Alhasan et al. 2016; Provost 2016). However, while our knowledge of the platelet transcriptome has markedly evolved over the last several years, its significance in immunity has to be further elucidated.

Platelet-Derived Microparticles

Microparticles are small (<1 μm), spherical secretory organelles of lipid composition (Cocucci et al. 2009; Nomura et al. 2008). Microparticles are shed from erythrocytes, leukocytes, platelets, and endothelial cells. However, 80 % of circulating microparticles originate from platelets (Horstman and Ahn 1999). Platelet-derived microparticles are usually smaller than 500 nm, the main populations being 100–250 nm in size (Aatonen et al. 2014). Microparticles could be derived both from activated and nonactivated or apoptotic platelets (Cauwenberghs et al. 2006; Morel et al. 2011; Vasina et al. 2011). Platelet-derived microparticles were shown to be an important transport mechanism for platelet-secreted pro-inflammatory and prothrombotic molecules, including tissue factor (TF), CD40L, IL-1β, or RANTES (Boilard et al. 2010; Elzey et al. 2005; Mause et al. 2005; Zwicker et al. 2011). Some authors have recently demonstrated that platelet-derived microparticles might also transport transcription factors such as nuclear factor kappa B (NFkB) and peroxisome proliferator-activated receptor gamma (PPARγ) (Lannan et al. 2015). Moreover, platelet microparticles could deliver platelet miRNA to target cells, especially endothelial cells and possibly other cells, such as neutrophils, and therefore alter gene expression in those cell types (Laffont et al. 2013; Lindsay and Edelstein 2016; Semple 2013). Detailed proteomic analysis has revealed that platelet activation pathways determine the number and the content of formed microparticles (Aatonen et al. 2014). A recent study showed that microparticles might not only represent a transport mechanism but also a storage system within platelet granules (Zhang and Yang 2012).

Platelets Recruit Immune Cells

Platelets possess a wide repertoire of adhesion molecules, β1 and β3 integrins ($\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_{IIb}\beta_3$ (GPIIbIIIa), and $\alpha_v\beta_3$), membrane glycoproteins (GPIb-V-IX, GPIIbIIIa ($\alpha_{IIb}\beta_3$ integrin), GPVI), selectins (P-selectin and P-selectin glycoprotein ligand 1, PSGL-1), and vWf, which allows them to directly interact with endothelial cells, neutrophils, and monocytes (Bennett 2005; Bennett et al. 2009; Kansas 1996; Ruggeri 2003; Zarbock et al. 2007).

Platelets Recruit Neutrophils

It has been well known for many years that platelets can recruit neutrophils to the endothelium via so-called secondary capture. Neutrophil rolling, firm adhesion, and transmigration are distinct steps in the recruitment process. Platelets adherent to the endothelium express P-selectin which tethers neutrophils to the vessel wall. Neutrophil rolling on adherent platelets is mediated by interaction of platelet P-selectin with neutrophil PSGL-1 (Yang et al. 1999). The production of PAF activates integrins on neutrophils and allows them to firmly adhere to immobilized platelets (McIntyre et al. 2003; Ostrovsky et al. 1998; Weber and Springer 1997). The integrins involved include macrophage-1 antigen (Mac-1, CD11b/CD18) on neutrophils and GPIIbIIIa or GPIbα on platelets, although some authors have reported that lymphocyte function-associated antigen 1 (LFA-1, CD11a/CD18) which binds to intercellular adhesion molecule 2 (ICAM-2) on platelets also plays a role (Diacovo et al. 1994, 1996; Evangelista et al. 1996; McIntyre et al. 2003; Piccardoni et al. 1996; Simon et al. 2000; Weber and Springer 1997; Zarbock et al. 2007). This mechanism of neutrophil recruitment has been demonstrated in numerous diseases including acute lung injury, ischemia reperfusion in the bowel and kidney, autoimmune glomerulonephritis, and cholestatic hepatitis. Platelet depletion, as well as P-selectin and GPIIbIIIa blockade, significantly decreased the number of

neutrophils recruited to the site of injury and improved outcome of a dysregulated immune response (Devi et al. 2010; Laschke et al. 2008; Salter et al. 2001; Singbartl et al. 2000; Zarbock and Ley 2009; Zarbock et al. 2006, 2007).

Platelets Recruit Monocytes

Similarly, platelets adherent to the endothelium recruit circulating monocytes through P-selectin/PSGL-1 interactions. Secretion and deposition of RANTES promote firm adhesion of monocytes (Kuijper et al. 1998; Schober et al. 2002; von Hundelshausen et al. 2001; Weyrich et al. 2002). Integrins involved in firm adhesion of monocytes to platelets involve Mac-1 on monocytes and GPIbα on platelets, although some authors have suggested that other receptors—ICAM-2, junctional adhesion molecule 3 (JAM-3), and GPIIbIIIa via fibrinogen bridges—might also play a role (Diacovo et al. 1994; Santoso et al. 2002; Simon et al. 2000). The exact importance of each of these molecules remains to be delineated, and this is not trivial as this mechanism of monocyte recruitment by platelets has been described in atherosclerosis and vascular restenosis (Gawaz et al. 2005; Lievens and von Hundelshausen 2011; Wang et al. 2005).

Circulating Heterotypic Platelet Aggregates

Activated platelets could adhere to leukocytes in circulating blood via P-selectin/PSGL-1 interactions, forming heterotypic aggregates. Circulating heterotypic platelet-neutrophil and platelet-monocyte aggregates were demonstrated in many diseases. These include, but are not limited to, atherosclerosis, acute coronary syndromes, acute cerebral ischemia, diabetes, smoking, thromboembolic disease, cystic fibrosis, ulcerative colitis, rheumatoid arthritis, systemic lupus erythematosus, myeloproliferative diseases, sepsis, acute lung injury, dengue, and post renal transplant (Smyth et al. 2009; Vieira-de-Abreu et al. 2012; Weyrich and Zimmerman 2004). Some authors consider formation of platelet-monocyte aggregates in vivo the most sensitive marker of platelet activation (Michelson et al. 2001), although their distinct role is not yet fully understood. Platelets in heterotypic aggregates induce activation of leukocytes including expression of β_2 integrins and release of chemokines, such as monocyte chemoattractant protein 1 (MCP-1, CCL2) and cytokines (IL-1β, IL-8, TNFα) (Weyrich et al. 1995, 1996). Others have demonstrated that monocytes engaged in circulating heterotypic platelet aggregates transmigrate more easily (da Costa Martins et al. 2006).

Platelets Are Recruited by Both Neutrophils and Endothelium

Platelets Are Recruited by Neutrophils

It has been known for many years that platelet sequestration to inflamed tissues is neutrophil and P-selectin dependent (Andonegui et al. 2005; Bednar et al. 1985; Hamburger and McEver 1990; Issekutz et al. 1983). However, the exact mechanism of platelet recruitment by neutrophils was not identified. Recently, it has been shown that neutrophils recruited to inflamed vessels extend a PSGL-1-bearing microdomain in the uropod into the vessel lumen that scans for activated platelets present in the bloodstream through P-selectin. Interaction of platelet P-selectin with the neutrophil uropod-localized cluster of PSGL-1 is essential for neutrophil chemotaxis and further propagation of inflammation (Jenne et al. 2013b; Sreeramkumar et al. 2014). In addition, the binding of platelets by neutrophils also appears to induce NET formation, although under these conditions P-selectin may not be the dominant adhesion molecule. Indeed, McDonald et al. reported an important role for LFA-1, but not P-selectin, in bacterial-induced platelet recruitment by neutrophils (McDonald et al. 2012). By contrast, virally induced platelet recruitment by neutrophils appeared to be more dependent upon Mac-1 and CD41 (integrin αIIb, GPIIb) (Jenne et al. 2013b).

Platelets Are Recruited by Inflamed Endothelium

Both activated and resting platelets can be recruited to the inflamed endothelium, and several different mechanisms have been described. Activated endothelial cells express P-selectin to which platelets bind via the GPIb-V-IX complex or PSGL-1 (Frenette et al. 2000; Romo et al. 1999). Alternatively, activated platelets expressing P-selectin adhere to endothelial PSGL-1 (da Costa et al. 2007). Some authors have shown that vWf could also play an important role in platelet adhesion to inflamed endothelium (Etingin et al. 1993). Others still have demonstrated that platelets are recruited to the inflamed endothelium through GPIIbIIIa/fibrinogen interaction with ICAM-1, eventually in cooperation with GPVI (Devi et al. 2010; Khandoga et al. 2002; Massberg et al. 1999). Recently, a novel mechanism of platelet recruitment to the inflamed endothelium was described by Meyer Dos et al. who demonstrated that flowing platelets could be captured, activated, and immobilized directly on endothelial chemokine CXCL16 in atherosclerotic plaques (Meyer Dos et al. 2015). This firm platelet adhesion through GPIIbIIIa leads to expression of CD40L (CD154) and IL-1β by platelets which induce a

pro-inflammatory phenotype of the endothelium. Endothelial cells release chemokines (MCP-1) and cytokines (CD40L, IL-6, IL-8, TF), express adhesion molecules (E-selectin, P-selectin, VCAM-1, ICAM-1, αvβ3), and interact with leukocytes further propagating the inflammatory response (Gawaz et al. 2000; Hawrylowicz et al. 1991; Henn et al. 1998; Kaplanski et al. 1993; McIntyre et al. 2003).

Platelets in Sterile Inflammation

In sterile inflammation, the immune system is activated by nonmicrobial signals. Damaged or dead cells liberate a plethora of endogenous molecules, recognized by the innate immune system as danger signals, DAMPs, or alarmins. Immune cells sense alarmins through PRRs which translates to generation of the IL-1β inflammasome and downstream propagation of the inflammatory response by neutrophils, monocytes/macrophages, and endothelial cells (Chen and Nunez 2010; Kono and Rock 2008; McDonald and Kubes 2011). Platelets were not considered an integral part of sterile inflammatory responses until recently. However, there is now a growing body of evidence that platelets propagate and/or modulate the inflammatory response of other immune cells, although their distinct role in sterile inflammation is not yet fully clarified (Fig. 1).

Platelets express several functional PRRs (TLR1, 2, 3, 4, 5, 6, 7, and 9, CD14, CD40, and FPR) which gives them a capacity to sense danger signals (alarmins) (Andonegui et al. 2005; Aslam et al. 2006; Czapiga et al. 2005; Semple and Freedman 2010). Engagement of these receptors was shown to cause platelet activation, adhesion, aggregation, and P-selectin expression during infection (Aslam et al. 2006; Blair et al. 2009; Clawson and White 1971; Cognasse et al. 2008; Matera et al. 1992). However, there is only limited evidence that platelets are able to sense and become directly activated by DAMPs. As reviewed by Kono and Chen, the following are the signals which could be sensed by the above receptors expressed on platelets: high-mobility group box 1, HMGB-1 (TLR2, 4, and 9); heat shock proteins, HSPs (TLR2, TLR4, CD14, CD40); ribonucleic acid, RNA (TLR3); deoxyribonucleic acid, DNA (TLR9); uric acid (TLR2, 4, CD14); *N*-formylated peptides (FPR-1, FPR-L1); defensins (TLR4); hyaluronan (TLR2, 4); biglycan (TLR2, 4); versican (TLR2); heparan sulfate (TLR4); and IL-1α (IL-1R) (Chen and Nunez 2010; Kono and Rock 2008). To date, only some of these danger signals were shown to be sensed by platelets with functional consequences. Sensing HMGB-1 via platelet TLR4 was documented to cause platelet aggregation through GPIIbIIIa (Yang et al. 2015), while other authors have demonstrated that HMGB-1 binds to activated platelets via receptor for advanced glycation end products (RAGE) and have suggested a potential role for this mechanism in atherothrombosis (Ahrens et al. 2015). Activated platelets were also shown to present HMGB-1 to neutrophils promoting NET formation and autophagy (Maugeri et al. 2014). Engagement of TLR4 ligands on platelets resulted in differential release of various cytokines, including RANTES, CD40L, and PF4 (Cognasse et al. 2008). Binding of *N*-formyl peptide to the surface of activated platelets resulted in platelet chemotaxis (Czapiga et al. 2005). Other authors showed that advanced glycation end products (AGEs), substances which are considered worsening factors in many chronic sterile inflammatory diseases, like diabetes and atherosclerosis, bind to platelet CD36 inducing prothrombotic and pro-inflammatory phenotypes (Zhu et al. 2012). On the other hand, uric acid did not affect platelet activation and aggregation (Ciompi et al. 1983), and some of the HSPs were demonstrated to even inhibit platelet activation and aggregation (Matsuno et al. 1998; Tsujimoto et al. 2015). It seems that platelets are able to sense several alarmins, many of which directly activate platelets, while others have no effect or even inhibit platelet functions. This means that platelets might be involved in sterile inflammation in different ways. However, activation of platelets with some danger signals leads to an increase in aggregation and secretion of pro-inflammatory mediators, resulting in paracrine activation and direct interaction with other immune cells. However, whether platelets further propagate or regulate immune responses to sterile inflammation remains unclear (Duerschmied et al. 2014; Maugeri et al. 2012; Morrell et al. 2014; Projahn and Koenen 2012; Rondina and Garraud 2014).

The role of platelets in sterile inflammation has been studied in multiple diseases, including atherosclerosis, acute lung injury, ischemia/reperfusion, and autoimmune disorders. Their role was demonstrated mostly as pro-inflammatory, and modulation of platelet activation in these diseases often improved outcome (Boilard et al. 2012; Gawaz et al. 2005; Langer et al. 2012; Lievens and von Hundelshausen 2011; Salter et al. 2001; Singbartl et al. 2000; Zarbock and Ley 2009; Zarbock et al. 2006).

Platelets in Atherosclerosis and Metabolic Diseases

In atherosclerosis platelets were shown to be critical in the induction of vascular wall inflammation leading to the development of atherosclerotic lesions and so-called atherothrombosis. The evolution of atherosclerotic plaques starts with activated platelets which roll (via selectins) and subsequently firmly adhere (via β3 integrins) to endothelial cells. Secretion of CD40L and IL-1β inflames the

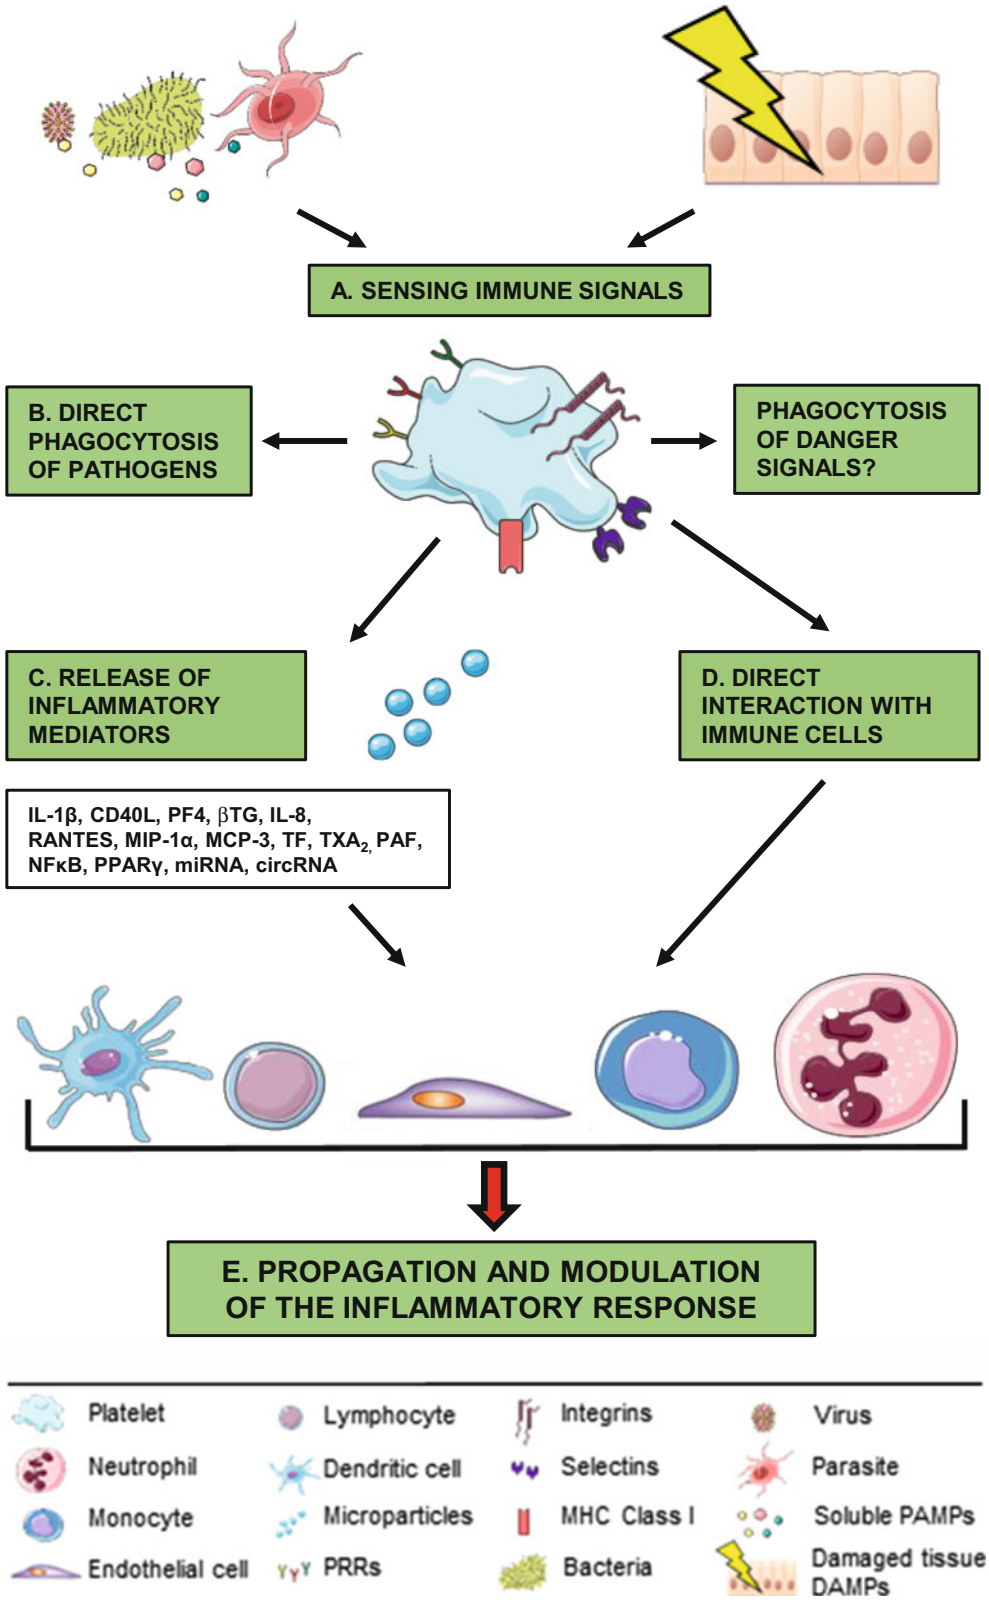

Fig. 1 Platelets and the immune system. (**A**) Platelets sense immune signals. Platelets express pathogen recognition receptors, like TLRs, CD40, and FPR, allowing them to sense immune signals derived from pathogens (PAMPs) as well as damaged tissue (DAMPs). (**B**) Direct phagocytosis of pathogens. In response to pathogens, platelets are directed to sites of infection, cluster around the microorganisms, and directly phagocytose them. It is not clear whether platelets phagocytose also parts of damaged tissues. (**C**) Release of pro-inflammatory

endothelium. Subsequently, platelets recruit circulating leukocytes (through deposition of RANTES and adhesion via selectins and β_2 and β_3 integrins) and facilitate their transmigration and foam cell formation (Huo et al. 2003; Massberg et al. 2002). Badrnya et al. recently described that forming of heterotypic platelet-monocyte aggregates in hyperlipoproteinemia facilitates uptake of low-density lipoprotein by monocytes and their extravasation and foam cell formation (Badrnya et al. 2014). Platelets are understood to be central orchestrators of atherosclerotic plaque formation, and antiplatelet therapy has become a mainstay in the treatment of cardiovascular and cerebrovascular diseases (Coutts et al. 2015; Gawaz et al. 2005; Lievens and von Hundelshausen 2011; Tanguay et al. 2013). Based on a close interplay between sterile inflammation and thrombosis, atherosclerosis has been quoted as a thromboinflammatory disease (Nagareddy and Smyth 2013; Nieswandt et al. 2011). Similarly, metabolic syndromes such as obesity and diabetes mellitus have sterile inflammation as a common denominator. Loss of platelet inhibition by insulin leads to platelet activation, increased expression of P-selectin and GPIIbIIIa on the platelet surface, and the systemic thromboinflammatory state (Anfossi et al. 2009; Morange and Alessi 2013). It was suggested that platelet signaling to monocytes and macrophages links leukocyte activation, cytokine production, and insulin resistance together in these syndromes (Gustafson et al. 2007; Neels and Olefsky 2006).

Platelets in Acute Lung Injury (ALI)

The interplay between platelets, neutrophils, and endothelial cells was demonstrated to be critical in the etiology of acute lung injury. Activated platelets form heterotypic platelet-neutrophil aggregates and induce sequestration of neutrophils to the pulmonary vasculature. Interaction of platelets and neutrophils with endothelial cells induces secretion of TXA_2 which has detrimental effects on vascular permeability and oxygenation. Blocking either platelets (using a P-selectin antibody or platelet depletion) or neutrophils dramatically improved gas exchange and survival. Although these authors stated that the precise mechanism of the role of platelets for neutrophil recruitment into the inflamed lungs remained to be elucidated, it seemed very compelling that platelets were key modulators of sterile inflammatory response in ALI (Zarbock et al. 2006, 2007).

Platelets in Ischemia/Reperfusion Injury

Similarly to ALI, a platelet-neutrophil-endothelium interplay was shown to be central in the pathogenesis of mesenteric ischemia/reperfusion injury. Neutrophil recruitment into postischemic venules and their emigration to tissues were shown to be platelet dependent. Blocking either P-selectin, GPIIbIIIa, or fibrinogen significantly reduced the number of adherent and emigrated leukocytes. Indeed, platelets seemed to have a pivotal role in modulating the inflammatory response to sterile injury in bowel ischemia (Salter et al. 2001). A central role of neutrophils, endothelium, and platelets was also suggested in a model of ischemia-/reperfusion-induced acute renal failure. Authors demonstrated that blocking P-selectin significantly decreased neutrophil recruitment and prevented onset of acute renal failure. However, the contribution of platelet P-selectin versus endothelial P-selectin remained to be clarified in this model (Singbartl et al. 2000). Platelet-neutrophil complexes were shown to play an important role both in myocardial and liver ischemia/reperfusion injury.

mediators. Engagement of PRRs on platelet surface leads to platelet activation, adhesion, aggregation, and release of pro-inflammatory and procoagulant molecules. These include, but not limited to, cytokines (IL-1β, CD40L, IL-8), chemokines (RANTES, PF4, MIP-1α, MCP-3, βTG), procoagulant molecules (TF, TXA_2, PAF), and nuclear factors (NFkB, PPARγ). Some of these molecules, like IL-1β, TF, CD40L, RANTES, NFkB, PPARγ, and miRNA, could be stored and released in the form of microparticles. Defensins, thrombocidins, and kinocidins secreted by platelets have direct bactericidal and fungicidal properties. (**D**) Direct interaction with immune cells. Platelets express a repertoire of selectins, β1 and β3 integrins, and membrane glycoproteins which allows them to directly interact with immune cells. Platelets adherent to the vascular wall recruit neutrophils and monocytes via so-called secondary capture. Platelet P-selectin tethers leukocytes to the vascular wall, followed by rolling via P-selectin/PSGL-1 and subsequent firm adhesion through integrins. Adhesion molecules include Mac-1 and LFA-1 on leukocytes and GPIIbIIIa, GPIbα, or ICAM-2 on platelets. Platelets and leukocytes also form circulating heterotypic aggregates which are considered to be a sign of platelet activation and promote activation of neutrophils and monocytes and their recruitment to tissues. Platelet interaction with neutrophils induces NET formation allowing to entrap pathogens in flowing blood. Firm platelet adhesion via GPIIbIIIa and secretion of CD40L and IL-1β induces pro-inflammatory phenotype of the endothelium, release of chemokines (MCP-1) and cytokines (CD40L, IL-6, IL-8, TF), and expression of adhesion molecules (E-selectin, P-selectin, VCAM, ICAM, αvβ3). Similarly, platelets themselves can be recruited by leukocytes and inflamed endothelium. Recently, platelets were demonstrated to be involved in T cell responses and induce B cell isotype switch, dendritic cell maturation, and antigen presentation. (**E**) Propagation and modulation of the inflammatory response. A wide array of pro-inflammatory mediators and direct interactions with immune cells lead to global activation of the immune system and further propagation and modulation of the inflammatory response. Platelets were shown to contribute to systemic inflammation in many sterile inflammatory diseases, to be indispensable in elimination of pathogens, and to link innate and adaptive responses together

Vasodilator-stimulated phosphoprotein (VASP), a central cytoskeleton protein affecting actin dynamics, was identified as a key regulator of platelet-neutrophil complex formation during the reperfusion phase, and inhibition of VASP significantly reduced formation and deposition of platelet-neutrophil complexes, as well as the extent of ischemia/reperfusion injury (Kohler et al. 2011a, b). Similarly, platelet activation and their interaction with monocytes played an important role in early graft dysfunction caused by reperfusion injury subsequent to cold ischemia in orthotopic liver transplantation (OLT) (Esch et al. 2010).

Platelets in Autoimmune Diseases

A significant contribution of platelets has been suggested to be involved in several autoimmune diseases, particularly in multiple sclerosis (MS), rheumatoid arthritis (RA), and systemic lupus erythematosus (SLE) (Habets et al. 2013). In experimental autoimmune encephalitis (EAE), a model of MS, platelets were present in MS lesions and promoted central nervous system inflammation. Neutrophil recruitment to the brain lesions was demonstrated to be platelet dependent, and attenuation of platelets and their receptors (GPIbα and GPIIbIIIa) significantly reduced severity of the disease (Langer et al. 2012). Neutrophil recruitment to the MS brain lesions could be promoted by platelet-derived serotonin, and treatment of MS patients with selective serotonin reuptake inhibitors (SSRI) also reduced severity of the disease (Duerschmied et al. 2013; Hofstetter et al. 2005).

Different mechanisms of platelet involvement were described in RA and SLE. In RA, platelets and platelet-derived proteins were shown to be present in the synovium and synovial fluid in higher amounts, and serum levels of platelet-derived P-selectin and CD40L correlated with disease activity (Ertenli et al. 1998; Knijff-Dutmer et al. 2002; Tamura et al. 2001). Recently, Boilard et al. demonstrated that platelet production of IL-1β positive microparticles inflamed synovial fibroblasts which were central to joint inflammation. The production of IL-1β-positive microparticles from platelets was triggered by stimulation of collagen receptors, GPVI. Platelet-derived serotonin and prostaglandins further increased vascular permeability and synovial inflammation (Boilard et al. 2010).

In SLE, platelets are activated by circulating immune complexes through their FcγRIIA receptor. Activated platelets signal plasmacytoid dendritic cells through CD40L-CD40 juxtacrine interaction which leads to secretion of IFNα production by dendritic cells. Platelet depletion or inhibition of P2Y12 receptor decreased severity of the disease and improved overall survival (Boilard et al. 2012; Duffau et al. 2010). Platelets also played an important role in lupus nephritis, where they induced proliferation of mesangial cells and production of profibrotic TGF-β (Delmas et al. 2005).

As a constant pool of circulating pro-inflammatory mediators and now recognized as sentinel immune cells, platelets are readily available for intercellular interactions able to contribute to many other autoimmune diseases as recently suggested in systemic sclerosis and Graves' disease (Kuznik et al. 2014; Ramirez et al. 2012).

Platelets in Localized Sterile Injury

Contrary to systemic sterile inflammatory diseases like atherosclerosis, ischemia/reperfusion, or autoimmune diseases where platelets have been demonstrated to have detrimental pro-inflammatory effects, in a localized sterile injury such as that occurs following trauma or burns, platelets were shown to be beneficial to the host by augmenting neutrophil recruitment to allow subsequent wound repair (Slaba et al. 2015). It is intriguing that so few studies are available in the area of platelets and sterile injury and repair, considering that platelets are used clinically to help in repair (Lacci and Dardik 2010; Toscano and Holtzclaw 2008).

Platelets in Infection

In infection PAMPs are detected by innate immune cells via PRRs. Pathogens are eliminated by a coordinated innate immune response, followed by adaptive immune responses (Janeway Charles et al. 2001). The role of platelets in antimicrobial host defense has been intensively studied, and it is becoming quite well understood. Platelets are targeted to the sites of infection and directly interact with bacteria. They become activated and contribute to the host defense by direct clearance of pathogens and by signaling to other immune cells (Jenne and Kubes 2015; Semple and Freedman 2010; Semple et al. 2011; Yeaman 2010, 2014).

Platelets Are Targeted to Sites of Infection and Directly Interact with Pathogens

The evidence that platelets are activated by pathogens and PAMPs has been documented by many authors. Platelets were shown to express TLRs (1, 2, 4, 6, and 9), and their engagement or stimulation of platelets with bacterial products (LPS) or bacteria themselves leads to platelet activation (P-selectin and GPIIbIIIa expression), adhesion, aggregation, secretion of CD40L and PAF, formation of platelet-neutrophil heterotypic aggregates, and production of TNFα by macrophages (Aslam et al. 2006; Blair et al. 2009; Clawson and White 1971; Cognasse et al. 2005, 2008;

Matera et al. 1992; Zhang et al. 2009). Furthermore, it has been shown that platelets could be directly activated by viruses through TLR7 and engagement of TLR3 induced platelet-neutrophil interaction and NET formation (Jenne et al. 2013b; Koupenova et al. 2014). Activated platelets were directed to the sites of infection, platelets formed clusters around microorganisms, encapsulated them, and facilitated their clearance (Calderone et al. 1978; Ferguson et al. 1986; Herd and Page 1995; Scheld et al. 1978; Wong et al. 2013; Yeaman 2010). Platelets have also been shown to rapidly accumulate at the sites of vascular infections, like infective endocarditis, thrombophlebitis, catheter site infections, vascular prosthesis, and stents (Ferguson et al. 1986; Scheld and Sande 1995; Scheld et al. 1978; Vinter et al. 1984). More recent work has suggested that platelets are able to migrate to extravascular space where they can affect infections (Pitchford et al. 2008). Direct contact of platelets with bacteria, viruses, and parasites may induce phagocytosis of the pathogen by platelets. For example, *S. aureus*, HIV, influenza, dengue, HCV, *P. vivax*, and *T. gondii* are all pathogens which have been shown to be phagocytosed by activated platelets (DaMatta et al. 1998; Danon et al. 1959; de Almeida et al. 2009; Fajardo 1979; Jaff et al. 1985; Movat et al. 1965; Noisakran et al. 2009; Youssefian et al. 2002). Platelets also produce several bactericidal and fungicidal proteins and peptides, defensins, thrombocidins (thrombin-induced platelet microbicidal proteins), and kinocidins (chemokines with microbicidal activity) allowing direct pathogen killing (Cole et al. 2001; Koo et al. 1996; Krijgsveld et al. 2000; Yang et al. 2003; Yeaman 2010, 2014). Moreover, platelet microbicidal proteins have synergistic effects and enhance antibiotic-induced bacterial killing (Mercier et al. 2004; Yeaman et al. 1992).

Platelets Contribute to Elimination of Pathogens by Signaling to Other Immune Cells

Platelets activated by interaction with pathogens signal to other immune cells through their secretome and direct intercellular interactions. Activated platelets secrete a number of chemokines attracting neutrophils as well as cytokines CD40L and IL-1β which inflame endothelial cells. Inflamed endothelial cells express an array of adhesion molecules, such as ICAM-1, VCAM-1, and E-selectin, promoting neutrophil recruitment (Henn et al. 1998). Platelets can also promote neutrophil recruitment via so-called secondary capture where neutrophil rolling on inflamed endothelium is mediated by P-selectin expressed by adherent platelets (Yang et al. 1999).

Platelet secretion of CD40L was shown to significantly increase phagocytosis by macrophages during infection with *Leishmania amazonensis* (Soong et al. 1996). CD40L also increases reactive oxygen species (ROS) production by neutrophils which enhances their capacity to phagocytose pathogens (Elzey et al. 2011). Platelet activation by LPS via TLR4 induced binding to neutrophils and NET formation leading to entrapment of bacteria (Clark et al. 2007; McDonald et al. 2012). Platelet-neutrophil interaction in NET formation was shown to be LFA-1 dependent in bacterial infection and Mac-1 dependent in viral infection (Jenne et al. 2013b; McDonald et al. 2012). Furthermore, platelet-neutrophil interaction resulting in NET formation was observed not only in the presence of LPS but also in sepsis induced by Gram-negative bacteria (*Escherichia coli*), Gram-positive bacteria (*Staphylococcus aureus*), and viral infections (Jenne et al. 2013b; McDonald et al. 2012). Besides NET formation, LPS-activated platelets induced neutrophil degranulation and increased phagocytosis. Moreover, platelets were demonstrated to be essential for neutrophil responses to pathogen as this was significantly decreased in the presence of TLR2-deficient platelets incapable of pathogen detection (Assinger et al. 2011; Clark et al. 2007). Recently, platelets were identified to be an important surveillance mechanism to resident liver macrophages (Kupffer cells) during blood-borne infection. Trapping of bacteria by Kupffer cells triggers firm adhesion of platelets to their surface, encasing and helping to kill the bacteria (Wong et al. 2013).

Significance of Platelets in Host Defense

Platelets seem to be an active and integral part of the host defense against pathogens as inhibition of platelet aggregation was shown to aggravate acute bacterial infection and worsen outcome (Zhang et al. 2011). Platelets were found to have a protective role during pneumococcal pneumonia independent from their aggregation (van den Boogaard et al. 2015). Moreover, platelet-induced NET formation by neutrophils protects against dissemination of bacterial infection to distant organs (McDonald et al. 2012). Interestingly, some authors have documented that *Streptococcus pyogenes* bacteria can bind to platelets and thus promote dissemination of bacterial infection (Kahn et al. 2013). Therefore, it can be seen that the role of platelets in sepsis is very complex and numerous authors have documented that thrombocytopenia is associated with severely impaired survival in sepsis (Akca et al. 2002; Baughman et al. 1993; Brogly et al. 2007; Claushuis et al. 2016; de Stoppelaar et al. 2014a, b; Moreau et al. 2007; Sharma et al. 2007; Strauss et al. 2002; van den Boogaard et al. 2015; Vanderschueren et al. 2000).

In viral infections, platelets were recently shown to be essential in both host response and survival in infections induced by hepatitis B and C virus (HBV, HCV),

encephalomyocarditis virus (EMCV), lymphocytic choriomeningitis virus (LCMV), oncolytic poxvirus, and myxoma virus (Iannacone et al. 2005; Jenne et al. 2013b; Koupenova et al. 2014; Loria et al. 2013). However, while platelet activation might be necessary for the host defense against certain viruses, it could also promote immunopathology in the affected organ—as shown in viral hepatitis where platelets could mediate cytotoxic T cell-mediated liver damage (Iannacone et al. 2005). Thus, antiplatelet therapy in chronic hepatitis B might potentially reduce chronic inflammation, liver fibrosis, and hepatocellular carcinoma (Aiolfi and Sitia 2015). In addition, in HIV infection, platelets actively capture and transfer HIV-1, possibly facilitating HIV-1 dissemination in infected patients (Chaipan et al. 2006).

Platelets have also been shown to have protective effects against parasitic protozoal infections. It has been noted that there is a strong association between thrombocytopenia and outcome in malaria suggestive of a potential role for platelets in this disease (Cox and McConkey 2010). In this condition, platelets were found to bind infected red blood cells and induce their destruction and intracellular parasite killing via a mechanism involving both PF4 and Duffy antigen (McMorran et al. 2009, 2012, 2013). Platelets were also demonstrated to interact with fungi, and the platelet-derived chemokines, CCL5 (RANTES) and CXCL4 (PF4), exhibit direct antimicrobial activity against *Candida* species (Drago et al. 2013; Netea et al. 2015; Speth et al. 2014). However, the significance of platelets to host defense against fungal infections has to be further investigated. There is an emerging evidence that platelets might be involved in response to *Mycobacterium tuberculosis* infection, specifically by modulation of macrophage function and their transformation into multinucleated giant cells observed in the granulomas characteristic of tuberculosis (Feng et al. 2014; Lugo-Villarino and Neyrolles 2014). However, a distinct role for platelets in the pathogenesis of tuberculosis has yet to be clarified. Lastly, it was speculated that platelets are not only direct effectors of host defense but also function as circulating sentinels that bind infectious agents and present them to the reticuloendothelial system (RES) (Aslam et al. 2006).

Platelets Link Innate Immune Responses to Adaptive Immunity

There is increasing evidence that platelets are involved in adaptive immunity and possibly link innate and adaptive responses together. Platelets have been shown to be involved in T cell responses, to induce B cell isotype switch and dendritic cell maturation (Morrell et al. 2014).

Furthermore, some of the mediators secreted by platelets create a direct link between innate and adaptive immunity. For example, platelet-derived chemokines (PF4, RANTES) and thromboxane were demonstrated to influence T cell trafficking, activation, and differentiation (Morrell et al. 2014; Sakata et al. 2010; Shi et al. 2014; Srivastava et al. 2008; Swaim et al. 2010). Conversely, T cells might activate platelets through CD40L/CD40 interactions, leading to the release of RANTES and increased T cell recruitment (Danese et al. 2004). T_{Reg} differentiation is dependent on TGF-β, and it is therefore of considerable interest that studies of patients with immune thrombocytopenia have demonstrated that platelets might be the primary source of this factor suggesting that platelets might be important for T_{Reg} homeostasis (Stasi et al. 2008; Tran 2012). Platelets were recently shown to enhance T_{Reg} responses by promoting $FoxP3^+$ T cell proliferation and to induce the suppression phase of Th1 responses by TGF-β-mediated selective inhibition of $FoxP3^-$ T cell proliferation (Zhu et al. 2014). Platelet-derived CD40L was shown to significantly promote protective adaptive responses as CD40L augments T cell responses to bacterial and viral challenge and induces maturation of dendritic cells, B cell differentiation, and immunoglobulin isotype switching (Elzey et al. 2003, 2005, 2008, 2011; Sprague et al. 2008). Moreover, platelet CD40L and IL-1β represent major danger signals for dendritic cells, and at least CD40L induces DC maturation.

Together with RANTES, IL-1β and CD40L are also major regulators of DC activity. Platelets were shown to decrease the production of pro-inflammatory cytokines IL-12p70 and TNFα by DCs and to mediate production of anti-inflammatory cytokine IL-10 (Banchereau and Steinman 1998; Gallucci and Matzinger 2001; Kissel et al. 2006). Recently, some authors demonstrated that PDGF inhibited maturation of DCs and induced IL-10 secretion through upregulation of C-type lectin-like receptor 2 (CLEC-2) on DCs and induction of T regulatory cells (Agrawal et al. 2015). Other authors showed that platelets can recruit and activate dendritic cells directly through interaction of Mac-1 on dendritic cells and the platelet junctional adhesion molecule C (JAM-C) (Langer et al. 2007). Lastly, in some bloodstream infections, platelets rapidly associate with a portion of pathogens and subsequently direct the bacteria to dendritic cells inducing antibacterial immunity rather than rapid bacterial clearance (Verschoor et al. 2011). Indeed, platelets were shown to process and present antigen in MHC class I and directly activate naive T cells in a platelet MHC class I-dependent manner (Chapman et al. 2012).

Summary

Platelets, although small and anucleated, are now emerging as powerful entities broadly involved in inflammation, infection, and adaptive immune responses. We have reviewed the role of platelets in different components of the immune

system. Platelets are equipped to sense inflammatory stimuli and to secrete pro-inflammatory, prothrombotic, and proangiogenic mediators as well as being able to directly interact with other immune cells, especially neutrophils and monocytes. Platelets directly interact with bacteria and significantly contribute to bacterial clearance. Platelets create a link not only between hemostasis and immunity but also between innate and adaptive immune responses. Considering the availability of multiple antiplatelet drugs in clinical medicine, it would seem sensible to consider using these agents as potential treatments for immune-mediated diseases.

Take Home Messages

Pathogen Recognition Receptors Expressed by Platelets

- Platelets express several types of PRRs: TLRs 1–9, CD14, CD40, and FPR, allowing them to sense both pathogen- and danger-associated signals.
- Engagement of PRRs on platelets leads to an increase in intracellular calcium, platelet adhesion and aggregation, GPIIbIIIa expression, cytokine release, chemotaxis, and NET formation.

Platelets Secrete Pro-inflammatory Molecules

- Platelets store and secrete over 1000 biologically active proteins, peptides, lipids, and eicosanoids. These include cytokines (IL-1β, IL-8, CD40L, and βTG), chemokines (PF4, RANTES, MIP-1α, and MCP-3), growth factors (PDGF, VEGF, TGF-β), and MHC class I antigen-presenting pathway proteins. Many of these substances contribute to intercellular signaling and inflammatory response at the local and systemic level.
- Some of the stored proteins are constitutively expressed on platelet membrane (GPIIbIIIa, GPVI, PECAM, GPIb-V-IX), while others, such as P-selectin, are exposed on the platelet surface only after platelet activation.
- Soluble platelet mediators are secreted in a paracrine, endocrine, or juxtacrine manner, retained on the platelet membrane bound to the receptor and available for intercellular signaling.
- Platelets contain a wide array of RNAs (mRNA, tRNA, miRNA, long noncoding RNA, circRNA), which role has to be further determined.
- Beside lipid mediators (PAF and TXA_2), platelets could synthesize proteins (IL-1β) in a process called signal-dependent translation.
- Platelet-derived microparticles are an important transport and possibly also storage mechanism for platelet-secreted molecules, like IL-1β, TF, CD40L, RANTES, NFkB, PPARγ, and miRNA.

Platelet Interaction with Immune Cells

- Platelets recruit leukocytes. Adherent platelets promote neutrophil and monocyte rolling on the endothelium via P-selectin and PSGL-1 interaction. The production of chemokines (PAF and RANTES, respectively) allows for firm adhesion of leukocytes. Integrins involved are Mac-1 or LFA-1 on neutrophils and GPIIbIIIa, GPIbα, or ICAM-2 on platelets. In many diseases activated platelets could adhere to leukocytes in circulating blood via P-selectin/PSGL-1 interaction, forming heterotypic aggregates.
- Platelets are recruited by neutrophils. Neutrophils recruited to inflamed vessels extend a PSGL-1-bearing microdomain on the uropod into the vessel lumen and scan for activated platelets expressing P-selectin. Binding of platelets by activated neutrophils induces NET formation. Integrins involved are LFA-1 in bacteria-induced NET formation and Mac-1/GPIIbIIIa in virally induced NET formation. NETs could be formed also in sterile inflammatory processes like deep venous thrombosis.
- Both activated and resting platelets could be recruited by inflamed endothelium. Endothelial ligands P-selectin, PSGL-1, and ICAM-1 recruit platelets via GPIb-V-IX or PSGL-1, P-selectin, and GPIIbIIIa, respectively. Involvement of vWf and GPVI was also suggested.
- Platelet interaction with immune cells is crucial in further propagation and modulation of inflammatory responses.

Platelets in Sterile Inflammation

- The role of platelets in sterile inflammation has been studied in multiple diseases, including atherosclerosis, acute lung injury, ischemia/reperfusion, and autoimmune disorders. Their role was demonstrated mostly as pro-inflammatory, and modulation of platelet activation and their interaction with neutrophils in these diseases often improved outcome.

(continued)

- Platelet-neutrophil interaction or release of IL-1-β-positive microparticles was shown to be in the center of the detrimental pro-inflammatory effects of platelets in sterile inflammation.
- In a localized sterile injury such as occurs following trauma or burns, platelets were shown to be beneficial to the host by augmenting neutrophil recruitment to allow subsequent wound repair.

Platelets in Infection

- Platelets are targeted to the sites of infection and directly interact with microbes. They cluster around microorganisms, encapsulate them, and facilitate their clearance.
- Direct contact of platelets with bacteria, viruses, and parasites may induce phagocytosis of the pathogen by platelets. Microbes reported to be phagocytosed by platelets include *Staphylococcus aureus*, HIV, influenza, dengue, HCV, *Plasmodium vivax*, and *Toxoplasma gondii*.
- Platelets produce several bactericidal and fungicidal proteins and peptides, defensins, thrombocidins (thrombin-induced platelet microbicidal proteins), and kinocidins (chemokines with microbicidal activity) allowing direct pathogen killing.
- Platelets contribute to elimination of pathogens also indirectly by interaction with other immune cells promoting their inflammatory response to pathogens.
- Platelet-neutrophil interaction in bacterial and viral infections results in NET formation and entrapment of the microorganisms. Integrins involved are LFA-1 in bacterial and Mac-1 in viral infection.
- Platelets were identified to be an important surveillance mechanism to resident liver macrophages (Kupffer cells) during blood-borne infection.
- Platelets were found to be indispensable in host defense; however in some infections, like HIV or *Streptococcus pyogenes*, platelets were reported to augment dissemination of infection.

Platelets in Adaptive Immunity

- Platelets have been shown to be involved in T cell responses, to induce B cell isotype switch and dendritic cell maturation.
- Some of the mediators secreted by platelets, such as IL-1β, CD40L, PF4, RANTES, and TXA_2, create a direct link between innate and adaptive immunity.
- Platelets are involved in bidirectional signaling and direct cell interactions with adaptive immune cells.
- Platelets were shown to process and present antigen in MHC class I and directly activate naive T cells in a platelet MHC class I-dependent manner.

Platelets in Neurological Disorders

Ilaria Canobbio, Gianni F. Guidetti, and Mauro Torti

Abstract

Although blood platelets are primarily involved in hemostasis and thrombosis, it is well recognized that they are also implicated in a number of different physiological and pathological events, including inflammation, host defense, and tumor metastasis. In this chapter, we provide an update on the complex interplay between platelets and some complex neurological disorders, such as Alzheimer's disease, depression, Parkinson's disease, and autism. Platelets and neurons share several biological features, and platelets have been regarded as a suitable and easily accessible cellular model to investigate the molecular mechanisms underlying complex neuropathological disorders for many years. Moreover, alterations of platelet function and responsiveness in patients affected by neurological diseases have been widely documented and have fueled the search for platelet-specific tests for diagnostic and prognostic assays. Although this ambitious goal still remains to be pursued, a large number of studies performed on this topic over the last decades have significantly increased our general knowledge on the pathogenesis of complex neurological disorders and have also provided important insights into novel aspects of platelet biology.

Introduction

Platelets are responsible for hemostasis, thrombosis, and wound healing, but recent evidence shows their involvement in many additional physiological and pathological processes, including atherogenesis, chronic inflammation, host defense, tumor metastasis, and neurological disorders. In this chapter, we will discuss the role of platelets in neurological diseases and the possibility to use platelets as a peripheral, easy to access, and reliable biomarkers for the diagnosis for monitoring of neurological disease progression.

The idea of using platelets as peripheral biomarkers for neurological disorders mainly derives from the observation that platelets share many similarities with neural cells and alterations of platelet structure, function, and metabolism are often associated with the onset of some neurodegenerative disorders. A significant amount of work has been performed over the last decades in an attempt to correlate specific aspects of platelet function or dysfunction to selective neurological diseases, in order to define a possible contribution of circulating platelets to these disorders, and to validate platelet-based tests to monitor both the progression of neurological diseases and the efficacy of drug-based therapies. Through all these efforts, the strong relationship between platelets and neurological diseases has been consolidated and the multiple correlations between neuropathologies and platelet dysfunctions have been often characterized at the molecular level. Although in many cases we are still far from having identified specific peripheral biomarkers for neurological disorders, the data collected over the years has strongly increased our general knowledge on the peripheral alterations associated with the onset of complex

neurological diseases, and also on specific aspects of blood platelet function.

Similarities Between Platelets and Neurons

Platelets and neurons have different embryological origin, as platelets are produced by fragmentation of megakaryocytes, polynucleated precursors of mesodermic derivation (Anastassova-Kristeva 2003), whereas neurons derive from ectoderm (Bjornsson et al. 2015). There are, however, reports erroneously indicating that platelets, as neurons, are of ectodermic origin. This derives for the misleading interpretation of the early finding that platelets express neuron specific enolase (Marangos et al. 1980), which, however, has been subsequently reported to be expressed in almost in all human tissues (Hullin et al. 1980). Nevertheless, although platelets and neurons have different embryological origin, many proteins specifically expressed in the brain are also present, at unusually high concentrations, in platelets. For instance, the neuronal glycoprotein reelin, that regulates cell migration, synaptic plasticity, and neuronal positioning (Assadi et al. 2003), is also expressed in plasma and in blood platelets (Tseng et al. 2010). Plasma reelin probably originates from the liver and is subsequently taken up by platelets and stored into α-granules. However, synthesis of reelin by megakaryocytes and megakaryocytic cell lines has also been documented (Chen et al. 2007). Therefore, platelets may release reelin upon secretion and reelin has been found to interact with platelets to regulate adhesion and spreading and to modulate thrombin generation (Tseng et al. 2010, 2014). Moreover, abnormalities of platelet function have found in neuronal disorders associated with defective reelin signaling (Botella-Lopez et al. 2006).

Platelets also express plasma membrane receptors which are typically expressed in neurons, where they participate in cell–cell contact and networking, including Eph (Murai and Pasquale 2011; Prevost et al. 2004), semaphorins (Rivera et al. 2009), and amyloid precursor protein (Van Nostrand et al. 1990). Importantly, as with neurons, platelets express a specific transporter for serotonin (Rausch et al. 2005), whose action is essential to keep very low serotonin plasma levels and is responsible for its accumulation into platelet dense granules (Yubero-Lahoz et al. 2013).

An important feature that associates platelets and neurons is the secretory nature of both cells types. Biogenesis of granules occurs through similar pathways, and platelet granule secretion is homologous to granules exocytosis in neurons (Reed et al. 2000; Goubau et al. 2013). Platelets contain specific secretory granules that are released upon activation: α-granules, that mainly store peptides and large proteins, and dense granules packed with different small molecules and bioreactive amines. During thrombus formation, the content of platelet granules is released into the bloodstream and into the inter-platelets space to recruit new cells and to reinforce platelet activation by an autocrine/paracrine mechanism involving bioreactive proteins.

Similarly, neurons have granules with different contents that are released into the synaptic space, where different neurons come into proximity. Neurons contain different secretory granules: small synaptic vesicles (containing GABA, glutamate, acetylcholine), small dense core vesicles (containing serotonin, dopamine, ATP), and large dense core vesicles (containing neuropeptides, growth factors, and hormones). The latter ones have been compared to platelet α-granules, that are heterogeneous and contain a wide range of polypeptides, growth factors, chemokines, cytokines, and adhesion molecules. Similarly, platelet dense granule content is very similar to that of small dense core vesicles (Von Bartheld and Altick 2011).

Proteins stored into granules are synthesized and packaged in the body of the cells and, in neurons, they are then transported to the synaptic end along the extended axon. Similarly, platelet granules are generated inside the megakaryocyte where, at the late stage of maturation, move through cytoplasmic extensions to the proplatelets tips, where they are packed into the released platelets. Trafficking and intracellular relocation of granules are driven by microtubule structures both in neurons and megakaryocytes (Battinelli et al. 2007; Hirokawa et al. 2010).

In circulating platelets, molecules stored granules may also be taken up by endocytosis from plasma. This process involves the formation of multivesicular bodies that represent intermediate compartments for storage and sorting. Multivesicular bodies are also present in neurons, where they participate in compartmentalization of endocytosed materials (Von Bartheld and Altick 2011). Mutations that alter normal trafficking of granules have been identified in many diseases known as "inherited disorders of trafficking." Interestingly, these disorders affect both platelets and neurons and are characterized by bleeding problems and neurological dysfunctions (Gissen and Maher 2007).

One of the most relevant common features between neurons and platelets is their ability to store several neurotransmitters and biological amines (5-HT (serotonin), dopamine, GABA, glutamate, and others). In this context, the ability of platelets to efficiently sequester and accumulate large amounts of serotonin has been considered the most relevant neuron-like feature of these cells for a long time. Serotonin is an important modulator of neural activity and plays a critical role in the control of behavior and in the development of several neuropsychological conditions. Moreover, drugs targeting the serotonin system are widely used in the control of mental and neurological disorders, such as depression, obsessive-compulsive disorders, anxiety, and others (Berger et al. 2009).

In spite of its great relevance for the biology of the brain, the largest amount of bodies serotonin localizes outside the

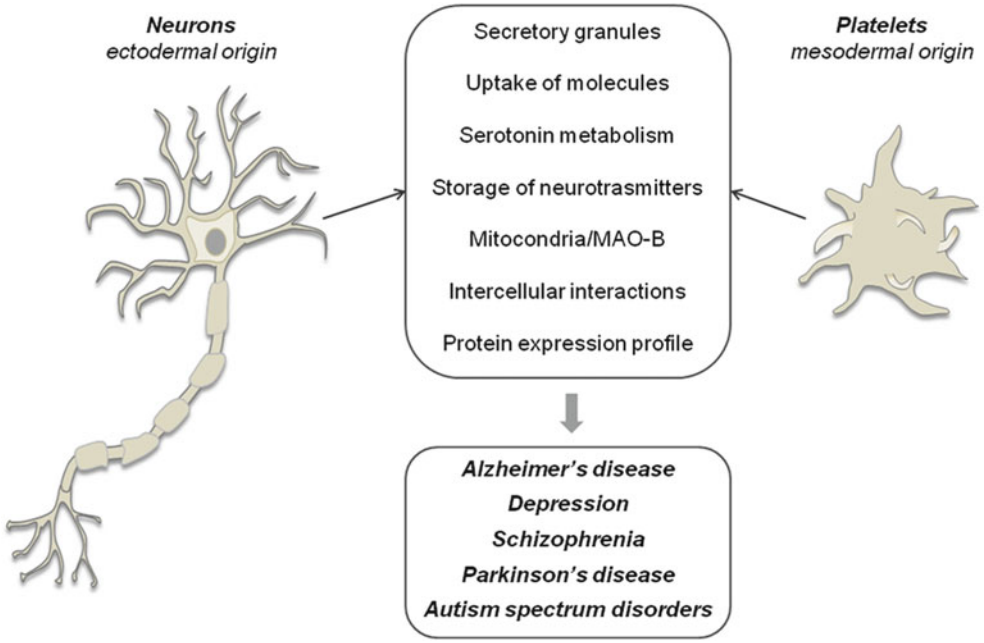

Fig. 1 Similarities between neurons and blood platelets. The major features and characteristics common to both neuronal cells and platelets are summarized. They are discussed in this chapter in relation to the indicated neurological disorders

nervous system, where it supports the activity of different organs and systems. Indeed, serotonin contributes to the control of breathing, cardiac function, as well as the gastrointestinal and genitourinary systems. In addition, serotonin is also a critical player in vascular biology and regulates blood pressure, hemostasis, and platelet function. Within the circulation, platelets themselves store high amounts of serotonin (Berger et al. 2009). Platelets do not express the enzymes required for the synthesis of serotonin, but they are able to take up plasma serotonin through specific membrane transporters and store it into dense granules (Ni and Watts 2006). During platelet activation the content of dense granule is secreted and serotonin acts a weak platelet agonist by a paracrine mechanism, contributing to enhance platelet stimulation and aggregation induced by other agents. These effects are mediated by G protein-coupled 5HT2 receptors that, through the activation of phospholipase C, lead to Ca^{2+} mobilization and platelet activation (Pletscher 1987). Interestingly, inhibition of serotonin reuptake can prolong bleeding time and patients under therapy with selective serotonin reuptake inhibitors display reduced platelet aggregation (Berger et al. 2009; Williams 2012).

Besides the shared physiological features, the possibility to consider platelets as peripheral models for neurons is also supported by the evidence that alterations of platelet function are often associated with neurological disorders and have been found to somehow mirror abnormalities observed in neurons. For instance, mitochondrial dysfunctions are often associated with psychiatric disorders including depression, bipolar disorders, schizophrenia, and anxiety. Defects in mitochondrial function may result in generation of reactive species, alteration of the oxidative phosphorylation and impaired energy production, unbalanced regulation of apoptosis and Ca^{2+} homeostasis, and alteration of monoamine oxidase (MAO) activity (Rezin et al. 2009; Asor and Ben-Shachar 2012). Under some circumstances, these defects are also mirrored by platelet mitochondria, and therefore analysis of mitochondria in platelets has been considered a reliable strategy to gain information on brain mitochondria dysfunctions. In this context, most studies have been performed on platelets isolated from schizophrenic patients, focusing in particular on the function of mitochondrial complex I, cytochrome C oxidase, and MAO-B. Conversely, drugs that target neurons also have an impact on platelets. Several compounds with psychotropic activity, such as the endocannabinoids, 2-arachidonoylglycerol, and anandamide, have been shown to act as agonists for human platelets activation through binding to the endocannabinoid receptors CB1 and CB2 present on circulating platelets (Maccarrone et al. 1999; MacCarrone et al. 2001; De Angelis et al. 2014). Endocannabinoids are also released by platelets and regulate hematopoiesis and atherosclerosis (Jiang et al. 2011; O'Sullivan 2015). Moreover, endocannabinoids also control platelet formation by human megakaryoblasts (Gasperi et al. 2014). Some of the major similarities between platelets and neurons are summarized in Fig. 1.

Implication of Platelets in Complex Neurological Disorders

The possibility to use blood platelets as peripheral biomarkers for complex neurological disorders has been considered a very attractive opportunity for a long time because of the evident technical advantages deriving from analysis of peripheral blood samples rather than brain

biopsies. Therefore, the morphology, structure, and function of platelets in patients affected by different neurological disorders have been intensively investigated since the early 1960s. These studies have provided a significant contribution to our knowledge of the platelet function and the implications for neurobiology, but in most cases this has not yet led to the definitive identification of specific and reliable peripheral biomarkers for diagnostic and prognostic purposes. As a matter of fact, the main interest of the scientific community appeared to switch from pathology to pathology over the years. For instance, the number of available publications clearly indicates that the interest for the involvement of platelets in depression or schizophrenia was maximal in the 1980s and then progressively reduced, despite the number of studies on this topic still remaining significantly elevated compared to other neurological disorders (Fig. 2). In contrast, the studies of the contribution of platelets to Alzheimer's disease have increased slowly, but constantly, since the late 1980s, indicating that this topic is still considered a promising field of investigation. Here we summarize the state of the art of our knowledge concerning the implications of platelets on selected neurological disorders, focusing on those pathologies that have received greatest attention over the years.

Platelets and Alzheimer's Disease

Metabolism of Amyloid Precursor Protein in Blood Platelets

Alzheimer's disease (AD) is the most invalidating dementia in western Countries. It affects over 45 million people worldwide and, together with the aging of the population, it is estimated to grow exponentially in the coming years (World Alzheimer Report 2015). AD is characterized by the abnormal deposition in the brain of senile plaques, composed of amyloid beta (Aβ) peptides derived from the altered metabolism of the amyloid precursor protein (APP). APP is a large glycoprotein expressed on cellular membrane and it is metabolized by two different, mutually exclusive, pathways (Gandy 2005). In the non-amyloidogenic pathway, APP is cleaved by α-secretase, producing soluble APPα and a carboxy-terminal membrane-bound CTFα fragment CTFα is then proteolyzed by γ-secretase complex to release the non-toxic peptide p3. Alternatively, APP may be metabolized by β-secretase, that releases a soluble APPβ fragment, and subsequently by a γ-secretase complex that produces and releases the neurotoxic peptide Aβ40 or the more fibrillogenic peptide Aβ42 (Canobbio et al. 2015).

Although AD is prevalently known as a neurological disorder, it is now well accepted that it actually represents a systemic disease. In fact, deposits of Aβ peptides are also found in cerebral vessel walls, where they may cause cerebral amyloid angiopathy. In addition, amyloid deposits are present in peripheral blood vessel walls. There is solid evidence that the onset of AD is related to alterations of the vascular system and is associated to vascular disorders, including stroke, atherosclerosis and hypertension (Honig et al. 2003; Mielke et al. 2007), and that AD patients suffer often thrombotic and hemorrhagic complications (Brundel et al. 2012). Conversely, several vascular risk factors may increase the risk for AD (Viswanathan and Greenberg 2011).

In the last decade increasing evidence has suggested that circulating blood platelets may be a reliable and accessible model for studying AD pathology and may represent a useful biomarker for diagnosis and prognosis of this disease (Cattabeni et al. 2004; Casoli et al. 2010; Rembach et al.

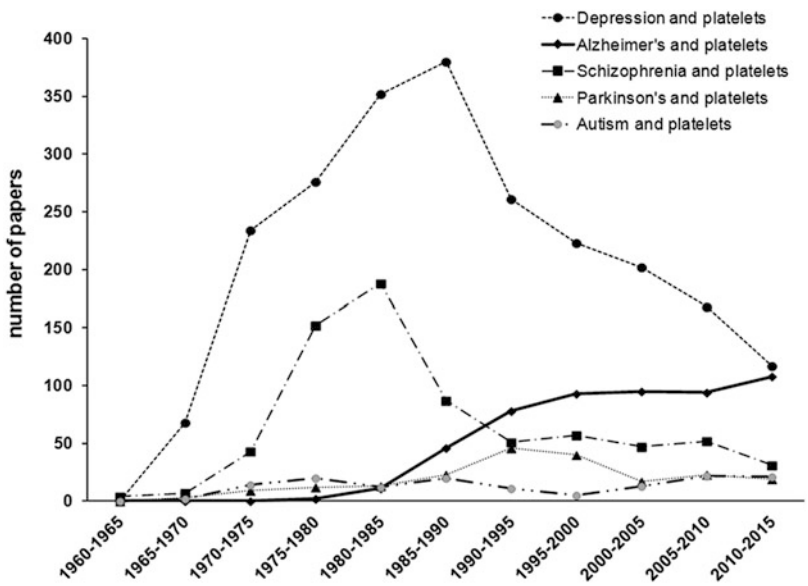

Fig. 2 Platelet studies related to neurological disorders. A search on the PubMed database was performed joining the term platelets and the name of the disorders (i.e., platelets AND autism), including autism, Alzheimer's disease, Parkinson's disease, schizophrenia, and depression. The number of published papers is plotted versus periods of time of 5 years from 1960

2013; Veitinger et al. 2014). Platelets express relatively high amounts of APP (9300 copies per platelet) (Burkhart et al. 2012). APP expressed on plasma membrane may function as a cell–cell receptor (Dawkins and Small 2014; Nalivaeva and Turner 2013) and it is able to bind Aβ peptides (Lorenzo et al. 2000). Platelets contain α-, β-, and γ-secretases necessary for APP metabolism, and process APP through pathways identical to those occurring in neurons (Di Luca et al. 2000). Platelets express two isoforms of APP on the plasma membrane, APP751 and APP770, containing the Kunitz type serine protease inhibitor domain KPI, which is known to inhibit several serine proteases of the coagulation cascade (Van Nostrand et al. 1989). In physiological conditions, platelets metabolize APP mainly through the non-amyloidogenic pathway operated by α- and γ-secretases. It has been shown that α-secretase is activated by platelet stimulation through Ca^{2+}-calmodulin dependent mechanism and that APP hydrolysis can be initiated in vitro by platelet treatment with the calmodulin antagonist W7 (Canobbio et al. 2011). Since non-amyloidogenic and amyloidogenic pathways are mutually exclusive, it is clear that improving non-amyloidogenic metabolism of APP may have significant impact on the onset of AD. In the central nervous system, APP has neurotrophic and neuroprotective actions (Kogel et al. 2012), but little is known on its physiological function in the circulation. Recombinant soluble APP has been demonstrated to inhibit platelet activation in vitro (Henry et al. 1998). APP, as well as the purified Kunitz protease inhibitor domain of APP, inhibits the activity of blood coagulation factors IXa, XIa, and Xa (Smith et al. 1990; Van Nostrand et al. 1992; Schmaier et al. 1993; Mahdi et al. 1995; Wu et al. 2012), indicating that platelet APP may be implicated in the regulation of hemostasis. Recently, Xu and collaborators have demonstrated that transgenic mice displaying a modest overexpression of APP either in platelets or in brain display a marked antithrombotic phenotype. In particular, they demonstrated that a twofold higher expression of APP in platelets caused a marked inhibition of cerebral thrombosis in vivo. In contrast, APP deficient mice showed a significant increase in thrombosis (Xu et al. 2005, 2007). These results indicate that APP actually regulates cerebral thrombosis.

Under pathological conditions platelets may also process APP through β- and γ-secretases (the amyloidogenic pathway) to produce and release Aβ peptides. Platelets are the second source of Aβ peptides after neurons, and the major source of Aβ peptides found in the circulation. Platelets store considerable amount of Aβ peptides in their α-granules (84 ng/g tissue of Aβ40 and 1.6 ng/g tissue of Aβ42) (Kokjohn et al. 2011) and release them in the bloodstream upon stimulation with physiological agonists. In the circulation, platelet-derived Aβ peptides activate platelets (Herczenik et al. 2007; Shen et al. 2008; Sonkar et al. 2014; Canobbio et al. 2014), endothelial cells (Ghiso et al. 2014), and neutrophils (Achilli et al. 2014), resulting in chronic vascular inflammation. Herczenik and coworkers showed that fibrillar Aβ40 induces platelet aggregation by binding to the scavenger receptor CD36 and to GPIbα, and by activating intracellular signaling pathways involving p38MAPK, cyclooxygenase1, and thromboxane A_2 production (Herczenik et al. 2007). Treatment of platelets with Aβ40 also promotes reactive oxygen species production, caspase activation, and membrane scrambling, indicating enhanced platelet apoptosis (Gowert et al. 2014). The ability of Aβ peptides to activate platelets has also been investigated using the synthetic peptide $Aβ_{25-35}$, which represents the biologically active region of Aβ (Kaminsky et al. 2010). $Aβ_{25-35}$ activates platelets, resulting in integrin $α_{IIb}β_3$ inside-out activation and aggregation (Shen et al. 2008; Canobbio et al. 2014). In the presence of extracellular $CaCl_2$, $Aβ_{25-35}$-induced platelet activation is promoted by an increase in intracellular Ca^{2+} concentration, which is likely related to the ability of Aβ peptides to form cations permeable pore on the plasma membrane (Di Scala et al. 2014). Ca^{2+} increases promote granule secretion and release of ADP, which in turn enhances platelet activation (Canobbio et al. 2014). Aβ peptides are also able to induce platelet adhesion under static conditions and to accelerate platelet adhesion to subendothelial matrices under flow (Canobbio et al. 2011). In vivo, preincubation of platelets with Aβ peptides increases platelet adhesion to injured carotid artery. Similarly, in AD transgenic mice, platelets are recruited to vascular amyloid deposits (Gowert et al. 2014).

It has been hypothesized that, by metabolizing membrane APP and releasing Aβ in the bloodstream, platelets may also contribute to the deposition of Aβ peptides in the brain. It is known that Aβ undergoes active transport across the blood–brain barrier (Deane et al. 2003; Deane and Zlokovic 2007). Recently, it has been demonstrated that intraperitoneal inoculation of Aβ-rich extracts induces β-amyloidosis in the brain of AD transgenic mice, although to a lesser extent than intracerebral inoculation (Eisele et al. 2010). This evidence sheds new light on the possible involvement of circulating Aβ in the deposition of amyloid in the brain and the progression of AD, but further investigations are certainly needed.

Another important morphological hallmark of brain neurons in AD is the presence of neurofibrillar tangles, abnormal intracellular deposits of the microtubule-associated protein tau in its hyperphosphorylated form. Maccioni and coworkers have recently shown that platelets also express tau (Neumann et al. 2011). This study investigated tau expression in platelets by immunoblotting and immunofluorescence, and reported also the presence of high molecular weight oligomers of tau, more evident in AD patients compared to healthy subjects (Neumann et al.

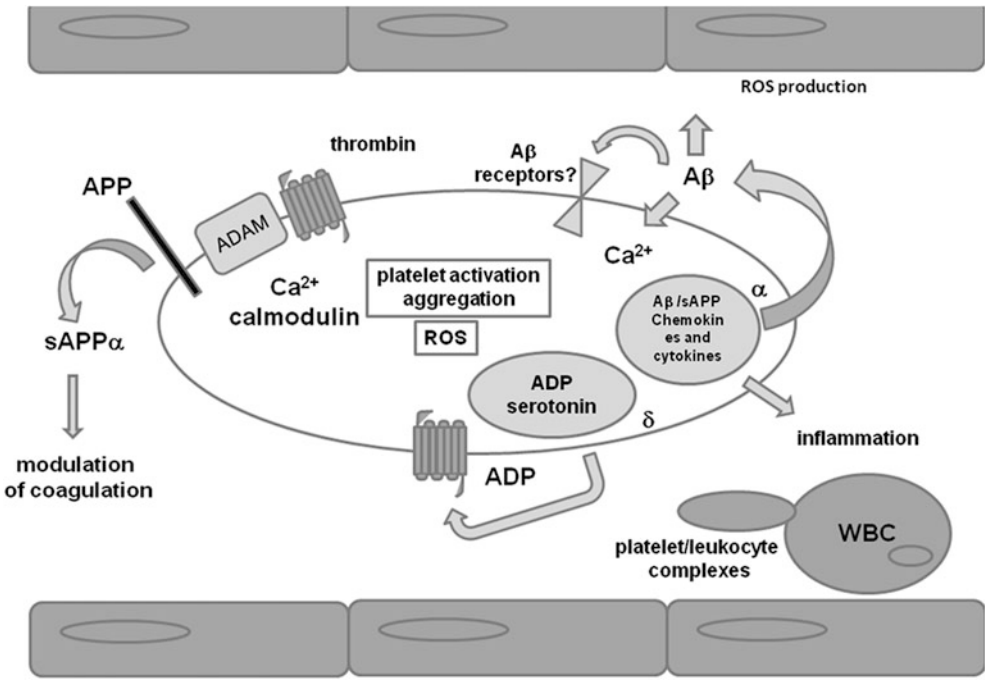

Fig. 3 Amyloid precursor protein metabolism in platelets and implications for Alzheimer's disease. Platelet express amyloid precursor protein (APP) on the plasma membrane and possess α, β, and γ secretases required for its metabolism. APP is proteolyzed through Ca^{2+}-calmodulin activated ADAM and releases soluble APPα that negatively regulates platelet activation. Soluble APP fragments including the amyloidogenic peptide Aβ are also stored in α-granules and released upon platelet stimulation. Secreted Aβ peptides activate platelets possibly by binding to a still unidentified receptors or by directly promoting extracellular Ca^{2+} influx to stimulate and potentiate platelet aggregation. Aβ peptides also activate leukocytes (WBC) and endothelial cells triggering inflammation and favoring platelet–leukocyte interactions

2011). The presence of tau in human platelets has been confirmed by the study of Mukaetova-Ladinska et al. (2012), but it is not supported by proteomic studies that failed to reveal the presence of tau protein in platelets (Burkhart et al. 2012). This discrepancy may be due to the fact that proteomic analysis covers about 80–85 % of the entire proteome and therefore may miss some proteins. However, further analyses are needed to definitively confirm the presence of tau in platelets and its role as a potential peripheral biomarker for AD. It is of interest, however, that glycogen synthase kinase 3β (GSK3β) is the kinase responsible for tau phosphorylation in neurons and that GSK3β activity is increased within the AD brain (Hooper et al. 2008; Balaraman et al. 2006). GSK3β is constitutively expressed in all cells, including platelets (Barry et al. 2003), and is primarily inhibited via Akt-mediated phosphorylation (Cross et al. 1995). Platelet GSK3β has been shown to be upregulated in mild cognitive impairment and AD patients (Forlenza et al. 2011). The complex interplay between platelets and AD is illustrated in Fig. 3.

Platelet Abnormalities in AD Patients

There are several studies documenting that alterations of platelet functionality and metabolism are common in patients with AD (Veitinger et al. 2014). Nevertheless, caution is recommended when considering the data found in the literature, as the methodology and the approach adopted may significantly affect the outcome of the study.

One of the most important and reliable changes observed in platelets from AD patients is the altered ratio among different APP isoforms (Schlossmacher et al. 1992). Immunoblotting analysis of platelet lysates with the anti-APP antibody 22C11, whose epitope is located in the extracellular N-terminal domain of APP, typically reveals two reactive bands with apparent molecular mass of about 130 and 110 kDa, which have been suggested to possibly correspond to the full length APP and to soluble fragments (sAPPα/sAAPβ). The 130 kDa/110 kDa bands ratio is lower in platelets from patients affected by mild cognitive impairment and sporadic AD compared to platelets prepared from either control subjects or from patients affected by other kinds of dementia (Di Luca et al. 2000; Borroni et al. 2005, 2010; Chatterjee et al. 2015). The altered APP ratio may be suggestive of an enhanced metabolism of the protein in platelets from AD patients. Moreover, the altered APP bands ratio in platelets shows a positive and specific correlation with the progression of the disease. This correlation is also present in preclinical stages of AD, suggesting that this can be a useful biomarker for AD.

AD platelets also show alteration in the expression or activation of α- and β-secretases, which are diminished and

increased, respectively (Colciaghi et al. 2004; Tang et al. 2006). This likely results in increased production of Aβ peptides in plasma. However, all the efforts to measure the plasma levels of Aβ have met with little success: many studies have examined plasma Aβ as a biomarker for AD, but findings from these studies have been contradictory. Some studies detected higher levels of Aβ in plasma from AD patients whereas others were unable to confirm this observation (Irizarry 2004; Blennow et al. 2010). To date, based on the currently available measurements, the level of Aβ peptides in plasma appears to fluctuate significantly among individuals, ranging from 16 to 659 pg/ml, both in healthy controls and in AD possibly because these peptides are adsorbed to a variety of plasma proteins as a consequence of their intrinsic hydrophobicity. This observation hampers the possibility to use Aβ peptide concentrations in plasma as a reliable biomarker of AD (Roher et al. 2009).

A number of other alterations of protein expression and function in platelets have been proposed to be associated with the onset and progression of AD, but reported results are often controversial and the overall picture still remains unclear. A decreased activity of phospholipase A_2 has been reported in platelets from AD patients in different studies performed in the same laboratory (Gattaz et al. 1996, 2004, 2014), which have been questioned by others (Krzystanek et al. 2007). MAO-B is responsible for the degradation of neurotransmitters in the nervous system and is also expressed in platelets (Paasonen et al. 1964). Several studies independently documented an increase in MAO-B expression and activity in brain and platelets from AD patients (Bongioanni et al. 1997; Meszaros et al. 1998; Zellner et al. 2012; Cai 2014). Other studies, however, failed to detect any increase of platelet MAO-B activity related to AD (Mann et al. 1981; Konings et al. 1995; Muck-Seler et al. 2009).

It has been suggested that serotonin levels in platelets may be a marker for AD, although results from different laboratories are rather inconsistent. Some studies demonstrated a decreased serotonin uptake by platelets from AD patients (Koren et al. 1993; Inestrosa et al. 1993), whilst at least two other investigators found no differences (Tukiainen et al. 1981; Arora et al. 1991) or opposite results (Kumar et al. 1995). Further analysis is clearly needed to define the precise role of platelet serotonin in AD pathology.

Progression of AD in the brain also affects platelet reactivity. Sevush and collaborators reported a significant increase in circulating platelet aggregates and leukocyte-platelet complexes, as well as an increase of P-selectin exposure in resting platelets from AD patients, demonstrating that more platelets circulate in a pre-activated state in patients with AD compared to healthy controls (Sevush et al. 1998). More recently, Stellos and coworkers demonstrated that integrin $\alpha_{IIb}\beta_3$ is activated on the plasma membrane of resting platelets from AD subjects (Stellos et al. 2010; Laske et al. 2012). Interestingly, in a 1 year follow-up study, platelet activation parameters were found to correlate with the rate of cognitive decline. Importantly, anti-platelet therapy reduced cognitive decline in AD patients (Laske et al. 2010; Sakurai et al. 2013). The pre-activated state of platelets from AD patients is also confirmed by the increased number of circulating coated platelets in AD patients (Prodan et al. 2008, 2011). Coated platelets are a subset of activated platelets characterized by high pro-coagulant activity (Dale 2005). The hyper reactivity of platelets in AD has also been reported in transgenic mouse models of AD (Jarre et al. 2014; Canobbio et al. 2016). Besides platelet hyper activation, abnormal clot formation and degradation has been observed in AD patients accounting for altered coagulation (Cortes-Canteli et al. 2012). This may be related with the ability of Aβ peptides to bind fibrinogen forming a fibrin clot that is more stable and resistant to degradation (Ahn et al. 2010). The prothrombotic state of AD patients may also depend on increased levels of the adhesive protein von Willebrand factor (Mari et al. 1996), increased thrombin generation (Gupta et al. 2005), and increased activity of coagulation factor VII (Mari et al. 1996). As a result, microinfarcts and cerebral emboli are common in AD patients (Purandare and Burns 2009; Brundel et al. 2012).

In conclusion, the available information clearly demonstrates multiple correlations between platelets and AD. In addition to providing several possible diagnostic and prognostic biomarkers of the disease, whose reliability still requires validation, it also emerged that platelets may have an unexpected causative role in the onset and progression of AD, a possibility that opens up new perspectives in the understanding of this neurodegenerative disorder.

Platelets and Schizophrenia

Schizophrenia is a mental disorder characterized by a broad spectrum of symptoms, which display a great heterogeneity among different individuals and, for each patient, also among different periods of time. Emotional, behavioral and cognitive alterations are commonly reported. The correct diagnosis of schizophrenia is often challenging and, in spite of the extensive research performed, the biological mechanisms causing the disease are largely unknown and no reliable biomarkers have been identified. The chance to consider blood platelets as sources of possible peripheral markers for schizophrenia has thus appeared very attractive. Several studies reported an association between schizophrenia and alterations of platelet MAO activity. Platelets express only the MAO-B form, which is also the most abundant isoform in the brain (Youdim 1988). In 1972, an important study by Murphy et al. documented a reduced

MAO-B activity in platelets from schizophrenic patients (Murphy and Wyatt 1972), and this finding generated a strong impulse to the idea that platelet MAO-B could represent a reliable marker for schizophrenia. Subsequent studies on platelet MAO-B expression and activity were more accurately performed by distinguishing different patient subgroups defined in the light of selected parameters, including specific symptoms, genetic influence, and the effect of treatment (Baron et al. 1984; Baron 1985; Duncavage et al. 1982; Marcolin and Davis 1992). A major problem in this respect is that platelet MAO-B activity was found to vary significantly also in the control healthy population with age and gender, and it is also altered in several other psychiatric disorders (Asor and Ben-Shachar 2012). Moreover treatment with neuroleptic drugs was found to alter MAO-B activity in platelets; because of the difficulties of a precise diagnosis and the methodological issues for a standardized evaluation of MAO activity, the results collected over the years, instead of being conclusive, were rather controversial and inconsistent, and did not allow to establish a straightforward link between platelet MAO-B activity and schizophrenia.

As for other neurological disorders, several investigations have been performed to determine a possible link between dysfunctions in platelet serotonin metabolism and schizophrenia. High levels of platelet serotonin have been found in patients affected by chronic schizophrenia and are associated with auditory hallucinations (Stahl et al. 1983; Jackman et al. 1983; Muck-Seler et al. 1991). Interestingly, schizophrenic patients born in winter display the highest levels of platelet serotonin, whereas birth season has no effect on normal controls. Moreover, in schizophrenia patients, but not in healthy subjects, seasonal variations of serotonin levels were observed, with a positive peak in spring (Jakovljevic et al. 1997; Muck-Seler et al. 1999). A single study also showed that low levels of platelet serotonin can be correlated to non-paranoid schizophrenia (Muck-Seler et al. 1991). Conflicting results have been collected about the effects of antipsychotic drugs on platelet serotonin levels and serotonin receptor density. Similarly, the attempts of defining a correlation between schizophrenia and alterations in platelet serotonin uptake have provided controversial results and essentially suggested that this parameter is unlikely to be useful as a marker for the disease (Asor and Ben-Shachar 2012).

In addition to serotonin, the platelet metabolism of other neurotransmitters critical for the development of schizophrenia has been considered as potential peripheral markers for this disease. Different studies approached the problem by analyzing differences in schizophrenic patients in responses to a variety of parameters including platelet dopamine uptake and platelet activation, downstream glutamate, and α2-adrenergic receptors function. However, these studies failed to provide definitive clear results (Sundram et al. 1994; Baier et al. 2009).

The alteration of platelet function in schizophrenia has also been deeply investigated, since patients under antipsychotic therapy present a higher risk of mortality due to cardiovascular and thrombotic diseases (Asor and Ben-Shachar 2012). However, studies on unmedicated patients reported contradictory results, with some reports showing a stronger platelet responsiveness to ADP (Dietrich-Muszalska and Olas 2009; Yao et al. 1994) and lower sensitivity to collagen and serotonin (Dietrich-Muszalska and Olas 2009; McAdams and Leonard 1992), whilst others have shown that platelet responsiveness to these agonists was unaltered (Dinan 1987). It cannot be excluded that a more precise investigation on specific subpopulations of patients may help to clarify the importance of these observations.

Particular attention has been focused on the platelet prostaglandin metabolism, because alterations in the levels of prostaglandins are potentially involved in the development and the evolution of schizophrenia (Horrobin 1977; Feldberg 1976). A poor sensitivity of platelets to prostaglandin E1 was observed in schizophrenic patients (Kanof et al. 1987), associated with a reduced rise in cAMP and impaired inhibition of platelet aggregation (Kaiya et al. 1990; Ofuji et al. 1989). Platelets from schizophrenic patients also display an altered arachidonic acid metabolism and an increased phospholipase A_2 activity that are normalized by antipsychotic treatment (Gattaz et al. 1995). Analysis of intracellular signaling messengers for platelet activation revealed that schizophrenia is associated with a potentiated thrombin-stimulated activation of phospholipase C and increased levels of diacylglycerol, which can be a precursor for arachidonic acid generation, and inositol tris phosphate, that can be responsible for the raise of intracellular Ca^{2+} concentrations (Yao and van Kammen 1996; Ripova et al. 1997). A more recent study documented an alteration of the metabolism of plasmalogens in platelets from schizophrenic patients, characterized by decreased levels of platelet ethanolamine plasmalogens and docosahexaenoic acid, and increased amounts of choline plasmalogens compared to healthy controls (Wood et al. 2015).

A number of additional alterations of platelet markers have been reported to be associated with schizophrenia, including the levels of glutamine synthetase-like protein, the reduced expression of the tyrosine kinase Fyn, the reduced phosphorylation of GSK3β, and the increased activity of platelet mitochondrial complex I (Ben-Shachar et al. 2007; Burbaeva et al. 2006; Ferreira et al. 2015; Hattori et al. 2009; Dietrich-Muszalska and Kwiatkowska 2014). Nevertheless, despite the very high number of studies performed on this topic, there is a general inconsistency among the reported observations and thus the possibility to reliably exploit blood platelets as biomarkers for schizophrenia still remains elusive.

Platelets and Depression

Depression is bidirectionally linked to cardiovascular diseases. The incidence of major depression is dramatically increased in patients that have suffered a myocardial infarction (Forrester et al. 1992; Williams 2012) and, in turn, people affected by major depression display a higher risk to develop cardiovascular events. Depression is also associated with a faster and adverse progression of cardiovascular disease, resulting in an increased morbidity and mortality (Glassman 2007; Frasure-Smith et al. 1993; Thombs et al. 2006; Lesperance et al. 2002; Seligman and Nemeroff 2015). However, the mechanisms linking depression to cardiovascular diseases are still largely unknown, but platelets have been considered to play an important role in the bidirectional connection between these disorders. In particular, platelet dysfunction in depressed patients is thought to represent a major risk factor for the development of cardiovascular diseases.

Several studies have documented a significant platelet hyperreactivity, measured as platelet aggregation, integrin activation, and granule secretion, in depressed patients compared to healthy volunteers (Musselman et al. 1996; Markovitz et al. 2000; Lederbogen et al. 2001; Shimbo et al. 2002; Walsh et al. 2002; Serebruany et al. 2003). Increased platelet activation was observed in response to the major platelet agonists such as thrombin and collagen, and, importantly, also upon treatment with serotonin. It has been suggested that platelet hyper reactivity to thrombin is associated with increased phosphoinositides metabolism and inositol phosphate production. By contrast no differences in platelet aggregation induced by ADP were observed between depressed and non-depressed patients. Although many studies documented the hyper reactivity of platelets in depression, another study reported decreased platelet aggregation in response to collagen and serotonin in depressed subjects compared to controls (McAdams and Leonard 1992), a discrepancy that, however, may be related to methodological approach, as well as to the general study design (Williams 2012; Parakh et al. 2008).

The correlation between depression and platelets function is also supported by the fact that several biological molecules and pathways known to play important roles in depression, including α-adrenergic, adenosine and glutamate receptors, brain-derived neurotrophic factor (BDNF), and the serotonin pathway, are also part of the platelet signaling machinery (Williams 2012).

Serotonin metabolism is critical in depression and represents the preferential target of antidepressant therapy. Platelets store a significant part of the total body's serotonin, which can be secreted upon endothelial injury and platelet activation, and also express both serotonin transporters and receptors. Therefore, platelets represent an ideal peripheral model to obtain valuable information about dysfunctions of the serotonin pathway associated with major depression. In this context, reduced levels of platelet serotonin have been found in depressed patients and inhibitors of serotonin reuptake cause a strongest reduction of platelet serotonin in depressed people than in healthy controls (Maurer-Spurej et al. 2004, 2007; Muck-Seler et al. 2004). The effect of genetic polymorphisms of either serotonin transporters or receptors associated with depression and platelet function has been investigated, but these studies failed to provide straightforward results (Du et al. 2000; Minov et al. 2001; Zhang et al. 1997; Eley et al. 2004). An interesting possible peripheral marker for depression is the density of serotonin receptor, which was found to be strongly increased in depressed patients, whereas serotonin transporter binding and serotonin uptake rate were downregulated (Hrdina et al. 1995; Schins et al. 2003).

The observation that depressed patients display reduced platelet Ca^{2+} movements induced by stimulation of adenosine receptors, and a potentiated Ca^{2+} response upon stimulation of glutamate receptors suggested that dysregulation of these signaling pathways in platelets could be considered as additional peripheral marker for depressive diseases (Berk et al. 2001a, b). BDNF is an important regulator of neuron function and its reduction is considered among the causes for the atrophy of limbic structures observed in depressed patients (Duman and Monteggia 2006). BDNF is also present in blood, and depressed patients display decreased platelet levels, but increased plasma levels of this factor. Interestingly, improvements in the symptoms of the disease were paired to the normalization of BDNF levels (Serra-Millas et al. 2011).

Mitochondrial dysfunction is implicated in different complex neurological pathologies and it has also been suggested to participate in the development of mood disorders. A recent observation describes alterations of mitochondrial respiratory rate in platelets from patients with diagnosis of depressive disorder, suggesting that this alteration could be adopted as a novel biological marker of depression (Hroudova et al. 2013).

An interesting recent proteomic study performed using 2D electrophoresis revealed that a number of platelet signaling proteins can be differently expressed in depressed patients compared to healthy controls. For instance, the levels of protein disulfide-isomerase A3 (PDIA3) and F-actin-capping protein subunit beta (CAPZB) are significantly higher in patients with major depression than in healthy controls. Conversely, other proteins as fibrinogen β chain (FIBB), fibrinogen γ chain (FIBG), retinoic acid receptor beta (RARB), glutathione peroxidase 1 (GPX1), SH3 domain-containing protein 19 (SH319), and T-complex protein 1 subunit beta (TCPB) are expressed at lower levels in patients with major depression (Huang et al. 2014). In

addition to the expression level, also the activation state of some platelet signaling proteins is altered in depression, and thus has been proposed to represent a valuable peripheral marker. For instance, it has been recently shown that AD patients with depression symptoms display significant lower levels of platelet GSK3β phosphorylation, compared to controls and to AD patients without depression. Reduced GSK3 phosphorylation is typically associated with increased activity, suggesting a possible link between dysregulation of this kinase function and the occurrence of depressive symptoms (Platenik et al. 2014). Another research failed to detect alterations in GSK3β expression or phosphorylation in patients suffering bipolar disorders during depression episodes. However, the same investigation showed that lithium therapy promotes GSK3β phosphorylation and inhibition, that inversely correlates with clinical improvements (de Sousa et al. 2015).

Interestingly, major depression is also associated with an increased mean platelet volume that can be normalized by antidepressant therapy (Ataoglu and Canan 2009; Canan et al. 2012). Nevertheless, it should be noted that platelet volume, along with other platelet physical parameters, can be extremely variable also inside a population of healthy volunteers and can be influenced by age, origin, gender, and genetic factors (de Gaetano et al. 2012), implying that powerful verifications, that include a high number of samples, are required before considering this aspect of platelet biology use as peripheral markers of depression.

Platelets and Parkinson's Disease

Parkinson's disease (PD) is a neurodegenerative disorder characterized by slowed movements, tremor, and rigidity, and associated with degeneration of dopaminergic neurons in the substantia nigra region of the brain. The therapy for the motor symptoms of PD is based on the use of dopamine and MAO inhibitors. Through the years, platelets have been adopted as a model to study the uptake of dopamine and L-DOPA in PD patients under pharmacological treatment (Goubau et al. 2014; Boullin and O'Brien 1970; Barbeau et al. 1975). Moreover, platelets have also been used to investigate the molecular mechanisms involved in the onset of PD, and many studies have been focused to outline alterations of platelet MAO-B activity and expression in PD patients. Platelet MAO-B may represent a useful tool to monitor the efficacy of MAO-B inhibitors used in the treatment of PD (Goubau et al. 2014). Several works have reported that PD is associated with an increased MAO activity in platelets (Danielczyk et al. 1988; Steventon et al. 1989; Bonuccelli et al. 1990; Bongioanni et al. 1996; Zhou et al. 2001; Husain et al. 2009). However, other investigations recommended caution in interpreting the correlation between the disease and the levels of platelet MAO-B (Zellner et al. 2012; Kuhn et al. 1998).

An important hallmark of the disease is the presence of intracellular inclusions called Lewi bodies, which are enriched in α-synuclein, a neuronal protein playing a critical role in the development of neurodegenerative diseases (El-Agnaf et al. 1998; Saha et al. 2000; Sung et al. 2001; Recasens and Dehay 2014). α-synuclein is also expressed in platelets, but direct investigations do not support the possibility to adopt the analysis of platelet α-synuclein expression and phosphorylation as an appropriate peripheral biomarker of PD (Michell et al. 2005; Shults et al. 2006; Li et al. 2002).

Mitochondrial dysfunction is a typical trait of PD and is not restricted to neuronal cells. Mitochondrial dysfunctions in platelets from PD patients have been extensively investigated, as they could potentially represent a biomarker for diagnosis of the disease. Several authors reported a significant, up to 50 % reduction of complex I activity in the enriched preparations of platelet mitochondria from PD patients (Parker et al. 1989; Benecke et al. 1993; Krige et al. 1992), whereas others failed to detect any significant difference between healthy controls and PD patients (Blake et al. 1997; Mann et al. 1992). It has been suggested that these controversial results could derive from major differences in the methodological approaches, and, specifically, in the different procedure for enzyme extraction (Antony et al. 2015).

An early study showed that platelets from PD patients display an impaired aggregation in response to ADP and epinephrine, but not to collagen (Sharma et al. 1991) and other investigations suggested that PD could be associated with reduced glutamate uptake in platelets (Ferrarese et al. 1999, 2001), reduced expression of platelet α2-adrenoreceptors (Villeneuve et al. 1985), and increased mean platelet volume (Kocer et al. 2013).

Platelets and Autism Spectrum Disorder

Autism spectrum disorder (ASD) includes a variety of disorders of brain development characterized by difficulties in social interaction, verbal/nonverbal communication, and repetitive behaviors (Subramanian et al. 2015). Autism has been associated with developmental alterations in serotonin signaling (Janusonis 2014). Serotonin blood levels are also elevated in ASD patients (Gabriele et al. 2014). A large number of studies have described and confirmed elevated serotonin levels in circulating blood platelets (platelet hyperserotonemia) (Schain and Freedman 1961; Coutinho et al. 2004; Hranilovic et al. 2008; Tordjman et al. 2013; Anderson et al. 2002). The biological bases for the platelet hyperserotonemia, however, remain unknown.

Hyperserotonemia in autism may rely on increased synthesis of serotonin by tryptophan hydroxylase, increased uptake into platelets through the serotonin transporter, decreased release from platelets, and decreased metabolism by MAO-B (Hranilovic et al. 2008). Some data point out to a synergistic effect of genes regulating serotonin synthesis and degradation in dysregulation of the peripheral serotonin homeostasis of autistic patients (Hranilovic et al. 2008). In addition, variants of the serotonin transporter gene (*SLC6A4*) significantly contribute to hyperserotonemia in autism (Coutinho et al. 2004). More recently, defects in genes *NBEA*, *SCAMP5*, and *STXBP6* which are related with sporadic form of autism have been described and result in smaller dense core in granules compared to normal platelets (Castermans et al. 2010).

Conclusions

The possibility to use platelets as peripheral markers of complex neurological disorders represents a very attractive opportunity, as these cells could provide a non-invasive, reliable, and easy-to-obtain alternative cellular model for neurons. The enormous expectation coming from the possibility to identify specific platelet biomarkers for the diagnosis and prognosis of neurological disorders, however, has been largely disappointed. Despite the high number of studies performed on this topic over the last decades, results from different laboratories still remain highly controversial and in some cases contradictory. Nevertheless, the interest in this fled still remains very high, as all the studies so far performed unequivocally demonstrated that several complex neurological disorders have significant impacts on platelet function, that can be associated with an elevated risk of cardiovascular diseases. There is also a general awareness and agreement that neurological disorders are often very heterogeneous diseases. Thus it is likely that more accurate investigations on platelet physiology, focused on well-characterized specific subset of patients, may provide more reproducible results in the future. It should be remarked, however, that this field of investigation has importantly improved our general knowledge on platelet function and dysfunction. In some circumstances, for instance in the case of sporadic Alzheimer's disease, a novel possible contribution of circulating platelets to the onset and progression of the disease has emerged from a number of preliminary studies. All these findings clearly open up new perspectives, not only in the interpretation of the physiopathology of neurological disorders, but also in the characterization of the roles of platelets beyond hemostasis and thrombosis.

Take Home Messages

- Platelets display many structural and functional similarities with neurons
- Alterations of platelet function are often associated with several neurological disorders
- Platelets are good candidate as peripheral biomarkers for complex neurological disorders
- The study of platelet function and metabolism of selected platelet proteins may help to understand the biochemical alterations and pathogenetic mechanisms of some neurological diseases
- Platelets themselves can contribute to the onset and progression of some neurodegenerative disorders such as Alzheimer's disease.

The Role of Platelets During Development and Reproduction

Shrey Kohli and Berend Isermann

Abstract

Platelets are an essential component of the hemostatic system in non-pregnant and more so in pregnant women. Low platelet counts during pregnancy can be harmful both to the mother and the fetus and can lead to several complications during and after pregnancy. Studies in mice have demonstrated that platelets conduct important functions that ultimately contribute to normal development of the embryo and successful outcome of the pregnancy. While embryonic platelets are dispensable during intrauterine development, they are strictly required during the neonatal period to control hemostasis and closure of the ductus arteriosus. Conversely, maternal platelets—in addition to hemostasis—also regulate placental function, potentially through platelet-released mediators, and studies in mice suggest that increased platelet activation contributes towards the pathogenesis of hypertensive disorders of pregnancy (HDP). Maternal platelet activation has important but poorly defined functions at the feto-maternal vascular bed. This is exemplified by the crucial role of platelets for placental and developmental failure due to defects in the TM-EPCR coagulation system. The relevance of increased platelet activation for HDP is supported by the beneficial effects of inhibition of platelet activation on pregnancy outcome in women with HDP, as shown in large meta-analyses. However, there remains limited and meager mechanistic information on platelet associated pregnancy disorders, which coupled with the challenges of conducting clinical trials in pregnant women is restricting the development of novel therapeutics targeting platelet dependent patho-mechanisms during pregnancy.

Introduction

Changes in the hemostatic system during pregnancy are well established. During pregnancy the mother acquires a slight pro-thrombotic state, which increases the risk of thrombotic events. This potential disadvantage is thought to be outweighed by a decreased risk of hemorrhage and excessive blood loss during delivery. However the physiological relevance of the acquired pregnancy-associated hypercoagulable state remains unknown. Hypercoagulability is associated with an increase of pro-coagulant coagulation factors (e.g., factors I, V, VII, VIII, IX, X), increased platelet activation paralleled by a decreased number of circulating platelets, and increased microparticles (MP) (Fay et al. 1983; Bretelle et al. 2003; Aharon et al. 2004).

Thrombocytopenia During Pregnancy

Gestational thrombocytopenia, defined as a platelet count below 150,000/μl during pregnancy, is a common phenomenon occurring frequently (~8–10 % of pregnancies) in the

third trimester (Burrows and Kelton 1993a, b; Boehlen et al. 2000; Sainio et al. 2000), although a moderate drop of platelets is not associated with adverse maternal or fetal outcomes. A moderate thrombocytopenia may reflect an increased platelet turnover or a relative dilution due to an increased plasma volume. Inherited defects in platelet activation or number may also be detected for the first time during pregnancy and other potential causes, such as hepatitis C or hematological disorders, need to be considered as well. However, in the context of other pathologies, such as immune thrombocytopenic purpura (ITP), HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), or heparin-induced thrombocytopenia, a fall of the platelet count indicates a potential harmful pregnancy-associated disease process and the loss of platelet function itself may indeed become harmful.

Immune thrombocytopenia purpura (ITP) is an autoimmune disorder caused by the development of autoantibodies against platelet glycoproteins affecting about 0.2 % of pregnant women (Gernsheimer 2012). Platelets coated with IgG autoantibodies undergo accelerated clearance through Fcγ receptor-mediated phagocytosis by macrophages, preferably in the spleen and liver, causing a rapid platelet clearance from maternal circulation (Beardsley 2002; Cines and Blanchette 2002; Schwartz 2007). Some antiviral antibodies have been shown to cross-react with platelets, increasing the possibility of platelet antigen presentation by MHC class II on phagocytic cells (Wright et al. 1996). As these antibodies may cross the placenta they may also cause thrombocytopenia in the infant. ITP is therefore potentially harmful to both the mother and the fetus. ITP increases the risk of maternal bleeding especially during delivery and about one fifth of pregnant women with ITP develop moderate or severe hemorrhage (Webert et al. 2003). On the embryonic site intracerebral hemorrhage is a rare (less than 1 %), but dreaded complication, but hemorrhage at other anatomical sites is also possible (Burrows and Kelton 1993a, b; Fujimura et al. 2002; Stavrou and McCrae 2009). Of note, the platelet count nadir may occur after delivery and hence careful postnatal monitoring of platelet numbers is advisable. Due to a lack of reliable laboratory tests it can be challenging to differentiate ITP, a potentially harmful disorder, from the benign gestational thrombocytopenia, which accounts for the majority of thrombocytopenias during pregnancy (65–80 %) (Kadir and McLintock 2011; Gernsheimer 2012). Low platelet numbers (e.g., below 80×10^9/L), in particular during the first half of the pregnancy, are considered to occur only in ITP, but not gestational thrombocytopenia. Other causes of thrombocytopenia have to be excluded (Gernsheimer 2012). Management of ITP in pregnancy has been reviewed elsewhere (Kadir and McLintock 2011).

Platelets in Placental Dysfunction

Hypertensive disorders of pregnancy (HDP) such as preeclampsia and HELLP syndrome are a major cause of maternal, fetal, and neonatal morbidity and mortality affecting approximately 5–7 % of pregnancies (Huppertz 2008). These pregnancy-associated diseases are associated with endothelial dysfunction and a low platelet count. One of the key diagnostic criteria of HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) is a drop of platelet numbers in the peripheral blood (below 100,000/μl) (American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy 2013). An early drop of platelet numbers before the onset of renal changes has been demonstrated, compatible with a causative role of platelet activation (Hutt et al. 1994). Pregnancy in general, and hypertensive disorders of pregnancy in particular, are associated with increased activity of the hemostatic system, but to which extent the activated coagulation system contributes to the drop in platelet numbers is not known. However, hypertensive disorders are likewise associated with an imbalance of prostacyclin (a vasodilator and platelet inhibitor) and thromboxane (a platelet activator and vasoconstrictor) and hence changes in platelet numbers and activation may be simply the consequence of an underlying disorder. Additionally, platelet properties change in the context of hypertensive disorders of pregnancy, as they display an increase in membrane fluidity, cholesterol concentration (independent of plasma levels), and an increased ratio between unsaturated and saturated fatty acids (Coata et al. 1992; Rabini et al. 1995).

Markers of platelet activation such as β-thromboglobulin, thromboxane β2, platelet factor-4, or soluble P-selectin are associated with hypertensive disorders of pregnancy, reflecting increased platelet activation in these disorders (Pekonen et al. 1986; Louden et al. 1991; Jaremo et al. 2000; Harlow et al. 2002). Interestingly, platelet reactivity and the propensity to secrete ATP also increase in HDPs (Morrison et al. 1985; Hayashi et al. 1999). Further by-products of platelet activation are microparticles. Several studies have suggested an association of pro-coagulant microparticles with pregnancy complications and fetal loss (Laude et al. 2001; Bretelle et al. 2003) and in vitro microparticles isolated from women with pregnancy complications cause endothelial dysfunction in isolated myometrial arteries from healthy pregnant women (Vanwijk et al. 2002). Of note, not only platelet derived microparticles, but also microparticles of other cellular origin are associated with impaired pregnancy outcome (Marques et al. 2012). Indeed, syncytiotrophoblast derived MP interact with thrombin activated platelets, and this

interaction increases when using syncytiotrophoblast derived microparticles (MP) from pregnant women with preeclampsia compared to those from women without preeclampsia (Tannetta et al. 2015). The occurrence of microparticles may hence reflect general cell activation and maybe part of a self-propagating disease process. Accordingly, endothelial cell activation is well established in hypertensive pregnancy disorders, which likely contributes to MP formation and itself may cause platelet activation (Taylor et al. 1998; Kim et al. 2004; Powers et al. 2008). Other potential causes of increased platelet activation in hypertensive pregnancy disorders are activation of the renin–angiotensin–aldosterone system, increased levels of cytokines (TNFα, IL1β), or changed prostacyclin and thromboxane synthesis (Nadar and Lip 2004). Collectively, these studies imply a function of platelet activation and potentially microparticles for pregnancy-associated vascular dysfunction and fetal loss. It is conceivable that platelets either directly cause or propagate the disease process. However causality and potential mechanisms remain to be established.

Relevance of Maternal and Embryonic Platelets in Development

Early megakaryocyte like cells can be found as early as day 7.5 post-coitum (p.c.) (Xu et al. 2001). Thus megakaryocyte and potentially platelets are present in the embryo during the establishment of a cardiovascular system and formation of the hemochorial placenta. This raises the question as to whether platelets may be required for the development of the cardiovascular system or the placenta. Qualitative defects with less responsive platelets owing to absence of the Gαq subunit or the thrombin receptors, protease activated receptor-4 (PAR4) or PAR3, have no effect on placentation or pregnancy outcome (Offermanns et al. 1997; Camerer et al. 2004). Unlike in human platelets, in which PAR1 is the pivotal thrombin receptor required for thrombin dependent platelet activation, PAR4 activation by thrombin primarily fulfills this function in rodents, while PAR1 is dispensable. PAR3 is an accessory thrombin receptor on rodent platelets, enhancing PAR4 activation by thrombin, but it is not strictly required (Coughlin 2000). As both PAR3 and PAR4 deficiency does not impede placental or embryonic development, similar to that observed in Gαq deficient mice, qualitative platelet activation defects are entirely compatible with normal embryonic development and placentation in mice.

However, a severe quantitative platelet deficiency owing to the inactivation of the p45 subunit of the NF-E2 (nuclear factor erythroid derived 2) transcription factor, which regulates megakaryopoiesis and is required for pro-platelet formation, does result in a growth retardation of the embryo and placental malperfusion (Shivdasani et al. 1995; Shivdasani and Orkin 1995; Kashif et al. 2011). The absence of such defects in Gαq or PAR4 deficiency already indicates a function of platelets for placentation independent of their activation potential, or a specific function of p45 NF-E2 independent of platelets for placentation. Specific restoration of p45 NF-E2 expression in trophoblast cells by tetraploid aggregation or lentiviral infection of trophectoderm paired with platelet restoration experiments excluded a function of embryonic platelets and established a function of the transcription factor p45 NF-E2 in trophoblast cells for placentation (Kashif et al. 2011). These studies demonstrated for the first time a function of p45 NF-E2 beyond the regulation of megakaryocyte function and platelet formation. In detail, specific reconstitution of p45 NF-E2 in trophectodermal cell lineages is sufficient to restore placental vascularization and embryonic growth despite persistent platelet deficiency (Kashif et al. 2011). Expression of p45 NF-E2 in cells of the trophectodermal cell lineage is required to restrict extensive syncytiotrophoblast formation and permitting normal placental vascularization and embryonic growth (Kashif et al. 2011). p45 NF-E2 modulates Gcm-1 expression by increasing acetylation of JunD and thus its binding to the Gcm-1 promoter (Kashif et al. 2012). These studies clearly establish that p45 NF-E2 has a cell-autonomous function in trophoblast cells, modulating their differentiation, while embryonic platelets are dispensable for placentation and embryonic development. Whether the regulation of megakaryopoiesis and pro-platelet formation by p45 NF-E2 depends on a similar function as in trophoblast differentiation remains unknown.

Akin to the situation in humans, mice lacking platelets display a hemorrhagic diastasis, which in mice is of minor relevance prenatally, but causes frequently postnatal death (Palumbo et al. 2004) (Fig. 1). Of note, fibrinogen deficiency combined with defective platelet function, either quantitative (p45 NF-E2 deficiency) or qualitative (Gαq or PAR4), is compatible with normal placentation and embryonic development in mice, demonstrating that the primary endpoint of hemostasis, the formation of a fibrin-platelet aggregate (Camerer et al. 2004; Palumbo et al. 2004), is not required for intrauterine development. The combined loss of fibrinogen and platelet function results, however, in postnatal hemorrhagic death likely secondary to trauma during vaginal delivery or mild trauma postnatally. The development defects observed in mice with PAR1 deficiency (which is not expressed on murine platelets) or combined PAR1 and PAR2 deficiency must be conveyed independent of platelets and interestingly depends at least in part on proteases not related to coagulation (Camerer et al. 2010).

Platelets do, however, convey an important postnatal developmental function unrelated to the prevention of hemorrhage. Echtler and colleagues established that platelets are crucial for closure of the ductus arteriosus (DA) which is a physiological arterial shunt connecting the pulmonary artery

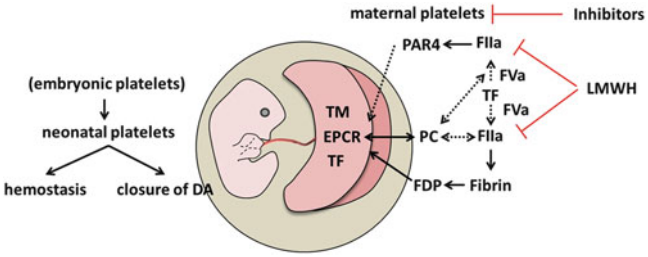

Fig. 1 Scheme summarizing the effects of platelets in reproduction. Embryonic platelets are not required during intrauterine development. However, postnatally they are required for normal hemostasis and they contribute to the proper closure of the ductus arteriosus (DA). Conversely, maternal platelets are required for proper placental function. Through poorly defined mechanisms they contribute to normal placentation. Excess platelet activation via PAR4, e.g. secondary to a disturbed interaction of embryonic (thrombomodulin, TM, endothelial protein C receptor, EPCR, tissue factor, TF) and maternal (thrombin, FIIa; fibrinogen and fibrin, activated factor V, FVa) coagulation regulators at the placental fetal–maternal interface cause placental dysfunction and embryonic demise. These effects can be improved by treatment with low-molecular weight heparin (LMWH) or inhibition of platelet activation

with the aortic arch in the fetus. Its presence in fetal life is required to bypass the non-ventilated lungs. However, its closure within 24–48 h in human newborns is important to avoid cardio-pulmonary complications (Tada and Kishimoto 1990; Hammerman and Kaplan 2001). Patency of DA (PDA) occurs in about 0.2 % preterm neonates and is a major cause of neonatal congenital heart diseases (Mitchell et al. 1971). In this context, platelets play an important role by adhering to DA lumen minutes after birth, which triggers rapid DA closure by thrombotic obstruction (Fig. 1). A quantitative defect of platelets such as in p45 NFE2−/− mice neonates results in DA occlusion defects in about 70 % pups and in persistence of a hemodynamically relevant left-to-right shunt and pulmonary hypertension, leading to right ventricular remodeling (Echtler et al. 2010). These findings are well correlated with human newborns where platelets adhere at the sites of endothelial denudation in constricted DAs but not in PDAs. Additionally, thrombocytopenic preterm neonates had a higher incidence of PDA (68 %) compared to neonates with normal platelet counts (16 %). This indicates an imperative role of platelets in closure of DA in the neonatal period (Echtler et al. 2010).

Unlike the dispensability of embryonic platelets, maternal platelets are required during placentation. Placental tissues from p45 NF-E2 null mothers display large blood pools indicating hemorrhage into the placenta, which, however, does not impair maternal or embryonic survival or embryonic development. This phenotype is specific to maternal platelet deficiency and independent of the embryonic platelet deficiency (Fig. 1). Strikingly, maternal fibrinogen deficiency causes excessive bleeding into the placenta and the uterine cavity, resulting in abortion and hemorrhagic death of the mother in mid-gestation (Suh et al. 1995). These contrasting phenotypes of p45NF-E2 and fibrinogen deficient mice indicate that fibrinogen mediates a crucial function of placentation beyond blood clotting. It is conceivable, but remains to be shown, that fibrinogen, fibrin, or fibrinogen derived peptides have a function during placentation independent of blood clotting, such as tissue-remodeling or cell-adhesion. Intriguingly, low-TF (tissue factor) activity in pregnant female mice results in placental hemorrhage, but also subtle structural alterations within the placenta (Erlich et al. 1999). Whether the impaired TF-activity and loss of fibrinogen share a common mechanism in placentation and whether maternal platelets contribute to these functions remains unknown.

Role of Platelets in TM-EPCR Pathway During Development

While the question as to whether fibrinogen has a function in placentation independent of blood clotting (e.g., the fibrin-platelet aggregate formation) remains unknown, a function of the cell-surface expressed coagulation regulators thrombomodulin (TM) and endothelial protein C receptor (EPCR) independent of blood clotting is established (Healy et al. 1995; Gu et al. 2002). Loss of TM is embryonic lethal at day 8.5 p.c., causing rapid resorption until day 9.5 p.c. Likewise, loss of EPCR causes embryonic death around day 8.5 p.c., but the phenotype is less protruding and resorption of death embryos is protracted (Healy et al. 1995; Gu et al. 2002). The rapid resorption of TM-deficient embryos reflects the dual role of TM both in activating protein C and inhibiting fibrinolysis through activation of thrombin activatable fibrinolysis inhibitor (TAFI, aka as carboxypeptidase N) (Nesheim et al. 1997; Isermann et al. 2003). Increased fibrinolysis and generation of fibrin-split products in TM-null placentae with reduced TAFI activation induces trophoblast cell death and hence rapid resorption (Isermann et al. 2003). The TM-null and EPCR-null embryonic lethal phenotype can be both rescued by trophoblast specific expression of TM or EPCR, respectively, establishing that the expression of both anticoagulant regulators is required on embryonic trophoblast cells at the embryonic maternal interface (Isermann et al. 2001; Li et al. 2005) (Figs. 1 and 2). High levels of thrombin generation in these mice could potentially activate PAR receptors on trophoblast cells of the placenta. Deficiency of PAR1 or PAR2 from the trophoblast and embryo is, however, not protective in TM null embryos, establishing that the placental defect in TM-null embryos is independent of excessive PAR1 or PAR2 activation (Sood et al. 2008). Intriguingly, maternal—but not embryonic—PAR4 deficiency is able to partial rescue TM null embryos (Sood et al. 2008). Additionally, maternal platelet deficiency in p45 NF-E2-null mice or platelet depletion by antiplatelet antibodies likewise partially rescues TM-null embryos

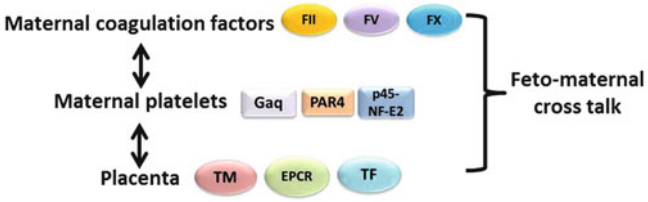

Fig. 2 Maternal coagulation factors and coagulation protease signaling regulated by the TM-EPCR system on trophoblast cells maintain the feto-maternal cross talk at the placental vascular bed and are required for normal placentation, placental function, and embryonic platelets. Maternal platelets play an important mediator in modulating this hemostatic balance and their activation can lead to placental dysfunction and pregnancy failure. *FII* Factor II, *FV* Factor V, *FX* Factor X, *Gαq receptor* Gαq, *PAR4* protease activated receptor 4, *p45-NF-E2* p45 subunit nuclear factor erythroid derived 2, *TM* thrombomodulin, *EPCR* endothelial protein C receptor, *TF* tissue factor

(Sood et al. 2008). These studies establish a role of maternal platelets and platelet activation in regulating the lethality of TM-null embryos (Figs. 1 and 2). The only partial rescue of TM-null embryos in the presence of maternal platelet deficiency indicates the involvement of other unidentified mechanisms or simply partial efficacy in platelet depletion.

The developmental function of TM depends on TF mediated activation of the coagulation system. Expression of tissue factor on the placental trophoblast cells, which are in direct contact with maternal blood, provides a constitutive pro-coagulant stimulus in the placental vascular bed. TM-EPCR-dependent mechanisms, potentially restricting excessive coagulation activation, are required to restrict harmful TF-dependent effects. The precise mechanistic interactions of TM and TF remain unknown. Embryonic lethality of TM-null embryos can be rescued by concomitant embryonic TF-deficiency, establishing a functional interaction. As excessive blood clotting has not been detected in TM-null embryos the death promoting mechanism of TM-null embryos must be independent of occlusive blood clot, but related to a blood-clot-independent interaction between TM and TF. Of note, as platelet deficiency improves survival of TM-null embryos, the mechanism must depend on platelets. Importantly, these findings establish that maternal platelets interact with coagulation regulators expressed within the placenta (TM, TF) and that this interaction of maternal and fetal coagulation components is required for successful placentation. While TF-deficiency rescues the TM-null associated lethality, the reverse is not true. The vascular defect (e.g., in the yolk sac) and embryonic lethality observed in TF-deficient embryos around day 10.5 p.c. persist despite TM-deficiency (Isermann et al. 2003).

The translational relevance of these insights is emphasized by the interaction of a frequent thrombophilic risk factor, the factor V Leiden (FVL) mutation, resulting in resistance to activated protein C, with hypomorphic embryonic TM expressed within the placenta and maternal platelets. The FVL mutation is associated with fetal loss and adverse pregnancy outcomes and the combined presence of maternal FVL and partial loss of TM-dependent protein C activation on trophoblast (by expression of the G404P TM-mutant, TM^{Pro}, with markedly reduced ability to activate protein C) is embryonic lethal (Sood et al. 2007). For example, intercrossing mice with homozygous FVL-mutation along with one TM^{Pro} allele ($TM^{Pro/+}$) shows a complete lethality of $Fv^{qq}TM^{ProPro}$ and fewer $Fv^{qq}TM^{Pro+}$ embryos. TM^{ProPro} embryos in $Fv^{qq}TM^{Pro+}$ mothers possess developmental defects at day 9.5 p.c. and are lost by day 10.5 p.c. The placentae of these embryos are smaller and lack a well-formed labyrinth layer, reflecting a failure of vascular remodeling and potential invasion of embryonic blood vessels into the developing placenta. This placental phenotype is, however, not associated with signs of thrombosis or impaired placental perfusion secondary to thrombosis (Sood et al. 2007). Importantly, maternal platelet depletion starting at day 7.5 p.c., but not at day 9.5 p.c., prevents embryonic loss (Sood et al. 2007). Similar to the results obtained in TM-null embryos, PAR4 deficiency, resulting in platelets unresponsive to thrombin, rescues the developmental block of TM^{ProPro} embryos in $FV^{qqTMPro+}$ mothers. This suggests that increased platelet activation during early placentation (~day 7.5 p.c.) impairs placental development and/or function and proper embryonic development in a pro-thrombotic maternal environment. Intriguingly, the authors consistently were unable to detect blood clots within the placenta. Nevertheless, low-molecular weight heparin (LMWH) treatment, which is expected to dampen coagulation and hence platelet activation, is protective in this model of platelet dependent abortion. Strikingly, while the authors concluded that thrombin mediated maternal platelet activation is central for placental failure, other anticoagulants, including the direct thrombin inhibitor lepirudin, failed to be protective (An et al. 2013). Hence, the precise mechanism causing platelet activation and subsequent placental failure remains unknown.

Role of Platelets on Trophoblast Cells: The Other Side of the Coin

Inappropriate physiological remodeling of maternal spiral arteries is one of the most common phenomena seen in cases of preeclampsia and embryonic growth restriction. Normally, placental cytotrophoblasts differentiate into extra villous trophoblasts (EVTs) that migrate towards the maternal decidua and blood vessels, in particular the spiral artery. Perivascular EVTs disrupt the muscular lining and even replace the endothelium thereby reducing the vascular resistance and ensuring adequate supply of nutrients from the mother to the fetus through the placenta (Ramsey 1981; Khong et al. 1986). Hence a sufficient placental perfusion is

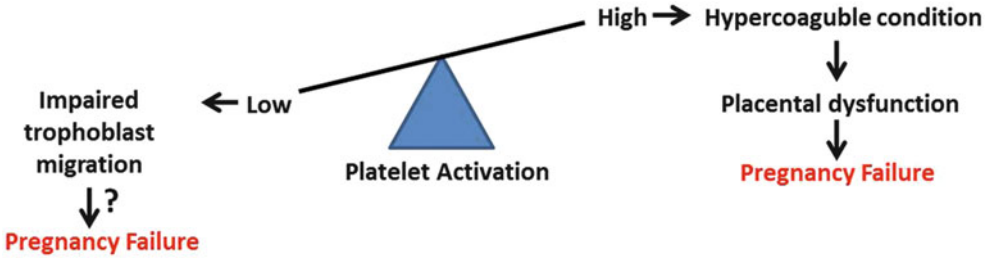

Fig. 3 Model reflecting the requirement of well-balanced maternal platelet activation for successful pregnancy. On one hand, enhanced platelet activation causes impaired placentation and placental dysfunction leading to pregnancy failure and embryonic demise, while on the other hand activation of platelets is required for trophoblast migration and spiral artery remodeling and its failure can likewise promote placental and pregnancy failure

dependent on an efficient migratory system by EVTs. The breaching of maternal blood vessels by EVTs allows direct contact between embryonic trophoblast cells and maternal blood components, including blood cells such as platelets. The direct interaction of trophoblast cells with maternal blood cells is characteristic for the hemochorial placentation as found in humans and mice (Malassine et al. 2003). The relevance of this is exemplified by the interaction of maternal soluble coagulation regulators (e.g., factor V and platelets) and embryonic blood coagulation regulators expressed by trophoblast cells (e.g., thrombomodulin), as described in the previous section. The interaction of maternal platelets with the placenta may, however, extend beyond the regulation of blood clotting. Activated platelets can adhere to isolated EVTs in vitro and—in a matrigel assay—enhance invasion of isolated EVTs via platelet derived chemo-attractants and the receptor CCR1 (Sato et al. 2005). Additionally, the platelets promote a phenotypical switch of ETVs towards an endovascular phenotype, characterized among others by integrin α1 expression (Fig. 3). The exact role of platelets during the process of trophoblast invasion and differentiation and the potential physiological or pathophysiological role of the platelet-trophoblast interaction remains unknown. Of note, the physiological decline of circulating platelets has been attributed to an increased consumption of platelets in the utero-placental circulation, supporting the concept that platelets bind to and accumulate in the placenta (Juan et al. 2011). This assumption remains, however, unproven. Based on the relevance of platelets for embryonic abortion in a hypercoagulable placental environment, one has to assume that excess platelet activation impairs successful placentation, although the underlying mechanism remains poorly defined (Fig. 3).

Clinical Implications and Antiplatelet Therapy

A physiological role of the pregnancy-associated pro-thrombotic state in reducing the bleeding risk at delivery has been proposed. However, at the same time this may increase the risk for adverse outcomes, such as thrombotic events or placental complications. High platelet aggregation and concentration of coagulation factors especially during the third trimester of pregnancy may initiate a vicious cycle of platelet activation, release of platelet derived factors, and further pronounced platelet activation, impairing placental development and pregnancy outcome. As outlined above, only maternal, but not embryonic, platelets are a risk contributor in this setting. However, it is the interaction between the mother and fetus, which is crucial and instigates adverse events at the feto-maternal placental barrier leading to developmental failure and pregnancy loss. Given the contribution of embryonic trophoblast paternal genes and risk factors are expected to contribute to the risk of placental dysfunction—a widely understudied aspect (Galanaud et al. 2010).

Anticoagulants and antiplatelet agents are used to reduce this risk associated with thrombophilia and HDP. In regard to thrombophilia the evidence remains weak at best (Magee et al. 2008, 2014) and careful consideration of the expected benefit and side-effects is required. Anticoagulants such as heparin are associated with a risk of heparin-induced thrombocytopenia or osteoporosis (Nelson-Piercy 1997). Yet, heparins are the most common therapy during thromboembolic events of pregnancy, reflecting the good clinical experience in using these anticoagulants during pregnancy and the fact that they do not cross the placenta (Omri et al. 1989). While anticoagulants (heparins) are established for the treatment of thromboembolic events in pregnancy and have been frequently proposed to convey a therapeutic benefit in thrombophilia associated placental dysfunction, the role of anticoagulants such as heparins during HDP remains unclear.

Considering the above-described role of platelets during placentation antiplatelet agents may be an interesting alternative for HDP. According to a Cochrane review that looked at 39 trials involving >30,000 women, treatment with antiplatelet agents significantly reduces the risk of pre-eclampsia by 15 % (Knight et al. 2000; Duley et al. 2001). Intriguingly, the risk of hypertension in pregnancy was not affected, implying a specific role of platelets in preeclampsia (Knight et al. 2000; Duley et al. 2001). To prevent one case of preeclampsia 85 women need to be treated. Use of

antiplatelet agents was also associated with a small, but significant, reduction in the risk of delivery before 37 weeks (−8 %) or infant death (−14 %). In regard to the risk reduction of HDP, aspirin, the most commonly used antiplatelet agent, showed a beneficial effect. Reliable suggestions for the best dosage regimen cannot be made and the suggestion to use 75 mg or less simply reflects the fact that most studies used such low dosages of aspirin (Knight et al. 2000; Duley et al. 2001). Other platelet inhibitors, such as TXA2 synthase inhibitors, TXA2 receptor antagonists, 5-hydroxytryptamine receptor type 2 blockers, have been proposed, but experience in women with HPD is limited. Clopidogrel has been found to be effective with animal models with no fetal toxicity, but data from human patients is limited (Santiago-Diaz et al. 2009; De Santis et al. 2011). Prasugrel and Ticagrelor are two other recent antiplatelet agents that have been investigated, but to date only in animal studies (Patti et al. 2014). Anticoagulants such as hirudin have been likewise considered, but at face-value heparins, which do not cross the placenta, appear to be a safer alternative (Omri et al. 1989). Endothelin antagonists target specific endothelial dysfunction in HPD and have also shown protective effects in animal models (Olson et al. 1999). By increasing endothelial nitrite oxide endothelin antagonists would also restrict platelet activation. Evaluating the efficacy of antiplatelet therapies for pregnancy-associated complications such as HDP has been limited hitherto reflecting the difficulties to conduct randomized controlled trials in pregnant women. It remains a major challenge to test agents which might be potential relevance and benefit for affected pregnant women.

Take Home Messages

Thrombocytopenia During Pregnancy

- Platelets are essential to maintain the hemostatic balance during pregnancy.
- Gestational thrombocytopenia is characterized by a moderate drop of platelets. It is frequent, but harmless.
- ITP can cause thrombocytopenia in the mother and the infant and requires careful work-up and close monitoring.

Relevance of Maternal and Embryonic Platelets in Development

- Qualitative or quantitative embryonic platelet defects are compatible with normal placentation and embryonic development.
- Postnatally platelets are required for proper closure of the ductus arteriosus and for hemostasis.
- Maternal platelets and fibrinogen are required for proper placentation.
- The transcription factor p45 NF-E2 is expressed in hematopoietic and trophoblast cells. p45 NF-E2 regulates placentation and embryonic development independent of platelets.

Role of Platelets in TM-EPCR Pathway During Development

- Maternal platelets interact with embryonic coagulation regulators expressed within the placenta and regulate the hemostatic balance at the feto-maternal interface.
- Excess maternal platelet activation contributes to the poor placentation and embryonic growth restriction or lethality caused by defects in the TM-PC system.

Clinical Implications and Antiplatelet Therapy

- Antiplatelet agents can reduce the risk associated with thrombophilia and HDP and may constitute an interesting therapeutic approach.
- Further research is required to define the clinical value of antiplatelet therapy for HDP.

Platelet-Derived Inhibitors of Platelet Activation

A.J. Unsworth, A.P. Bye, and J.M. Gibbins

Abstract

Negative regulators of platelet activation are a relatively unexplored aspect of platelet physiology yet have an important role in tempering thrombus development by contributing much needed negative regulation to a process that is amplified by several positive feedback mechanisms. Some negative regulators, such as RASA3 and JAM-A, act as gatekeepers that modulate key mediators of activation and provide barriers that must be deactivated to permit full activation and stable thrombus formation. Other negative regulators, such as PECAM-1 and other proteins that signal through ITIMs, come into play once platelets are activated and provide restraining, negative feedback for activatory pathways. Many platelet-derived inhibitors have been identified but not fully characterised and so questions remain regarding the mechanisms that underlie the effects on platelet activity following their activation, inhibition or genetic disruption. However, dysregulation of inhibitory signals is believed to contribute to enhanced risk of thrombosis in diseases such as diabetes and other pathological conditions. In this chapter we have described platelet-derived inhibitors of platelet function that are secreted by or expressed within platelets themselves to provide inhibition or negative regulation to the processes that underpin activation.

Introduction

When blood vessels are damaged, circulating platelets come into contact with activating stimuli that trigger aggregation and enable them to form a hemostatic plug. This process is subject to both positive and negative feedback to ensure that platelets respond appropriately to damage and do not form thrombi that totally occlude the vessel. It is believed that dysregulation of negative feedback mechanisms contributes to increased risk of thrombosis associated with some diseases. Despite this association with thrombosis, platelet-derived negative regulators of platelet activation are relatively poorly understood in comparison to mediators of platelet activation. However, it is becoming increasingly apparent that the mechanisms by which platelets restrain activation are diverse and of equal complexity to those that mediate positive signaling. Some regulators, such as RASA3 and JAM-A, act as gatekeepers that must be deactivated before platelet activation can occur. In contrast, regulators that contain ITIMs, such as PECAM-1, are activated following stimulation and mediate negative regulation via phosphatases that restrain activation. Wnt3a and ESAM are thought to directly limit platelet-platelet adhesion by blocking activation of the fibrinogen receptor, integrin $\alpha_{IIB}\beta_3$. The various isoforms of PKC expressed by platelets elicit a diverse and complex array of inhibitory effects including receptor desensitisation. Many platelet derived inhibitors have been identified but not yet fully characterized and so questions remain regarding the details of their roles in the regulation of platelet activity. In this chapter we have described platelet-derived inhibitors of platelet function that are secreted by or expressed within platelets themselves to

provide inhibition or negative regulation to the processes that underpin activation (Table 1).

ITIM Signaling

Immunoreceptor tyrosine-based inhibitory motif (ITIM) containing receptors are capable, following ligand binding, of triggering cell signaling mechanisms that counteract activation processes. The ITIM consensus sequence L/I/V/S-x-Y-x-x-L/V usually found in the cytoplasmic tail has been identified in several proteins that are expressed in platelets, including PECAM-1, CEACAM, G6b-B, and LILRB2/PIRB which are associated with the negative regulation of platelet activation (Wu and Lian 1997; Cicmil et al. 2000; Jones et al. 2001; Wong et al. 2009; Alshahrani et al. 2014; Yip et al. 2015; Newland et al. 2007; Mori et al. 2008; Coxon et al. 2012). When ITIM-bearing receptors bind their ligand, the receptors cluster and src family kinases phosphorylate the tyrosine residues in the ITIM motif. The phosphorylated ITIM is then able to recruit negative regulators including phosphatases such as SHP1/SHP2 (Kharitonenkov et al. 1997) and SHIP1/SHIP2 (Bruhns et al. 2000). The recruited phosphatases are localised within close proximity to their substrates, which allows them to inactivate molecules involved in activatory cell signaling including tyrosine kinases and phosphatidylinositol 3-kinase (PI3K) (Fig. 1). ITIMs were initially considered to be the 'off switch' that counteracts the positive signaling initiated by ITAM (Immunoreceptor tyrosine-based activation motif, consensus sequence $Yxx(L/I)x_{6-12}Yxx(L/I)$) containing receptors such as the GPVI (glycoprotein VI) receptor complex. However, studies have now identified negative regulation of GPCR signaling by PECAM-1 and G6b-B that are independent of ITAM signaling pathways (Newland et al. 2007; Jones et al. 2009) (Fig. 1).

PECAM-1

Platelet endothelial cell adhesion molecule-1 (PECAM-1) is a 130 kDa member of the immunoglobulin superfamily that is expressed on several haematopoietic cells including platelets, monocytes, neutrophils, some types of T cells and endothelial cells and is associated with several biological processes including negative regulation of platelet activation (Newman 1997). PECAM-1 contains a 574 amino acid extracellular domain that is composed of 6 Ig-like domains and mediates homophilic interactions with other PECAM-1 molecules. It also contains a short 19 amino acid single transmembrane spanning domain and a 118 amino acid cytoplasmic domain that includes the ITIM (Sun et al. 1996; Newton et al. 1997; Goyert et al. 1986; Lyons et al. 1988). Expression levels of PECAM-1 are variable with copy numbers ranging between 5,000 and 20,000 present at the cell surface per platelet (Jones et al. 2009). PECAM-1 is present in platelet α-granules, resulting in an increase in cell surface expression following platelet activation and granule secretion (Hidari et al. 1997; Wu and Lian 1997; Metzelaar et al. 1991; Jones et al. 2009). PECAM-1 is believed to be activated by homomeric clustering (Thai le et al. 2003) but interactions with other receptors have also been reported (Buckley et al. 1996). Clustering of PECAM-1 to ITAM containing receptors or ligation of PECAM-1 using anti-PECAM-1 antibodies or recombinant human PECAM-1 immunoglobulin chimeras has been shown to inhibit GPVI, GPIb and GPCR-stimulated platelet aggregation. Activation of PECAM-1 has broad effects on signal transduction, including reduced total tyrosine phosphorylation, inositol tris-phosphate production, Ca^{2+} mobilisation and granule secretion which underpins a reduction in thrombus formation (Cicmil et al. 2002; Jones et al. 2001, 2009; Thai et al. 2003; Rathore et al. 2003). PECAM-$1^{-/-}$ platelets exhibit hyperreactivity when stimulated with low concentrations of collagen and CRP (collagen related peptide) but not thrombin, ADP or PAR receptor agonists. Studies that have measured laser-induced thrombus formation in cremaster muscle arterioles in vivo using mice deficient in PECAM-1

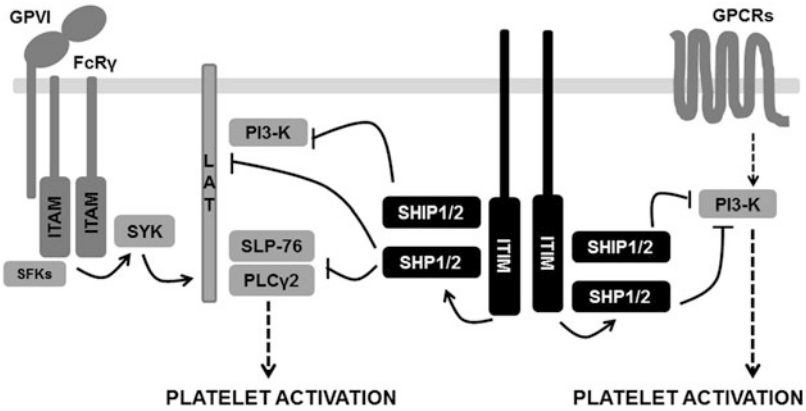

Fig. 1 ITIM signaling. When ITIM-bearing receptors bind their ligand they cluster and the ITIM domains are phosphorylated. The phosphorylated ITIM domains recruit phosphatases through their SH2 domains, bringing them into close proximity with their substrates. The phosphatases SHP1/2 and SHIP1/2 dephosphorylate PI3K, LAT and PLCγ2 and other molecules in the signaling pathways evoked by ITAM containing/linked receptors, such as GPVI, causing inactivation and contributing to negative regulation. The phosphatases recruited by ITIMs are also able to negatively regulate PI3K downstream of GPCRs, contributing negative regulation to non-ITAM signaling pathways

indicate an inhibitory role for PECAM-1 in the regulation of thrombus formation, as increased thrombus size and stability is observed (Falati et al. 2006).

PECAM-1 is regulated by phosphorylation of its cytoplasmic tail at the tyrosine residues Y663 and Y686 within the ITIM and ITSM (immunoreceptor tyrosine-based switch motif) motifs. PECAM-1 is constitutively phosphorylated at low levels in resting platelets and phosphorylation is increased following anti-PECAM-1 antibody induced crosslinking, but also in response to several platelet agonists including collagen, convulxin, thrombin and GPIb agonists suggesting that PECAM-1 provides a negative feedback mechanism to control the level of platelet activation and thrombus formation (Jackson et al. 1997; Modderman et al. 1994; Cicmil et al. 2000; Jones et al. 2001; Rathore et al. 2003). Phosphorylation of PECAM-1 at an ITIM is mediated by activation of Src family kinases and Fyn, Lyn, Src, Yes and Hck have all been shown to coimmunoprecipitate with PECAM-1 (Cao et al. 1998; Cicmil et al. 2000). Phosphorylated ITIMs provide a binding and activation platform for SH2 domain containing proteins, including phosphatases SHP1 and SHP2, SHIP1 and PP2A (Pumphrey et al. 1999; Relou et al. 2003; Henshall et al. 2001) that are associated with the negative regulation of platelet activity. Following activation of GPVI signaling, PI3K associates with the LAT signalosome which is located in lipid rafts that are enriched with the phosphoinositide substrates of PI3K. In contrast to LAT, the majority of PECAM-1 molecules are excluded from lipid rafts. Following crosslinking of PECAM-1, SHP2 is recruited to PECAM-1 and associates with PI3K, relocalising PI3K away from lipid rafts and the LAT signalosome, preventing association with and activation of PI3K (Moraes et al. 2010a). Most recently the mechanism by which PECAM-1 negatively regulates responses to non-GPVI agonists such as thrombin and VWF has also been described (Jones et al. 2014). PECAM-1 inhibits fibrinogen binding and secretion stimulated by thrombin but not PAR1 and PAR4 activating peptides, which suggests that PECAM-1 has a role in regulating GPIbα, a receptor that recruits thrombin to the platelet plasma membrane facilitating stimulation of PARs (Jones et al. 2012). PECAM-1 was found to mediate the internalisation of GPIbα in platelets through dual AKT/glycogen synthase kinase-3/dynamin-dependent and $\alpha_{IIb}\beta_3$-dependent mechanisms.

A study looking at the expression patterns of PECAM-1 in platelets has identified that expression levels of PECAM-1 are variable within the human population with approximately 5,000–20,000 copies estimated to be present at the cell surface. Analysis of the relationship between receptor expression levels and platelet responsiveness to platelet agonists revealed an inverse relationship between levels of PECAM-1 expression and platelet response to stimulation by CRP and ADP (Jones et al. 2009). Although the association is described as modest accounting for 6–10 % of total variability in responses, this was at a similar level of magnitude to that observed for the positive correlation of GPVI or $\alpha_{IIb}\beta_3$ expression levels with platelet responsiveness.

Despite the overall negative role for PECAM-1 in the regulation of platelet activity, PECAM-1 signaling in other cell types is associated with the regulation of integrin function, whereby crosslinking of PECAM-1 enhances adhesion mediated by integrins (Tanaka et al. 1992; Piali et al. 1993; Leavesley et al. 1994; Berman et al. 1996; Varon et al. 1998; Chiba et al. 1999; Zhao and Newman 2001). Studies in human platelets have shown that antibody crosslinking of PECAM-1 enhances adhesion and spreading on fibrinogen (Zhao and Newman 2001) indicating a positive role for PECAM-1 in the regulation of integrin $\alpha_{IIb}\beta_3$. Mouse platelets deficient in PECAM-1 show impaired spreading and adhesion on fibrinogen, clot retraction and phosphorylation of focal adhesion

kinase, suggesting a defect in integrin $\alpha_{IIb}\beta_3$ outside-in signaling (Wee and Jackson 2005). It has been hypothesised that a dual role for PECAM-1 could therefore exist, in which it initially functions to suppress platelet activation but once platelets are strongly activated, PECAM-1 positively regulates functions mediated by integrin outside-in signaling (Jones et al. 2012).

High plasma cholesterol levels significantly increase an individual's risk of atherosclerosis, coronary heart disease, heart attacks and stroke. Statins are widely prescribed as cholesterol lowering drugs and have been shown to reduce platelet activation. It has been described that one possible mechanism by which statins inhibit platelet function is through the activation and regulation of PECAM-1 (Moraes et al. 2013). Treatment of platelets with simvastatin results in increased PECAM-1 phosphorylation and recruitment of SHP2 to the ITIM which are essential for the negative function of PECAM-1. In further support of statins working through PECAM-1, PECAM-1 deficient mouse platelets showed reduced sensitivity to statins compared to WT controls indicating that statins exert their effects via PECAM-1.

CEACAM1 and CEACAM2

Carcinoembryonic antigen (CEA)-related cell adhesion molecules, CEACAM1 and CEACAM2 are ITIM containing membrane receptors that are expressed in both human and mouse platelets. CEACAM1 and 2 both contain extracellular glycosylated Ig-domains (four in CEACAM1 and two in CEACAM2), a transmembrane domain and a long cytoplasmic tail that contains the ITIM which is almost identical between the two proteins (Salaheldeen et al. 2012). CEACAM1 is activated following clustering via a homophilic interaction. The endogenous ligand of CEACAM2 has not yet been identified but can be activated by the murine coronavirus mouse hepatitis virus spike glycoprotein(s) (Robitaille et al. 1999). Studies using other cell types including T-cells and epithelial cells (Nagaishi et al. 2006) have shown that CEACAM1 and CEACAM2 use their ITIMs to recruit SHP1 and, to a lesser degree, SHP2 which can then initiate negative regulation of positive signaling pathways (Beauchemin et al. 1997).

Mice deficient in either CEACAM1 or CEACAM-2 show increased adhesion to fibrillar collagen and increased aggregation and secretion evoked by GPVI which indicates a role for both receptors in the negative regulation of GPVI signaling and platelet responses (Wong et al. 2009; Alshahrani et al. 2014). CEACAM2 deficient platelets have also been shown to exhibit increased platelet responses to CLEC-2 agonist Rhodocytin. Platelets deficient in either CEACAM1 or CEACAM2 show increased tyrosine phosphorylation of Syk and PLCγ2 following stimulation by CRP and also Rhodocytin in CEACAM2$^{-/-}$ platelets. Platelets from mice deficient in either CEACAM1 or CEACAM2 display increased thrombus growth in vitro and in vivo suggesting that CEACAM1 and 2, like PECAM-1, are negative regulators of platelet GPVI signaling. Also similar to that observed with PECAM-1, it has been recently described that CEACAM1$^{-/-}$ platelets show reduced signaling and activation through $\alpha_{IIb}\beta_3$ suggesting an alternative, positive regulatory mechanism for CEACAM1 in platelets (Yip et al. 2015). The role of CEACAM2 in the regulation of integrin $\alpha_{IIb}\beta_3$ is as yet unknown .

G6b-B

The transmembrane protein G6b was identified through both proteomics and gene expression studies (Macaulay et al. 2007; Senis et al. 2007) and the G6b-B variant was confirmed to be present in platelets (Senis et al. 2007). G6b-B contains an extracellular domain consisting of 125 amino acids and a cytoplasmic tail that contains two ITIM sequences. The endogenous ligand of G6b-B has not yet been identified, but G6b-B has been shown to be constitutively phosphorylated in resting platelets, and this increases following stimulation with GPVI specific agonist CRP or thrombin (Senis et al. 2007). Treatment of cells expressing G6b-B with pervanadate to inhibit phosphatases enhances tyrosine phosphorylation of G6b-B and the recruitment of SHP1 and SHP2 (de Vet et al. 2001; Coxon et al. 2012), thereby suggesting that G6b-B works via a similar mechanism to other ITIM containing proteins to inhibit platelets. Interestingly, studies using the DT40 cell line show that inhibition of GPVI signaling following G6b-B expression is retained in the absence of both SHP1 and SHP2, and is also retained in the absence of SHIP suggesting redundancy between these phosphatases or the involvement of other inhibitory molecules and mechanisms of action (Mori et al. 2008). Recent studies have identified that G6b-B is capable of interacting with several key signaling molecules, including Csk, Src, Fyn, Syk, PLCγ2 and PI3K, and it has been suggested that G6b-B may mediate its inhibitory effects on signaling and platelet activity by redistributing signaling molecules away from their substrates (Coxon et al. 2012). Further evidence of a negative regulatory role for G6b-B in platelets was found by using a crosslinking antibody for G6b-B which caused inhibition of platelet aggregation to CRP, and ADP. No alteration in ADP-stimulated Ca^{2+} signaling was observed suggesting that G6b-B acts downstream of Ca^{2+} release. This suggests that G6b-B may act via an alternative inhibitory mechanism to that observed downstream of other ITIM containing receptors such as PECAM and CEACAM, where G6b-B is capable of inhibiting signaling events downstream of mobilisation of intracellular Ca^{2+} (Newland et al. 2007). However, G6b-B deficient mice do not show platelet hyperreactivity, although this is likely to be attributed to an

increase in GPVI receptor shedding, that is observed as a result of enhanced metalloproteinase production in the megakaryocytes of these mice (Mazharian et al. 2012). This indicates an important role for G6b-B in megakaryocytes but the physiological role of G6b-B in platelets remains unclear (Mazharian et al. 2012).

PIRB/LILRB

The leukocyte immunoglobulin like receptors (LILRs) include two subfamilies, LILRA and LILRB, whilst the LILRA proteins contain an ITAM domain, the LILRB family members are characterised as containing an ITIM. Human platelets express LILRB2 and mouse platelets express its homolog PIRB which contains four cytoplasmic ITIMs (Takai 2005). Platelets have also been found to express the PIRB ligand ANGPTL2, which is found in alpha granules, and may suggest that autocrine self-negative regulation of platelets via PIRB/LILRB2 following their activation may occur (Zheng et al. 2012; Fan et al. 2014). Recent studies have identified that treatment of platelets with purified ANGPTL2 results in an inhibition of their activation to several agonists including CRP, ADP and thrombin while adhesion and spreading on fibrinogen is also inhibited (Fan et al. 2014). PIRB-TM mutant mice, which are unable to mediate intracellular signaling through this receptor, have a hyper-reactive platelet phenotype with increased aggregation evoked by CRP, increased spreading on fibrinogen and increased clot retraction. Key GPVI signaling events following activation by CRP including phosphorylation of LAT, SLP-76 and PLCγ2 are inhibited following ANGPTL2 treatment and increased in PIRB-TM mutants. During adhesion to fibrinogen, phosphorylation of FAK and β3 is also enhanced in PIRB-TM mouse platelets. PIRB dependent inhibition of GPVI and integrin $\alpha_{IIb}\beta_3$ signaling has been linked to the recruitment of SHP1 and SHP2 phosphatases, as both are recruited to PIRB and are phosphorylated following treatment with ANGPTL2 but their recruitment and phosphorylation is reduced in PIRB-TM expressing mice (Fan et al. 2014).

Intracellular Nuclear Receptors

Several intracellular nuclear receptors have been identified and characterised in human platelets including the peroxisome proliferator activating receptors (PPAR)s, PPARα, PPARβ/δ and PPARγ, the retinoid X receptor (RXR), liver X receptor (LXR), farnesoid X receptor (FXR) and glucocorticoid receptor (GR) (Moraes et al. 2005a, 2007, 2010c; Spyridon et al. 2011; Ali et al. 2006a) (Fig. 2).

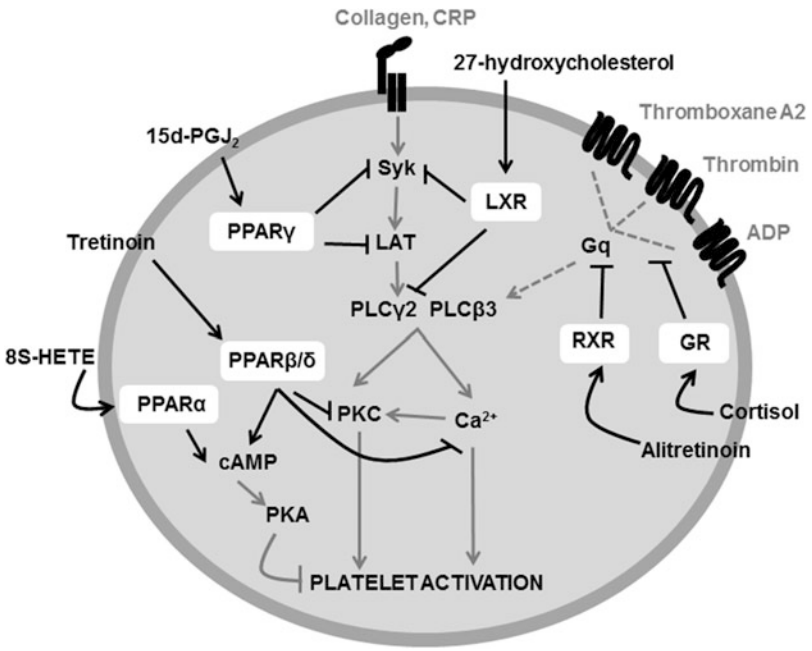

Fig. 2 Intracellular nuclear receptor signaling. Several intracellular nuclear receptors have been identified and characterised in human platelets including the peroxisome proliferator activating receptors (PPAR)s, PPARα, PPARβ/δ and PPARγ, the retinoid X receptor (RXR), liver X receptor (LXR), farnesoid X receptor (FXR) and glucocorticoid receptor (GR). The nuclear receptors are believed to negatively regulate platelet activity through various mechanisms following activation by their ligands, although these mechanisms are not well characterised. Both PPARα and PPARβ/δ are thought to negatively regulate platelet function through regulation of cAMP levels, whilst PPARγ and LXR receptors interact with and inhibit components of early GPVI signaling. In contrast RXR and GR appear to inhibit Gq signaling events. *Grey lines* represent platelet agonist signaling and *black arrows* represent the pathways or proteins that are modulated by nuclear receptor agonists in platelets

Peroxisome Proliferator Activated Receptors

PPARs represent three nuclear receptor isoforms, PPARα, PPARβ and PPARγ (Berry et al. 2003) which are involved in cell development, differentiation, cholesterol and fatty acid metabolism and glucose homeostasis (O'Brien et al. 2007; Barak et al. 1999; Kersten et al. 2000). All three isoforms of PPAR, upon binding to their ligands, are capable of heterodimerising with RXR, another nuclear receptor and all have been identified to have acute non-genomic negative regulatory effects in human platelets.

Treatment of platelets with ligands for PPARα such as fenofibrate and statins was found to increase intracellular levels of cAMP resulting in inhibition of ADP-stimulated platelet activation. Fenofibrate was also found to inhibit platelet activation and increase bleeding time in WT mice but not mice deficient in PPARα$^{-/-}$ (Ali et al. 2009a). Following activation by fenofibrate, PPARα was found to associate with PKCα a key positive mediator of platelet activation, and it is thought that this interaction may in part contribute to the negative regulation of platelet activation that is observed following treatment with PPARα ligands.

PPARβ/δ has been shown to decrease plaque formation and attenuate the progression of atherosclerosis (Lee et al. 2003). Studies using synthetic agonists for PPARβ/δ, GW0742 and L-165041 have identified inhibitory actions for PPARβ/δ ligands on the mobilisation of intracellular Ca^{2+} and platelet aggregation following stimulation by ADP and other platelet agonists (Ali et al. 2006b). PGI_2 a key inhibitory mediator of platelet function is also a ligand for PPARβ/δ and some of its inhibitory effects on platelet activity could be mediated through PPARβ/δ (Forman et al. 1997). As with PPARα, treatment of platelets with agonists of PPARβ/δ results in an increase in cAMP levels and PKCα has been identified as a potential binding partner of the receptor and a potential mechanism by which PPARβ/δ may regulate platelet reactivity (Ali et al. 2009b).

Agonists of PPARγ, the thiazolidinediones are currently in use for the treatment of type 2 diabetes mellitus and have been observed clinically to have cardio-protective properties and reduce the risk of myocardial infarction (Dormandy et al. 2005; Sauer et al. 2006). The emerging role of PPARγ agonists as negative regulators of platelet function may provide a mechanistic basis for this observation. A clinical study that measured platelet function in patients with coronary heart disease treated with rosiglitazone reported long-term anti-platelet effects with down-regulation of P-selectin exposure and granule secretion in treated patients (Sidhu et al. 2004). Treatment of platelets ex vivo with the endogenous agonist of PPARγ, $15dPGJ_2$ or the synthetic agonist rosiglitazone results in reduced platelet responses including granule secretion and thromboxane B_2 (T_XB_2) synthesis in response to thrombin or ADP (Akbiyik et al. 2004). Agonists of PPARγ have also been shown to suppress platelet activation stimulated by GPVI agonists, with platelet aggregation, granule secretion and mobilisation of intracellular Ca^{2+} inhibited following treatment with $15dPGJ_2$ (Moraes et al. 2010c). Treatment with PPARγ agonists results in reduced thrombus formation in vitro and in vivo (Moraes et al. 2010c; Li et al. 2005).

Additionally statins that are routinely prescribed as cholesterol lowering drugs have also been shown to activate PPARs (Ali et al. 2009a). Treatment of human whole blood with the statins, pravastatin, fluvastatin and simvastatin all resulted in a reduction in platelet aggregation to ADP. This decrease in platelet activity was attributed to a PPAR mediated increase in cAMP levels.

RXR

Human platelets and megakaryocytes express RXRα and RXRβ (Moraes et al. 2007). Treatment of platelets with the endogenous agonist of RXR, 9-cis-retinoic acid or the synthetic agonist, methoprene acid, results in an inhibition of Gq protein coupled induced platelet aggregation that is stimulated by ADP and thromboxane A2 (TxA2). It is thought RXR regulates GPCR mediated platelet activation by binding to Gq in a ligand-dependent manner inhibiting Gq induced rac activation and intracellular Ca^{2+} release (Moraes et al. 2007).

LXR

The LXRα and LXRβ isoforms of LXR are implicated in the regulation of fatty acid, cholesterol and glucose homeostasis (Viennois et al. 2011, 2012) and agonists for LXR have been described to have anti-inflammatory effects and be atheroprotective (Joseph et al. 2002; Tangirala et al. 2002). LXRβ has been identified as the isoform present in platelets (Spyridon et al. 2011), and endogenous ligands for the LXR receptors include oxysterols (oxygenated derivatives of cholesterol) and several synthetic agonists including GW3965 and T0901317 also exist (Gabbi et al. 2014; Wójcicka et al. 2015). Treatment of platelets with synthetic agonist GW3965 results in inhibition of platelet activation, including aggregation, secretion and integrin activation stimulated by collagen, CRP or thrombin. GW3965-treated mice form smaller, less stable thrombi following laser injury of the cremaster arterioles. LXR has also been shown to interact with several components of the GPVI signaling pathway following treatment with GW3965, including Syk and PLCγ2, resulting in decreased phosphorylation and signaling (Spyridon et al. 2011; Moraes et al. 2010b).

Glucocorticoid Receptor

The glucocorticoid receptor (GR) is activated by glucocorticoid steroid hormones, a major class of anti-inflammatory hormones, and prednisolone a synthetic derivative of cortisol that has been used to understand the role of GR in the regulation of platelet function. Platelets preincubated with prednisolone prior to agonist stimulation show reduced aggregation and TxB_2 release in response to both ADP and TxA_2 mimetic U46619 which could be reversed following treatment with a GR antagonist mifepristone (Moraes et al. 2005b). However, the mechanism underlying negative regulation of platelet function by GR agonists is still poorly understood.

Negative Regulators of Small GTPases and Integrin $\alpha_{IIb}\beta_3$ Activation

One of the key processes that underpin thrombus formation is the activation of the integrin $\alpha_{IIb}\beta_3$. Activation of $\alpha_{IIb}\beta_3$ results in a conformational change in the receptor that enables fibrinogen binding and aggregation, and also initiates outside in signaling which sustains platelet activation. Suppression of integrin $\alpha_{IIb}\beta_3$ activation prevents inappropriate platelet aggregation and excessive thrombus formation that can cause vessel occlusion (Fig. 3).

RASA3

RASA3 has recently been identified as an important inhibitor of integrin $\alpha_{IIb}\beta_3$ activation (Stefanini et al. 2015) through the regulation of Rap1b which is a critical regulator of integrin function in platelets (Chrzanowska-Wodnicka et al. 2005; Stefanini et al. 2012). Rap1b is positively regulated by the Ca^{2+}-sensing guanine exchange factor (GEF), CAlDAG-GEF1 (Crittenden et al. 2004) and RASA3 provides opposing, negative regulation that maintains platelets in a quiescent state when at resting $[Ca^{2+}]_i$ (Stefanini et al. 2015). RASA3 deficiency is embryonically lethal in mice but homozygous expression of a mutated form of RASA3 with impaired activity results in viable animals with platelet hyperreactivity that can be rescued by simultaneous deficiency of CALDAG-GEF1. However, integrin $\alpha_{IIb}\beta_3$ activation in the double knockout mouse occurs independently of the ADP receptor P2Y12 and PI3K.

JAM-A

JAM-A is a transmembrane protein of the CTX family that is expressed on cell surface and has been identified in platelets. Mice deficient in JAM-A display increased aggregation to several platelet agonists, increased spreading on fibrinogen and clot retraction and increased thrombus formation indicating a role for JAM-A in the negative regulation of integrin $\alpha_{IIb}\beta_3$ (Naik et al. 2012). JAM-A is phosphorylated in resting platelets and associates with $\alpha_{IIb}\beta_3$ (Naik et al. 2012). JAM-A is proposed to keep the integrin inactive by binding C-terminal src kinase (Csk) via its SH2 domain which recruits it to the integrin. Recruitment of Csk ensures that c-Src, which is associated with the integrin, remains in an inactive state through phosphorylation of the inhibitory Y529 in c-Src's regulatory domain (Naik et al. 2014). On platelet activation JAM-A is dephosphorylated, Csk dissociates enabling activation of c-Src and integrin $\alpha_{IIb}\beta_3$ activation.

Studies using ApoE deficient mice that model high plasma cholesterol levels and atherosclerosis have highlighted the importance of the platelet inhibitory receptor JAM-A in the development of the disease state. A recent study has shown that platelet deficiency in the

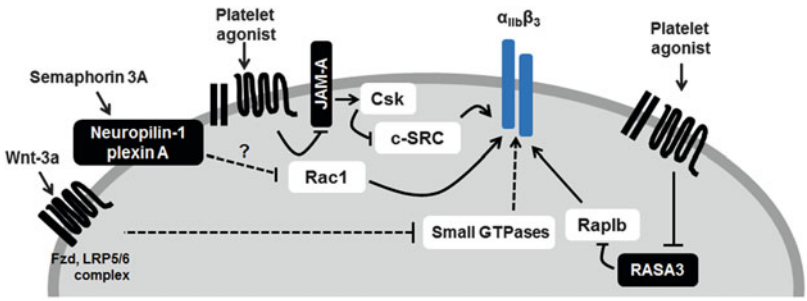

Fig. 3 Negative regulators of small GTPases and integrin $\alpha_{IIb}\beta_3$. RASA3 inhibits Rap1b, preventing signal transduction that enables integrin $\alpha_{IIb}\beta_3$ activation until PI3K activation downstream of Gi-coupled P2Y12 inhibits RASA3. Wnt 3a activates the β-catenin signaling pathway that negatively regulates small GTPases including Rac1 and Rap1 that underpin integrin activation. The neuropilin-1-plexin A complex is activated by semaphorin 3A which also negatively regulates Rac1. JAM-A inhibits c-Src-dependent integrin $\alpha_{IIb}\beta_3$ outside-in signaling through activation of Csk which negatively regulates c-Src. Stimulation with agonists causes dissociation of JAM-A from integrin $\alpha_{IIb}\beta_3$, reducing Csk activity and enabling activation of c-Src mediated integrin $\alpha_{IIb}\beta_3$ outside-in signaling. Semaphorin 3A is believed to activate the neuropilin-1 plexin A complex which inhibits Rac1 causing inhibition of integrin $\alpha_{IIb}\beta_3$ activation

inhibitory receptor JAM-A in ApoE$^{-/-}$ mice fed a high fat diet increases aortic plaque formation and recruitment of inflammatory cells, suggesting that platelet hyperreactivity such as that observed in JAM-A$^{-/-}$ platelets can contribute to atherosclerotic plaque formation (Karshovska et al. 2015).

ESAM

ESAM, a transmembrane glycoprotein, like JAM-A is a member of the CTX family and is also suggested to be involved in the negative regulation of adhesion and integrin $\alpha_{IIb}\beta_3$ outside-in signaling. In contrast to JAM-A, ESAM appears to negatively regulate integrin $\alpha_{IIb}\beta_3$ and limit its activity following platelet activation. ESAM is contained in platelet alpha granules and is translocated to the cell surface on activation (Nasdala et al. 2002). Mouse platelets deficient in ESAM show increased aggregation to GPCR agonists, inhibition of clot retraction, increased thrombus formation in vivo and reduced tail bleeding (Stalker et al. 2009). The mechanism by which ESAM functions is currently unknown, although interaction via its PDZ domain with NHERF-1, a scaffold protein highlights possible interaction with and regulation of several proteins, including GPCRs (Hall et al. 1998), G proteins and PLCβ (Rochdi et al. 2002) and components of the cytoskeleton (Shenolikar et al. 2004).

Wnt3a

Wnt3a is a glycoprotein that is released from endothelial cells (Goodwin et al. 2006) and also from TRAP stimulated platelets, enabling platelets to self-regulate and limit activation (Steele et al. 2009). Treatment of platelets with Wnt3a results in an inhibition of platelet adhesion and shape change, reduced dense granule secretion and reduced RhoA activation leading to diminished integrin $\alpha_{IIb}\beta_3$ activation and aggregation. In platelets, Wnt3a is thought to exert its effects through activation of the canonical Wnt-β-catenin signaling pathway components that also appear to be present in platelets (Semenov et al. 2007; MacDonald et al. 2007; Huang and He 2008). In other cell types β-catenin has been shown to play a role in the regulation of cell adhesion, where it is involved in supporting the interaction of cadherins to the cytoskeleton (Huang and He 2008). Negative regulation of platelet activation via Wnt3a signaling is thought to occur through regulation of small GTPase activity, including Rap1, Cdc42, Rac1, RhoA (Steele et al. 2012). It is thought that by favouring the GDP-bound state of Rap1 and Rho via the regulation of Rap1GAP and RhoA GTPase activity, whilst increasing levels of Cdc42 and Rac1 GTP levels, Wnt3a inhibits integrin $\alpha_{IIb}\beta_3$ adhesion and spreading.

Neuropilin-1-Plexin A Complex

Semaphorin 3A exists as a soluble covalently bound homodimer and is secreted by vascular endothelial cells (Serini et al. 2003). Semaphorin 3A negatively regulates platelet function through binding to the neuropilin-1-plexin A receptor complex which has been identified in platelets (Takahashi et al. 1999; Tamagnone et al. 1999; Kashiwagi et al. 2005). Semaphorin 3A treatment inhibits platelet function, possibly through regulation of integrin $\alpha_{IIb}\beta_3$ as activation of the integrin, aggregation and adhesion and spreading evoked by several platelet agonists are impaired. The exact mechanisms by which Semaphorin 3A inhibits platelet function have not been fully elucidated, although inhibition of the GTPase Rac1 appears to be a key regulatory step in the negative regulation of $\alpha_{IIb}\beta_3$ and cytoskeletal rearrangements (Kashiwagi et al. 2005).

Cyclic Nucleotide Signaling

Cyclic nucleotides cAMP and cGMP are well-established inhibitors of platelet activation. Endothelium derived prostacyclin (PGI_2) and nitric oxide (NO) activate the production of cAMP and cGMP, respectively, and play essential roles in keeping platelets in the resting state in the circulation. The regulation of platelets by these molecules is discussed in detail in Chapter X.

cAMP and Protein Kinase A

PGI_2 binds to and activates the prostaglandin receptor on the platelet surface (Dutta-Roy and Sinha 1987), which then propagates inhibitory signaling through the activation of Gs subunits that activate adenylyl cyclase and stimulate the production of cAMP from ATP (Gorman et al. 1977). cAMP activates cAMP dependent protein kinase A (PKA). Following platelet activation by agonists such as ADP and thrombin, adenylyl cyclase activity is inhibited and cAMP levels reduced through Gi signaling (Jantzen et al. 2001; Yang et al. 2002). PKA phosphorylates multiple target proteins that maintain platelets in an inactive resting state by limiting platelet activation. Several substrates of PKA have been well characterised and are linked to the negative regulation of platelets, including VASP which is involved in cytoskeletal rearrangements (Waldmann et al. 1987; Butt et al. 1994), inhibition of Rap1b a key regulator of integrin $\alpha_{IIb}\beta_3$ affinity (Schultess et al. 2005; Miura et al. 1992), inositol

trisphosphate receptor (IP_3R) which is involved in Ca^{2+} regulation (Cavallini et al. 1996) and the thromboxane A2 receptor (Reid and Kinsella 2003). Other targets also include Gα13 (Manganello et al. 1999), GPIbβ (Wardell et al. 1989) and CALDAG-GEFI (Schultess et al. 2005)

Recent studies have identified a cAMP independent mechanism of PKA activation following stimulation of platelets by thrombin or collagen (Gambaryan et al. 2010). In resting platelets a population of platelet PKA appears to be associated with NFkB-IkBα. Following stimulation by collagen or thrombin the catalytic subunit of PKA dissociates from NFkB-IkBα and is activated, enabling phosphorylation and activation of its substrates. This identifies an inhibitory feedback mechanism that prevents excessive platelet activation in response to stimuli (Gambaryan et al. 2010).

Regulation of cGMP and PKG by Platelet-Derived NO

The cyclic nucleotide cGMP is a key negative regulator of platelet activation that inhibits platelets to keep them in the resting state in the healthy vasculature (Smolenski 2012). Endothelial release of nitric oxide (NO) keeps platelets inactive by regulating their intracellular levels of cGMP (Mellion et al. 1981; Radomski et al. 1987). Following the synthesis and release of NO from the healthy endothelium, NO crosses the platelet plasma membrane and binds to and activates, soluble guanyl cyclase (sGC), leading to the increased production of cGMP from GTP and activation of protein kinase G (PKG). Levels of cGMP are controlled by the phosphodiesterase, PDE5A which is present in platelets (Haslam et al. 1999). Platelets deficient in PKG are insensitive to cGMP-mediated inhibition of intracellular Ca^{2+} release (Eigenthaler et al. 1993) and PKG knockout mice have a prothrombotic phenotype and exhibit increased intravascular adhesion and aggregation following ischaemia (Massberg et al. 1999).

Platelets are now also considered to be a source of NO. The mechanism by which platelets synthesise NO and whether or not it is of physiological importance is, however, still an area of contention. Although NO itself is an established negative regulator of platelet function, the vascular endothelium has traditionally been considered the dominant source of NO within blood vessels. Platelets have been reported to express two nitric oxide synthase (NOS) isoforms, iNOS and eNOS but generate less NO than endothelial cells (Radomski et al. 1990b) and the presence of eNOS is contentious (Gambaryan et al. 2008). Studies into the effects of platelet-derived NO on platelet function using iNOS/eNOS knockout mice have suggested that eNOS is not a major regulator of platelet function (Gambaryan et al. 2008; Tymvios et al. 2009). There is evidence that platelets can produce NO from nitrate although further research is needed to understand the mechanism (Apostoli et al. 2014). Platelet NO production is inducible and is mediated by Ca^{2+} elevation (Radomski et al. 1990b) and is therefore stimulated by many platelet agonists such as ADP and arachidonic acid. However, the question of whether platelet-derived NO can inhibit platelet aggregation is a source of debate (Gkaliagkousi et al. 2007) with some reports describing platelet-derived NO-mediated inhibition (Radomski et al. 1990a, b) and others reporting no effect (Thomas et al. 1990; Thompson et al. 1986). More recent studies have provided further evidence for the presence of functional eNOS in platelets by measuring NO production in single platelets under flow (Cozzi et al. 2015) and also highlighted the anti-thrombotic potential of drugs that modulate platelet eNOS activity (Momi et al. 2014).

Defects in cAMP/cGMP signaling pathways have the potential to contribute to platelet hyperreactivity in cardiovascular disease including ischemic heart disease, heart failure and diabetes where the reduced sensitivity of platelets to the inhibitory effects of NO contributes to platelet hyperreactivity (Chirkov and Horowitz 2007). Platelets from patients with type 2 diabetes mellitus and insulin insensitivity, for example, have reduced sensitivity to NO and prostacyclin and consequently higher platelet reactivity. Additionally a number of individuals with genetic abnormalities in prostacyclin signaling have reduced cAMP levels, resulting in hyper-reactive platelets and a prothrombotic state, and defects in sGC function are linked to an increase prevalence of ischemic heart disease, heart failure and diabetes (van Geet et al. 2009). In contrast patients with hypersensitivity to prostacyclin signaling, as a result of increased activity of Gs proteins show an increased risk of bleeding which is attributed to increased cAMP levels and an increased inhibition of platelet function (van Geet et al. 2009). It is also suggested that in patients with obesity in addition to defects in sGC function, cAMP synthesis may also be altered and defects in downstream effectors of cAMP and cGMP signaling may contribute to platelet hyperreactivity (Russo et al. 2010).

Other Mechanisms of Platelet Inhibition

Phosphatases

Protein modification by phosphorylation is a key mechanism of signal transduction in platelets. Phosphorylation is a reversible post-translational modification that enables regulation of signal transduction and platelet function by phosphatase dependent dephosphorylation of key signaling proteins. Phosphatases are key mediators of several negative signaling pathways in platelets such as those exhibited by

the ITIM containing receptors. Protein tyrosine phosphatases such as SHP1 and SHP2, SHIP1 and SHIP2, PP2, PTEN and TULA2 have well-established roles in the negative regulation of platelet signaling, in general negatively regulating receptor proximal signaling events leading to reduced mobilisation of Ca^{2+}, granule secretion and integrin activation (Senis 2013). SHP2 is well-established for its roles in the negative regulation of platelet signaling events downstream of the majority of platelet agonists, including GPVI and GPCRs (Ma et al. 2012; Jackson et al. 1997). These observations are supported by studies using mouse platelets deficient in SHP2 which show enhanced activation to fibrinogen (Mazharian et al. 2013). The histidine phosphatase TULA2 dephosphorylates and inactivates Syk preventing further downstream signaling (Thomas et al. 2010). TULA2 deficient mice platelets show increased hyperreactivity to GPVI agonists, and also increased thrombus formation and reduced bleeding times. The phosphoinositide phosphatases SHIP1 and PTEN are involved in the regulation of PI3K function through alteration of the phosphoinositol cycle (Laurent et al. 2014). PTEN-deficient platelets which show hyper-responsiveness to collagen exhibit increased PI3K activity and show reduced bleeding times in vivo. Finally the serine/threonine kinase phosphatase PP2A is involved in the negative regulation of integrin $\alpha_{IIb}\beta_3$ function and signaling (Pradhan et al. 2010; Gushiken et al. 2008). PP2A mediates dephosphorylation of PKCζ and PTP-1B which reduces Src phosphorylation and activation (Mayanglambam et al. 2011; Pradhan et al. 2010; Gushiken et al. 2008). It is important to note, however, that whilst several phosphatases are associated with negative regulation of platelet function, many positive regulatory functions for phosphatases have been identified in platelets (Senis 2013).

Receptor Desensitisation

Platelets can regulate and limit their responsiveness to platelet agonists, through desensitisation of their receptors following agonist stimulation. ADP, for example, is a critical secondary mediator of platelet signaling, yet despite this it has been shown that platelets desensitise following continued exposure to ADP (Mundell et al. 2006; Hardy et al. 2005; Cunningham et al. 2013). This diminished response is attributed to desensitisation of both the P2Y1 and P2Y12 receptors via agonist mediated internalisation of each receptor. Studies using both platelets and 1321N1 cells have identified that the P2Y1 and P2Y12 receptors are desensitised by different mechanisms following platelet agonist stimulation. Desensitisation of the P2Y1 receptor is mediated by both classical and novel isoforms of protein kinase C (PKC), whilst P2Y12 desensitisation is mediated by G protein coupled receptor kinase and the novel isoforms of PKC (Hardy et al. 2005).

PKC Isoforms

Protein kinase C (PKC), a family of serine/threonine kinases regulates many aspects of platelet signaling. The different isoforms of PKC are classified into three different subtypes classical, novel and atypical isoforms, according to their structure and mechanism of regulation. Several isoforms have been identified in human platelets although expression of some isoforms is controversial (Newton 1997; Mellor and Parker 1998; Murugappan et al. 2004; Buensuceso et al. 2005; Hall et al. 2008; Pears et al. 2008; Konopatskaya et al. 2009; Bynagari et al. 2009; Nagy et al. 2009; Harper and Poole 2010). Historically the PKC family were considered to play an overall positive role in the regulation of platelet activity, as broad spectrum PKC inhibitors were shown to inhibit granule secretion, TxA_2 synthesis, integrin activation, aggregation and thrombus formation (Harper and Poole 2010). However, negative regulatory roles have subsequently also been identified for the PKC family. Studies using broad spectrum inhibitors have also identified negative roles in the regulation of receptor desensitisation (see section on receptor desensitisation) and Ca^{2+} release, and studies using isoform specific deficient mice have identified negative regulatory roles for the novel isoforms PKCδ and PKCθ (Harper and Poole 2010).

Transgenic mice deficient in PKCδ have identified a negative regulatory role for PKCδ in the regulation of integrin $\alpha_{IIb}\beta_3$ outside-in signaling and filopodia formation on fibrinogen due to an interaction between PKCδ and VASP (Pula et al. 2006). PKCδ has also been shown to negatively regulate GPVI-induced platelet responses, as platelets from PKCδ deficient mice have enhanced aggregation and dense granule secretion in comparison to WT controls. This was also confirmed in human platelets using a cell permeable peptide that is designed to block the interaction of PKCδ and δ(V1-1)-TAT (Chari et al. 2009). Contrasting reports, however, also exist as other groups found no abnormality in GPVI-dependent dense granule secretion in $PKC\delta^{-/-}$ platelets (Pula et al. 2006). PKCδ deficient platelets generate larger thrombi when measured in vitro but not when measured in vivo (Gilio et al. 2010; Chari et al. 2009). The overall role of PKCδ has therefore been difficult to define, possibly as a consequence of diverse positive and negative regulatory roles played by this PKC isoform.

Studies that have utilised PKCθ isoform-specific inhibitors have identified negative roles for PKCθ in several processes in GPVI-induced platelet activation, including aggregation, α-granule secretion, $\alpha_{IIb}\beta_3$ activation and changes in intracellular Ca^{2+} levels, as all were increased following treatment of platelets with the inhibitor. Studies that have utilised PKCθ deficient mice have generated conflicting reports of both positive and negative roles in the regulation of platelet activation (Hall et al. 2008; Nagy et al. 2009; Harper and Poole 2009, 2010; Cohen et al. 2011;

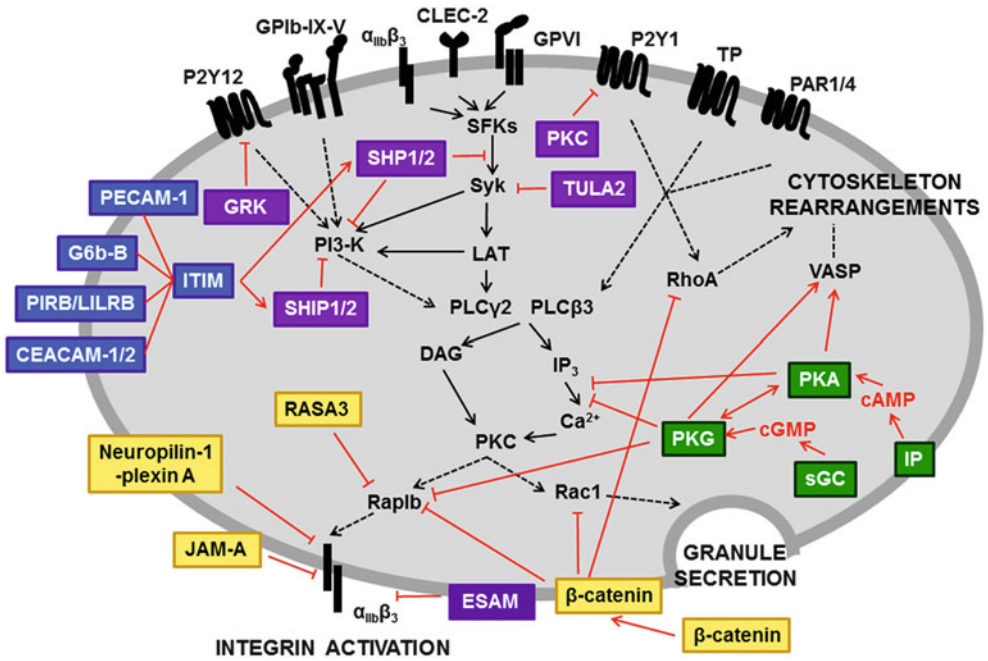

Fig. 4 Platelet-derived inhibitors of platelet function. Well-characterised activatory pathways (*black*) are regulated by multiple inhibitory pathways that regulate platelet responses to support their role in hemostasis. Receptors that signal through ITIMs (*blue*) recruit SHP1/2 and SHIP1/2 in close proximity to ITAM receptors where they dephosphorylate components of activation pathways, inactivating them to provide negative regulation. Small GTPases regulate several important process in platelets such as granule secretion and integrin $\alpha_{IIb}\beta_3$ activation and so inhibitors of small GTPases (*yellow*) such as RASA3 and Wnt3a/β-catenin provide negative regulation for these key events. PKA and PKG are inhibitory kinases that are regulated by cyclic nucleotides (*green*), although these pathways are primarily regulated by non-platelet-derived inhibitors they are also potentially regulated by platelet-derived NO and non-cAMP dependent PKA activation. Other negative regulators (*purple*) such as phosphatases and kinases that regulate receptor desensitisation do not easily fit into discrete categories and mediate negative feedback via diverse mechanisms

Unsworth et al. 2012; Gilio et al. 2010). These differences have been attributed to different experimental conditions whereby PKCθ may have a negative role following exposure to low agonist concentrations, and a positive role following exposure to higher concentrations of platelet agonists (Hall et al. 2008; Nagy et al. 2009; Cohen et al. 2011).

Conclusion

Platelet-derived mediators of negative regulation all function to limit or restrict platelet activation, yet are mechanistically diverse and affect pathways involved in many different processes (Fig. 4). While many negative regulators have been identified, many of the processes that they regulate to achieve platelet inhibition are not yet fully characterised. However, it is becoming increasingly clear that negative regulatory mechanisms rival the complexity of the positive regulators of platelet activation. The key challenge in the field of inhibitory platelet signaling will be to establish the physiological and pathological importance of these proteins, their potential as drug targets and their role in determining disease risk.

Take Home Messages

- Platelet activation is triggered by stimuli that arise within the circulation
- Activated platelets initiate their own positive feedback mechanisms that support thrombus growth
- Platelets also generate negative feedback signals that can limit thrombus development
- The mechanisms of negative regulators are diverse and many have not yet been fully characterised
- Negative regulatory mechanisms may be as important as positive regulators to understand disease risk and discover new drug targets and therapies

Methodology

Platelet Function Tests

Marie Lordkipanidzé and Paul Harrison

Abstract

Many platelet function assays have been developed over the last century in an attempt to capture the natural ability of platelets to form aggregates in response to vascular injury. From physiological assays, such as the bleeding time, to diagnostic assays used within specialized hematology departments, to point-of-care assays that are intended as clinical decision aids on wards and in operating rooms, and finally to high-throughput deep phenotyping assays intended for precision medicine, platelet function assays have become increasingly commonplace in many settings. This chapter presents an overview of the most commonly used platelet functions assays and discusses important variables to take into account when performing platelet function testing, ranging from pre-analytical issues to the clinical utility of individual tests.

Introduction

Many platelet function assays have been developed over the last century in an attempt to mimic the natural ability of platelets to form aggregates in response to vascular injury. From physiological assays, such as the bleeding time, to diagnostic assays, such as those used to this day in specialized hematology departments, to point-of-care assays that are intended as clinical decision aids on wards and in operating rooms, and finally to high-throughput deep phenotyping assays intended for precision medicine, platelet function assays have become increasingly commonplace in many settings. The continued interest in platelets and their contribution to health and disease continuously drives innovation in this field, tackling the challenges of working with live, dynamic, and sensitive cells.

In order to accomplish their many roles, not only in maintaining hemostasis, but also in inflammation, host defense and immunity, wound healing, fetal vascular remodeling, tumor growth and metastasis, liver disease, and angiogenesis, to name a few, platelets are a treasure trove of membrane receptors and anchoring proteins, diverse granular contents, and *de novo*-generated mediators (Nurden 2011; McFadyen and Kaplan 2015). These need to intervene in a coordinated fashion to ensure appropriate platelet activation, degranulation and aggregation, as any imbalance may lead to either bleeding or thrombotic events. Because of this biological complexity, with many redundant activation pathways working in concert, studying platelet function can be difficult and requires specialized methods to capture this diversity of platelet responses.

In this chapter, we discuss general principles in platelet function testing, with special attention to pre-analytical variables, and highlight areas of standardization where guidelines are available. We also present an overview of currently available platelet function assays and their clinical usefulness. Specific techniques of platelet flow cytometry (Carubbi et al. 2017) and platelet aggregometry (Hayward

and Moffat 2017) are detailed further in the following sections, along with applications including monitoring of antiplatelet therapy (Tantry et al. 2017) and diagnosis of platelet defects (Mezzano and Pereira 2017).

Bleeding Time: A Physiological Approach to Platelet Function Testing

The first assessment of platelet function to be successfully used was initially described as a coagulation test by M.G. Milian in 1901 (Milian 1901). Shown to be correlated with platelet dysfunction by W.W. Duke in 1910 (Duke 1910), the test underwent further refinement at the hands of A. C. Ivy in 1941 and has become known as the Duke-Ivy Bleeding Time (Ivy et al. 1941). In its most accepted form, the assay is carried out on the ventral surface of the forearm where skin thickness is uniform, with a blood pressure cuff applied to the upper arm and inflated to 40 mmHg. The technique consists of recording the time required for a blood clot to form at the site of a 5 mm long by 1 mm deep longitudinal incision, and the test ends when the flow of blood is stopped. Commercial spring-loaded devices containing sterile blades (e.g., Simplate II® by the Organon Teknika Corporation and later Surgicutt® by the International Technidyne Corporation) have further standardized the procedure, which has remained the most useful screening test of platelet function until the early 1990s (The British Society for Haematology BCSH Haemostasis and Thrombosis Task Force 1988). This assay has brought forward a new understanding of platelet function in vivo, including the effect of platelets on hemostasis, the interaction of platelets with vascular endothelial cells and other blood elements, co-activation of platelets and the coagulation system, platelet release reactions in vivo, and various platelet diatheses (Gresele et al. 1987, 2003; Kyrle et al. 1987; Michelson et al. 1991; Weiss and Lages 1993; Weltermann et al. 1999; Ciferri et al. 2000; Undas et al. 2001; Falcinelli et al. 2007; Lubsczyk et al. 2010; Giannini et al. 2011; Traby et al. 2016).

Among the advantages of this assay are its simplicity and its accessibility, as no expensive equipment or specialized laboratory is required. This ensured the test's widespread use in and outside of specialized centers for decades. The Duke-Ivy Bleeding Time measures physiological hemostasis driven by platelets and plasma adhesive proteins such as von Willebrand factor (VWF), as well as the interplay of blood components with the vessel wall. For this reason, it cannot pinpoint the origin of the defect, but an abnormally prolonged Bleeding Time is indicative of a hemostatic deficiency.

Several factors have led to the downfall of the Bleeding Time as a screening assay, in favor of novel platelet function tests. Chiefly, they included the poor reproducibility despite the use of standardized devices, the invasive nature of the test which could lead to scarring, and the relative insensitivity of the Bleeding Time to many mild platelet defects. In the early 1990s, several investigators concluded that an accurate bleeding history was a more valuable screening test, as it captured mild bleeding tendency more robustly than the Bleeding Time (Rodgers and Levin 1990; Lind 1991; Peterson et al. 1998). As a result, widespread use of the bleeding time has rapidly declined over the last 20 years, to be replaced by other less invasive platelet function assays carried out ex vivo on freshly collected blood samples (Harrison et al. 2011).

Important Considerations in Platelet Function Testing

Most platelet function assays have strict requirements in terms of blood drawing and sample preparations. Recent surveys have highlighted that platelet function testing practices can vary significantly between laboratories (Moffat et al. 2005; Jennings et al. 2008; Cattaneo et al. 2009; Gresele et al. 2014). These differences may explain some of the discrepancies reported between laboratories and emphasize the importance of standardized laboratory approaches. Because platelets can be artifactually activated by inappropriate sample handling, important pre-analytical variables must be taken into consideration before platelet function testing can be performed. Failure to apply some of these key considerations may lead to spurious results (Harrison et al. 2011). This is particularly important, as there are no widely available internal or external quality control materials for platelet function testing (Favaloro 2009), with the exception of the PFA-100/200® device where quality controls have been proposed (Favaloro 2013; Favaloro and Bonar 2014). For this reason, most assays are performed side-by-side with a fresh blood sample from a drug-naïve healthy volunteer, which ensures the viability of reagents and appropriate assay settings (Harrison and Lordkipanidzé 2013). Alternatively, some laboratories derive local reference ranges from a cohort of healthy volunteers, and carry out their platelet function testing according to rigorous standard operating procedures, to limit operator-induced variability. Finally, cartridge-based point-of-care assays have built-in electronic control measures that limit inappropriate test procedures, but pre-analytical conditions may still lead to aberrant test results. The main key pre-analytical considerations are detailed below.

Physiological and Medical Conditions

A number of physiological conditions may influence platelet function results. These include circadian rhythms (Hartley 2012), strenuous exercise (Davis et al. 1990), fasting (Ahuja

et al. 2009), coffee and caffeine-containing beverage consumption (Varani et al. 2000; Natella et al. 2008), and smoking (Rival et al. 1987). Although guidelines in the past have suggested that platelet function studies should only be performed on samples obtained from individuals who were fasting and resting, and who refrained from smoking, caffeine ingestion, and rigorous exercise on the day of testing, pragmatically many of these conditions are hard to control and only have a minor influence on platelet function results (Kottke-Marchant and Corcoran 2002; Harrison et al. 2011; Cattaneo et al. 2013). However, it is necessary to ensure that subjects have refrained from medication or substances known to affect platelet function (which include non-steroidal anti-inflammatory drugs, antiplatelet agents, phosphodiesterase inhibitors, certain psychotropics, and herbal remedies) for 10–14 days, to account for normal platelet turnover (Kottke-Marchant and Corcoran 2002; Harrison et al. 2011; Lordkipanidzé 2012; Cattaneo et al. 2013). This washout period can be longer in case of drugs with a long effective half-life, such as the antiplatelet drug vorapaxar which may take weeks or even months to wear off (Gurbel et al. 2011). An unexpected finding in platelet function results should prompt investigations into these potential confounders, and repeat testing on a fresh blood sample under more suitable conditions may be warranted.

In some instances, deferring platelet function testing or stopping antiplatelet medications cannot be considered. For example, in the context of acute coronary syndromes or in patients requiring chronic antiplatelet therapy as secondary prevention of acute thrombotic events, platelet function testing must be carried out promptly and on-treatment. A number of expert opinion documents have been published with recommendations in terms of interpretation of platelet function results in this context (Michelson et al. 2005; Pulcinelli and Riondino 2006; Kuliczkowski et al. 2009; Tantry et al. 2013; Aradi et al. 2014), and these are treated in more detail in a dedicated section in this book (Tantry et al. 2017).

Venipuncture

Blood should be collected by an experienced phlebotomist, from the antecubital vena fossa, applying a standardized, atraumatic protocol of a clean venipuncture using minimum tourniquet pressure (Harrison et al. 2011). As shear is an important inducer of platelet activation, needles or butterfly cannulae of 19–21 gauge should be preferred, in conjunction with either an evacuated tube system or plastic syringe. A discard tube of 5 ml should be drawn first to avoid tissue factor-induced aggregation from the venipuncture, but this practice is rarely applied in clinical centers with little to no impact on the quality of the blood sample (Favaloro et al. 2008). Underfilling or overfilling of collection tubes is a frequently encountered problem. Collection tubes should be filled to 90 % capacity or to the manufacturer-specified mark, to avoid incorrect sample dilution/anticoagulation which can negatively impact platelet function tests (Favaloro et al. 2008). Samples should be handled gently and inverted three to six times to provide adequate mixing of test sample with the anticoagulant.

Anticoagulants

The most commonly employed anticoagulant for platelet function testing is sodium citrate (Harrison et al. 2011). Other commonly used anticoagulants include acid-citrate-dextrose (ACD), the potent thrombin inhibitor D-phenylalanyl-L-prolyl-L-arginine chloromethyl ketone (PPACK), hirudin, heparin, and the dual thrombin/factor Xa inhibitor benzylsulfonyl-D-Arg-Pro-4-amidinobenzylamide (BAPA). There is no consensus on the best anticoagulant for platelet function testing, and most assays can be performed in samples anticoagulated with any of these agents (Kaiser et al. 2012). Particular precautions must be taken to avoid EDTA-containing tubes, and whenever these are required (e.g., for full blood counts), these should be collected last to avoid potential contamination by carryover (Favaloro et al. 2008).

Specimen Processing

Blood samples collected for platelet function testing should ideally be left to rest for 30 min at room temperature (20–25 °C). Placing samples in a refrigerator/ice pack or in a warm water bath prior to platelet function testing negatively impacts platelet responses (Harrison et al. 2011). Ideally, samples should be collected close to the laboratory, but if transport is necessary, it is important to avoid vibration, shaking, vortexing, or agitation. For this reason, pneumatic tube systems are considered inappropriate for transporting platelet function testing specimens (Thalen et al. 2013). The time delay between collection, transport and analysis should ideally be between 30 min and 2 h, but should not exceed 4 h (Harrison et al. 2011).

For platelet function assays that require the preparation of platelet-rich plasma (PRP), whole blood samples should be centrifuged without using a brake at 200 g for 10 min and at room temperature (Cattaneo et al. 2013). These conditions were shown to result in high quality PRP, by reducing contamination with other blood cells and optimizing platelet reactivity (Femia et al. 2012). Once the PRP has been removed by gentle pipetting, the remaining portion of the blood sample can be centrifuged at room temperature at 1500 g for 15 min to prepare platelet-poor plasma (PPP) (Cattaneo et al. 2013). There is no need to adjust platelet

count in PRP with autologous PPP to a standardized value, as this practice induces extra variability to platelet function results (Cattaneo et al. 2007; Linnemann et al. 2008).

Platelet Function Assays

An impressive array of platelet function assays are available to platelet researchers (Table 1). Many require dedicated skill, expertise, and machinery to run and to interpret, but increasingly, point-of-care instruments are being developed with the intent of applying this technology outside of specialized laboratories. The more commonly used assays are described in more detail below.

Light Transmission Aggregometry

First described by Gustav Born in 1962 and considered by many as the historical gold standard in platelet function testing (Born 1962), light transmission aggregometry (also known as optical aggregometry) measures the increase in light transmission through a PRP sample as platelets aggregate in response to an external stimulus. Addition of a platelet agonist induces the platelets to activate and clump together, which decreases the turbidity of the sample and results in greater light transmission (autologous PPP being used to define 100 % light transmission). The aggregometer captures this dynamic interaction of platelets with each other in real time, resulting in a time-dependent platelet aggregation curve (described in further detail in Section 2.4). An adaptation of this technology allows for luminescence to be read concomitantly to light transmission. By using a luciferin-luciferase substrate added to PRP, a measurement of dense granule secretion can then be performed in parallel with platelet aggregation (Pai et al. 2011) (described in further detail in Wersäll et al. 2017).

This assay offers several advantages. It is very flexible, as there is no restriction to the platelet agonists or agonist concentrations that can be used to stimulate platelets (Hayward et al. 2010; Harrison et al. 2011). The real-time nature of the assay also provides with kinetic information of platelet–platelet interactions; this includes initial platelet shape change, degranulation, and reversible or irreversible aggregate formation (Cazenave et al. 2004). These factors have contributed to making the assay the preferred platelet function test in most specialized laboratories over the world for the better part of the last century (Cattaneo et al. 2013).

Among the disadvantages of the assay, it is important to note that LTA is carried out in PRP, making it relatively non-physiological, stirred at low shear conditions not representative of arterial shear rates where platelet activation normally occurs, and platelets in this assay only form aggregates after a platelet agonist has been added. These conditions do not entirely mimic platelet adhesion, activation and aggregation as they would occur in response to damage to the vessel wall (Harrison and Lordkipanidzé 2013). It is also a time-, labor-, and blood-volume intensive technique. To run a full panel of agonists, conventional LTA requires large blood volumes and a dedicated and experienced operator (Dawood et al. 2012). Interpretation of tracings can also be challenging, which often limits its use to specialist tertiary centers that can maintain their expertise through a high patient volume. This has triggered several attempts at automation of LTA (Lawrie et al. 2014), as well as development of new, and faster approaches to LTA (Sun et al. 2001; Moran et al. 2006; Chan et al. 2011) that are described below.

96-Well Plate-Based Light Transmission Aggregometry

The requirement for a dedicated aggregometer has hampered the availability of LTA in many laboratories. However, as modern 96-well plate readers capable of recording light transmission through multiple samples within a few minutes have become widely available in standard laboratories, several groups have attempted to adapt LTA principles to a high-throughput 96-well plate design (Bednar et al. 1995; Sun et al. 2001; Moran et al. 2006; Chan et al. 2011). This requires the coating of wells with platelet agonists, either in solution or lyophilized, to trigger platelet aggregation after PRP is added to each well with a multichannel pipette. The plate is quickly transferred to a heater-shaker that can maintain the samples at 37 °C and stir the samples to facilitate platelet–platelet interactions. Depending on the plate reader setting, light transmission can be read either at set intervals (e.g., 15 s) or at the end of a fixed period (e.g., 5 min), thus providing either kinetic curves similar to LTA, or an endpoint assessment of platelet aggregation (Chan et al. 2011; Chan and Warner 2012). Similarly to LTA, light transmission is converted into % aggregation by measuring light transmission in PRP and autologous PPP samples.

Despite the fact that various versions of this technique are in use in research laboratories, the experience in clinical settings remains limited. In a head-to-head comparison of the assay with LTA in a group of patients with idiopathic bleeding, the assay was shown to be a promising tool for the screening of bleeding disorders and monitoring of antiplatelet drugs (Lordkipanidzé et al. 2014). Its main use presently is as a tool for a better understanding of basic pathophysiology of platelets (Mylotte et al. 2012; Cooke et al. 2013; Lordkipanidzé et al. 2014).

Table 1 Non-exhaustive list of commonly used platelet function assays

Name of test	Principle	Advantages	Disadvantages	Frequency of use
Global assays of hemostasis				
Bleeding time	In vivo cessation of blood flow	In vivo test, physiological POC	Insensitive, invasive, scarring, high CV	Was widely used, now less popular
Thromboelastography (TEG® or ROTEM®)	Monitoring of rate and quality of clot formation	Global whole blood test	Measures clot properties only, largely platelet-independent unless platelet activators are used	Widely used in surgery and trauma
TEG-6S	Monitoring of rate and quality of clot formation	POC	POC equivalent to TEG or ROTEM	No clinical experience
Electron microscopy	Ultrastructural analysis of platelets	Diagnostic Whole mount technique useful for dense granular imaging	Expensive, specialized equipment	Only available in special units
Platelet activation-based assays				
Flow cytometry	Measurement of platelet glycoproteins and activation markers by fluorescence	Whole blood test, small blood volumes, wide variety of tests	Specialized operator, expensive, samples prone to artifact unless carefully prepared	Frequently used either in core laboratories or as benchtop instruments in research labs
VASP	Flow cytometric or ELISA measurement of phosphorylation of VASP	Measurement of $P2Y_{12}$ receptor signaling	Insensitive to intermediate inhibition of $P2Y_{12}$	Increasing use
Platelet aggregation-based assays				
Light transmission aggregometry (LTA)	Low shear platelet-to-platelet aggregation in response to classic agonists	Gold standard	Time-consuming, sample preparation, poorly standardized	Widely used in specialized labs
96-well-plate based assays in PRP	Based on LTA principles	Lower blood/PRP volumes than LTA. Many replicates and dose–response curves possible	Little widespread experience	Little widespread experience
Plateletworks®	Platelet counting pre- and post-activation	Rapid, simple, POC, small blood volume	Indirect test measuring count after aggregation	Used in surgery and cardiology
VerifyNow®	Fully automated platelet aggregometer to measure antiplatelet therapy	Simple, POC, 3 test cartridges (aspirin, $P2Y_{12}$, and $\alpha_{IIb}\beta_3$)	Inflexible, cartridges can only be used for single purpose	Widely used
WBA	Monitors changes in impedance in response to classic agonists	Whole blood test, multichannel version available	Dependent on platelet count, older instruments require electrodes to be cleaned and recycled	Widely used in specialized labs although less than LTA
Shear-based assays				
PFA-100/200®	High-shear platelet adhesion and aggregation during formation of a platelet plug	Whole blood test, high shear, small blood volumes, simple, rapid, POC, 3 test cartridges (CEPI, CADP and INNOVANCE P2Y)	Inflexible, VWF-dependent, Hct-and platelet count dependent	Widely used
Microfluidic devices	Miniaturized multichannel devices	Whole blood, real-time thrombus formation	Little widespread experience	Research only at present
Assays measuring platelet release reactions				
Lumi-aggregometry	Combined WBA or LTA and nucleotide release	Monitors release reaction with secondary aggregation	Semiquantitative	Widely used in specialized labs, although less than LTA
Adenine nucleotides	Measurement of total and released nucleotides by luminescence or HPLC	Sensitive	Sample preparation, assay calibration, extra equipment	Restricted to specialized labs

(continued)

Table 1 (continued)

Name of test	Principle	Advantages	Disadvantages	Frequency of use
Soluble platelet release markers and sheddome (e.g., serotonin, PF4, βTG, sCD40L, sCD62P, GPV, and GPVI)	Usually by ELISA, also available through bead-based flow cytometry	Relatively simple	Prone to artifact during blood collection and processing	Fairly widely used in research
Serum thromboxane B_2	Immunoassay	Dependent upon platelet COX-1 activity	Prone to artifact	Widespread use
AspirinWorks®	Immunoassay of urinary 11-dehydrothromboxane B_2	Measures stable thromboxane metabolite, dependent upon COX-1 activity	Indirect assay, not platelet-specific, renal function-dependent	Increasing use

COX-1 cyclooxygenase 1, *CV* coefficient of variation, *ELISA* enzyme-linked immunoassay, *GP* glycoprotein, *Hct* hematocrit, *HPLC* high-performance liquid chromatography, *LTA* light transmission aggregometry, *PFA-100/200®* platelet function analyzer 100/200, *PF4* platelet factor 4, *POC* point of care, *PPP* platelet-poor plasma, *PRP* platelet-rich plasma, *sCD40L* soluble CD40 ligand, *sCD62P* soluble CD62P (P-selectin), *βTG* β-thromboglobulin, *VASP* vasodilator-stimulated phosphoprotein, *WBA* whole blood aggregometry

Whole Blood Aggregometry

As its name suggests, whole blood aggregometry (WBA) measures platelet aggregation as it occurs ex vivo, in whole blood. The technique is based on electrical impedance resulting from aggregate formation onto two electrodes immersed in saline-diluted whole blood stimulated with platelet agonists (Cardinal and Flower 1980). There are currently two manufacturers of whole blood aggregometers. The Chronolog apparatus is a two- to four-channel computerized aggregometer, which is compatible with both a disposable single-use set of electrodes and reusable electrodes that require thorough and careful cleaning between uses. The more commonly used instrument in clinical laboratories is the Multiplate® analyzer, mainly because it is semi-automated, highly standardized and uses disposable cuvettes/electrodes with preselected agonists for different applications, including diagnosis of bleeding and monitoring of antiplatelet therapy (Solomon et al. 2011; Valarche et al. 2011; Aradi et al. 2014).

The assay's advantages include performance in whole blood, thus eliminating potential artefactual activation of platelets during the PRP preparation steps; relative ease of use and rapidity, as compared with LTA; the compatibility with a large array of platelet agonists at various concentrations, thus allowing for a better understanding of various activation pathways; and the smaller blood volume requirement as opposed to LTA (Aradi et al. 2014; Kong et al. 2015). However, the assay is influenced by a number of factors, which include platelet count and hematocrit, the anticoagulant used, and the delay between blood sample collection and platelet function testing (Stissing et al. 2011; Kaiser et al. 2012; Rubak et al. 2012; Wurtz et al. 2014). Its use in the clinic is mostly centered on monitoring of antiplatelet therapy (Tantry et al. 2013; Aradi et al. 2014), as there is little published data on the assay's usefulness in investigating inherited platelet disorders (Albanyan et al. 2015).

VerifyNow®

The VerifyNow® system is perhaps the most commonly used point-of-care assay. It is specifically developed to monitor antiplatelet therapy, with dedicated cartridges to assess the effect of aspirin, $P2Y_{12}$ ADP receptor inhibitors, and GPIIbIIIa antagonists. Its ease-of-use, speed, and requirement for little to no technical expertise have made this assay highly popular in settings where platelet function testing could be used to guide antiplatelet therapy, such as in cardiac catheterization laboratories. However, its clinical predictiveness has been questioned lately in view of large clinical trials using the VerifyNow® $P2Y_{12}$ assay to guide antiplatelet therapy having failed to provide clinical benefit (Siller-Matula et al. 2015). Notwithstanding, consensus documents still recommend the use of the VerifyNow® $P2Y_{12}$ assay, as a potential predictor of future cardiovascular and bleeding events (Aradi et al. 2014).

Platelet Function Analyzer (PFA-100/200®)

The recently updated PFA-200® instrument is a cartridge-based assay. It was intended to provide an in vitro equivalent to the bleeding time, and its mode of action requires blood to be aspirated through an aperture in a membrane coated with platelet agonists, and to record the time for a platelet plug to occlude the aperture which is reported by the system as "closure time" (Favaloro and Bonar 2014). Three cartridges are currently available; the CADP cartridge contains collagen and ADP, the CEPI cartridge contains collagen and epinephrine and the INNOVANCE P2Y cartridge contains ADP and PGE_1 supplemented with calcium, with a smaller aperture (100 μm vs 150 μM) (Favaloro 2008; Koessler et al. 2011). The INNOVANCE P2Y cartridge is significantly more sensitive to P2Y12 receptor inhibition than the CADP cartridge and has shown promise in monitoring of antiplatelet drugs as well as in evaluation of congenital

$P2Y_{12}$ receptor defects (Koessler et al. 2011, 2012; Edwards et al. 2012; Scavone et al. 2014).

The assay has gained popularity as a general screening tool for hemostatic disorders due to its ease of use, speed, small blood volume requirement, and the need for little to no specialist training. It is also the only platelet function assay where an external quality control program is available (Favaloro 2009; Favaloro and Bonar 2014). However, a number of factors are known to affect the assay's performance, and these must be taken into account when interpreting the results. Hematocrit and platelet count influence closure time, which makes the assay not suitable for patients with a platelet count below 50×10^9/L or hematocrit below 25 % (Carcao et al. 2002). Patients with non-O blood groups have shorter closure times than blood group O patients, potentially requiring adapted reference ranges that take into account the patient's blood group (Cho et al. 2008). The concentration of sodium citrate used to anticoagulate the sample also influences the results, with 3.8 % giving greater stability of results (Jilma 2001). The high dependence of the assay on von Willebrand factor (due to the high-shear conditions when blood is aspirated through the aperture) makes it an interesting assay for screening of von Willebrand disease, but makes it unsuitable for platelet function testing in this cohort (Favaloro 2002, 2008).

Recent guidelines have suggested that the assay could be used as a screening test to rule out a significant platelet defect in a patient whose clinical history for bleeding is unlikely to point to an inherited platelet disorder, but should not be used as evidence of absence of a platelet defect in patients at high suspicion of inherited platelet dysfunction (Hayward et al. 2006; Harrison et al. 2011).

Thromboelastography® (TEG®)

Thromboelastography® (TEG) and Rotational TEG (ROTEG® or ROTEM®) are similar technologies that assess the hemostatic function as a whole, from thrombus formation to lysis (Luddington 2005; Chen and Teruya 2009). The instruments differ slightly, but the methodology is the same, as a whole blood sample is stirred in a cup with a suspended pin. In anticoagulated samples, the motion between the cup and the pin is unaffected. However, as clot formation is triggered by addition of coagulation or platelet activators, the motion of the cup/pin is hampered, and this translates into a curve depicting clot strength. Both re-calcified plasma and whole blood can be used in this assay, with activators of the tissue factor or contact factor pathways (Chen and Teruya 2009). Arachidonic acid and ADP can also be used as agonists to pre-activate platelets within the TEG system (PlateletMapping™ technology).

The TEG®/ROTEM® tests are well established, mostly in the context of assessing global hemostasis for the management of bleeding and thrombotic risk in surgical, cardiovascular, and trauma patients despite a relatively weak clinical evidence-base (Kozek-Langenecker et al. 2013; Hunt et al. 2015). They are, however, labor-intensive, which has prompted the development of a novel point-of-care microfluidic assay named TEG-6S (Gurbel et al. 2016). It provides all the same test results as traditional TEG, but is a cartridge-based point-of-care rapid analyzer. How this new assay compares with traditional TEG, and whether it will provide clinically meaningful results remains to be established.

Flow Cytometry

Important technological advances have made flow cytometers available not only in specialized core laboratories, but also as benchtop instruments in non-dedicated laboratories. A vast array of antibodies coupled with fluorochromes is commercially available, specifically targeted against individual platelet proteins, granules, and lipid membranes. Flow cytometry is therefore a powerful and popular tool to study many aspects of platelet biology and function, and is described in more detail in Carubbi et al. (2017).

Assessment of platelet function by flow cytometry can be performed on isolated platelets, but the use of diluted anticoagulated blood is preferred. The most common markers of platelet activation used in the literature are P-selectin expression on the platelet surface as a marker of α-granule secretion; the conformational change in integrin $\alpha_{IIb}\beta_3$ into its active state with the PAC-1 antibody; and phosphorylation of vasodilator-stimulated phosphoprotein [VASP] as a marker of $P2Y_{12}$ receptor activation-dependent signaling (Schmitz et al. 1998; Matzdorff 2005). However, the field is in constant progress, especially with novel multiplex technologies that allow for the concomitant measurement of multiple analytes in blood samples as small as a few microliters (Spurgeon et al. 2014). Moreover, the assay is being actively developed for assessing platelet function in patients with thrombocytopenia, as it is performed independently of platelet count (Frelinger et al. 2015). Efforts have been made to standardize the use of flow cytometry for platelet function testing (Schmitz et al. 1998; Lee et al. 2008), but it remains a challenging assay to homogenize, which makes comparisons between laboratories difficult. More recently, reagents have become available so that remote activation and fixing can be performed reliably before analysis within a central core laboratory (Dovlatova et al. 2015).

Conclusion

The last century has seen many developments in platelet function testing and has brought forward a better understanding of platelet biology, physiology, and pathology (Coller 2011). The time when functional assessment of platelets was confined to specialized laboratories and required dedicated equipment and personnel has given way to point-of-care, near-patient instruments of platelet function assessment and changed the way platelet studies are conducted (Harrison and Lordkipanidzé 2013). Today's challenges in platelet function testing include determining the true clinical usefulness of these assays for predicting thrombosis and bleeding, and the development of individualized approaches to mitigate risks in individual patients (Aradi et al. 2015; Siller-Matula et al. 2015).

Increasingly, a deeper phenotyping approach is required to capture the many functions platelets accomplish, through an intrinsically complex array of activation pathways. Comprehensive platelet function testing requires the development of new techniques that allow not only detailed characterization of platelet responses, but are also high-throughput to investigate a large number of individuals. Promising technologies include devices that measure global platelet reactivity in response to shear alone (Wurtz et al. 2012), microfluidic devices with pre-coated adhesion or activation molecules (Conant et al. 2011; Westein et al. 2012; Lucitt et al. 2013; de Witt et al. 2014), assays that measure calcium flux in platelets by fluorescent imaging (Liu and Abell 2006), ELISA-type assays that capture platelets on agonist-coated surfaces (Salles et al. 2010; Baker-Groberg et al. 2014), modified light transmission aggregometry techniques carried out on 96-well plates (Mylotte et al. 2011; Lordkipanidzé et al. 2014) and luminometric assays of platelet secretion in response to various platelet agonists (Sun et al. 2001). All of these techniques have significantly improved our ability to investigate platelet responses to multiple platelet agonists in a shorter time than traditional approaches. In the future, investigators will need to harvest the wealth of data generated by high throughput deep phenotyping approaches and translate these platelet function findings into actionable determinants of disease.

Take Home Messages

- An impressive array of platelet function assays are available to platelet researchers. Many require dedicated skill, expertise, and machinery to run and to interpret, but increasingly, point-of-care instruments are being developed with the intent of applying this technology outside of specialized laboratories.
- Most platelet function assays have strict requirements in terms of blood drawing and sample preparations, in order to help with the standardization and generalizability of results.
- Today's challenges in platelet function testing include determining the true clinical usefulness of these assays for predicting thrombosis and bleeding, and the development of individualized approaches to mitigate risks in individual patients.
- Increasingly, a deeper phenotyping approach is required to capture the many functions platelets accomplish, through an intrinsically complex array of activation pathways. In the future, investigators will need to harvest the wealth of data generated by high throughput deep phenotyping approaches and translate these platelet function findings into actionable determinants of disease.

Platelet Counting and Measurement of Platelet Dimensions

Patrizia Noris and Carlo Zaninetti

Abstract

Since the introduction of automated blood cell analyzers, platelet counting and platelet dimension measurements are greatly improved in accuracy and disposability. No doubts in considering their relevance evident in routine clinical practice, particularly in diagnosis and management of many bleeding and thrombotic imbalances.

Besides the impedance-based one, the first performed, and to date the most diffused, several others automated counting methods have been developed making platelet recognition increasingly more accurate. Platelet counting is now obtained not only by size but also by density and surface glycoproteins' expression.

Although these technological improvements, spurious abnormalities of platelet count such as pseudothrombocytopenia and pseudothrombocytosis can still occur, posing serious diagnostic difficulties. Therefore, in few selected clinical settings, the manual microscopy techniques are still considered of great utility to correctly identify and enumerate platelets.

Moreover, the widespread automated cell blood counters make today available additional platelet parameters like the mean platelet volume and the amount of young platelets, calculated as reticulated platelets or immature platelet fraction. Although methodological issues remain to be solved, the availability of these further platelets' parameters can also drive effectively the diagnosis of common or rare platelet disorders such as immune thrombocytopenia and inherited thrombocytopenias. The relevance in diagnosis and prognosis of these parameters is still under investigations in a large number of platelet diseases and in disorders not primarily affecting platelets.

Introduction

Platelet counting is essential for the diagnosis and management of many bleeding and thrombotic disorders: its accuracy greatly improved during the last decades with the introduction of automated counters which replaced the routine manual method. Although a number of technical efforts, the impedance analyzers, which are the first-generation automated counters, still cannot distinguish platelets from other particles of the same size because they rely only on particle size. To solve this issue, several counters have been developed based on different techniques in which platelets are recognized on their size and density or on their surface glycoproteins. Despite new methodologies, pseudothrombocytopenia and other spurious abnormalities of platelet count can still occur.

The widespread diffusion of automated counter greatly increased the detection of both inherited and acquired thrombocytopenias and thrombocytosis; emerging age, sex, and ethnical differences of platelet number suggest the need for new personalized reference ranges.

Automated cell blood counters made available additional platelet parameters: in particular, the diagnostic and therapeutic relevance of young platelets, measured as reticulated platelets or immature platelet fraction, and of platelet size, calculated as mean platelet volume or mean platelet diameter, is emerging although some methodological issue remained to be solved.

Platelet Counting

Platelet counting has become a basic analysis for clinical and research laboratories. In the clinical setting, a reliable enumeration of platelets is required not only for diagnostic purpose but also for therapeutic decision: in fact, clinical guidelines suggest platelet transfusions for platelets less than 10×10^9/L, a number associated with poor reliability of both automated and manual platelet counting. All methods available will be discussed, although only a few of them are routinely used in the clinical practice; they are summarized in Table 1. The main technical characteristics of most automated cell counters now commercially available are reported in Table 2. Methods for enumeration of youngest platelets, namely reticulated platelets, will be discussed with their clinical relevance.

Methods for Platelet Counting

Manual Platelet Counting by Optical Microscopy Since 1988 and until a few years ago, the manual phase-contrast microscopy method, described more than half a century ago, was the only reference technique for platelet counting (Brecher et al. 1953; ICSH 1988): after dilution in ammonium oxalate of ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood and lysis of red blood cells (RBCs), platelets are counted in a hemocytometer, by a phase-contrast microscope with a 40× objective, where platelets appear as small and refractive particles (England et al. 1988). Although it is inexpensive and widespread used prior to the advent of automated methods, this technique has a number of significant limitations: it is laborious and time-consuming but especially suffers from imprecision and poor reliability, with an interoperator coefficient of variation of 10–25 %, which is much higher for low platelet counts (Harrison et al. 2000). Nowadays it is used in less-resourced laboratories and in research laboratories. More importantly, it is performed in routine laboratory when platelet count is unexpectedly low and in both routine and research laboratories when atypical platelets are present in the sample (i.e., giant platelets), in order to obtain a more reliable platelet count (Noris et al. 2009; Salignac et al. 2013).

Table 1 Methods for platelet counting

Manual platelet counting	In a hemocytometer, by a phase-contrast microscope
	On a May-Grünwald-Giemsa-stained peripheral blood smear, by an optical microscope
Semiautomated platelet counting	Immunoplatelet counting
Automated platelet counting	Impedance platelet counting
	Optical platelet counting
	Optical fluorescence platelet counting
	Automated immunological platelet counting

Manual Platelet Counting on Peripheral Blood Smear It was developed in the era preceding the introduction of automated counters; later, it was used when automated platelet counting was not reliable because of different reasons (i.e., giant platelets, RBC microcytosis/fragmentation). While the first methods provided indirect platelet counting referred to RBCs (Fonio 1912), a more recent one supplies a platelet count referred to the automated leukocyte count (Sutor et al. 2001). It is now devoted to rule out artifacts leading to spurious increase or decreases in automated platelet counts.

Immunoplatelet Counting Given the poor reliability of the manual phase-contrast platelet counting, the widespread diffusion of automated cell counters, and the number of interferences causing inaccuracy of automated platelet count, an immunological platelet technique has been proposed as the new reference method (Harrison et al. 2000; Harrison et al. 2001); it was soon accepted by the ICSH and the ISLH as the gold standard in the process of whole blood calibration of automated hematology analyzers (ICSH 2001).

It is an indirect method where platelet count is obtained from the ratio of fluorescent platelets to RBCs contained in the same sample. Platelets are labeled with directly conjugated, fluorescein isothiocyanate (FITC)-labeled monoclonal antibodies (MoAbs) against two distinct epitopes of integrin $\alpha_{2b}\beta_3$; sample is then analyzed in a flow cytometer where platelets are definitely identified and distinguished from non-platelet elements based on their fluorescence (Log FL1) and cell granularity (Log FS). A minimum of 50,000 total events and 1000 platelet events are collected to determine the RBC/platelet ratio. Afterward, the reference platelet count is calculated from this ratio and the RBC count obtained in a semiautomated, single-channel, impedance counter using the formula: impedance RBC count/(RBC events/PLT events). In the validation procedure, this method demonstrated an excellent intra-assay and acceptable inter-laboratory precision (ICSH 2001); it is especially useful in

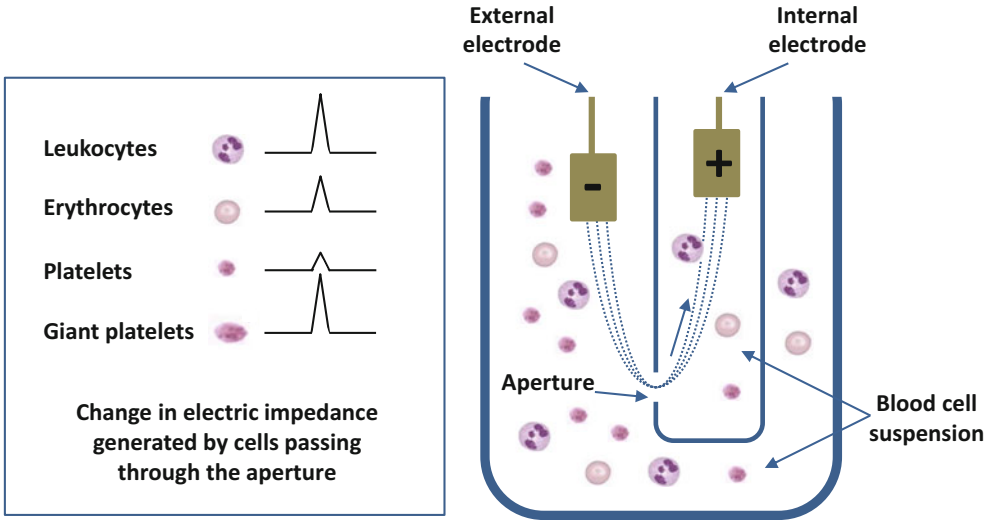

Fig. 1 The principle of impedance platelet counting (Coulter principle). During the analysis, a constant direct current is maintained between two electrodes. When a blood cell passes through a small aperture encompassed by two electrodes (sensing zone), a change in electric impedance is detected: the number of pulses corresponds to the number of particles, the amplitude of the pulse corresponds to the size of individual cells

cases of severe thrombocytopenia, where a reliable platelet count may influence prophylactic platelet transfusion use (Norris et al. 2003). It is not suitable for routine laboratory use because it is time-consuming and quite expensive, but especially because it requires the availability of a flow cytometer and experienced technicians.

Impedance Platelet Counting It is based on the so-called Coulter principle, or impedance method, patented by Coulter in 1953 which made possible the development of the first automated method for cell counting: blood cells are regarded as nonconductive resistivity particles resuspended in a diluent which serves as an electrolyte solution. When a blood cell passes through a small aperture encompassed by two electrodes (sensing zone), a change in electric impedance is detected (Fig. 1): the number of pulses corresponds to the number of particles that pass through, and the amplitude of the pulse corresponds to the size of individual cells. This method, which is the most widely used, was originally used for counting of RBCs and leukocytes in whole blood, and for platelets in platelet rich plasma as at the beginning it was not possible to differentiate RBCs from platelets. It was only in the 1970s that the correction of the coincidence and the introduction of hydrodynamic focusing allowed a reliable enumeration of platelets in whole blood samples (Patterson 1997): the first phenomenon is responsible for incorrect cell counting when more than one single cell passes simultaneously through the sensing zone, and its magnitude increases with the concentration of cells in suspension. The hydrodynamic focusing has been developed to ensure that the stream of cells remains focused in the very center of the orifice of the detecting zone: this prevents the generation of irregular impedance profiles resulting in false estimates of the cell size when they pass through the sensing zone close to the wall where the current density is higher. Further additional improvements have been made to overcome the

recirculation problem leading to an overestimation of platelet count occurring when platelets are trapped in eddy currents behind the orifice where they recirculate and are recounted (Patterson 1997).

The commonly in use impedance analyzers (Table 2) calculate the platelet number by counting blood elements within a specific size range, which is different among the different counters. In the Beckman Coulter DxH800, the platelet size distribution count is produced between two floating windows: one threshold is fixed at 12 fL, while the lower and the upper may move between certain limits in order to distinguish platelets from debris (at the lower end moving between 2 and 6 fL) and from small/fragmented erythrocytes (at the upper end moving from 12 to 25 fL). A platelet size histogram is generated, and afterward, log-normal curves are fitted to this histogram and actual data are calculated. In the LH750 analyzers, particles between two fixed thresholds (2 and 20 fL) are counted as platelets, with possible extrapolation up to 60 fL.

Inaccuracies of platelet counting obtained by methods relying on cell size can result in both overestimation and underestimation of platelet count (Table 3). A false increase of platelet counting can be observed in the presence of non-platelet particles with the same size of platelets, as small or fragmented erythrocytes, fragments of nucleated cells, bacteria, fungi, lipids, and cryoglobulins (Latger-Cannard et al. 2009; Noris and Balduini 2014). Conversely, a false decrease in the platelet number can be observed in case of platelet agglutination (mainly related to EDTA, but also to other anticoagulants), platelet satellitism around leukocytes, platelet-neutrophil agglutination, and in the presence of large platelets exciding the normal range of platelet size (Fig. 1) (Zandecki et al. 2007; Latger-Cannard et al. 2009; Noris et al. 2009). Some abnormalities of platelet count will be further discussed more extensively.

Optical Platelet Counting Optical light scatter methods have been developed more recently, based on light diffraction in a flow cytometry system: when cells are hit by a bundle of light, they can absorb the light, or scatter it, into different directions depending on a number of cellular properties. One-dimensional platelet analysis have been developed first; because the discriminant to distinguish platelets from non-platelets was based only on the size of blood elements, the method did not offer significant advantages over impedance counting. Then, a two-dimensional laser system has been developed (Fig. 2) where platelets are recognized both on their size and granularity. The light scattered by each cell passing through a laser beam is measured at two different angles and converted into volume (platelet size) and refractive index (platelet density). Different counters use different angles: Siemens counters measure two angles of laser diffraction at 2–3° and 5–15°, converted into volume and refractive index, respectively, allowing the recognition of non-platelet particles and large platelets between 1 and 60 fL (Harris et al. 2005). CELL-DYN Sapphire platelet parameters are obtained measuring light scatter at 7° and 90°: in this counter platelets are measured simultaneously by impedance method, and an alert flag is generated when discrepancies are detected suggesting the presence of interfering phenomenon. By optical method, a number of inaccuracies of impedance platelet counting have been overcome: small or fragmented RBCs with the same volume of platelets are recognized because of a greater refractive index, while RBC ghosts are separated from platelets for a reduced refractive index. Moreover, large platelets with volumes between 30 and 60 fL are correctly identified based on their peculiar density: in a study on patients with different inherited macrothrombocytopenias, the optical method was found to be more reliable than the impedance one (Noris et al. 2009).

Table 3 Conditions responsible for spurious platelet count obtained by automated cell counters and possible additional alterations of complete blood count parameters (in bracket)

Spurious decrease of platelet count	Spurious increase of platelet count
Clotting of the sample for inadequate mixing blood sample, or overfilling of the sample tube, or difficult venipuncture (abnormal CBC)	Red blood cells microcytosis (abnormal PLT histogram and RBC distribution width)
In vitro hemolysis (spurious reduction of RBC)	Fragmented red blood cells (abnormal PLT histogram and RBC distribution width)
Venipuncture site, i.e., site proximal to a drip or blood collected from a line (spurious reduction of RBC and WBC)	Cytoplasmic fragments of nucleated blood cells (abnormal RBC distribution width)
Platelet agglutination, i.e., EDTA-dependent pseudothrombocytopenia or related to other anticoagulants (spurious increase of WBC)	Microorganisms, i.e., bacteria and fungi
Platelet satellitism around white blood cells and phagocytosis	Cryoglobulins and cryofibrinogen (spurious increase of WBC and RBC)
EDTA-dependent platelet-neutrophil agglutination (spurious reduction of WBC)	Lipids (spurious increase of WBC and RBC)
Giant or large platelets (abnormal RBC distribution width)	

PLT platelets, *RBC* red blood cells, *WBC* white blood cells

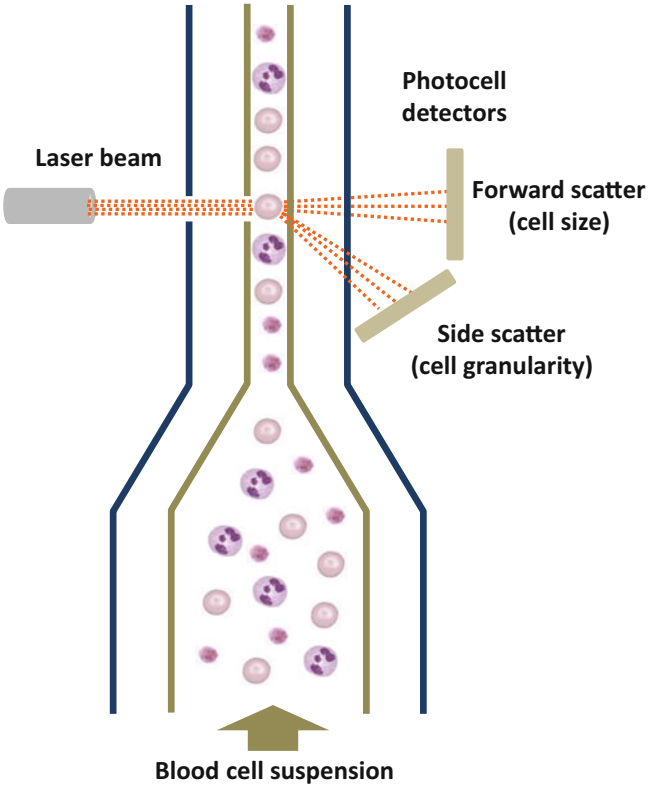

Fig. 2 The principle of optical platelet counting. A cell suspension, passing through a chamber as a single cell stream, interact with a laser beam. The light scattered by each cell is measured at two different angles (forward scatter and side scatter) and generates pulses converted to electronic signals providing information on cell size and internal structure/density

Optical Fluorescence Platelet Counting It is available in two counters (Table 2), the Sysmex XN (starting from Sysmex XE-2100 analyzer) and the Mindray BC-6800, where platelets are counted in the reticulocyte channel. A fluorescent dye is used to stain nucleic acids of reticulocytes and platelets, which after irradiation with a semiconductor laser beam are correctly recognized and counted based on their volume (forward scattered light) and side fluorescence intensity. This technique is present in automated analyzers in addition to impedance method, allowing the recognition of large platelets and the exclusion of non-platelet particles. A switching algorithm has been designed to report the most accurate counting: the optical fluorescence technique resulted more reliable at low platelet count when clinical decisions on platelet transfusions are more critical (Briggs et al. 2012; Schoorl et al. 2013) and in the presence of fragmented RBC (Tanaka et al. 2014). Not conclusive results have been reported for platelet count of patients undergoing chemotherapy, probably because of an erroneous staining of white cell fragments following apoptosis (Van der Meer et al. 2003; Tanaka et al. 2014).

Automated Immunological Platelet Counting A fully automated immunoplatelet count has been initially introduced on CELL-DYN 4000 analyzer and is now available also on the CELL-DYN Sapphire (Table 2). This method relies on the ability to recognize all platelets because they are labeled with a specific FITC MoAb against β_3 integrin. During analysis, the counter aspirates blood inside a special tube containing the lyophilized MoAb fixed to the bottom of the tube. After appropriate incubation, the cell suspension is passed through an optic bench where light scatter is measured at the two angles of 7° and 90° along with the fluorescent emission. The number of CD61+ platelets will be obtained taking into account the dilution of the sample, the dilution flow rate, and the duration of the analysis. This method may be regarded as the fully automated version of the international reference method (ICSH 2001), and the unique which is potentially able to overcome all erroneous platelet counts deriving from non-platelet artifacts (Cid et al. 2010). It is easy to perform, rapid, fully automated, and therefore not requiring skilled technicians; however, its usage is strongly limited in the routine laboratory practice because of the poor diffusion of the specific counter and the cost of each single platelet analysis. It can provide underestimation of platelet count in presence of platelet aggregates, while it is useless in patients with Glanzmann Thrombasthenia.

Reference Interval of Platelet Count

Defining laboratory reference intervals in a healthy population and identifying differences occurring during life, between sexes and within different ethnic groups, are important for both clinical orientations and therapeutic decisions. This also applies to platelets, especially for counts only slightly altered compared to the upper and lower limits of the reference interval: it is especially true now that a lower platelet threshold ($\geq 450 \times 10^9$/L) has been identified as a major criteria for the diagnosis of essential thrombocythemia (Tefferi and Vardiman 2008), a disease associated with increased risk of thrombosis. On the other hand, a slight reduction of platelet count might remain stable over time without developing any disorder (Stasi et al. 2006), meaning that, at least in a selected population, no specific, expensive, and invasive tests are always needed.

The current range of platelet count (150 to 400–450 $\times$ 10^9/L), used in the large majority of Western countries, has been identified based on results obtained from several thousands of blood samples of unselected donors analyzed after the introduction of automated counters (Giles 1981; Graham et al. 1987; Biino et al. 2013). Thanks to the increased diffusion of cell counters, subsequent studies placed

some doubt on their universal validity: in particular, previous small and further large population studies remarked that platelet count may vary by sex (Biino et al. 2013), age (Santimone et al. 2011; Biino et al. 2011; Biino et al. 2013; Ambayya et al. 2014; El Graoui et al. 2014; Qiao et al. 2014; Adeli et al. 2015), ethnicity (Bain 1996; Segal and Moliterno 2006), and also within the same geographic area (Biino et al. 2012; Hong et al. 2015). Therefore, many authors suggested the need for personalized reference ranges for platelet count rather than the adoption of generalized intervals and cutoff. The first proposal for a reference interval of platelet count taking into account gender, age, and ethnicity was made a decade ago in the USA (Cheng et al. 2004): it resulted to be unsuitable for clinical practice and is not currently used. A new personalized reference interval has been recently proposed for the Italian population based on data collected on 40,987 inhabitants of 7 Italian areas including 6 geographic isolates (Biino et al. 2011; Santimone et al. 2011; Biino et al. 2012): estimated reference intervals for platelet count have been provided for three age classes (children, under 15 years; adults, between 15 and 64 years; old, over 64 years) and by sex, limited to adult and old people (Biino et al. 2013). This new range has been recently applied to a consecutive series of 917 adult Italian patients admitted to a single institution: the personalized range reduced by 21 % the number of patients with thrombocytopenia, but more importantly, it reduced by 44.8 % the number of subjects with unexpectedly low platelet count (Zaninetti et al. 2015). Based on this first experience, the introduction of the new range into the clinical practice is expected to prevent many subjects to receive a series of unnecessary and expensive tests, this benefiting both involved people and the health system.

The mechanisms of age- and sex-related differences of platelet count are unknown; it is possible to speculate that sex-related differences, which become more evident after puberty, might be partially related to both hormonal differences and body iron content (Evstatiev et al. 2014).

The molecular basis of platelet number heterogeneity is under active investigations: multiple genetic loci have been found to influence interindividual variation in platelet traits, which might be involved in multiple functional pathways relevant to thrombopoiesis (Soranzo et al. 2009; Gieger et al. 2011; Qayyum et al. 2012; Shameer et al. 2014). Five genes (*ACTN1*, *ETV7*, *GABBR1-MOG*, *MEF2C*, and *ZBTB9-BAK1*), one of which already known to be responsible for an inherited macrothrombocytopenia (Pecci 2016), have been recently identified as genetic factors associated with platelet count in a genome wide association study in Hispanic/Latino Americans (Schick et al. 2016).

Reticulated Platelets and Immature Platelet Fraction

Reticulated platelets (retPLT), described by Ingram and Coopersmith in 1969, are the youngest platelets into the blood stream, named "reticulated" in analogy with reticulocytes: they contain residual amounts of RNA which become evident after supravital staining with methylene blue (Ingram and Coopersmith 1969). More recently, a flow cytometric assay analyzing retPLT based on their RNA thiazole orange staining (Kienast and Schmitz 1990; Richards and Baglin 1995) was developed and used to investigate the clinical utility of retPLT in a large number of conditions, mainly characterized by thrombocytopenia, thrombocytosis, or thrombosis (Hoffmann 2014). Although all studies confirmed that retPLT may represent a useful and noninvasive marker of megakaryopoiesis, they also pointed out a number of critical methodological issues (type and concentration of the dye, incubation time, temperature) only partially related to lack of standardization: the major problem is the non-RNA-specific binding of the dye, resulting in a background of fluorescence dependent on the platelet size, which may be solved only by applying a two-dimensional gating process (Matic et al. 1998). This method, unsuitable for routine clinical application, has been overcome by the introduction of a fully automated technique in two counters (Table 2): in the Sysmex XE and XN, where retPLT were renamed "immature platelet fraction" (IPF), and in CELL-DYN Sapphire by Abbott. In the XN Sysmex, IPF are measured in a dedicated fluorescence platelet assay where platelet RNA is stained with a oxazine-based dye: IPF is derived from the forward light scatter intensity, reflecting cell size, and side fluorescence intensity, reflecting the amount of nucleic acid within the cells. In the Abbott analyzers, retPLT are measured in the reticulocyte assay based on the fluorescence dye CD4K530: platelets are distinguished from erythrocytes by a multi-dimensional separation obtained recording fluorescence against an intermediate angle scatter (7°). Since comparison of IPF counting by Sysmex and retPLT by CELL-Dyn Sapphire showed weak correlation, it has been concluded that they probably reflect a different aspect of thrombopoiesis and cannot be used interchangeably (Meintker et al. 2013). In healthy subjects the reference range for Sysmex IPF is 0.5–6.6 %, while for Abbott retPLT is 0.4–6.0 % (Hoffmann 2014). A correlation between retPLT and age has been described in healthy subjects, while differences among sex were not significant (Hoffmann et al. 2013). This parameter is now also available on a third cell counter, the BC-6800 from Mindray.

Clinical Utility of retPLT and IPF The first application of retPLT or IPF was in the field of differential diagnosis of thrombocytopenias: it is now accepted that retPLT/IPF decrease in case of bone marrow failure and reduced platelet production, while they increase in case of accelerated platelet destruction, such as in immune thrombocytopenia (ITP) (Hoffmann 2014; Adly et al. 2015; Sakuragi et al. 2015). In ITP patients, the IPF correlates with the phase of the disease and the response to treatment: patients with active ITP have the highest IPF, and those in complete remission the lowest (Adly et al. 2015). Searching for tests predictive of bleeding in pediatric ITP patients to make therapeutic decisions more appropriate to the severity of the disease, higher percentages or absolute counts of IPF were associated with higher bleeding scores (Greene et al. 2014; Frelinger et al. 2015) suggesting a role as markers of future bleeding risk in ITP.

RetPLT and IPF are considered a valuable marker for monitoring the thrombocytopenic phase after chemotherapy and the hematopoietic assessment after hematopoietic stem cell transplantation (Zucker et al. 2006; Michur et al. 2008; Martinelli et al. 2009; Goncalo et al. 2011; Hoffmann 2014; Morkis et al. 2015): in both conditions their number generally increases 2–3 days before platelet recovery, and by most they are considered precious tools in the decision for platelet transfusion, better than the platelet count (Hennel et al. 2012). In some cases the absolute count of IPF was a better indicator rather than its percentage for predicting platelet recovery after chemotherapy in pediatric patients (Have et al. 2013).

In the field of acute coronary syndrome (ACS), former studies have associated the rate of IPF with premature coronary artery disease, acute cardiovascular events, and impaired response to antiplatelet agents (Gonzalez-Porras et al. 2010; Perl et al. 2014); more recent studies did not confirm the correlation between IPF and the occurrence of residual high-on treatment platelet reactivity (Verdoia et al. 2015), neither the ability of IPF to assist clinicians in the diagnosis of ACS in patients presenting with acute chest pain (Berny-Lang et al. 2015).

The role of these parameters remains to be better defined also in many other diseases where they are extensively investigated.

Measurement of Platelet Dimensions

Since a long time, there is a general consensus that the evaluation of platelet size may be a useful tool in differential diagnosis of platelet disorders; only more recently this parameter has also been explored in diagnosis and prognosis of a variety of thrombotic and non-thrombotic diseases: the usefulness of this parameter has yet to be fully established because of several potential laboratory issues.

Information on platelet size can be acquired by two different methods: by automated counters (Table 2) which measure the mean platelet volume (MPV) and, manually, by optical microscopy, where the mean platelet diameter (MPD) is obtained on peripheral blood smears.

Mean Platelet Volume

After the introduction of automated counters, the MPV has become a simple, inexpensive, and widely available parameter in clinical practice. However, a number of pre-analytical and intra-analytical factors, summarized in Table 4, may result in unreliable MPV.

Pre-analytical Variables The method of venipuncture and the accuracy of filling the tube and mixing the sample may account for altered MPV since the possible platelet activation occurring in the tube may lead to aggregation of platelets which will not be included in both counting and sizing of platelets (Table 3).

Among all available anticoagulants, EDTA and sodium citrate are the most commonly used in the routine analyses and their effect on MPV the most extensively investigated. Since 1954, platelet exposure to EDTA was known to be associated with change of platelet morphology (Zucker and Borrelli 1954) from elliptical to spherical and with cellular swelling secondary to changes in membrane permeability, dilatation of the open canalicular system, and decreased number of internal organelles (White et al. 1999; White 2000; Diaz-Ricart et al. 2010). Such platelet swelling is responsible for an increased MPV when measured by impedance technology but for a decreased MPV obtained by optical technology, reflecting a reduced platelet density. Different concentrations of a same anticoagulant may result in different effects on platelet volume: a platelet swelling has been described with high (1:4 v/v with blood) but not with low concentrations (1:9 v/v with blood) of sodium citrate (Bath 1993). Based on this methodological problem, in 1993 the ICSH recommended the use of K_2-EDTA (1.5–2.2 mg/mL blood) as reference method:

Table 4 Analytical variables influencing the measurement of mean platelet volume

Pre-analytical variables
Method of venipuncture, accuracy of filling the tube and mixing the sample
Type of anticoagulant
Temperature of storage
Time to analysis
Intra-analytical variables
Platelet counting principle of automated analyzer
Calibration of the automated analyzer

nevertheless, many anticoagulants are still used in routine and research settings (England et al. 1993).

Changes of MPV start immediately after blood exposure to anticoagulant and proceed over time: the MPV increase is usually higher during the first 2 h but it can be recorded also after 24–39 h (Jackson and Carter 1993; Diaz-Ricart et al. 2010; Lancé et al. 2012). In K_2-EDTA blood samples, the MPV may increase up to 27 % after 24 h; the phenomenon may be partially prevented by the addition of inhibitors of signaling pathways and storage at 4 °C (Diaz-Ricart et al. 2010).

Only a few studies explored the influence of the storage temperature of blood samples on MPV: cooling of samples from 37 °C to 4 °C resulted in a reduction of MPV up to 18 % in sodium citrate samples (Threatte et al. 1984; Park et al. 2002). A significant increase in MPV has been recently reported also for EDTA-anticoagulated samples, but only after 24 h storage at room temperature or at 4 °C (Daves et al. 2015).

Intra-analytical Variables By impedance counters, the MVP is calculated on the basis of the volume of elements which are recognized, and counted as platelets based on their dimensions (for details, see "Impedance Platelet Counting"): MPV is derived from the platelet size distribution curve generated during platelet counting by dividing the plateletcrit for the number of platelets (Briggs 2009). Inaccuracies of MPV measurements can potentially result from all conditions leading to under- or overestimation of platelet count (Table 3) but in particular in the presence of giant platelets exciding the normal range of platelet size (Fig. 3) (Zandecki et al. 2007; Noris et al. 2009, Lancé et al. 2012): in patients suffering from *MYH9*-related disease or biallelic Bernard-Soulier syndrome, for example, either the number of platelets or the MPV may be unreliable being underestimated or not even calculated (Noris et al. 2009; Pecci et al. 2014). Moreover, MPV values may differ not only because they are achieved by impedance counters from different manufacturer but also by similar platforms depending on their calibrations (Latger-Cannard et al. 2012; Lippi et al. 2015).

In optical counters the MPV is obtained measuring the light scattered at the lower angle of laser diffraction (for details, see "Optical Platelet Counting"); a platelet histogram is produced from measurements corresponding to the size and number of platelets, and then the MPV is calculated from the geometrical mode of such histogram (Briggs 2009). Based on the specific technology, both platelet counting and sizing obtained by optical counters are expected to be more reliable than the impedance ones: in particular, large platelets are correctly identified based on their peculiar density and then correctly counted and sized.

The reference range of MPV has been investigated in different populations because of the increasing interest about its role in several disorders. Since population studies have been achieved with different cell counters and without standardization of reading times, MPVs of healthy peoples resulted very different, ranging from 6.0 to 13.2 fL in the different studies (Demirin et al. 2011; Hoffmann 2012; Lippi et al. 2012).

No definitive results are available on sex variability: while no differences were observed in a large Italian population study (Santimone et al. 2011), MPV was higher in females compared with males enrolled in a population-based study on adult German individuals (Panova-Noeva et al. 2016). In particular, higher MPV values were found to be significantly associated with age, smoking, hypertension, and glucose levels in men and oral contraceptives and menstruation in women. Importantly, seven and four single nucleotide polymorphisms in women and man, respectively, were found to be significant determinants of larger platelet size (Panova-Noeva et al. 2016).

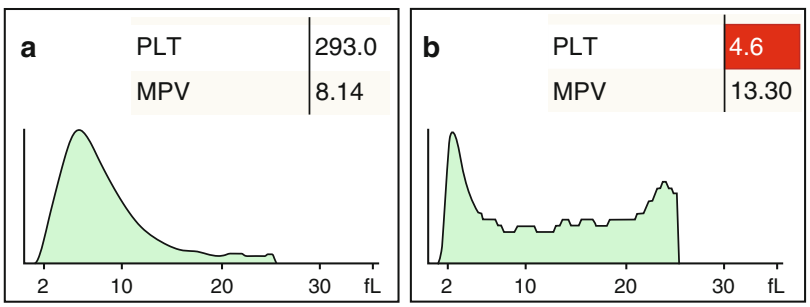

Fig. 3 Histograms of platelet distribution size obtained by the impedance counter DxH800 from Beckman Coulter. Panel **a**: Histogram obtained from a healthy subject (platelets 293 × 10^9/L, MPV 8.14 fL). Panel **b**: Histogram from a *MYH9*-related disease patient with severe thrombocytopenia and extreme platelet macrocytosis. The impedance counter underestimated the MPV of the patient (MPV 13.3 fL, normal range 8–13 fL); because of platelet macrocytosis, also the automated platelet counting was significantly underestimated with respect to the manual counting obtained by optical microscopy (4.6 × 10^9/L vs 32 × 10^9/L, respectively)

Mean Platelet Diameter

An alternative method for platelet sizing has been developed to overcome the abovementioned variables affecting MPV by automated cell counters: it relies on the measurement of platelet diameters by optical microscopy on May-Grünwald-Giemsa-stained peripheral blood films and software-assisted image analysis. The largest diameter of each platelet is measured and the mean platelet diameter (MPD) is the mean value obtained in 200 platelet measurements (Noris et al. 2009) (Fig. 4). Although it is time-consuming and difficult to apply in clinical practice, this method has some strengths: it allows the collection of reliable and comparable measurements in different laboratories and from samples collected long before the analysis. There are no potential variables interfering with the MPD measurement, except for an optimal monolayer preparation of the smear which should be obtained from non-anticoagulated capillary blood. The normal range of MPD has been calculated in 55 Caucasian healthy people (95 % CI 2.4–2.7 μm, mean 2.58 μm) (Noris et al. 2014).

Clinical Utility of MPV and MPD

The field in which platelet size was definitely proven to have a diagnostic role is that of inherited thrombocytopenias (ITs): in fact, the evaluation of platelet size is the first step to distinguish among the different forms of IT whose number is constantly increasing (Noris et al. 2004; Pecci 2016; chapter "Inherited Thrombocytopenias").

The clinical utility of platelet size has been underlined also in the differential diagnosis of ITP from ITs, whose platelet dimensions are frequently overlapping and increased: however, since MPV may be underestimated in presence of giant platelets, only the simultaneous assessment of MPV and MPD demonstrated diagnostic efficacy (Noris et al. 2009; Noris et al. 2013). In a study evaluating MPDs in ITs and ITP, the percentage of platelets larger (40 %) or smaller (10 %) than half an erythrocyte, a parameter easy to obtain by optical microscopy, turned out to be helpful in discriminating ITP from ITs associated with giant platelets or with normal/reduced platelet size, respectively (Noris et al. 2014).

Although there are several methodological limitations (different methodologies and thresholds for MPV, lack of standardization, heterogeneity of the studies, heterogeneity of patients enrolled in the studies) that must be solved (Lancé 2014), the role of MPV has been explored in a number of non-platelet diseases: an increased MPV was significantly associated with risk of myocardial infarction (Chu et al. 2010), venous thromboembolism (Braekkan et al. 2010), a worse prognosis in cancer patients (Kumagai et al. 2015), and cardiovascular events in patients with coronary artery disease (Asher et al. 2014; Sansanayudh et al. 2015); limited to cancer patients, high MPV have been associated with decreased VTE risk (Ferroni et al. 2014) and improved survival (Riedl et al. 2014).

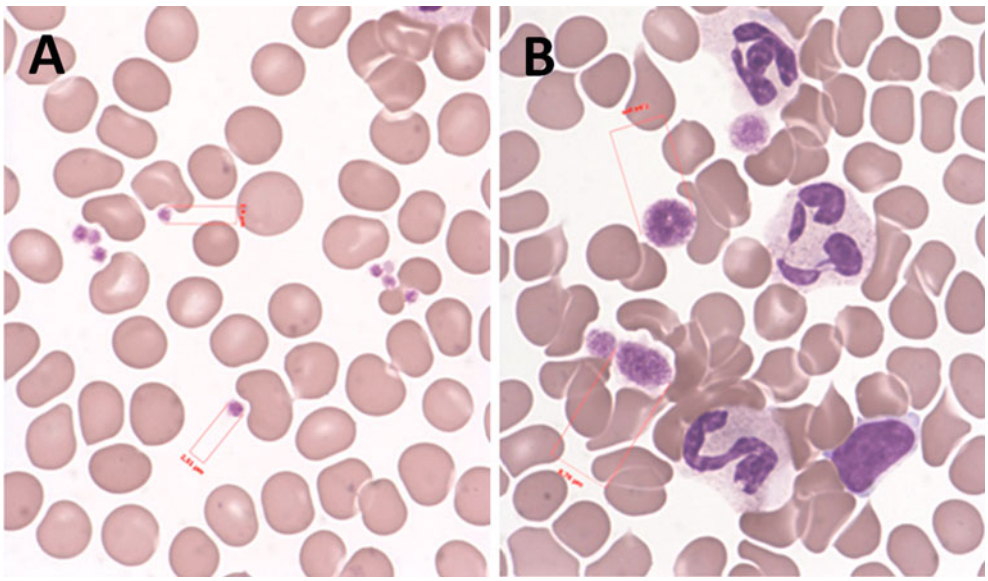

Fig. 4 Measure of platelet diameters provided by the specific tool of the Axio Vision 4.5® software (Carl Zeiss) performed on May--Grünwald-Giemsa-stained peripheral blood smears. Representative examples of the measure are shown. Panel **a**: Measures obtained in a control subject whose mean platelet diameter calculated on 200 platelets was 2.5 μm. Panel **b**: Measures obtained in a patient with *MYH9*-related disease whose mean platelet diameter was 5.6 μm. The range of mean platelet diameter calculated in 55 healthy subjects is 2.2–2.8 μm [Modified with permission from Noris et al. (2009) J Thromb Haemost 7:2131–2136]

In a multivariate analysis combining both clinical and genetic determinants of a large population-based study, Panova-Noeva et al. (2016) observed a higher mortality rate in males with MPV above the upper limit of the reference range during a median follow-up period of 5.0 years.

Finally, the role of MPV as an inflammatory marker still remains to be determined although it is extensively investigated in many different conditions (Varol and Ozaydin 2014; Soydinc et al. 2014; Ataş et al. 2015; Agapakis et al. 2016).

Additional Platelet Parameters from Automated Cell Counters

In addition to retPLT/IPF and MPV, a number of additional platelet parameters may be generated by some automated cell counters (Table 2): among all, the platelet large cell ratio (P-LCR) calculated by ADVIA analyzers represents the number of platelets larger than 12 fL divided by the total number of platelets, while the mean platelet component (MPC) corresponds to platelet density and provides information on anticoagulant induced as well as thrombin-stimulated platelet activation (Salignac et al. 2013). Their clinical utility is still under investigation.

Pseudothrombocytopenia and Other Causes of Spurious Platelet Count

Despite significant technical improvement of automated cell counters, spurious platelet counts can still occur: pseudothrombocytopenia, mainly related to anticoagulants, is the most frequent but a number of other circumstances can lead to erroneous platelet counting (Table 3). They are usually not frequent but their knowledge is important to make practitioners sensible about their possible occurrence, especially in specific clinical setting.

EDTA-Dependent Pseudothrombocytopenia

The frequency of EDTA-dependent pseudothrombocytopenia (EDP) ranges from 0.07 to 0.2 % of all blood counts, and it is not affected by sex but increases with age (Bizzaro 1995; Wu et al. 2011; Xiao et al. 2015). Among patients evaluated for isolated thrombocytopenia, its prevalence is more common in hospitalized than in outpatients (Silvestri et al. 1995; Cohen et al. 2000).

Immunological, chemical, and physical factors are chorally involved in the physiopathology of this phenomenon described first in 1969 (Gowland et al. 1969). It is now acknowledged that platelets' agglutination depends on Abs toward platelet antigens exposed on membrane glycoproteins thanks to EDTA and low temperature action (Onder et al. 1980; Pegels et al. 1982). IgG are more frequently involved, although all Ig classes may elicit the reaction: most of them are cold agglutinins, except for IgM, that usually behave either as room temperature and wide heat range-agglutinins (Onder et al. 1980; Bizzaro 1995). The specific antigen's seat is the $\alpha_{2b}\beta_3$ integrin, especially its α_{2b} subunit (Van Vilet et al. 1986). In basic condition, the epitope is hidden within the integrin. Thanks to the chelating effect of EDTA on calcium ions and low temperature influence, a dissociation of the structure occurs enabling binding of antiplatelet Abs, which in turn cause agglutination (Fig. 5, panel a) (Pidard et al. 1986). Other anticoagulant agents such as heparin, hirudin, oxalate, and citrate may also induce pseudothrombocytopenia (Robier et al. 2010; Nagler et al. 2014; Lin et al. 2015); rarely it can be both EDTA and citrate dependent (<0.02 % of all blood counts) or even more than two anticoagulant dependent (Bizzaro 1995; Zhou et al. 2011). When elicited by EDTA, it could be prevented and sometime reverted by addition of aminoglycosides (Sakurai et al. 1997; Lin et al. 2015). Despite no definite association has been proven, EDP has been frequently observed after viral infections including rubella, mumps, cytomegalovirus,

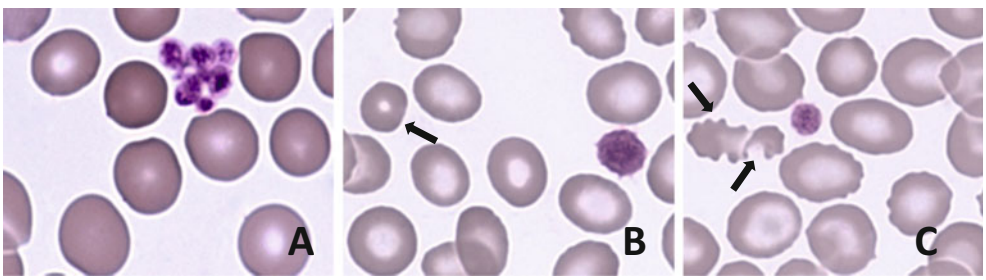

Fig. 5 Conditions leading to spurious low platelet count. Panel **a**: May-Grünwald-Giemsa-stained peripheral blood smear obtained by EDTA-anticoagulated blood from a patient with EDTA-dependent pseudothrombocytopenia: small clumps may be counted as leukocytes leading to pseudoleukocytosis. Panels **b**, **c**: May-Grünwald-Giemsa-stained peripheral blood smear obtained by a patient with β-thalassemia minor and mild thrombocytopenia, due to chronic ITP, where platelets have similar size to some microcytic erythrocytes (*arrow*). In this patient the platelet count was overestimated because microcytic erythrocytes were counted as platelets

Epstein-Barr virus, and hepatitis A virus (Hsieh et al. 2003; Choe et al. 2013).

Clinical Relapses Being a laboratory artifact, EDP is a clinically harmless condition without hemorrhagic risk. Nevertheless, its clinical importance is not irrelevant. A prompt recognition of EDP is mandatory to avoid inappropriate and potentially dangerous treatments or diagnostic procedures: the lack of recognition of EDP in critically ill patients can wrongly influence the process of differential diagnosis (Lau et al. 2004; Kocum et al. 2008; Yoshikawa et al. 2006). Conversely, in a real thrombocytopenic patient for any cause, EDP may overestimate the severity of thrombocytopenia leading to unnecessary platelet transfusion and additional testing (Podda et al. 2012).

Laboratory Picture In case of EDP the electronic cell counters typically reveal a spurious thrombocytopenia because platelet agglutinates are usually counted as small leukocytes. Although the majority of the modern blood analyzers may recognize platelet clumps due to specific scattergram patterns and warning flags, false negatives or positives are not uncommon (Batels et al. 1997): small clumps can be counted as leukocytes and none warning produced except for pseudoleukocytosis (Lombarts and De Kieviet 1988). When a suspicion of EDP is generated, pseudothrombocytopenia can be straightforwardly confirmed by the microscopic observation of platelet clumps in the blood smear obtained by EDTA-anticoagulated tube (Fig. 5, panel a), a procedure useful also for confirmation or exclusion of other causes of machine-determined or overestimated thrombocytopenia, as what happens in all cases of platelet macrocytosis (myeloproliferative syndromes, myelodysplastic disorders, ITs) (Bernard and Soulier 1948; Seri et al. 2003; Noris et al. 2009, Pecci et al. 2014). In these subjects an accurate platelet count may be achieved with alternative anticoagulants like citrate-pyridoxalphosphate-tris (CPT) or magnesium sulfate, effective either for prevention of pseudothrombocytopenia and for obtaining accurate routine hematology data (Lippi and Plebani 2012; Schuff-Werner et al. 2013). When only EDTA-tubes are available, EDP may be avoided collecting blood in a pre-warmed tube and processing the sample, stored at 37 °C, as soon as possible; in alternative, blood may be collected by finger stick and platelets counted manually by optical microscopy (Bizzaro 1995).

Other Causes of Spurious Platelet Count

Platelet Satellitism Named alternatively rosetting or satellitosis, platelet satellitism is a quite rare (1 of 12,000 blood counts) in vitro phenomenon characterized by platelet adherence to normal or abnormal leukocytes in EDTA-anticoagulated blood samples (Zandecki et al. 2007). Polymorphonuclear neutrophils (PMN) are more frequently involved, but rosetting around monocytes, basophils, eosinophils, lymphocytes, and lymphoma cells has been also described (Salignac et al. 2013). Besides EDTA, platelet satellitism has been observed in blood samples anticoagulated with heparin. It has been reported to be unrelated to any pathological conditions, except for some rare reports speculating on a possible relation with autoimmune processes. The responsible mechanism seems to be similar to that of EDP: IgG or IgM auto-Abs against a α_{2b} antigen, unmasked by EDTA, would be accountable for forming bridges between platelets and PMN via their Fcγ receptor (Lazo-Langner et al. 2002).

EDTA-Dependent Platelet-Neutrophil Agglutination The formation of large clumps containing hundreds of PMN and platelets, leading to a spurious reduction of platelet and/or PMN automatic count, could represent the final step of a process started by platelet rosetting around PMN. Because of the low number of cases described, the understanding of mechanism of clumping and the difference with classical satellitism is far to be fully understood (Zandecki et al. 2007). This in vitro phenomenon must be distinguished from platelets-WBC aggregates observed in vivo during thrombotic and inflammatory conditions with marked platelet activation and consequent enhanced expression of P-selectin (Hu et al. 2003).

Platelet Macrocytosis As already discussed (see "Impedance Platelet Counting"), platelet macrocytosis can result in an erroneous low platelet count when obtained by impedance counters relying only on the cell size (Noris et al. 2009; Latger-Cannard et al. 2012).

RBC Microcytosis and Cytoplasmic Fragments of Blood Cells RBC of extremely low volume, such as what occurs in severe iron-deficiency anemia or thalassemia, can disturb the ability of automatic analyzers to distinguish platelets and RBC (Figs. 5, panels b, c and 6) leading to a spurious elevated platelet count and/or reduced RBC count (Savage and Hoffman 1985, Noris and Balduini 2014) since small RBCs are wrongly counted as platelets. Similar eventualities can occur in presence of a large number of schistocytes or microspherocytes, the last during acute burns (Zandecki et al. 2007). Fragments of cytoplasm from other blood cells such as myeloblasts, lymphoblasts, and cells of lymphocytic lymphoma in leukemic phase can lead to a same spurious altered platelet count (Frotscher et al. 2015). Onco-hematologic clinical setting and various types of flags generated by the newest automatic analyzers can suggest the

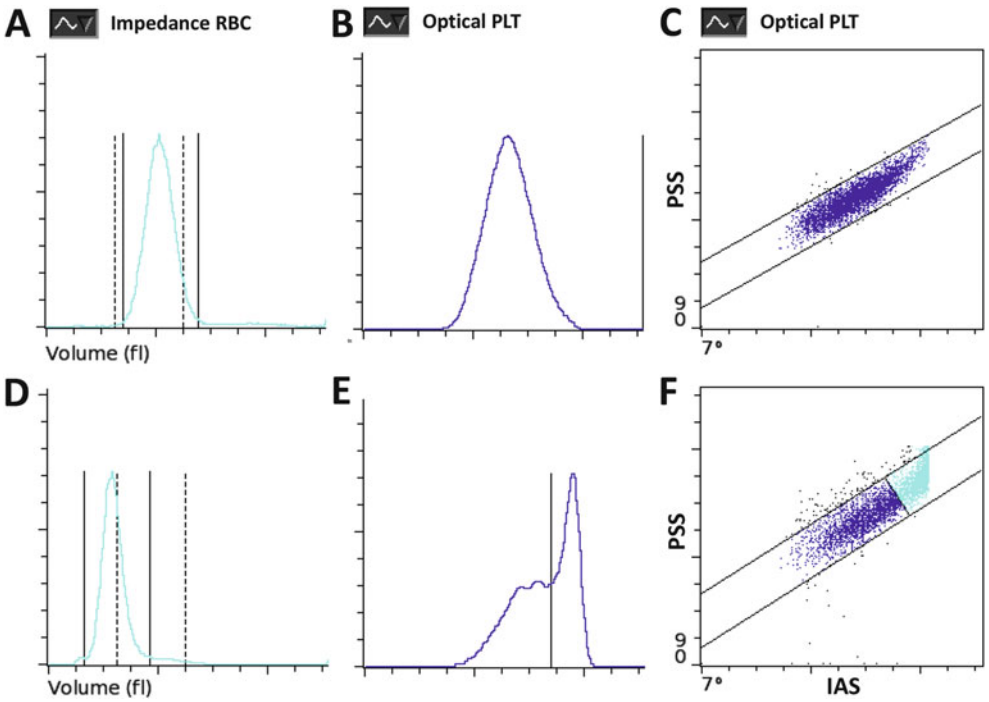

Fig. 6 Impedance red blood cell (RBC) histograms and optical platelet histograms and scatterplots with dynamic threshold produced by a CELL-DYN Sapphire from a normal subject (panels **a**–**c**) and a subject with β-thalassemia minor and mild thrombocytopenia (panels **d**–**f**, see also Fig. 5, panels **b** and **c**). The impedance RBC histogram from the patient clearly displays the red blood cell microcytosis (**d**) interfering with the correct determination of the volume (**e**) and, thereafter, of platelet counting. Microcytic RBCs are visible in the platelet optical scatterplot (**f**, *light blue*) where they are distinguished from platelets (**f**, *dark blue*) based on their density. In this patient the impedance platelet count was 168×10^9/L, while the optical platelet count, based on both dimension and complexity of cells, was 85×10^9/L, superimposable to counting obtained manually by optical microscopy. *IAS* intermediate angle scatter measuring cell complexity/internal structure, *PSS* polarized side scatter measuring nuclear segmentation/lobularity

situations described above that should be ruled out by careful examination of peripheral blood smears.

Microorganisms Spuriously elevated platelet counts may rarely be caused by bacteria or bacterial aggregates, fungi, and trophozoites. These phenomena has been described typically in patients with extremely severe clinical conditions and bacteremia. Similar conditions can even depend on pre-analytical variable such as unsterile tubes used for blood sampling allowing bacterial overgrowth (Zandecki et al. 2007).

Cryoglobulins According to their size, immune complexes precipitating at temperature lower than 37 °C can lead to overestimation of platelet, leukocyte, and rarely RBC count according to their size (Emori et al. 1973). A cryoglobulin-depending spuriously high platelet count typically recovers when repeating the analysis after warming the sample for 30 min at 37 °C. A spurious increased platelet count may be similarly generated by cryofibrinogen (Zandecki et al. 2007).

Lipids Abnormally high levels of lipids in blood (hyperchylomicronemia, samples obtained during parenteral nutrition or infusion of therapeutic agents containing lipids) may result in the in vitro formation of micellae or droplets that can be misdetected as platelets by either optical and impedance automated blood counters (Kabutomori et al. 1999). Similarly to platelets, also hemoglobin concentration and RBC and WBC counts may be affected by abnormal concentrations of lipids (Zandecki et al. 2007).

Take Home Messages

The coming of automated blood cell counters has made platelets' number and dimension evaluation a basic analysis for clinical and research aims. Recently it has been suggested the need for personalized reference ranges for platelets count taking into account gender, age, and ethnicity.

The most commonly in use analyzers, which calculate blood cell number relying on their size, can results in both overestimation or underestimation of platelet count. To solve this matter, several automated methods based on alternative techniques, primarily optical and immunological, have been developed.

(continued)

Despite technical improvements, some methodological issues remain to be solved; in few selected diagnostic routes, the manual method of analysis of platelet parameters (by optical or phase-contrast microscope) is still to be considered irreplaceable.

In clinical setting, platelet count is required not only for diagnostic purpose but also for arduous therapeutic decision. To this aim, having available additional platelet parameters (i.e., large platelets, reticulated platelets, immature platelet fraction) can drive clinical judgment in challenging situations.

Flow Cytometry

Cecilia Carubbi, Elena Masselli, and Marco Vitale

Abstract

Flow cytometric platelet analysis is becoming increasingly popular for both experimental and clinical applications. Flow cytometry (FCM) can feasibly analyze platelet biology both in vivo and ex vivo, providing information on platelet turnover and count, structure, antigen expression, activation state, interaction with other blood components, and response to agonists.

Reduced sample volume, minimal manipulation, and single-shot multiparametric characterization of platelet populations are the main advantages of FCM platelet studies. However, some aspects need to be carefully considered, including activation-dependent changes resulting from inaccurate sample collection, the need for a dedicated operator, and standardization.

Relevant clinical applications include assessment of thrombotic risk in cardiovascular diseases and cancer, monitoring of pharmacological anti-aggregation, and diagnosis of inherited and acquired platelet function disorders. This chapter focuses on the main applications of FCM in studies that are relevant for both research and clinical settings.

Generalities on Flow Cytometry

First developed as a rapid and automatic technique for determining the nuclear DNA content, flow cytometry (FCM) now finds its most common applications in the phenotypic and functional characterization of various cell types because of its ability to detect several specific characteristics of a large number of individual cells in suspension in a time range of seconds.

In the flow cytometer, suspended aligned cells pass through a flow cell where they are hit by the focused beam of a laser. Detectors process the light scattering and, in the case of fluorescent labeling, the emitted fluorescence of each cell. Cell parameters that can be assessed by FCM are divided into two groups:

- *Physical or intrinsic parameters*, represented by the forward-scattered light (FS), which is proportional to cell dimensions, and the side-scattered light (SS), which is proportional to the structural complexity of the cell.
- *Fluorescent parameters*, obtained by labeling cells, before analysis, with fluorophore-conjugated monoclonal antibodies (targeting specific cell antigens) or cell-permeable fluorescent proteins that are activated at specific excitation wavelengths by a laser beam. The intensity of the fluorophore-emitted light is directly proportional to the antigen density. The wide range of labeled antibodies or cell-permeable fluorescent proteins commercially available permits not only the analysis of

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_40

several cell parameters in one single shot, but also a detailed study of cell phenotype and function, cell–cell interaction, cell activation, apoptosis, and cell cycle, to name just a few (McCoy 2002).

Advantages of the Use of FCM in Platelet Studies

FCM allows rapid analysis of platelet turnover and count, morphology, structure, activation state, and response to agonists. This means that it is a versatile and reliable diagnostic tool for analysis of platelet disorders, evaluating the effects of antiplatelet agents, and assessment of circulating activated platelets in the context of thrombotic risk.

In recent years, the use of FMC in the field of hemostasis and thrombosis has become widespread thanks to its feasibility compared with time-consuming and expensive conventional platelet assays such as enzyme-linked immunoassay (ELISA), transmission electron microscopy (TEM), fluorescence microscopy, C^{14} labeling, high performance liquid chromatography (HPLC), particle gel immunoassay (PaGIA), aggregometry, and radioimmunoassay (Carubbi et al. 2014a).

Additionally, the reduced blood volume required for analysis, minimal sample manipulation, and high number of commercially available monoclonal antibodies allowing single-shot multiparametric evaluation make FCM a fundamental technique in platelet studies. However, some aspects need to be carefully considered when using FCM in platelet studies. In particular, the operator should be aware of the risk of platelet activation as a result of inadequate sample collection and/or time delays. The principal advantages and disadvantages of FCM are summarized in Table 1.

Methodological Aspects

Peripheral Blood Draw: Suggested Procedure and Sample Preparation

In platelet studies, a careful execution of peripheral blood draw is mandatory to minimize platelet activation. For this purpose, a 20–21G needle is recommended. Additionally, it is helpful to rapidly remove the tourniquet and discard the first 2 mL of blood. The sample should then be conserved at room temperature and processed within 30 min. These precautions are strongly recommended when the activation state of circulating platelets is to be determined.

The choice of anticoagulant relies mainly on specific tests: in the case of ex vivo platelet response to agonists, sodium citrate is recommended because it does not interfere with platelet activation. By contrast, if seeking to minimize platelet activation after sampling, anticoagulants should be chosen that contain platelet inhibitors such as CTAD (citrate, theophylline, adenosine, and dipyridamole). Ethylenediamine tetraacetic acid (EDTA) is suitable for platelet count measurements (Michelson et al. 2000).

Platelet Source

The starting material for platelet studies by FCM can consist of platelet-rich plasma (PRP), washed platelets, or whole blood. The choice depends mainly on the test type. PRP, obtained by blood centrifugation at 125–150 *g* for 10–20 min, is suggested by some authors for calcium flux analysis.For detection of platelet microparticles, two centrifugations (1500 *g* for 15 min followed by 13,000 *g* for 2 min) are recommended in standardized protocols. Washed platelets are utilized in activation studies with strong agonists (i.e., thrombin), which can cause clot formation in the presence of plasma fibrin (Hickerson and Bode 2002; Robert et al. 2009).

Nevertheless, in clinical studies, whole blood is by far the most convenient platelet source (Shattil et al. 1987) because platelets are kept in their physiological milieu of red cells, leukocytes, and plasma components, which clearly affects platelet activation (Santos et al. 1991; LaRosa et al. 1994b). Moreover, the sample is minimally manipulated, preventing artifactual ex vivo activation and potential loss of platelet subpopulations (Michelson et al. 1991; Abrams and Shattil 1991; Shattil et al. 1987). Also, only minuscule volumes of blood are required (2–5 μL), allowing accurate analyses on newborns and profound thrombocythopenic patients (Shattil et al. 1987; Michelson et al. 1991; Rajasekhar et al. 1994). Michelson and colleagues (Michelson et al. 1991; Michelson 1994; Kestin et al. 1993) developed a method for studying

Table 1 FCM in platelet studies

Advantages	Disadvantages
Minimal sample manipulation	Dedicated operator
Minimal volumes required (2–5 μL per test)	Activation-dependent changes as a result of inaccurate sample collection
Physiological milieu (whole blood)	
Applicable in profound thrombocythopenias	
Detection of activation-dependent changes	
Quantitative results	

platelet activation by thrombin directly in whole blood, based on addition of the synthetic tetrapeptide GPRP (glycyl-L-prolyl-L-arginyl-L-proline) that competitively prevents fibrin polymerization and, via inhibition of fibrinogen binding to its receptor, partially blocks platelet aggregation. The same effect is also mediated by Arg-Gly-Asp (RGD)-containing peptides that, mimicking fibrinogen binding sites, act as glycoprotein IIb/IIIa (GPIIb/IIIa) antagonists. These assays allow simultaneous analysis of the activation state and reactivity of circulating platelets. An alternative is use of the thrombin receptor agonist peptide (TRAP), although it may not fully reflect all aspects of thrombin-induced activation because it is a peptide fragment of the "tethered ligand" receptor for thrombin (Yamamoto et al. 1991).

Expression of Antibody Binding

In FCM, platelet population is conventionally identified by a "morphological gate" according to platelet physical properties and is represented on a dot plot of FS versus logarithmic SS. However, for discrimination of platelets from other blood cells it is more appropraite to use a light scatter parameter versus the fluorescence signal of platelet-specific constitutive antigens (i.e., "immunological gate"). Photomultiplier voltages are adjusted to give light scatter signals in the midrange of the logarithmic scale of the instrument. Amplification of fluorescence signal is selected to give a platelet autofluorescence signal that falls within the first logarithmic decade of the instrument. Because of spectral emission overlap, appropriate electronic color compensation must be set for each combination of antibodies (fluorophores) according to the manufacturer's instructions and confirmed by each laboratory.

Antibody binding can be expressed as the percentage of cells staining positive for a particular antibody or as mean fluorescence intensity (MFI). The percentage of positive cells identifies a subpopulation of platelets expressing a specific antigen, in comparison with the negative fluorescence of a predominant platelet population. A threshold value for the positive signal intensity is defined on the basis of an appropriate value for false-positive events, conventionally including 1–2 % of positive cells in a one-parameter histogram analysis of a matched negative control sample stained for the determination of nonspecific fluorescence (e.g., sample stained with isotype control). This method is not affected by variations in signal amplification because the negative control signal increases in proportion with the test sample. Moreover, as a result of its high sensitivity, the method allows detection of changes in antigen expression by small subpopulations of cells, which results in a heterogeneous platelet staining pattern. Indeed, the "percentage of positive platelets" method can detect subpopulations of platelets arising from a local in vivo insult and is the most appropriate method for analysis of antigens expressed upon activation. However, this method is inappropriate for measuring variations in the expression of antigens that are homogeneously exposed across platelet subpopulations (i.e., CD41). Moreover, antibody-positive platelets may have very little antigen expressed at their surface.

If the goal is to determine variations in homogeneously expressed antigens or the total amount of platelet surface antigens, MFI is the method of choice. MFI is defined as the mean fluorescence intensity of the analyzed population and represents the mean antigen density on the cell surface. Therefore, an increase or decrease in MFI represents a similar increase or decrease in antigen expression per single platelet. Quantification of the number of antibodies specifically bound to platelets is based on a calibration curve established for each directly conjugated antibody using multiple bead populations with a defined number of specific binding sites. For this purpose, commercial kits equipped with a set of calibrated fluorescent standards and software can be used to determine molecules of equivalent soluble fluorochrome (MESF). An additional advantage of the routine utilization of these standards allows data comparison over time and between different instruments and laboratories (Michelson et al. 2000).

An interesting technique for the calculation of binding index that takes into account both MFI and the percentage of positive platelets has also been described (Hjemdahl et al. 1994; Zeller et al. 1999; Leytin et al. 2000).

FCM Evaluation of Platelet Activation Markers

As previously stated, FCM is a helpful tool for assessing platelet activation state both in vivo (circulating platelets) and ex vivo (platelet reactivity to agonists). When activated, platelets undergo several changes in surface antigen expression and granule release (Fig. 1). FCM can detect these events as changes in the binding of specific monoclonal antibodies that recognize markers of platelet activation. The most common markers are summarized in Fig. 1 and Table 2 and can be divided into surface markers and intracellular markers. Additionally, other parameters of platelet activation are represented by platelet–leukocyte aggregates (PLAs) and platelet microparticles (PMPs).

Activation-Dependent Surface Markers

Compared with other cells, platelet surface antigens constitute a larger proportion of platelet cellular mass and are primarily represented by platelet–membrane receptors.

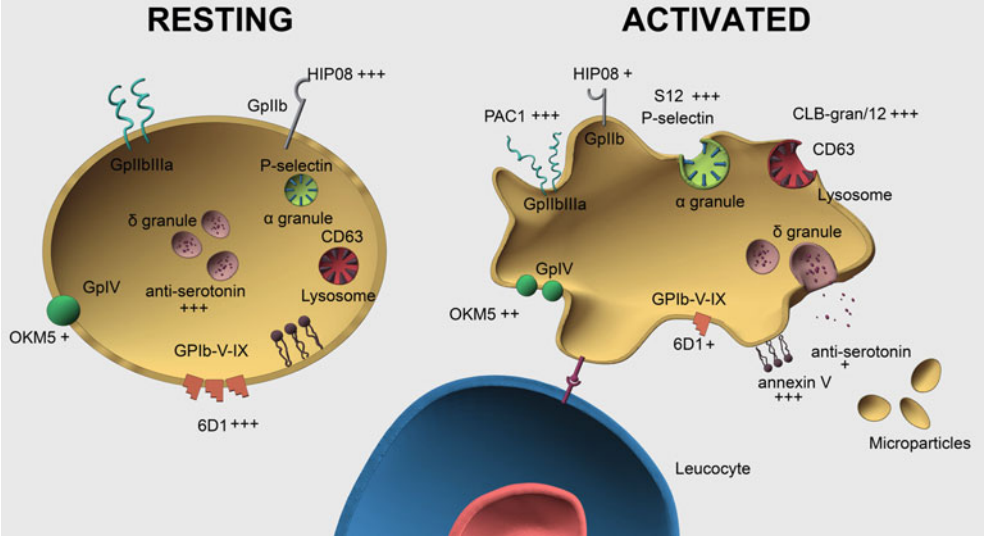

Fig. 1 Surface and intracellular platelet markers in resting and activated platelets studied by flow cytometry

Table 2 Flow cytometric markers of platelet activation

Marker	Description/function	Prototypic antibody	Binding: resting platelets	Binding: activated platelets
Surface markers				
Activated form of $\alpha_{IIb}\beta_3$	Platelet membrane glycoprotein; binds to fibrinogen and vWF	Anti-CD41/CD61 (activated form)	–	+++
P-selectin	Component of α-granule membrane; mediates adhesion to neutrophils and monocytes	Anti-CD62P	–	+++
Lysosomal integral membrane protein	Integral protein of platelet lysosomal membrane and δ-granules	Anti-CD63	–	+++
GPIV	Platelet membrane glycoprotein; binds to collagen and thrombospondin	Anti-CD36	+	++
GPIb-V-IX complex	Platelet membrane glycoprotein; binds to vWF	Anti-CD42a-d	+++	+
Phosphatidylserine	Anionic phospholipid of platelet membrane bilayer	Fluorescently conjugated annexin V	–	+++
Activated form of GPIIb	Platelet membrane glycoprotein complexed with GPIIIa; binds to fibrinogen and vWF	Anti-CD41a, HIP08 clone	+++	+
Intracellular markers				
Serotonin	Stored in δ-granules; mild platelet agonist	Anti-serotonin	+++	+
Vasodilator-stimulated phosphoprotein (VASP)	Intracellular signaling molecule that is not phosphorylated in the basal state and phosphorylated in PGE1-inhibited platelets		+++ (PGE1-inhibited)	–
Others				
Leukocyte–platelet aggregates	Activated platelet–monocyte/neutrophil complexes	Anti-CD41, -CD61, -CD42, -CD3, -CD19, -CD56, -CD16, -CD14	+	+++
Platelet microparticles	Platelet fragments	Anti-CD62P CD107A, CD63	+	+++

Conformational modifications or changes in the levels of their expression on the cellular surface can be used to trace platelet activation and, for this purpose, FCM is the method of choice for its accuracy and rapidity. Platelet–membrane receptors are grouped into eight types:

1. Integrins ($\alpha_{IIb}\beta_3$, $\alpha_2\beta_1$)
2. Leucine-rich repeat receptors (GPIb-IX-V complex, Toll-like receptors)
3. Seven-transmembrane receptors (thrombin, prostaglandin, ADP, lipid, and chemokine receptors)

4. Immunoglobulin superfamily (GPVI, FcγRIIa, FcεRI, junction adhesion molecules, intracellular adhesion molecules, PECAM-1, CD47)
5. C-type lectin receptor family (P-selectin, CD72, CD93)
6. Tetraspanins (CD9, CD63, CD82, CD515), glycosylphoshatidylinositol-anchored proteins (CD55 and CD59)
7. Tyrosine-kinase receptors (thrombopoietin, insulin and leptin receptor, PDGF receptor)
8. Others (CD36, lysosomal-associated membrane proteins, CD40L) (Clemetson and Clemetson 2013).

The two most widely utilized activation-dependent surface antigens are P-selectin and the $\alpha_{IIb}\beta_3$ complex (Shattil et al. 1985; Stenberg et al. 1985) (see Table 2 and Fig. 1).

P-selectin (or CD62P) is a component of the α-granule membrane of resting platelets that mediates adhesion to neutrophils and monocytes. It is expressed on their surface only after platelet degranulation (Fig. 1). Therefore, P-selectin-specific monoclonal antibodies (see Fig. 2 and Table 2) bind exclusively to activated platelets.

The $\alpha_{IIb}\beta_3$ complex is a receptor for fibrinogen, von Willebrand factor (vWF), vitronectin, and fibronectin. It undergoes a conformational change in response to platelet activation. The change is recognized by the monoclonal antibody PAC-1 (Fig. 1), which binds specifically to the fibrinogen binding site of $\alpha_{IIb}\beta_3$ that is exposed during its activation-dependent re-shaping (see Fig. 2 and Table 2).

As an alternative to $\alpha_{IIb}\beta_3$-specific monoclonal antibodies, fluorescein isothiocyanate (FITC)-conjugated fibrinogen can also be used to detect the activated form of the surface glycoprotein. Fluorescein–fibrinogen binding is saturable, dependent on agonist activation, but competitively inhibited by unlabeled fibrinogen in the plasma and released from platelet α-granules (Faraday et al. 1994; Heilmann et al. 1994).

Other common markers of platelet activation are represented by CD63 (also known as lysosomal integral membrane protein, LIMP), CD36 (or GPIV), and CD40L. CD63 is a component of lysosomal membranes whose role has yet to be clarified. When granules are released, CD63 is exposed on the platelet surface where its expression increases from 650 to 12,600 molecules per platelet (Fig. 1) (Nieuwenhuis et al. 1987). Although CD63, compared with P-selectin, can be considered a more stable marker of platelet activation because of a reduced tendency to undergo proteolysis, it is not an ideal candidate for platelet activation studies because of a requirement for a greater level of activation for adequate surface antigen expression. Consequently, P-selectin remains the marker of choice for the majority of investigations (Nishibori et al. 1993).

The monoclonal antibody OKM5 is directed against an epitope on GPIV that binds thrombospondin. OKM5 also recognizes resting platelets but its binding is increased by thrombin stimulation (see Fig. 1). The GPIb-IX complex binds to vWF, mediating adhesion to damaged blood vessel walls and is recognized by the monoclonal antibody 6D1. Platelet activation leads to a redistribution of GPIb-IX complexes from the surface into the open canalicular system (Hourdille et al. 1990, 1992; Michelson et al. 1994). The decreased binding of 6D1 to activated platelets is a very sensitive marker of activation both ex vivo and in vivo (Kestin et al. 1993) (Fig. 1).

CD40 ligand (CD40L, also known as CD154) is a trimeric transmembrane protein and member of the tumor necrosis factor family. It is a component of the α-granule membrane of resting platelets and is quickly exposed on the platelet surface after activation. Expression of CD40L on the activated platelet surface is transient because it is rapidly cleaved from the platelet membrane, generating a soluble fragment known as soluble CD40L (Aloui et al. 2014). FCM studies with the monoclonal antibody TRAP-1 demonstrated that CD40L is undetectable on resting platelets and that platelet activation by thrombin results in maximal expression of CD40L within 1 min (Henn et al. 1998). Platelet activation in cardiovascular disease is associated with a significant increase in expression of CD40L (Garlichs et al. 2001; Abu el-Makrem et al. 2009; Pignatelli et al. 2011; Ferroni et al. 2012). However, in the majority of recent papers, detection of soluble CD40L by ELISA is preferred to detection of surface CD40L, probably because of the transient expression of the latter (Ferroni et al. 2012).

Binding of FITC-conjugated annexin V is a widely utilized marker of platelet activation. A crucial step in the activation of the coagulation cascade is the result of a flip–flop in anionic phospholipids (predominantly phosphatidylserine; PS) from the inner to the outer leaflet of the platelet membrane bilayer, which forms a binding substrate for the prothrombinase complex (Fig. 1). Annexin V is a Ca^{2+}-dependent phospholipid-binding protein that allows detection of PS exposure on the outer cell surface of activated platelets (Dachary-Prigent et al. 1993) (see Fig. 2 and Table 2).

Intracellular Markers

FCM can be utilized to evaluate intracellular markers such as specific δ-granule components (serotonin and adenine nucleotides) and specific phosphoproteins. Serotonin release from the δ-granules, where it is stored in steady-state conditions, is a crucial step for platelet aggregation (Fig. 1). However, its measurement has relied for years on expensive and laborious techniques (HPLC, ELISA, C^{14} labeling). Our group has described an FCM method for assessing intracellular serotonin content in resting and activated platelets after fixation and permeabilization using

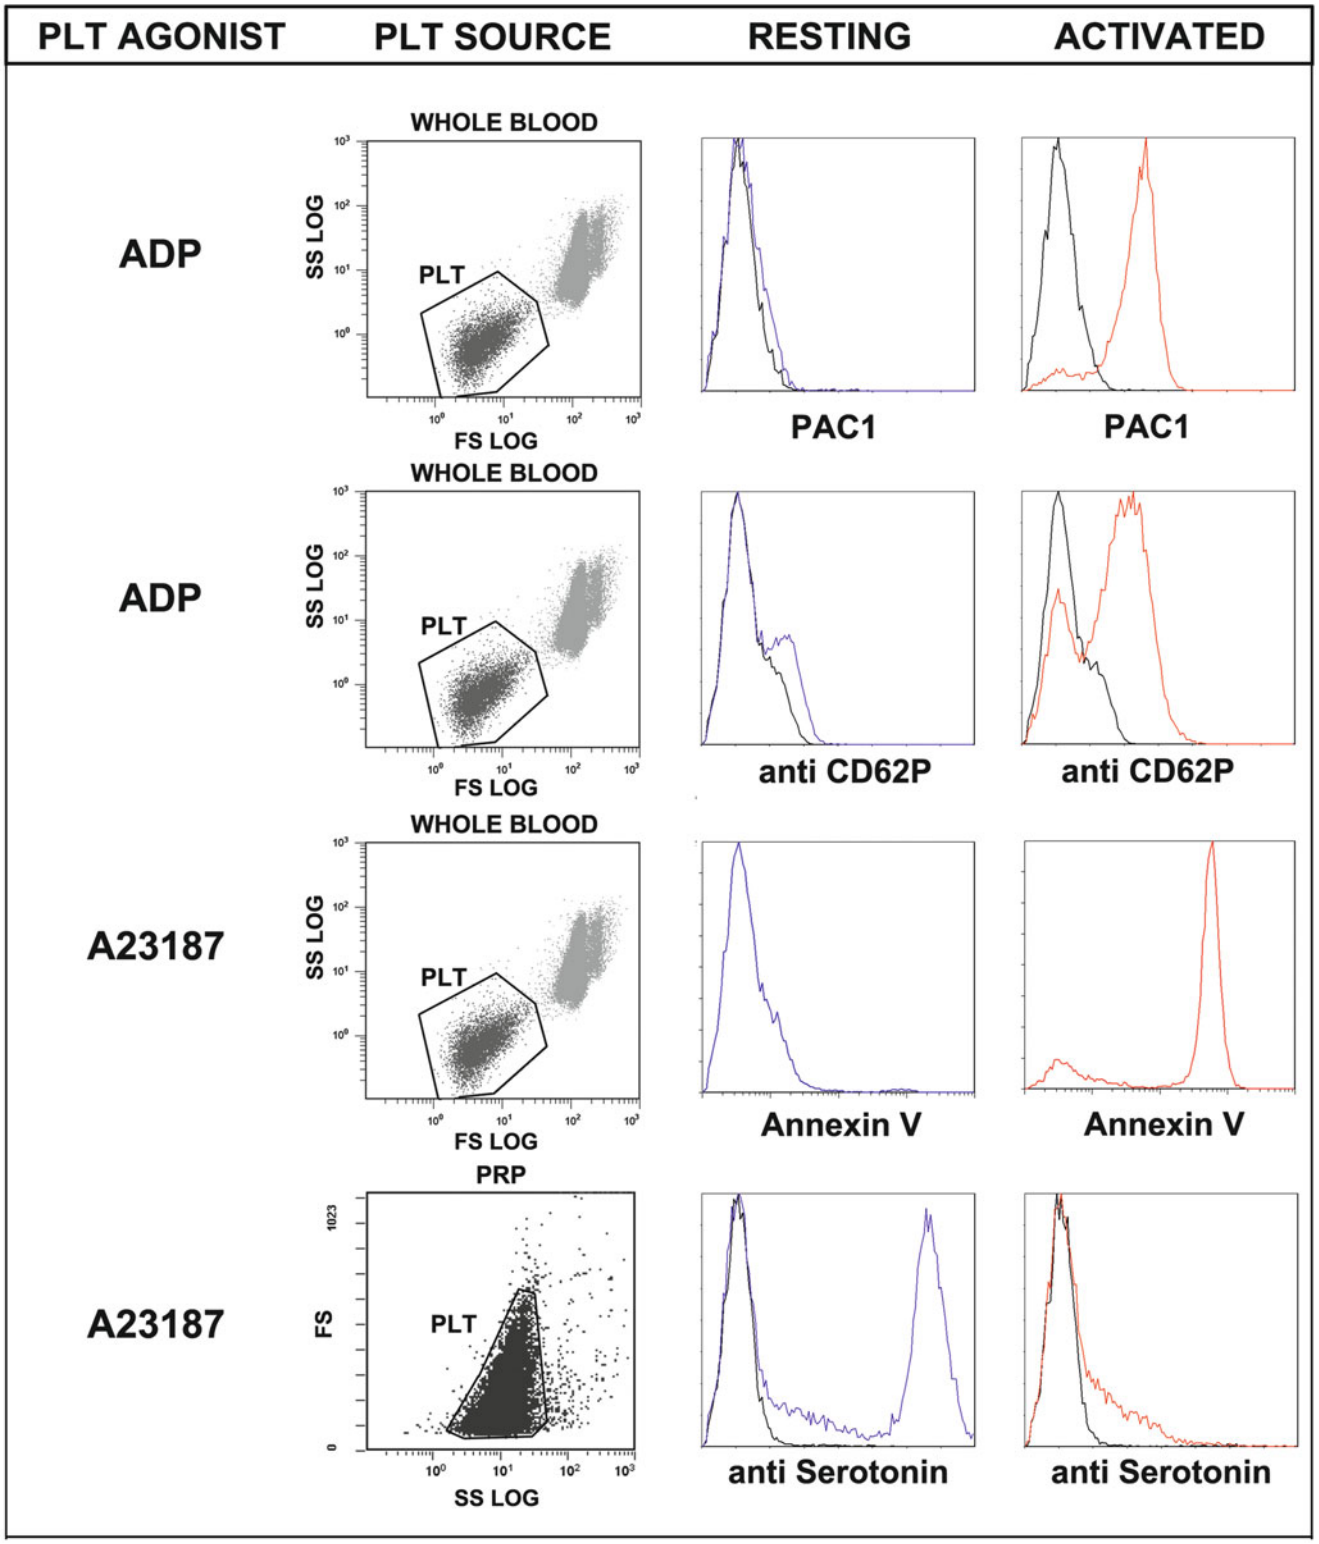

Fig. 2 Flow cytometric analysis of the most utilized activation markers before and after platelet activation with different agonists (ADP and calcium ionophore A23187). Analysis was performed on whole blood or platelet-rich plasma (PRP), as indicated

an anti-serotonin–R-phycoerythrin (RPE) conjugated antibody coupled with anti-CD41 surface marker staining (Gobbi et al. 2003) (see Fig. 2 and Table 2).

Adenine nucleotides can be detected by mepacrine (quinacrine) staining. Mepacrine is a green fluorescent dye capable of selectively binding adenine nucleotides and, consequently, provides information on the uptake and release of δ-granule content (Gordon et al. 1995).

Vasodilator-stimulated phosphoproteins (VASPs) are intracellular signaling molecules that are nonphosphorylated in the basal state and phosphorylated in prostaglandin E1-inhibited platelets. VASPs are targets of the ADP/$P2Y_{12}$ receptor, a seven-transmembrane domain receptor linked to an inhibitory G-protein. The degree of VASP phosphorylation (reported as platelet reactivity index) reflects $P2Y_{12}$ activity and can be measured using a commercial assay developed by BioCytex (Schwarz et al. 1999).

Platelet–Leukocyte Aggregates

As previously described in chapter "Platelet-Leukocyte Interactions" (Evangelista et al. 2017), it has been well known since 1989 that activated platelets bind to monocytes or neutrophils via P-selectin interaction with the PSGL-1 counter-receptor on the leukocyte surface (Larsen et al. 1989). It has been demonstrated that the level of circulating platelet–leukocytes aggregates (PLAs) is increased in pathological conditions such as ischemic stroke (Marquardt et al. 2009) and diabetes mellitus (Elalamy et al. 2008) and in patients with coronary artery disease (Mickelson et al. 1996; Furman et al. 1998; Ott et al. 1996; Neumann et al. 1997b; Sarma et al. 2002). PLAs are currently utilized as platelet activation markers (Nagasawa et al. 2013; Pearson et al. 2009) (Fig. 1 and Table 2).

FCM is a sensitive and rapid method for qualitative (mean fluorescence intensity) and quantitative (percentage positive events) measurement of PLAs. To minimize ex vivo platelet activation attributable to centrifugation and washing steps, whole blood analysis is recommended. In addition, sample fixation reduces uncontrolled changes in the platelet surface. Although some authors discourage red cell lysis because it can lead to artifactual activation (Pearson et al. 2009; Li et al. 1997), other investigators have used red cell lysis to provide clearer delineation of platelet and white cell populations, reporting that the lysis procedure does not affect platelet–monocyte aggregation (Furman et al. 1998; Ray et al. 2005; Harding et al. 2007).

Usually, FCM detection of PLAs is based on a combination of a platelet-specific antibody (usually CD41, CD42 and/or CD61) and leukocyte-specific antibody. Specifically, in whole blood analysis, leukocytes can be discriminated from erythrocytes by anti-CD45 binding. Moreover, the specific leukocyte population interacting with platelets can be identified using antibody against CD3 (T-lymphocytes), CD19 (B-lymphocytes), CD56 (natural killer cells), CD14 (monocytes), CD16 (neutrophil), anti-CD4, and anti-CD8 (to discriminate T cell subsets) (Michelson et al. 2001; Yip et al. 2013; Pearson et al. 2009; Nkambule et al. 2015) (Table 2).

Platelet-Derived Microparticles

As previously mentioned in chapter "Platelet-Derived Microparticles" (Cointe et al. 2017), platelet microparticles (PMPs) are fragments with a size ranging from 0.1 to 1 μm. They circulate in the bloodstream at a concentration of 100–1000/μL. They are shed from platelets when activated and during aging and destruction; therefore, they have a phospholipid-based structure with functional receptors belonging to the platelet membrane. Specifically, PMPs express common megakaryocyte-platelet glycoprotein receptors (CD41, CD42b) and platelet activation markers such as PS, P-selectin, and CD63. In recent years, there has been increasing interest in PMPs because of their clinical applications. PMPs are used as platelet activation markers ex vivo, such as after stimulation with specific agonists such as thrombin, collagen, and calcium ionophore A23187 (Michelson et al. 2001; Italiano et al. 2010) (Fig. 1 and Table 2), and also in vivo. In fact, aberrant levels of plasma PMPs have been associated with bleeding or thromboembolic complications and can be considered a biomarker of ongoing thrombosis (Ramacciotti et al. 2009).

PMP detection techniques have been implemented and new methodologies are currently under investigation, including TEM, ELISA, FCM, atomic force microscopy, nanoparticle tracking analysis, and resistive pulse sensing (Nomura et al. 2009; Dragovic et al. 2011; Yuana et al. 2010). At present, FCM is still the most widely utilized method for PMP identification.

Several methodological issues must be taken into account when analyzing PMPs from peripheral blood. PMP detection can be affected by several sample processing steps, ranging from blood collection, plasma isolation, and storage to staining of phospholipids and surface antigens for determining the cellular origin of the microparticles (Shah et al. 2008; Shet 2008).

Although the standardization of pre-analytical steps remains a challenge, an overall consensus has been reached on the following specific issues (Lacroix et al. 2010, 2012; Yuana et al. 2011): It is recommended that samples are collected carefully to avoid sheer stress and endothelial activation, using a light tourniquet, large needles (20–21G), and discarding the first 2–3 mL of blood. Citrate tubes are preferred over EDTA, because the latter is known to interfere with microparticle measurement (Shah et al. 2008; Trummer et al. 2009). In a hospital setting, it is

important to note that patients' samples are not collected in the laboratory, therefore sample transportation and time delay between blood sampling and microparticle preparation can impact the analysis. It was demonstrated that a time delay of 2 h before the first sample centrifugation is acceptable because any increase in the number of microparticles during this period remains moderate. Moreover, transporting blood tubes in the vertical rather than horizontal position limits the extent of in vitro microparticle generation (Lacroix et al. 2012).

Platelets need to be removed from the plasma to avoid cellular activation, which can lead to inadvertent production of microparticles. For this purpose, the most common protocol for FCM microparticle analysis consists of one centrifugation at 1500 *g* for 15 min followed by a second centrifugation at 13,000 *g* × 2 min to obtain platelet-free plasma (Yuana et al. 2011; Robert et al. 2009; Sabatier et al. 2002). However, some investigators perform the analysis directly on platelet-poor plasma obtained after a first blood centrifugation at 1500 *g* for 15 min and a second re-centrifugation of plasma at 1500 *g* for10 min (Jy et al. 2004; Enjeti et al. 2008; Dignat-George et al. 2009).

Lacroix and coworkers demonstrated that two successive centrifugations of 2500 *g* for 15 min at room temperature are more efficient for platelet removal (Lacroix et al. 2012). Dey-Hazra and colleagues also suggested that the filtration of buffer using a 0.2-μm filter is a useful step for reducing the amount of background noise, cell debris, and precipitates. The latter have the same size range as microparticles and could influence or disturb the analysis (Dey-Hazra et al. 2010).

In multicenter studies and prospective trials it is often inevitable that plasma samples are frozen and stored before performing the assay. In these cases, plasma is first snap-frozen in liquid nitrogen before being stored at −80 °C, or, alternatively, plasma is directly frozen at −80 °C (Yuana et al. 2011). It has been demonstrated that directly freezing at −80 °C and quickly thawing in a water bath at 37 °C at the time of the assay do not strongly influence PMP analysis (Lacroix et al. 2012).

Regardless of the biological source (peripheral blood or cell culture), one of the most important steps for PMP detection is the identification of PMP populations according to their light scattering properties. Indeed, PMPs are submicrometer fragments, therefore their discrimination from platelets and debris relies on the setting and resolution of the instruments used.

To promote standardization, the ISTH SSC Working Group on Vascular Biology proposed the use of calibrated latex beads with sizes of 0.5, 0.9, and 3 μm (MegaMix Beads BioCytex, Marseille, France) to adjust the instrument settings and increase the resolution of FCM. The dimensions of this bead population cover both the PMP (0.5 and 0.9 μm) and platelet populations (0.9 and 3 μm) (Lacroix et al. 2010; Robert et al. 2009). A multicenter study, performed with several types of FCM, demonstrated that standardization of PMP enumeration by FCM is feasible but dependent on the intrinsic characteristics of FCM and on the calibration strategy. Although latex beads remain an imperfect model for defining the cutoff of PMP populations, because the refractive index of the plastic beads is different to that of PMPs, they are currently considered useful standards that allow instrument qualification and follow up (Lacroix et al. 2010).

PMP staining with fluorescently labeled antibodies is recommended for more precise identification of PMP populations. PS is a well-established marker for PMPs, regardless of their cellular origin. Fluorophore-labeled annexin V is commonly used to measure the total number of PMPs with FCM. However, more specific platelet antigens should be used to distinguish PMPs from microparticles derived from leukocytes, erythrocytes, and endothelial cells. Von Willebrand factor and fibrinogen receptors are markers for microparticles derived from both platelets and megakaryocytes; however, monoclonal antibodies specific for platelet activation markers such as P-selectin, CD107A, and CD63 are recommended for selective identification of PMPs (Flaumenhaft et al. 2009).

To provide the concentration or absolute count of PMPs in a sample, counting beads of a known concentration are used. When they are used as internal standard, the beads are added to each sample before FCM measurement. For use as an external standard, the counting beads are processed at the same FCM settings/conditions used for the samples. FCM counts the number of beads and/or microparticles in the sample until the acquisition time is reached and, from this number, the concentration of microparticles can be calculated (Yuana et al. 2010; van der Zee et al. 2006; Robert et al. 2009; Shet et al. 2003).

Ex Vivo Platelet Activation

Platelet reactivity after ex vivo stimulation with different agonists can be performed on whole blood, PRP, or washed platelets (Fig. 2). Whole blood analysis allows detection of high degrees of platelet activation, limiting selective cell losses (Shattil et al. 1987).

Several agonists, both fully synthetic or isolated from organisms, are commercially available and allow highly reproducible and standardized ex vivo activation. Such agonists include ADP, stable thromboxane analogs, and PAR1 agonists such as TRAP-6 (SFLLRN) and TRAP-14 (SFLLRNPNDKYEPF) (Giesberts et al. 1995; Michelson et al. 1991). GPVI-specific agonists include collagen-related peptide [Gly-Lys (or Cys)-Hyp-(Gly-Pro-Hyp)10-

Gly-Lys (or Cys)-Hyp-Gly] (Morton et al. 1995; Kehrel et al. 1998), the snake toxin convulxin (Polgar et al. 1997), and poly(Pro-Hyp-Gly), which induces platelet aggregation independently of thromboxane A_2 and $\alpha_2\beta_1$ (Inoue et al. 2009).

Shear stressed-induced activation can also be used: the friction forces generated by forcing the sample through a capillary tube produces a platelet activation state similar to that registered in vivo at an injury site or stenotic vessel. The activation markers that can be monitored are listed in Table 2.

Main applications of ex vivo platelet activation studies are monitoring of antiplatelet drugs and pathological conditions associated with platelet hypo- or hyperreactivity, as described next.

In Vivo Platelet Activation

An activated platelet phenotype may reflect an ongoing acute thrombotic process such as acute coronary syndrome, as well as chronic pathological conditions such as diabetes, peripheral arteriopathy, allergic asthma, or cancer (Tschoepe et al. 1991; Tomer 2004). Analysis of circulating activated platelets (i.e., in vivo platelet activation) requires extremely careful sample collection and manipulation to avoid activation induced by venipuncture and storage. If the sample cannot be processed within a short time frame, stabilization with activation antagonists and fixatives is strongly encouraged (Shattil et al. 1987; Dovlatova et al. 2014). Platelet subpopulations that are heterogeneous in their activation state can be detected; in fact, the lower limit of detection of platelet activation for FCM assays is about 1 % activated platelets in a sampled population of stimulated and unstimulated platelets (Shattil et al. 1987).

FCM is the most appropriate technique for in vivo platelet activation studies. Basically, all the FCM platelet activation markers previously described can be utilized to assess the activation state of circulating platelets (Table 2), although some concerns have been raised concerning the transient expression of P-selectin and the rapid reversibility of activated $\alpha_{IIb}\beta_3$ (Schmitz et al. 1998). The choice of marker relies mainly on the clinical application and the disease of interest. Platelet degranulation markers such as P-selectin have been utilized in hypertension (Stumpf et al. 2005) and activated $\alpha_{IIb}\beta_3$ in antiphospholipid antibody syndrome (Joseph et al. 2001). PLAs and PMPs have been extensively studied in solid and hematologic malignancies, acute myocardial infarction, coronary revascularization procedures, diabetes, and asthma (Michelson et al. 2001; Mallat et al. 2000; Pitchford et al. 2003; Falanga et al. 2005).

Platelet Turnover

Platelet Count

Obtaining accurate platelet counts has been a long-standing problem for both pathologists and clinicians, as demonstrated by the fact that platelet counting methods have evolved from manual phase contrast microscopy through the era of automated cell analyzers to FCM, which is currently considered the gold standard technique, as discussed in detail in chapter "Platelet Counting and Measurement of Platelet Dimension" (Noris and Zaninetti 2017).

In FCM, platelets are identified with a fluorescent monoclonal antibody specific to a cluster of differentiation common to all (resting and activated) platelets, with the advantage that platelets are immunologically recognized independently of size. Thus, FCM allows unequivocal identification of platelets from other cellular elements of similar size. This is of great relevance in thrombocytopenic samples, for which platelet counting is known to be problematic because of the presence of giant platelets or particles (i.e., fragmented red cells and immune complexes). In these cases, FCM platelet count (in contrast to impedance analysis or optical counting) can include giant platelets in the count because they are clearly resolved from red cells, and particles with sizes similar to those of platelets are excluded (Ault et al. 1999; Tanaka et al. 1996; Harrison et al. 2001).

Because most flow cytometers cannot be programmed to process a fixed volume of sample, counting procedures involve indirect derivation of platelet number. For this purpose, various approaches have been proposed (Tanaka et al. 1996; Davis and Bigelow 1999). Specifically, in the late 1990s, an immunoplatelet counting procedure was introduced that was based on a reference standard of fluorescent beads with a predefined concentration. In this method, a known amount of fluorescent calibration beads is added to the sample, and platelet number calculated as bead ratio (Dickerhoff and Von Ruecker 1995; Matzdorff et al. 1998). However, this method lacks standardization and an alternative procedure using FCM platelet count based on red blood cells as internal standard has been demonstrated to satisfy the criteria for a reference method (Harrison et al. 2001).

The International Council for Standardization in Haematology (ICSH) and the International Society of Laboratory Hematology (ISLH) recommend FCM-based counting, based on the ratio of platelets to red blood cells, as a reference method for platelet counting (International Society of Laboratory Hematology Task Force on Platelet Counting, International Council for Standardization in Haematology Expert Panel on Cytometry 2001).

The assay involves dilution of EDTA-anticoagulated blood specimen in a sterile buffered solution, followed by staining of platelets with specific fluorescent antibodies. The

stained platelets in solution are diluted to the counting concentration, and the platelets and red blood cells (RBCs) counted on a flow cytometer with thresholds set to discriminate platelets from RBCs on the basis of fluorescence amplitude and scatter amplitude. The RBC/platelet ratio is determined, and the platelet count is calculated from an accurate RBC count of the sample, obtained using a cell counter that meets previous ICSH specifications (International Council for Standardization in Haematology 1994). The main advantage of this technique is that, by using RBCs as internal standard, the count obtained is independent of potential pipetting artifacts (Harrison et al. 2001).

Multicenter studies using different approaches have been undertaken to improve the accuracy of platelet counts (De la Salle et al. 2012; Masters and Harrison 2014; Sehgal et al. 2010; Sandhaus et al. 2002; van der Meer et al. 2012).

Reticulated Platelets

Reticulated platelets (or young platelets) are rich in mRNA. Platelet mRNA derives from megakaryocytes during thrombopoiesis, and, because of its instability, is present in a larger amount in young platelets than in older ones and can be utilized to identify newly released platelets from the bone marrow.

FCM is the method of choice for reticulated platelets analysis. This technique relies on the use of a fluorescent dye, thiazole orange (TO), which has a large fluorescence enhancement and high quantum yield upon binding to nucleic acids, especially RNA. Reticulated platelets can thus be distinguished from mature platelets by FCM according to their dye uptake (Kienast and Schmitz 1990; Bonan et al. 1993).

Protocols have been successively optimized to associate TO labeling with platelet-identifying antibodies for better characterization of platelet populations (Chavda et al. 1996) and a consistent number of papers describing clinical applications of reticulated platelet analysis have been published. However, it also became evident that the FCM assay is prone to methodological variation, which makes it difficult to compare results obtained with different assays; for example, the normal reference range is reported to lie between 1 and 15 % (Romp et al. 1994; Matic et al. 1998). Many factors that contribute to this analytical issue have been identified: type and concentration of fluorescent dye, incubation time and temperature, fixation, RNAse treatment, and FCM data analysis, including gating and threshold settings (Richards and Baglin 1995; Watanabe et al. 1995; Matic et al. 1998; Bonan et al. 1993; Rapi et al. 1998). One of the major problems is that platelets show non-RNA-specific binding of fluorescent dye, resulting in background staining, which is size-dependent (Matic et al. 1998; Robinson et al. 1998; Balduini et al. 1999). New initiatives have been undertaken that are aimed at developing a method with the potential to become a future international reference method (Hedley and Keeney 2013; Machin 2013). According to these studies, reticulated platelet analysis should be performed in whole blood, with stringent control of incubation time and temperatures and with sample fixation after labeling. Concerning gating strategy, platelets should be identified according to CD41 and CD61 expression and then analyzed using a dot-plot of SS versus TO. A threshold of 1 % for TO-positive platelets is defined using a negative control unstained for TO. Platelet enumeration is performed according to the ICSH guidelines using the platelet/RBC ratio as described above (Hedley et al. 2015; Hoffmann 2014).

The main clinical application of reticulated platelet assessment is to determine, in thrombocythopenic patients, whether the low platelet count is a result of abnormally accelerated destruction or of impaired bone marrow output. Because megakaryopoietic activity is low in patients with bone marrow failure, the assumption is that the ratio of reticulated platelets to total platelets is also low. By contrast, in conditions typified by enhanced compensatory megakaryocypoiesis (e.g., immune thrombocytopenia or postchemotherapy recovery) the absolute number of reticulated platelets, and consequently the ratio of reticulated platelets to total platelets, is expected to be high (Kienast and Schmitz 1990; Pons et al. 2010; Thomas-Kaskel et al. 2007; Rinder et al. 1998; Ryningen et al. 2006; Romp et al. 1994; Richards et al. 1996; Catani et al. 1999; Stohlawetz et al. 1999). Interestingly, in the thrombocytopenic phase after chemotherapy and transplantation for hematological malignancies, reticulated platelets have been monitored by FCM and it has been observed that an increase in reticulated platelets precedes the recovery of platelet count by 2–3 days. This creates the opportunity to defer platelet transfusions that would be given if transfusion decisions were based only on platelet count. However, clinical evidence supporting this concept is limited and there is need for randomized, controlled clinical studies in this field (Macchi et al. 2002; Wang et al. 2002; Michur et al. 2008; Chaoui et al. 2005).

Reticulated platelets have also been utilized for risk assessment and drug monitoring in patients with coronary artery disease (Guthikonda et al. 2008; Lakkis et al. 2004; McBane et al. 2014; Perl et al. 2014).

Recently, Hedley and colleagues (Hedley et al. 2015) demonstrated that macrothrombocytopenic patients show an increase in the immature platelet fraction that, in agglutination tests, increases during the formation of platelet clumps. The data indicate that measurement of the immature platelet fraction is influenced by platelet size and could be a useful parameter in the differential diagnosis of macrothrombocytopenia (Miyazaki et al. 2015; Hoffmann 2014).

Clinical Applications

Clinical Disorders Associated with Abnormal Platelet Reactivity

Several thrombotic and nonthrombotic disorders are typified by alterations in the number of circulating activated platelets and an abnormal expression of platelet activation markers. Both these conditions can be evaluated by FCM.

Coronary Syndromes

FCM studies have demonstrated the presence of circulating activated platelets in patients affected by coronary artery disease (CAD), including stable angina, unstable angina, and acute myocardial infarction (AMI), as well as after percutaneous coronary intervention (PCI). In this setting, analysis of platelet activation markers is not only beneficial in terms of diagnosis but also provides information on clinical outcome and can be utilized for the optimization of antiplatelet therapies

Specifically, CD62P-expressing platelets and circulating PLAs at baseline and after stimulation with exogenous agonists are higher in patients with stable CAD, unstable angina, and AMI than in healthy subjects (Furman et al. 1998; Langford et al. 1996; Carubbi et al. 2012).

Interestingly, these two platelet activation markers, both detected by FCM, show a different sensitivity. PLAs are a more sensitive marker of in vivo platelet activation than CD62P in patients that have undergone PCI and with AMI, and are therefore potential candidates as early diagnostic markers of AMI (Michelson et al. 2001; Furman et al. 2001).

Other studies reported an increase in PMPs, CD40L, and platelet collagen receptor (GPVI) in acute coronary syndrome (Katopodis et al. 1997; Bigalke et al. 2007; Ferroni et al. 2012; Skeppholm et al. 2012).

Interestingly, analysis of the expression of platelet activation markers can be of prognostic value for thrombotic risk after PCI. It has been demonstrated that patients developing acute events after PCI showed a higher expression of platelet CD62P, CD63, and the active form of $\alpha_{IIb}\beta_3$ before intervention. The authors suggest that FCM analysis of platelet function in PCI candidates can stratify patients into those at high and low risk of cardiac events after PCI (Kabbani et al. 2001, 2003; Tschoepe et al. 1993; Gawaz et al. 1997).

Cerebrovascular Ischemia

It has been extensively demonstrated that almost all platelet activation markers, including CD62P, CD63, activated $\alpha_{IIb}\beta_3$, PMPs, and PLAs, are increased in patients with cerebrovascular ischemia (McCabe et al. 2004; Cao et al. 2009; Grau et al. 1998; Zeller et al. 1999; Meiklejohn et al. 2001; Yamazaki et al. 2001; Cherian et al. 2003; Yip et al. 2004; Smout et al. 2009; Tsai et al. 2009; Marquardt et al. 2002; Htun et al. 2006; Minamino et al. 1998; Bigalke et al. 2010; Lee et al. 1993; Geiser et al. 1998; Fateh-Moghadam et al. 2005; Koyama et al. 2003). Interestingly, the expression levels of these markers have been associated with different subtypes of ischemic stroke.

Specifically, patients with large-vessel cerebral infarction elicit higher platelet activation than those with small-vessel infarction, whereas the role of platelet activation is still controversial in cardioembolic stroke (Cao et al. 2009; Grau et al. 1998; Zeller et al. 1999; Meiklejohn et al. 2001; Yamazaki et al. 2001; Cherian et al. 2003; Yip et al. 2004; McCabe et al. 2004; Smout et al. 2009; Tsai et al. 2009; Marquardt et al. 2002; Oberheiden et al. 2012; Turgut et al. 2011). Furthermore, FCM analysis of CD62P, CD63, and PMPs suggests that platelet activation occurs chronically in these diseases, as demonstrated by the fact that, despite the specific effects of antithrombotic therapies, their expression levels are higher at 1, 3, and 6 months before the acute event than in healthy controls (Grau et al. 1998; Cherian et al. 2003; Meiklejohn et al. 2001; Yamazaki et al. 2001; Marquardt et al. 2009).

Aggregation with different leukocyte subtypes was also investigated. Results showed that an increase in monocyte–platelet aggregates is short-lived and could reflect an acute reaction to cerebral ischemia. By contrast, granulocyte–platelet aggregate formation persists into the subacute phase, suggesting that specific PLAs could reflect the prothrombotic state and the inflammatory processes after stroke (Marquardt et al. 2009).

Peripheral Vascular Disease

The use of FCM to assess platelet function in patients with peripheral arterial disease (PAD) has been documented since 1991. Data published in the last 10–15 years show an increase in platelet hyperreactivity and circulating activated platelets in these patients compared with healthy subjects. It has been demonstrated that P-selectin expression, the number of PMPs, and the number of platelet aggregates are significantly higher for both resting and stimulated platelets in the PAD group compared with controls (Robless et al. 2003; Cassar et al. 2003; Koksch et al. 2001; Zeiger et al. 2000). Interestingly, platelet activation parameters are correlated with the severity of vascular disease. P-selectin and PLAs, specifically platelet–monocyte aggregates (PMAs), are significantly increased in patients with severe limb ischemia compared with those with intermittent claudication (Rajagopalan et al. 2007; Tan et al. 2005). Moreover, it has been demonstrated that in the early postoperative period after infrainguinal bypass, the level of PLAs, including PMAs and platelet–neutrophil aggregates, is

significantly greater in patients who had experienced graft occlusion compared with patients whose graft remained patent at 6 months. The authors suggest that this analysis allows identification of a patient subset with a high risk of graft occlusion that would benefit from more aggressive antiplatelet therapy (Esposito et al. 2003).

All patients affected by peripheral venous disease, irrespective of the degree of chronic venous insufficiency, are characterized by higher levels of PMAs and platelet–neutrophil aggregates in the bloodstream and an increased propensity to form platelet aggregates in response to platelet agonists than control group subjects. However, this increase in platelet reactivity appears unrelated to the presence of ulceration (Powell et al. 1999). Moreover, higher circulating levels of PMAs persist after complete correction of chronic venous insufficiency, suggesting that the increased number of PMAs identified in these patients is not secondary to the presence of venous reflux, but could be involved in the primary etiology of chronic venous insufficiency (Rohrer et al. 2002).

Cancer

The association between platelet and cancer dates to the mid-1800s, when Armand Trousseau linked venous thrombus formation with an underlying undiagnosed malignancy (Dammacco et al. 2013). Since then, several studies have reported platelets as major players, not only in thrombus generation in neoplastic patients, but also in promoting tumor growth, invasiveness, and angiogenesis. Many authors now point to the "platelet–cancer loop" as a pivotal mechanism in tumorigenesis (Hasselbalch 2014). In this setting, detection of platelet activation markers by FCM is as a useful tool. For solid tumors, most reports concern tumor-derived microparticles. Toth and colleagues showed that PMPs are higher in breast cancer patients than in those with benign lesions. PMP levels correlate with tumor invasiveness, but no association was established with prothrombin levels and thrombin formation (Toth et al. 2008). In hormone-refractory prostate cancer, Helley and coworkers demonstrated a correlation between circulating PMP levels and Gleason score, patient performance status, and overall survival, with a poorer outcome in patients with more than 6867 PMPs/μL (Helley et al. 2009). In patients with gastric cancer, the mean number of CD62P molecules on the platelet surface was significantly higher than in the healthy group, and further increased after stimulation with TRAP (6- to 12-fold in neoplastic patients and threefold in the control group) (Osada et al. 2010).

Platelet activation has been extensively investigated in hematologic malignancies. Myeloproliferative disorders (MPD) are characterized by an increased risk of thrombo-hemorrhagic events, probably related to platelet dysfunction (Finazzi et al. 1996; Wehmeier et al. 1997). Platelet aggregation studies in MPD have revealed a tendency toward spontaneous platelet aggregation and a correlation between agonist-induced platelet hyperactivation and a history of thrombosis (Balduini et al. 1991). Similarly, FCM analyses showed an increased percentage of CD62P-expressing platelets, PLAs, and PMAs in the bloodstream of patients with MPD compared wth healthy controls (Jensen et al. 2000, 2001; Villmow et al. 2002).

Additionally, MPD patients with a previous history of thrombosis or microvascular disturbances had a higher percentage of platelet–granulo/monocytes and PMAs than patients with no history of these events (Jensen et al. 2001). Moreover, in vitro formation of platelet–polymorphonuclear leukocyte aggregates was enhanced in essential thrombocythemia patients without pharmacological antiaggregation but reduced in essential thrombocythemia patients treated with aspirin (Falanga et al. 2005).

Hemorrhage is one of the principal symptoms associated with acute myeloid leukaemia (AML). It may be responsible for a lethal course of the disease and is related to different factors, including thrombocytopenia and defects in platelet function (Cowan et al. 1975; Estey et al. 1982). Leinoe and colleagues demonstrated that in vitro expression of CD62P was reduced in AML patients with bleeding tendency, suggesting that FCM analysis of platelet function is a putative biological marker of hemorrhage in this disease (Leinoe et al. 2004).

AML can arise in a context of genetic predisposition, as in the case of familial platelet disorder with a predisposition to acute myelogenous leukemia (FPD/AML), an autosomal dominant platelet disorder characterized by thrombocytopenia, platelet function defects, and a lifelong risk of the development of hematologic neoplasms. The disorder is associated with germline heterozygous mutations in the transcription factor gene *RUNX1*. Analysis of defective $\alpha_{IIb}\beta_3$-dependent activation pathways has been documented as reduced binding of FITC-conjugated PAC-1 and Alexa Fluor 488-conjugated fibrinogen (Glembotsky et al. 2014).

Monitoring of Antiplatelet Therapies

FCM is a useful tool for monitoring antiplatelet therapies. Medical therapy to reduce platelet activation is the mainstay in prevention of atherothrombotic events in many vascular diseases. Several antiplatelet drug are available, the most popular being aspirin and clopidogrel (a $P2Y_{12}$ inhibitor), but other $P2Y_{12}$ and GPIIb/III antagonists have been developed, including prasugrel, ticagrelor, and tirofiban (Ford 2015; Rollini et al. 2016; Savonitto et al. 2015). Clinical trials assessing the efficacy of these drugs have been mainl

based on evaluation of platelet reactivity using FCM analysis of both surface antigens and intracellular VASP.

VASP assay, based on FCM, is a reliable index of platelet ability to be activated by ADP. The degree of VASP phosphorylation can be measured in a direct, cost-effective, and automated manner as described above (see "Intracellulars Markers of Platelet Activation"). This method has been used to detect clopidogrel resistance and to compare the efficacy of different $P2Y_{12}$ inhibitors (Aleil et al. 2005; Bednar et al. 2015).

Detection of surface marker CD62P is used to evaluate the contribution of antithrombotic therapy on platelet activation after acute coronary syndrome and after coronary intervention (Gawaz et al. 1996; Neumann et al. 1997a; Ault et al. 1999). Other activation markers can be utilized, usually in combination with P-selectin, to monitor antiplatelet therapies. Indeed, results from the PRINCIPLE-TIMI 44 study show a correlation between platelet reactivity before and after $P2Y_{12}$ blockade, as assessed by FCM measurement of CD62P and PMAs (Frelinger et al. 2011). Moreover, we have described an FCM-based method for assessing the effects of clopidogrel and tirofiban on platelet activation using 5 μL of whole blood as starting material. Peripheral blood samples were collected from patients before drug administration and after 2, 6, and 24 h of treatment with tirofiban and clopidogrel alone and in combination. Pharmacological treatment was able to induce modulation of platelet reactivity to ADP-induced activation, as assessed by PAC-1 and P-selectin (Solinas et al. 2009).

Monitoring platelet reactivity is extremely relevant, not only in CAD patients but also in the setting of ischemic stroke, in which it is well established that antiplatelet therapy reduces the frequency of secondary events (Hennekens 2002; Smith et al. 1999; Serebruany et al. 2004, 2005; Yip et al. 2004; Grau et al. 2003; Klinkhardt et al. 2003; Moshfegh et al. 2000). FCM detection of CD62P and CD63 expression shows that platelet activity is significantly more suppressed in patients on clopidogrel than in those taking aspirin in the subacute and convalescent phases of non-cardioembolic ischemic stroke. No time-dependent modulation of CD62P expression could be detected in patients on anticoagulants (warfarin) (Tsai et al. 2010; Yip et al. 2004). An innovative and promising use of FCM is documented by Serebruany and coworkers, combining aggregometry tests with FCM determination of 14 platelet surface receptors. The authors found a marked heterogeneity of platelet characteristics in patients after ischemic stroke, suggesting that bleeding complications and hemorrhagic transformation after aggressive antiplatelet regimens could be related to the decreased or normal baseline platelet characteristics in such patients (Serebruany et al. 2004).

Diagnosis of Platelet Function and/or Number Disorders

Among the clinical applications of FCM platelet analysis, diagnosis of specific platelet function disorders (PFDs) is one of the most relevant. PFDs encompasses a heterogeneous group of both inherited and acquired diseases that affect platelet function and/or number and lead to a defective primary hemostasis. Disorders include Bernard-Soulier syndrome (BSS), Glanzman thromboasthenia (GT), platelet-type von Willebrand disease, storage pool diseases, Scott syndrome, heparin-induced thrombocytopenia (HIT), immune-mediated thrombocytopenias, and rare inherited conditions associated with somatic defects, such as MYH9-related diseases and thrombocytopenias associated with skeletal defects (Carubbi et al. 2014b).

The diagnostic laboratory work-up for PFDs is challenging and involves several methodologies, including bleeding time, light transmission or impedance aggregometry (the leading assay for investigating PFDs), PFA-100, lumiaggregometry, HPLC, fluorescence microscopy, TEM, ELISA, and radioimmunoassay (Paniccia et al. 2015).

The main drawbacks of these tests are a high false-positive rate (~20 %), unreliability in cases of platelet count below 50×10^9/L, lack of standardization, and variation in result interpretation. Additionally, their use is still limited to specialized laboratories (Pai and Hayward 2009; Miller 2009).

In this scenario, FCM is a rapid, reliable, and feasible technique for the diagnosis of PFDs characterized by surface glycoprotein deficiency (e.g., GT and BSS, for which it is the method of choice), storage pool disease, and Scott syndrome (Carubbi et al. 2014b; Nurden and Nurden 2014).

In more detail, diagnosis of BSS is based on the demonstration of GPIb-IX-V deficiency by specific monoclonal antibodies targeting glycoproteins Ib, IX, and V. By this means, abnormalities in the complex structure and levels of expression can be detected, also allowing discrimination between homozygous and heterozygous states (Andrews and Berndt 2013).

In GT, FCM analysis of $\alpha_{IIb}\beta_3$ integrin expression by monoclonal antibodies recognizing GPIIb (CD41) and GPIIIa (CD61) is used as a confirmatory diagnostic tool. FCM can determine the levels of expression of $\alpha_{IIb}\beta_3$ per platelet, allowing GT patients to be subclassified as having type I, II, or III disease according to the amount of $\alpha_{IIb}\beta_3$ present per platelet (respectively <5 %, 10–20 %, or equal to 50 % of the normal amount) (Nurden et al. 2012). Moreover, in heterozygous patients, this methodology can establish $\alpha_{IIb}\beta_3$ levels in various platelet populations and, consequently, whether the clinical picture is the result of a global reduction in antigen expression by all platelets or the

coexistence of normal platelets and platelets lacking $\alpha_{IIb}\beta_3$ (Sharp et al. 1998).

Auto- and allo-antibodies or paraproteins directed against $\alpha_{IIb}\beta_3$ can mimic inherited GT and are responsible for so-called acquired GT (aGT). aGT is an extremely rare bleeding disorder whose diagnostic work-up relies on complex and time-consuming laboratory assays that demonstrate the presence of circulating proteins interfering with platelet function. The assays include aggregation tests, platelet adhesion to a collagenated surface, ELISA, and mixing studies. Giannini and coworkers describe an FCM-based method for investigating aGT by assessing PAC-1 and fibrinogen binding to patient's platelets (absent), expression of the $\alpha_{IIb}\beta_3$ complex on patient's platelets using different monoclonal antibodies against GPIIb (clones SZ22, P2, A2A9/6; decreased) or GPIIIa (clones SZ21, SAP; normal), and PAC-1 and A2A9/6 binding to control platelets in the presence of patient's serum (reduced). Overall, FCM emerged as the only test able to characterize both the functional effect and the molecular target of the patient's autoantibody on platelets (Giannini et al. 2008).

FCM has expedited the diagnostic procedure for δ-storage pool disease. FCM assay relies on the same principles as fluorescence microscopy (for decades the gold standard in the diagnosis of these disorders), detecting the fluorescence of mepacrine, a dye that selectively binds to adenine nucleotides stored in δ-granules (Gordon et al. 1995).

FCM can rapidly and effectively detect Scott syndrome platelet abnormality, characterized by defective scrambling of membrane PS, which fails to be exposed on the outer membrane leaflet after platelet activation. This defect can be feasibly identified by the annexin V binding test, which is based on annexin V binding to phospholipid exposed after activation and can reveal a lack of PS exposure (Zwaal et al. 2004).

Experimental applications of FCM in PFDs include assessment of serotonin release in δ-granule storage disease (Gobbi et al. 2003), quantification of von Willebrand binding induced by ristocetin to fresh or formalin-fixed donor platelets for differential diagnosis between platelet-type von Willebrand disease and von Willebrand disease (Giannini et al. 2007, 2010), and analysis of defective platelet activation pathways in the rare FPD/AML disorders (Glembotsky et al. 2014).

Additionally, FCM can offer a simple, easy-to-perform diagnostic pre-test for patients with a bleeding history suggestive of PFD, as proposed by Dovlatovla and colleagues. The authors describe an FCM-based platelet function test to select, among patients with excessive bleeding, those that would benefit from further, extensive platelet phenotyping. The sample is stabilized for up to 9 days using a fixing solution (PAMFix; Platelet Solutions, Nottingham, UK) and then tested for P-selectin, as a marker of α-granule secretion and a general indicator of platelet reactivity, and for CD63 to evaluates δ-granule secretion after stimulation with combinations of ADP, the thromboxane A_2 analog U46619, arachidonic acid, epinephrine, and TRAP. The assay shows good agreement with conventional lumiaggregometry and could thus be an appealing screening tool in this complex clinical scenario (Dovlatova et al. 2014).

FCM currently holds a marginal but expanding role in the routine diagnostic work-up of acquired thrombocytopenias such as immune-mediated thrombocytopenias and heparin-induced thrombocytopenia (HIT). In the case of HIT, FCM rapidly detects platelet activation induced by heparin-dependent cell-activating anti-PF4/heparin antibodies by annexin V binding (Tomer 1997), serotonin release (Gobbi et al. 2003), CD62P expression (Vitale et al. 2001), and platelet microparticle formation (Mullier et al. 2010).

Immune-mediated thrombocytopenias include a wide group of disorders typified by a reduction in platelet number as a result of production of antibodies directed against self-platelet antigens (immune thrombocytopenia; ITP) or neonatal/donor platelet antigens, most commonly human platelet antigen (HPA)-1a, as in the case of neonatal alloimmune thrombocytopenia, (NATP) and post-transfusion purpura (PTP). Innovative FCM assays have been developed to identify circulating autoantibodies and platelet-bound autoantibodies in ITP (Tomer et al. 2005; Tomer 2006) and to detect human leukocyte antigen-directed antibodies in the case of alloimmunization after repeated platelet transfusions (Carrick et al. 2011). FCM has proven to be a very sensitive method for detection of alloantibodies, as it is capable of detecting very small amounts of platelet-bound antibodies.

Interestingly, Freliger and colleagues utilized FCM-based platelet activation tests to investigate bleeding tendency in ITP patients. The following markers of activation were considered: CD62P expression, PAC-1-binding, and TRAP-stimulated platelet surface CD42b. The authors conclude that unstimulated platelet surface P-selectin and CD42b expression, together with higher levels of immature platelet fraction and platelet forward light scatter, were associated with a higher bleeding score, independently of platelet count, and could consequently be considered FCM markers of bleeding risk in ITP patients (Frelinger et al. 2015).

In the diagnostic algorithm of NATP, FCM is used to test maternal serum against paternal and maternal platelets and a small panel of platelets from normal group O donors typed for selected common HPA antigens. In the assay, washed platelets are sensitized with maternal or control serum for up to 60 min at room temperature. Platelets are then carefully washed to remove nonspecific immunoglobulins. Platelet-bound antibodies are detected with a fluorescently labeled

(usually FITC) polyclonal or monoclonal antibody specific for human immunoglobulin. Results are expressed as the ratio of the fluorescence (mean or peak) emitted by normal platelets sensitized with maternal serum to that emitted by normal platelets incubated in normal serum. To prevent nonspecific binding of the immunoglobulin probe via Fc receptors on the target platelets, the probe antibodies are enzyme-treated to remove the Fc end of the molecule. A second fluorescent label, usually phycoerythrin (PE), can be attached to an anti-human IgM probe to detect IgM anti-platelet antibodies. Tests can be run simultaneously on the same sample of washed sensitized platelets, allowing detection of anti-platelet IgG and IgM in the course of the same acquisition (McFarland 2003; Peterson et al. 2013; Curtis and McFarland 2009). The same assay also applies to PTP, as described in the section "Platelet Crossmatching".

A common potential drawback of the above-described FCM-based method of detection of serum alloantibodies is the fact that it does not differentiate between platelet-specific (i.e., platelet glycoprotein-directed) and non-platelet-specific (i.e., human luekocyte antigen- and ABO-directed) antibodies, leading to potential non-platelet-specific reactivity.

In addition to the detection of circulating anti-HPA-1a antibodies, FCM has been proposed as a rapid, simple, and reliable tool for platelet immunophenotyping in the setting of large-scale screenings to identify HPA-1a-negative subjects, potentially at risk of NATP, PTP, and refractoriness to platelet transfusion (Killie et al. 2004; Sorel et al. 2004; Tazzari et al. 1998). Of these three alloimmune disorders, NATP requires parental platelet antigen typing when a personal obstetric history suggestive of NATP is present, or in the case of maternal sister(s) with an obstetric history of laboratory-confirmed NATP or suggestive of NATP.

FCM-based platelet immophenotyping relies on the fact that polyporphisms of the HPA-1 system antigen, which account for alloimmune thrombocytopenias, result in different expression of binding sites for monoclonal antibodies of platelet membrane glycoproteins. Weiss and coworkers (Weiss et al. 1995) first characterized a monoclonal antibody, SZ21, directed against GPIIIa and able to distinguish between HPA-1a and HPA-1b genotypes because of its markedly reduced binding to platelets with the HPA-1b genotype. Starting from this finding, Schwippert-Houtermans and coworkers developed and standardized an FCM method for classifying the HPA-1 genotype, utilizing SZ21 monoclonal antibody (Schwippert-Houtermans et al. 2001). This method was subsequently implemented by coupling SZ21 with P2 antibody (targeting the $\alpha_{IIb}\beta_3$ complex), which allows discrimination of HPA-1a/1a phenotype from HPA-1a/1b thanks to absence of overlapping of P2/SZ21 mean fluorescence intensity ratios between the two phenotypes (Sorel et al. 2004).

FCM analysis using immunofluorescence labeling with specific alloantisera has been described (Forsberg et al. 1995; Tazzari et al. 1998), but is not able to distinguish HPA-1a/1b hetererozygous from HPA-1a homozygous subjects.

Today, the development of DNA-based methods allowing simultaneous genotyping of as many as 17 HPAs has made serological typing for HPA antigens obsolete (Bertrand and Conti 2015).

Blood Bank Applications

FCM is available in platelet blood banking, especially for (1) enumeration of residual white blood cells in red blood cells and platelet concentrates (PCs); (2) determination of platelet function in PCs by measuring platelet activation markers; (3) sterility testing of PCs to assess bacterial risk; and (4) platelet crossmatching.

Enumeration of Residual White Blood Cells in Red Blood Cells and Platelet Concentrates

FCM methods for counting residual white blood cells (WBC) in PCs are well established and widely used (van der Meer et al. 2012; Fischer et al. 2012). Traditionally, the methods are based on propidium iodide DNA staining for WBC detection and on fluorescent beads, at known concentration, as internal standard for leukocyte enumeration (Barclay et al. 1998; Backteman et al. 2002; Dijkstra-Tiekstra et al. 2004; Santana and Dumont 2006). Other FCM methods have also been proposed; for example, using a fluorescent anti-glycophorin A antibody that allows the simultaneous enumeration of residual WBCs and residual RBCs (Schmidt et al. 2009), and the use of specific WBC fluorescent antibody to discriminate WBCs from other nucleated cells (i.e., nucleated red blood cells) that are responsible for the overestimation of WBC content (Fischer et al. 2012).

Determination of Platelet Function in Platelet Concentrates by Platelet Activation Markers

Platelet transfusions are routinely used as life-saving procedures during surgery, myeloablative therapies, and in patients with particular bleeding disorders. The primary objective of platelet transfusion is to provide a sufficient amount of platelets with preserved hemostatic function. Unfortunately, platelet storage and pathogen reduction technologies (PRTs) cause a decrease in functionality over time, often referred to as "platelet storage lesion" (PSL)

(Thon et al. 2008). In vitro platelet function tests, mainly FCM tests, have been used to determine the platelet reactivity of PCs during storage and to compare it with that of PCs prepared with different PRTs.

Although FCM detection of platelet-derived extracellular vesicles and LAMP-1 (lysosme-associated membrane protein-1) have been proposed as new markers of PSL (Black et al. 2015; Sodergren et al. 2015; Pienimaeki-Roemer et al. 2014), the assessment of platelet functionality in PCs primarily relies on the evaluation of activation-dependent changes in platelet surface markers in a resting state and after agonist stimulation (Cardigan et al. 2005). The physiological increase in CD62p, $\alpha_{IIb}\beta_3$, and fibrinogen binding in response to platelet agonists is hampered during platelet storage (Curvers et al. 2004; Lozano et al. 1997; Rock et al. 2003; Leytin et al. 2004), whereas GpIII expression is enhanced. This increase, measured both by western blot and FCM, is a result of translation mechanisms that, in turn, may be involved in the initiation or exacerbation of PSL (Thon and Devine 2007).

Several reports now associate GPIbα shedding and increased expression of CD63 and PS to augmented platelet clearance, leading to reduced post-transfusion platelet survival (Ohto and Nollet 2011; Canault et al. 2010; Albanyan et al. 2009a, b; Metzelaar et al. 1993).

A controversial aspect of FCM application in PC storage is the evaluation of P-selectin expression for quality control. Because P-selectin expression is the most commonly applied parameter of platelet activation in PCs stored in blood banks, efforts have made to standardize its measurement (Middelburg et al. 2013; Curvers et al. 2008). Expression of P-selectin is widely used as predictor of platelet survival and function in vivo; furthermore, FCM detection of CD62p is often used to study the effects of pathogen reduction strategies on PSL (Ostrowski et al. 2010; Galan et al. 2011; Johnson et al. 2011; Castrillo et al. 2013; Ignatova et al. 2015).

However, some authors debate the use of P-selectin as a predictor of platelet survival in vivo, providing data in support of the fact it does not mediate platelet clearance. Specifically, in a nonhuman primate model, infused degranulated platelets rapidly lose surface P-selectin to the plasma pool but continue to circulate and function in vivo (Michelson et al. 1996). Moreover, platelets from wild-type and P-selectin knockdown mice had identical life spans, and, in a thrombocytopenic rabbit model, thrombin-activated human platelets that lose surface P-selectin survive and are effective in the rabbit circulation for as long as fresh human platelets (Berger et al. 1998; Krishnamurti et al. 1999).

Future studies are needed to clarify how PC studies translate to platelet function in vivo after transfusion (Cardigan et al. 2005).

Sterility Testing of PCs to Assess Bacterial Risk

One of the most frequent infectious complications in platelet transfusion therapy is related to bacterial contamination of PCs. To preserve platelet function, PCs are stored at room temperature and this facilitates bacterial contamination (Vollmer et al. 2012). Several works have demonstrated that sterility testing of PCs by FCM is a feasible approach both for buffy coat-derived PCs and PRP-derived PCs (Mohr et al. 2006a, b; Schmidt et al. 2006a, b; Lee et al. 2012). Traditionally, TO staining is used for detection of bacteria and, before testing, it is suggested that the PC sample is incubated for 20–24 h at 37 °C, which should be prolonged for up to 2 days for slow-growing bacteria (Mohr et al. 2006a). This inevitably protracts the assay results. In 2009, Dreier and coworkers introduced an FCM-based assay (BactiFlow) that fulfils the requirements for a point-of-issue testing of PCs with a time-to-result of approximately 1 h, combined with a high sensitivity of 150 colony forming units/mL (Dreier et al. 2009). This method was subsequently implemented as a routine method for the identification of contaminated PCs (Vollmer et al. 2011). Multicenter studies have since validated BactiFlow as a very convenient test for PC bacterial screening (Vollmer et al. 2012).

Platelet Crossmatching

Transfusion of crossmatch-compatible platelets is a consolidated strategy for transfusion of alloimmunized patients, who show refractoriness to platelet transfusion (Rebulla 2005; Rebulla et al. 2004).

Serum from alloimmunized patients can be crossmatched with platelets from PCs already available for transfusion or with frozen or refrigerated aliquots of platelets from potential donors. HLA-specific and HPA-specific antibodies in the patient's plasma react with platelets expressing incompatible antigens. Only platelet components that are compatible are transfused (Stroncek and Rebulla 2007). Several methods have been used to crossmatch patient samples, including ELISA, platelet immunofluorescence (PIFT), solid phase red cell adherence assay (SPRCA), and FCM. In FCM tests, donor platelets are incubated with a patient's serum or plasma. Binding of the patient's antibodies on donor platelets is detect using fluorescently labeled anti-human IgG antibodies. A platelet-specific monoclonal antibody (such as anti-CD41) should be added so that the analysis is performed exclusively on the platelet population (Sayed et al. 2011). The test must include the donor serum as negative control. Data are usually presented as the fluorescence ratio, defined as the ratio between the fluorescence intensity of gated platelets after incubation with the patient's serum and the fluorescence intensity of the negative control

(Dohlinger et al. 2005; Sayed et al. 2011). It has been demonstrated that platelet donor selection using FCM crossmatch gives a better clinical outcome for transfusion in many thrombocytopenic alloimmunized patients (Sintnicolaas and Lowenberg 1996; Sayed et al. 2011). Moreover, this method has proved useful for comparing the detection of platelet antibodies in fresh and frozen cells in attempts to standardize the storage of donated platelets (Dohlinger et al. 2005).

Other Applications

Intraplatelet Production of Reactive Oxygen Species

Platelet aggregation is associated with considerable production of reactive oxygen species (ROS), which is not counterbalanced by adequate intracellular content of antioxidants (Krotz et al. 2004). Generation of intraplatelet ROS occurs in both physiological and pathological conditions (Ghoti et al. 2007; Amer et al. 2005; Becatti et al. 2013; Mondal et al. 2015) and has been implicated in the regulation of $\alpha_{IIb}\beta_3$ activation, granule secretion, platelet shape change, and, more generally, in platelet reactivity (Begonja et al. 2005).

Detection and quantification of ROS production is relevant for measurment of platelet oxidative stress, and FCM offers a simple and rapid assay for this. The technique essentially relies on the incubation of platelets with dyes that can diffuse across the cell membrane. In basal conditions the dyes are not fluorescent, but, when oxidized by ROS, they emit a fluorescent signal that is detected by the flow cytometer. The most commonly used dyes are 2′,7-′-dichlorodihydrofluorescein diacetate (H_2-DCFDA) and dihydrorhodamine 123 (DHR). Fluorescence is measured in the FL1 green channel. The test can be performed directly on whole blood.

Calcium Flux

Cytosolic free calcium ions (Ca^{2+}) are important second messengers and markers of platelet activation and reactivity. Therefore, quantitative measurement of intraplatelet calcium provides additional information for evaluation of platelet status. Traditionally, Ca^{2+} dynamics has been studied by cuvette-based methods, whose main drawback is the necessity of platelet isolation steps that are not only time consuming, but can also interfere with platelet activation status. One of the first FCM-based methods for the assessment of intraplatelet Ca^{2+} dynamics relied on the use of Indo-1 as fluorescent dye. However, excitation of Indo-1 requires a laser in the UV range (not standard on most flow cytometers) and the staining precludes the combined use of compounds that exhibit fluorescence when excited by UV light (i.e., oxidized lipids/lipoproteins), so this method has very limited application (Dustin 2000). Other dyes have been proposed that have the advantage of being excited by a standard blue argon laser, such as fluo-3-acetoxymethyl ester (Fluo-3) and its derivative, the brighter and more photostable Fluo-4. The fluorescence of Fluo-4 can be detected in the FL1 green channel and is enhanced by binding of Ca^{2+}. Cellular loading and accumulation of these dyes results from esterase-mediated cleavage that convert the lipophilic (pro)dyes into polar membrane-impermeable forms that thereby also acquire the ability to bind Ca^{2+}. These dyes can be coupled with anti-CD61 (Labios et al. 2006) or anti-CD41 (do Ceu Monteiro et al. 1999) antibodies that identify platelet populations. Tests can be run both on PRP and whole blood.

More recently, Assinger and coworkers described a method that, combining Fluo-4 with Fura Red, (another acetoxy-methyl ester derivative whose fluorescence is decreased by Ca^{2+} binding and is detected in the FL3 red channel) can rule out an enhanced signal resulting from the presence of aggregates (Assinger et al. 2015).

Platelet Cytoskeleton Studies

Actin polymerization in filamentous form (F-actin) is an early event in platelet activation and is associated with shape change, granule centralization, and glycoprotein redistribution. Additionally, in the basal state, F-actin content varies between individuals (Oda et al. 1992) and can be increased in pathological conditions such as type 1 diabetes (Spangenberg et al. 1989).

Variations in platelet F-actin content can be rapidly detected by FCM. This method is uses fluorescent phalloidin and phallacidin derivatives for labeling and quantifying actin filaments. These phallotoxins (isolated from *Amanita Phalloides* mushroom) are bicyclic peptides that differ by two amino acid residues and can be interchangeably used as probes for F-actin. They stain F-actin at nanomolar concentrations and have similar affinities for both large and small filaments, binding in a stoichiometric ratio of one phallotoxin molecule to one actin subunit.

The most utilized fluorescent phallotoxin probes are 7-nitrobenz-2-oxa-l,3–phallacidin (NBD–phallacidin) (Oda et al. 1992), BIODIPY–phallacidin (Semple et al. 1997) and FITC–phalloidin (LaRosa et al. 1994a).

Prior to incubation with fluorescent phallotoxin probes, platelets can be blocked with unlabeled phallotoxins to reduce nonspecific staining (Semple et al. 1997). Fixation is required.

FCM and Platelet Aggregation

Platelet aggregation can be measured by a whole blood FCM assay (Fox et al. 2004). This method is based on measuring the decrease in the number of single platelets as they form aggregates in stimulated and stirred whole blood. The platelet number can be measured in small subsamples removed from the test tube at different time points to provide kinetic information on platelet aggregation. Platelets are labeled with platelet-specific antibody and the number of red cells is used as a reference for counting individual platelets.

The method is sensitive to microaggregate formation and can provide information on platelet disaggregation, although the approach is quite elaborate. A modification of this protocol has been described, in which platelets are labeled with two platelet-specific markers (one type of antibody conjugated with two different fluorocromes), mixed together, and stimulated with various platelet agonists (phorbol myristate acetate, collagene, ristocetin). The increase in events characterized by both fluorescent labels is representative of aggregate formation.

To date, the performance of this method has been tested in both experimental (mouse models) and clinical (GT patients, full-term neonates at 24-h of life) settings in which limited blood sampling is beneficial. Indeed, FCM proved to be a very promising tool for testing platelet activation and aggregation using a small amount of whole blood (De Cuyper et al. 2013; Baker-Groberg et al. 2016).

RNA Interference

It is well established that platelets contain megakaryocyte-transcribed mRNAs that are translated into proteins in response to physiological stimuli regulating platelet function (Weyrich et al. 2004). Manipulation of platelet RNA expression is a fascinating scenario for both research and clinical purposes, such as for characterization of the specific role of platelet proteins and microRNAs, and for manipulation of platelet function and lifespan to overcome platelet storage lesion in transfusion medicine.

It was previously demonstrated that FCM provides reliable assessment of the efficiency of short interfering RNA (siRNA) in cell populations (Ho et al. 2006). More recently, Hong and coworkers demonstrated, for the first time, that human platelets could be transfected with siRNA and that transfection efficiency could be assessed by FCM. The authors transfected fluorescently labeled siRNAs in human PRP and washed platelets, testing multiple transfection conditions and identifying the optimal method for measuring the fluorescence of transfected platelets and negative controls by FCM. The authors also demonstrated knockdown of the mRNA target in transfected platelets isolated by FCM cell sorting (Hong et al. 2011).

Platelet Count During In Vitro Megakaryocytopoiesis

FCM can be utilized for monitoring platelet production during in vitro megakaryocytopoiesis from purified hematopoietic stem cells. The method allows discrimination of in vitro produced platelets from cellular debris by combining calcein-AM staining (a hydrophilic molecule that confers a green fluorescence to living cells) with anti-CD41 monoclonal antibody. The simultaneous use of calibrated beads provides the absolute platelet count (Fig. 3). This technique is useful for monitoring end-stage in vitro megakaryocytic differentiation and for testing the effect of drugs on in vitro platelet production (Gobbi et al. 2007, 2009, 2013; Nurden et al. 2010; Carubbi et al. 2014a).

Animal Models

Animal models are important tools in laboratory studies. In our setting, platelet function tests in different animal species have a wide range of applications. In particular, ex vivo pharmacological and toxicological studies have been undertaken in experimental animal models, including works of primary veterinary interest and studies in animal models of human platelet-derived disease. Flow cytometry can be applied to platelet studies in animal models, with similar considerations as those described for human platelets.

Given the fact that human and murine hemostasis are overlapping processes, mouse models are by far the most utilized. Indeed, engineered mice mimicking human acquired and inherited bleeding disorders have been developed, helping to clarify the role of specific transcription factors, receptors, and intracellular proteins or the effects of drugs (Aktas et al. 2005; McKenzie and Reilly 2004; Magallon et al. 2011; Graham et al. 2009; Pitchford et al. 2005; Pozgajova et al. 2006; Strassel et al. 2007; Kato et al. 2004; Kassassir et al. 2013; Chow et al. 2010; Musaji et al. 2004).

During FCM platelet analysis in mouse models, we have first to consider that murine platelets are smaller and more concentrated than human platelets (Nieswandt et al. 2004). An FCM method for determining the number and activation state of circulating platelets from a single mouse over an extended period of time has been described, using only 5 μL of blood collected by tail cut. Platelets are identified using a specific fluorescent antibody and a known number of fluorescent beads for counting standardization. The authors

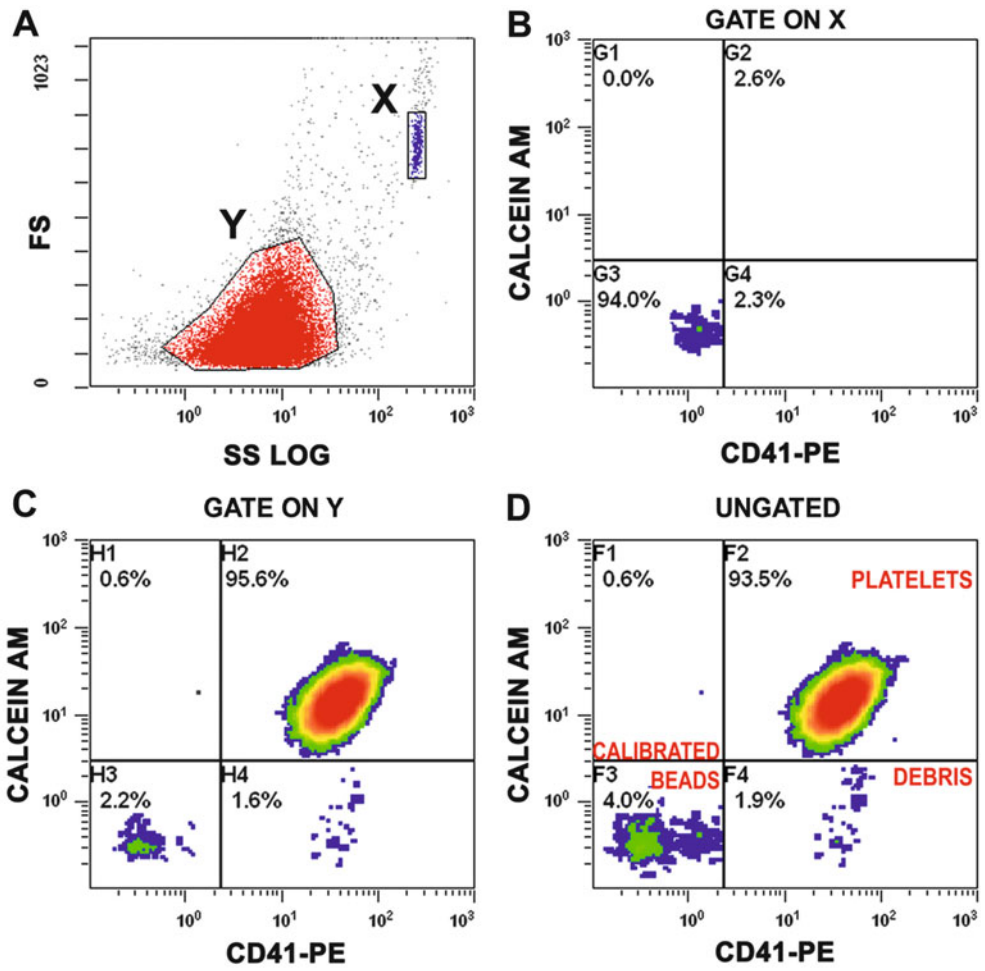

Fig. 3 Platelet quantification by flow cytometric analysis. (**A**) Distribution of platelets (*Y*) and calibrated beads (*X*) according to their forward scatter (*FS*) and side scatter (*SC*, on a logarithmic scale). (**B**) Calibrated beads appear as a well-defined and clearly distinguishable population ($CD41^-$/calcein-AM^-). (**C**) CD41 and calcein-AM staining allows discrimination between platelets ($CD41^+$/calcein-AM^+) and debris ($CD41^+$/calcein-AM^-). (**D**) Ungated plot permits calculation of platelet number according to the number of events in the *lower-left quadrant* and in the *upper-right quadrant*

demonstrated that tail vein bleeding does not activate platelets and that the method is rapid, accurate, and reproducible (Alugupalli et al. 2001).

In addition, Shipper and colleagues have validated a single-platform protocol for counting human platelets after transfusion and cord blood transplantation in the peripheral blood of NOD/SCID mice, using an anti-human CD41 antibody against human platelets and counting beads (Schipper et al. 2007).

As described for human platelets, FCM analysis of surface exposure of P-selectin and activated $\alpha_{IIb}\beta_3$ (recognized by the monoclonal JON/A antibody, equivalent to PAC-1 for murine platelets) (Bergmeier et al. 2002), as well as detection of PLAs and PMPs, are routinely utilized to assess platelet activation in vivo and ex vivo in murine models of different diseases (Pitchford et al. 2005; Ohno et al. 2014; Lamrani et al. 2014; Chen et al. 2003; Henry et al. 2009; Yokoyama et al. 2005).

It has been pointed out that the pig is a very good model for study of atherosclerosis and thrombosis (Vilahur et al. 2011). This model is being increasingly used in cardiovascular and platelet research, and a reliable method for detecting the activation of porcine platelets has been described. The authors identified a set of commercially available antibodies that bind activated platelets, also setting the optimal platelet source (whole blood or PRP) for these purposes (Krajewski et al. 2012).

FCM has also been utilized in veterinary studies investigating platelet function in various species. As an example, dogs harboring inflammatory diseases show an increase in platelet activation markers, such as PLAs and CD62p, and their expression correlates with clinical

outcome of the disease (Moritz et al. 2003, 2005; Goddard et al. 2015; Majoy et al. 2015).

More recently, the analysis of platelet surface receptors has been suggested as a useful tool in equine clinical medicine for investigation of new therapeutic strategies for the prevention or treatment of equine recurrent airway obstruction. FCM analysis has demonstrated that horses with this disease show an increase in CD41/61 and a decrease in CD62p platelet expression (Iwaszko-Simonik et al. 2015).

Acknowledgement We are grateful to Dr. Giovanni Panico for graphical support.

Take Home Messages

- Platelet morphology and function can be comprehensively evaluated by flow cytometry
- Flow cytometry has become routinely used not only for research purposes but also in the clinic
- Relatively high costs and interlaboratory standardization are the main drawbacks that limit the application of flow cytometry

Platelet Aggregation

Catherine P.M. Hayward and Karen A. Moffat

Abstract

Platelet aggregometry is an important technique for assessing platelet function for diagnostic and research purposes. Platelet aggregometry remains the most important, established platelet function test for evaluating platelet function for diagnostic purposes. Light transmittance platelet aggregometry and whole blood aggregometry are more popular methods for testing platelet aggregation responses than flow cytometry and platelet counting methods. In recent years, there have been considerable efforts to improve and standardize the assessment of platelet function by aggregometry. The focus has been on light transmittance platelet aggregometry as there are many more publications on this method, and more information on how the test performs for the diagnosis of bleeding disorders. Guidelines are now available on when and how to perform aggregometry (including choices of agonists, and final agonist concentrations), and how to interpret the test findings for diagnostic purposes. This chapter focuses on the principles and uses of aggregometry, with emphasis on using the test for diagnosing platelet function disorders, with proper quality control of all steps from sample procurement, processing, analysis to interpretation and reporting. Examples are provided of abnormal aggregation responses due to a variety of clinical conditions, including rare and more common platelet function disorders that impair aggregation responses. Interesting data continues to emerge on the causes of common platelet function disorders that impair aggregation responses, a number of which reflect mutations in genes encoding transcription factors that are important for generating normal, functional platelets.

Platelet aggregometry is an important technique for assessing platelet function for diagnostic and research purposes. The first descriptions of platelet aggregometry date back to more than 50 years ago, when two, independent reports by Born (1962) and O'Brien (1962) were published that described the assessment of platelet aggregation responses by light transmittance aggregometry (LTA). Later, methods were developed to test whole blood aggregation responses using changes in electrical impedance as the endpoint (Cardinal and Flower 1980; Sweeney et al. 1989a) and to test dense granule adenosine triphosphate (ATP) release simultaneously with aggregation (Feinman et al. 1977; Ingerman-Wojenski et al. 1983; Ingerman-Wojenski and Silver 1984). More than half a century later, LTA remains the most important, established platelet function test for evaluating platelet function for diagnostic purposes (Gresele et al. 2014; Cattaneo 2009). While laboratories

continue to test LTA by the methods of Born and O'Brien, there have been considerable efforts to improve the assessment of platelet function by aggregometry, as practice surveys have highlighted the need for standardization of aggregometry tests in both research and diagnostic laboratories (Moffat et al. 2005; Jennings et al. 2008; Duncan et al. 2009; Cattaneo et al. 2009; Gresele et al. 2014). Guidelines are now available on how to perform aggregometry, and how to interpret LTA findings for diagnostic purposes (Christie et al. 2008; Hayward et al. 2010; Harrison et al. 2011; Cattaneo et al. 2013; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015). This chapter focuses on the principles and uses of aggregometry, with emphasis on using the test for diagnosing platelet function disorders. This chapter pays particular attention to LTA as it is the best characterized and most popular aggregometry method for assessing platelet function in clinical and research laboratories (Moffat et al. 2005; Cattaneo et al. 2009; Gresele et al. 2014).

Overview and General Principles of Aggregometry

Platelet aggregometry assesses platelet–platelet interactions that are induced by adding platelet stimulating agonists to a sample. The sample tested can be whole blood (diluted or undiluted) for whole blood aggregometry (WBA) (Feinman et al. 1977; Cardinal and Flower 1980; Ingerman-Wojenski et al. 1983; Ingerman-Wojenski and Silver 1984; Swart et al. 1984; Sweeney et al. 1989a; McGlasson and Fritsma 2009), flow cytometry (Gatt et al. 2014; Rubak et al. 2015), and platelet counting methods (Lordkipanidze et al. 2009; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015). For LTA, the sample testing is usually platelet rich plasma but washed platelet suspensions can also be tested (typically only for research purposes) (Born 1962; O'Brien 1962).

The extent of platelet aggregation in response to an agonist can be quantified by measuring:

1. Turbidimetric changes for LTA (Born 1962; O'Brien 1962),
2. Changes in electrical impendence changes for WBA (Cardinal and Flower 1980; Ingerman-Wojenski et al. 1983; Ingerman-Wojenski and Silver 1984; Swart et al. 1984),
3. The loss of single platelets (due to aggregate formation) by platelet counting methods (Sweeney et al. 1989a; Lordkipanidze et al. 2009) and
4. The formation of larger aggregates, and loss of single platelets, when aggregation is quantified by flow cytometry methods (Gatt et al. 2014; Rubak et al. 2015).

LTA and WBA are the more commonly used methods for quantifying aggregation responses (Moffat et al. 2005; Cattaneo et al. 2009; Gresele et al. 2014). Because there is more information published on LTA than WBA, particularly for diagnosing platelet function disorders, the majority of laboratories use LTA for diagnosing platelet function disorders (Moffat et al. 2005; Cattaneo et al. 2009; Gresele et al. 2014).

For LTA and WBA aggregation tests, samples are stirred at low shear force (Christie et al. 2008; Cattaneo et al. 2013). Under these conditions, aggregation tests assess platelet–platelet interactions mediated by the binding of the γ chain of fibrinogen to $\alpha_{IIb}\beta_3$ receptors on adjacent platelets (Ni and Freedman 2003). For LTA, cloudiness of the sample from lipemia can interfere with quantifying the aggregation responses, as can large numbers of contaminating leukocytes, red cells, or red cell fragments in a sample (Christie et al. 2008).

More details on LTA and WBA are provided in the sections that discuss these methods for evaluating platelet function.

Preparation of Samples for Aggregometry

Process control is important for obtaining proper samples for aggregometry and controlling the analytical and post-analytical steps of platelet function testing (Hayward and Eikelboom 2007; Favaloro 2009; Hayward et al. 2012). The box below summarizes important quality assurance considerations for preparing samples to test by platelet aggregometry. Although other anticoagulants have been explored (Hellstern et al. 2007; Haubelt et al. 2008; Tauer et al. 2010; Loreth and Klose 2010; Kaiser et al. 2011; Gresele et al. 2014), most blood samples for aggregometry are collected into buffered sodium citrate anticoagulant as aggregation responses are influenced by pH and calcium chelation (Lages and Weiss 1981; Hellstern et al. 2007; Haubelt et al. 2008; Tauer et al. 2010). The most commonly used anticoagulants are 109 and 129 mM buffered sodium citrate, which increase aggregation responses to some weak agonists that are useful for diagnostic aggregometry, such as epinephrine (adrenaline) and adenosine diphosphate (ADP) (Mustard et al. 1975; Lages and Weiss 1981).

Quality Assurance Considerations for the Preanalytical Components of Aggregation Testing
The recommendations summarized are compiled from recent guidelines (Christie et al. 2008; Hayward et al. 2010; Harrison et al. 2011; Cattaneo et al. 2013; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015).

Subject preparation

Blood samples should be collected from subjects after a short rest period. Subjects should refrain from smoking for at least 30 min, and abstain from caffeine for at least 2 h.

Medications taken during the previous week should be reviewed for ingestion of drugs that reversibly inhibit platelet function. Reversible non-steroidal anti-inflammatory drugs need to be stopped at least 3 days before samples are taken whereas aspirin and thienopyridines need to be stopped at least 10 days in advance. When drugs that inhibit platelet function cannot be stopped, their effects on platelet function need to be considered when interpreting the findings.

There is diurnal variation in aggregation responses so most laboratories schedule the testing for the morning and early afternoon.

Blood collection

Aggregometry samples should be collected with **minimal or no venostasis, using a 21 gauge or larger needle. The first 3–4 ml of blood can be discarded or used for other coagulation tests. The discard volume should be minimized or omitted for small children.**

The blood should be collected into plastic (polypropylene) **or siliconized glass tubes containing 109 mM (3.2 %) or 129 mM (3.8 %) buffered sodium citrate anticoagulant**, taking care to properly fill the collection tubes. Under-filled tubes may only be used to exclude severe platelet function disorders (i.e., **Glanzmann thrombasthenia or Bernard Soulier syndrome).**

Preparation of platelet rich and platelet poor plasma for LTA

Blood samples should "rest" at room temperature for 15 min before centrifugation.

Platelet rich plasma should be prepared by centrifuging samples at 200 g for 10 min, at ambient temperature, without using the centrifuge brake.

When the subject has thrombocytopenia and giant platelets, platelet rich plasma should be harvested without centrifugation, by allowing the sample to sediment.

Platelet poor plasma should be prepared by centrifuging whole blood, or the leftovers from the tube used to prepare platelet rich plasma, at 1500 g for 15 min, at ambient temperature.

Visual check for sample quality

Grossly hemolyzed samples should be discarded.

If the sample is lipemic, the final report should state this.

Samples of platelet rich plasma should appear uniform, pearly, and swirl when gently pipetted up and down.

Assessment of the sample

Platelet count of the aggregometry samples **should be quantified and compared to whole blood platelet counts. Normally, platelet counts are higher in platelet rich plasma compared to whole blood (typically double). The sample should have minimal leukocyte and red blood cell contamination.**

Aggregation responses can be impaired when the sample platelet count is $<150 \times 10^9$/l.

Low platelet count samples are useful to exclude some platelet function disorders associated with thrombocytopenia such as variant Glanzmann thrombasthenia, Bernard Soulier syndrome, type 2B and platelet type von Willebrand disease.

Samples can be left without an adjustment to a standardized platelet count, or adjusted to a standardized value, based on the procedure validated by the laboratory (recent guidelines suggest not to adjust, **although one study found adjusted samples superior for diagnosing platelet disorders** (Castilloux et al. 2011)).

Aggregation is typically evaluated at 37 °C during the test to mimic normal physiology (Born 1962; O'Brien 1962; Christie et al. 2008; Cattaneo 2009; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015).

Light Transmittance Platelet Aggregometry

LTA is a turbidimetric-based method that quantifies alterations in the optical density of a platelet suspension (placed in a clear receptor) that follow the addition of a platelet-activating agonists to a stirred platelet suspension, as first described by Born and O'Brien (Born 1962; O'Brien 1962). There are a number of commercial instruments that have been designed to measure LTA, and these allow for continuous monitoring of changes to the turbidity of a platelet rich plasma sample after adding an agonist. The test is

done after setting the optical limits for the sample that correspond to "no aggregation" (i.e., same turbidity as the starting sample) and full (100 %) aggregation (i.e., turbidity reduced to that of platelet poor plasma) (Cattaneo 2009). Aggregation is typically monitored for a brief period before adding the agonist to ensure that the baseline is stable (Cattaneo et al. 2013). Shortly after adding the agonist, there is often a slight reduction in the sample turbidity (from the added volume of the agonist) before platelet shape change (Sanderson et al. 1996) (which increases the turbidity), which is then followed by a reduction in turbidity due to aggregate formation (e.g., Fig. 1). Responses are usually monitored for 5 min although longer monitoring is required to reach stable final aggregation with some agonists (e.g., 10 min monitoring for epinephrine, Fig. 1) (Cattaneo et al. 2013). The monitoring should be sufficient to achieve

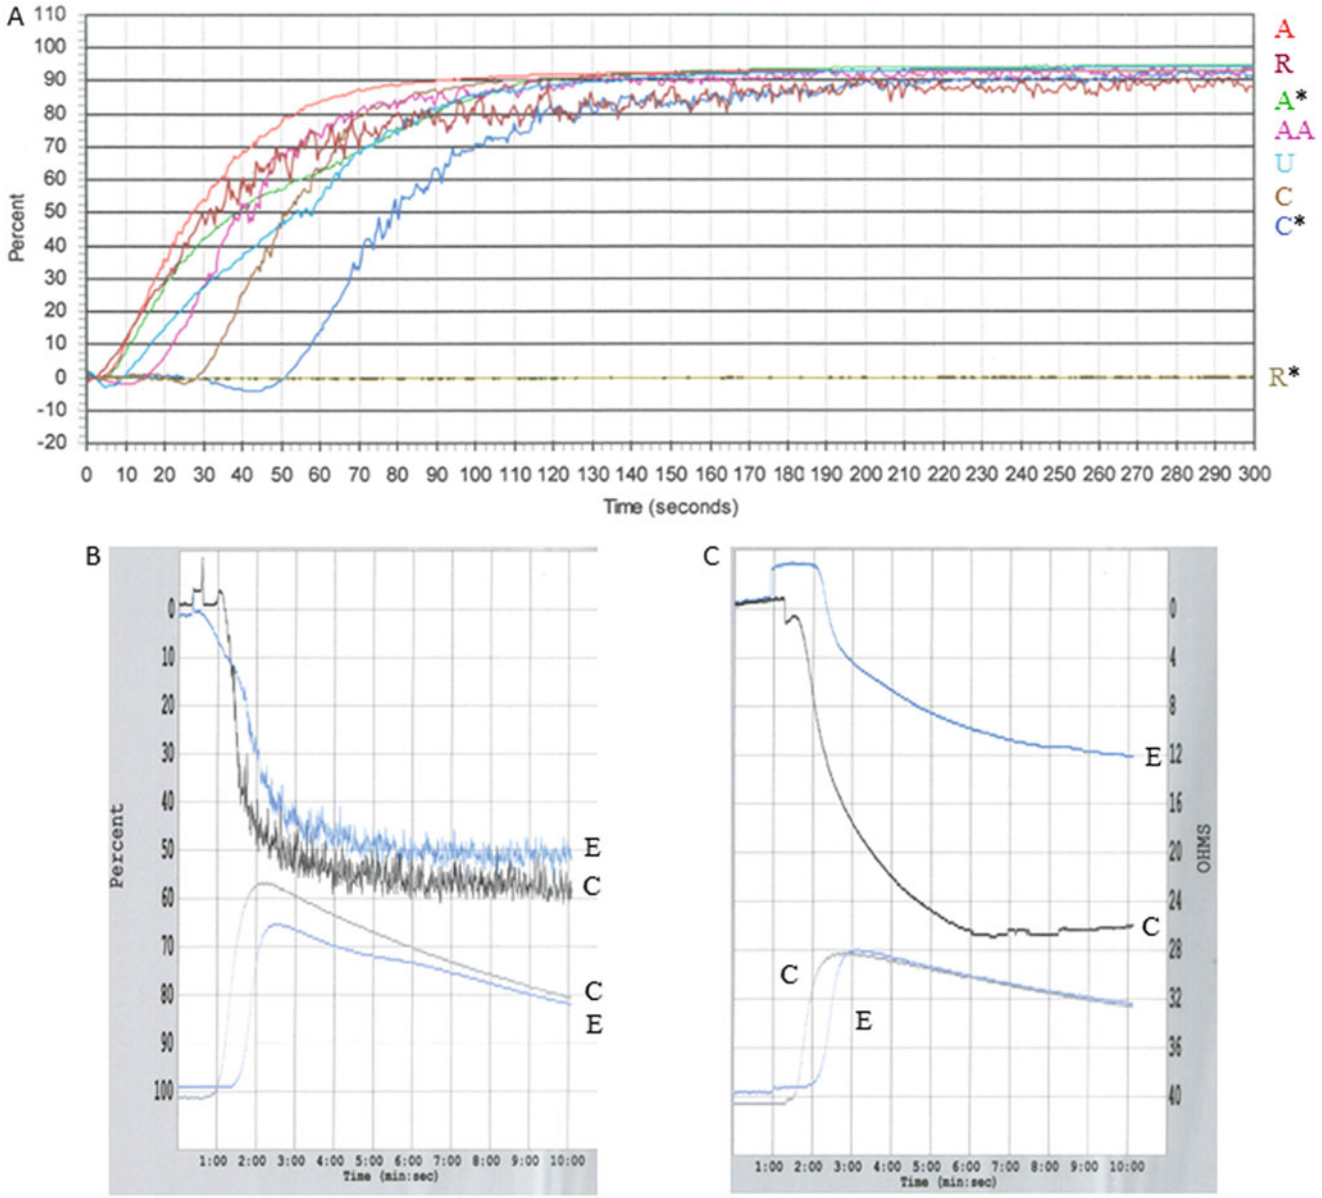

Fig. 1 Comparison of normal aggregation responses detected by light transmission and whole blood aggregometry. In the upper panel, there is no aggregation with 0.5 mg/l ristocetin (R*) and extensive aggregation with (agonist abbreviation, reference interval cutoffs): 2.5 (A*, >24 %) and 5.0 (A, >43 %) μM ADP; 1.25 mg/ml ristocetin (R, >75 %);1.6 mM arachidonic acid (AA, >77 %); 1 mM thromboxane analogue U46619 (U, >70 %); 1.25 (C*, >51 %) and 5 mg/ml collagen (C, >85 %). In the lower panels, aggregation (LTA as %; WBA in Ohms) was measured simultaneously with dense granule ATP release (nM). Shape change (increase in turbidity, before aggregation) with Horm collagen (C) is evident by LTA but not WBA. While the primary aggregation response to 6 μM epinephrine (E) occurs before dense granule release, and the start of secondary aggregation by LTA, in the WBA tracing, secretion appears to occur simultaneously with the aggregation response to epinephrine

maximal and stable aggregation responses. The maximal aggregation (maximal change in turbidity relative to the baseline) is the most important endpoint to quantify (Hayward et al. 2009). Other measures that can be reported include the final aggregation (taken at the end of the test) (Cattaneo et al. 2013) which will be lower than the maximal aggregation if there is partial or complete deaggregation (e.g., Fig. 2). The extent of deaggregation can also be quantified by subtracting the percentage final aggregation from the percentage maximal aggregation. Many instruments allow collection of additional numerical data, such as the slope or lag of the aggregation response. Numerical values should be reported along with a reference interval to aid in the interpretation of the findings.

Aggregation curves require visual inspection for proper interpretation. The baseline should be stable before adding the agonist, and tracings should be free of artifacts (e.g., abrupt changes in turbidity from a bubble in the sample, electrical interference or strong vibrations) (Cattaneo et al. 2013).

Tracings will typically show one or two phases of aggregation (Fig. 1). Biphasic LTA responses are typical of some weak agonists, such as epinephrine (Fig. 1), when buffered sodium citrate is used as the anticoagulant (Charo et al. 1977; Lages and Weiss 1980). The second wave of aggregation with epinephrine represents more rapid and extensive aggregation that occurs at the time of dense granule release and thromboxane A_2 generation (Fig. 1) (Charo et al. 1977; Lages and Weiss 1980). Biphasic responses to ADP are normal, but when this agonist is tested at recommended concentrations (e.g., 2–5 μM), the biphasic response may not be evident unless the ADP concentration is titrated downward (in Fig. 2, a more rapid, second wave of aggregation with 5 μM ADP starts at approximately 130 s).

There are differences in LTA responses to epinephrine and ADP for native (undiluted) compared to platelet count adjusted samples whereas the responses to other agonists are very similar (Mani et al. 2005; Cattaneo et al. 2007; Castilloux et al. 2011). Accordingly, LTA findings need to be reported with a reference range that was determined for the specific sample type evaluated. While biphasic aggregation with epinephrine is normal for both sample types, absent secondary aggregation with epinephrine is only abnormal for native samples (Castilloux et al. 2011). Accordingly, laboratories need to know the range of aggregation response patterns expected for healthy control samples, for the specific methods that they use, when they are interpreting the findings.

Aggregation tracings should be routinely inspected for evidence of any de- or disaggregation, which can be quantified (percentage difference between maximal and final aggregation) (Cattaneo et al. 2013). Extensive deaggregation is usually only seen when there is significantly reduced maximal aggregation (Fig. 2). Some deaggregation can be normal with low concentrations of ADP (e.g., 1–2.5 μM final), but it is usually not evident with other agonists, if they are tested at recommended concentrations (e.g., concentrations shown in Table 1). When aggregation responses are delayed, the maximal aggregation achieved is usually reduced.

When a biphasic response is observed with ristocetin, the curve should be inspected carefully as this often reflects a delay in the initial agglutination response (e.g., as seen with significant VWF deficiency, Fig. 3) (Dowling et al. 1975). If there is an impairment in the aggregation response that follows ristocetin-induced agglutination (e.g., as seen in some platelet function disorders, including Glanzmann thrombasthenia, Fig. 4), the maximal aggregation achieved is reduced.

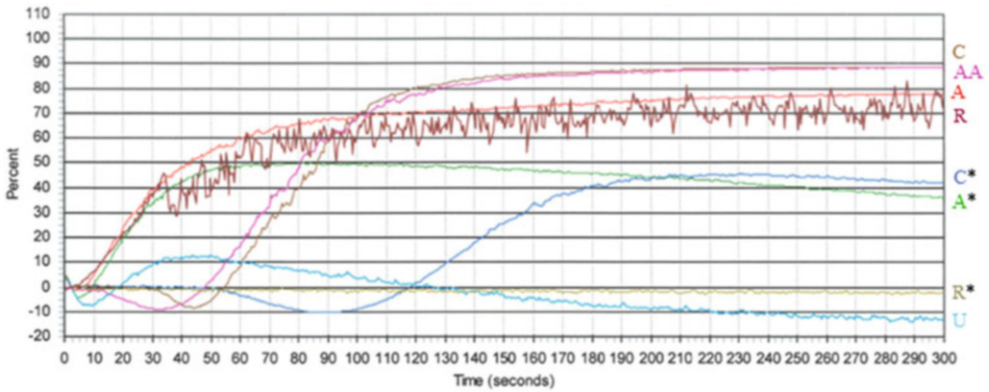

Fig. 2 Example of abnormal aggregation, and deaggregation accompanying reduced maximal aggregation. The subject has a platelet function disorder that is associated with reduced maximal aggregation (abbreviation for agonist, reference interval), and full deaggregation with 1 μM thromboxane analogue U46619 (U, >70 %), in addition to reduced aggregation with 1.25 mg/ml collagen (C*, >51 %) and 1.25 mg/ml ristocetin (R, >75 %). However, there is normal aggregation with 2.5 (A* >24 %) and 5.0 (A, >43 %) μM ADP; 5 mg/ml collagen (C, >85 %); 1.6 mM arachidonic acid (AA, >77 %); and 0.5 (R*, <7 %) and 1.25 mg/ml ristocetin (R, >75 %)

Table 1 Summary of agonists, receptors, and pathways, and recent recommendations on agonist concentrations for testing platelet responses by light transmission aggregometry

Agonist	Receptor(s) and pathway	Concentrations		Additional comments
		Commonly used	ISTH-recommended	
Adenosine diphosphate	Activation through $P2Y_1$ and $P2Y_{12}$, followed by aggregation mediated by $\alpha_{IIb}\beta_3$	2–10 μM	2 μM	Test higher concentration if the response is impaired
Epinephrine	Activation through the α_2 adrenergic receptor (A2AR), followed by aggregation mediated by $\alpha_{IIb}\beta_3$	2.5–20 μM	5 μM	Test higher concentration if the response is impaired
Collagen	Adhesion to α2β1 (adhesion) and activation via GPVI, followed by aggregation mediated by $\alpha_{IIb}\beta_3$	1–5 μg/ml type 1 collagen	A concentration that induces sufficient aggregation of normal platelets (e.g., 2 μg/ml Horm or type 1 collagen)	Test higher concentration if the response is impaired
Arachidonic acid	Requires conversion by cyclooxygenase 1 (COX1) and thromboxane A_2 synthase before activating platelets through the thromboxane A_2 receptor (TP), leading to aggregation mediated by $\alpha_{IIb}\beta_3$	1–1.6 mM	1 mM	Test higher concentration if response is impaired
Thromboxane A_2 mimetic U46619	Thromboxane A_2 receptor (TP) and aggregation mediated by $\alpha_{IIb}\beta_3$	1–2 μM	1 μM	Test higher concentration if response is impaired
Ristocetin	Agglutination of platelets through the binding of von Willebrand factor to GPIbIXV, followed by aggregation mediated by $\alpha_{IIb}\beta_3$	High: 1.2–1.5 mg/ml Low: 0.5–0.6 mg/ml	High: 1.2 mg/ml Low: 0.5–0.7 mg/ml	Test both concentrations or test the low concentration after verifying there is a response to the higher concentration
Thrombin receptor activating peptide (PAR1-AP; TRAP-6)	Protease-activated receptor 1 (PAR1)	5–20 μM	10 μM	Test higher concentration if response is impaired
γ-thrombin (free of α-thrombin)	PAR1 and PAR4	0.5–1.0 U/ml	–	γ-thrombin does not bind to fibrinogen

The final agonist concentrations that are commonly used (25–75 % percentiles for concentrations that laboratories reported using in Cattaneo et al. 2009) and the concentration that are recommended in the 2013 ISTH guidelines by Cattaneo et al. (2013) are summarized

LTA responses to collagen are more complex than with other agonists as the initial phase reflects platelets adhering to, and being activated by collagen fibrils (Jarvis et al. 2002). This results in a more pronounced "shape change" before full aggregation occurs (Fig. 1). At lower collagen concentrations, the shape change and aggregation responses occur more slowly (e.g., Fig. 2).

Whole Blood Aggregometry

WBA is typically assessed using samples of whole blood that are first diluted 50:50 with saline, a step that can be omitted when the sample has a low platelet count (Mengistu et al. 2009). Aggregometry is measured in Ohms of impedance, reflecting the electrical changes that occur when aggregating platelet attach to the electrode, which follows the attachment of a platelet monolayer (Cardinal and Flower 1980; Ingerman-Wojenski et al. 1983; Ingerman-Wojenski and Silver 1984; Swart et al. 1984; Lehmann et al. 1985; Sweeney et al. 1989b; Seyfert et al. 2007; McGlasson and Fritsma 2009). The method does not detect platelet shape change. The timing of release, relative to aggregation, can be more rapid in WBA (Ingerman-Wojenski et al. 1983). Biphasic aggregation responses are often more difficult to detect (Ingerman-Wojenski et al. 1983). As all blood cells are present, the function of all platelets, including those that are very large, are evaluated (Ingerman-Wojenski and Silver 1984). However, the measured WBA with collagen also reflects the attachment of leukocytes, in addition to platelets (Lehmann et al. 1985). On the other hand, responses to ADP (and some other agonists) reflect mainly platelet attachment to the electrode (Lehmann et al. 1985). Despite the differences in the way LTA and WBA are measured, the aggregation curves generally look quite similar (Fig. 1). WBA has the benefit of requiring less sample processing

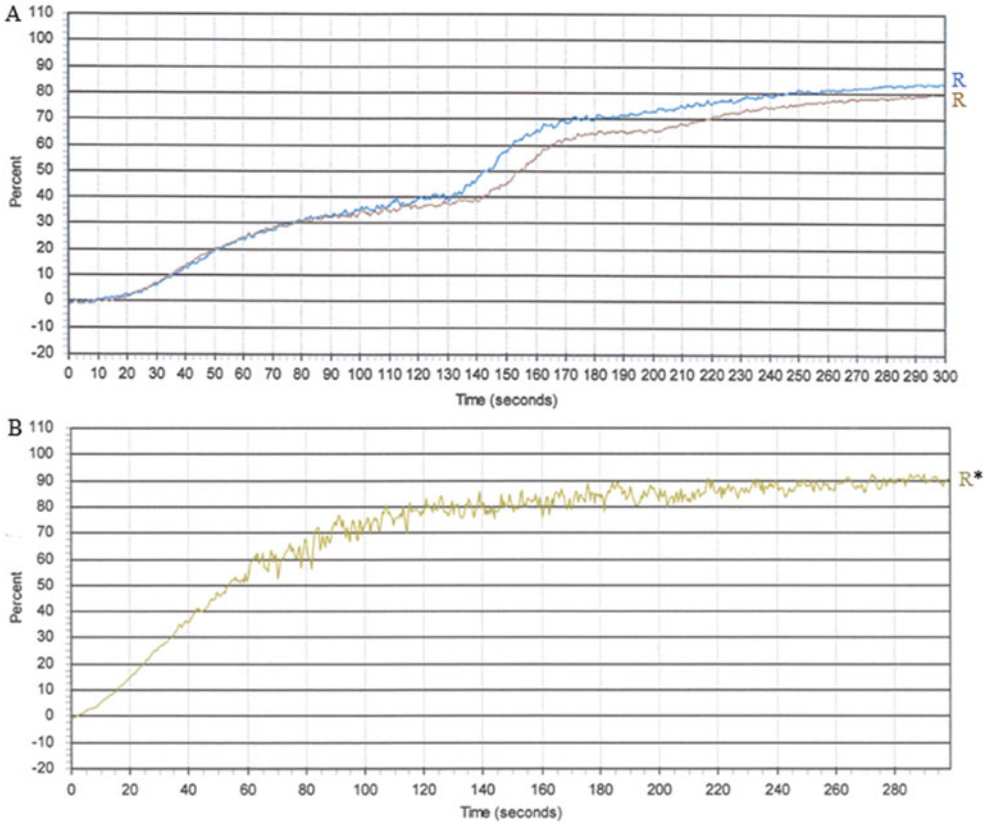

Fig. 3 Abnormal aggregation responses to ristocetin. Panel **A** shows LTA for a subject with type 2M von Willebrand disease who had a pronounced diphasic response to 1.25 mg/ml ristocetin (R, >75 %), due to the impaired agglutination. Panel **B** shows strikingly increased maximal aggregation with 0.5 mg/ml ristocetin (R*, <7 %) due to type 2B von Willebrand disease

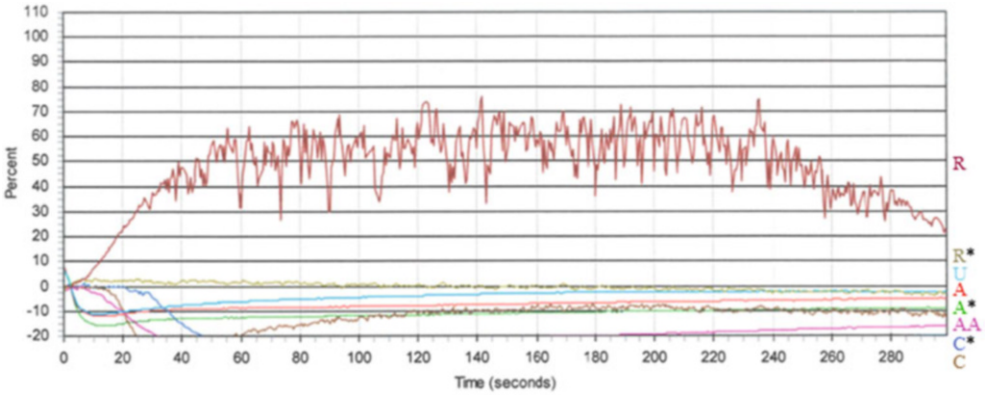

Fig. 4 Aggregation abnormalities due to Glanzmann thrombasthenia. Agglutination is present with 1.25 mg/ml (R) but not with 0.5 mg/ml ristocetin (R*). There is no visible aggregation response to: 1 μM thromboxane analogue U46619 (U); 2.5 (A*) or 5.0 (A) μM ADP; 1.25 (C*) or 5 mg/ml collagen (C); 1.6 mM arachidonic acid (AA). The response to 1.25 mg/ml ristocetin (R, >75 %) is reduced, with some deaggregation, as there is a failure to stabilize the agglutinated platelets due to absent aggregation

prior to testing and it is not affected by lipemia (Cardinal and Flower 1980; Ingerman-Wojenski and Silver 1984; Sweeney et al. 1989a, b, c; McGlasson and Fritsma 2009). Some agonists (e.g., epinephrine) are omitted when testing WBA as absent responses can be normal (Joseph et al. 1987). While LTA and WBA have been evaluated for the diagnosis of bleeding disorders (Weiss 1967, 2004; Ingerman-Wojenski and Silver 1984; Lages and Weiss 1988; Cattaneo et al. 1994; Israels et al. 2003; Hayward et al. 2009; Quiroga et al. 2009; Mezzano et al. 2009; Frontroth et al. 2010; Castilloux et al. 2011), non-inferiority or superiority of one method over the alternative has not been established.

Establishing and Verifying Aggregation Test Reference Intervals

The aggregation responses of platelets to many agonists is not normally distributed (Hayward et al. 2008) and this needs to be considered when developing reference intervals

for the test. The use of nonparametric statistical approaches is recommended as this allows for the estimation of the 95 % confidence intervals, for all types (including non-Gaussian) of data distributions (Hayward et al. 2008; Rubak et al. 2012). For LTA, maximal aggregation does not show a strong association to the sample platelet count for samples collected from donors with normal platelet counts (Castilloux et al. 2011), whereas WBA is strongly influenced by the sample platelet count (Rubak et al. 2012). For low platelet count samples, regression has been used to estimate the 95 % confidence intervals for maximal aggregation by LTA, according to the sample platelet count, for aggregometry samples containing less than 250×10^9 platelets/l (Hayward et al. 2008).

Quality Control of Aggregation Tests

Because LTA and WBA must be performed on fresh samples, ideally within 4 h of collection, the quality control of aggregation tests is often limited to testing a healthy control sample in parallel with a patient's sample, and validating new reagent lots by parallel testing with the current lot (Hayward and Eikelboom 2007; Favaloro 2009; Hayward et al. 2012; Gresele and Subcommittee on Platelet Physiology of the International Society on Thrombosis and Hemostasis, ISTH, 2015). Although most abnormalities are confirmed by repeat determinations (Hayward et al. 2009; Quiroga et al. 2009), it is a reasonable practice to do repeat determinations whenever the amount of aggregation falls outside the reference interval. External quality assurance exercises have been developed to evaluate aggregation test interpretations (Hayward et al. 2012). The other approach that has been tried for aggregometry monitoring is to test a sample spiked with unknown additives to induce a particular type of platelet function abnormality (Favaloro 2009).

Agonists Used to Assess Aggregation Responses

Table 1 summarizes the most commonly used agonists for platelet aggregometry (i.e., ADP, epinephrine, collagen, arachidonic acid, and ristocetin) and the concentrations of these agonists, and of the thromboxane A_2 mimetic U46619 and thrombin receptor acting peptide (PAR1-AP), that are typically used for LTA. Some agonists are used less frequently, including: the thromboxane A_2 mimetic U46619, α- or γ-thrombin, PAR1-AP, PAR 4-AP, convulxin, CRP, calcium ionophore A23187 and PMA (Cattaneo et al. 2009). Such agonists can be considered for secondary investigations of platelet function, as recommended in recent guidelines published by the ISTH (Cattaneo et al. 2013; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015). ISTH has made specific recommendations on the final concentrations of many agonists for LTA (in the aggregation test) in an effort to reduce variations in laboratory practice (see Table 1). It should be noted that the recommended final agonist concentrations, after addition to a sample, differ for LTA and WBA and some agonists (e.g., epinephrine) are recommended for LTA but not WBA (Christie et al. 2008; Hayward et al. 2010; Harrison et al. 2011; Cattaneo et al. 2013; Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015). Evidence suggests that a limited number of agonists detect most common platelet function disorders (Hayward et al. 2009). Experts have recommended using additional agonists for secondary investigations (Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015), although the benefit of testing some of these additional agonists for the detection and diagnosis of common and rare platelet function disorders is uncertain.

The following recommended agonists bind to unique seven transmembrane domain receptors on platelets, and trigger platelet activation and aggregation: ADP, epinephrine, thromboxane analogue U46619, thrombin, and the thrombin receptor activated peptides selective for the protease-activated receptor (PAR) PAR1 or PAR 4 (Gresele and Subcommittee on Platelet Physiology of the International Society on T, Hemostasis 2015; Nurden and Nurden 2014). Collagen, convulxin, and collagen related peptide (CRP) activate platelets through glycoprotein VI and assess aggregation responses induced by glycoprotein VI signaling pathways (Jarvis et al. 2002). Horm or type 1 collagen binds to glycoprotein VI and to the platelet integrin α2β1, which augments aggregation with collagen (Jarvis et al. 2002).

Some agonists that have been recommended for evaluating platelet function lead to platelet activation and aggregation by other mechanisms. For example, arachidonic acid requires multistep, enzymatic conversion by platelet cyclooxygenase 1 (COX1) and thromboxane A_2 synthase, to activate platelets via the thromboxane A_2 receptor which is followed by aggregation (Kinlough-Rathbone et al. 1977; Khan et al. 2015). Calcium ionophore A23187 activates platelets through triggering the release of calcium from intracellular stores, which leads to aggregation (Cattaneo and Lecchi 2001). 4 beta-Phorbol-12-myristate-13-acetate (PMA) activates platelets through effects on protein kinase C, which triggers signaling that leads to aggregation (Yamaguchi et al. 1987; Jerushalmy et al. 1988). Ristocetin is an antibiotic that agglutinates but does not directly activate platelets: it triggers the binding of von Willebrand

factor to glycoprotein IbIXV, which leads to platelet agglutination, which is normally followed by platelet secretion and aggregation due to the close platelet–platelet contact induced by the agglutination (Dowling et al. 1975; Kao et al. 1979; Cattaneo et al. 1989; Sweeney et al. 1989c; Weiss 2004).

Weak and strong agonists have different effects on granule secretion and aggregation (Lages and Weiss 1988; Cattaneo 2009). Strong agonists induce more rapid aggregation than weak agonists and the maximal aggregation achieved is often more variable with weak than with strong agonists (Hayward et al. 2008, 2009; Cattaneo 2009). Weak agonists, such as epinephrine, stimulate aggregation but do not induce dense granule secretion until thromboxane A_2 generation and granule secretion occur (Fig. 1) (Lages and Weiss 1980, 1981, 1988; Cattaneo 2009). With epinephrine, this is manifested by a primary wave (initial slower aggregation) that is followed by more rapid, further aggregation (Cattaneo 2009). With other weak agonists (e.g., ADP), the primary and secondary aggregation waves often appear fused unless the agonist concentration is titrated downward until both waves are evident. Weak agonists can act synergistically, inducing more aggregation when added together than predicted by the sum of aggregation responses to the individual agonists (e.g., synergistic responses to epinephrine and ADP) (Kinlough-Rathbone et al. 1977; Vanags et al. 1992). Synergistic responses are not usually evaluated when aggregation tests are performed for diagnostic reasons. Strong agonists that induce rapid aggregation and simultaneous dense granule secretion can behave like weak agonists, if tested at lower concentrations (Cattaneo 2009). Spontaneous platelet aggregation (i.e., aggregation without an added agonist) is rarely evaluated.

Data from knockout mouse studies indicate that the extent and stability of platelet aggregates are influenced not only by fibrinogen but also by other $\alpha_{IIb}\beta_3$ ligands, such as vitronectin (Hou et al. 2015). Whether vitronectin and other $\alpha_{IIb}\beta_3$ ligands influence human platelet aggregation responses is less certain as there are no human disorder equivalents to these knockout mice.

Adhesive Receptors That Influence Platelet Aggregation

The receptors that support platelet aggregation induced by commonly used agonists are summarized in Table 1. LTA and WBA evaluate platelet–platelet interactions at low shear forces, induced by stirring of the cell suspension. The signaling pathways induced by most agonists lead to activation of the platelet integrin $\alpha_{IIb}\beta_3$, which allows fibrinogen (a dimeric protein) to bind $\alpha_{IIb}\beta_3$ receptors and leads to the formation of aggregates, as fibrinogen forms bridges between $\alpha_{IIb}\beta_3$ receptors on adjacent platelets (Holmback et al. 1996). While $\alpha_{IIb}\beta_3$ is not required for platelet agglutination mediated by ristocetin, the agglutination leads to the activation of $\alpha_{IIb}\beta_3$ (Navdaev et al. 2014). Accordingly, defective aggregation with ristocetin can reflect defects in VWF (Fig. 3), loss or dysfunction of $\alpha_{IIb}\beta_3$ (Fig. 4) or GPIbIXV (Fig. 5), or impairments in platelet activation and signaling that follow ristocetin-induced agglutination and affect $\alpha_{IIb}\beta_3$ activation (e.g., Fig. 7). Gain-of-function defects in platelet agglutination mediated by VWF binding to GPIbIXV occur in type 2B or platelet type von Willebrand disease, which selectively increases aggregation responses to low concentrations of ristocetin (Fig. 3b) (Dowling et al. 1975; Weiss 2004; Othman and Emsley 2014).

Examples of Aggregation Abnormalities Due to Inherited and Acquired Platelet Function Disorders

Defects in aggregation responses can reflect defects in receptors for agonists, adhesive receptors or their ligands, signaling pathways or complex defects. The causes of common inherited platelet disorders, which are often inherited as a dominant trait, are emerging to be caused by mutations in genes encoding transcription factors with key roles in megakaryopoiesis and the production of normal, functional platelets (Bunimov et al. 2013; Hayward 2011; Songdej and Rao 2015). Furthermore, defects that are limited to specific pathway(s) are important but less common causes of platelet function disorders (Bunimov et al. 2013; Freson et al. 2014; Nurden and Nurden 2014).

Figure 4 shows typical aggregation findings for Glanzmann thrombasthenia, which are less severe in variant Glanzmann thrombasthenia, due to activating mutations in either αIIb or β3 (Awidi et al. 2009; Nurden and Nurden 2011; Nurden et al. 2011). When $\alpha_{IIb}\beta_3$ is absent or severely impaired, agglutination is present with ristocetin whereas aggregation responses are absent with all other agonists. Similar abnormalities can be seen in subjects with strong inhibitory antibodies against $\alpha_{IIb}\beta_3$, or that have received treatment with a potent $\alpha_{IIb}\beta_3$ inhibitor.

Figure 5 shows aggregation abnormalities that are typical of Bernard Soulier syndrome (Nurden and Nurden 2011; Noris et al. 2012). In all cases, the hallmark finding is absent

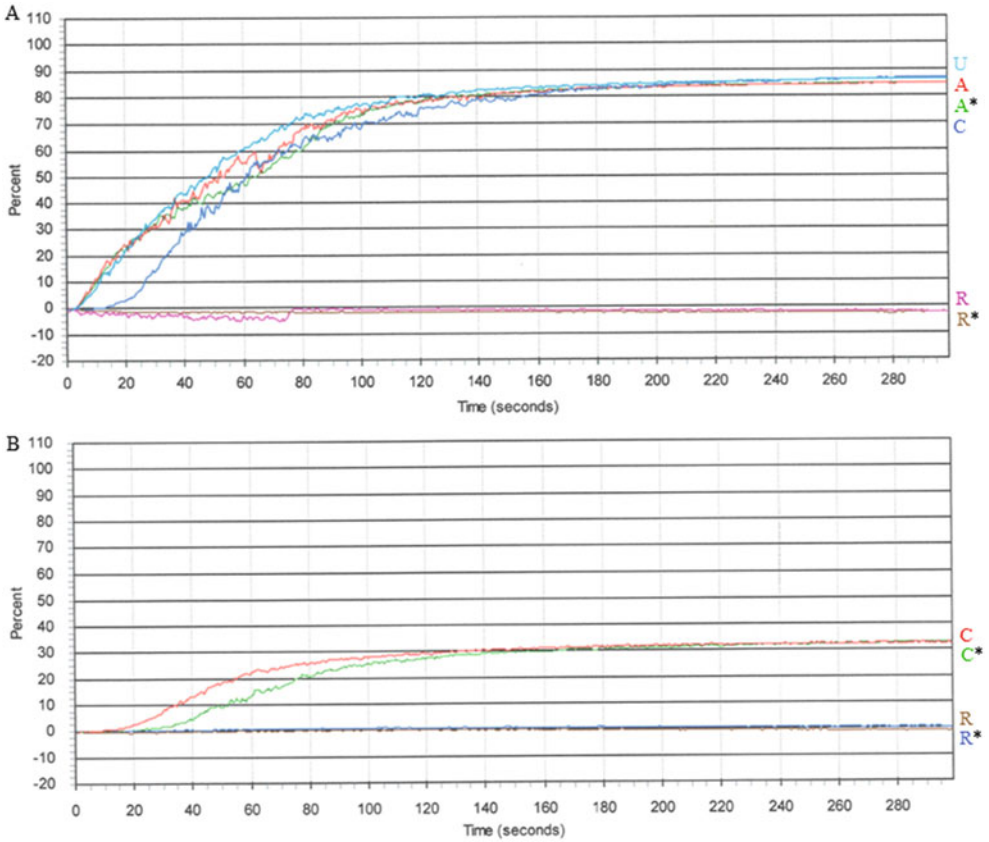

Fig. 5 Examples of aggregation abnormalities due to congenital Bernard Soulier syndrome. Panels show responses for subjects with different degrees of thrombocytopenia (respective sample platelet counts: A: 102 × 10^9/l; B: 17 × 10^9/l). In panel **A**, there is no agglutination with 0.5 (R*) or 1.25 (R) mg/ml ristocetin (R), whereas there is considerable aggregation with 5 µg/ml collagen (C), 2.5 (A*) and 5.0 (A) µM ADP and 1 µM thromboxane analogue U46619 (U). In panel **B**, there is no agglutination with ristocetin and the responses to both concentrations of Horm collagen (C*, 1.25 µg/ml; C, 5 µg/ml) appear reduced but is due to very low platelet count of the sample

agglutination with ristocetin (Fig. 5). In cases with more severe thrombocytopenia, the hallmark finding may be accompanied by reductions in maximal aggregation responses to other agonists, which are attributable to the thrombocytopenia (e.g., Fig. 5 lower panel).

Figure 3a shows an isolated abnormality in the aggregation response to ristocetin, tested at a concentration that agglutinates normal platelets (e.g., 1.25 mg/ml). In this case, the delayed agglutination with ristocetin is due to type 2M von Willebrand disease. Figure 3b illustrates a gain-of-function defect in the agglutination response to a low concentration of ristocetin (e.g., 0.5 mg/ml) in a subject with type 2B von Willebrand disease results in increased agglutination, followed by aggregation (<7 % aggregation is considered normal).

Figure 6 shows aggregation abnormalities that are typical of aspirin and non-steroidal anti-inflammatory drugs (NSAID) that inhibit platelet cyclooxygenase 1 (COX1) but can also result from inherited defects in COX1 and thromboxane synthase (Mustard et al. 1975; Cattaneo et al. 1982). Aggregation is markedly impaired or absent with arachidonic acid; however, the aggregation response to exogenous thromboxane (in this case, thromboxane analogue U46619) is completely normal. With NSAID-induced defects, or inherited, aspirin-like defects, aggregation is typically more impaired with low compared to high concentrations of collagen. Commonly, there is no secondary aggregation response to epinephrine. In some cases, ristocetin-induced platelet aggregation is also impaired. Responses to ADP are typically attenuated compared to responses off NSAIDs, but in many cases, the response to ADP falls within the reference interval for maximal aggregation.

Figure 7 shows aggregation responses to a number of agonists in a subject with impaired platelet function that is evident in both aggregation and secretion tests due to a *RUNX1* mutation. In this example, the responses to arachidonic acid, thromboxane analogue U46619, and the lower concentration of collagen are impaired and there is no secondary aggregation response to epinephrine. There is potential to confuse the findings with aspirin-like defects, which can be avoided by including thromboxane analogue in the panel.

Figure 8 illustrated impaired epinephrine aggregation responses in a subject with Quebec platelet disorder. In this condition, the typical finding is minimal aggregation, or absent secondary aggregation, with epinephrine in LTA assays with either native or platelet count adjusted samples.

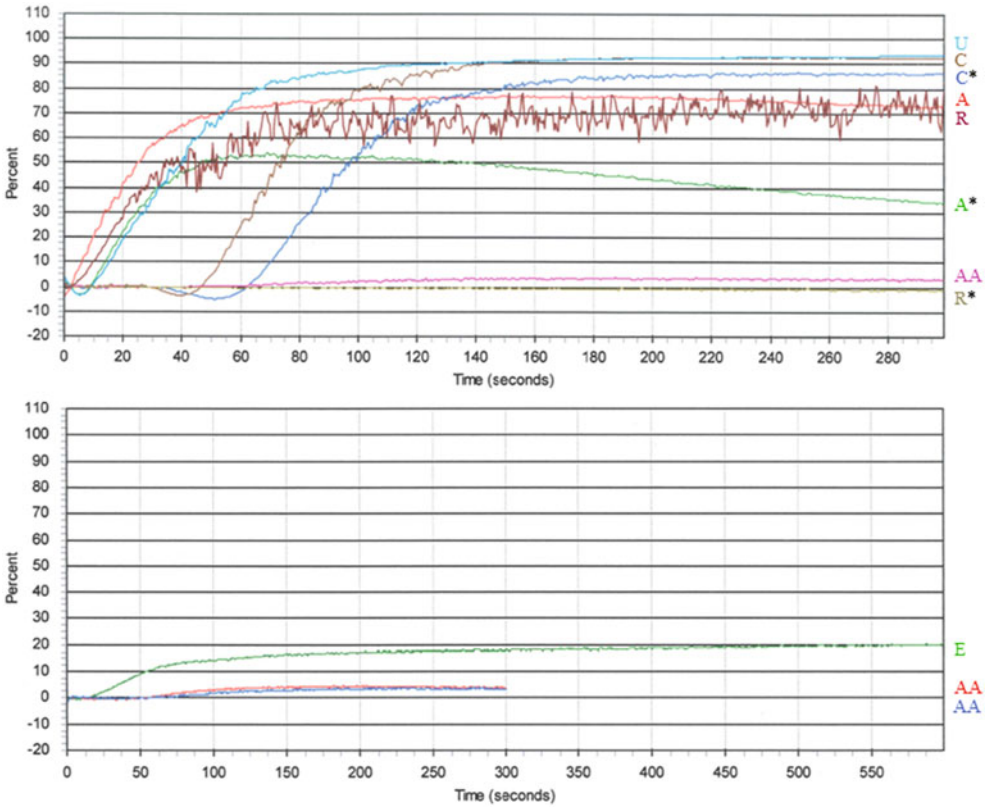

Fig. 6 Impaired platelet aggregation responses due to non-steroidal anti-inflammatory drugs that inhibit cyclooxygenase 1. Based on reference intervals (RI, shown after each agonist abbreviation) for maximal aggregation, there is markedly impaired aggregation with 1.6 mM arachidonic acid (AA >77 %) but a normal response to thromboxane analogue 1 μM U46619 (U >70 %). The maximal aggregation responses to 1.25 and 5 μg/ml Horm collagen (C* >51; C >85 %), 2.5 and 5 μM ADP (A* >24 %; A >43 %) and 0.5 mg/ml and 1.25 mg/ml ristocetin (R* <7 %; R >75 %) are normal. There is a small amount of deaggregation with both concentrations of ADP, which is not normal at the higher concentration. Lower panel: absent secondary aggregation with epinephrine (E) is a typical finding in addition to the reduced aggregation with arachidonic acid (AA)

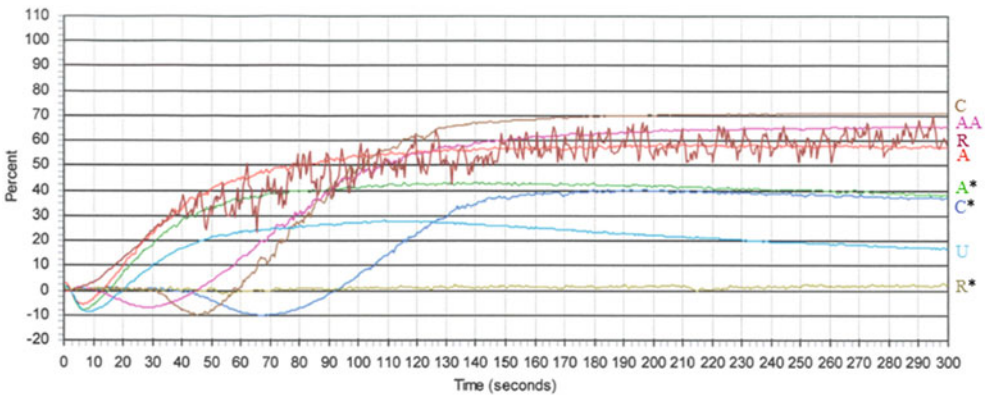

Fig. 7 Impaired platelet aggregation responses from a congenital platelet disorder caused by a *RUNX1* mutation. Based on maximal aggregation reference intervals, there is reduced aggregation with 1.6 mM arachidonic acid (AA >77 %), 1.25 and 5 μg/ml Horm collagen (C* >51; C >85 %), and reduced aggregation and some deaggregation with 1 μM thromboxane analogue U46619 (U >70 %). Responses to 2.5 and 5.0 μM ADP (A* >24 %; A >43 %) and 0.5 and 1.25 mg/ml ristocetin (R* <7 %; R >75 %) are normal

Primary aggregation can be reduced, as illustrated in this example.

Figure 9 shows an aggregation study of a subject with dense granule deficiency. The aggregation findings are typically normal in about one third of cases (as observed for this example), with other cases showing impairments with one or more agonists, and absent secondary responses to epinephrine. Typically, the aggregation responses to ADP are normal when there is an isolated dense granule deficiency, reflecting that adding exogenous ADP can overcome the functional consequences of having reduced platelet stores of ADP and other dense granule components. It can be challenging to distinguish platelet function disorders due to dense granule deficiency from defects that impair platelet secretion due to other causes unless dense granules, or their contents, are directly evaluated.

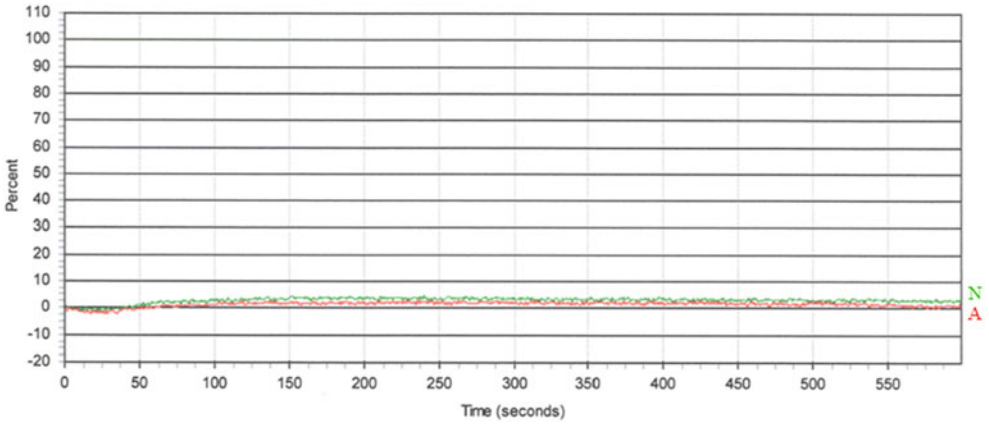

Fig. 8 Impaired aggregation with 6 μM epinephrine due to Quebec platelet disorder. The primary aggregation response to epinephrine is markedly reduced with both native (N) and platelet count adjusted (A) platelet rich plasma. Secondary aggregation is absent

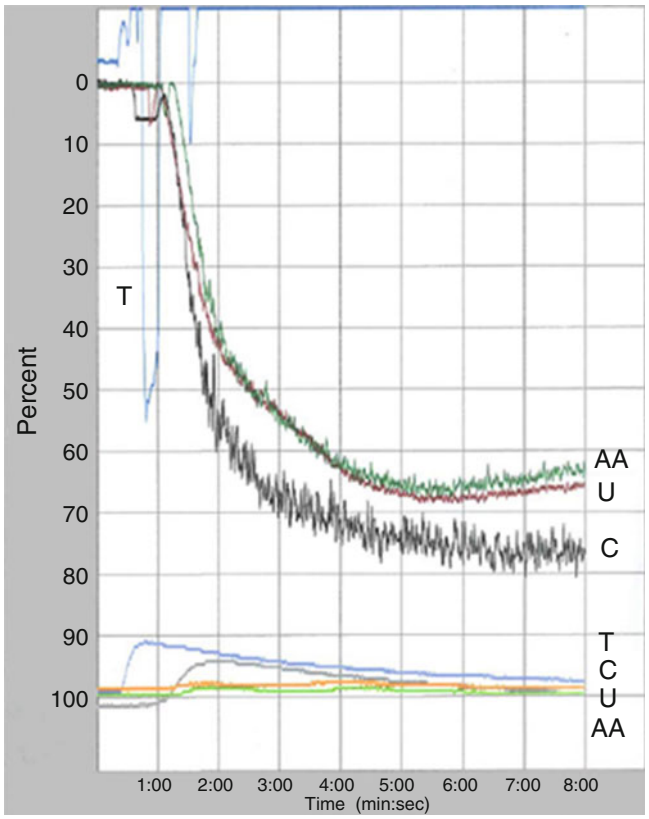

Fig. 9 Aggregation findings for a subject with dense granule deficiency. In this case, there is minimal ATP release (lower tracings) with the strong agonists thrombin (T) and collagen (C), and even less release with arachidonic acid (AA) and thromboxane analogue (U). The aggregation tracing with thrombin shows clotting of the sample

First steps in the clinical interpretation of aggregation findings

It is useful to consider guideline recommendations (Hayward et al. 2010), and the following list of questions, whenever aggregation studies are to be interpreted.

Were the responses for the responses for the quality control sample within reference ranges?

Was the subject thrombocytopenic? If yes, be cautious as a low platelet count affects aggregation responses to many agonists.

Is this a first or a repeat test? If it is a repeat test, the findings should be reviewed with comparison to previous results.

Did the subject have platelets of normal size or were they abnormally large (macrothrombocytopenic? giant?)

Was the sample normal in appearance or lipemic?

Were there any deviations from the standard operating procedure (e.g., was testing completed within 4 h?)

Was the full panel of agonists tested, and if any responses were impaired, was there sufficient sample to retest and confirm all findings outside the reference interval?

If the sample tested by aggregometry had a normal platelet count, consider:

Do any maximal aggregation findings fall below the laboratory's reference range for healthy controls (or above the reference range for the low concentration of ristocetin)? If yes, was there abnormal deaggregation with any of the agonists?

If all aggregation findings were within reference intervals, the test can be reported as non-diagnostic.

*Note: normal aggregation findings only exclude some platelet disorders as some conditions (*e.g.*, dense granule deficiency) are not always associated with*

(continued)

*impaired aggregation responses. Furthermore, some platelet disorders (*e.g.*, MHY9 related disorders) do not typically cause aggregation abnormalities.*

Guidelines have been published to standardize and improve the interpretation of aggregation tests as many diagnostic laboratories that assess platelet function by aggregometry have difficulty with interpreting the findings (Hayward et al. 2010, 2012). The authors approach to interpretation (which considers these guideline recommendations) is summarized in Table 2.

Evaluation of Aggregation Findings for Low Platelet Count Samples

Subjects who have mild thrombocytopenia often have platelet rich plasma platelet counts that are $\geq$ 200–250 $\times$ 10^9 platelet/l, including those with type 2B and platelet type

Table 2 Approach to interpreting aggregation abnormalities, based on the test findings

Aggregation finding	Interpretation
Aggregation is absent or markedly reduced with arachidonic acid, but the response to thromboxane analogue is normal. There may also be reduced aggregation with low concentrations of collagen, and absent secondary aggregation with epinephrine	The aggregation findings suggest an aspirin-like defect, which can be drug-induced or inherited. The drug history should be reviewed, with consideration of repeat testing when subject is not taking aspirin or non-steroidal anti-inflammatory drugs. *Note: If the testing did not include an evaluation of aggregation with thromboxane analogue, the interpretation needs to also state:* There are many other potential explanations for the aggregation abnormalities, which could reflect a congenital or acquired defect in platelet function. If drug-induced causes are excluded, further testing should be considered to evaluate for associated defects in dense granule release and/or dense granule numbers
Aggregation is present only with ristocetin. The extent of aggregation with ristocetin may be reduced	The aggregation findings suggest possible Glanzmann thrombasthenia, which can be inherited or acquired due to drugs, autoantibodies, and other causes. Repeat aggregation studies should be considered, along with flow cytometry studies to assess for $\alpha_{IIb}\beta_3$ deficiency
Aggregation is absent with high concentrations of ristocetin. Records show that the subject has normal von Willebrand factor levels. There may also be thrombocytopenia and very large platelets	The aggregation findings suggest Bernard Soulier syndrome, which can be inherited or acquired due to autoantibodies and other causes. Repeat aggregation studies should be considered, along with flow cytometry studies to assess for glycoprotein IbIXV deficiency
Aggregation is abnormally increased with low concentrations of ristocetin. If available, von Willebrand factor levels should be reviewed	There is abnormally increased aggregation with ristocetin, which suggests the possibility of type 2B or platelet type von Willebrand disease. Further testing should be considered, to exclude a false positive, with consideration of genetic studies if the finding is confirmed and/or associated with abnormalities in von Willebrand factor
Aggregation is impaired with a number of agonists and there is marked impairment in the response to ADP, with significant deaggregation	The marked impairment in ADP aggregation responses suggest the possibility of a defect involving the platelet ADP receptor, P2Y12, which can be congenital or acquired due to drugs. If the history excludes a drug-induced defect, repeat aggregation testing should be considered
Aggregation responses show other abnormalities with $\geq$2 agonists	The interpretation should first state which aggregation responses are impaired and which show deaggregation. The impaired aggregation responses to multiple agonists suggest a platelet function disorder. In this case, the abnormalities are not consistent with Glanzmann thrombasthenia, or a defect induced by aspirin, non-steroidal anti-inflammatory drugs or P2Y12 inhibitors. Further testing should be considered to confirm the findings and to assess for associated defects in dense granule release and/or dense granule numbers
Aggregation is abnormal with only 1 agonist, which is not ristocetin or collagen	The interpretation should state which response is abnormal. A single agonist abnormality is considered non-diagnostic and could represent a false-positive. Repeat aggregation studies should be considered, along with an assessment for defects in dense granule release and/or dense granule numbers

A number of defects have inherited and acquired causes so it is important that the interpretation of findings considers all possibilities. The recommendations in this table consider the North American guidelines (Hayward et al. 2010), and new information on the findings for different congenital platelet function disorders. If dense granule release is performed at the same time as aggregation studies, the interpretation should be modified to describe the results for both endpoints

von Willebrand disease. With some conditions, including Bernard Soulier syndrome, the thrombocytopenia is often much more severe. With some agonists, including arachidonic and thromboxane analogue U46619, minor reductions in sample platelet count can have profound effects on the aggregation response, whereas ristocetin can usually be tested, even if the platelet count of a sample is very low (see Fig. 5). There is more variability in aggregation responses when the sample platelet count is quite low (Hayward et al. 2008). Some laboratories use accumulated data for healthy control samples adjusted with platelet poor plasma to match the platelet count of thrombocytopenic patient samples to guide the test interpretation (Hayward et al. 2008) as was done for the case of Bernard Soulier syndrome shown in Fig. 5b. Laboratories should be prepared to accept aggregation requests for subjects with severe thrombocytopenia, although when the platelet count is very low, testing may not be possible with most agonists, except ristocetin. Failure to accept samples from individuals with thrombocytopenia can compromise the diagnosis of Bernard Soulier syndrome. In a recent quality assurance exercise, many laboratories that perform diagnostic LTA failed to recognize that the case in Fig. 5b was an example of Bernard Soulier syndrome (Hayward et al. 2012). Similar pitfalls likely exist in testing thrombocytopenic individuals for variant Glanzmann thrombasthenia (Nurden et al. 2011).

Pitfalls to Avoid in Aggregation Test Interpretation

Quality assurance exercises, to evaluate the interpretation of LTA, have provided important insights on common errors and pitfalls (Hayward et al. 2012). A number of common mistakes made by clinical laboratories are summarized below. Many of these mistakes could be avoided if laboratories followed guidelines and recommendations on how to interpret platelet aggregation responses (Hayward et al. 2010, 2012).

Common errors in the interpretation of aggregation findings

Failure to recognize normal variants (e.g., no secondary aggregation with epinephrine for aggregation studies performed with platelet count adjusted samples).

Failure to consider that the abnormalities could have congenital or acquired causes.

Failure to report the findings along with a proper reference interval, derived by nonparametric statistical approaches (most agonist responses are not normally distributed).

Failure to consider that use of a limited agonist panel may reduce detection of abnormalities, or the ability to distinguish probable false from true positives.

Failure to check if the patient is taking a potentially interfering substance.

Failure to consider the effect of a low platelet count on platelet aggregation responses.

Attributing an abnormality to a drug, without adequately considering the full range of potential causes, particularly when aggregation is reduced with arachidonic acid, as this can reflect a range of conditions that include secretion defects, with or without dense granule deficiency.

Concluding that a single agonist abnormality is significant when it often represents a false positive (exception: abnormalities that affect only collagen or ristocetin could have a biological explanation).

Concluding that aggregation abnormalities are due to a secretion defect or dense granule deficiency when neither secretion responses nor dense granule numbers were directly evaluated.

Reporting incorrect diagnoses.

Reporting that a finding is diagnostic of a platelet disorder when further testing is needed.

Failure to consider a less common explanation for an abnormality (e.g., platelet type von Willebrand disease when aggregation is increased with the low concentration of ristocetin).

Failure to recognize patterns for rare disorders, such as Glanzmann thrombasthenia and Bernard Soulier syndrome, and/or recommend further testing for these disorders.

Reporting an interpretation that is difficult for a clinician to understand.

Current Challenges in Diagnostic Aggregometry

Since the description of LTA by Born (1962) and O'Brien (1962), there have been only modest improvements in the instrumentation for performing aggregometry, which remains one of the most time-consuming, manual tests performed by coagulation laboratories. There has never

been a prospective study to determine if WBA is non-inferior to LTA, or if one of these methods is superior for diagnosing a bleeding disorder. Such studies are very much needed. Many of the guideline recommendations for aggregometry would benefit from research studies to test expert recommendations. Many laboratories report difficulties with procuring healthy control samples for ongoing quality monitoring of their aggregation assays and for establishing appropriate reference intervals for the test parameters. Few laboratories have assessed their method to validate if their procedure provides adequate detection of common and rare platelet function disorders. There is need for further research to address the value of aggregometry for bleeding disorder diagnosis, and to generate more evidence on appropriate protocols and procedures for diagnosing bleeding disorders using aggregometry. As there are increasing requirements in many developed countries for clinical laboratories to thoroughly validate all non-commercial, "laboratory developed" protocols and methods (which by its nature, includes aggregometry), this poses further challenges to adopting recommendations that lack published evidence. There are emerging complex reasons why platelet aggregometry responses are impaired in many common platelet function disorders. Accordingly, aggregation phenotype/genotype relationships need to be explored to a greater depth in order to develop more evidence-based approaches to the evaluation of platelet function disorders.

Take Home Messages

- Platelet aggregometry is a fifty-year-old method that remains important for assessing platelet function for diagnostic and research purposes.
- Laboratories that perform platelet aggregation testing should be aware of recent guidelines on how to prepare and process samples, test aggregation responses, and how to analyze, interpret, and report the findings.
- Maximal aggregation responses are very important for interpreting aggregation findings, which needs to consider which agonist response(s) are abnormal, and the potential congenital and acquired defects that could cause the observed abnormalities, including preanalytical and analytical errors and false positive findings.
- There is now good evidence that platelet aggregometry is useful for bleeding disorder diagnosis, if performed by validated methods, with appropriate quality controls to verify assay performance, and reference intervals to guide the test interpretation.
- At the present time, LTA remains the best validated aggregometry procedure. Comparison studies would be useful to determine if WBA is non-inferior to LTA for the purpose of diagnosing a bleeding disorder.

Platelet Secretion

Andreas Wersäll, Ewelina M. Golebiewska, and Alastair W. Poole

Abstract

In this chapter, we summarise existing methods for the measurement of platelet δ, α-granule and lysosome secretion, discussing the advantages and disadvantages of their application in both the clinic and research laboratories.

Introduction

Platelet Granules and Contents

Under physiological conditions, platelets are relatively inert circulatory cells primarily engaged in 'surveying' the vasculature in search of damage to the endothelium. A range of extracellular matrix structures are revealed upon endothelial damage that can initiate a rapidly propagating signalling cascade in platelets, which eventually leads to the formation of a stable clot, or thrombus, at the site of vascular injury. In addition, platelet activation leads to the secretion of 300+ bioactive molecules from releasable granules. Platelet secretion remains incompletely understood (Golebiewska and Poole 2013), but it is becoming increasingly clear that it plays a role in physiological and pathological processes beyond the 'traditional' thrombotic/haemostatic scenarios (Golebiewska and Poole 2015).

The function of each of the platelet secretory granules (principally dense granule, α-granule and lysosome) is defined by their contents. The diversity of granule cargoes and specific examples of each granule contents and function are illustrated in Table 1.

Utility of Platelet Secretion Testing

Inherited Storage Pool Disorders

The synthesis and packaging of granules are thought to occur mainly at the early megakaryocyte stage (Machlus and Italiano 2013), but little is known about exact mechanisms of granules sorting and trafficking to their final destination in platelets (Ambrosio et al. 2012). Defective granule synthesis results in storage pool disorders (SPD), where platelets are usually devoid of either dense (δ) granules (Hermansky-Pudlak syndrome, HPS, and Chediak-Higashi syndrome, CHS (Masliah-Planchon et al. 2013)), or alpha (α) granules (grey platelet syndrome, GPS). Bleeding manifestations among SPD patients include spontaneous bruising, epistaxis, menorrhagia and prolonged oozing after trauma or minor surgery such as a tooth extraction (Nurden et al. 2012). Storage pool disorders are one of the most prevalent inherited platelet disorders, with some estimates attributing almost 90 % of platelet disorders to defects in secretion (Mumford et al. 2015). Unlike in cases of severe inherited platelet defects such as Glanzmann's thrombasthenia or Bernard-Soulier syndrome, in which platelets have a profound aggregation defect and diagnosis can be confirmed by measurement of surface glycoproteins ($\alpha_{IIb}\beta_3$ and GPIb-V-IX, respectively), diagnosis of SPD requires a more complex array of tests, and it is likely that a high proportion of SPD patients go undiagnosed. Recently, the International Society on Thrombosis and Haemostasis (ISTH) included α and δ-granule secretion testing as first-line tests recommended for diagnosis of inherited platelet disorders, to rule in or out SPD (Gresele and Subcommittee on Platelet 2015).

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_42

Table 1 Summary of some of the platelet granule cargoes and their functional classification

Granule type	Cargo	Examples	Function
Dense	Small molecules	ADP, ATP, 5-HT polyphosphates	Platelet agonists coagulation cofactor
Alpha	Proteins	P-selectin, vWF	Adhesion molecules
		PF-4, RANTES, PDGF	Chemo/cytokines
		VEGF, SDF-1α	Pro-angiogenic factors
		Endostatin, angiostatin	Anti-angiogenic factors
		Factor V, factor XII Amyloid precursor protein	Coagulation factors Integral membrane protein
Lysosomes	Proteins	β-Hexosaminidase, lactate dehydrogenase, metalloproteinases	Enzymes (clot remodelling)
		LAMP-3	Membrane proteins

Other Secretion Defects

SPD can also develop in response to a number of external factors ('acquired' SPD)—limited reports implicate clinical conditions including idiopathic myelofibrosis (Mouly et al. 2000), lupus (Pareti et al. 1980; Weiss et al. 1980) and renal failure (Soslau et al. 1990) as well as clinical interventions such as tamoxifen treatment (Nayak and Schmaier 2012) and bone marrow transplantation (Sakashita et al. 2001) in causing SPD. While the aetiology of acquired SPD remains unclear, one of the mechanisms may be exposure of platelets to activators such as damaged endothelium, thrombin and immune complexes leading to degranulation and circulation of 'exhausted' platelets (Pareti et al. 1980; O'Brien 1978). Acquired SPD is likely more prevalent than hereditary SPD and can lead to exacerbation of the underlying condition. Platelet secretion testing in those conditions known to be associated with platelet 'exhaustion' may therefore aid diagnosis and treatment. SPD or secretion defects may also arise in platelets during preparation for platelet transfusions (Washitani et al. 1988), in which case secretion testing may be a useful 'quality control' measure for this application (Deckmyn and Feys 2013).

Secretion testing of platelets may also aid in the diagnosis of a range of other systemic disorders associated with membrane trafficking. For instance, familial haemophagocytic lymphohistiocytosis (FHL) subtypes 3, 4 and 5 result from genetic mutation/deletion of Munc13-4, Syntaxin 11 and Munc18-2, respectively, all of which are essential in the secretory machinery of platelets (Golebiewska and Poole 2013; Ye et al. 2012; Al Hawas et al. 2012).

At the other end of the spectrum, an increase in platelet secretion can indicate generalised hyperactivity of platelets, which in turn may lead to increased cardiovascular risk. For example, platelets of diabetic patients have been shown to have increased ATP content and ATP secretion (Guo et al. 2009; Michno et al. 2007). Monitoring platelet secretion in those patients may predict increased risk of cardiovascular disease as comorbidity with diabetes. Equally importantly, the platelet serotonin release assay is 'virtually diagnostic of heparin-induced thrombocytopenia' (Warkentin et al. 2015) when used in appropriate clinical context, allowing for management of this potentially life-threatening adverse reaction to routine heparin treatment (Sheridan et al. 1986).

Platelets as Biomarkers

The platelet secretome is of particular interest in the rapidly expanding array of functions for platelets beyond 'traditional' haemostasis and thrombosis. For example, platelets are known to express several components of the pathway associated with Alzheimer's disease and thus have been used in the search for biomarkers of the disease (Veitinger et al. 2014; Gowert et al. 2014). Platelets are the most prominent peripheral source of APP (amyloid precursor protein), and it has been shown that secretion of a variant sAPP-beta but not sAPP-alpha is significantly increased in Alzheimer's patients (Evin and Li 2012). It is also specifically secreted upon activation of platelets, after cleavage by beta-site APP-cleaving enzyme (BACE1), a secretase associated with Alzheimer's development (Evin and Li 2012; Marksteiner and Humpel 2013). There is therefore a potential for using platelets as a non-invasive source of biomarkers for early Alzheimer's diagnosis.

There is also great potential for platelets as biomarkers in cancer. Platelets have been shown to sequester proteins in the bloodstream, and the concentration of pro-angiogenic markers in platelets, but not in plasma, is increased in the presence of the tumour (Almog and Klement 2010). Platelet factor 4 (PF-4) in particular has been shown to be a marker of early tumour growth in animal models (Cervi et al. 2008). Therefore, measuring platelet secretion can be an indirect means of measuring angiogenic activity in the body.

Methods for Platelet Secretion Measurements

Platelet Preparation Considerations

As with all platelet function studies, it is important to consider how platelets are prepared and/or isolated for assessment of secretion (Cazenave et al. 2004). Whole-blood

(WB) preparations are closest to physiological conditions but also contain a proportionately large volume of anticoagulant and must be constantly mixed by the use of a roller before assessment of secretion. It is for this reason that whole-blood impedance-based lumi-aggregometry is rarely performed and not validated for clinical assessment (McGlasson and Fritsma 2009; Gresele et al. 2014). Platelet-rich plasma (PRP) preparations usually require the use of a centrifuge to isolate platelets together with plasma proteins, which is beneficial to multiple assays due to the lack of red blood cells. However, both PRP and whole-blood preparations are not ideal for ELISAs, microarrays or imaging due to the presence of other blood components—which make interpreting results much harder.

Operators may consider opting for washed platelet (WP) preparations rather than PRP or whole blood in certain instances. These preparations require two separate centrifugation steps, before the platelets are resuspended in HEPES-Tyrode's solution, resulting in a pure platelet suspension with minimal contamination of other blood cells and plasma proteins. Like other platelet preparations, washed platelet preparations require the addition of a specific combination of anticoagulants to prevent platelet activation due to handling, something which should be carefully considered. For example, apyrase, which is sometimes used to minimise P2Y1/12-mediated activation by scavenging free ADP during platelet preparation, may, if used at too high a concentration, block the effect of ADP used as an agonist in the assay. While addition of inhibitors can limit activation, the sensitivity of the response of washed platelets still declines rapidly, and therefore this preparation is most suitable for immediate analysis (Truss et al. 2009). Additionally, washed platelets are highly sensitive to ion concentration and pH of the preparation, and care must be taken to ensure an optimal response is achieved.

Overall, choosing the right preparation will depend upon the type and aims of the assay to be performed (Table 2). It may also be beneficial, where possible, to test different preparations in parallel, e.g. when testing the efficacy of novel anti-platelet therapies, as the presence of plasma proteins can influence drug receptor binding and give different results in whole blood, PRP and washed platelet preparations (Sun et al. 2001; Chlopicki et al. 2012).

Bioluminescent Assays

In clinical settings, lumi-aggregometry is the most commonly used technique to analyse platelet secretion (Gresele et al. 2014) and is one of the primary analyses for the evaluation of any suspected platelet function disorder (Harrison et al. 2011; Lambert 2011; Brass 2010). In this procedure firefly luciferin-luciferase is used to produce a light output proportional to ATP released into the extracellular medium by stimulated platelets (Feinman et al. 1977; Heath 2004). Light output is detected by a photometer, calibrated against a standard of known ATP concentration. It is also possible to measure ADP and AMP release using a modification to this approach that sequentially phosphorylates these nucleotides up to ATP, allowing reaction with luciferin-luciferase. So, addition of pyruvate kinase and phosphoenolpyruvate allows the measurement of ADP,

Table 2 An overview of the main techniques used to assess different types of platelet secretion and the appropriate platelet preparation to be used with each method

	Granule	Marker	Preparation
Impedance-based lumi-aggregometry	δ	ATP	WB
Light transmission lumi-aggregometry	δ	ATP	PRP, WP
Flow cytometry	α	P-selectin, fibrinogen	WB, PRP, WP
	δ	Mepacrine	WB, PRP, WP
	Lys	CD63	WB, PRP, WP
14C/3H 5-HT release assay	δ	ATP	WP
HPLC/LC-MS	δ	ATP, 5-HT	WP
ELISA	α	e.g., P-selectin, PF-4, β-TG	WP
	δ	5-HT	WP
Microarray	α	P-selectin, PF-4, APP, pro-/anti-angiogenic profile, etc.	WP
	δ	5-HT	WP
Lysosomal secretion assays	Lys	β-Hex, LDH	WP
Standard TEM	α, δ	–	WP
Whole mount TEM	δ	–	WP, PRP
Immunofluorescence	α	P-selectin, PF-4	WP
	δ	5-HT	WP

WB whole blood, *PRP* platelet-rich plasma, *WP* washed platelets

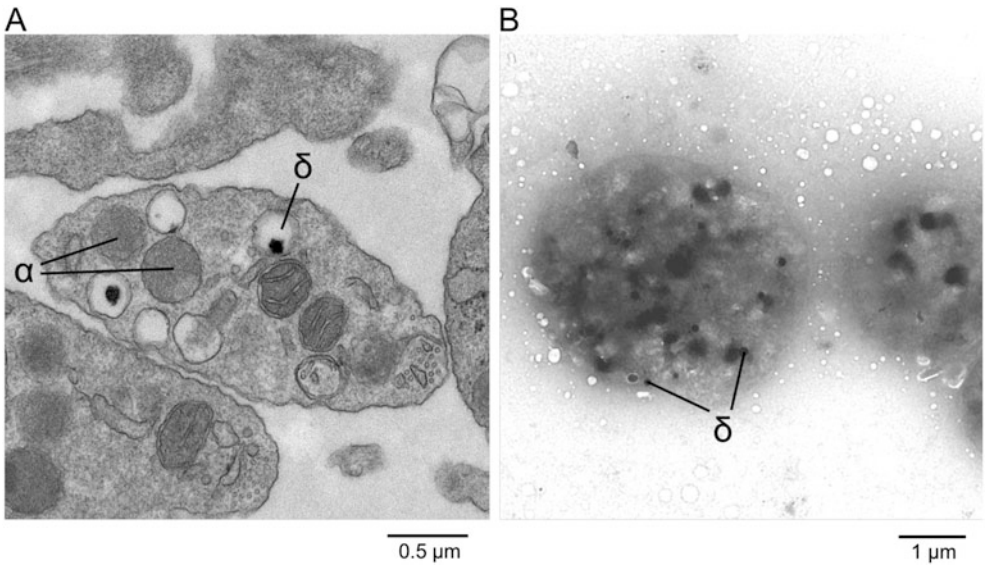

Fig. 1 Images of human platelets generated with TEM using both standard (**a**) and whole mount (**b**) preparations. Standard TEM allows for identification of both δ- and α-granules, whereas it is only possible to reliably identify δ-granules in whole mount preparations due to the lower-resolution achieved. with a further addition of adenylate kinase and cytidine 5′-triphosphate allowing for measurement of AMP release (Heath 2004).

$$\text{ATP} + \text{D-luciferin} + \text{O}_2 \rightarrow \text{AMP} + \text{PP}_\text{i} + \text{oxyluciferin} + \text{CO}_2 + \text{light}$$

$$\text{ADP} + \text{PEP} \rightarrow \text{ATP} + \text{pyruvate}$$

$$\text{AMP} + \text{CTP} \rightarrow \text{ADP} + \text{CDP}$$

As releasable nucleotides are stored in δ-granules (Fig. 1), this technique is classed as a direct measure of δ-granule secretion and is therefore used clinically to detect defects in this type of secretion (Harrison et al. 2011). Historically, lumi-aggregometry has been extremely important to the field of platelet research, allowing for the study of the molecular mechanisms and signalling pathways associated with δ-granule secretion (Golebiewska and Poole 2015). The methodology itself also allows simultaneous aggregation traces to be recorded which can be used clinically to aid the identification of platelet defects.

Lumi-aggregometry may also aid in the discrimination between storage pool defects such as Hermansky-Pudlak syndrome (HPS) (Li et al. 2003; DePinho and Kaplan 1985) and secretory machinery defects such as familial hemophagocytic lymphohistiocytosis type 3 (Nakamura et al. 2015). Calculation of released ATP/ADP ratios may indicate the presence of a storage pool defect if the ratio is >2, because in healthy subjects ADP is released in greater concentrations than ATP with typical physiological ratios being in the 0.65–0.78 range (Holmsen and Weiss 1972; Weiss et al. 1979). However, there are limitations to consider when performing lumi-aggregometry, such as the high rates of intra- and interindividual variability. Patient platelet responses should therefore be tested against a healthy control sample with a panel of agonists over several days (Pai et al. 2011; Lotta et al. 2013). Between laboratories it is also not uncommon to see large variability in ATP secretion results (Moffat et al. 2005), which can make interpretation of multisite studies challenging. Despite these variabilities in lumi-aggregometry for the measurement of platelet δ-granule secretion, its relative ease of use, low price of consumables and rapid acquisition of results mean that it will continue to be used as a valuable research and diagnostic tool. An alternative approach is the use of whole-blood impedance aggregometry coupled with bioluminescence, which in a recent study was shown to be more sensitive to changes in platelet function than optical lumi-aggregometry (McGlasson and Fritsma 2009). This technique is also less technically demanding, particularly since no platelet isolation steps are required for preparation of samples, and is therefore a potentially attractive clinical diagnostic approach.

Flow Cytometry

Clinically, flow cytometry is routinely used to measure surface expression of glycoproteins on platelets in suspected cases of Glanzmann's thrombasthenia and Bernard-Soulier syndrome, but is less often used to measure platelet secretion (Gresele et al. 2014; Nurden and Caen 1974; Shulman and Karpatkin 1980). In the research laboratory, however, it is a commonly used approach for measurement particularly of α-granule secretion. Upon platelet activation and subsequent secretion, integral granule membrane proteins become incorporated into the plasma membrane, upon fusion of granules with the membrane, and therefore become

surface-exposed (Rosa et al. 1987). The plasma membrane bound proteins can then be detected with fluorescently-labelled primary or secondary antibodies and an appropriately calibrated flow cytometer which identifies the platelet sub-population by forward and side scatter values, allowing for the measurement of platelet secretion (Johnston et al. 1987; Tschoepe et al. 1990). Typically the expression of the α-granule marker P-selectin (CD62P) is used as a measure of α-granule secretion (Michelson et al. 2000), although it must be noted that low levels of P-selectin are also present in δ-granules (Israels et al. 1992). A recent study has shown CD40L (CD154) to be present in α-granules (Charafeddine et al. 2012), which could therefore also be used as an α-granule secretion marker—with antibodies readily available for such purposes (Furman et al. 2004). Some studies have however shown the release of CD40L to be slower than other α-granule content, suggesting its measurement may not be properly reflected α-granule secretion, or that it may be localised to sites other than α-granules (Henn et al. 2001; Jin et al. 2001; Nannizzi-Alaimo et al. 2003). CD63 (LAMP-3) expression is regularly used as a marker of both δ-granule and lysosomal secretion due to the presence of this protein in the membrane of both of these secretory granules (Nishibori et al. 1993). Ideally, platelets would be stimulated with a panel of agonists at multiple concentrations (including a vehicle and unstained control) in parallel with a healthy control sample, before analysis by flow cytometry.

Flow cytometry as a technique for analysing both platelet function and secretion has several advantages. In a recent study, nearly 60 % of haematology laboratories surveyed had access to a flow cytometer—making it one of the most accessible techniques in the clinic (Gresele et al. 2014). If access to a flow cytometer is not available, off-site analysis of fixed preparations is also possible and has been successfully performed during multisite testing of anti-platelet agents (Frelinger et al. 2011; Michelson et al. 2007). Fixation of whole blood for flow cytometric analysis at a remote site can be made with proprietary fixative solutions, such as PAMfix (Platelet Solutions, Nottingham, UK), which enables flow cytometric platelet analysis to be undertaken remotely (Dovlatova 2015). Another major advantage of flow cytometry is that relatively few platelets are required for analysis, making it a technique appealing to situations involving both paediatric and thrombocytopenic patients. The possibility of using multiple fluorophores (with appropriate compensation controls) also allows for the monitoring of multiple aspects of platelet function simultaneously, further reducing the number of platelets needed for assessment.

Flow cytometry can also be used to measure platelet δ-granule storage and secretion using a mepacrine (quinacrine) uptake and release assay (Wall et al. 1995; Gordon et al. 1995; Ramstrom et al. 1999). Samples of platelets are incubated with the fluorescent marker mepacrine, which is rapidly taken up into δ-granules (Da Prada and Pletscher 1975; Ambrosio et al. 2012), before analysis of uptake by flow cytometry against a control sample. Mepacrine release is then monitored after platelet stimulation, allowing for calculation of the difference between mepacrine-stained platelets before and after stimulation—quantifying δ-granule secretion. It is therefore suggested that this method would be able to discriminate between δ-granule storage pool defects and secretory machinery defects. However, further validation work will be needed to adopt this approach, since only a handful of groups have currently worked with this technique. The lack of studies could be due to the drawbacks associated with using mepacrine—including rapid loss of fluorescence, retention of mepacrine in the cytoplasm and a semi-quantitative end point (Mumford et al. 2015). It is also possible to use fluorescently labelled anti-5-HT antibodies to detect cargo in δ-granules, which has the potential for assessing storage pool disorders. However, this approach has not been widely reported (Maurer-Spurej et al. 2002) and suffers from the fact that the platelets need to be fixed and permeabilised as part of the preparation steps, introducing potential additional points of variability.

Flow cytometry is therefore a powerful approach for the assessment of platelet secretion in both clinical and research settings. It is a complex technique that requires skilled operators, and the initial cost of purchase and maintenance of the machine is expensive. However, reagent costs are generally low, and there are several smaller and cheaper 'bench top' flow cytometers now available, with parameters more tailored to platelet studies (Masters and Harrison 2014), which will make this technique increasingly accessible to investigators and clinics in the future (Tung et al. 2007).

5-HT Release Assay

Radioisotope Based Assay

Long considered to be the 'gold standard' in measuring δ-granule secretion, the [^{14}C]/[^{3}H] 5-HT release assay was one of the first assays developed to measure platelet secretion and is still used as a diagnostic tool over three decades later (Quiroga et al. 2009; Warkentin 2011). The assay itself is based on the exploitation of 5-HT uptake and release using either ^{14}C-5-HT or ^{3}H-5-HT. A small quantity of radiolabelled 5-HT is incubated with the platelet suspension, which is rapidly taken up into the platelet cytoplasm via the ligand gated ion channel SERT and subsequently translocated into δ-granules via the vesicular monoamine

transporter VMAT2 (Jedlitschky et al. 2012). Platelets are then stimulated with an appropriate agonist (or combination of agonists) causing degranulation and the release of radiolabelled 5-HT into the medium. A scintillation counter is used to determine the amount of released radiolabelled 5-HT, with the final value expressed as a fraction of the total 5-HT content in the platelets.

Overall this assay is fast and relatively cheap—with a recently published study highlighting the reproducibility of the technique (Quiroga et al. 2009). It also benefits from the ability to simultaneously record light transmission aggregometry, which can be used in conjunction with secretion data to evaluate potential platelet defects. Used alongside lumi-aggregometry, the [^{14}C]/[^{3}H] 5-HT release assay also allows operators to deduce if platelet defects are due to δ-granule biogenesis/loading or secretory machinery defects. However, due to its use of radio-isotopes, this assay has fallen out of favour with many laboratories, with only 16 % of ISTH surveyed laboratories now using this method (Gresele et al. 2014). It is also somewhat more laborious and time-consuming, requiring additional pieces of equipment, than luminometric approaches to δ-granule secretion.

Other Approaches

The use of *o*-phthalaldehyde provides another attractive radiolabel-free alternative to [^{14}C]/[^{3}H] 5-HT, which forms a fluorophore with 5-HT in situ (Drummond and Gordon 1974; Holmsen and Dangelmaier 1989). Platelets can then be stimulated with agonists leading to changes in fluorescence, signifying δ-granule secretion, being measured by a plate reader or similar fluorometer (Jedlitschky et al. 2010; Cattaneo et al. 2000).

Recently, a technique capable of measuring real-time 5-HT release has been described based on the electroactive nature of the endogenous serotonin molecules. It uses fast scan cyclic voltammetry, through carbon-fibre microelectrodes, but because of the specialist nature of the equipment required, it is not yet a first choice for routine analysis of platelet function in the clinic (Ge et al. 2011). High-performance liquid chromatography (HPLC) and ELISA-based approaches are also being investigated (see below). The drive to develop new 5-HT detection methods clearly supports its widely accepted clinical utility (Warkentin et al. 2015).

Liquid Chromatography and Mass Spectrometry

Chromatography techniques are powerful approaches to the separation and identification of molecules from complex mixed solutions. They are much more accessible to both researchers and clinicians than previously, largely due to the movement from gas to liquid chromatography-based systems (Adaway et al. 2015). Tandem mass spectral detection continues also to develop rapidly, and systems nowadays are remarkably sensitive as well as being able to deal with complex samples (Seger 2012; Wu and French 2013). They are therefore versatile, but specialist, assays developed to monitor platelet secretion in some haematology and research laboratories (Gresele et al. 2014).

High-performance liquid chromatography (HPLC) has been used to evaluate the storage and release of nucleotide pools in platelets, allowing for the specific separation and detection of adenine, guanine and cyclic nucleotides, with sensitivities down to picomolar concentrations using ultraviolet detectors (D'Souza and Glueck 1977; Leoncini et al. 1987). More recent studies have shown effective assessment of stored and released 5-HT in platelets with the use of HPLC and amperometric (Kumar et al. 1990; Flachaire et al. 1990), fluorescent (Anderson et al. 1992; Sa et al. 2012) and mass spectrometry (Torfs et al. 2012) methods of detection. Due to the highly sensitive measurement capabilities of LC-MS, it has also been suggested that it could be used as a reference method for other techniques (Mumford et al. 2015) and potentially be optimised to measure α-granule and lysosomal secretion.

Although chromatography techniques offer highly sensitive and precise ways to quantify total and secreted concentrations of molecules in platelets, the initial cost and maintenance of LC-MS instruments are very high. The high complexity of the instrumentation usually requires a dedicated operator to direct initial assay development and run samples. The 'static' nature of the assays also means that LC-MS does not readily provide information about the kinetics of platelet secretion (Anderson et al. 1992). For these reasons, its adoption is currently small, but the strength of the approach, coupled with proteomics analytics, means that it could be used to provide large-scale information on secreted products from platelets (Clutterbuck et al. 2011)—making it a strong candidate for advancing platelet 'secretomics' research, with wider-scale clinical applicability in the future.

Immunodetection Techniques

ELISAs

Radioimmunoassays have classically been used to measure concentrations of specific molecules present in platelet preparations or plasma (Kaplan et al. 1978), but have largely been replaced with ELISAs in both research and clinical settings. Studies have shown successful measurement of α-granule secretion using PF4, β-TG and PDGF as markers (Takahashi et al. 1988; Schraw and Whiteheart 2005; Harrison et al. 1994), with δ-granule secretion being

detected with the use of 5-HT as a marker, although the latter was shown to be inferior to an LC-MS method of detection (Torfs et al. 2012). As well as now being widely available commercially, ELISAs also benefit from being relatively easy to perform with all reactions taking place in the same 96-well (or 384-well) assay plate.

Performing an ELISA requires antibodies (or antigens, if antibodies are to be measured in the test sample) to be immobilised to the assay plate before incubation with test samples, which allows complexes to form between the target protein and the immobilised antibodies (Gan and Patel 2013). The test sample is then washed out of the well before the addition of an antibody to detect the bound target protein. This antibody is then itself detected by the use of a secondary enzyme-conjugated antibody, before the addition of a chromogenic substrate for the enzyme which yields a visible colour change or fluorescence—indicating the presence of the target protein. This colour change/fluorescence can then be measured using an appropriate plate reader.

The quality of the output from ELISAs relies upon the binding activity and specificity of the antibody. Naturally this can be a drawback to the technique, with poor performing antibodies leading to both false positives and negatives. Operators must also carefully consider the specificity of expression of target molecules for accurate results.

Although ELISAs are used clinically for the diagnosis of numerous pathologies, including platelet disorders such as heparin-induced thrombocytopenia (Francis 2004), adoption for the measurement of platelet secretion is low. Despite availability of commercial 5-HT ELISA kits, only 1/207 laboratories surveyed by ISTH used it to assess δ-granule content, with no respondents using ELISAs to measure α-granule content or release (Gresele et al. 2014). It is assumed that lack of adoption can be attributed to variability of results and the currently high cost of commercially available assay kits.

Microarrays

Based on the same principle of antigen detection as ELISAs, antibody microarrays offer another method for measuring protein levels in complex samples such as platelet releasates (Wingren and Borrebaeck 2009; Angenendt 2005; Coppinger et al. 2007). This technology works around the ambient analyte model of Ekins and colleagues (Ekins and Chu 1999), where 'microspot' assays which rely on the immobilisation of antibodies (or antigens) on a few square microns should, in principle, be able to detect analytes with greater sensitivity when compared with macroscopic immunoassays. Although much of the methodology and principles of antibody microarrays overlap with ELISAs, they benefit from the significantly smaller sample volumes needed alongside the ability to multiplex multiple antibody probes onto one plate, with 'mega-dense' nanoarrays allowing for up to 10,000 probes to be used (Wingren and Borrebaeck 2007). Detection is achieved with either labelling techniques such as fluorescent dyes and enzyme conjugations, or with label-free techniques such as electrochemical readouts. Although the use of antibody arrays in other fields of medical sciences is now routine, studies into platelet secretion with these techniques have so far been limited (Coppinger et al. 2007).

As the use of immunodetection techniques allows for the quantification of the abundance of specific analytes in platelet releasates, they have the potential to be used in the diagnosis of other pathologies which may indirectly affect the content of platelet granules. In the future, with development of cheaper, more reproducible ELISA- and microarray-based assays of platelet secretion, the potential of 'platelets as biomarkers' can be realised.

β-Hexosaminidase and Lactate Dehydrogenase Activity Assays

Although the physiological role of lysosomal secretion in platelets has not been completely elucidated (Polasek 1989), their release can be altered in disease states and potentially contribute to thrombotic processes and complications (Emiliani et al. 2006). Measurement of lysosomal secretion is achieved with the use of simple colorimetric assays performed in 96-well assay plates which rely on the activity of enzymes secreted from lysosomes in platelets. Typically platelets are stimulated with the desired agonists before centrifugation and transfer of the supernatant to wells of an assay plate. A chromogenic enzyme substrate is then added to the supernatant which causes a colorimetric change that can be measured with the use of a plate reader. In these assays β-hexosaminidase is commonly measured with 4-methyl-umbellyferyl-*N*-acetyl-β-D-glucosaminide, whereas lactate dehydrogenase is measured with a combination of NADH and sodium pyruvate (Rodriguez et al. 1997).

As a whole these assays are very cheap to perform, with reagents available separately or as complete kits from large suppliers. As these assays only measure lysosomal secretion, they present an advantage over the use of flow cytometry, where the use of CD63 fluorescent antibodies detect both δ-granule and lysosomal secretion. They are also readily quantifiable and may provide more quantitative data than flow cytometry. However, because of our lack of understanding of the role of lysosomal secretion, there is currently no clear clinical need for this assay, and this technique is therefore currently reserved for dedicated platelet research laboratories. This was reflected in a recent ISTH survey, with none of the 207 participating laboratories using lysosomal secretion assays to investigate platelet function (Gresele et al. 2014).

Imaging Techniques

Standard TEM

Transmission electron microscopy (TEM) was initially developed as a research tool to observe inorganic materials at ~1000 times greater resolution than could be seen with a light microscope based on the use of electrons as opposed to light waves. With the use of appropriate fixatives, this method was then applied to biological tissues, allowing for the study of the ultrastructure of cells and eventually platelets (Glauert 1979; Wyffels 2001; Clauser and Cramer-Borde 2009). The subsequent widespread adoption of TEM techniques has since given tremendous insights into platelet structure, function and pathological roles. The ability to visualise membranes, secretory granules and the platelet cytoskeleton has also allowed for the use of TEM as a diagnostic tool in conjunction with the previously described functional assays. However, due to the often slow-turn around and specialist workload associated with preparing platelets for TEM, this technique is frequently reserved for special cases where the use of traditional functional assays for the evaluation of platelet secretion disorders alone may not be sufficient.

The observation of abnormalities in both the quantity and appearance of secretory granules is used in the validation of multiple secretory defects such as granule biogenesis and storage diseases. In normal platelets, α-granules are the most numerous and appear as dark electron dense structures with marginally lighter peripheral zones encircled by a visible membrane. In both grey platelet syndrome (GPS) and Paris-Trousseau/Jacobsen syndrome, α-granules appear enlarged (Raccuglia 1971), whereas there are no obvious disparities in Quebec platelet disorder (Hayward et al. 1997). Further investigation with labelling or staining techniques can then be used to identify these specific disorders, with Wright stain marking α-granules as grey in GPS (Raccuglia 1971). The number of δ-granules in platelets is far fewer than that of α-granules (a mean of 5 per platelet), and they are clearly identified due to their morphology—an electron dense core surrounded by a visible 'halo' (Clauser and Cramer-Borde 2009). In δ-storage pool diseases such as HPS and CHS, the number of δ-granules are markedly reduced or completely absent, with the added presence of giant intracytoplasmic lysosomes in the latter (Hardisty and Hutton 1967; Rendu et al. 1983; White 1978).

It is important to consider how platelets are prepared for study by TEM due to the range of methods available and the benefits of each. The most common technique, which also allows for the generation of the highest resolution images, involves treating the platelets with a series of fixative steps before being dehydrated and subsequently embedded in a plastic resin (Clauser and Cramer-Borde 2009). This plastic block is then cut into ultrathin (700 Å) sections using an ultramicrotome before contrast enhancement with heavy metal staining. This method allows the visualisation of the complete platelet morphology, including secretory granules (Fig. 2a). However, operators should be aware that due to the limited number of δ-granules present in platelets, it is possible that cross-section images do not capture them, and therefore numerous sections should be imaged (White et al. 2007).

Whole Mount TEM

For this reason, a whole mount platelet preparation is usually favoured over embedding techniques, and this approach also offers the advantage of relative simplicity and rapid turnaround. In this preparation, small drops of PRP are placed on formvar-coated, carbon-stabilised (or similar) grids which are rinsed briefly with drops of

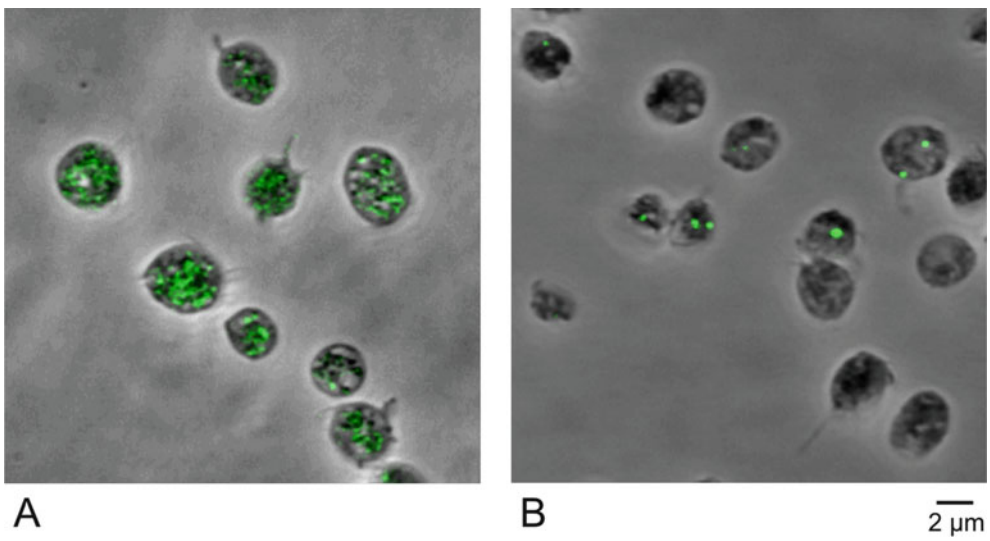

Fig. 2 Human platelets fixed and labelled with fluorophore-conjugated antibodies targeting P-selectin (**a**) and 5-HT (**b**), allowing for the visualisation of α- and δ-granules respectively. Images courtesy of Dr Chris Williams, University of Bristol, UK

distilled water (Witkop et al. 1987). Residual moisture is then air-dried from the grids before imaging via TEM. The images produced with this technique are of a lower resolution when compared directly with embedding techniques, but allow for direct enumeration and visualisation of δ-granules (Fig. 2b). It must however be mentioned that due to the lower resolution, the identification of α-granules can prove difficult, making whole mount preparations unsuitable for the analysis of α-granule defects.

With minor modifications to protocols, TEM also allows for the labelling of proteins at the ultrastructure level with the use of immunogold reagents in both embedded and whole mount preparations (Skepper and Powell 2008; Engelhardt et al. 2007). Due to the level of expertise required for these techniques, they are often limited to dedicated research laboratories. In a similar vein EM preparations utilising the staining properties of serotonin and the natural density of calcium have also been described, but their use is limited due to the complexity of the preparations (Clauser and Cramer-Borde 2009).

Although TEM is not commonly used in clinical laboratories, with only 7 of 202 ISTH surveyed haematology labs having access to an electron microscope (Gresele et al. 2014), it is a powerful technique which can be used as an adjunct to functional assays in the evaluation of platelet secretion disorders, particularly in the diagnosis of δ-granule-related storage pool disorders.

Immunofluorescence

Fluorophore-conjugated antibodies can be used to identify and visualise the locations of specific proteins in fixed platelet samples. This technique can be extended to platelet secretion by targetting specific cargoes such as vWf, fibrinogen and P-selectin for α-granules, with 5-HT being used as a marker for δ-granules (Fig. 2) (Kamykowski et al. 2011; Sehgal and Storrie 2007; Zufferey et al. 2014). Typically washed platelets are fixed before being cryospun onto coverslip and fixative removed before being permeabilised. Permeabilised platelets are then blocked for a brief period of time before incubation with a primary antibody and subsequently a fluorophore-conjugated secondary antibody. Images can then be generated with the use of a fluorescence microscope—allowing for the evaluation of SPDs. Compared with TEM techniques, it is far easier to label molecules of interest with the use of immunofluorescence, but the overall resolution of the images is greatly reduced. Naturally this technique also relies on the performance of the chosen antibody and may therefore require several optimisation steps. Due to the difficulties associated with this form of imaging, it is often only performed in research laboratories.

Concluding Remarks

Platelet secretion is a major positive feedback mechanism driving haemostasis and thrombosis and is therefore routinely assessed in the evaluation of any suspected platelet disorder (Harrison et al. 2011; Israels 2015). Although there is clearly significant value in assessing platelet secretion, in the management of a range of pathological conditions, and although there is a range of different approaches to assess secretion, there are difficulties associated with many of the methods used. Platelet secretion methods have remained principally the same since their first description some 40 years ago: platelets, either in whole blood, plasma or washed, are activated with agonists, and the release of contents into the medium is quantified—yet, little technological advance has been made in the routinely employed secretion test. While these methods may still be sufficient for the purposes of storage pool disease diagnosis, if our understanding of 'non-canonical' roles of platelets is to improve, some developments are needed.

Clinically, lack of standardisation and poor adoption levels are still an issue with platelet secretion assays—in the recent survey by the ISTH, fewer than half of the 202 surveyed haematology laboratories measured platelet nucleotide secretion in the process of diagnosis of potential inherited platelet function disorders, and only a third used α-granule release methods (Gresele et al. 2014). Guidelines for the diagnosis of inherited platelet disorders recommend granule secretion testing (Gresele and Subcommittee on Platelet 2015), yet no technological recommendations were made.

With the advent of high-resolution microscopy and high-throughput analytical methods such as mass spectrometry, there are the beginnings of progress in the field. The decreasing price of commercially available tests with applications to platelets will also facilitate progress in the field; however, for the time being guidelines on the appropriate use of existing tests are required for wider adoption.

Beyond improvements in the affordability and performance of instrumentation, novel methods to assess platelet secretion are still being investigated. The use of thrombin and prothrombinase generation assays to measure secreted platelet factor V have shown promise in quantifying α-granule secretion (Castoldi and Rosing 2011) and could prove useful in both clinical and research environments with the appropriate standardisation (Berntorp and Salvagno 2008; Dargaud et al. 2012). It has also been suggested that δ-granule secretion could be quantified with the use of the fluorescent dye 4′,6-diamidino-2-phenylindol (DAPI), which binds to secreted polyphosphates and can then be analysed by PAGE (Smith and Morrissey 2007). Whether

these methods are adopted in the clinic to measure platelet secretion will depend on further investigation and optimisation by research laboratories.

Take Home Messages

- As well as being a major contributor to haemostasis and thrombosis, platelet secretion is believed to play a role in numerous other physiological and pathological states including blood vessel formation, cancer, autoimmune diseases and inflammatory conditions.
- Evaluation of platelet secretion can be performed in multiple ways, allowing for quantification of distinct types of platelet secretion—as well as the relative contents of secretory granules.
- Recent advances in technology have made techniques such as flow cytometry and ELISA more readily available, allowing for rapid and reliable detection of platelet secretion from small sample volumes.
- Further understanding of platelet secretion and its contribution to disease states will allow for more sophisticated biomarker development and implementation in a variety of clinical settings.

Acknowledgments The authors are grateful to Dr. Ed Brown and Dr. Christopher Williams, University of Bristol, UK, and Dr. Rob Goggs, Cornell University, USA, for the images shown in Figs. 1 and 2. Platelet Activation Under Conditions of Flow

Philip G. de Groot and Rolf T. Urbanus

Abstract

Platelets circulate at high velocity through the vasculature. Due to their small size, they are pushed towards the vascular wall. This allows them to rapidly respond to injuries through the formation of a platelet plug and seal off any defect they encounter. Platelets are continuously exposed to shear forces and are well adapted to changes in rheology. They can withstand huge shear stress and are equipped with receptors that allow them to interact with a variety of extracellular matrix proteins. Most of the knowledge we have on platelet function under conditions of flow was obtained with flow chambers. In recent years, flow chambers have evolved to become a versatile platform for studying haemostasis and thrombosis. This chapter describes several extracellular matrix proteins to which platelets can adhere and the receptors they interact with. Furthermore, it provides an overview of the current state of the art with respect to flow chambers.

Introduction

Platelets are small anucleate cell fragments produced by megakaryocytes in the bone marrow. They contribute to the maintenance of the normal circulation by taking care of the integrity of the vessel wall. They circulate in the blood in a resting state until they are needed and can react immediately when necessary. They continuously monitor the vessel wall for injuries. Their surfaces express specific receptors to support this search. When an injury is detected via a receptor, platelets immediately adhere to the exposed subendothelial structures. Here they rapidly activate and aggregate to form a platelet plug that covers the injury. This plug can stop the bleeding temporarily. To ensure complete healing, a fibrin network should stabilize the clot (Ruggeri 2009).

Platelet adhesion is the first step in the haemostatic response, and knowledge of the mechanisms of platelet adhesion can be an important lead for the development of selective antithrombotic drugs. The adhesive proteins responsible for optimal platelet adhesion to injured vessel walls are different from adhesive proteins involved in the adhesion of platelets to other cells, because platelet adhesion has several unique features. Platelet adhesion takes place in flowing blood, which means that the adhesive process must take place rapidly and that the interaction must be firm enough to resist shear forces exerted on the adherent platelet by the flowing blood. This had led to the evolution of adhesive receptors and ligands unique for platelet adhesion. Flow-based assays are indispensable for understanding the dynamics of platelet function.

Rheology and Platelet Adhesion

Blood is the transport system of the body and flows through the vasculature. Blood flow has a major impact on platelet adhesion. There are two ways in which blood flow influences platelet function: through convection and shear forces (Goldsmith and Turitto 1986). For proteins and cells to initiate a reaction, they need to establish contact with each other. In a test tube, proteins and cells move by diffusion, which is a slow process. To increase the probability of collision in this test tube, reaction substances are always stirred to creating bulk movement of the fluid (convection). Because blood flows, there is a constant supply (and removal) of platelets to the vessel wall, causing a greatly increased number of collisions as compared with static conditions; the greater the flow rate, the higher the number of collisions. In simple reaction kinetics terminology, this means that in the comparative reaction ($V = k$[conc]) the concentration is greatly increased, thus accelerating the reaction. A clear example of this is that the number of platelets that adhere to a surface strongly increases with higher flow rates of the blood (Remuzzi et al. 1985). Only at very high shear rates will the number of collisions become high enough for the reaction kinetics to determine the rate of adhesion. The presence of erythrocytes is important for the adhesion of platelets as well (Aarts et al. 1988). Red cells occupy about 40 % of the blood volume and assemble in the middle of the blood vessel due to their larger size, pushing the smaller platelets outwards to the vascular wall and increasing the concentration of blood platelets near the vessel wall. This implies that a mild bleeding tendency can arise when the haematocrit is low (anaemia).

Shear forces are the forces exerted on the blood cells when they circulate. Shear forces are proportional to the differences in velocity between adjacent fluid layers as they slide along each other. Under laminar flow conditions, the velocity will be greatest in the centre of the blood vessel and zero at the vascular wall. Hence, shear forces are highest near the vascular wall, where the flowing blood interacts with the stationary vascular wall. As this is exactly the site where a thrombus develops, an adhering platelet needs to compensate for these shear forces with a high affinity for vascular wall proteins. To deal with the high shear forces, evolution has provided us with von Willebrand factor (VWF) (Lenting et al. 2015). At low shear stress, blood platelets can adhere to many proteins in the vessel wall. However, when the flow rate increases to arterial blood flow velocities, the presence of VWF is essential for effective primary haemostasis. The mechanism of action of VWF is adapted to its specific function at higher shear forces. VWF is a very long molecule that is irregularly folded in on itself in circulation. In this coiled conformation, the platelet binding sites are not exposed and no interaction with platelets can take place. When VWF binds to the vessel wall, those portions of the molecule that extend outward from the vessel wall are exposed to high shear forces exerted by the blood. This induces the uncoiling of the molecule, leading to the exposure of binding sites for platelets (Siedlecki et al. 1996).

General Mechanism of Platelet Adhesion

The vascular wall is lined with a continuous layer of endothelial cells. Platelets circulate close to the vessel wall without displaying any stable interaction with the endothelial cell lining, because endothelial cells do not express any adhesive proteins that can support platelet adhesion under the shear forces exposed by the flowing blood. Moreover, endothelial cells release prostacyclin and nitric oxide, two low molecular weight components with strong anti-adhesive properties (van Hinsbergh 2012). When the endothelial cell layer is damaged, platelets immediately interact with the exposed subendothelial structures (Ruggeri and Mendolicchio 2015). Stable platelet adhesion requires the interaction between several platelet receptors and matrix proteins. The matrix proteins involved determine the degree of platelet activation and aggregate formation. Which matrix proteins and accessory receptors are involved in the adhesive process depends on the local environment. At higher shear rates, the first interaction of a platelet with the vessel wall will be mediated by VWF (Fig. 1). VWF is present in the subendothelial tissue, in plasma and in the alpha-granules of the platelets and Weibel-Palade bodies of endothelial cells (Savage et al. 2002). After injury, collagens will be exposed to the circulation and the VWF in plasma will immediately bind to these collagens. The initial contact will take place via the GPIb-V-IX receptor complex present on the platelets. This interaction initiates tethering of the circulating platelet to the vessel wall. Driven by shear forces, platelets will roll over VWF in the direction of flow and slow down (Weiss 1995). This enables their interaction with other matrix proteins present in the subendothelium, resulting in firm attachment on the vessel wall. Platelet express many receptors specific for different matrix proteins, the collagen receptors GPVI and $\alpha_2\beta_1$, the fibronectin receptors $\alpha_{IIb}\beta_3$ (historically known as GPIIb:IIIa) and $\alpha_5\beta_1$, the laminin receptor $\alpha_6\beta_1$ and the fibrinogen receptor $\alpha_{IIb}\beta_3$. After adhesion is achieved, the platelet will spread on the surface (Weiss 1995). Spreading is an essential part of the adhesion process, as the multiple interactions of the platelet with the subendothelium enables the platelet to withstand the shear forces exposed by the flowing blood. Each spread platelet provides a new surface for a next platelet to adhere and is the basis of a platelet aggregate. There is a certain similarity between adhesion and aggregation. Both for adhesion and aggregation

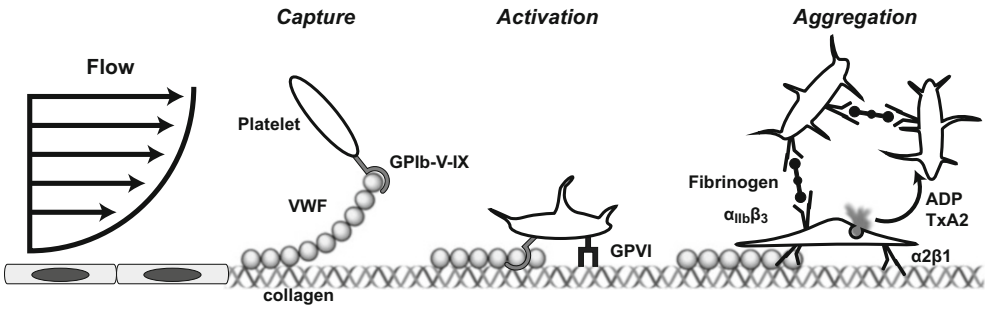

Fig. 1 Platelet adhesion to the injured vascular wall. Platelets are captured from the circulation by collagen-bound VWF through an interaction with the GPIb-V-IX receptor complex. Platelets will tether and adhere to the vascular wall, after which they become activated through the interaction of GPVI with the exposed collagen. The activated platelets will spread on the surface and form tight interactions with VWF through the integrin $\alpha_{IIb}\beta_3$ and with collagen through the integrin $\alpha_2\beta_1$. In addition, they release several soluble agonists, such as ADP and thromboxane A2 (TxA2), which will activate other platelets. This will result in aggregation of platelets

circulating platelets must attach to an adhesive protein, while shear forces are applied on the adhering platelets by the flowing blood. Both VWF and fibrinogen are major players in both processes.

Perfusion Chambers for the Study of Platelet Adhesion

Since the 1970s, major advances have been made in the development of flow chambers for the study of haemostasis. By pumping blood through a chamber with well-defined geometries at a certain infusion rate with a syringe pump, wall shear rates can be accurately controlled. The first flow chambers consisted of a rod on which an inverted dissected blood vessel was placed, which was then placed inside a cylinder through which blood was perfused (Baumgartner and Haudenschild 1972). By varying the distance between the rod and the outer cylinder, shear rates could be controlled. Although this allowed the evaluation of platelet-vessel-wall interactions, the analysis of platelet adhesion and fibrin formation was time consuming and labour intensive. These annular flow chambers were rapidly replaced with parallel platelet flow chambers that consist of two rectangular plates between which the perfusion channel is located (Sakariassen et al. 1983). The wall shear stress (τ) (in Pa) in these chambers depends on the height (h, in m) and width (w, in m) of the chamber, the volumetric flow rate (Q, in m^3/s) and the viscosity of the fluid (μ, in Pa·s) and can be calculated with the following equation (Slack and Turitto 1994):

$$\tau = \frac{6Q\mu}{h^2 w}$$

Flow in these chambers is laminar, as the conditions used to study arterial or venous shear rates are typically associated with a low Reynolds number (Re). Reynolds numbers in rectangular flow chambers can be calculated according to the following equation:

$$\mathrm{Re} = \frac{D_h v \rho}{\mu},$$

in which

$$v = \frac{Q}{A}$$

and D_h is the hydraulic diameter (m), v is the average velocity of the fluid (m/s), A is the cross-sectional area of the flow channel (m) and ρ is the density of the fluid (kg/m^3). For rectangular tubes with a high aspect ratio, the hydraulic diameter equals 2 times the height of the chamber (Fox et al. 2004), as

$$D_h = \frac{2h}{1 + \frac{h}{w}}$$

Flow is considered laminar when the $\mathrm{Re} < 2300$.

One of the plates in a parallel plate perfusion chamber typically consists of a polycarbonate slab, whereas the other plate is a glass or plastic coverslip, which can be coated with a variety of adhesive surfaces. The flow channel can be either cut into the polycarbonate slab or made by placing a silicon gasket in between the two plates. A major advantage of these chambers is that they allow detailed microscopic analysis of thrombus formation. Whereas the first models of the parallel plate perfusion chamber required large amounts of blood to achieve the desired wall shear rate, current designs allow analysis of platelet function with only several hundred microlitres of blood.

With the development of microfluidic devices, the volumes of blood needed to study platelet function have

decreased even further. Soft lithography has allowed researchers to design flow chambers with features down to a few μm, resulting in flow chambers that require microlitres rather than millilitres. In general, soft lithography is based on the fabrication of a positive relief master, on which a replica of polydimethylsiloxane (PDMS) is subsequently moulded (McDonald et al. 2000) (Fig. 2). Researchers can simply design any flow chamber with the dimensions they desire, which is then printed on a transparency at high resolution. This transparency is used as a photomask to create a master on a silicon wafer that has been spin coated with a photocurable epoxy such as SU-8 to the desired height of the flow channel. In this procedure, the photomask is placed in close contact with the wafer, after which the wafer is exposed to UV light. This will induce cross-linking and polymerization of the epoxy substrate. Unpolymerized epoxy is then washed away with a developing solution, after which the master mould is ready for replica moulding with PDMS. Hereto, a volume of PDMS is added to the master mould and cured at 60 °C. The resulting PDMS flow chambers can then be attached to a variety of surfaces, such as glass or the fluoropolymer ACLAR.

The possibilities of PDMS flow chambers are many, as it is relatively easy to create chambers with a stenosis (Nesbitt et al. 2009) or posts that divide the flowpath (Herbig and Diamond 2015). Due to their small size and the excellent optical properties of PDMS, these chambers are highly suitable for analysis of platelet adhesion in real time with differential interference contrast or fluorescence microscopy. Soft lithography has also been used to make scaffolds for 3D cultures of endothelial cells in a hydrogel, leading to the formation of engineered microvasculature with a continuous endothelial lining (Morgan et al. 2013; Zheng et al. 2012). These microvessels can be used to study angiogenesis and the interaction of platelets with the vessel wall.

Adhesive Substrates

Von Willebrand Factor

The gene for VWF is located on the short arm of chromosome 12. Transcription of the VWF gene results in a pre-pro-VWF precursor protein of 2813 amino acids (Ginsburg et al. 1985). The precursor protein is composed of a signal peptide of 22 amino acids, a propeptide of 742 amino acids and a mature protein of 2050 amino acids. The mature protein contains four structurally different domain types, arranged in the sequence D′-D3-A1-A2-A3-D4-C1-C2-C-C4-C5-C6-CK (Zhou et al. 2012). VWF is a multimeric protein and this multimerization is essential for its function. Two VWF subunits are dimerized via a C-terminal disulphide bridge in the endoplasmic reticulum. A second disulphide bridge is subsequently formed in the trans-Golgi network via the N-terminal D′-D3 domains, which requires the release of the propeptides (Vischer and Wagner 1994). VWF is synthesized by endothelial cells and megakaryocytes. In both cases, VWF is targeted to storage organelles: Weibel-Palade bodies in endothelial cells and α-granules in platelets (Sporn et al. 1985; Wagner et al. 1982). It can be released

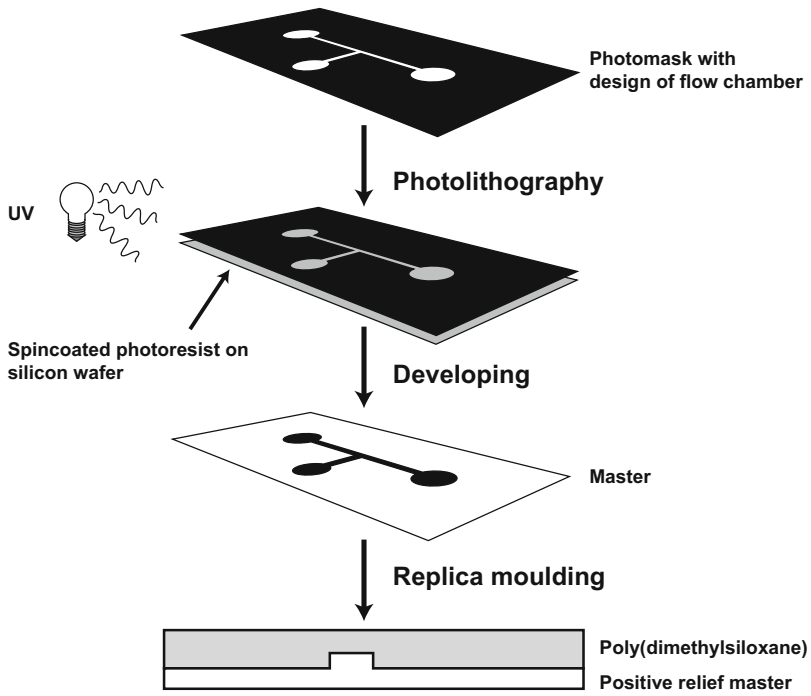

Fig. 2 Soft lithography for the design of microfluidic flow chambers. A design of a microfluidic device is printed on a transparency at high resolution. This is placed on a silicon wafer that has been spin coated with a photocurable epoxy to the desired height of the microfluidic device. The epoxy polymerizes after exposure to UV light, after which the unpolymerized epoxy is washed away with a developer solution. The resulting positive relief master can be used for replica moulding of hundreds of poly(dimethylsiloxane) microfluidic devices

from both storage sites upon activation of these cells. After release, VWF can self-associate with VWF from the circulation, creating extremely large fibres (Savage et al. 2002). Spontaneous self-association of plasma VWF has been described to occur in regions of flow deceleration under high shear conditions (Nesbitt et al. 2009) and can be mimicked in flow chambers with a stenosis or posts that divide the flowpath (Herbig and Diamond 2015). These fibres are an ideal runway for the circulating platelets. Self-association may involve thiol-disulphide exchange (Choi et al. 2007). Apart from activated release, endothelial cells also secrete VWF constitutively. This process is thought to be the predominant source of VWF in plasma. Experiments in flow chambers with cultured human endothelial cells show that stimulation of these cells with a secretagogue such as histamine induces the release of ultralarge VWF (Dong et al. 2002). These VWF fibres can span several millimetres in the absence of the protease ADAMTS13 (Zheng et al. 2015), a condition encountered in patients with thrombotic thrombocytopenic purpura (TTP). This endothelium-suspended ultralarge VWF provides an adhesive surface for platelets that can be visualized as "beads on a string" (Fig. 3). However, secreted VWF will be rapidly cleaved in the presence of ADAMTS13, which prevents platelet adhesion (Dong et al. 2002).

VWF has three major functions. It is essential for the adhesion of platelets to injured vessel walls, it is involved in platelet-platelet interaction at higher shear rates and it is the carrier protein in plasma for factor VIII. Without VWF, factor VIII is rapidly cleared from the circulation (Lenting et al. 2010). VWF circulates in plasma with an average plasma concentration of 10 μg/mL and the average concentration in platelets is 280 ng/10^9 platelets (Rodeghiero et al. 1992). The normal range of plasma VWF is broad and is strongly influenced by the ABO blood group, with 25 % lower levels in blood group O and higher levels in blood group AB (Sarode et al. 2000). Interestingly, platelet VWF is independent of blood group (Matsui et al. 1999). Low VWF levels will result in a bleeding tendency while high levels of VWF are correlated with a thrombotic tendency.

After a vascular injury, circulating VWF immediately binds to the exposed collagens present in the subendothelium via the A3-domain (Romijn et al. 2003). Binding of VWF results in the exposure of a cryptic epitope in the A1-domain of VWF, which will be recognized by GPIbα (Auton et al. 2010), one of the subunits of the GPIb-V-IX complex on the platelet membrane. This interaction will result in rolling of platelets over VWF in the direction of flow, allowing the platelet to interact with other matrix protein to reach stable interaction. During this rolling process, the platelet will interact with VWF through other receptors as well. One of these receptors is the $\alpha_{IIb}\beta_3$ integrin, which can bind an RGD sequence in the C4-domain of VWF (Berliner et al. 1988). The importance of the interaction of VWF with the GPIb-V-IX complex is illustrated in patients with Bernard-Soulier syndrome who fail to produce a functional GPIb-V-IX complex (Ware et al. 1993) and have a moderate to severe bleeding tendency.

The crystal structure of the complex of the VWF A1-domain and the N-terminal fragment of GPIbα has been solved (Huizinga et al. 2002). The crystal structure of the complex shows that the globular A1-domain interacts with the concave face of GPIbα with two distinct areas of tight interactions, one at the top and one at the bottom of the A1-domain. One would expect that the lifetime of the bond between GPIbα and VWF would diminish with force. However, there are indications that the bond between GPIbα and VWF increases with increased shear stress. This would suggest that the interaction between GPIbα and VWF behaves as a catch bond (Yago et al. 2008), in which interactions become stronger when force is applied. However, detailed molecular analyses of the interaction between VWF-A1 and GPIbα indicate that the bond between the two molecules switches between two distinct states with slip-bond characteristics, a low-affinity state and a high-affinity state (Kim et al. 2010). Application of force to the bond between VWF and GPIbα causes the transition of the low-affinity state to the high-affinity state, probably due to a conformational change in VWF.

Binding of GPIb-V-IX complex to VWF induces platelet activation, converting $\alpha_{IIb}\beta_3$ into a high-affinity receptor for different ligands (Andrews and Berndt 2004). This is an essential step in platelet spreading and stable adhesion. How GPIb-V-IX contributes to platelet activation and thrombus formation is controversial and seems to be dependent on the shear stresses exposed.

Patients with low or absent VWF suffer from a bleeding tendency known as von Willebrand disease (VWD)

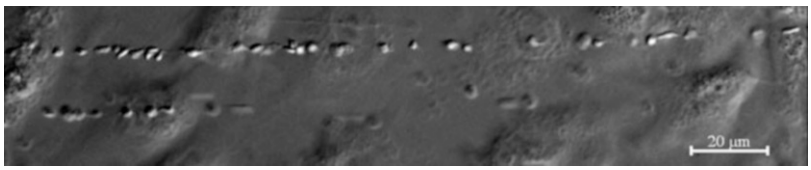

Fig. 3 Platelets adhere to VWF strings attached to the endothelium. Endothelial cells were grown to confluence and stimulated with histamine. Washed platelets were perfused over the endothelial cells at a shear rate of 100 s^{-1}

(Ng et al. 2015). VWD is classified into three major types. VWD type I is characterized by a partial deficiency of VWF and is the most common type. Nowadays plasma levels of VWF between 20 % and 50 % are considered a risk factor for bleeding, while VWD type I is diagnosed when VWF levels are below 20 %. Type III is a very rare condition in which VWF levels are below 1 %. In contrast to types I and III, which are quantitative deficiencies, type II VWD is characterized by qualitative defects. Type II is divided into four subtypes. Type 2A is characterized by deficient large multimers and consequently a reduced function. Type 2M is the result of a mutation in the A1-domain of VWF resulting in a loss of interaction with GPIb-V-IX complex. Type 2M has a normal multimer pattern. Type 2B is characterized by an increased affinity of VWF for GPIb-V-IX complex. As the consequence of the mutation, the cryptic epitope in the A1-domain of VWF is already expressed in the circulating plasma VWF. As a result patients also suffered from thrombocytopenia and the highest multimers of VWF are absent. Type 2N mutations result in deficient factor VIII binding and haemophilia A-like symptoms.

Collagens

Collagens are distinguishable from other extracellular matrix proteins by their triple-helical conformation. All fibrillar collagens have a very similar tertiary protein structure and are composed of three peptide chains (α-chains). The amino acid sequences of these α-chains show two unique features. There is a glycine residue at every third position, generating a repeating $(Gly\text{-}X\text{-}Y)_n$ pattern, and there is a high proportion of proline and hydroxyproline (Hyp) on the X and Y position, respectively. These features are essential to establish a stable triple helix (Farndale et al. 2003). The triple helix conformation always consists of three parallel polypeptide chains that are staggered by one amino acid residue. The glycine residues are buried in the backbone of the helix while the X and Y are exposed on the outside. The amino acids on the X and Y position determine the specificity of collagens for certain interactions. Platelet GPVI recognizes a repeat of the Gly-Pro-Hyp motif (Morton et al. 1995), and $\alpha_2\beta_1$ recognizes a Gly-Phe-Hyp-Gly-Glu-Arg motif (Knight et al. 1998). VWF specifically recognizes an Arg-Gly-Gln-Hyp-Val-Met-Gly-Phe sequence, a highly evolutionary conserved sequence (Lisman et al. 2006). Interestingly, this complex sequence overlaps with the binding site for a number of other proteins, such as SPARC (osteonectin) and discoidin domain receptors 1 and 2 (Hohenester et al. 2008). This sequence is not present in collagen type I, and analysis of a crystal structure of the peptide with the A3-domain of VWF showed that VWF recognizes amino acids from different collagen I polypeptide chains present in the same helix structure (Brondijk et al. 2012).

Collagens are the most abundant proteins in mammals. The collagen family comprises 28 members that contain at least one triple-helical domain (Mienaltowski and Birk 2014). At least seven different collagens have been identified in the vessel wall, of which collagen types I, III, IV and VI are able to support platelet adhesion. Collagens are insoluble proteins, and the methods used to solubilize them in order to test their reactivity in vitro could influence their structural integrity. The fibrillary structures of collagens in vivo display a different banded pattern compared to the in vitro formed fibrils (Farndale et al. 2004). Also, interactions of collagens with other matrix proteins might influence their reactivity towards platelets. Matrix metalloproteinases will degrade the fibres which will result in disappearance or exposure of reactive sites (Guglielmini et al. 2015). The affinity of collagen receptors for collagens strongly depends on the conformation of the collagen fibrils. The in vitro experiments on platelet interaction with different types of collagen might underestimate the role of collagens in vivo. Experiments with genetically manipulated collagens in animal models should help us to understand the exact role of collagen in platelet adhesion.

Although several collagen receptors on platelets have been proposed (Nuyttens et al. 2011), GPVI and $\alpha_2\beta_1$ are the only collagen receptors that have been shown to be relevant because deficiencies of these receptors result in mild bleeding disorders. Other proposed receptors such as GPIV (CD36) seem unlikely, because 5 % of the Japanese population is deficient for this receptor without consequences for their platelet function (Masuda et al. 2015). Platelet adhesion to collagen is strongly affected by the presence of Mg^{2+} and Ca^{2+} (van Zanten et al. 1996). Platelet adhesion to collagen is stimulated by the presence of Mg^{2+} whereas Ca^{2+} has an inhibitory effect.

Experiments with triple-helical collagen peptides have indicated shear-dependent differences in the requirements for collagen receptors during platelet adhesion. The VWF binding site enhances thrombus formation at all shear rates, but is only required at high shear rates ($>3000\ s^{-1}$). Whereas the presence of both the integrin $\alpha_2\beta_1$ and GPVI binding sites is necessary for platelet adhesion at a low shear rate, the presence of either binding site in combination with the VWF binding site is sufficient for platelet adhesion at a shear rate of $1000\ s^{-1}$ (Pugh et al. 2010).

Fibrinogen

Fibrinogen is not a structural component of the vessel wall, as it is not synthesized by vascular cells. Nevertheless, it is

present in the vessel wall as the result of adsorption from plasma. Platelet adhesion to fibrinogen has received much attention, because fibrinogen is the dominant plasma protein that adsorbs to biomaterials such as stents and grafts. The adsorbed fibrinogen provides an ideal surface for platelet adhesion (Hantgan et al. 1990) (Fig. 4). Moreover, the adhesion to a fibrin network is a key event in the haemostatic response (Miszta et al. 2014). The integrin $\alpha_{IIb}\beta_3$ is the major receptor for both fibrinogen and fibrin at all shear rates. Fibrinogen has three potential epitopes that are able to interact with $\alpha_{IIb}\beta_3$. There are two RGD sequences in the α-chain of fibrinogen and an AGDV sequence at position 407–411 of the γ-chain. Different studies have shown that the RGD sequences are not important for platelet adhesion, while the sequence in the γ-chain is essential (Hantgan et al. 1995; Zaidi et al. 1996). The binding of soluble fibrinogen to platelets only takes place after stimulation of the platelets. Stimulation of platelets opens the $\alpha_{IIb}\beta_3$ integrin. However, fibrinogen that is adsorbed to a surface supports the adhesion of non-stimulated platelets via the $\alpha_{IIb}\beta_3$ integrin (Savage and Ruggeri 1991).

Platelet adhesion to fibrin and fibrinogen at high shear rates not only depends on $\alpha_{IIb}\beta_3$ integrin, but also on a secondary interaction between the GPIb-V-IX complex and VWF (Endenburg et al. 1995). This latter interaction is necessary for the adhered platelet to withstand the shear forces. Recent studies have shown that VWF is incorporated into fibrin in the presence of thrombin (Miszta et al. 2014). Because fibrin is rapidly formed in vessels with low shear rates, the contribution of fibrin to the adhesion process might be more relevant in the venous circulation. A recent study has identified GPVI as a third platelet receptor for polymerized fibrin (Mammadova-Bach et al. 2015). Due to its function in platelet activation, GPVI-fibrin interaction results in amplification of thrombin generation. Earlier studies failed to identify the proposed role of GPVI in the adhesion of platelets, probably because all in vitro studies on platelet adhesion to fibrin were performed in citrated blood. Interestingly, a single nucleotide polymorphism in GPVI was identified as a risk factor for venous thrombosis in a large study on genetic variants associated with venous thrombosis (Bezemer et al. 2008).

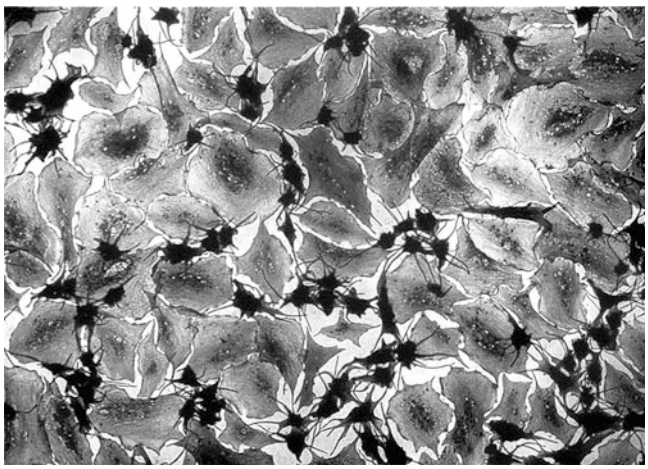

Fig. 4 Platelet spreading on a fibrinogen-coated surface. Human platelets were allowed to adhere to fibrinogen for 30 minutes

Fibronectin

Fibronectin is a ubiquitous glycoprotein composed of two structurally similar but not identical subunits of approximately 220 kDa, linked by a pair of disulphide bonds. The two chains are different due to alternative splicing in the so-called III connecting segment (Huelsz-Prince et al. 2013). Fibronectin is present in two forms: as a soluble plasma form and as a high-molecular-weight aggregate that is present in tissues. Fibronectin is an essential adhesive protein and involved in many fundamental biological processes. Platelets contain two receptors for fibronectin on their surface, $\alpha_5\beta_1$ and $\alpha_{IIb}\beta_3$ (Ginsberg et al. 1993). Mice without $\alpha_{IIb}\beta_3$ are unable to form platelet thrombi under these conditions (Smyth et al. 2001), suggesting that fibronectin can function as an adhesive protein for platelets. Indeed, mice conditionally deficient in fibronectin show delayed thrombus formation (Ni et al. 2003). However, mice triple deficient in VWF, fibrinogen and fibronectin show more platelet adhesion than mice deficient in VWF and fibrinogen, suggesting that fibronectin inhibits the adhesion process (Reheman et al. 2009). Different roles of plasma and tissue fibronectin might complicate the whole issue. In vitro, fibronectin is a rather poor substrate for platelet adhesion (Beumer et al. 1994). Interestingly, a splice variant of fibronectin known as EDA-fibronectin that is normally present in the extracellular matrix but is detected in plasma in certain diseases has been found to increase in vivo and in vitro thrombus formation (Chauhan et al. 2008). There are at least 20 different isoforms of fibronectin in humans (White and Muro 2011). The exact function of fibronectin in platelet-vessel wall interactions might be difficult to elucidate due to the presence of all of these isoforms.

Thrombospondin

The thrombospondin family consists of five members (Halper and Kjaer 2014). Platelets contain thrombospondin-1 in their α-granules. After platelet activation, thrombospondin-1 is secreted, binds to the platelet membrane and mediates adhesion (Wencel-Drake et al. 1985). In vitro, thrombospondin-1 can support platelet adhesion at high shear rates (up to 4000 s^{-1}). The primary receptor involved in the adhesion

to thrombospondin-1 is GPIb-V-IX; however, the adhesion to thrombospondin-1 seems to be independent of VWF (Jurk et al. 2003). A secondary role for GPIV (CD36) has been suggested. The subendothelium contains thrombospondin-2 and its absence in mice has been associated with a haemostatic defect (Kyriakides et al. 1998). However, whether this is a causal relation is not certain and the significance of the thrombospondins for optimal platelet adhesion is not known.

Laminin

Laminin is a ubiquitous basement membrane protein. Two forms of laminin, laminin 8 and laminin 10, are highly expressed in the subendothelium. Platelets contain laminins 8, 10 and 11, which are secreted after activation (Nigatu et al. 2006). In vitro, the laminin molecule shows a cross-shaped structure with a molecular weight of 850 kDa. It is build up of three distinct chains, and it interacts with collagen type IV and heparan sulphate proteoglycans to form the structural part of the basement membrane. Platelet adhesion to laminin is mediated by the integrin $\alpha_6\beta_1$ (Hindriks et al. 1992). Adhesion to laminin is strongly dependent on the presence of Mg^{2+} and Ca^{2+}. Platelet adhesion to laminin via $\alpha_6\beta_1$ does not result in activation of platelets. The interaction of GPVI with laminin is reported to mediate platelet activation after adhesion to laminin, resulting in lamellipodia formation (Inoue et al. 2006).

Vitronectin

The contribution of vitronectin to thrombus formation is controversial. Mice deficient in vitronectin show impaired thrombus formation that can be restored by administration of vitronectin (Reheman et al. 2005). Additional experiments show that thrombi formed in the absence of vitronectin are unstable, suggesting that vitronectin is involved in platelet-platelet contacts and not in primary adhesion of platelets to the vessel wall (Wu et al. 2004).

Platelet Interaction with Other Components of the Vessel Wall

In general, all tissue components that are able to interact with platelets can contribute to platelet adhesion and thrombus formation. The extracellular matrix is a complex system in which many proteins and proteoglycans interact with each other. These interactions might also involve binding sites that are thought to be involved in platelet adhesion. Some proteins might modulate platelet interaction with the vessel wall, which will never be observed in experiments with purified proteins. As said, purification of the often insoluble proteins could also influence their adhesive properties. Moreover, some proteins exist in plasma as well as the subendothelium and both forms are not necessarily identical. Experiments with the plasma form of the protein not always reflect the properties of the matrix form. Experiments with purified proteins will teach us about the receptors involved and the subsequent consequences for the activation of the platelet, but whether it reflects the in vivo situation remains to be established.

Regional Differences Within the Growing Thrombus

With the improvement of visualization techniques, our view of the growing thrombus has changed significantly. Traditionally, the growing thrombus was viewed as a mass of activated platelets interspersed with fibrin fibres, wherein several activation pathways work in concert throughout the growing thrombus to create a haemostatic plug. Studies with high-resolution real-time in vivo confocal microscopy have led to a nuanced view of the same process, as there appear to be large regional and temporal differences in platelet activation status and in the availability of soluble platelet agonists within the thrombus. By injection of fluorophore-conjugated antibodies against P-selectin, fibrin or platelet markers such as GPIbα or the α_{IIb} integrin subunit into the blood stream of the mouse, it has become possible to study the temporal and spatial differences in platelet activation upon vascular injury (Dubois et al. 2007; Falati et al. 2002; Hayashi et al. 2008; Stalker et al. 2013). We now know that those platelets that are directly adhered to the site of injury are fully spread, have released the content of their granules and form a tight, densely packed, interconnected mass. Together, they form the dense core of the growing thrombus (Dubois et al. 2007; Hayashi et al. 2008; Stalker et al. 2013). The layers of platelets that are added to this dense core region by the flowing blood are progressively less activated, depending on their distance from the site of injury. The platelets in this boundary layer have not released the content of their granules and make up the shell of the thrombus (Stalker et al. 2013). In vitro models with side-view microfluidic flow chambers show a similar thrombus architecture and are promising tools for further investigation into the dynamics of thrombus formation in human samples (Welsh et al. 2012).

By using fluorescently labelled proteins or dextrans of varying molecular weight, it has become possible to study differences in packing density in the growing thrombus (Stalker et al. 2013). Platelets will contract during the consolidation of the dense core of the thrombus, resulting in even smaller gaps between adjacent platelets through which soluble agonists can diffuse. This results in the formation of

a microenvironment that is protected from the influences of shear stress and blood flow and causes the retention of locally produced agonists (Welsh et al. 2014). Thrombin formation appears to be limited to the core of the growing thrombus and the surrounding endothelium (Ivanciu et al. 2014; Welsh et al. 2012). This makes sense, as the relatively large size of thrombin would prevent its diffusion from the densely packed platelets at the core of the thrombus. The soluble platelet agonists ADP and thromboxane A2 are much smaller and will diffuse readily through the different layers of activated platelets. As only the platelets present in the core of the thrombus express P-selectin, these platelets are the source of ADP (Dubois et al. 2007; Hayashi et al. 2008; Stalker et al. 2013). The ADP that diffuses from this layer causes mild activation of the platelets in the shell region of the thrombus, but does not lead to granule secretion, allowing further growth of the thrombus. The importance of ADP in growth of the shell region is illustrated by the consequences of inhibition of ADP-induced platelet activation with P2Y12 antagonists (Fig. 5). Whereas the densely packed, P-selectin positive core region remains similar in size under these conditions, the size of the shell region is substantially reduced (Stalker et al. 2013). Conversely, thrombi formed in mice with a gain-of-function mutation in $G_{i\alpha}$ that renders platelets more sensitive to stimulation of P2Y12 show a marked increase in shell size (Stalker et al. 2013). These observations explain the relative safety of P2Y12 antagonists over $\alpha_{IIb}\beta_3$ antagonists.

The Interplay Between Coagulation and Platelets

Collagens and thrombin are widely regarded as the most important platelet agonists in vivo. When platelets are captured from the circulation and firmly adhere to the site of injury, they will be rapidly activated through the interaction of GPVI with the exposed subendothelial collagens, which leads to both $\alpha_{IIb}\beta_3$ activation and granule release. At the same time, thrombin formation will be initiated in the extravascular tissue and the damaged endothelium immediately adjacent to the site of injury. Thrombin will cleave fibrinogen, leading to fibrin formation, and will cause additional platelet activation. Studies with Fcγ-knockout mice lacking a functional GPVI collagen receptor emphasize the relatively minor contribution of GPVI in the formation of the platelet plug, as stable thrombi formed in the absence of GPVI (Mangin et al. 2006). Moreover, congenital deficiency of GPVI is usually associated with a mild bleeding phenotype in humans (Kojima et al. 2006; Moroi et al. 1989; Takahashi and Moroi 2001). The importance of thrombin in the formation of a stable thrombus is illustrated by the greatly decreased expression of P-selectin in the region covering the site of injury in mice treated with hirudin (Stalker et al. 2013). As the thrombi formed under these conditions mostly consist of mildly activated platelets, they are likely to embolize and will eventually be sheared away by the flowing blood.

Anticoagulation

Traditionally, platelet adhesion is studied in blood anticoagulated with calcium chelators such as sodium citrate or coagulation inhibitors such as heparin, pentasaccharide, Phe-Pro-Arg-chloromethylketone (PPACK) and the newer direct oral anticoagulants, thereby fully excluding the influence of thrombin and fibrin on the formation of thrombi. The evidence derived from animal models has prompted researchers to further investigate the complexities of the interplay between coagulation and platelets. Ex vivo, this can be achieved when blood is drawn directly from the antecubital vein of the donor through the flow chamber, but these kind of experiments usually require large volumes of blood and are associated with significant contact activation in the tubing (Heyligers et al. 2006; Kirchhofer et al. 1994; Orvim et al. 1997). For this reason, most researchers prefer the use of (minimally) anticoagulated blood. During blood collection, contact activation will rapidly cause clotting. Collecting blood in tubes with corn trypsin inhibitor

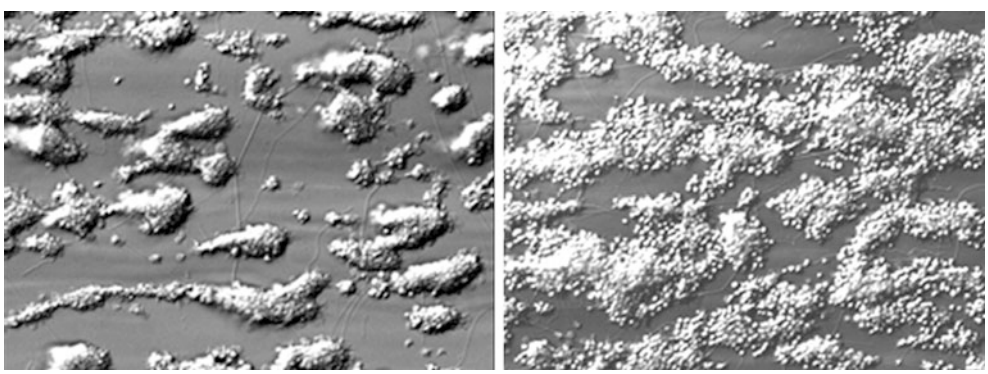

Fig. 5 P2Y12 inhibition greatly reduces thrombus height. Whole blood from a healthy donor (*left*) and a donor receiving clopidogrel treatment (*right*) was perfused over a collagen-coated surface at 1200 s^{-1} for 5 minutes, after which the thrombi were perfused with buffer

(CTI), a specific FXIIa inhibitor, will postpone contact activation, but does not prevent the activation of FXII entirely (Rand et al. 1996). Samples collected in CTI should therefore be processed within minutes of venepuncture. Newer inhibitors of contact activation such as direct FXIIa inhibitors such as infestin-4 (Hagedorn et al. 2010) or blocking anti-FXI antibodies (Cheng et al. 2010) are currently under investigation. An alternative to blocking the contact pathway is the recalcification of citrated whole blood. Trisodium citrate chelates Ca^{2+}, Mg^{2+} and Zn^{2+} ions but leaves metal ion-dependent proteins such as integrin $\alpha_{IIb}\beta_3$ intact. Recalcification with a mixture of Ca^{2+}, Mg^{2+} and Zn^{2+} fully restores the coagulation potential of a blood sample at the expense of dilution.

Coagulation Under Conditions of Flow

Physiologically relevant coagulation reactions start with the exposure of blood to tissue factor (TF). TF has been introduced in flow experiments in several ways. Endothelial cells have been grown to confluence on glass coverslips, stimulated with phorbol 12-myristate 13-acetate (PMA) or TNFα to fully activate the quiescent endothelium and subsequently lysed with NH_4Cl to create subendothelial matrix that contains TF, as well as VWF and fibronectin (Zwaginga et al. 1990). Others have directly adsorbed lipidated TF onto the wall of the flow channel or attached lipidated TF to the immobilized collagen (Welsh et al. 2012). As there is evidence for a surface TF threshold for fibrin formation, it is important to calculate TF surface density (Okorie et al. 2008). By conjugating a fluorescent thrombin sensor to an antibody that targets the platelet surface, thrombin formation can be visualized in real time in the growing thrombus (Welsh et al. 2012). Whether or not the targeting of the thrombin sensor to platelets provides an accurate representation of thrombin formation in vivo remains to be determined, as recent evidence suggests that the prothrombinase complex is primarily present on the endothelium directly adjacent to the vascular injury and not on the platelets present in the thrombus (Ivanciu et al. 2014). The role of the contact system in thrombus formation has received renewed attention since the description of the protective effect of FXII-deficiency on thrombus formation in murine arterial thrombosis models (Renné et al. 2005). Polyphosphates are stored in platelet dense granules and are released after platelet activation (Ruiz et al. 2004). They have been shown to support contact activation (Muller et al. 2009), but have also been shown to enhance coagulation reactions independent of FXII (Morrissey et al. 2012). Most of the data on the role of FXII and polyphosphates in thrombus formation are derived from murine models, and translation of these findings to the human situation is difficult. Flow chambers with TF- and collagen-coated surfaces provide a means to study the role of platelet polyphosphates during thrombus formation under standardized conditions. Data derived from such studies indicate that the effect of polyphosphate on thrombus formation can occur independent from FXII (Zhu et al. 2015).

Conclusions

Platelet adhesion under conditions of flow is a complex process in which many adhesive proteins and receptors participate. The development of new perfusion devices has led to major advances in our understanding of the mechanisms that are responsible for platelet thrombus formation on injured vessel walls in flowing blood. The in vitro results obtained with perfusion chambers and purified matrix proteins in the past are now challenged by observations made with genetically modified mice. We now know that there are major regional differences in platelet interaction with the vessel wall and we begin to understand the roles the different adhesive proteins and receptors play locally. But there is still a lot to do. There is an ongoing debate on how the different matrix proteins are involved in the activation of the adhered platelets. Until now, we have focused on the prothrombotic roles of adhesive proteins without thinking on the possibility that some proteins might modulate the prothrombotic properties of other adhesive proteins (Agbanyo et al. 1993). Our knowledge on the interplay between platelet function and coagulation is still limited. The observation that patients with Glanzmann's disease can be efficiently treated with factor VIIa points to an intense interaction (Poon 2007). The role of fibrinolysis is underestimated as well. Finally, thrombus formation predominantly takes place on atherosclerotic vessels and our knowledge on the changes that have taken place in the composition of the subendothelial structures in an atherosclerotic vessel are limited. The newly developed flow chambers in which a stenosis or a bifurcation has been introduced will teach us about the specific influences a sudden change in shear forces will have on thrombus formation.

Take Home Messages

- Platelets can interact with a variety of extracellular matrix components.
- Soft lithography in combination with positive relief moulding provides a versatile means for the manufacturing of microfluidic devices from poly (dimethylsiloxane) (PDMS).

(continued)

- Advancements in visualization techniques and real-time video microscopy have led to a better understanding of thrombus dynamics.
- With the development of disposable microfluidic devices, it has become possible to study the interplay between coagulation and platelets in vitro.

In Vivo Imaging of Thrombosis and Hemostasis

Anil K. Chauhan

Abstract

Hemostasis and thrombosis are complex processes, which require blood cellular components as well as plasma components. In vivo imaging is a powerful tool that is beginning to provide quantitative and dynamic insights into the field of thrombosis and hemostasis. This chapter provides an overview, how in vivo imaging provides an opportunity to complement and confirm data generated from in vitro studies in the physiological context.

Introduction

In the last two decades, in vivo imaging has significantly contributed to advancing our understanding of the field of hemostasis and thrombosis. Although in vitro experiments are instrumental in asking fundamental questions about mechanisms at the cellular or molecular levels, they fail to take into account the complex architecture and physiology of multicellular tissues. For this reason in vivo imaging was developed to allow researchers to test concepts generated in vitro and provide new insights in the physiological context. The aim of this chapter is to highlight the power of in vivo imaging to address questions in the context of thrombus formation that cannot otherwise be answered, due to the limitations of in vitro studies. I will provide an overview by discussing instrumentation and other components required for in vivo imaging, types of vessels studied in models of experimental thrombosis, methods of inducing vascular injury, effects of mechanical ventilation in experimental thrombosis, and methods of visualizing and quantifying data.

Equipment for In Vivo Imaging

To image platelet adhesion and thrombus formation in real time, one requires a wide-field microscope (inverted or upright), appropriate objectives, a bright or fluorescent light source, a high-speed camera, software, and a computer to acquire images. Microscopes can be equipped with a motorized XY stage that allows precise computer-controlled lateral movement between XY positions and a Z control to allow rapid changes in the focal plane. The in vivo imaging systems in our laboratory are developed utilizing a Nikon F1 fixed stage (upright microscope) and a Nikon TI-U inverted microscope (Prakash et al. 2015a, b; Dhanesha et al. 2015). The upright microscope has CF1 Fluor 10×, 20× (numerical aperture (NA), 0.50), 40× (NA, 0.80), and 60× (NA, 90) water-immersion objectives. The inverted microscope has CFI Super Fluor (10×, 20×, and 40×) objectives. The microscopes have motorized Z control and are equipped with a Lambda DG-4 high-speed wavelength switcher based on dual scanning galvanometers from a 175-W xenon light source with ET-Sedat Quad filters (402 ± 8 nm, 490 ± 10 nm, and 555 ± 12 and 645 ± 15 nm) matched to individual filter sets for DAPI, FITC, Cy3, and Cy5 (Chroma, Brattleboro, Vermont) in the body of the microscope. These components allow for simultaneous collection of images in two or three fluorescence channels. Images are collected through a high-speed camera (EM) that captures up to 30 frames/s or up to 60 frames/s using 2 × 2 binning. The microscope imaging software from Nikon

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_44

(NIS element) is used for offline data analysis. The software can merge acquired images from each channel automatically, and the fluorescence of each channel can be independently adjusted using a renormalization tool of the software.

Some laboratories use high-speed confocal and wide-field microscopes for in vivo imaging of thrombus in the cremaster muscle vasculature, which was first developed by the Furie laboratory group (Falati et al. 2002; Welsh et al. 2014). The imaging system is developed utilizing an Olympus AX70 microscope equipped with a trinocular head, long-distance condenser, and 40× (NA, 0.80) and 60× (NA, 90) water-immersion objectives. For confocal fluorescence microscopy, a Yokogawa CSU-10 confocal scanner (Perkinelmer, Gaithersburg, Maryland) is used. The imaging system is equipped with an argon-krypton 3-line laser for excitation at 488, 568, and 647 nm and a Sutter Lambda L-10 filter wheel (Novato, California) on the excitation source. Wide-field in vivo microscopy is carried out using a Sutter Lambda DG-4 high-speed wavelength changer with a 175-W xenon light source equipped with excitation filters (360, 480, and 590 nm) matched to a triple-band filter for DAPI, FITC, and Cy5 (Chroma, Brattleboro, Vermont) in the body of the microscope. To provide a bright-field channel while collecting image data in fluorescence channels, a Uniblitz (Vincent Associates, Rochester, New York) shutter is used for transmitted light. For both confocal and wide-field imaging, light is amplified using a videoscope image intensifier. A Cooke SensiCam CCD camera (640 × 480 format) is used to capture up to 60 frames/s using 2 × 2 binning. A Dell workstation equipped with SlideBook software (Intelligent Imaging Innovations, Denver, Colorado) is used for data capture, component control, and image analysis.

Types of Blood Vessels Used for In Vivo Imaging

The mouse is a common choice for in vivo imaging because 99 % of human genes have orthologs in mouse, and they are easy to manipulate genetically, thus making them an ideal "model organism" to study function of human genes in health and disease. With their small size, short gestation period, and ease of breeding, maintenance of mice is simple, feasible, and inexpensive. Although there are other species that are more closely related to humans (such as dogs, pigs, and nonhuman primates), it is more difficult to perform in vivo imaging in such species because of the larger size of the vessels (which impedes light transmission), long gestation period, and lack of efficient methods for genetic manipulation. In order to perform in vivo imaging of thrombus formation in small or large vessels, the mouse must remain anesthetized for 45 min to 2 h depending on the experiment. The most commonly used anesthesia is a mixture of ketamine (60–100 mg/kg) and xylazine (10–50 mg/kg), which is injected intraperitoneally. Alternative anesthetics included pentobarbital (50 mg/kg, IP), midazolam (0.3–0.5 mg/kg, SC), or continuous inhalation of isoflurane (1–3 %) mixed with medical air. Some of the most common vessels that are used by researchers for imaging thrombosis in vivo are described below:

1. *Carotid artery* (Prakash et al. 2015b; Dhanesha et al. 2015): Mice (age 8–10 weeks) are anesthetized, and an incision is made to carefully expose the right or left common carotid artery using blunt dissection. The artery is carefully dissected and made free of any surrounding tissue or fat before the animal is placed on the upright microscope platform. Care should be taken to keep the carotid artery moist by superfusion with warm phosphate-buffered saline (37 °C). One can attach a Doppler flow probe to measure flow rate, which ranges from 1300 to 1800 s^{-1}. The carotid artery is visualized using a water-immersion lens. Following injury, time-lapse images are recorded for later quantification. Advantages of the carotid artery include: (1) dissection of the muscle does not traumatize carotid vessel, (2) mechanical injury can be induced, (3) a Doppler flow probe can be used to calculate flow rate, and (4) the method has clinical relevance to thromboembolic stroke. Disadvantages are that it is not possible to record bright-field images because of the tissue underlying the vessel, and only fluorescent images can be taken.
2. *Mesenteric vessels* (Denis et al. 1998; Chauhan et al. 2006, 2008; Ni et al. 2000, 2003): Younger mice (3–4 weeks) are used because older mice have more fat around the mesenteric vessels, which makes it difficult to image them. An incision is made in the anesthetized mouse through the abdominal wall to expose the mesentery. Arterioles of diameter approximately 100–150 μm with shear rates of ~1300–1800 s^{-1} and venules of diameter 150–400 μm with shear rates of 100–300 s^{-1} are placed on a Plexiglas plate to view under the inverted microscope. The exposed mesentery is kept moist and warm by superfusion with warm phosphate-buffered saline (37 °C). Care should be taken not to traumatize the vessel or mechanically activate the endothelium. Advantages of this preparation include: (1) mesenteric vessels are thinner than carotid vessels, which makes it easier to focus light and get both bright-field and fluorescent images, (2) the ease of quantifying adhesion of single platelets, and (3) although not preferred, multiple vessels can be studied in a single mouse. Disadvantages are that vessels get traumatized easily, and it is not feasible to study older mice because of the large amount of fat around the vessels.

3. *Cremaster muscle vasculature* (Welsh et al. 2014; Falati et al. 2002): Male adult mice (8–24 weeks) are anesthetized, and the cremaster muscle is exteriorized through an incision in the scrotum. The muscle is pinned around a coverslip mounted on a miniature platform using a dissecting microscope. Care should be taken during dissection to avoid traumatizing the cremasteric vessels and disturbing the blood supply. The cremaster muscle is superfused throughout the experiment with preheated (37–38 °C) bicarbonate-buffered saline drip aerated with 5 % CO_2/95 % N_2, with the mouse body temperature maintained at 37–38 °C using a rectal probe or heated blanket. The purpose of the bicarbonate saline is to maintain the viability of the cremaster muscle and to prevent muscle spasm. Advantages of studying the cremaster muscle vasculature compared to carotid or mesentery vessels are as follows: (1) cremasteric vessels are thin, and therefore, it is relatively easy to obtain high-resolution bright-field images, (2) the cremaster muscle can be isolated in mice from 4 to 25 weeks of age, and (3) multiple mild pinpoint injuries can be induced in cremaster arterioles (usually 20–40 μm in diameter) using a pulsed nitrogen dye laser. Disadvantages include the following: (1) only male mice can be studied, (2) cremasteric arterioles and venules are too small to induce a mechanical injury, (3) it is difficult to measure flow rate using a Doppler flow probe, and (4) a laser-induced thrombus grows to maximum size in approximately 1 min and then gradually disintegrates within 2–3 min.

Methods of Induction of Injury

Several methods can be used to induce thrombus formation in vivo.

1. *Ferric chloride* (*$FeCl_3$*): $FeCl_3$ is one of the most widely used methods to induce thrombosis in vivo. $FeCl_3$ solution (5–20 %) is either directly superfused on the artery or topically applied using a filter paper (1 × 1 mm) saturated with $FeCl_3$ (5–20 %) for 3–5 min. The severity of injury and resulting time to occlusion depends on the concentration of $FeCl_3$ solution used for injury. A stable and completely occlusive thrombus generally forms within 20 min from the time 7.5 % $FeCl_3$ solution is applied. Using in vivo microscopy, it is possible to measure adhesion of single platelets beginning 3–5 min after injury and then to monitor thrombus growth kinetics and time to occlusion (Prakash et al. 2015b). Alternatively, using a Doppler flow probe, one can monitor blood flow within an artery and calculate the time to occlusion. Several studies suggest that this model is sensitive to both anticoagulant and antiplatelet drugs (Day et al. 2004, 2005; Wang et al. 2005; Pinel et al. 2004; Marsh Lyle et al. 1998). The mechanism of $FeCl_3$-induced vascular injury appears to be complex. Previously, it was shown that $FeCl_3$ causes oxidative stress with the generation of free radicals leading to lipid peroxidation that results in denudation of the endothelium leading to exposure of the subendothelium (Tseng et al. 2006; Eckly et al. 2011). In contrast, other studies have suggested that $FeCl_3$ does not result in endothelial denudation (Barr et al. 2013; Ciciliano et al. 2015). Another study suggested that $FeCl_3$-induced injury is indirect and occurs as a consequence of erythrocyte lysis (Woollard et al. 2009). A recent study suggests that $FeCl_3$ induces early aggregation of plasma proteins and blood cells, which is mediated by charge-based binding of proteins (either cell surface bound or soluble) to the Fe^{3+} ions (Ciciliano et al. 2015). Whatever the multifaceted mechanism of $FeCl_3$ is on thrombosis, this model remains a valuable tool to screen inhibitors of platelet activation and subsequent thrombus formation in vivo (Day et al. 2004, 2005; Wang et al. 2005; Pinel et al. 2004; Marsh Lyle et al. 1998).
2. *Photochemical injury with Rose Bengal* (Wilson et al. 2003; Day et al. 2004): This method requires systemic administration of photoreactive substance, Rose Bengal, followed by local transillumination of the target vessel with a green laser light (540 nm). Rose Bengal is known to accumulate in the lipid bilayer of endothelial cells (Saniabadi et al. 1995). A photochemical reaction between green light and Rose Bengal produces singlet oxygen and promotes formation of other reactive oxygen species that damage the endothelium and initiate thrombus formation. This model results in a milder injury compared to the $FeCl_3$ method, and therefore, the time to form occlusive thrombus is longer, approximately 40 min. Time to occlusion can be measured using a Doppler flow probe or by in vivo microscopy. Mice are injected typically with 10–50 mg/kg Rose Bengal using a jugular vein, femoral vein, or tail vein. Several factors are necessary to obtain reproducible results: (1) the same amount of Rose Bengal per gram should be infused in each animal; (2) laser light should be maintained at a constant distance, usually 5–6 cm, from the blood vessel; and (3) the vessel should be illuminated with the laser light before the Rose Bengal infusion is begun. This method has been used widely to study carotid artery thrombosis in mice that are genetically altered for hemostatic or fibrinolytic factors involved in thrombus formation as well as in mice with hyperlipidemia or leptin deficiency (Eitzman et al. 2000).
3. *Laser-induced injury* (Falati et al. 2002; Stalker et al. 2014): Injury is initiated in the microvasculature using a

micropoint laser ablation system. The user can obtain precise illumination of the area of interest through the microscope eyepiece or with the imaging system in real time. The wavelength of light used for illumination is in the range of 365–400 nm with maximum output from 50 to 500 μJ that can be selected by the user via a dye cell and an attenuator to adjust the energy. The power and frequency of bursts are controlled by software and can be empirically defined depending on the thickness of the vessel. Care must be taken to assure that the emission filter being used absorbs light at the frequency of the laser, to avoid stray reflections that might damage the intensifier or the camera. Thrombi can be generated either in arterioles or venules. The laser injury-induced thrombus grows to its maximum size in approximately 1 min and then gradually disintegrates in the following 2–3 min. Multiple thrombi can be generated over the course of a 60–90 min experiment either in a single vessel or multiple vessels in a single mouse.

4. *Mechanical injury* (Stockmans et al. 1991; Roque et al. 2000): Endothelial injury in the vessel is either induced using forceps or by passage of an angioplasty guide wire. In the latter case, femoral or carotid arteries are temporarily clamped, and an arteriotomy is made to introduce the angioplasty guide wire. Endothelial injury is made by rotating the wire to ensure uniform and complete endothelial denudation. After removing the wire, the arteriotomy site is ligated and platelet-vessel wall interactions can be studied using intravital microscopy.
5. *Electrolytic injury* (Cooley 2011): Injury is induced on the surface of the carotid artery with a 30 s, 3-V direct current application, touching the surface of the vessel with the blunt end of a 140-μm diameter steel needle connected to the anode, completing the circuit by contacting local subdermal tissue with the cathode. The thrombosis with the electrolytic injury is similar to $FeCl_3$ injury-induced thrombosis (Cooley 2011).

Effect of Mechanical Ventilation on Thrombosis

Some research groups mechanically ventilate mice during anesthesia in studies of experimental thrombosis. Prolonged anesthesia has been shown to be associated with respiratory acidosis and increased cerebral blood flow (Dalkara et al. 1995; Vogel et al. 2000). Lentz and colleagues have demonstrated that mice (C57BL6/J or BALB/c genetic background) anesthetized with sodium pentobarbital (70–90 mg/kg body weight, intraperitoneally) without mechanical ventilation and exhibit hypercapnia, acidosis, and increased carotid artery blood flow with prolonged times to complete occlusion after photochemical injury (Wilson et al. 2003). Adequate mechanical ventilation with room air and supplemental oxygen (80 breaths/min, tidal volume 0.2–0.5 mL) prevented hypercapnia and acidosis, normalized carotid artery blood flow, and shortened the time to carotid artery occlusion. However, it was not shown and remains uncertain whether the effect of anesthesia on acidosis and carotid blood flow is a general phenomenon or depends on the type and dose of anesthesia used for the study. Although this study was done in the context of carotid artery thrombosis, the possibility that mechanical ventilation may influence the susceptibility to thrombosis in other vascular beds, including the femoral artery, mesenteric vessels, and cremaster muscle microcirculation, cannot be ruled out. Nevertheless, this study clearly suggests that to study thrombosis in vivo, it is advisable to mechanically ventilate mice in order to maintain physiological conditions, particularly during prolonged periods of anesthesia.

Methods of Visualizing and Quantifying Various Components of Thrombi

There are several approaches that can be used to visualize various components of the thrombus in real time. For multichannel microscopy, platelets and plasma proteins can be labeled simultaneously with different fluorochromes. Care should be taken to account for tissue autofluorescence and crossover (bleeding) of signals from one fluorochrome to another. Common fluorochromes used are Alexa 350, 448, 567, and 660. The best choice is to use two fluorochromes that are wider in excitation wavelength. For example, for two-channel simultaneous imaging, it is better to use Alexa 448 with Alexa 660. In case of three-channel imaging, one can use Alexa 350, 448, and 660. Tail vein, femoral vein, and jugular vein are the obvious choices to infuse fluorescent antibodies, reagents, and drugs into the circulation.

To quantitatively assess thrombus growth in real time, the following parameters can be evaluated:

(1) Single platelet-vessel wall interactions determined as the number of fluorescent platelets that are deposited on the injured vessel wall segment during 1 min (beginning 2–3 min after injury)
(2) The time required for formation of the first thrombus larger than 30–50 μm
(3) Thrombus growth rate
(4) Thrombus stability, determined by measuring the number of thrombi of diameter larger than 30–50 μm embolizing before vessel occlusion
(5) Time to occlusion (i.e., the time required for blood to stop flowing for 30 s)
(6) The site of vessel occlusion (i.e., whether the occlusion occurs at the site of injury or downstream)

To quantify all these parameters, it is important to label platelets with fluorescent dyes or Alexa-labeled antibodies

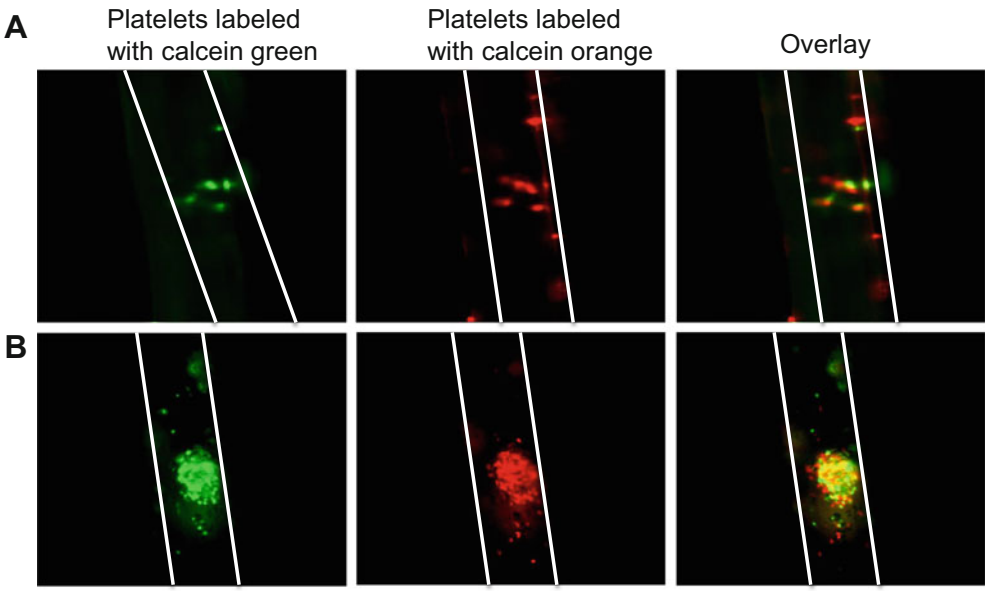

Fig. 1 In vivo imaging of platelets/thrombosis in wild-type mouse. Injury was made in mesenteric arterioles (100–125 μM) using 5 % $FeCl_3$. Platelets were labeled ex vivo with calcein green or calcein orange and infused in the recipient mouse. (**a**) Microphotographs show single platelet adhesion following 3–4 min after injury. (**b**) Microphotographs show platelet thrombi following 10–12 min after injury. *White line* delineates vessel

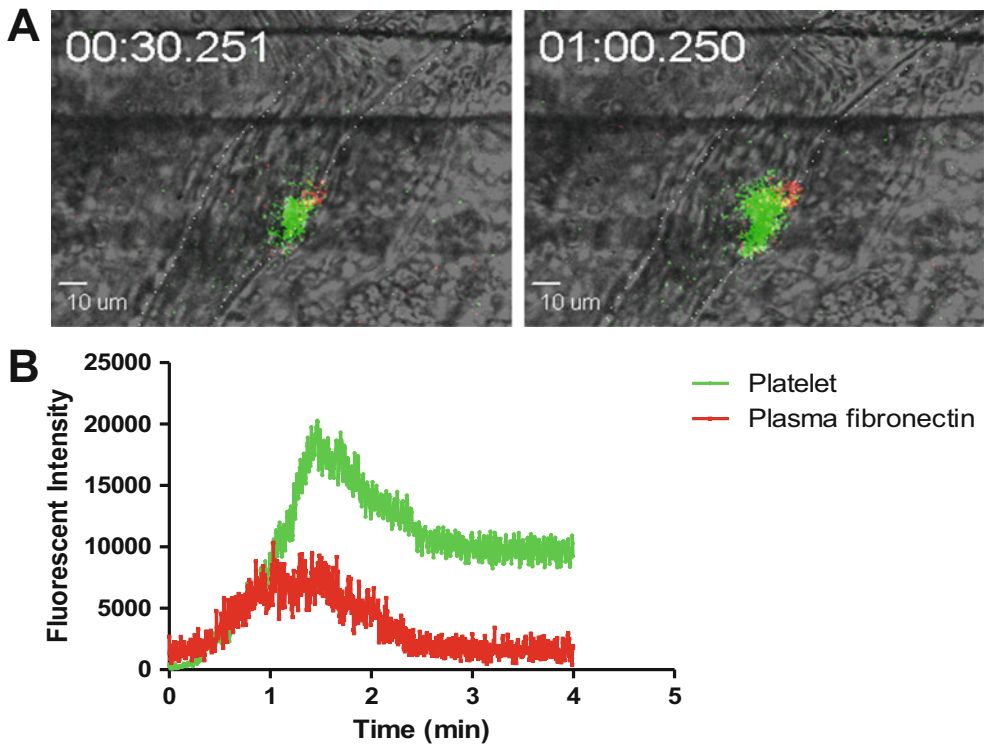

Fig. 2 In vivo imaging of thrombus in laser-induced cremaster arterial thrombosis model. (**a**) The platelets are labeled with anti-GPIb antibody conjugated with DyLight 488 (*green*) and plasma fibronectin conjugated with AF647 (*red*). (**b**) Kinetics of platelet accumulation and plasma fibronectin deposition in growing thrombus. Figure provided by Dr. Heyu Ni

that are specific for platelets, taking care that the antibodies do not cause thrombocytopenia or interfere with important platelet functions. Platelets can be isolated from donor mice and fluorescently labeled with calcein AM (2.5 μg/mL, Molecular Probes) ex vivo and infused into recipient mice of the same genotype through a tail vein at a concentration of 2.5×10^9 platelets/kg body weight (Fig. 1) (Denis et al. 1998; Chauhan et al. 2006). The use of fluorescently labeled anti-GPIbβ (Emfret analytics) or anti-CD41 ($F(ab)_2$ fragment) antibodies can also be used to label endogenous platelets in vivo (Fig. 2) (Dubois et al. 2007; Falati et al. 2002; Stalker et al. 2014; Welsh et al. 2014). It is important to utilize the correct isotype-matched controls and to pay attention to the relative fluorescence labeling of each antibody. The use of $F(ab)_2$ fragments is preferable, to minimize the clearance of platelets via Fc receptors, which may result in moderate to severe thrombocytopenia.

To measure other parameters of platelet activation in vivo, one can monitor calcium mobilization and/or P-selectin expression. To quantify cytosolic calcium

mobilization in platelets, Fura 2-AM, a calcium ion-binding fluorochrome, is used (Dubois et al. 2007; Panicot-Dubois et al. 2007). Washed platelets are labeled with Fura 2-AM and infused into a recipient mouse of the same genotype. Calcium binding to Fura-2 results in a shift in the absorbance of the dye from 380 to 340 nm. Fura 2-AM-loaded platelets in growing thrombus are visualized after excitation at 380 nm, and calcium mobilization during thrombus formation is visualized after excitation at 340 nm (Dubois et al. 2007; Panicot-Dubois et al. 2007). To determine the kinetics of calcium mobilization within a growing thrombus, medium integrated fluorescent intensities are compared. To label P-selectin, fluorescent anti-CD62P is used. Similarly, tissue factor and fibrin can be quantified in real time within the growing thrombus using appropriate antibodies and their respective controls (Falati et al. 2002).

Recent studies from the Brass laboratory have shown that it is possible to measure intra-thrombus molecular transport rates in real time during thrombus formation (Welsh et al. 2014; Stalker et al. 2014). In this method, albumin is labeled with caged fluorescein (cAlb) molecules that become stably fluorescent only after being uncaged by exposure at 405 nm. Once uncaged, cAlb in the thrombus is measured as decay in mean fluorescence intensity over time (Stalker et al. 2014; Welsh et al. 2014). The same group has also developed a thrombin activity sensor mTHS-Ab (Welsh et al. 2012). This sensor is a thrombin substrate consisting of a fluorescence resonance energy transfer-based fluorogenic peptide linked to an anti-mCD41 antibody targeted to the platelet surface. Cleavage of the peptide by thrombin releases a quencher, allowing an increase in fluorescence signal, which represents the spatial distribution of cumulative thrombin activity (Welsh et al. 2014).

Conclusion

Hemostasis and thrombosis are complex processes, which require blood cellular components as well as plasma components. The main strength of in vivo imaging is that it provides information about these processes in live animals that cannot be obtained by in vitro or ex vivo methods. A clear example is the response of the vasculature to platelets under conditions of physiological and pathological stimuli. Although in vitro or ex vivo approaches such as flow chambers, aggregation, and spreading assays provide information about platelet activation, in vivo imaging enables determining the role and relative contribution of several blood components including platelets and plasma proteins in a physiological context in an intact animal. In the past years, the data generated from in vivo imaging has been instrumental in understanding the mechanisms of thrombus formation and designing effective antithrombotic agents.

Take Home Messages

- In vivo imaging has increased our understanding of the mechanism of thrombus formation in the physiological context.
- The information provided in this chapter may assist in designing and testing the efficacy of antithrombotic drugs in preclinical models.

Monitoring of Antiplatelet Therapy

Udaya S. Tantry, Aung Myat, and Paul A. Gurbel

Abstract

The variability of response to antiplatelet agents and its potential relation to the occurrence of recurrent ischemic events have stimulated the concept of antiplatelet therapy monitoring over the last decade. This has been driven further by the development of user-friendly point-of-care methods to assess platelet reactivity to adenosine diphosphate. Large observational studies have established an independent relation between the results of point-of-care platelet function testing and adverse clinical outcomes, particularly in patients undergoing coronary artery stenting. Furthermore, the concept of a "therapeutic window" for $P2Y_{12}$ receptor reactivity has been proposed, with an upper threshold associated with ischemic events and a lower threshold associated with bleeding. Prospective randomized trials have, however, failed to demonstrate that tailored antiplatelet therapy based on point-of-care assessment of platelet function is effective in reducing ischemic event occurrences. In the absence of robust prospective evidence to support a personalized approach, decisions regarding antiplatelet therapy rest on patient comorbidity, the large body of observational data, national and international guidelines, and recognition of the fundamental importance of platelet physiology in causing catastrophic events in those with high-risk coronary artery disease.

Introduction

Overwhelming evidence exists to support the theory that platelet-rich thrombus generation at the sites of plaque rupture and vessel wall erosion is a primary process causing ischemic events in patients with coronary artery disease. Following spontaneous plaque rupture in acute coronary syndrome (ACS) and induced rupture during percutaneous coronary intervention (PCI), platelets adhere to the injured vessel wall and undergo activation that is followed by release of the secondary agonists thromboxane A_2 (TxA_2) and adenosine diphosphate (ADP). Although TxA_2 and ADP act synergistically during platelet aggregation, the ADP–$P2Y_{12}$ receptor interaction plays a central role in sustaining the activation of glycoprotein IIb/IIIa ($\alpha_{IIb}\beta_3$) receptors by amplifying the response to agonists, leading to stable platelet-rich thrombus generation at the site of vessel wall injury. A vicious cycle occurs in which coagulation factors are formed on the activated platelet surface, generating more thrombin and further enhancing platelet activation and coagulation processes. The platelet-rich thrombus is further stabilized by fibrin mesh formation that is simultaneously generated by thrombin through the coagulation cascade (Gurbel et al. 2004) (Fig. 1). These observations position the platelet as a "nidus of evil" and are the rationale for dual signaling pathway blockade with cyclooxygenase 1 (COX-1) and $P2Y_{12}$ receptor inhibitors in patients with ACS and those undergoing PCI (Gurbel and Tantry 2010).

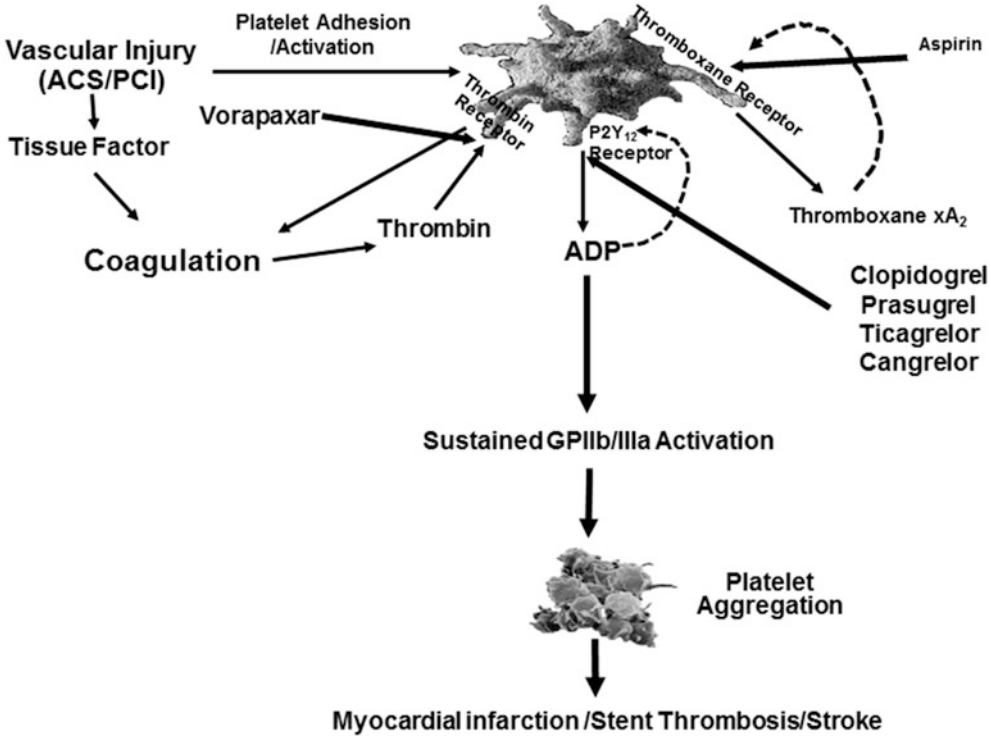

Fig. 1 Role of different platelet receptors in thrombotic events. Following vascular injury, platelets adhere to the injury site and undergo activation. Platelet activation results in the release of three important platelet agonists: thromboxane A_2 (TxA_2), adenosine diphosphate (ADP), and thrombin. The thrombin–protease activated receptor-1, TxA_2–thromboxane receptor, and ADP–$P2Y_{12}$ receptor pathways amplify the response to platelets, resulting in sustained platelet aggregation via activated $\alpha_{IIb}\beta_3$ receptor. The ADP–$P2Y_{12}$ interaction plays a central role. Formation of occlusive platelet-rich thrombus formation at the site of plaque rupture is mainly responsible for the occurrence of arterial thrombotic events such as myocardial infarction, stent thrombosis, and stroke

Current guidelines recommend a non-monitored or universal "one-size-fits-all" approach, despite the fact that the pharmacodynamic effect of $P2Y_{12}$ inhibitors is widely variable, resulting in both poor and enhanced responders to therapy (Bonello et al. 2010; Aradi et al. 2014; Tantry et al. 2013). There has been a longstanding reluctance to assess platelet function because of the potential introduction of artifacts by laboratory methods, incomplete reflection of the actual in vivo thrombotic process, and failure to establish unequivocally a causal relation between the results of the test and thrombotic event occurrence (Hirsh et al. 1981). In the last decade, understanding of platelet receptor physiology has markedly improved and more potent $P2Y_{12}$ receptor blockers that can overcome some of the limitations of clopidogrel have been developed. The introduction of more user-friendly platelet function assays that can reliably determine the antiplatelet effect of clopidogrel have spurred renewed interest in antiplatelet therapy monitoring (Bonello et al. 2010; Aradi et al. 2014; Tantry et al. 2013).

Resistance to Dual Antiplatelet Therapy

Despite appropriate dual antiplatelet therapy (DAPT), a significant percentage of patients (~10 %) continue to suffer major adverse cardiovascular and cerebrovascular events following ACS and coronary stenting (Bonello et al. 2010; Aradi et al. 2014; Tantry et al. 2013; Hirsh et al. 1981). Importantly, late stent thrombosis, especially in the era of drug-eluting stents, can occur in 1–2 % of patients and the rate is reported to increase by 0.3–0.6% each year (Mauri et al. 2014). This has lead to the postulation that those individuals suffering recurrent events may represent a cohort of patients who have a less than adequate response to antiplatelet therapy.

The term "antiplatelet resistance" is controversial in this context because it has been used to encompass both failure of the antiplatelet agent to achieve its intended pharmacodynamic effect and also failure to prevent the clinical condition for which it is intended. Because the pathophysiology of

atherothrombosis involves a complex interplay between platelet function, thrombosis, inflammation, innate vascular biology, and changing hemodynamics, no single class of agent can be expected to abolish all ischemic events completely. Furthermore, a patient may have the appropriate platelet response to a given therapy but have recurrent events mediated by non-platelet factors. For these reasons, the term "antiplatelet resistance" is meaningful only when inadequate pharmacodynamic response, as indicated by a specific laboratory assay, is associated with continued occurrence of ischemic events despite adequate duration of antiplatelet therapy, dosing, and compliance.

Importance of Monitoring of Aspirin Responsiveness

Earlier studies attempted to demonstrate aspirin nonresponsiveness/resistance using laboratory methods and relate the results to clinical outcome (Gum et al. 2003; Chen et al. 2007). Laboratory methods, including point-of-care tests, use agonists such as ADP, collagen, shear stress, and epinephrine to stimulate platelets and indicate aspirin responsiveness. These methods do not exclusively indicate the level of COX-1 activity, the target of aspirin antiplatelet activity, and are considered COX-1 nonspecific methods. The optimal definition of resistance or nonresponsiveness to aspirin is the demonstration of residual activity of the COX-1 enzyme. Measurement of arachidonic acid-induced platelet aggregation is the most widely used method for indicating COX-1 activity (COX-1-specific methods) (Tantry et al. 2009; Gurbel et al. 2007). There is wide variability in values for the prevalence of aspirin resistance (<1–57 %) as a result of differences in ex vivo methods and in criteria used to define aspirin resistance. However, it has been clearly established that in the presence of even low-dose aspirin therapy the prevalence of aspirin resistance, as indicated by COX-1 activity, is rare (<5 %). Reports of a higher prevalence of aspirin resistance have been attributed to COX-1 nonspecific methods, noncompliance, or inadequate doses of aspirin in selected patients (Tantry et al. 2005, 2009; Gurbel et al. 2007). The relation of aspirin resistance (based on the VerifyNow assay) to ischemic outcome was not demonstrated in a recent large scale study (Stone et al. 2013). Moreover, in two large clinical studies, high levels of urinary 11-dehydro-thromboxane B_2 (a stable metabolite of TxA_2), as measured by enzyme-linked immunoassay, were shown to be associated with heightened risk of occurrence of a cardiovascular ischemic event (Eikelboom et al. 2002, 2008). However, a reliable and specific laboratory method for identifying aspirin resistance has not yet been uniformly accepted by investigators. Other than in research trials, it is not currently recommended to test for aspirin resistance in patients or to change therapy on the basis of such findings (Michelson et al. 2005).

Importance of Monitoring of $P2Y_{12}$ Receptor Blocker Responsiveness

A key development in the field of platelet function assessment occurred in 1962 when a quantitative ex vivo method to measure platelet function, conventional/light transmittance aggregation (LTA), was developed in the Gustav Born laboratory. Born demonstrated that platelets underwent aggregation following the addition of ADP and that it was possible to record a decrease in optical density over time that was proportional to the concentration of platelets in plasma (Born 1965). LTA, even though considered the gold standard assay for assessment of platelet function, is labor-intensive, requires expert personnel, involves centrifugation steps, and can be subject to interlaboratory differences. Two different point-of-care whole blood assays, the VerifyNow $P2Y_{12}$ assay (Accriva Diagnostics, San Diego, California) and the Multiplate Analyzer (Dynabyte Informationssysteme, Munich, Germany) (both employing ADP as the agonist) have been developed to measure platelet reactivity. The VerifyNow $P2Y_{12}$ assay is a turbidimetric assay that measures aggregation of platelets to fibrinogen-coated beads in whole blood. The Multiplate Analyzer allows measurement of platelet function in whole blood using impedance aggregometry, requires no centrifugation step, and can be used for a variety of applications such as monitoring of antiplatelet therapy and assessment of perioperative platelet function disorders in a near-patient environment. In addition, whole blood thrombelastography with platelet mapping can be used to assess $P2Y_{12}$ receptor reactivity. A point-of-care thrombelastograph known as TEG6s (Haemonetics, Braintree, MS) has also become recently available. The vasodilator-stimulated phosphoprotein phosphorylation (VASP-P) assay, based on flow cytometry, is more specific for assessment of the $P2Y_{12}$ receptor response. A more user-friendly, enzyme-linked immunoassay test is also now available (Fig. 2).

In an earlier prospective study, clopidogrel response variability and resistance was demonstrated by measuring ADP-induced platelet aggregation by LTA and expression of p-selectin and activated $\alpha_{IIb}\beta_3$ by flow cytometry serially for 30 days following stenting and administration of a 300 mg load/75 mg per day maintenance dose of clopidogrel. In this study, about 30 % of patients were resistant to clopidogrel at days 1 and 5 post-stenting, and 15 % were resistant at day 30. "Resistance" in these patients was defined as ≤10 % absolute difference between maximal pre- and post-treatment platelet aggregation induced by 5 μM ADP (Gurbel et al. 2003). Since then, numerous studies have been conducted worldwide to demonstrate a link between high platelet reactivity (HPR) to

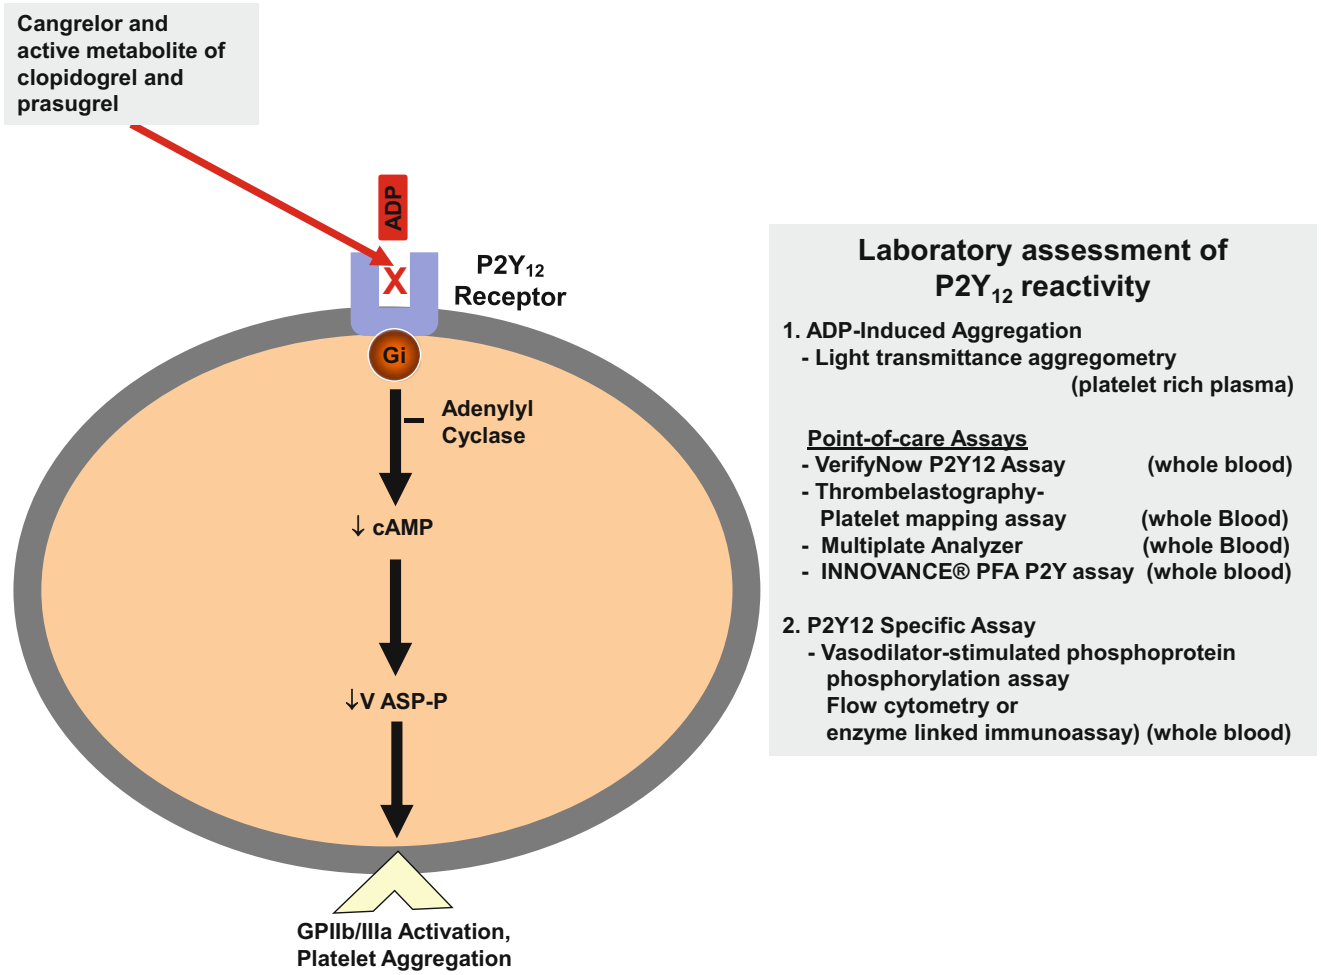

Fig. 2 Laboratory assessment of $P2Y_{12}$ receptor reactivity

ADP and ischemic outcomes. Various laboratory methods have been used, such as conventional aggregation, flow cytometry to measure P-selectin and activated $\alpha_{IIb}\beta_3$ receptor expression and vasodilator-stimulated phosphoprotein phosphorylation levels, and the point-of-care methods VerifyNow $P2Y_{12}$ assay, platelet mapping with thrombelastography, and the Multiplate Analyzer. The results of these studies have provided the strongest rationale for ex vivo quantification of the intensity of the ADP–$P2Y_{12}$ interaction in patients treated with $P2Y_{12}$ receptor blockers (Gurbel and Tantry 2012).

Relation of Ex Vivo Platelet Function Measurement to Clinical Outcome

Small early studies suggested that ischemic event occurrence was not linearly related to on-treatment platelet reactivity but instead occurred above a moderate level of platelet reactivity to ADP. The relation between an upper threshold of on-treatment platelet reactivity to post-PCI ischemic events was first demonstrated in the study PREPARE POST-STENTING (platelet reactivity in patients and recurrent events post-stenting) (Gurbel et al. 2005a). Similarly, ADP-induced platelet aggregation was shown to correlate with stent thrombosis and with increased ischemic event occurrence within 12 months of PCI (Gurbel et al. 2005b; Bliden et al. 2007). Subsequent studies used receiver operating characteristic (ROC) curve analysis to define an optimal cutoff for on-treatment platelet reactivity for predicting thrombotic risk. In 2010, a consensus statement proposed cutoff values (based on ROC curve analysis) for different platelet function assays to be used in future studies of personalized antiplatelet therapy (Bonello et al. 2010).

Personalized Antiplatelet Therapy Trials

Prospective, albeit small, tailored antiplatelet therapy studies provided initial evidence that HPR might not just be useful as a diagnostic marker but also as a modifiable risk factor for

post-PCI ischemic event occurrence. In two trials, tailored incremental loading doses of clopidogrel before PCI overcame HPR and were effective in reducing the occurrence of major adverse cardiac events within 30 days of PCI (Bonello et al. 2008, 2009). Similarly, two other studies demonstrated that administration of selective $\alpha_{IIb}\beta_3$ receptor blocker to PCI patients who demonstrated HPR following clopidogrel loading was effective in reducing subsequent periprocedural as well as long-term (1 year) ischemic outcomes (Campo et al. 2010; Cuisset et al. 2008). These studies were the first to suggest that the cutoff value used to identify PCI-treated patients at increased risk of thrombotic event occurrence were also useful for individualizing therapy and led to an improved outcome.

The first large-scale investigation of personalized antiplatelet therapy, conducted in stable patients treated with coronary stents, was GRAVITAS (gauging responsiveness with a VerifyNow assay: impact on thrombosis and safety) ($n = 2214$). In GRAVITAS, patients with HPR after treatment with clopidogrel were randomly assigned to continue standard clopidogrel dosing or to be treated with a higher clopidogrel dose. The 6-month composite ischemic event occurrence rate was identical (2.3 %) for the high-dose clopidogrel treatment arm (600 mg extra loading dose given the day after stenting, followed by a 150 mg daily maintenance therapy) and the standard dose treatment arm (75 mg daily maintenance therapy) (Price et al. 2011). Potential explanations for the neutral observation of GRAVITAS have been proposed and include suboptimal efficacy of high-dose clopidogrel to overcome HPR, a cutoff for HPR that was too high, and enrollment of predominantly low-risk patients with stable coronary artery disease, which resulted in a very low event rate and undersizing of the study (Gurbel and Tantry 2011).

The study TRIGGER-PCI (testing platelet reactivity in patients undergoing elective stent placement on clopidogrel to guide alternative therapy with prasugrel) ($n = 212$) was conducted in elective stable PCI patients, excluding non-ST-segment elevation and ST-segment-elevation myocardial infarction (NSTEMI and STEMI, respectively) patients. A 10 mg daily dose of prasugrel was used in the active arm to treat patients with HPR and was highly effective in reducing its prevalence; only ~6 % of patients had HPR after 90 days of prasugrel therapy. However, the study was terminated early because of futility. There was only one occurrence of the primary end point among 236 patients who completed 6 months of follow-up. In addition, ~30 % of the enrolled patients declined randomization after being identified as having HPR (Trenk et al. 2012).

In the study ARCTIC (assessment by a double randomization of a conventional antiplatelet strategy versus a monitoring-guided strategy for drug-eluting stent implantation and of treatment interruption versus continuation one year after stenting) ($n = 2440$), patients who had undergone successful coronary stenting were randomly assigned to a strategy of platelet-function monitoring, with adjustment of antiplatelet therapy in patients who had a poor response to clopidogrel (>208 $P2Y_{12}$ reaction units as assessed by VerifyNow $P2Y_{12}$ assay) or to a conventional strategy without monitoring and drug adjustment. The 1-year primary composite end point of death, myocardial infarction, stent thrombosis, stroke, or urgent revascularization was not different in the monitoring arm compared with the conventional arm (34.6 % versus 31.1 %, hazard ratio 1.13; $p = 0.10$). The prevalence of patients with ACS was low (27 % NSTE-ACS compared with 73 % patients with stable coronary artery disease). STEMI patients, a group at high risk for early atherothrombotic events, were excluded. HPR was mainly treated as in the GRAVITAS trial, with double-dose clopidogrel. Prasugrel, a superior alternative to double-dose clopidogrel for overcoming HPR, was only administered to ~10 % of patients (Collet et al. 2012).

These randomized studies all used the VerifyNow assay to assess platelet reactivity to ADP and to identify HPR. The study included mostly low-risk patients undergoing PCI and had resultant low event rates irrespective of platelet reactivity. Given the post-discharge event rates observed in ARCTIC, it was estimated that 17,540 patients would be necessary to refute the utility of personalized therapy (De Caterina et al. 2013). The results of all these studies also suggest that high-dose clopidogrel is not an optimal strategy for overcoming HPR and improving clinical outcomes.

Although a major risk factor for post-PCI thrombotic event occurrence, HPR is not the sole factor responsible for these events. In contrast, the absence of HPR is the best reassurance thus far for a low likelihood of future ischemic events. The HPR cutoff values reported in many studies are associated with high negative predictive values and low positive predictive values. However, given the overall low prevalence of thrombotic events in these studies, the low positive predictive values and high negative predictive values are understandable. Other factors, including demographic, clinical, and angiographic factors, must be taken into consideration for optimal identification of patients at greatest risk. Along this line, recent studies have suggested that adding clinical variables and genotype to platelet reactivity measurements (a combined risk factor) could improve risk prediction (Geisler et al. 2008; Fontana et al. 2010).

Therapeutic Window Concept for $P2Y_{12}$ Receptor Reactivity

In addition to the upper threshold for ischemic risk (i.e., HPR) described earlier, the relationship between low platelet reactivity and bleeding was demonstrated in small

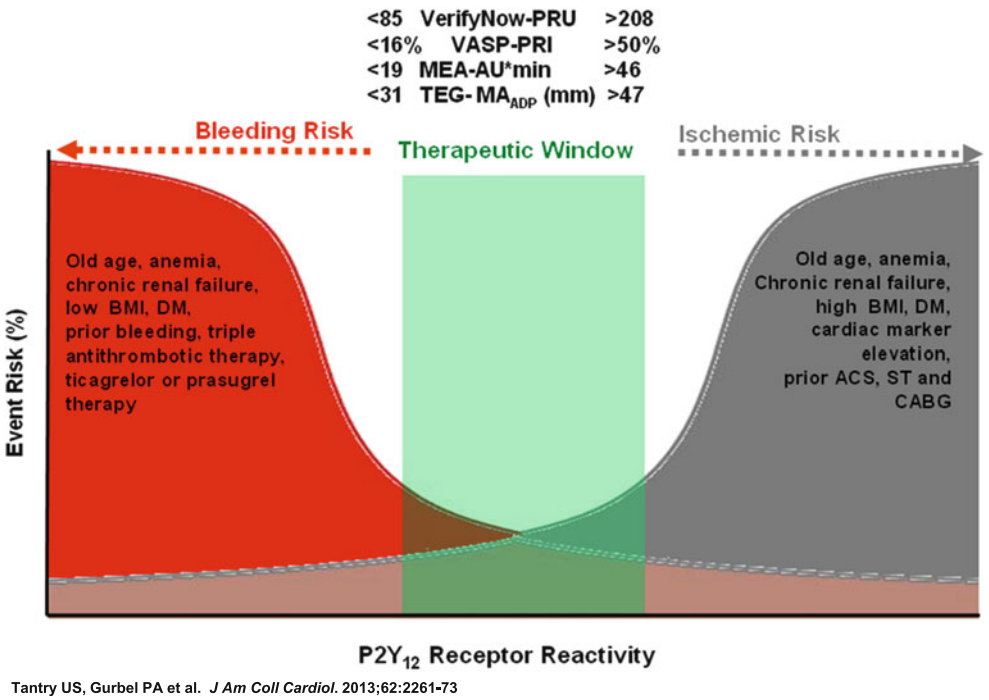

Fig. 3 Evidence for $P2Y_{12}$ receptor reactivity associated with post-PCI ischemic and bleeding events. Adapted from Tantry et al. (2013). Similar to previously proposed high on-treatment platelet reactivity to ADP associated with post-PCI ischemic events, recent data suggest that low on-treatment platelet reactivity to ADP is associated with a higher risk of bleeding. Cutoff values for both ischemic and bleeding events based on various platelet function assays are shown. Both ischemic and bleeding events are influenced by various demographic variables, as indicated. *ACS* acute coronary syndromes, *AU* arbitrary aggregation units, *BMI* body mass index, *CABG* coronary artery bypass graft, *DM* diabetes mellitus, *MA* maximum amplitude, *MEA* multiplate analyzer, *PRI* platelet reactivity index, *PRU* $P2Y_{12}$ reaction units, *ST* stent thrombosis, *TEG* thrombelastography, *VASP* vasodilator stimulated phosphoprotein-phosphorylation

Table 1 Platelet reactivity cutoff associated with ischemic and bleeding events (therapeutic window)

	Cutoff associated with ischemic event occurrences	Cutoff associated with bleeding event occurrences
VerifyNow PRU Assay (PRU)	>208 (Campo et al. 2011)	<85 (Campo et al. 2011)
Multiplate Analyzer ADP-induced aggregation (AU × min)	>46 (Sibbing et al. 2010)	<19 (Sibbing et al. 2010)
Thrombelastography Platelet Mapping Assay ADP-induced platelet-fibrin clot strength (mm)	>47 (Gurbel et al. 2010)	<31 (Gurbel et al. 2010)
VASP-PRI (%)	≥50 (Bonello et al. 2012)	<16 (Bonello et al. 2012)

translational research studies. The concept of a "therapeutic window" for $P2Y_{12}$ receptor reactivity associated with both ischemic event occurrence (upper threshold) and bleeding risk (lower threshold) has been proposed. A consensus document highlighting the above observations, with a therapeutic window concept with updated cutoffs for HPR and low platelet reactivity in the setting of $P2Y_{12}$ inhibitor therapy, has been published (Fig. 3, Table 1). This approach is more meaningful when treating patients with potent $P2Y_{12}$ receptor blockers that are known to be associated with increased incidences of bleeding (Stone et al. 2013; Campo et al. 2011; Sibbing et al. 2010; Gurbel et al. 2010; Bonello et al. 2012).

The study ADAPT-DES (platelet reactivity and clinical outcomes after coronary artery implantation of drug-eluting stents) was a multinational prospective registry of 8582 patients (~50 % of patients with ACS). HPR was defined as >208 PRU and was independently associated with a twofold increased risk of 2-year definite/probable stent thrombosis (hazard ratio 1.84, $p = 0.009$) and inversely correlated with major bleeding (hazard ratio 0.82, $p = 0.02$), with a trend towards all-cause death (hazard ratio 1.27, $p = 0.06$). In a later report, the authors further analyzed ADAPT-DES platelet reactivity data categorized in quintiles (a continuous variable rather than the dichotomous variable used with HPR) in relation to clinical

outcomes. They found that PRU was associated in a monotonic fashion with stent thrombosis and that stent thrombosis was independently associated with highest quintile PRU. All-cause mortality was only associated with higher PRU in an unadjusted analysis (Stone et al. 2013; Kirtane 2013).

Personalized Antiplatelet Therapy in Patients Undergoing Surgery

The major rationale for 5–7 days discontinuation of $P2Y_{12}$ receptor inhibitor treatment recommended by the guidelines in patients undergoing coronary artery bypass grafting (CABG) was to allow platelet function recovery, thereby avoiding excessive perioperative bleeding. In a small prospective study, it was demonstrated that clopidogrel-treated patients undergoing on-pump CABG for the first time had similar bleeding (24-h chest tube output and number of transfused red blood cells) to clopidogrel-naïve patients when surgery was scheduled on the basis of a preoperative assessment of platelet reactivity to ADP. Moreover, the individualized timing of surgery reduced the overall preoperative waiting period by ~50 % as compared with the time recommended in the guidelines. Preoperative platelet reactivity to ADP was measured by thrombelastography (TEG with platelet mapping). Surgery in patients treated with clopidogrel was scheduled within 24 h of the last dose of clopidogrel in those with a maximum amplitude (MA_{ADP}) of >50 mm, within 3–5 days of the last dose in those with an MA_{ADP} of 35–50 mm, and 5 days after the last dose in those with an MA_{ADP} of <35 mm (Mahla et al. 2012).

Guidelines

In 2012, updated American and European practice guidelines included a Class IIb recommendation for platelet function testing to facilitate the choice of $P2Y_{12}$ receptor inhibitor in selected high-risk patients treated with PCI (Jneid et al. 2012; Hamm et al. 2011; Levine et al. 2011). In the 2012 update to the Society of Thoracic Surgeons guideline on use of antiplatelet drugs in patients having cardiac and non-cardiac operations, there is a Class IIa recommendation for platelet function testing in clopidogrel-treated patients to shorten the preoperative waiting period (Ferraris et al. 2012). Similarly, there is a Class IIb recommendation to consider platelet function testing for shortening the time interval to CABG following $P2Y_{12}$ inhibitor discontinuation in the 2015 European Society of Cardiologists guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation (Roffi et al. 2016).

Conclusions

Platelet activation and aggregation resulting in thrombus generation at the site of plaque rupture is a primary underlying factor responsible for the development of ischemic events in patients with cardiovascular disease. The development of user-friendly methods for assessing platelet reactivity to ADP has resulted in a large body of data supporting a strong association between the results of ex vivo platelet function testing and clinical event occurrence. Based on observational studies conducted in thousands of patients, international consensus accepts that HPR is a major risk factor for post-PCI ischemic event occurrence. However, large prospective trials utilizing the VerifyNow assay have thus far failed to demonstrate that personalized antiplatelet therapy is effective in reducing ischemic events. Potential explanations for the neutral results could be related to the assay itself, the lower risk of the patient group studied, the potency of the $P2Y_{12}$ inhibitor chosen to address HPR, the number of patients enrolled, and that HPR may not be a modifiable risk factor. The HPR cutoff values have high negative predictive value for thrombotic event occurrence, but the positive predictive value is low. The latter is a result of very low thrombotic event rate and the fact that although HPR is a major determinant of thrombotic event occurrences, it is not associated with all-cause mortality. Moreover, all-cause mortality is dependent on multiple factors in addition to HPR. Therefore, although HPR is not a stand-alone risk factor, it should be part of the risk algorithm along with biomarker testing (akin to CRUSADE or GRACE risk scores) to improve risk prediction and facilitate personalization of antiplatelet therapy.

In addition, atherothrombosis is a dynamic process and it is unclear whether the platelet reactivity phenotype and the hypercoagulability state remain stable over time. The results of ADAPT-DES and PEGASUS studies suggest that although long-term ticagrelor and prasugrel treatment can improve net outcomes in patients with a low bleeding risk, there is continued risk of recurrent ischemic events in selected patients even after 3–4 years of DAPT (Stone et al. 2013; Bonaca et al. 2016). The optimal treatment of these high-risk patients may require assessment of markers that better identify the presence of vulnerable vasculature and vulnerable blood, including continued monitoring of $P2Y_{12}$ receptor reactivity to improve patient selection (Gurbel and Tantry 2016).

The concept of a therapeutic window for $P2Y_{12}$ receptor reactivity associated with both ischemic event occurrence (upper threshold) and bleeding risk (lower threshold) has been proposed. The ongoing study TROPICAL ACS (testing responsiveness to platelet inhibition on chronic antiplatelet treatment for acute coronary syndromes)

($n = 2600$) aims to evaluate an approach guided by platelet function (assessed by impedence aggregometry using the Multiplate Analyzer) for personalizing antiplatelet therapy in ACS patients treated with PCI. At this time, in the absence of strong prospective evidence to support personalized antiplatelet therapy, clinical decision-making about antiplatelet therapy rests on the large body of observational data and the fundamental importance of platelet physiology in catastrophic event occurrence in patients with high-risk coronary artery disease.

Take Home Message

1. The central role of platelets provides the rationale for dual signaling pathway blockade with COX-1 and $P2Y_{12}$ receptor inhibitors in patients with ACS and those undergoing PCI.
2. High on-treatment platelet reactivity to ADP in the presence of $P2Y_{12}$ receptor blockade is an independent risk factor for ischemic event occurrence in patients undergoing coronary artery stenting.
3. The above observation is the strongest rationale for ex vivo quantification of the intensity of the ADP–$P2Y_{12}$ interaction in patients treated with $P2Y_{12}$ receptor blockers.
4. The "therapeutic window" concept for $P2Y_{12}$ receptor reactivity includes an upper threshold associated with ischemic events and a lower threshold associated with bleeding.
5. Large prospective trials utilizing the VerifyNow assay have thus far failed to demonstrate that personalized antiplatelet therapy is effective in reducing ischemic events; however, these trials have important limitations.
6. At this time, in the absence of strong prospective evidence to support personalized antiplatelet therapy, clinical decision-making about antiplatelet therapy rests on the large body of observational data and the fundamental importance of platelet physiology in catastrophic event occurrence in patients with high-risk coronary artery disease.

Mouse Models of Thrombosis

Deya Cherpokova and Bernhard Nieswandt

Abstract

Platelet activation and aggregation at sites of vascular injury is essential to prevent excessive blood loss, but may also trigger life-threatening cardio- and cerebrovascular disease conditions. In vitro studies have significantly contributed to the current knowledge of central signaling pathways underlying platelet activation. However, in vitro experimental conditions cannot reproduce the complex environment with specific hemodynamic conditions in which interactions between platelets, other blood cell types, and the vessel wall take place. Intravital microscopy studies in experimental animal models, in particular mice, have advanced our understanding of the spatiotemporal characteristics and molecular pathways controlling thrombus formation in vivo. State-of-the-art imaging modalities together with essential tools allowing manipulations of the mouse genome have enabled us to explore new avenues toward the development of novel effective, yet safe antiplatelet drugs. This chapter summarizes widely used techniques to study in vivo thrombus formation and highlights data obtained in mouse models on the role of distinct platelet surface receptors, soluble platelet agonists, and the intrinsic coagulation cascade in thrombosis. Based on experimental evidence, the suitability of several platelet receptors and coagulation factors as novel targets for antithrombotic therapy is discussed.

Introduction

Platelets are small anucleate blood cells that survey the integrity of the vessel wall. They are constantly produced by their bone marrow-resident precursors, the megakaryocytes, to maintain the normal range of circulating platelet numbers (150–400 $\times$ 10^3/μl in humans and 1000 $\times$ 10^3/μl in mice). Most of the platelets never undergo adhesion before they are removed from the circulation by resident macrophages in the spleen and liver (Grozovsky et al. 2010). However, upon damage to the vessel wall, platelets come into contact with components of the exposed extracellular matrix which induces their activation, adhesion, and aggregation, followed by the formation of a thrombus that seals vessel lesions, minimizes blood loss, and prevents infections. Importantly, if uncontrolled thrombus formation occurs in pathological conditions, such as found in diseased atherosclerotic vessels, this may lead to life-threatening occlusive cardio- and cerebrovascular disease states which currently represent the leading cause of death and permanent disability worldwide (Lozano et al. 2012). Therefore, cellular activation needs to be tightly regulated by a complex interplay between activating and inhibitory mechanisms in platelets that ensure spatially and temporally controlled responses.

Currently available treatment options in acute ischemic disease states are limited, and antiplatelet agents are contraindicative in many cases because of increased incidence of bleeding complications that often outweigh therapeutic benefits. The adverse effects of clinically used platelet inhibitors on primary hemostasis emphasize the necessity to

identify and characterize novel pharmacological targets for antiplatelet drugs with a powerful, yet safe antithrombotic profile. Recent advances in the development of novel therapeutic approaches have been greatly facilitated by studies in (genetically modified) mice that have significantly broadened our knowledge of the cellular and molecular interactions underlying hemostatic plug formation and pathological thrombosis. This chapter summarizes murine models that have substantially contributed to our understanding of in vivo arterial thrombus formation and may become instrumental for the development of both therapeutic strategies and new research directions (Table 1).

Mice as a Model Organism in Thrombosis Research

Considerable effort has been made to develop animal models for the investigation of platelet-dependent physiological and pathophysiological processes, such as hemostatic plug formation, arterial and venous thrombosis, atherosclerosis, and wound healing. During the past two decades, major improvements in intravital microscopy and the possibility to generate genetically engineered animal models have greatly facilitated investigations on the role of different platelet receptors and signaling cascades in in vivo thrombus formation, and have provided valuable insights into critical steps of this multifaceted process. Most of the key results summarized and discussed in this chapter have been obtained in mice which remain the most frequently used species in thrombosis research, particularly because of the following critical features: similarity to humans in anatomy, physiology and genetics, high fertility and short reproduction times, small size, and relatively low breeding costs (Sachs and Nieswandt 2007). Significantly, the invention of genetic methods that allow targeted manipulations of the mouse genome has been instrumental in unraveling the function of specific proteins in platelets. A major breakthrough was the generation of the platelet factor 4 (Pf4)-Cre transgenic mouse line that carries the Cre recombinase under the control of the Pf4 promoter and thus enables researchers to generate mouse lines with a megakaryocyte-/platelet-specific gene deletion (Tiedt et al. 2007). Of note, the recently developed CRISPR (clustered, regularly interspaced, short palindromic repeat)-Cas9 system is a highly efficient technology for genome editing of mouse zygotes (Wang et al. 2013; Sander and Joung 2014) that will undoubtedly further facilitate the generation of mutant mouse strains and will thereby also promote in vivo studies on both platelet production and on signaling pathways which control thrombus growth and resolution.

Although the mouse genome shares a substantial similarity with the human genome (approximately 95 %), thus emphasizing the suitability of the mouse as a model organism to study the role of numerous proteins in health and disease, direct extrapolation of data and translation of therapeutic approaches from the animal model to patient care may not be possible due to several differences between the two species (Sachs and Nieswandt 2007; Kim et al. 2010). Significant differences between mice and humans include the peripheral platelet count (150–400 $\times$ 10^3/μl in humans and 1000 $\times$ 10^3/μl in mice), the platelet life span (10 vs. 5 days), their diameter (3–4 μm vs. 1–2 μm), and, correspondingly, the platelet volume. Finally, the expression pattern of individual proteins is not identical between both species e.g., the alternative use of protease-activated receptors (PARs), the absence of the FcRγIIA receptor on mouse platelets. Nonetheless, these differences are significantly outweighed by the similarities and the suitability of laboratory mice for research purposes.

Importantly, inherent differences between inbred mouse strains with regard to platelet aggregation in vitro, hemostatic parameters, occlusive thrombus formation upon vascular injury, activity of tissue factor (TF), and TF pathway inhibitor (TFPI) have been increasingly recognized (Sudo et al. 2006; White et al. 2010). In addition, the role of environmental clues, housing, and husbandry have gained particular attention in recent years, and it has been recommended to use littermates and establish congenic colonies. Besides mice, rats, rabbits, zebrafish, guinea pigs, pigs, dogs, and nonhuman primates have been used in thrombosis research. Especially advanced phase investigations of novel thrombolytics have been predominantly performed in baboons due to the significant similarity to human (patho-)physiology. Nevertheless, because of ethical, experimental, methodological, and economic aspects, studies on in vivo thrombus formation will likely continue to use primarily murine models of thrombosis. In the following, we will provide a summary of the most commonly used methods for the induction of arterial thrombosis in mice and will subsequently focus on the role of central platelet adhesion receptors and downstream signaling pathways for initiation and stabilization of growing thrombi in vivo.

Platelet Activation and Thrombus Formation at Sites of Injury

At sites of vascular injury, subendothelial matrix components and several plasma constituents become immobilized onto exposed tissue. Thereby, different proteins, including von Willebrand factor (vWF), fibrillar collagens, fibronectin, and laminin, come into contact with circulating platelets. These interactions induce (1) initial platelet contact with the exposed

[a]As assessed by tail bleeding time assays

extracellular matrix (ECM) (tethering); (2) adhesion, activation, and release of second-wave mediators to reinforce persistent activation; and (3) firm adhesion to the ECM and thrombus growth (Fig. 1).

Initial platelet tethering to exposed components of the ECM is mediated by binding of immobilized vWF to its major ligand on the platelet surface—glycoprotein (GP) Ibα (Savage et al. 1998). GPIbα-vWF interactions result in rapid deceleration of circulating platelets, but do not lead to firm adhesion to the ECM. Instead, platelet rolling enables binding of collagen to its major activating receptor on the platelet surface—GPVI (Nieswandt and Watson 2003). Collagen-activated platelets undergo a series of signaling events, culminating in a sustained rise of intracellular Ca^{2+} concentration, surface exposure of negatively charged procoagulant phosphatidylserine (PS), rearrangements of the cytoskeleton, mobilization of α- and dense granules, and release of soluble platelet agonists, such as adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) (Nieswandt et al. 2011; Dutting et al. 2012). Activated platelets also release polyphosphates that are considered to potently activate coagulation factor XII (FXII, Hageman factor)—the starting point of the intrinsic coagulation cascade (Muller et al. 2009). Furthermore, PS on the outer leaflet of the platelet membrane provides high-affinity binding sites for coagulation factors and together with exposed TF triggers thrombin generation (Heemskerk et al. 2013). Locally generated thrombins, ADP and TxA_2 reinforce cellular activation in an autocrine and paracrine fashion and recruit additional platelets to the growing thrombus. Finally, extra- and intracellular signaling events culminate in the induction of a conformational change of integrin adhesion receptors, most notably $\alpha_{II}b\beta_3$ (GPIIb/IIIa), from a low- to high-affinity state which triggers firm platelet adhesion and aggregation, and stabilizes the growing thrombus (Varga-Szabo et al. 2008).

Mouse Models for Assessment of Hemostatic Functions

An important requirement for antithrombotic agents is that they prevent thrombosis while only mildly affecting hemostatic functions. A major side effect of several widely used antiplatelet drugs is their adverse effect on primary hemostasis and the increased incidence of bleeding complications. The overall hemostatic function in mice is most frequently assessed in the tail bleeding assay, in which a small segment of the tail tip is cut by a surgical blade and the time to cessation of bleeding recorded (Fig. 2). Besides measurement of bleeding times, further important parameters include determination of total blood volume loss, rebleeding, and animal survival after challenge. Upon removal of the tail tip,

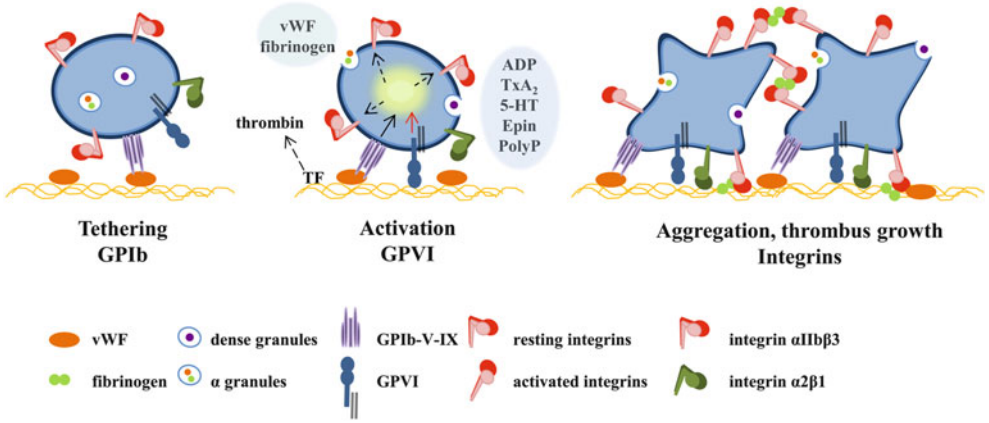

Fig. 1 Simplified model of thrombus formation. At sites of vascular injury, initial contact (tethering) of platelets with immobilized components of the exposed ECM is enabled through GPIb-vWF interactions. Subsequently, GPVI can bind to collagen which initiates a powerful signaling cascade that mediates increase in cytosolic Ca^{2+} concentration (not shown), release of α- and dense granules, and a conformational change of integrins to a high-affinity state. Released platelet agonists, such as ADP and thromboxane A_2 (TxA_2), together with locally produced thrombin, reinforce cellular activation in an autocrine and paracrine fashion. Activated integrins support firm platelet adhesion to the ECM which together with locally secreted or synthesized platelet agonists facilitates thrombus growth. *TF* tissue factor, *Epin*. epinephrine

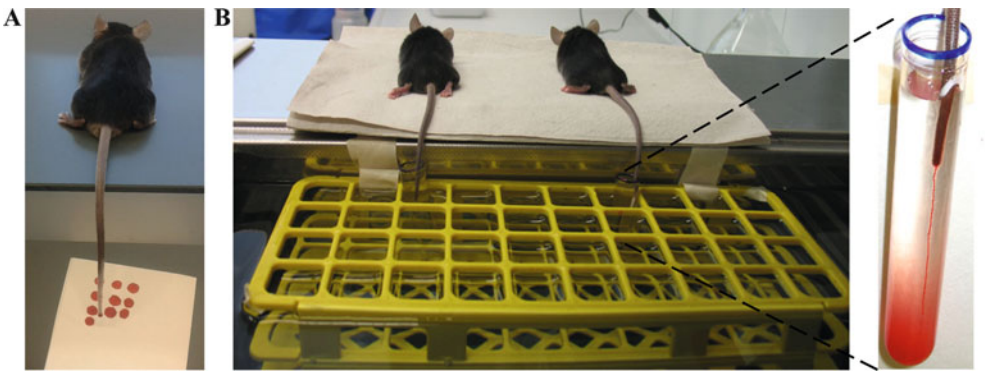

Fig. 2 Mouse models for assessment of hemostatic functions. (**a**) The tail tip of an anesthetized mouse is cut using surgical blade, and blood is gently adsorbed on filter paper without making contact with the wound site at 20-s intervals until cessation of blood loss. (**b**) Clipped mouse tail tips are immersed in warm (37 °C) 0.9 % isotonic saline

the tail is immersed in warm saline or PBS or blood is collected with Whatman paper or in a reaction tube.

Notably, the tail bleeding assay is susceptible to considerable variability even within the same mouse strain, and multiple factors may influence the outcome. For instance, the genetic background accounts for variations in total blood loss between different mouse strains (Schiviz et al. 2014). In addition, gender, age, weight, and, importantly, the type of anesthesia play a critical role for the time of cessation of bleeding. Of note, increased tail bleeding times do not necessarily correlate with compromised ability of platelets to maintain the vascular integrity at sites of thrombosis and inflammation. For example, blockade of the vWF receptor on the platelet surface—GPIbα—significantly prolongs the time to cessation of blood loss in the tail tip model, but leads to a profound protection in a murine model of acute ischemic stroke, without increasing the incidence of intracranial hemorrhage (Kleinschnitz et al. 2007) (Stoll et al 2017 in this volume). In summary, despite its dependence on different variables, the tail tip assay remains the most frequently used test of hemostatic functions in mice.

Murine Models of In Vivo Arterial Thrombus Formation

Although a substantial body of knowledge about the central signaling pathways mediating platelet activation has been gained by in vitro studies, a major advance in our understanding of the complex interplay between platelets, the vessel wall, and local hemodynamic conditions that govern thrombus growth has been achieved only after the introduction of

intravital microscopy techniques. Widely used in vivo arterial thrombus formation models differ in the size of the vascular bed, and the method to induce endothelial denudation by laser, chemical, or mechanical injury.

One largely used technique to study thrombus formation in the microcirculation by fluorescence intravital microscopy is the laser-induced vessel wall injury model (Falati et al. 2002; Rosen et al. 2001). The intensity of the laser power in this minimally invasive injury model can be varied to modulate the severity of injury which in turn has been shown to determine the major pathways governing platelet activation at the site of injury (Nonne et al. 2005). The exposure of collagen fibers has been proposed to be the predominant mechanism underlying thrombus formation upon superficial injury, whereas a more severe injury leads to massive thrombin generation which appears to be sufficient to drive thrombus formation largely independently of collagen-induced activation events (Mangin et al. 2006). Of note, laser-induced endothelial denudation leads to rapid platelet accumulation at sites of injury which, however, typically triggers nonocclusive thrombus formation.

Recent seminal work has provided insight into the complex architecture of a hemostatic plug in the microcirculation formed after laser injury. These experiments revealed that platelet activation is not necessarily uniformly distributed, but is rather heterogeneous and depends on the spatial and temporal regulation of agonist distribution within the thrombus (Stalker et al. 2014). Based on the expression of α-granule P-selectin on the platelet surface upon powerful cellular activation, observational studies detected the presence of a stable densely packed core close to the injury site composed of fully activated platelets and a more loosely organized and accordingly less stable outer shell built by P-selectin-negative platelets (Stalker et al. 2013). Detailed investigations also identified a distinct distribution of soluble platelet agonist gradients. Thrombin generation and fibrin deposition are typically found in the core region, adjacent to the laser-induced lesion, and are spatially restricted to the distribution of procoagulant membranes of platelets and endothelial cells at the site of injury (Stalker et al. 2013; Ivanciu et al. 2014; Welsh et al. 2014). By contrast, inhibition of the activity of ADP, which is secreted from platelet dense granules or released from damaged cells at injury sites, plays an important role for the reduction of the outer shell region (Stalker et al. 2013). The localization of TxA_2, which is generated and secreted by activated platelets and reinforces cellular activation in an autocrine and paracrine fashion, is less well defined, and likely depends predominantly on its major source—activated platelets (Stalker et al. 2014). Recent computational models ascribed the different distribution of soluble agonists to the physically heterogeneous structure and density of the platelet plug that accounts for distinct transport properties of the core and the shell region (Welsh et al. 2014; Stalker et al. 2014). Taken together, a better understanding of the complex architecture of the thrombus with a defined localization of prominent platelet agonists may have important implications for both the use of currently available therapies and the development of new antithrombotics.

Chemical injury by a topical application of ferric chloride ($FeCl_3$) onto the surface of a vessel is one of the most frequently used experimental procedures to induce thrombosis in rodents (Fig. 3) (Schoenwaelder and Jackson 2015). The method was initially described for the induction of arterial thrombosis in rats (Kurz et al. 1990) and is meanwhile one of the most commonly applied techniques to investigate in vivo thrombus formation in mice because of the relative simplicity of implementation. Ferric chloride is typically applied to vessels accessible to a Doppler flow probe (such as the common carotid artery) to monitor the blood flow rate upon injury. Alternatively, accumulation of labeled platelets and the subsequent formation of an occlusive thrombus at sites of injury can be visualized by intravital microscopy of arterioles in the mesentery or the cremaster muscle.

Despite its common use, the exact mechanisms of $FeCl_3$-induced thrombosis are not fully elucidated yet, and therefore remain controversially discussed. A long-standing theory that the major effects of this type of chemical injury are restricted to the vasculature has been recently refined. A few studies have demonstrated that ferric chloride is taken up by endothelial cells and afterwards released into the vessel lumen (Tseng et al. 2006; Eckly et al. 2011). Several investigators then assumed that the high concentration of iron and potentially reactive oxygen species generation may lead to endothelial denudation and subsequent exposure of subendothelial components that trigger thrombosis (Kurz et al. 1990; Li et al. 2013). Importantly, however, further studies identified only minor endothelial lesions and collagen exposure and detected instead considerable accumulation of red blood cells at sites of $FeCl_3$-injury, followed by rapid platelet recruitment (Eckly et al. 2011; Barr et al. 2013; Woollard et al. 2009). Furthermore, TF was detected on ferric chloride particles which can mediate platelet adhesion and fibrin deposition (Eckly et al. 2011). Of note, the effects of $FeCl_3$ on the vasculature and on different blood cell populations likely depend on the applied concentration and exposure time, and differences in these two parameters may explain the controversy regarding the mode of action.

Another way to induce chemical injury that triggers arterial thrombosis is intravenous administration of the photoactive stain rose bengal. This substance rapidly accumulates in the membranes of endothelial and other cells upon application. A photochemical reaction is mediated by the exposure of an artery to green light (540 nm) which induces the generation of reactive oxygen species and lesion of the endothelium that fuels arterial thrombosis (Matsuno et al. 1991; Kikuchi et al. 1998; Westrick et al. 2007).

Finally, arterial thrombosis can be triggered by mechanical injury of large arteries (e.g., the abdominal aorta (Fig. 3),

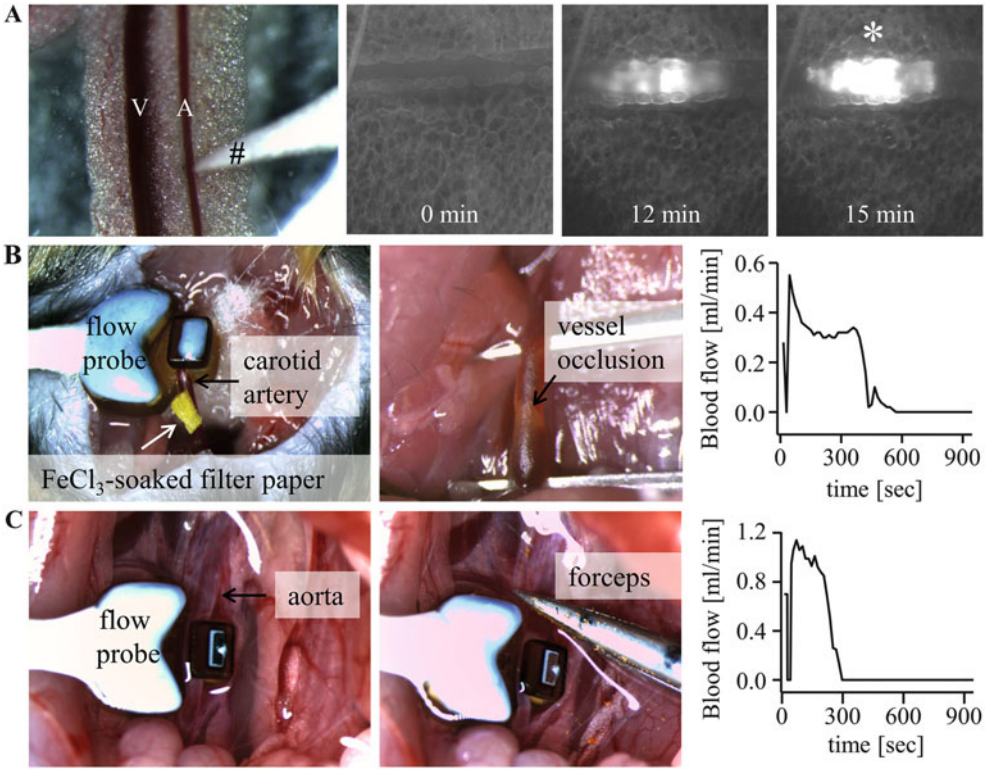

Fig. 3 Arterial thrombosis models. (**a**) Thrombus formation in $FeCl_3$-injured mesenteric arterioles. (*Left*) $FeCl_3$ is topically applied to an arteriole (**A**). *V* vein, *number sign* tip of the $FeCl_3$-soaked filter paper. (*Middle* and *right*) Accumulation of fluorescently labeled platelets at the site of injury at the indicated time points after $FeCl_3$-application as observed by intravital microscopy. *Asterisk* denotes stable vessel occlusion. (**b**) Thrombus formation in the $FeCl_3$-injured carotid artery. (*Left*) Experimental setup. Blood flow is monitored with an ultrasonic flow probe. (*Middle*) Stable vessel occlusion due to thrombus formation (*arrow*). (*Right*) Representative blood flow curve. (**c**) Mechanical injury of the abdominal aorta is triggered by a single firm compression with forceps (*middle*). (*Right*) Representative blood flow rates as measured with an ultrasonic flow probe

the common carotid arteries, or femoral arteries). Endothelial damage can be mediated indirectly by a firm compression of the vessel with a forceps or by ligation with a filament (Massberg et al. 2003; Renne et al. 2005), by combination of both techniques (Mangin et al. 2006), or directly by introducing a guidewire into the vessel (Konishi et al. 2002; Massberg et al. 2003). Thrombus formation following compression or ligation of arterial vessels occurs mainly through collagen-dependent mechanisms, as demonstrated by the profound protection from arterial thrombosis in mice deficient for GPVI, the central activating collagen receptor on the platelet surface (Massberg et al. 2003; Bender et al. 2011).

A relatively simple method to study thrombotic activity in mice is the infusion of a mixture of collagen and epinephrine or collagen and ADP which induces rapid platelet consumption due to intravascular thrombus formation and typically leads to lethal pulmonary thromboembolism in wild-type animals within a few minutes (DiMinno and Silver 1983). Radiolabeling of platelets (e.g., with ^{111}Indium oxine (Thakur et al. 1976)) can be applied for in vivo monitoring of aggregate formation in the lung after induction of thromboembolism (Oyekan and Botting 1986; Tymvios et al. 2008). Antibody-mediated depletion of GPVI (Nieswandt et al. 2001c) or its genetic deficiency (Pozgajova et al. 2006) provided a profound protection from collagen/epinephrine-induced thromboembolism. Likewise, mice lacking the α_{2A}-adrenergic receptor were resistant to thromboembolism in this model (Pozgajova et al. 2006), as were animals deficient for the ADP receptor $P2Y_1$ (Fabre et al. 1999; Leon et al. 1999) or mice treated with the selective $P2Y_1$ receptor antagonist MRS2500 (Hechler et al. 2006). Similarly, mice deficient for G-protein α-subunits, such as $G\alpha_q^{-/-}$ (Offermanns et al. 1997) or $G\alpha_z^{-/-}$ (Yang et al. 2000), were protected from the systemic effects triggered by the collagen/epinephrine challenge.

Alternatively, mechanisms of pulmonary embolism can be studied in a thrombin-dependent model in which infusion of thromboplastin (TF) mimics TF exposure (Leon et al. 2001). The thrombin receptors on mouse platelets PAR3 and PAR4 (Weiss et al. 2002; Hamilton et al. 2004) as well as the ADP receptor $P2Y_1$ have been identified to critically contribute to pulmonary thrombosis in this model.

The arterial thrombosis models presented here differ in the severity and extent of injury, vessel size, degree of vessel occlusion, and signaling pathways that initiate thrombus formation. Therefore, critical requirements to future research include a better understanding of the molecular mechanisms which predominantly drive thrombus growth in different injury models, increased recognition of advantages and disadvantages of each thrombosis model, and a recommendation to apply different models before drawing a conclusion on the role of distinct molecules in arterial thrombosis. Still, one major limitation that applies to all thrombosis models is the fact that mice are naturally not susceptible to atherothrombosis, and vessel occlusion is

induced in the healthy vasculature of experimental animals, whereas arterial thrombosis in humans occurs in diseased vessels.

Platelet Adhesion and Activation Receptors

GPIb

GPIb is part of the megakaryocyte-/platelet-specific GPIb-V-IX receptor complex and plays a crucial role for platelet tethering at sites of vascular injury through binding to vWF. Besides vWF, GPIb also interacts with P-selectin, thrombospondin, thrombin, macrophage antigen 1 (Mac-1), the coagulation factors XI and XII, and high-molecular-weight kininogen. Lack or dysfunction of GPIb-V-IX in humans is associated with the Bernard-Soulier syndrome (BSS), a rare inherited bleeding disorder characterized by the presence of giant platelets, thrombocytopenia and a bleeding phenotype (Andrews and Berndt 2013). These key features of the disease are recapitulated in mouse models deficient in GPIbα (Ware et al. 2000) or GPIbβ (Kato et al. 2004). Of note, mutations within genes encoding GPIbα, GPIbβ, and GPIX (but not GPV) have been identified to cause BSS, and, similarly, GPV-deficient mice do not reproduce the phenotype of the disease (Kahn et al. 1999).

The role of the GPIb-vWF axis for arterial thrombus formation has been extensively studied. Blockade of the vWF binding site on GPIbα by administration of anti-GPIbα Fab fragments (p0p/B) to wild-type mice significantly reduced platelet tethering to the injured carotid artery and correspondingly resulted in an abolished aggregate formation at sites of vascular injury (Massberg et al. 2003). Likewise, transgenic mice in which the extracellular domain of GPIbα was replaced by the α-subunit of the human IL-4 receptor exhibited a severe bleeding phenotype and were profoundly protected from $FeCl_3$-induced arterial thrombosis (Kanaji et al. 2002; Bergmeier et al. 2006; Konstantinides et al. 2006). Similarly, vWF-deficient mice displayed increased tail bleeding times or were unable to stop bleeding, and approximately 10 % of neonates were affected by spontaneous intra-abdominal bleeding (Denis et al. 1998). $vWf^{-/-}$ mice did not form occlusive thrombi in mesenteric arterioles upon ferric chloride-induced injury (Denis et al. 1998). Interestingly, however, platelet tethering was still occasionally observed in injured arterioles of $vWf^{-/-}$ mice and subsequently led to delayed appearance of first thrombi (Ni et al. 2000), demonstrating that the antithrombotic effects of GPIbα-deletion are more profound than those observed in mice deficient for its major ligand—vWF (Bergmeier et al. 2006; Denis et al. 1998). Importantly, the antithrombotic potential of targeting the GPIb-vWF axis has been documented also in baboons (Cauwenberghs et al. 2000; Wu et al. 2002).

Ultra-large vWF is a multimeric protein (up to 20,000 kDa) which is synthesized in endothelial cells and megakaryocytes. vWF multimers are rapidly cleaved in the plasma to less thrombogenic forms by the enzyme A disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13). The naturally occurring antithrombotic activity of ADAMTS13 is critical for dampening thrombosis, as revealed by accelerated thrombus formation in chemically injured arterioles of $Adamts13^{-/-}$ mice (Chauhan et al. 2006; Banno et al. 2009). Remarkably, concomitant deficiency of vWF abolishes the prothrombotic state in $Adamts13^{-/-}$ mice (Chauhan et al. 2008). Recombinant human ADAMTS13 which is currently in a phase I clinical study for the treatment of hereditary thrombotic thrombocytopenia purpura (TTP) (ClinicalTrails.gov identifier: NCT02216084) may have both antithrombotic and thrombolytic properties, but this awaits further experimental and clinical confirmation. An alternative approach to interfere with the GPIb-vWF axis could be the targeted downregulation of GPIbα from the platelet surface by proteolytical cleavage via A disintegrin and metalloproteinase 17 (ADAM17)/tumor necrosis factor-alpha-converting enzyme (TACE) (Bergmeier et al. 2004; Bender et al. 2010).

Further experimental support that interference with GPIb-vWF may become a potential approach for future treatment strategies in occlusive thrombotic disease conditions came from studies in mice which lack phospholipase D1 (PLD1). PLD1 activity is important for signaling transduction downstream of vWF-engaged GPIbα and thus controls GPIb-dependent $\alpha_{IIb}\beta_3$ activation and aggregate formation under high shear conditions (Elvers et al. 2010). Correspondingly, $Pld1^{-/-}$ mice were protected from arterial thrombosis in the chemically injured carotid artery and in the mechanically injured abdominal aorta, importantly, without affecting hemostasis (Elvers et al. 2010). In agreement with these findings, pharmacological blockade of PLD isoforms by the small molecule PLD inhibitor, 5-fluoro-2-indolyl des-chlorohalopemide (FIPI), reproduced the protection from arterial thrombosis in wild-type mice, thereby demonstrating that modulating the signaling cascade downstream of GPIb-vWF may emerge as a novel therapeutic approach (Stegner et al. 2013).

The (Hem)ITAM Receptors GPVI and CLEC-2

The central activating collagen receptor GPVI is a megakaryocyte-/platelet-specific transmembrane type I receptor which is non-covalently associated with the FcRγ-chain that serves as the signaling subunit of the receptor complex

because it contains an immunoreceptor tyrosine-based activation motif (ITAM) in its cytoplasmic tail (Nieswandt and Watson 2003). To date, a few patients with GPVI-associated defects have been reported. These defects have been ascribed to autoantibody-triggered receptor loss (Sugiyama et al. 1987; Boylan et al. 2004; Arthur et al. 2007) and compound heterozygous (Dumont et al. 2009; Hermans et al. 2009) and homozygous mutations in the *GP6* gene (Matus et al. 2013). Platelets isolated from these patients displayed abolished aggregation following stimulation with collagen, whereas the patients showed only a mild bleeding tendency. Likewise, genetic (Kato et al. 2003; Mangin et al. 2006; Lockyer et al. 2006; Bender et al. 2013) or antibody-induced deficiency of GPVI (Nieswandt et al. 2001c; Bender et al. 2013) had no or only a mild effect on tail bleeding times.

A large body of experimental data has documented a profound protection from arterial thrombosis induced in different vascular beds and by a variety of injury methods in wild-type mice depleted of GPVI (Massberg et al. 2003; Bender et al. 2011, 2013), in $Gp6^{-/-}$ mice (Konstantinides et al. 2006; Bender et al. 2011), or in FcRγ-deficient mice which also lack GPVI (Nieswandt et al. 2000; Konishi et al. 2002; Gruner et al. 2005; Dubois et al. 2006). By contrast, increased receptor density and enhanced GPVI signaling are associated with accelerated occlusive thrombus formation in mice (Cherpokova et al. 2015). Furthermore, the efficacy of GPVI inhibition as a promising novel antithrombotic strategy was further emphasized by studies in rats and nonhuman primates treated with Fab fragments of anti-GPVI antibodies (Matsumoto et al. 2006; Li et al. 2007; Ohlmann et al. 2008). Of note, a few studies identified GPVI-independent mechanisms of arterial thrombus formation which are likely related to altered severity or extent of vascular injury (Mangin et al. 2006; Dubois et al. 2006; Eckly et al. 2011). Remarkably, previously unrecognized properties of GPVI to bind to polymerized fibrin have been only very recently identified, and these interactions may have an important function for the stabilization of the growing thrombus (Mammadova-Bach et al. 2015; Alshehri et al. 2015).

Based on the findings that GPVI deficiency, blockade, or antibody-mediated depletion in mice and other experimental animals provides powerful protection from arterial thrombosis without affecting hemostasis, the receptor has emerged as an attractive potential target for antithrombotic therapy (Dutting et al. 2012). Current GPVI targeting strategies under development focus on three different approaches. They include (1) blockade of the GPVI-collagen interaction, (2) immunodepletion of GPVI via monoclonal antibodies, or (3) interference with key signaling molecules downstream of the receptor, such as the tyrosine kinase Syk (Stegner et al. 2014). GPVI immunodepletion by monoclonal antibodies induces specific and irreversible removal of the receptor from the surface of murine platelets, resulting in a GPVI-knockout-like phenotype for at least 2 weeks which is accompanied only by a short thrombocytopenia and a transiently reduced PAR4 activity at early time points after antibody administration (Nieswandt et al. 2001c; Schulte et al. 2003, 2006). Antibody-triggered GPVI downregulation in vivo is still incompletely understood, but experimental evidence suggests that receptor depletion occurs through two principal mechanisms: ectodomain shedding and internalization followed by intracellular degradation (Nieswandt et al. 2001c; Boylan et al. 2006; Rabie et al. 2007; Takayama et al. 2008; Bender et al. 2010). Both mechanisms require signaling through the ITAMs in the FcRγ-chain (Rabie et al. 2007). Importantly, studies in nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice demonstrated that GPVI can also be removed from the surface of circulating human platelets (Boylan et al. 2006). Similar to the effects observed in mice following antibody-induced GPVI downregulation (Schulte et al. 2006), immunodepletion of GPVI from the surface of human platelets was associated with reduced responsiveness to G-protein-coupled receptor (GPCR) activation, implicating that removal of GPVI may have a broader impact on platelet function than previously assumed (Boylan et al. 2006).

Although compelling experimental data corroborate the notion that GPVI may become a promising antithrombotic target, careful assessment of the safety profile of an anti-GPVI therapy is warranted. GPVI immunodepletion severely compromises the overall hemostatic capacity in mice deficient for the hemITAM receptor C-type lectin-like receptor 2 (CLEC-2) (Boulaftali et al. 2013; Bender et al. 2013), another collagen receptor on the platelet surface—α2β1, or concomitantly treated with acetylsalicyclic acid (ASA) (Gruner et al. 2004). These findings reveal a critical functional redundancy between (hem)ITAM-bearing receptors, on the one hand, and between collagen receptors, on the other, in the maintenance of platelet hemostatic functions in mice which may explain the mild bleeding tendency in the absence of GPVI in mice and humans. Moreover, these experimental data emphasize the necessity to evaluate the functional status of other receptors prior to and during GPVI targeting.

Based on initial studies on the role of the second (hem) ITAM-containing receptor on mouse platelets CLEC-2 in thrombosis and hemostasis, it has been proposed that the receptor might become a target for antithrombotic therapy. Antibody-mediated downregulation of CLEC-2 from circulating platelets (May et al. 2009) or genetic ablation of the receptor (Suzuki-Inoue et al. 2010) was accompanied by a significant protection from occlusive arterial thrombosis in mice and resulted only in a moderate increase in bleeding

times. However, recent findings that revealed a pivotal role for CLEC-2 in a plethora of processes, including development of lymph nodes, maintenance of the integrity of high endothelial venules, and blood/lymph vessel separation, question the suitability of the hemITAM receptor as a safe antithrombotic target (Boulaftali et al. 2014). The third ITAM-bearing receptor—FcγRIIa—is not expressed on the surface of mouse platelets. A study utilizing a transgenic mouse model that expresses the human FcγRIIa (McKenzie et al. 1999) demonstrated enhanced arterial thrombus formation in the laser-injured cremaster muscle arterioles (Zhi et al. 2013). These data together with the well-established role of FcγRIIa in the pathogenesis of several disease conditions related to immune-mediated thrombocytopenia and thrombosis syndrome suggest that modulating the activity of the receptor may have important implications in future antithrombotic and anti-inflammatory therapies.

A naturally occurring mechanism to attenuate constitutive signaling through (hem)ITAM receptors is mediated by the action of immunoreceptor tyrosine-based inhibitory motif (ITIM)-bearing receptors. To date, the expression of a few ITIM-containing receptors in platelets has been described, including platelet endothelial cell adhesion molecule-1 (PECAM-1), G6b-B, TREM-like transcript-1 (TLT-1), and carcinoembryonic antigen-related cell adhesion molecule-1 (CEACAM1) and CEACAM2. Deficiency of PECAM-1 (Falati et al. 2006), CEACAM1 (Wong et al. 2009), or CEACAM2 (Alshahrani et al. 2014) was associated with slightly enhanced arterial thrombus formation upon injury which demonstrates a minor inhibitory role of individual ITIM receptors in this process and points toward a substantial functional redundancy among inhibitory mechanisms in platelets. In addition, a few proteins which interact with the GPVI signalosome, such as CLP36 (Gupta et al. 2012) and Src-like adapter proteins (SLAP/SLAP2) (Cherpokova et al. 2015), have been identified, and deficiency of these molecules resulted in a profound prothrombotic phenotype, thus revealing an important inhibitory function of the adapter molecules in dampening excessive ITAM signaling at sites of vascular injury.

α2β1

The second prominent collagen receptor on the platelet surface—integrin α2β1—contributes to, but is not essential for, platelet adhesion on collagen under flow (Nieswandt et al. 2001b; Nieswandt and Watson 2003). Antibody-induced blockade of α2 or genetic deficiency of the integrin subunit in mice (*Itga2*$^{-/-}$) was reported to have no or only a very minor inhibitory effect on arterial thrombus formation (Holtkotter et al. 2002; Chen et al. 2002; He et al. 2003; Gruner et al. 2003; Kuijpers et al. 2007; Shida et al. 2014). These rather mild effects could be attributed to the still largely intact response of the platelets to collagen via GPVI and platelet adhesion to multiple components of the ECM through other integrins (most notably $\alpha_{IIb}\beta_3$). In line with the findings in α2-deficient mice, deletion of integrin β1 specifically in platelets, which besides α2β1, also ablates α5β1 (fibronectin receptor) and α6β1 (laminin receptor) expression, did not affect platelet aggregation and stable thrombus formation in the injured carotid artery (Gruner et al. 2003). Furthermore, these studies also pointed toward a principal role of integrin $\alpha_{IIb}\beta_3$ for firm platelet adhesion at sites of vascular injury (Gruner et al. 2003).

Platelet Aggregation

As mentioned above, platelet aggregation plays a pivotal role for the formation of a stable thrombus at the injured vessel wall. Key to this process is the activity of the integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa). Integrin $\alpha_{IIb}\beta_3$ supports thrombus stabilization through binding to fibrinogen, thereby mediating bridging of adjacent cells. In addition, $\alpha_{IIb}\beta_3$ interacts with several other proteins exposed on the ECM, including fibronectin, vWF, thrombospondin, and vitronectin (Bergmeier and Hynes 2012). Congenital deficiency or dysfunction of integrin $\alpha_{IIb}\beta_3$ in humans is associated with Glanzmann thrombasthenia characterized by a severe bleeding diathesis and inability of platelets to adhere (Nurden et al. 2013). Similarly, mice deficient for either αIIb (GPIIb) or β3 (GPIIIa) integrin subunit phenocopied key features of the disease by displaying defective platelet aggregation, clot retraction and severe hemostatic defects and, in addition, abolished thrombus formation in injured vessels (Hodivala-Dilke et al. 1999; Tronik-Le Roux et al. 2000; Smyth et al. 2001). Likewise, mice lacking the major integrin $\alpha_{IIb}\beta_3$ ligand—fibrinogen—suffer from severe bleedings after birth, and their platelets failed to aggregate or induce blood clotting (Suh et al. 1995). Mice which express a truncated form of fibrinogen (FgγΔ5) that lacks the integrin $\alpha_{IIb}\beta_3$ binding motif, but conversion to fibrin remains unaffected by the mutation, could not stop bleeding from the tail tip, but were able to prevent excessive blood loss at other injury sites and displayed unaltered clot retraction in vitro (Holmback et al. 1996). Interestingly, both fibrinogen-deficient and FgγΔ5 mice formed thrombi in $FeCl_3$-injured mesenteric arterioles which, however, often embolized, thereby emphasizing the critical role of fibrinogen for thrombus stabilization by bridging $\alpha_{IIb}\beta_3$ of adjacent platelets (Ni et al. 2000, 2003a). Unexpectedly, occlusive thrombus formation still occurred in mice with a fibrinogen/vWF double deficiency, albeit thrombi were more fragile, leading to frequent embolization and resultant vessel occlusion downstream of the site of injury (Ni et al. 2000). Recent

studies identified that fibronectin, which is required for stable thrombus growth in $FeCl_3$-injured arterioles (Ni et al. 2003b), likely accounts for fibrinogen/vWF-independent platelet aggregation and occlusive thrombus formation (Wang et al. 2014).

To date, a plethora of proteins have been identified to interact with cytoplasmic tails of integrin subunits and have been proposed to modulate integrin inside-out and outside-in signaling (Nieswandt et al. 2009). However, the exact contribution of numerous of these proteins to integrin activation is still under investigation or has been controversially discussed. By contrast, the functional significance of only a few of these molecules has been elucidated in detail. For instance, talin-1 which binds to the cytoplasmic tail of both αIIb and β3 is essential for integrin activation, platelet aggregation, platelet hemostatic functions, and stable thrombus formation in injured vessels (Nieswandt et al. 2007; Petrich et al. 2007). Likewise, deficiency of another critical component of the integrin activation machinery in platelets—kindlin-3—resulted in abrogated activation of $\alpha_{IIb}\beta_3$ and β1 integrins and was accompanied by a severe hemostatic defect and abolished arterial thrombus formation (Moser et al. 2008). Importantly, mutations in *FERMT3*, the gene encoding human kindlin-3, have been identified in humans suffering from a disease condition termed leukocyte adhesion deficiency III (LAD-III), characterized by a severe bleeding diathesis, dramatically increased susceptibility to infections and poor wound healing, among other symptoms (Malinin et al. 2009; Mory et al. 2008; Svensson et al. 2009).

Several molecules have been implicated to be critically involved in orchestrating the complex signaling cascade that eventually leads to talin-1/kindlin-3-dependent integrin activation. Among the numerous constituents of this signaling machinery, Rap1, Ca^{2+} and diacylglycerol-regulated guanine-nucleotide-exchange factor 1 (CalDAG-GEFI) and RASA3, but unexpectedly not Rap1-GTP-interacting adapter molecule (RIAM), have been demonstrated to control hemostasis and arterial thrombosis in mice (Chrzanowska-Wodnicka et al. 2005; Crittenden et al. 2004; Stolla et al. 2011; Stefanini et al. 2015; Stritt et al. 2015).

Soluble Platelet Agonists

Thrombin

Thrombin is rapidly generated at sites of vascular injury and induces rapid and powerful platelet activation via receptors of the PAR family (PAR1 and PAR4 in human platelets and PAR3 and PAR4 in mouse platelets). Absence of PAR3 or PAR4 is associated with a profound protection in murine models of arterial thrombosis (Kahn et al. 1998; Weiss et al. 2002; Sambrano et al. 2001; Vandendries et al. 2007). Interestingly, PAR3-deficient platelets displayed a weak response to thrombin, whereas PAR4-deficiency was accompanied by a complete resistance to thrombin activation, emphasizing that PAR4 is the sole signaling protease-activated receptor for thrombin in mouse platelets (Weiss et al. 2002; Sambrano et al. 2001). A series of intravital microscopy studies revealed that the activity of thrombin is spatially and temporally restricted to the stable core of the growing thrombus composed of fully activated platelets where thrombin plays a critical role for its stabilization (Stalker et al. 2013, 2014).

Other Platelet Agonist Operating via GPCRs

ADP

ADP is released from platelet dense granules and other activated cells at the site of injury and potentiates platelets responses by engagement of two receptors—$P2Y_1$ and $P2Y_{12}$. $P2Y_1$-deficient mice displayed moderately increased tail bleeding times and a significant protection in a model of collagen/epinephrine-induced thromboembolism (Fabre et al. 1999; Leon et al. 1999). The significance of $P2Y_{12}$ for platelet activation is exemplified by currently available $P2Y_{12}$ antagonists that efficiently inhibit platelet activation and protect from thrombotic events in humans (Michelson 2010). This hallmark of $P2Y_{12}$ blockade is recapitulated in mice which were treated with $P2Y_{12}$ antagonists or genetically engineered mice that lack $P2Y_{12}$ or $G\alpha_{i2}$, the principal G-protein coupled to $P2Y_{12}$, which displayed unstable nonocclusive arterial thrombus formation, accompanied, however, by prolonged tail bleeding times (Foster et al. 2001; Andre et al. 2003; Stolla et al. 2011; Devanathan et al. 2015). Recent elegant studies demonstrated that $P2Y_{12}$ inhibition is most efficient in reducing the size of the outer shell of loosely packed platelets, whereas $P2Y_{12}$ antagonists did not significantly affect the thrombus core (Stalker et al. 2013). These findings provide an important insight into the mode of action of clinically used $P2Y_{12}$ antagonists and help to explain their safety profile.

TxA_2

Similar to ADP, TxA_2 is secreted from activated platelets and reinforces cellular activation. TxA_2 is synthesized from arachidonic acid via the cyclooxygenase-1 pathway which is sensitive to treatment with ASA. Significantly, the importance of TxA_2 synthesis inhibition in antiplatelet therapies is illustrated by the efficacy of ASA in the prevention of (recurrent) occlusive thrombotic events in humans, albeit accompanied by an increased risk of bleeding (Michelson 2010).

TxA_2 activates platelets via engagement of the TxA_2 receptor α and β. TxA_2 receptor-deficient mice exhibited

prolonged tail bleeding times and a delayed response to collagen activation in vitro (Thomas et al. 1998). Similarly, ASA treatment led to mildly increased bleeding times in wild-type mice, but, depending on the model and applied dose, had diverging effects on experimental arterial thrombosis (Gruner et al. 2004; Kuijpers et al. 2007; Dutting et al. 2014). For instance, administration of 10 mg/kg body weight ASA to wild-type mice resulted in decreased thrombus stability and increased embolization in $FeCl_3$-injured mesenteric arterioles (Kuijpers et al. 2007), whereas 1 mg/kg body weight ASA affected occlusion times only very mildly in this model and had virtually no effect on the time to stable vessel occlusion in the mechanically injured abdominal aorta (Dutting et al. 2014). By contrast, ASA treatment was accompanied by defective thrombus formation in growth factor receptor-bound protein 2 (Grb2)-deficient mice, whose platelets displayed markedly impaired reactivity to (hem)ITAM-specific receptor stimulation (Dutting et al. 2014). Collectively, these experimental data further emphasize that an important functional redundancy exists between (hem)ITAM and TxA_2-induced GPCR signaling in in vivo thrombus formation.

Monoamines

Platelets take up serotonin (5-hydroxytryptamine, 5-HT) circulating in the periphery and store it in their dense granules. Following platelet activation, serotonin is released and as part of a positive-feedback loop can potentiate cellular activation by acting on G_q-coupled 5-HT_{2A} receptors on the platelet surface (Offermanns 2006). Mice deficient for tryptophan-hydroxylase 1 (Tph1), the rate-limiting enzyme in serotonin biosynthesis in the periphery (Walther et al. 2003a), which consequently also lack peripheral 5-HT, were protected from $FeCl_3$-triggered occlusive thrombus formation in arterioles and displayed significantly prolonged bleeding times (Walther et al. 2003b). Likewise, deficiency of the serotonin transporter 5-HTT in mice (Bengel et al. 1998) which abolishes serotonin uptake into platelets was associated with increased bleeding times and instable thrombus formation in the mechanically injured abdominal aorta or the chemically injured carotid artery (Wolf et al. 2016). Conversely, systemically elevated 5-HT plasma levels through in vivo administration of 5-HT into mice resulted in shortened tail bleeding times and accelerated occlusion rates in $FeCl_3$-injured carotid arteries (Ziu et al. 2012). Studies on serotonin antagonists have long been hampered by the lack of specificity of these agents for the 5-HT_{2A} receptor. Both the prophylactic (prior to injury) and the therapeutic administration of APD791, a selective inverse agonist of the 5-HT_{2A} receptor which does not display functional activity on 5-HT_{2B} and 5-HT_{2C}, have been reported to be protective in a canine model of recurrent coronary thrombosis without affecting hemostatic functions (Przyklenk et al. 2010). However, these studies did not directly address the question whether the protection is solely platelet-dependent or if it can be ascribed in addition to attenuation of serotonin-induced vasoconstriction (Przyklenk et al. 2010). The suitability of 5-HT_{2A} receptor inhibitors to complement existing antithrombotic agents remains to be determined.

Similar to serotonin, epinephrine is a weak platelet agonist which can potentiate existing cellular activation via the α_{2A}-adrenergic receptor that preferentially couples to the G_i-protein G_z on platelets (Nieswandt et al. 2001a; Offermanns 2006). In vitro studies revealed unaltered responses of α_{2A}-deficient platelets to several major platelet agonists, including thrombin, collagen, ADP, and the TxA_2 analog U-46619 (Pozgajova et al. 2006). Interestingly, α_{2A}-deficient mice exhibited reduced thrombus stability and frequent embolization in $FeCl_3$-injured mesenteric arterioles and in the mechanically injured abdominal aorta, which was attributed to reduced potentiation of platelet activation through the α_{2A}-adrenergic receptor at sites of vascular injury (Pozgajova et al. 2006).

The Contact Phase of Blood Coagulation

Recent experimental evidence suggested that the contact phase of blood coagulation, specifically the coagulation factors FXI and FXII, promote arterial thrombosis (Rosen et al. 2002; Wang et al. 2005; Renne et al. 2005; Muller et al. 2011). However, the mechanisms by which platelets activate the intrinsic coagulation pathway remain elusive, and it is currently unclear whether direct interactions between both coagulation factors and platelets indeed occur (e.g., via GPIbα or polyphosphates) (Muller et al. 2009; Heemskerk et al. 2013). Pharmacological inhibition of activated FXII mediated a profound protection from occlusive arterial thrombosis in mice, importantly, without increasing the bleeding risk, which mirrors findings in $F12^{-/-}$ mice and FXII-deficient humans, thus emphasizing the potential of FXII targeting as a novel and safe antithrombotic strategy (Renne et al. 2005; Hagedorn et al. 2010). Of note, several inhibitors of FXI and FXII have been developed, and their in vivo antithrombotic efficacy and safety are currently under preclinical investigation (Kenne and Renne 2014).

Concluding Remarks

Experimental animal models and particularly the use of genetically engineered mice have substantially advanced our understanding of the complex mechanisms underlying thrombus formation in vivo. Genome editing methods

together with significant improvements in intravital microscopy techniques have been instrumental for the refinement of long-standing theories and for the development of novel strategies for the treatment of thrombotic and inflammatory disease conditions. Work in this research area is likely to be significantly accelerated in the future by the large number of mutant mouse strains available from public sources and additionally by the recently introduced CRISPR-Cas9 technique that allows highly efficient genome editing. Constant improvements in resolution enable us now to draw conclusions on the contribution of cell-cell and cell-matrix interactions for the initiation and progression of thrombus growth. Furthermore, these technical advances are increasingly used for the investigation of functions of platelets beyond their well-established role in thrombosis, e.g., for the progression of ischemic stroke or during critical steps of blood/lymphatic vessel separation.

Experimental animal models will remain instrumental for the characterization of novel antiplatelet agents in preclinical research. A significant challenge in this field remains the uncoupling of efficient protection from thrombotic events from undesired side effects on hemostatic functions. This requirement is central to the development of better strategies or the improvement of existing ones for the control of acute and chronic cardio- and cerebrovascular syndromes.

Take-Home Messages

- Intravital microscopy studies in mice have substantially advanced our understanding of the interactions between platelets, other blood cell types, and the vessel wall that controls thrombus growth.
- The tail bleeding time assay is the most frequently used test to assess overall hemostatic functions in mice.
- Widely used mouse in vivo arterial thrombus formation models differ in the size of the vascular bed and the method to induce endothelial denudation by laser, chemical, or mechanical injury.
- Mouse models of thrombosis are indispensable for the development and characterization of antiplatelet drugs.
- State-of-the-art intravital microscopy and tools allowing manipulations of the mouse genome have allowed the identification of novel targets for effective, yet safe, antithrombotic therapy.

Next-Generation Sequencing in the Study of Platelets

Vincenzo C. Leo

Abstract

Platelet function disorders (PFDs) arise as a result of defects in platelet formation or function, which can lead to a bleeding diathesis of varying severity, and are often accompanied by additional syndromic features. Well-characterised disorders such as Glanzmann thrombasthenia and Bernard–Soullier syndrome can be diagnosed by extensive platelet phenotyping and confirmed by downstream genetic analysis directed to one or several target genes. However, because of the complexity and heterogeneity of most PFDs, diagnosis and identification of the underlying genetic defect is difficult to obtain. Recent advances in the use of next-generation sequencing (NGS) technologies have facilitated the identification of many novel genetic defects underlying disease. Use of this technology produces a vast amount of genetic information and requires a pipeline of analysis for candidate variant prioritisation. Many studies exclude synonymous and common variants because the most likely candidates are thought to be rare or novel and alter the encoded protein. Identification of the causative variant is greatly aided by the inclusion of multiple affected or unaffected family members. The use of NGS will continue to identify novel genes in association with PFDs and unravel the intracellular mechanisms involved in platelet formation and function, possibly contributing to the development of novel therapies for bleeding disorders and cardiovascular disease.

Platelets play a pivotal role in stemming bleeding following vascular injury. Crucial to thrombus formation is the presence of abundant platelets within the blood stream and their correct functionality. DNA alterations in the genes encoding the proteins that function in a number of cellular processes within a platelet can result in impaired platelet production or function, ultimately leading to a platelet function disorder (PFD). PFDs are characterised by symptoms of excessive bleeding, including easy bruising, epistaxis, gum bleeding and prolonged bleeding following trauma or surgery. It is important to determine whether the disorder is the result of an acquired or inherited defect or is secondary to another disorder. This is usually identified through a detailed clinical history. However, diagnosis of a PFD is difficult if based solely on the clinical symptoms. Following referral, a range of laboratory investigations are carried out to test for coagulopathies such as haemophilia and von Willebrand disease. Platelet number and size are then obtained and further investigations carried out in the form of platelet function tests. These tests include light transmission aggregometry (LTA), which measures platelet aggregation in response to a panel of agonists at a range of concentrations and is usually performed alongside a control subject. In addition, several other techniques can be utilised to provide a full platelet phenotype and include lumiaggregometry to detect dense granule secretion, flow cytometry to detect α-granule secretion and a range of receptor protein levels, and electron microscopy to visualise granule number and morphology (Watson et al. 2013).

Platelet phenotyping can be used to directly diagnose patients with well-characterised disorders caused by qualitative and/or quantitative impairment of platelet receptors, such as Bernard–Soulier syndrome (BSS) and Glanzmann thrombasthenia, which are confirmed through genetic analysis of target genes. In addition, the results of LTA can suggest less-characterised PFDs associated with defects in platelet receptors, including the $P2Y_{12}$ ADP receptor (Dawood et al. 2012), GPVI (Dumont et al. 2009) and the thromboxane receptor (Hirata et al. 1994; Nisar et al. 2011), directing downstream analysis for identification of the underlying genetic defect.

However, the majority of platelet phenotypes from cases presenting with PFDs do not direct downstream genetic analysis and, therefore, diagnosis of the underlying genetic cause becomes problematic. Potential reasons for this could be gaps in the understanding of the genes involved in specific molecular mechanisms important for platelet function and the redundancy that exists within platelet signalling, leading to difficulties in linking phenotype to genotype.

Use of Next-Generation Sequencing in Identification of Novel Genes Associated with PFDs

The development of next-generation sequencing (NGS) technologies has permitted large-scale simultaneous genetic analysis of a targeted panel of genes, the whole exome or the whole genome. Sequencing of a targeted panel of genes, known or predicted to be involved in a particular disorder, can be more cost-effective than whole exome or genome sequencing. It also provides a higher coverage of the genes of interest and reduces the complexity of analysis. However, as the number of target genes grows for a particular disorder or group of disorders, it becomes more cost-effective to perform whole exome sequencing (WES). Because the majority of disease-causing mutations occur within the coding regions of the genome, WES offers an attractive approach for large-scale genetic analysis. Similarly, because exons account for only 1 % of the genome, the complexity of analysis is reduced compared with that of whole genome sequencing (WGS). However, a complete genetic profile is only provided with WGS, which may identify more novel genetic alterations associated with disease than other types of NGS methods. Interpretation and analysis of WGS data becomes more complex as the amount of information generated increases. All NGS methodologies have proven effective in identifying the underlying genetic causes of many PFDs in cases where the defect was previously unknown. This chapter reviews the novel genes identified as associated with PFDs and discovered using NGS-based methods.

NBEAL2

The earliest benefit of NGS in the diagnosis of bleeding disorders was achieved in 2011 by sequencing the exome of four unrelated patients with gray platelet syndrome (GPS), a recessive disorder characterised by thrombocytopenia, moderate bleeding and a lack of α-granules (Albers et al. 2011). Because the disorder has an autosomal recessive mode of inheritance, homozygous variants or genes in which two or more variants were detected (suggestive of a compound heterozygous mutation) were prioritised and all previously reported single nucleotide variants (SNVs) were removed from analysis. Homozygous or compound heterozygous mutations were identified in the gene *NBEAL2* in all four subjects. Simultaneously, using different approaches, two other groups identified *NBEAL2* as the candidate gene responsible for GPS . Kahr et al. (2011) performed RNA sequencing analysis for the platelets of patients from three families and identified abnormal *NBEAL2* transcripts. Analysis of the *NBEAL2* gene subsequently identified genetic alterations. In a third parallel study, Gunay-Aygun et al. (2011) used genome-wide linkage analysis and homozygosity mapping of 25 individuals from 14 families to identify the disease locus to a 9.4 Mb region. Sequencing of the genes within this region identified mutations in the gene *NBEAL2* in all families, providing further support for the association between this gene and GPS.

The *NBEAL2* gene encodes a Beige and Chediak-Higashi (BEACH)/ARM/WD40 domain protein. The exact role in α-granule biogenesis, however, remains unknown. Knockout of *NBEAL2* in zebrafish leads to impaired thrombocyte formation with spontaneous bleeding (Albers et al. 2011). Reduced α-granule secretion was observed in a knockout mouse model of *Nbeal2*, suggesting a conserved role for the BEACH domain protein in thrombus formation and granule biogenesis. Interestingly, study of $Nbeal2^{-/-}$ mice showed that the α-granules were generated, but not retained, within megakaryocytes and therefore could be a result of alterations in granule biogenesis that trigger granule degradation or improper function (Guerrero et al. 2014). *NBEAL2* expression has also been shown to be upregulated during megakaryocyte maturation, which might also coincide with the production of platelet granules, supporting a role for NBEAL2 in granule biogenesis. Interestingly, $Nbeal2^{-/-}$ mice also display splenomegaly and myelofibrosis, consistent with a GPS phenotype (Guerrero et al. 2014).

The three studies described above identified mutations predicting amino acid alterations that are distributed across the entire protein structure of NBEAL2, resulting in alterations affecting almost all known structural domains (Fig. 1). However, more than half of those identified alterations affect residues at the N-terminus and appear to cluster within the concanavalin A-like lectin (ConA-like) domain. This domain is shared between members of other

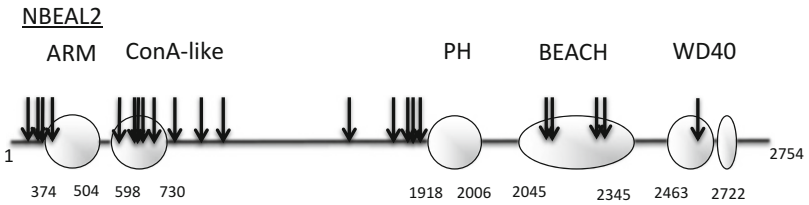

Fig. 1 NBEAL2 structural organisation and variant locations. Representation of the neurobeachin-like 2 (NBEAL2) protein structure of 2754 amino acid residues displaying the Armadillo-type fold (ARM), concanavalin A-like (ConA-like), Pleckstrin homology (PH) and WD40 domains. The locations of variants identified by Albers et al. (2011), Kahr et al. (2011) and Gunay-Aygun et al. (2011) are shown by the *black arrows*. Amino acid sequence and domain architecture are based on accession ID: NP_055990

BEACH domain proteins, including LYST, the causative protein of Chediak–Higashi syndrome (CHS) (Barbosa et al. 1996), and neurobeachin (NBEA), which is associated with myeloma (O'Neal et al. 2009). Lectins are a family of proteins that fuse to cell membranes through the binding and processing of carbohydrates (Chandra et al. 2001). Therefore, the ConA-like domain in BEACH proteins might be involved in oligosaccharide-binding to mediate vesicle fusion events (Burgess et al. 2009). In addition, several mutations were identified in the BEACH domain and a further eight (resulting in a premature stop codon or frameshift mutation) upstream of the BEACH domain. This domain is highly conserved and present in proteins that have a role in vesicle trafficking; however, the exact role remains to be clarified. Structural modelling of the BEACH domain from human NBEA suggests that the BEACH domain interacts with the Pleckstrin homology (PH) domain, which lies 40 amino acids upstream (Jogl et al. 2002). A large groove was also identified in the structure between the PH and BEACH domains, which might facilitate ligand binding (Jogl et al. 2002). In addition, tryptophan–aspartic acid (WD)40 repeat domains, located downstream of the BEACH domain, mediate protein–protein interactions (Neer et al. 1994) and are disrupted as a result of frameshift and stop-gain mutations. The structural sequence of NBEAL2 suggests a role in fusion and protein interactions and, therefore, supports the hypothesis that this BEACH domain protein plays an important role in granule biogenesis and that disturbance of one of several domains impairs protein activity and results in compromised granule biogenesis, as observed in GPS.

RBM8A

Thrombocytopenia with absent radii (TAR) syndrome is characterised by a low platelet count with malformations in limb development (Hall et al. 1969). A 200 kb deletion on chromosome 1q21.1 has been identified in the majority of cases using microarray-based comparative genomic hybridisation (array CGH) (Klopocki et al. 2007). However, the recessive mode of inheritance points to the presence of an additional defect. WES was performed on five patients with TAR syndrome and identified a variant in the 5′ untranslated region (UTR) of the *RBM8A* gene. Sequencing a further 48 TAR syndrome patients who harboured the 1q21.1 deletion revealed the presence of one of two variants located in the *RBM8A* 5′-UTR in 46 patients, with minor allele frequencies (MAFs) of 3.05 % and 0.42 %. It was postulated that the remaining two patients possess an additional defect that remains unidentified. In addition, in two patients with TAR syndrome, but without the 1q21.1 deletion, mutations were identified in the coding region of *RBM8A*. It is therefore postulated that the presence of a single null *RBM8A* allele is not sufficient to cause disease, but that both alleles should be non-functional. This is usually the result of compound inheritance of a rare null allele and one of two rare non-coding SNVs in *RBM8A* that affect regulation (Albers et al. 2012).

RBM8A encodes an RNA-binding protein that forms a component of the splicing-dependent multiprotein exon junction complex (EJC), thought to have a role in pre- and post-mRNA splicing (Kim and Dreyfuss 2001). In the absence of functional RBM8A, key processes such as nuclear mRNA export, translation and nonsense-mediated decay (NMD) are impaired; however, the exact genes mediating these processes via RBM8A remain unknown as do the molecular mechanisms underlying the disease.

ANKRD18A

Inherited thrombocytopenias are a group of highly heterogeneous disorders associated with defects in over 20 genes (Balduini and Savoia 2012; Rao and Songdej 2015). The disorders are characterised by a reduction in platelet number and, often, the presence of abnormally large platelets, with symptoms ranging from mild to severe bleeding tendencies. However, in 50 % of cases, the causative mutation has not been identified. In two siblings of a consanguineous family presenting with severe bleeding symptoms and a low platelet count, WES identified a mutation in the gene *ANKRD18A* in

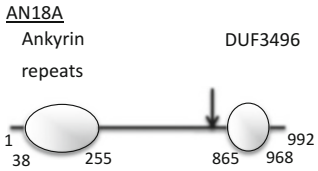

Fig. 2 AN18A structural organisation and variant location. Representation of the Ankyrin repeat domain 18A (AN18A) protein structure of 992 amino acid residues displaying Ankyrin repeats at the N-terminus of the protein and a domain of unknown function (DUF3496) at the C-terminus. The location of the variant identified by Lowe et al. (2012) is shown by the *black arrow*. Amino acid sequence and domain architecture are based on accession ID: NP_671728.2

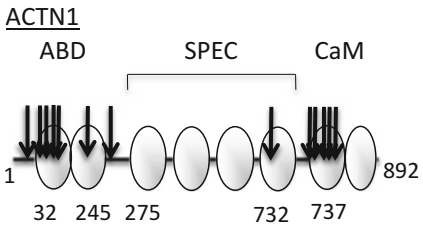

Fig. 3 ACTN1 structural organisation and variant locations. Representation of the actinin, alpha 1 (ACTN1) protein structure of 892 amino acid residues displaying the actin-binding domain (ABD), spectrin repeats (SPEC) and the C-terminal calmodulin domain (CaM). The location of the variants identified by Kunishima et al. (2013), Guéguen et al. (2013) and Bottega et al. (2015) are shown by the *black arrows*. Amino acid sequence and domain architecture are based on accession ID: NP_001093

both affected individuals. In addition to thrombocytopenia, the patients' platelets were also found to have impaired α-granule secretion and integrin activation, suggesting that the bleeding phenotype is the result of a combination of low platelet count and impaired platelet function (Lowe et al. 2012; Watson et al. 2013). The function of the *ANKRD18A*-encoded protein remains unknown but shares conserved regions of Ankyrin repeats and a domain of unknown function (DUF3496) (Fig. 2) with ANKRD26. Genetic mutations are associated with thrombocytopenia, α-granule deficiency and a predisposition to leukaemia (Al Daama et al. 2013; Noris et al. 2015). The mutations described in *ANKRD26* are located in the 5′-UTR regulatory region (Noris et al. 2015) or in the Ankyrin repeats, which is likely to affect protein binding. The mutation identified in *ANKRD18A* is an in-frame deletion upstream of DUF3496 (Al Daama et al. 2013); however, the effect of this mutation on protein function has yet to be investigated.

ACTN1

In six Japanese families presenting with mild or absent bleeding diatheses, reduced platelet counts, increased platelet size and anisocytosis, WES was applied in a total of 11 affected and 10 unaffected individuals (Kunishima et al. 2013). Following the removal of previously reported variants and prioritisation based on in silico predictions (assuming a dominant mode of inheritance), six genes were predicted to be pathogenic in more than one family. Calculation of significance based on the number of variations identified and the size of the coding region showed that *ACTN1* was the most significant and associated with disease in three families. Subsequently, the *ACTN1* gene was analysed using Sanger sequencing in a further seven families, three of which were found to harbour *ACTN1* mutations that co-segregate with disease (Kunishima et al. 2013). Accordingly, in a large French pedigree consisting of 55 members, 26 with inherited macrothrombocytopenia, a combination of linkage analysis and targeted NGS identified a single causative variant to lie within the gene *ACTN1* (Guéguen et al. 2013). A further study identified ten *ACTN1* mutations in thrombocytopenia patients, following WES analysis in seven index cases and another 128 cases using conventional sequencing methods. Of the ten mutations, seven resulted in novel amino acid substitutions (Bottega et al. 2015).

The *ACTN1* gene encodes the protein α-actinin, an actinin cross-linking protein involved in cytoskeletal organisation. In vitro expression studies demonstrated that most mutations caused cytoskeletal disorganisation, with a reduction in the number of proplatelets formed and an increase in platelet swelling, accounting for the enlarged platelets observed (Guéguen et al. 2013; Kunishima et al. 2013; Bottega et al. 2015). α-Actinin exists as a dimer with two functional domains, an actinin-binding domain (ABD), composed of two calponin homology regions, and a C-terminal calmodulin-like domain (CaM) made up of two EF-hand Ca^{2+}-binding motifs. Most of the identified *ACTN1* mutations across the three studies predict amino acid substitutions that reside within the ABD or the CaM domains (Fig. 3). Interestingly, a variant located outside of these functional domains, in a spectrin repeat, did not cause any alteration to cytoskeletal structure (Bottega et al. 2015), which supports the importance of actinin binding and Ca^{2+} binding in the function of α-actinin in mediating platelet formation.

FLI1 and *RUNX1*

The UK Genotyping and Phenotyping of Platelets (UK-GAPP) multicentre study aimed to recruit patients with PFDs and identify the underlying genetic defects responsible for the variety of platelet phenotypes (Watson et al. 2013). To date, over 500 patients have been recruited and platelet defects identified in 60 % of cases. LTA was

used to assess platelet function in patients with a suspected PFD. The differential responses in aggregation, using a range of agonists, allowed patients to be divided into diagnostic sub-groups (Dawood et al. 2012). The majority of patients diagnosed with PFDs fell into one of three sub-groups: dense granule secretion defect, Gi-signalling defect and thromboxane defect. Performing genetic analysis on patients grouped by platelet phenotype should increase the chances of identifying the causative variants in such a complex group of disorders. NGS of a targeted gene panel consisting of over 260 genes, known or predicted to have a role in platelet formation or function (Jones et al. 2012; Stockley et al. 2013), was undertaken in 13 index cases with severe defects in dense granule secretion. After the removal of duplicates and focussing on novel variants only, mutations were identified in *FLI1* or *RUNX1* that co-segregate with disease in 6 out of the 13 families (Stockley et al. 2013). Additional studies have since utilised the power of NGS technologies to identify *FLI1* aberrations. Sequencing of a targeted panel of 19 genes identified a homozygous variant in the *FLI1* gene in a patient with moderate thrombocytopenia from a family of consanguineous marriage (Stevenson et al. 2015). Further utilisation of WES also identified another *FLI1* variant in a patient with thrombocytopenia (Poggi et al. 2015). Interestingly, however, neither of these patients was found to have any defect in granule secretion (Stevenson et al. 2015; Poggi et al. 2015).

FLI1 and RUNX1 are transcription factors that cooperate during the late stages of megakaryopoiesis (Huang et al. 2009; Tijssen and Ghevaert 2013). Hemizygous loss of FLI1 has been associated with Paris–Trousseau syndrome (PTS), in which patients bleed excessively as a result of thrombocytopenia and the presence of abnormally large α-granules (Breton-Gorius et al. 1995; Favier et al. 2003). In accordance, the presence of abnormally large α-granules was observed in a subset of platelets from patients with *FLI1* genetic alterations (Stevenson et al. 2015; Leo et al. 2015a, b). However, it remains unknown how FLI1 is involved in the process of granule formation and function and how the mutations identified lead to a defect in dense granule secretion. The authors showed that the missense changes abolish transcriptional regulation of the FLI1 protein (Stockley et al. 2013; Stevenson et al. 2015) and, therefore, downregulation of target genes (yet to be identified) could be responsible for this phenotype. Furthermore, some patients with *FLI1* defects appear to have syndromic features such as eczema and alopecia with severe bleeding (Stockley et al. 2013), whereas others possess a mild bleeding tendency with no additional symptoms (Stevenson et al. 2015; Poggi et al. 2015). Therefore, an understanding of the genes regulated by FLI1 and the extent to which their regulation is compromised in each case is required to unravel the mechanism by which FLI1 functions.

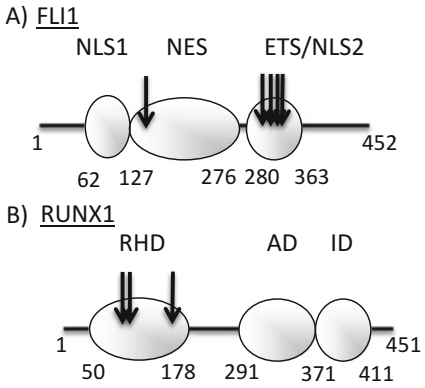

Fig. 4 FLI1 and RUNX1 structural organisation and variant locations. (**a**) Representation of the Friend leukaemia integration 1 transcription factor (FLI1) protein structure of 452 amino acid residues displaying nuclear localisation signals NLS1 and NLS2, nuclear export signal (NES) and the ETS DNA-binding domain. The location of the variants identified by Stockley et al. (2013), Stevenson et al. (2015), and Poggi et al. (2015) are shown by the *black arrows*. Amino acid sequence and domain architecture is based on accession ID: NP002008 and evidence from Hu et al. (2005). (**b**) Representation of the Runt-related transcription factor 1 (RUNX1) protein structure of 451 amino acid residues displaying the RUNT homology domain (RHD), activation domain (AD) and the inhibitory domain (ID). The location of the variants identified by Stockley et al. (2013) are shown by the *black arrows*. Amino acid sequence and domain architecture are based on accession ID: NP_001745

The FLI1 protein comprises two nuclear localisation signals (NLS1 and NLS2), a nuclear export signal (NES) and the ETS DNA-binding domain (Hu et al. 2005). It is clear that the ETS domain is of great importance to the function of FLI1, with four of the five variants located within this domain (Fig. 4a) abolishing transcriptional activity. These variants include those identified in three patients with severe bleeding symptoms and defects in dense granule secretion (Stockley et al. 2013), whereas the variant located within the NES appears to be less pathogenic (Poggi et al. 2015).

Mutations in *RUNX1* have been associated with a predisposition to acute myeloid leukaemia (AML) (Nurden et al. 2012); however, in the patients described in the study by Stockley et al. (2013) no family history of malignancy was evident. It has been demonstrated that *RUNX1* mutations lead to a reduction in the expression of several genes, most notably *MYL9* (Sun et al. 2007) as well as *PRKCQ* (Jalagadugula et al. 2011), *ALOX12* (Kaur et al. 2010) and *PLDN* (Mao et al. 2015). These genes have been shown to play a crucial role in dense-granule secretion, thereby explaining how alterations in the transcription factor could result in the platelet phenotype observed. The variants identified in the study by Stockley et al. (2013) were located to the RUNT domain (Fig. 4b), which is essential for DNA binding and therefore likely to impair transactivational capacity. The majority of mutations have also been

identified in the same domain in patients with a predisposition to AML (Michaud 2002). Therefore, the location of the alteration does not appear to discriminate between a PFD and malignancy, but is more probably caused by the nature of the mutation, with more severe consequences in protein activity as a result of homozygous or dominant-negative mutations increasing the risk of malignancy (Matheny et al. 2007). This is supported by a study that compared the transcriptome of two pedigrees harbouring *RUNX1* mutations, with and without a history of malignancy, which identified an association of absent *NR4A3* transcript levels with malignancy. Reduced, but detectable, levels lead to a PFD and symptoms of excessive bleeding only (Bluteau et al. 2011).

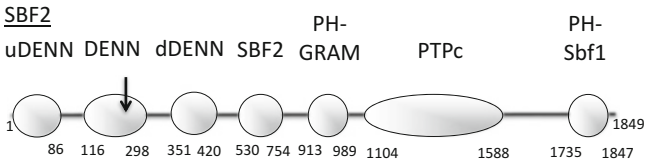

Fig. 5 SBF2 structural organisation and variant location. Representation of the SET binding factor (SBF2) protein structure of 1849 amino acid residues displaying the domain always found upstream of DENN domain (uDENN), the DENN domain, the domain always found downstream of DENN domain (dDENN), SBF2 domain, PH-GRAM_MTMR13 domain, the protein tyrosine phosphatases catalyse domain (PTPc) and a C-terminal PH-Sbf1_hMTMR5. The location of the variant identified by Abuzenadah et al. (2013) is shown by the *black arrow*. Amino acid sequence and domain architecture are based on accession ID: NP_112224

SBF2

A rare case of thrombocytopenia accompanied by reduced pigmentation was reported by Abuzenadah et al. (2013). Other platelet disorders have been reported to accompany the feature of albinism, as in the case of Griscelli syndrome (Griscelli et al. 1978), Hermansky–Pudlak syndrome (HPS) (Hermansky and Pudlak 1959) and CHS (Barbosa et al. 1996). However, the presence of a normal platelet count is observed in HPS and CHS, and with no immunological or neurological defects in the patient described by Abuzenadah et al. (2013), the disorder is unlikely to be Griscelli syndrome. Therefore, the patient and the unaffected father underwent exome sequence analysis, assuming a recessive mode of inheritance because both parents presented with no symptoms. Focussing on homozygous variants, predictions of pathogenicity using bioinformatic tools and the removal of previously reported variants, a single homozygous mutation in the gene *SBF2* was identified and later verified in an affected sibling. The mutation was heterozygous in both parents and absent in an unaffected sibling (Abuzenadah et al. 2013). SBF2 is a pseudo-phosphatase, part of the myotubularin family of lipid phosphatases, and has been associated with Charcot–Marie–Tooth 4 type B2 (CMT4B2) neuropathy (Bird 2014; Baets et al. 2011).

The mutation identified in association with CMT4B2 deletes the dDENN domain (Senderek 2003), whose exact function remains unknown. In contrast, the mutation associated with a novel form of thrombocytopenia was located in the DENN domain of the SBF2 protein (Fig. 5), which mediates interactions with the RAB family of small GTPases, including Rab27a and Rab28 (Marat et al. 2011). Given the known roles of the interacting partners in vesicle transport, it is possible that the patient's platelets exhibit an additional defect in granule biogenesis; however, this could not be tested because of the low platelet count. Further work is required to understand the role of *SBF2* in platelet production and how mutations in this gene can lead to the varied phenotypic features observed.

THPO

Aplastic anaemia is a condition that arises as a result of defects in all blood cell lineages, leading to symptoms of increased bleeding caused by thrombocytopenia, susceptibility to infection as a result of deficient leukocytes, and anaemia through inefficient red cells (Brodsky and Jones 2005). In a family with aplastic anaemia, array CGH was used initially to identify runs of homozygosity and copy number variations (CNV) to determine a candidate gene locus; however, no loci were identified. WES was subsequently undertaken, focussing on homozygous variants in the coding regions shared between two affected siblings and not previously reported on databases such as dbSNP or 1000 genomes. Seven homozygous variations were identified in seven genes. Confirmation and screening for the presence of these variants in an unaffected sibling and one parent using Sanger sequencing reduced the number of candidate defects to three. Use of in silico predictions strongly predicted a variant in the gene *THPO* to be highly pathogenic, whereas the other two variants were predicted to be benign (Dasouki et al. 2013).

THPO encodes thrombopoietin (TPO), a ligand for the c-Mpl receptor required for haematopoietic lineage differentiation (Hitchcock and Kaushansky 2014). The variant is located in the receptor binding domain (RBD) (Fig. 6); structural modelling of the variant suggests disturbance to the region. In vitro studies demonstrated a reduced ability to maintain cell proliferation, which probably contributes to the lower number of maturing blood cells. Knockout studies in mice have previously demonstrated an association of *Thpo* and *Mpl* with a decrease in the formation of all blood cell types (Alexander et al. 1996; Carver-Moore et al. 1996; Bunting et al. 1997; Dorsch et al. 1999).

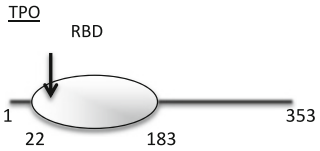

Fig. 6 TPO structural organisation and variant location. Representation of the thrombopoietin (TPO) protein structure of 353 amino acid residues displaying the receptor binding domain (RBD) and the N-terminal half of the protein. The location of the variant identified by Dasouki et al. (2013) is shown by the *black arrow*. Amino acid sequence and domain architecture are based on accession ID: NP_000451

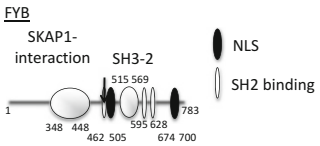

Fig. 7 FYB structural organisation and variant location. The location of the variant identified by Izumi et al. (2014) is shown by the *black arrow*. Amino acid sequence and domain architecture are based on accession ID: NP_001121699

FYB

WES was carried out in three affected and nine unaffected members of a consanguineous family with thrombocytopenia and small platelets. The analysis pipeline focussed on homozygosity resulting from the autosomal recessive mode of inheritance, taking into account that parental DNAs both contain one copy of the variant that is present in the homozygous state in affected individuals. Further prioritisation was achieved by removal of synonymous variants and those with a MAF of over 0.02. A single variant, a 2-bp deletion leading to a premature stop codon, was identified as segregating with disease in the gene *FYB* (Hamamy et al. 2014). Several groups have demonstrated a defect in platelet function resulting from *Fyb* knockout in mice, including an increased bleeding tendency (Kasirer-Friede et al. 2007) with mild thrombocytopenia, a reduction in splenic T cells and thymocyte number (Peterson et al. 2001) and enlarged spleens, which may reflect the removal of platelets from circulation (Jarvis et al. 2011).

FYB encodes the FYN binding protein, which associates with FYN via the SH2-binding domains and plays a role in intracellular signalling (da Silva et al. 1993). The frameshift deletion identified in the family reported by Hamamy et al. (2014) lies within one of several SH2-binding domains, altering the downstream sequence including two more SH2-binding domains (Fig. 7). Impaired affinity for FYN is likely to result in impaired intracellular signalling, which may alter megakaryocyte maturation or platelet formation and account for a low platelet count and small platelet size. In addition, FYN binding protein was shown to play a role in signalling mediated by the $\alpha_{IIb}\beta_3$ receptor, promoting platelet spreading and thrombus stabilisation under shear stress conditions (Kasirer-Friede et al. 2007). Therefore, in addition to a reduced platelet count, impaired platelet activation could also be responsible for the bleeding phenotype observed in $Fyb^{-/-}$ mice and patients with *FYB* mutations.

GNE

In a family presenting with thrombocytopenia accompanied by myopathy with rimmed vacuoles, WES analysis of two affected family members, in combination with array CGH, identified mutations in two candidate genes, *GNE* and *FLNB*, following a pipeline to exclude common variants and retain homozygous or compound heterozygous variants in accordance with the recessive mode of inheritance (Izumi et al. 2014). A compound heterozygous mutation was identified in the gene *GNE* in both affected family members. Each variant has been reported previously in association with distal myopathy with rimmed vacuoles (DMRV) (Tomimitsu et al. 2002, 2004).

GNE encodes the protein glucosamine (UDP-*N*-acetyl)-2-epimerase/*N*-acetylmannosamine kinase, an enzyme that produces sialic acid, which modifies surface proteins to influence a range of cellular functions that include cell signalling, adhesion and migration (Kelm et al. 1994; Bassagañas et al. 2014). The mutation is located in the GT1_UDP-GlcNAc_2-epimerase (GT1) domain of the encoded protein (Fig. 8), a critical region for the hydrolysis of UDP-GlcNAc to produce UDP-*N*-acetylmannosamine (UDP-ManNAc), a precursor to sialic acids (Marchler-Bauer et al. 2014). Therefore, the compound heterozygous mutation in *GNE* is a strong candidate as cause of the myopathic phenotype observed in these patients.

Additionally, platelets deficient in sialic acid have been shown to increase platelet clearance, resulting in thrombocytopenia (Sørensen et al. 2015). However, because thrombocytopenia has not been reported in previous cases of myopathy with rimmed vacuoles caused by genetic alterations in *GNE* (Tomimitsu et al. 2002, 2004; Nishino et al. 2015), the effect of the mutation in *FLNB* identified in the affected family members has yet to be determined. It may play a similar role to its homologue *FLNA*, which is associated with thrombocytopenia (Fox et al. 1998; Nurden et al. 2011), and so remains a plausible candidate.

PRKCAG

In a consanguineous family with macrothrombocytopenia, abnormal surface expression of GPIb-XI-V complex and αIIβ3 and defective α-granule secretion, whole exome data for two affected and three unaffected family members were scrutinised to identify the causative defect. Because the proband was of consanguineous marriage and neither parent presented with any bleeding symptoms, an autosomal recessive mode of inheritance was assumed and heterozygous variants removed. Further prioritisation was achieved following the removal of synonymous variants and focussing on those with a MAF of less than 0.01 (Manchev et al. 2014). Two variants were identified that segregated with disease, altering the genes *GNE* and *PRKCAG*.

PRKCAG encodes the gamma isoform of the catalytic subunit of cAMP-dependent PKA, which in turn phosphorylates filamin A (FLNA) (Jay et al. 2004) and GPIBβ (Bodnar et al. 2002), both being associated with macrothrombocytopenia. *GNE* mutations have been associated with myopathy, as described above (Eisenberg et al. 2001), but the patients exhibit no such phenotypic features. Therefore, the presence of a mutation in *PRKCAG* appeared to be the more likely candidate as a cause of the observed phenotype. Indeed, it was shown that FLNA levels were markedly reduced in the patients' platelets compared with control platelets, suggesting a lack of FLNA phosphorylation by PKA, which would otherwise protect the protein from degradation (Chen and Stracher 1989). FLNA is responsible for connecting platelet receptors to the cytoskeleton, which could explain the absence of platelet receptor activation (Nurden et al. 2011). Furthermore, megakaryocyte maturation was not affected by the mutation; however, the mutation did lead to a marked reduction in proplatelet formation compared with the wild type. The mutation identified lies within the serine/threonine/dual specificity protein kinase catalytic (STKc) domain (Fig. 9) and adjacent to an ATP-binding site. It could therefore conceivably alter the kinase activity of the protein towards phosphorylate targets such as FLNA.

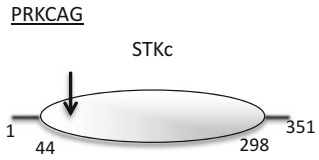

Fig. 9 PRKCAG structural organisation and variant location. Representation of the catalytic subunit C gamma of the cAMP-dependent protein kinase (PRKCAG) protein structure of 351 amino acid residues displaying a single Serine/threonine/dual specificity protein kinase, catalytic domain (STKc). The location of the variant identified by Manchev et al. (2014) is shown by the *black arrow*. Amino acid sequence and domain architecture are based on accession ID: NP_002723

ETV6

Two independent research groups have identified *ETV6* mutations as being associated with platelet production. In the study by Noetzli et al. (2015), WES was undertaken in five affected members of a single pedigree who presented with symptoms of mild to moderate bleeding, with two members developing B-cell precursor acute lymphoblastic leukaemia. A reduction in platelet number was detected, with a fraction containing elongated α-granules and an increased mean red blood cell volume. Analysis of the whole exome data identified a single gene defect that segregated with thrombocytopenia and a high red cell volume following the removal of synonymous variants and those with a MAF of over 1 % in the general population. The *ETV6* gene was subsequently screened in a further 23 families with thrombocytopenia, high mean red cell volume and increased incidence of leukaemia using conventional sequencing methods. *ETV6* genetic alterations were identified in two of the 23 families, with a predisposition to malignancy in one family (Noetzli et al. 2015).

In a parallel study, Zhang et al. (2015) analysed WES data from four affected and one unaffected family members presenting with similar features to the families described by Noetzli et al. (2015). Variants were filtered on the basis of an autosomal dominant mode of inheritance and removal of common and synonymous SNVs, which identified five variants segregating with disease. Sanger sequencing of all five genes in a further two unaffected family members revealed complete segregation of only the *ETV6* variant with disease. Targeted sequencing in 55 individuals then identified a further two families with *ETV6* mutations presenting with thrombocytopenia and haematologic malignancy (Zhang et al. 2015).

ETV6 is a transcription factor that binds to and represses the expression of target genes via the ETS domain (Kwiatkowski et al. 1998; Chakrabarti and Nucifora 1999; Fenrick et al. 1999; Lopez et al. 1999) and requires dimerisation in order to function (Green et al. 2010). Four

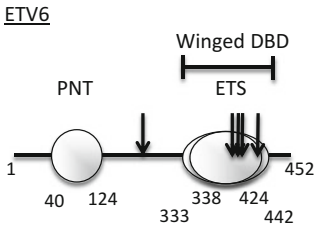

Fig. 10 ETV6 structural organisation and variant locations. Representation of the Ets variant 6 (ETV6) protein structure of 452 amino acid residues displaying a pointed domain (PNT) and an ETS DNA binding domain, within the winged helix-turn-helix DNA binding domain (Winged DBD). The location of the variants identified by Noetzli et al. (2015) and Zhang et al. (2015) are shown by the *black arrows*. Amino acid sequence and domain architecture are based on accession ID: NP_001978.1

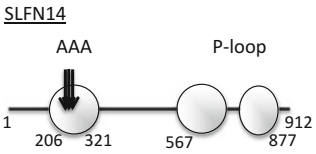

Fig. 11 SLFN14 structural organisation and variant location. Representation of the Schlafen family member 14 (SLFN14) protein structure of 912 amino acid residues displaying an ATPase-AAA domain (AAA) and a P-loop containing a nucleoside triphosphate hydrolase domain (P-loop). The location of the variants identified by Fletcher et al. (2015) are shown by the *black arrows*. Amino acid sequence and domain architecture are based on accession ID: NP_001123292

of the five mutations identified in patients with thrombocytopenia are located in the ETS domain and another within the central region of the protein (Fig. 10). Although the ETS domain is a highly conserved region across ETS transcription factor family members and crucial for DNA binding (Degnan et al. 1993), previous studies have identified mutations throughout the entire locus that are causative of various types of malignant haematologic disorders and solid tumours, suggesting important roles for regions spanning the entire protein. In support of this, the N-terminal pointed (PNT) domain is responsible for homodimerisation (Tognon et al. 2004) and the central regulatory region is required for post-translational modification and is essential for the repressive function of the protein (Zhang et al. 2015; Noetzli et al. 2015); therefore, alterations to any of these functions is likely to impair ETV6 activity. However, the majority of the mutations identified in families with thrombocytopenia accumulate within the ETS domain, with a single mutation in the central region, all of which function in a dominant-negative manner to decrease transcriptional repression, impair nuclear localisation and alter megakaryocyte maturation (Zhang et al. 2015; Noetzli et al. 2015).

The exact role of ETV6 in haematopoiesis and the association with malignancy in humans, mouse and zebrafish (Rasighaemi et al. 2014) requires further clarification, but bears remarkable similarities to that of RUNX1 (Song et al. 1999). Interestingly, ETV6 is known to bind to and repress FLI1 transcriptional activity (Kwiatkowski et al. 1998), which poses the questions of whether FLI1 activity is increased in these patients and what the underlying consequence is of increased transactivation capacity of FLI1.

SLFN14

As part of the UK-GAPP study, WES was carried out for three affected family members with thrombocytopenia, presenting with symptoms of excessive bleeding with a dominant mode of inheritance. Platelet phenotyping revealed that, in addition to a reduced platelet count, dense granule secretion and platelet aggregation in response to several agonists was impaired. Following removal of synonymous and previously identified variants, four remained that segregated with disease in this family. However, confirmation via Sanger sequencing left just two variants that were shared between all affected members. Cross-referencing both genes to the exomes of 35 index cases with thrombocytopenia and/or secretion defects recruited to the GAPP study highlighted *SLFN14* as a novel gene with an important role in the formation and function of platelets. Heterozygous *SLFN14* mutations were identified in three families with thrombocytopenia and defects in dense granule secretion (Fletcher et al. 2015). The patients' platelets were shown to contain fewer dense granules per platelet than those of a control subject, possibly accounting for the reduction in dense granule secretion. A reduction in Schlafen family member 14 (SLFN14) protein levels was also observed as a result of the mutations identified, with a 65–80 % reduction in SLFN14 protein levels following overexpression in transfected HEK293T cells and 66–76 % reduction in the patients' platelets, suggesting a dominant-negative effect.

Schlafen family members have been shown to play a role in cell proliferation and differentiation (Schwarz et al. 1998; Geserick et al. 2004; Brady et al. 2005; van Zuylen et al. 2011; Kuang et al. 2014) and are expressed in various cells of the haematopoietic lineage, including platelets (Rowley et al. 2011; Kim et al. 2014). The exact role of *SLFN14* and how mutations in this gene lead to the observed phenotype, however, remains to be elucidated. Interestingly, the three mutations identified in the three families are predicted to cause consecutive amino acid substitutions that lie within the ATPase-AAA domain (Fig. 11), a conserved region for all members of the Schlafen family. The domain is important for ATP/GTP hydrolysis (Hanson and Whiteheart 2005) and is present in proteins that play a number of cellular functions, including cell-cycle regulation and intracellular transport (Kedzierska 2006). The three consecutive residues

are also highly conserved across multiple species, suggesting high importance with regards to the function of SLFN14 (Fletcher et al. 2015).

Limitations of Next-Generation Sequencing

To facilitate prioritisation of candidate gene defects where NGS was applied, the majority of studies used a pipeline that excluded synonymous variants and variants with a MAF of over 0.01, as disease-causing mutations are mainly rare and alter the encoded protein. Furthermore, for heterogeneous disorders, multiple family members are vital for identification of causative genetic defects, with the addition of each family member reducing the number of candidate variants by 50 % (Gilissen et al. 2012). Identification of causative genes can be more difficult in a cohort of index cases where bleeding is the only clinical feature, but functional annotation analysis can aid the prioritisation of genes on the basis of functions within similar pathways (Leo et al. 2015a, b). Focussing on the whole exome and exclusion of synonymous variants could miss pathogenic mutations that would cause alterations in the splicing process or gene regulation (Gilissen et al. 2012). Other genetic mechanisms may have also been overlooked by NGS approaches, such as copy number variation and large insertions and deletions. If WES does not identify a causative mutation, those particular studies should include synonymous variants within the pipeline of analysis and consider the use of WGS. RNA expression profiles via RNA sequencing can also help narrow the search for candidate genes.

The Future for Use of Next-Generation Sequencing in Diagnosis of Platelet Disorders

The assignment of novel genetic aetiology to PFDs in the 1980s progressed relatively slowly and relied on extensive platelet phenotypic data that directed downstream genetic analysis (Table 1, Fig. 12). The mid-1990s saw a dramatic increase in the rate of discovery as a result of utilisation of linkage analysis, mapping genetic loci that segregate with disease. This technology assumes that, of the numerous SNVs or genetic markers distributed across the genome, those that lie within close proximity to the disease-causing allele are also inherited as a result of genetic linkage and therefore map the chromosomal location of the disease-causing gene(s) (Pulst 1999). This technique has been extremely powerful in gene discovery, particularly for cases where there are strong phenotypic features, such as Wiskott–Aldrich Syndrome (WAS) (Donner et al. 1988) and MYH9-related disorders (Seri et al. 2000; Martignetti et al. 2000; Cusano et al. 2000) (Table 1). At the turn of the century, linkage was still being utilised as the main method for gene discovery and maintained a steady rate of novel gene identification. However, the appearance of NGS technologies in the last 5 years has further enhanced the rate of gene discovery (Fig. 12), especially in more complex and heterogeneous disorders. This was sometimes achieved through a combination of linkage analysis with NGS (Guéguen et al. 2013; Stevenson et al. 2015); however, the sole use of WES in family studies is becoming increasingly more common for the identification of disease-causing variants (Table 1 and Fig. 12). As the cost of WGS continues to fall, it is likely that we will see a rise in its use for variant identification. Although the amount of data generated poses additional challenges for analysis and interpretation, combining this information with detailed laboratory and clinical phenotypes in large patient cohorts can ultimately facilitate identification of the underlying genetic causes in numerous cases. This approach is being utilised by the BRIDGE Bleeding and Platelet Disorder (BPD) study through the use of the Human Phenotype Ontology (HPO) database (Köhler et al. 2014), which relies on a library of terms describing phenotypes. The use of an algorithm phenotypically clusters cases based on HPO terms and aids identification of candidate genes on the basis of those shared within the cluster (Westbury et al. 2015). This approach is supported by the fact that 60 % of cases present with features additional to bleeding, with a median of seven HPO terms per case, and have replicated the findings of *MYH9*, *ACTN1* and*GFI1B* gene defects in patients that form clusters. In addition, a novel gene (*PKC*) has been identified in association with GPS-like syndrome characterised by macrothrombocytopenia, bleeding, myelofibrosis, facial abnormalities and bone pathologies (Wijgaerts 2015). As a branch of the BRIDGE–BPD study, the ThromboGenomics project aims to provide a platform for routine diagnosis of rare BPDs. The platform permits NGS analysis and rapid variant-identification for 77 genes associated with platelet and coagulation disorders, providing an efficient and affordable approach for genetic diagnosis (https://haemgen.haem.cam.ac.uk/thrombogenomics). It is also likely that the ThromboGenomics project will utilise phenotypic characteristic data through the HPO database to aid diagnosis of BPDs. Through NGS technologies, novel genes will continue to be identified in association with disease. Combining WGS data with RNA expression profiles and proteomics may help to stratify candidate gene identification and create a more complete picture of disease cause.

Table 1 The history of gene discovery associated with PFDs

Gene	Method of detection	Disorder	Reference
WAS	Linkage analysis	Wiskott–Aldrich Syndrome	Donner et al. (1988)
ITGA2B, ITGB3	Platelet phenotyping and restriction analysis	Glanzmann thrombasthenia	Bray and Shuman (1990)
GPIBA	Platelet phenotyping and Sanger sequencing	Bernard–Soullier Syndrome (BSS)	Ware et al. (1990)

NGS next generation sequencing, *WES* whole exome sequencing, *WGS* whole genome sequencing, *HPO* human phenotype ontology

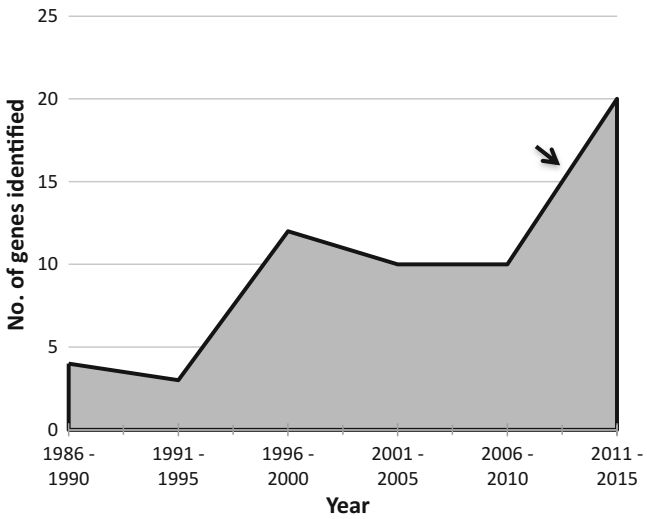

Fig. 12 Rate of gene discovery associated with PFDs. The graph represents the number of genes discovered in association with platelet function disorders in six blocks of 5-year periods between 1986 and 2015. The *arrow* represents the era in which next-generation sequencing technologies have been utilised for the majority of novel genes discovered

Identification of causative variants has obvious importance for diagnosis and in some circumstances can influence the treatment plan (e.g., immune thrombocytopenia versus inherited thrombocytopenia) (Drachman 2004). Greater understanding of the genetic basis could help develop novel treatments for bleeding disorders. Furthermore, increasing our understanding of platelet function may also identify targets for the development of novel antiplatelet agents for the treatment of cardiovascular disease.

Conclusion

The use of NGS technologies has greatly enhanced gene discovery in the field of haemostasis. Target gene panels and WES have been the major focus in the last 5 years, identifying 17 novel genetic associations with platelet bleeding disorders, mainly thrombocytopenia. As WGS becomes increasingly more economical, it is likely that its use will surpass the use of WES and targeted gene panels. Combining the genome data with detailed phenotypic information can provide a further method for candidate gene prioritisation.

Acknowledgements I would like to thank Prof. Paolo Gresele for the invitation to write this chapter and to Drs Daniel Hampshire and Martina Daly for their valuable advice regarding preparation of the manuscript.

Take Home Message

How has next-generation sequencing (NGS) impacted on the diagnosis of platelet disorders?

- NGS permits large-scale, simultaneous genetic analysis, increasing the accuracy and rate of identification of novel genes and mutations associated with disease.
- Identification of novel genes associated with platelet disorders enhances our understanding of platelet function, which is important in the development of new therapies for the treatment of thrombotic and non-thrombotic disorders.
- As NGS continues to become more cost-effective, the future of diagnosis of platelet disorders is likely to utilise the power of NGS in combination with phenotypic information.

Pathology: Hemostatic Disorders

Approach to the Patient with Platelet-Related Bleeding

Diego Mezzano and Jaime Pereira

Abstract

Mucous and skin bleeding are the major symptoms of platelet function disorders (PFDs) and thrombocytopenias. Usually, the severity of bleeding is inversely proportional to the platelet count and may be present in newborns with the more severe platelet aggregation (Glanzmann's disease) and adhesion (Bernard-Soulier (B-S) syndrome) defects. The pattern of bleeding is not characteristic of PFD, since symptoms are similar to those of patients with von Willebrand disease (VWD). Isolated or combined bleeding symptoms are frequent in otherwise healthy population, and bleeding assessment tools (BATs) have been developed to differentiate pathologic bleeding from bleeding proportional to injury. Apart from the non-specificity of symptoms, another confounder is the substantial proportion of clinically similar abnormal bleeders who, after being subjected to a complete battery of laboratory tests, end up without a known diagnosis. An additional difficulty in approaching bleeding and assigning the cause to some suspected PFD is the great variability of tests used in the diagnosis, some of them not fully validated. Furthermore, in the majority of inherited PFD bleeding tends to decrease with age. This chapter will review the clinical approach to bleeding, mainly related to PFD, highlighting the widely dissimilar results of different studies.

Introduction

Platelet function disorders (PFDs), platelet number defects, and also the platelet adhesion defect caused by low von Willebrand factor (VWF) in von Willebrand disease (VWD) are typically classified as disorders of primary hemostasis, expressed with mucous and skin bleeding. In contrast, hemarthrosis and deep muscle bleeding are distinctive symptoms of disorders of secondary hemostasis, as is the case of severe hemophilias. However, the symptoms of patients with mild to moderate deficiencies of clotting factors, including hemophilias, may be difficult to differentiate clinically from bleeding caused by PFD. In such cases, subtle differences may orient the clinician to distinguish primary from secondary hemostatic defects: spontaneous bleeding, immediate surgical bleeding, and petechiae are typical of platelet disorders and thrombocytopenias, whereas bleeding in mild disorders of secondary hemostasis, hyperfibrinolysis, and FXIII deficiency are better characterized by delayed surgical bleeding and are associated with some kind of trauma and petechial bleeding is absent or exceptional. (Table 1 summarizes these differences). An additional difficulty in assessing the cause of primary hemostasis bleeding is presented by the significant fraction of patients with unequivocal pathologic bleeding who end up with no diagnosis after comprehensive and repeated laboratory studies (Quiroga et al. 2007).

The severity of bleeding in PFD is widely variable, depending on the nature of the disorder, but also in not well understood inherited or acquired conditions of the

Table 1 Bleeding pattern in patients with primary hemostasis disorders (PHD) and patients with secondary hemostasis diseases (SHD) of different severity

	Hemostatic disorders		
Bleeding type	PHD	SHD (mild to moderate deficiency)	SHD (severe)
Petechiae	Yes	No	No
Hemarthrosis, deep hematomas	No	Occasionally, provoked	Yes, spontaneous
Ecchymoses	Yes	Yes	Yes
Mucous bleeding	Spontaneous	Yes, post-trauma	Yes
Surgical bleeding	Yes, immediate	Yes, delayed	Yes, delayed

patient. Generally, those patients with primary aggregation, e.g., Glanzmann's thrombasthenia (GT), or adhesion, e.g., Bernard-Soulier (B-S) syndrome defects, have more severe bleeding than the patients with other congenital (e.g., Hermansky-Pudlak) or secondary (e.g., drug-induced) secretion defects. GT or B-S heterozygous subjects usually have no pathological bleeding, although autosomal dominant negative GT variants exist, most of them associated with a bleeding diathesis of variable severity (Gresele et al. 2009; Nurden et al. 2011). Bleeding in isolated thrombocytopenias is more common when platelet counts fall below 20–30 $\times$ 10^3 platelets μL^{-1} or higher in syndromic inherited thrombocytopenias accompanied with platelet dysfunction; also, bleeding may manifest with higher platelet counts if associated with acquired conditions, such as infections, trauma, and drug intake, among others. It is not uncommon that relatives of index cases with inherited mild PFD share the laboratory abnormality but are clinically asymptomatic. This is analogous with the absence of hemorrhages in the overwhelming majority of subjects on aspirin treatment with a laboratory defect which is usually more severe than that of bleeders with mild inherited PFD.

This chapter will focus on the approach to the bleeding history and physical examination of patients with mucous and skin bleeding, characteristic of primary hemostasis disorders, with special emphasis in platelet disorders.

Bleeding History

A personal bleeding history is probably the most important predictor of bleeding risk. This highlights the importance of a comprehensive evaluation of symptoms and other clinical features, which help discerning between bleeding proportional to trauma and pathological bleeding. The personal and family history may disclose whether a bleeding disorder is inherited or acquired. Also, it must be taken into consideration that other concurrent inherited or acquired conditions or medications could explain or exacerbate bleeding in some patients. Repeated bleeding from several sites is characteristic of hemorrhagic disorders, whereas localized, single site of bleeding orients to a local cause. An overwhelming majority of isolated digestive tract (GI) bleeding, hematuria, or hemoptysis are explained by local causes and not by a genuine bleeding disorder.

A major confounder in differentiating normal from pathological bleeding is the high prevalence of bleeding symptoms among healthy subjects (Quiroga and Mezzano 2012). A report collecting the results of ten different studies in healthy subjects of both genres including children and adults calculated mean frequencies of 23 %, 20 %, 28 %, and 35 % for epistaxis, easy bruising, gum bleeding, and menorrhagia, respectively (Mauer et al. 2011). Another study in more than 1000 young, healthy women found that 73 % had one bleeding symptom, 43 % had two symptoms, and 23 % had more than two symptoms (Friberg et al. 2006). In 299 young healthy subjects "self-classified" as non-bleeders, we estimated that 19 %, 25 %, and 12.7 % had abnormal epistaxis, ecchymoses, and gum bleeding, respectively (Quiroga et al. 2007).

It is easier to qualify the clinical relevance of a bleeding episode in adults who have suffered different hemostatic insults along their lives. Similarly, in severe platelet defects, such as GT, B-S, and some inherited thrombocytopenias, bleeding is frequently evident at delivery, and, furthermore, bleeding may be diagnosed even in fetus suffering from isoimmune thrombocytopenia. In contrast, a genuine mild bleeding disorder may be missed in toddlers and children not yet exposed to hemostatic challenges; and menorrhagia and postpartum bleeding, major symptoms in women with platelet dysfunctions, are only evident after menarche. Finally, since mucous and skin bleeding tend to decrease with age in these patients, some adults do not appraise accurately the magnitude of their early life symptoms and may mislead the physician's perception on the severity of bleeding.

Worldwide, mild bleeding disorders are more frequently diagnosed in women than in men (Sramek et al. 1995; Quiroga et al. 2007; Podda et al. 2007), except for hemophilias. Although the causes for this predominance in women are not fully explained, menorrhagia and postpartum bleeding contribute to it; also, easy bruising is more frequent in women, who are also more aware of this symptom.

Several inherited diseases are characterized by PFD and/or changes in blood platelet count and size. In some of these syndromic defects, clinical bleeding may be only a minor component of the whole syndrome, but these associations facilitate the diagnosis. In this context, alpha-granule defects may be associated with myelofibrosis (gray platelet syndrome); increased fibrinolytic activity (Quebec platelet

disorder); arthrogryposis, renal failure, and cholestasis (gray platelet syndrome-like defect); albinism, immune and neurological disorders, lymphohistiocytosis, and giant inclusion bodies in blood smears (Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes); eczema, immune deficiency, and small platelet size (Wiskott-Aldrich syndrome); thrombocytopenia, giant platelets, giant inclusion bodies in leukocytes, hearing loss, cataracts, renal dysfunction (MYH9-related diseases, such as May-Hegglin anomaly and Sebastian, Epstein, and Fechtner syndromes), osteopetrosis, and thrombocytopenia (Ghosal syndrome); and several inherited thrombocytopenias, with or without abnormal platelet volume, which are associated with diverse bone or organ malformations (Nurden and Nurden 2011; Noris et al. 2014a).

The cause of bleeding in patients with severe acquired thrombocytopenia usually entails few diagnostic problems for the physician. This is the case, among others, of ITP, aplastic anemia, leukemias, and myelosuppressive therapy. More challenging is to diagnose a drug-induced immune thrombocytopenia (ITP), particularly when it is important to identify the causative drug (George and Aster 2009).

Bleeding Scores

In an attempt to overcome the difficulties for assessing the clinical significance of bleeding and to improve diagnostic accuracy, several bleeding scores (BS) have been developed in the last years in the form of structured questionnaires (bleeding assessment tools, BATs), which evaluate semiquantitatively each possible bleeding symptom. The weighted answers of the patients (i.e., site of bleeding, frequency, magnitude, type, need for treatment, and response to it) allow more accurate assessment of the clinical relevance of bleeding. The sum of this record allows adopting a cutoff value useful to distinguish normal from pathological bleeding and, at the same time, assessing its severity.

Of note, one of the first BATs (Sramek et al. 1995) was especially useful in a screening setting in busy clinics to predict future bleeding. The authors found that the history of bleeding following trauma, bleeding from surgery, and a family bleeding disorder were the most informative predictors for future events.

Several BATs have been developed since then (Rydz and James 2012), including the Vicenza BAT (Rodeghiero et al. 2005), the Molecular and Clinical Markers for the Diagnosis and Management of type 1 VWD (MCMDM-1) Bleeding Questionnaire (Tosetto et al. 2006), the Pediatric Bleeding Questionnaire (PBQ) (Bowman et al. 2009), and a bleeding questionnaire developed specifically for the Quebec Platelet Disorder (McKay et al. 2004). In a recent, prospective study in patients with VWD, a MCMDM-1 VWD with a BS >10 predicted the future use of desmopressin or factor concentrate replacement independent of VWD type or VWF levels (Federici et al. 2014). All this moved the International Society on Thrombosis and Haemostasis/Scientific Sub-committee (ISTH-SSC) to adopt and stimulate the use of a BAT ISTH-SSC in 2010, summarizing previous efforts and extending its scope to include bleeding assessment of patients with inherited bleeding diseases other than VWD (Rodeghiero et al. 2010). With regard to PFD, a small preliminary study found that a positive BS identified those patients with PFDs and VWD, whereas a negative BS identified those not needing specific laboratory testing (James et al. 2011); more recently, however, another report showed that ISTH-BAT did not predict the presence of a platelet defect in patients with inherited PFD diagnosed by lumiaggregometry (Lowe et al. 2013). However, confirmation of these initial results is needed to establish the usefulness of BATs in patients with PFD. Currently, consensus exists that BATs are useful tools to identify patients with abnormal bleeding, to provide more objective information on bleeding severity, and to facilitate communication of research results and, additionally, may be a bleeding predictor; however, BATs are still useless for diagnosis of individual diseases or for guiding the order of specific laboratory tests (Sramek et al. 1995).

Another important confounder is the evidence that a high proportion of those patients with unquestionable abnormal bleeding, similar to that of PFD and VWD, end up without a definite diagnosis after exhaustive and repeated laboratory testing (Quiroga et al. 2007). This pattern is constant in several prospective reports and ranges from 47 to 69 % (Parkin et al. 1992; Quiroga et al. 2007; Podda et al. 2007; Gupta et al. 2007; Agren et al. 2006; Marcus et al. 2011; Tosetto et al. 2011).

Table 2 shows the frequency of bleeding from different sites and family history in 65 patients with inherited PFD,

Table 2 Site and frequency of bleeding and family history in patients with platelet function defects

Symptoms	Platelet function defects (%) (*n*: 65)	Controls (%) (*n*: 299)

Family history	88	51

[a]Denotes subjects exposed to the risk

Modified from the original Table 3 in Quiroga T et al. High prevalence of bleeders of unknown cause among patients with inherited mucocutaneous bleeding. A prospective study of 280 patients and 299 controls. Haematologica 2007; 92:357–65, with permission from Haematologica Journal website http://www.haematologica.org

corresponding to 23 % of 280 patients with unequivocal abnormal bleeding. Among these patients, 46 had primary secretion defects (42 with abnormal and four with normal platelet aggregation), and 18 had only defective aggregation. Three of the patients with secretion defects had δ-storage pool disease (low platelet 5-HT and ADP and high ATP/ADP ratio), and the last patient had the phenotypic pattern of GT (Quiroga et al. 2007).

Epistaxis

Nosebleed is one of the most common manifestations of platelet function defects, thrombocytopenias, VWD, and hereditary hemorrhagic telangiectasias (Sandoval et al. 2002). Since a large fraction of the normal population has experienced one or more nosebleeds, it is important to inquire about the frequency, whether it is spontaneous or associated to trauma and if it requires medical evaluation or treatment, including packing and cautery. Bleeding restricted to only one nostril is likely caused by a local vascular abnormality rather than a true hemostatic disorder. It is important to consider the age when evaluating epistaxis, since like other hemorrhages in primary hemostasis disorders, spontaneous nosebleeds tend to diminish or even disappear after puberty.

Purpura

The assessment of clinical significance of bruises (ecchymoses) is difficult, because the recognition of the symptom and perception of its severity vary widely among patients. For example, someone with frequent bruises secondary to minor trauma may consider that this is normal. There is also a clear gender difference, being easy bruising much more common in women than in men. Ecchymoses presenting without noticeable trauma, especially on the trunk or back, and particularly if they are large (>2 in. in diameter), should be judged as pathological. The sudden appearance of new and multiple ecchymoses may be secondary to an acquired condition such as thrombocytopenia or blood coagulation factor inhibitor.

Petechiae typically appear as pinpoint hemorrhages in dependent portions of the vasculature, which do not blanch with pressure. Petechial purpura is characteristic in patients with very low platelet counts and severe platelet defects, such as GT and B-S syndrome. In physiological conditions, platelets maintain the stability of the vasculature through several mechanisms, including constitutive expression of trophogens on the platelet surface or constitutive release of cytokines and growth factors that preserve the structural and functional integrity of the vasculature (Nachman and Rafii 2008). Under a critical number of platelets, these trophic effects on the endothelium are impaired, and the cadherin complex of the vascular endothelium breaks down, allowing extravasation of red cells into the tissues (petechiae). Capillary hemorrhages occur more frequently in areas of increased capillary pressure, such as ankles. In infants, the increase in venous pressure with crying may be enough for the development of petechial lesions. Spontaneous petechiae or hemorrhagic bullae in the oral mucosa usually are a sign of severe thrombocytopenia.

Oral Mucosal Bleeding

The clinical evaluation of gum bleeding is particularly difficult since it is common in apparently healthy subjects, with around 50 % of them expressing this symptom at least occasionally. It is recommended to examine the patients for gum inflammation, which may cause or augment bleeding. In this setting, gum bleeding is a frequent manifestation of PFD, mainly after dental brushing and gum intervention procedures. For these reasons, it is important to record the frequency of gingival hemorrhage and whether it is spontaneous or after trauma or brisk tooth cleaning. Moreover, gingival bleeding is often the first hemorrhagic symptom denoting hemostatic derangement in thrombocytopenias secondary to chemotherapy. Dental extraction, especially of molars, constitutes a major hemostatic challenge, and excessive bleeding after such procedures is highly common in patients with PFD. Moreover, the high fibrinolytic activity of the oral mucosa apparently magnifies the hemostatic impairment, since hemorrhages are commonly controlled with the oral use of antifibrinolytic agents. It is important to assess the magnitude of the blood loss, the duration of hemorrhage (usually several hours), and the need to return to the dentist for packing or suturing.

Bleeding from Minor Cuts

Patients with platelet disorders very often bleed excessively from minor cuts, like shaving. It may be difficult to obtain accurate information regarding bleeding due to razor incisions, although it is of help to ask whether the patient has to delay leaving home because of persistent oozing (Coller and Schneiderman 1995). It is helpful to know if patients change from razor blades to electric razor to avoid bleeding. Bleeding secondary to other minor cuts is often hard to assess unless the patient spontaneously claims that he or she bleeds longer compared with friends or classmates. Some patients also confess longer bleeding when taking aspirin. It is not uncommon that patients perceive that they do not bleed longer than normal but do have a delayed wound scarring and cure (personal observation).

Surgical Bleeding

Details of every surgical procedure must be investigated, including statements made by the surgeon regarding abnormal bleeding during or after surgery. Often, surgeons notice the abnormal bleeding since the skin incision in patients with PFD, denoting oozing from capillaries and small vessels, in contrast with the bleeding observed in mild or moderate clotting factor deficiencies, which is more delayed or occurs after the end of the procedure. Particularly important is to inquire whether a blood transfusion was necessary. Tonsillectomy and adenoidectomy are considered major hemostatic challenges, and the hemorrhage may occur early after surgery or even after the scar falls. In patients undergoing adenotonsillar procedures, it is useful to identify the existence of PFD or other mild bleeding disorders, because adequate management may reduce considerably the hemorrhagic complications (Garcia-Matte et al. 2012). In this regard, hospital records may provide key information regarding clinical and laboratory data ignored by the patient.

Menorrhagia and Postpartum Hemorrhage

Heavy menstrual bleeding or menorrhagia is usually diagnosed when normal menstrual periods last more than 7 days and/or involve blood loss greater than 80 mL. The prevalence of menorrhagia is estimated at 11–13 % in the general population, increasing in women between 36 and 40 years to reach up to 24 % (Marret et al. 2010), and in approximately 50 % of the patients, the etiology remains unexplained. Given that the patient perception of the amount of blood loss during periods is highly subjective and has poor correlation with the actual blood loss, the time length of the menstrual periods is preferred to diagnose heavier than normal blood losses. Other accurate indices to assess the severity of menorrhagia include secondary iron deficiency anemia, the use of contraceptives to manage bleeding, impaired daily activities, and need for emergency hysterectomy or blood transfusions. Some estimations range between 15 % (Oehler and Rees 2003) and 20 % (James et al. 2006) the proportion of women seeking medical attention with an underlying bleeding disorder (Rydz and James 2012). Most of the reports on the etiology have been focused in VWD (James et al. 2009), with a prevalence widely dispersed between 5 and 36 % (Mills et al. 2014). The studies that have addressed the prevalence of PFD have used different diagnostic criteria and laboratory methods (whole blood and platelet-rich plasma lumiaggregometry, platelet function assay [PFA-100™], platelet aggregation with ristocetin). This explains the disparate reports about defects of platelet function, which range between 2 and 56 % in postmenarchial women (Mills et al. 2014; Miller et al. 2011). Table 2 shows that in a population of 25 women with diagnoses of platelet aggregation/secretion defects, measured with light transmission platelet aggregometry and ^{14}C-serotonin release assay, the most frequent symptom was heavy menstrual bleeding, which was present in 23 (92 %) of them (Quiroga et al. 2007).

Menorrhagia is also a common symptom in patients with aplastic anemia as well as in inherited, immune, and drug-induced thrombocytopenias (including post-chemotherapy) (Mathias et al. 2008; Bates et al. 2011).

Thrombocytopenia affects between 5 and 8 % of pregnancies, is likely dilutional in etiology, exceptionally falls below 80×10^3 platelets μL^{-1} (Lefkou and Hunt 2008), and does not cause bleeding. Pregnancies coursing with immune thrombocytopenic purpura have low frequency and are rarely fatal (British Committee for Standards in Haematology General Haematology Task Force 2003). Petechial purpura may be apparent with very low platelet counts, and intra- and postpartum bleeding is uncommon with platelet counts $>50 \times 10^3$ platelets μL^{-1}. Neonatal thrombocytopenia in ITP is severe in around 4 % of the cases (below 20×10^3 platelets μL^{-1}) presenting high risk of hemorrhage at birth. Up to 50 % of the patients with GT have severe bleeds at delivery and require strict control and prophylaxis. Other, less severe PFDs do not have such an increased bleeding risk, but peri-delivery care is recommended, mainly in those women highly symptomatic before pregnancy (Civaschi et al. 2015). Similarly, women with symptomatic hereditary thrombocytopenias and platelet counts below 50×10^3 platelets μL^{-1} have higher risk of bleeding (Noris et al. 2014b).

Central Nervous System Bleeding

Spontaneous hemorrhages in central nervous system are exceptional in patients with inherited PFD, even in those with severe bleeding from other sites (e.g., GT). In contrast, diffuse intracerebral petechial lesions or hemorrhagic strokes may occur in patients with severe thrombocytopenias. In immune thrombocytopenias (ITP), a recent systematic review compiling 51 prospective studies in children and adults showed that the weighted incidences of adult and children intracerebral hemorrhages were 1.4 % and 0.4 %, respectively (Neunert et al. 2015), mainly in those patients with chronic ITP (Neunert et al. 2015). Predictors of parenchymal bleeding were severe thrombocytopenia (<10 or 20×10^3 platelets μL^{-1}), newly diagnosed ITP, and previous minor bleedings (Buchanan and Adix 2002; Rosthoj et al. 2012).

Other Mucosal Bleeding

Hemoptysis is not a presenting symptom of a bleeding disorder, and it is also rare even in patients with severe bleeding diathesis. However, patients with an inherited bleeding disorder might have blood-tingled sputum, especially associated with respiratory tract infections (Quiroga et al. 2007).

GI bleeding is also uncommon as presenting symptom of a bleeding disorder, although a hemostatic defect may trigger or exacerbate a previous GI lesion. In fact, in the series of Quiroga T et al., close to 10 % of the patients with a mild bleeding disorder manifested suffering from previous GI hemorrhage (Quiroga et al. 2007).

Platelet disorders rarely present with hematuria. However, platelet dysfunction and thrombocytopenias may contribute to exacerbate hematuria caused by other disorders, such urinary tract infections. Among patients with VWD and PFD, less than 4 % complained of hematuria (Quiroga et al. 2007). However, hemoptysis, GI bleeding, and hematuria are not uncommon in patients with severe thrombocytopenias of any etiology.

Other rare platelet dysfunctions that must be taken into account are the Quebec platelet disorder (QPD) and the Scott syndrome. Both have a different bleeding pattern when compared with the most frequent PFD. Their key clinical feature is delayed-onset bleeding following surgery, dental procedures, or trauma, but spontaneous bleeding is infrequent. The type of bleeding in patients with QPD is similar to that observed in patients with hyperfibrinolysis and is explained by increased platelet urokinase (uPA) storage, which induces plasmin-mediated digestion of alpha-granules and also platelet release of uPA, which accelerates the clot lysis. The increased plasma fibrin/fibrinogen degradation products and the bleeding response to fibrinolytic inhibitors constitute distinctive features of this disorder (Blavignac et al. 2011). Scott syndrome exhibits a similar bleeding pattern, but in this case a defect of platelet procoagulant activity explains the symptoms. A diminished prothrombin consumption test and a striking decrease in annexin V binding constitute initial diagnostic approaches before genetic confirmation of the molecular defect (Parry et al. 1980; Weiss et al. 1979; Andrews et al. 2002).

Physicians must be alert for suspecting and diagnosing the platelet-type VWD (PT-VWD), a rare platelet function disorder phenotypically similar to type 2B VWD, mainly because both disorders have different treatments. It has been estimated that PT-VWD constitutes up to 15 % of the total number of patients diagnosed with type 2B VWD. Functional assays allow a correct phenotypic diagnosis, before confirmation through genetic testing (Kaur et al. 2014; Maurer et al. 2015).

Hereditary hemorrhagic telangiectasia (disease of Osler-Weber-Rendu) is a developmental disorder of the vasculature, which presents with mucous and skin telangiectases and A-V malformations frequently affecting the GI tract. Patients with this syndrome suffer from nose and GI bleeding without having quantitative and functional platelet defects (McDonald et al. 2011).

The classic subtype of Ehlers-Danlos syndrome, a disorder caused by deficiency of type V collagen, may present with easy bruising with normal platelet function and number. In this case, the diagnosis requires the presence of skin hyperextensibility, widened atrophic scars, and joint hypermobility as major diagnostic criteria (Vanakker et al. 2015).

Effect of Medications and Supplements

Drug-induced bleeding is caused by several drugs that affect platelet function and which are used with therapeutic intent (i.e., aspirin, thienopyridines). However, more than 100 drugs, foods, and supplements have been reported to inhibit the function of platelets; however, conclusive evidence for their association with clinical bleeding of most of these is lacking (Konkle 2011). Moreover, the clinical use of more than 300 drugs has been reported to induce immune thrombocytopenia, although the level of evidence for their pathogenic role is poor for the vast majority of them (George and Aster 2009).

Nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin impair platelet function by reversible and irreversible inhibition of platelet cyclooxygenase-1, respectively, and may trigger hemorrhages or even unveil a previously unnoticed platelet qualitative or quantitative defect. In fact, aspirin intake exacerbates bleeding in close to 30 % of the patients with PFD (Table 2) (Quiroga et al. 2007), and the combination of aspirin with warfarin increases two- to threefold the risk of major bleeding in patients with coronary stents (Andreotti et al. 2006). Many reports have addressed the issue of major bleeding in patients treated for depression with SSRIs. However, recent reviews show that the evidence for increased bleeding risk in pregnancy and postpartum hemorrhage (Bruning et al. 2015) and major digestive tract bleeding (Jiang et al. 2015) is still inconclusive.

The personal history of the patient must keep detailed information on the use of medications, considering that many drugs have detrimental effects on platelet count (Aster et al. 2009; Arnold et al. 2013) or function (Cattaneo 2011). The clinician should consider the possibility of an underlying hemostatic defect, even if the bleeding is contemporary to drug use.

Several herbal supplements, some foods, and spices may impair hemostasis, although the evidence for a bleeding risk is lacking for most of them. Fish oils rich in omega-3 fatty acids, polyphenols, and cocoa flavonoids, among others,

have been described to prolong the bleeding time and affect platelet function, but there is not enough evidence that their use is associated with bleeding or bleeding enhancement (McEwen 2014; Ostertag et al. 2010; Heptinstall et al. 2006; Srivastava et al. 1995).

Take Home Messages

- Mucous and skin bleeding are the hallmarks of platelet function disorders and thrombocytopenias, like in other disorders of primary hemostasis, but also frequently in mild to moderate clotting factor deficiencies.
- Most inherited platelet function defects are explained by abnormal granule secretion of yet unknown cause and course with a mild bleeding disorder. The severity of bleeding in thrombocytopenias is related to the magnitude of the platelet fall. Clinical bleeding increases when platelet defects coexist with acquired conditions.
- The screening tests (bleeding time, PFA-100™) lack sensitivity and are non-specific for diagnosing a particular disorder of primary hemostasis, excepting thrombocytopenias and mild/moderate clotting factor deficiencies.
- Initial laboratory diagnosis in patients with conclusive abnormal bleeding and/or high bleeding scores should initially include the study of von Willebrand disease but also of PFD.

Inherited Thrombocytopenias

Carlo L. Balduini, Federica Melazzini, and Alessandro Pecci

Abstract

Inherited thrombocytopenias are a heterogeneous group of disorders with different degrees of severity and complexity deriving from mutations in at least 25 genes. Only a few inherited thrombocytopenias are characterized by recurrent spontaneous hemorrhages due to a very low platelet count and/or associated platelet dysfunction, while the other forms expose patients to the risk of bleeding in connection with hemostatic challenges. Some of the genetic abnormalities resulting in thrombocytopenia also cause additional congenital defects. Moreover, some common forms of inherited thrombocytopenia predispose to acquire in childhood or adult life additional serious diseases, as bone marrow aplasia, hematological malignancies, or kidney failure. Making a definite diagnosis is difficult and requires a close collaboration of clinicians, lab technicians, and geneticists. Many therapeutic measures are available both for preventing and stopping bleeding. Different treatments are available also for many congenital or acquired defects that may associate with thrombocytopenia.

Introduction

Inherited thrombocytopenias (ITs) include at least 26 disorders caused by mutations in 30 different genes (Table 1), but their number is expected to be higher because a definite diagnosis is not possible in about half of patients as they do not meet the criteria for any of the diseases described so far. Therefore, new ITs are yet to be discovered.

ITs are rare diseases, with an estimated prevalence of at least 2.7 in 100,000 (Balduini et al. 2012). However, this figure probably underestimates their actual frequency because they are often misdiagnosed with immune thrombocytopenia (ITP).

ITs are clinically very heterogeneous, with great variability in the degree of platelet deficiency and bleeding tendency, as well as in the additional defects that may associate with thrombocytopenia. Moreover, some of these additional manifestations are present since birth, while others develop later in life.

Classification

Different types of classification have been proposed. For their usefulness in the diagnostic process, the classification based on the presence of defects that add to thrombocytopenia (Balduini et al. 2013) and the one based on the size of the platelets, which varies greatly from one disorder to another (Noris et al. 2014a), are the most commonly used. Also the classification of ITs according to the mode of transmission may be useful for diagnostic purposes, but the type of inheritance is not always identifiable because of the frequent occurrence of sporadic cases due to de novo mutations or recessive inheritance.

The classification we use in Table 1 takes into account both the presence of defects added to thrombocytopenia since birth and the risk of acquiring additional defects during

Table 1 Main features of inherited thrombocytopenias classified according to their clinical picture

Disease (abbreviation, OMIM entry) (references)	Reported families[a]	Inheritance	Gene (locus)	Thrombocytopenia[b]	Bleeding[c]	Additional features
Forms with additional clinically relevant congenital defects						
Wiskott–Aldrich syndrome (WAS, 301000) (Massaad et al. 2013)	++++	XL	*WAS* (Xp11)	+++	+++	Severe immunodeficiency. Eczema. Increased risk of malignancies and autoimmunity
X-linked thrombocytopenia (XLT, 313900) (Albert et al. 2010)				++/+++	++/+++	Thrombocytopenia may be intermittent. Mild immunodeficiency. Mild transient eczema. Increased risk of malignancies and autoimmunity. Also non-syndromic[d]
Paris–Trousseau thrombocytopenia (TCPT, 188025), Jacobsen syndrome (JBS, 147791) (Favier et al. 2015)	++++	AD	Deletions in 11q23	+++	++/+++	Thrombocytopenia may resolve over time. Growth delay, mental retardation, facial dysmorphisms, malformations of the cardiovascular system, CNS, gastrointestinal apparatus, kidney, and/or urinary tract; other malformations
Thrombocytopenia-absent radius syndrome (TAR, 274000) (Toriello 2011)	+++	AR	*RBM8A* (1q21)	+++	+++	Platelet count tends to rise over time and often normalizes. Bilateral radial aplasia ± other upper and lower limb bone abnormalities. Reduced/absent megakaryocytes in BM. Possible kidney, cardiac, and/or CNS malformations. Possible intolerance to cow's milk
GATA1-related diseases: X-linked thrombocytopenia with thalassemia (XLTT, 314050), X-linked thrombocytopenia with dyserythropoietic anemia (XLTDA, 300367) (Millikan et al. 2011)	++	XL	*GATA1* (Xp11)	+++	++/+++	Hemolytic anemia with laboratory abnormalities resembling beta-thalassemia, splenomegaly, dyserythropoietic anemia. May present with congenital erythropoietic porphyria
Thrombocytopenia associated with sitosterolemia (STSL, 210250) (Rees et al. 2005)	++	AR	*ABCG5*, *ABCG8* (2p21)	+/++	+/++	Hemolytic anemia with stomatocytosis. Splenomegaly. Early development of tendon and tuberous xanthomas. Premature atherosclerosis. Also non-syndromic[d]
Radioulnar synostosis with amegakaryocytic thrombocytopenia (RUSAT, 605432) (Albers et al. 2012)	+	AD	*HOXA11* (7p15)	+++	+++	Bilateral radioulnar synostosis ± other malformations. Reduced/absent megakaryocytes in BM. Possible evolution to bone marrow aplasia
FLNA-related thrombocytopenia (*FLNA*-RT, na) (Nurden et al. 2011a, b)	+	XL	*FLNA* (Xq28)	++	++	Periventricular nodular heterotopia (OMIM 300049). Also non-syndromic[d]
THPO-related disease (*THPO*-RD, na) (Dasouki et al. 2013)	+	AR	*THPO* (3q27.1)	++/+++	++	Bone marrow hypoplasia. Red cell macrocytosis. Possible mild thrombocytopenia in heterozygous subjects
Stormorken syndrome (STRMK, 185070) (Misceo et al. 2014)	+	AD	*STIM1* (11p15.4)	+/++	+/+++	Mild anemia, asplenia, myopathy, miosis, headache, ichthyosis, dyslexia
Forms predisposing to other illnesses						
MYH9-related disease (*MYH9*-RD, na) (Balduini et al. 2011a)	++++	AD	*MYH9* (22q12)	+/+++	+/+++	Risk of sensorineural deafness, nephropathy, cataract (genotype–phenotype correlations identified). Elevated liver enzymes in some

childhood or the adult life. Thus, this type of classification serves both diagnostic and prognostic purposes.

Clinical Picture

The main characteristics of ITs are reported in Table 1.

Bleeding Tendency and Platelet Count

The risk of bleeding in subjects with more than 100 × 10^9 platelets/L is not significantly different from that of healthy people. Patients with platelet counts between 50 and 100 × 10^9/L usually do not bleed spontaneously, but are at risk of hemorrhages on the occasion of major hemostatic challenges. When platelets are less than 50 × 10^9/L, especially when their count is below 20 × 10^9/L, patients may present with spontaneous mucocutaneous bleeding, such as petechiae, easy bruising, nose bleeds, menorrhagia, and gastrointestinal bleeding. Moreover, any hemostatic challenge may result in profuse blood loss.

Although the severity of thrombocytopenia and that of bleeding diathesis are usually closely related, this does not apply to the ITs deriving from genetic anomalies that also cause a defect of platelet function (Table 2), in that affected subjects have a bleeding tendency that is more severe than expected on the basis of platelet count. The most clinically relevant platelet dysfunction is observed in biallelic Bernard–Soulier syndrome (BSS), where platelets have defective glycoprotein (GP) Ib/IX/V complex and therefore fail to interact with the subendothelium at the site of vascular injuries (Berndt and Andrews 2011; Savoia et al. 2011). In this disorder, the severity of bleeding tendency does not associate at all with the degree of thrombocytopenia, as bleeding mainly derives from platelet dysfunction. Although to a lesser extent, platelet function is affected in gray platelet syndrome (GPS), *GFI1b*-related thrombocytopenia (*GFI1b*-RT), familial platelet disorder with propensity to acute myelogenous leukemia (FPD-AML), Paris–Trousseau thrombocytopenia (TCPT)/Jacobsen syndrome (JBS), *FLI1*-related thrombocytopenia (*FLI1*-RT), *PRKACG*-related thrombocytopenia (*PRKACG*-RT), *ITGA2B*/*ITGB3*-related thrombocytopenia (*ITGA2B*/*ITGB3*-RT), sitosterolemia (STSL), *SLFN14*-related thrombocytopenia (*SLFN14*-RT), and *FLNA*-related thrombocytopenia (*FLNA*-RT).

At variance, bleeding diathesis seems sometimes less severe than expected based on the platelet count. This discrepancy is only apparent, since it derives from the fact that the most commonly used cell counters identify platelets by their size and therefore fail to recognize the large platelets that are typical of many ITs (Noris et al. 2009). The difference between the actual platelet count and that measured by the counter may be very large in *MYH9*-related disease (*MYH9*-RD), biallelic BSS, *PRKACG*-RT, and STSL, where a high proportion of platelets are as large as red cells or even larger. Manual platelet counting with an optical microscope in a counting chamber (England et al. 1984) or cell counters that recognize platelets by the binding of platelet-specific antibodies provide the actual value of platelet concentration.

In most cases, the degree of thrombocytopenia remains stable in each patient during lifetime, but some exceptions are worthy of mention. Platelet count tends to raise over time and often normalizes in thrombocytopenia-absent radius syndrome (TAR) and TCPT/JBS (Toriello 2011), while a transient increase in platelet count may be observed in congenital amegakaryocytic thrombocytopenia (CAMT)

Table 2 Pathogenetic mechanisms of inherited thrombocytopenias and coexistence of clinically relevant defects of platelet function

Disease (references)	Function of defective gene	Pathogenesis of thrombocytopenia (defective platelet function)
Defect in early phases of megakaryopoiesis		
Congenital amegakaryocytic thrombocytopenia (Hirata et al. 2013)	*MPL* encodes for the receptor for thrombopoietin (THPO), a hematopoietic growth factor that regulates multipotent hematopoietic progenitor cells and promotes their differentiation into Mks	THPO defect affects commitment–differentiation of multipotent stem cells to Mk. Acquired bone marrow aplasia is due to failure to maintain multipotent hematopoietic cells
Thrombocytopenia-absent radius syndrome (Albers et al. 2013)	*RBM8A* encodes for the subunit member Y14 of the exon junction complex, which is involved in RNA processing and required for same basic cellular functions as nuclear export and subcellular localization of specific transcripts	It has been hypothesized that the low expression of *RBM8A* affects mRNA processing of unknown components of the THPO/MPL pathway
Radioulnar synostosis with amegakaryocytic thrombocytopenia (Horvat-Switzer and Thompson 2006)	*HOXA11* encodes for a homeobox transcription factor that regulates morphogenesis and differentiation. Its role in hemopoiesis is not clear	The molecular mechanisms translating HOXA11 mutations in amegakaryocytic thrombocytopenia, and, sometimes, bone marrow aplasia are unknown
THPO-related disease (Dasouki et al. 2013)	*THPO* is the gene for thrombopoietin, which is essential for survival of multipotent hematopoietic cells and for their differentiation into Mks	Defective thrombopoietin is expected to have consequences similar to those deriving from defective thrombopoietin receptor
Defect in megakaryocyte maturation		
Familial platelet disorder with propensity to acute myelogenous leukemia (Sakurai et al. 2014)	*RUNX1* encodes for the DNA-binding a subunit of the core binding factor (CBF) transcription complex. The CBF regulates the homeostasis between proliferation and differentiation of stem cells in adult hematopoiesis	Reduced expression of the THPO receptor. Defective Mk differentiation and maturation. Defective proplatelet formation. (Alpha/delta storage pool deficiency. Defect of $\alpha_{IIb}\beta_3$ activation and platelet aggregation)
ANKRD26-related thrombocytopenia (Bluteau et al. 2014)	The role of *ANKRD26* in megakaryopoiesis is poorly defined. The binding of RUNX1 and FLI1 silences *ANKRD26* during the latest phases of normal megakaryopoiesis	Loss of *ANKRD26* silencing induced by RUNX1 and FLI1 during Mk maturation cause persistent THPO/MPL pathway signaling. Dysmegakaryopoiesis and impaired proplatelet formation
ETV6-related thrombocytopenia (Noetzli et al. 2015)	*ETV6* encodes a transcriptional repressor that was initially identified as a tumor suppressor	Defective megakaryocyte maturation
FLI1-related thrombocytopenia (Stevenson et al. 2015a)	*FLI1* promotes platelet biogenesis by transactivation of many genes associated with Mk development, such as *MPL*, *GP9*, *GP1BA*, *ITGA2,* and *PF4*	Defective Mk maturation. (Defect of platelet GPVI, GPIb/IX, GPIIb, and abnormal alpha granules. Defect of platelet aggregation)
Paris–Trousseau thrombocytopenia/ Jacobsen syndrome (Favier et al. 2015)	Contiguous gene deletion syndrome. Different sizes and breakpoints of the deletions are responsible for the heterogeneity of the clinical picture. Deletion of *FLI1* causes thrombocytopenia	Maturation block in the megakaryocytic linage, with abundance of immature, hypolobulated, and dystrophic Mks. (Defect of platelet aggregation)
GATA1-related diseases (Songdej and Rao 2015)	*GATA1* regulates genes expressed in the Mk lineage, as *GP1BA*, *GP1BB*, *PF4*, *MPL,* and *NFE2*, and in the erythroid line, as *HBB*, *ALAS1,* and *BCL2L1*.	Alteration of Mk maturation. (Defective platelet aggregation after ristocetin and collagen in some cases)
GFI1b-related thrombocytopenia (Monteferrario et al. 2014)	GFI1B is a transcriptional factor involved in homeostasis of hematopoietic stem cells and development of the megakaryocytic and erythroid lineages	Altered Mk maturation with mild myelofibrosis and defective expression of several platelet proteins, as fibrinogen, P-selectin, and GPIbα. (Many pale platelets due to α alpha-granule deficiency. Variable defect of platelet activation and aggregation)
Gray platelet syndrome (Pecci and Balduini 2014)	*NBEAL2* codes for neurobeachin-like protein 2, which probably plays a role in protein–protein interactions, membrane dynamics, and vesicle trafficking	Defective Mk maturation. (Severe deficiency of platelet alpha granules causing "pale" platelets. Possible defects of platelet aggregation)
FYB-related thrombocytopenia (Levin et al. 2015)	The *FYB* protein (ADAP) is a candidate linker between cell membrane activation signals and intracellular events that regulate actin polymerization and organization	Because of the findings of immature Mks at bone marrow evaluation and activated platelets in blood, it has been hypothesized that thrombocytopenia derives from defective maturation of Mks and clearance of activated platelets

(continued)

Table 2 (continued)

Disease (references)		Function of defective gene	Pathogenesis of thrombocytopenia (defective platelet function)
Defect in platelet release			
MYH9-related disease (Balduini et al. 2011b)		The *MYH9* protein (NMMHC-IIA) is a motor molecule for cellular processes requiring force. It regulates the cytoskeleton and also acts as an end point for many signaling pathways, representing a master integrator of the activities that drives cell migration, cell–cell interaction, and cell-matrix adhesion	Ectopic platelet release resulting in ineffective platelet production and defective proplatelet formation
ACTN1-related thrombocytopenia (Kunishima et al. 2013)		The *ACTN1* protein (actinin, alpha1) organizes actin filaments into bundles	Defective proplatelet formation
FLNA-related thrombocytopenia (Nurden et al. 2011a)		The *FLNA* protein (filamin A) connects actin filaments to the cellular membrane. In platelets, filamin A tethers GPIbα and $\alpha_{IIb}\beta_3$ to the underlying cytoskeleton	Defective proplatelet formation has been hypothesized
Bernard–Soulier syndrome	Biallelic (Balduini et al. 2011b)	The genes *GP1BA*, *GP1BB,* and *GP9* code for GPIbα, GPIbβ, and GPIX, respectively, which form the membrane GPIb-IX-V complex in platelets and Mks. The intracellular domain of GPIbα binds the cytoskeleton though filamin A, the extracellular domain binds to von Willebrand factor	Defective proplatelet formation. (Severely reduced platelet adhesion to exposed subendothelium)
	Monoallelic (Balduini et al. 2009)		Mild defect of proplatelet formation
ITGA2B/*ITGB3*-related thrombocytopenia (Bury et al. 2012)		The gene *ITGA2B* and *ITGB3* encode the components of the $\alpha_{IIb}\beta_3$ complex, a fibrinogen receptor in Plts and Mks	A defective proplatelet formation has been hypothesized. (Defect of platelet aggregation)
TUBB1-related thrombocytopenia (Kunishima et al. 2009)		The *TUBB1* protein (β1 tubulin) is a major component of microtubules in Plts and Mks	Defective proplatelet formation
CYCS-related thrombocytopenia (Morison et al. 2008)		*CYCS* encodes cytochrome c, a mitochondrial protein that participates in mitochondrial respiration and initiation of the intrinsic pathway of apoptosis	It has been hypothesized that an ectopic, premature proplatelet formation causes thrombocytopenia
PRKACG-related thrombocytopenia (Manchev et al. 2014)		*PRKACG* encodes the gamma isoform of the catalytic subunit of cAMP-dependent protein kinase A	Defective proplatelet formation. (Defective platelet activation)
Shortened platelet survival			
Platelet-type von Willebrand disease (Guerrero et al. 2009)		The gene *GP1BA* encodes GPIbα, whose extracellular domain binds to von Willebrand factor at the site of vascular injuries. Mutations results in gain of function of GPIbα	It has been suggested that the increased affinity of platelet GPIbα for circulating von Willebrand factor results in platelet clumping and shortened platelet survival
Wiskott–Aldrich syndrome (Massaad et al. 2013)		The WAS protein plays a key role as regulator of the actin cytoskeleton	Premature, ectopic release of platelets in the bone marrow and increased clearance of platelets from circulation
X-linked thrombocytopenia (Massaad et al. 2013)			
Thrombocytopenia associated with sitosterolemia (Rees et al. 2005)		*ABCG5* and *ABCG8* proteins regulate plant sterol and cholesterol absorption and elimination from the body	It has been suggested that platelets are a target for the toxic effect of increased plasma phytosterols. (Defective platelet aggregation)
Unknown defect			
SLFN14-related thrombocytopenia (Fletcher et al. 2015)		The role of *SLFN14* protein is poorly known. Possible role as an endoribonuclease, regulating rRNA, and ribosome-associated mRNA cleavage	Pathogenesis of thrombocytopenia is unknown. (Defects of platelet dense granules and defective platelet aggregation)
Stormorken syndrome (Morin et al. 2014)		STIM1 is involved in store-operated Ca^{2+} entry	Gain of function mutations result in thrombocytopenia by an unknown mechanism. Platelets have high Ca^{2+} basal levels and are in a preactivated state

(Ballmaier and Germeshausen 2011). Transient increases in platelet count have been observed also in patients with *ANKRD26*-related thrombocytopenia (*ANKRD26*-RT) on the occasion of severe infections, probably because thrombopoietin (THPO) behaves as an acute phase protein and its increase in inflammatory conditions stimulates platelet production (Noris et al. 2011). Personal experience indicates that this phenomenon may occur also in other ITs. At variance, platelet count typically decreases over time in GPS, as a result of progressive marrow fibrosis and splenomegaly (Gunay-Aygun et al. 2010).

Other Congenital Defects

Many of the genetic abnormalities that are responsible for thrombocytopenia cause additional congenital defects (Fig. 1): bone malformations characterize TAR and radioulnar synostosis with amegakaryocytic thrombocytopenia (RUSAT) (Thompson et al. 2001); growth delay, mental retardation, facial dismorphisms, and a variety of other congenital malformations affect subjects with TCPT/JBS (Mattina et al. 2009); the complex neurological defects typical of periventricular nodular heterotopia are present in most cases of *FLNA*-related thrombocytopenia (*FLNA*-RT) (Nurden et al. 2011a). Hemolytic and dyserythropoietic anemia associate with thrombocytopenia in X-linked thrombocytopenia with thalassemia (XLTT) and X-linked thrombocytopenia with dyserythropoietic anemia (XLTDA) (Millikan et al. 2011), respectively, while bone marrow failure of variable severity has been described in *THPO*-related disease (*THPO*-RD) (Dasouki et al. 2013). Finally, patients with Wiskott–Aldrich syndrome (WAS) have severe immune dysregulation, resulting in recurrent infections, eczema, autoimmune phenomena, and increased risk of malignancies, especially lymphoproliferative disorders (Massaad et al. 2013).

Predisposition to Acquire Additional Illnesses

A recently identified aspect of ITs is that some of them predispose to acquire in childhood or adult life specific disorders that may endanger the life of patients much more than thrombocytopenia itself. The most complex and better characterized of these forms is *MYH9*-RD, which predisposes not only to presenile cataracts and sensorineural deafness but also to a proteinuric nephropathy that occurs at a mean age of 27 years and often evolves into end-stage renal failure (Seri et al. 2003). Proteinuria affects 25 % of patients, and about 40 % of them develop end-stage renal disease. Reliable genotype–phenotype correlations have been identified, with some mutations resulting in nephropathy in nearly all cases and others associated with no risk at all (Fig. 2). Similar results have been obtained for cataracts and deafness (Pecci et al. 2014a).

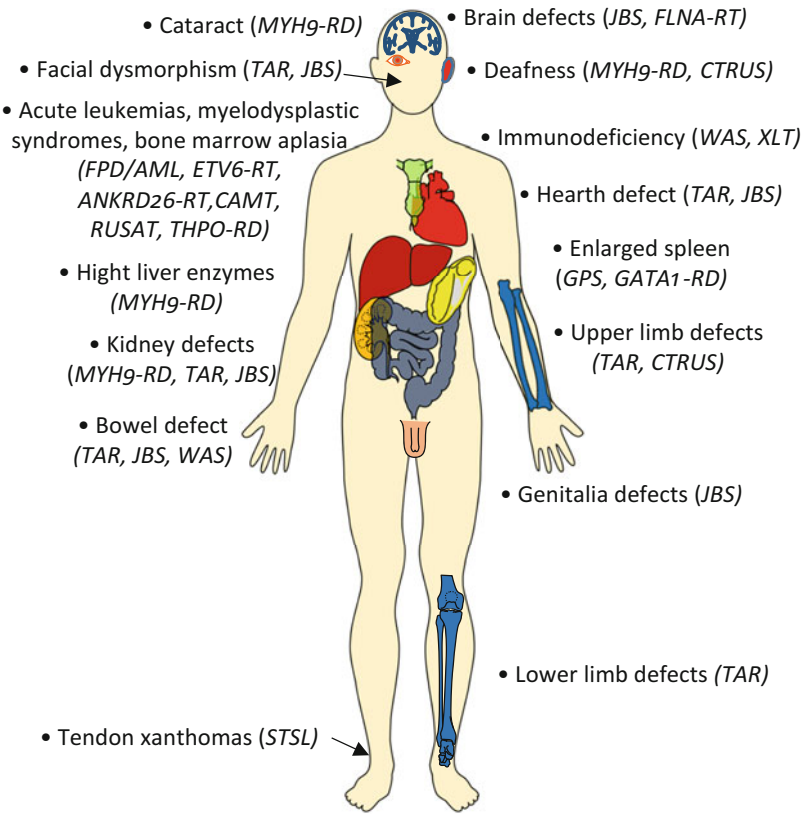

Fig. 1 Defects associated with low platelet count in some inherited thrombocytopenias. Schematic view of the most important defects/diseases, either congenital or acquired, that may affect patients with inherited thrombocytopenias. For abbreviations of disorders, see Table 1

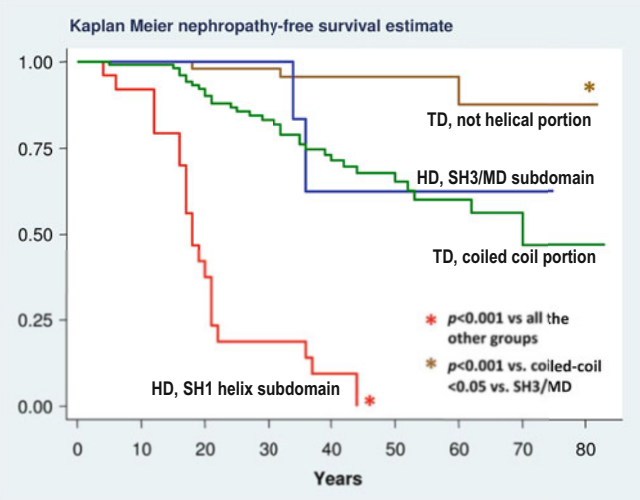

Fig. 2 Genotype–phenotype correlations in 255 patients with *MYH9*-related disease. MYH9 protein comprises three distinct domains: the N-terminal globular head domain (HD), which includes the SH1 helix and the SH3/MD subdomains; the neck; the C-terminal tail domain (TD), which includes the coiled coil portion and the C-terminal not helical portion. Propensity to develop nephropathy varies greatly depending on the location of the causative mutations. All subjects with mutations in the SH1 subdomain of HD (*red line*) are expected to develop nephropathy before age 45, while those with mutations in the terminal, not helical portion of the TD (*brown line*), very rarely suffer from this defect. Patients with mutations in the coiled-coil portion of TD (*green line*) or the SH3/MD subdomain of HD (*blue line*) have intermediate risk, and about 50 % of them develop kidney defect (modified from Pecci et al. 2014a, with permission)

Other forms of ITs are characterized by the propensity to develop hematological malignancies. Over 40 % of subjects with FDP-AML acquire acute myelogenous leukemia or myelodysplastic syndromes, with a median age at onset of 33 years (Liew and Owen 2011). Also the risk of acute lymphoblastic leukemia seems to be increased. The incidence of acute myeloid leukemia and that of chronic myelogenous leukemia is more than 20 times higher in *ANKRD26*-RT than in general population, while that of myelodysplastic syndrome is 10 times higher (Noris et al. 2011, 2013). Finally, several cases of acute lymphoblastic leukemia and other hematological malignancies have been reported in *ETV6*-related thrombocytopenia (*ETV6*-RT) (Noetzli et al. 2015; Zhang et al. 2015).

The most fearsome form of IT in terms of evolution is CAMT, in that it progresses in all cases to a bone marrow aplasia that is fatal unless patients receive hematopoietic stem cell transplantation (Ballmaier and Germeshausen 2011).

Pathogenesis

Defective platelet production is the cause of thrombocytopenia in most ITs, whereas in only few forms the low platelet count derives from reduced survival of platelets. Table 2 succinctly describes the pathogenesis of each IT and the functional role of the involved genes. It also indicates whether a defect of platelet function associates with thrombocytopenia. For a detailed discussion of the pathogenetic mechanisms of ITs, we refer to a recent review dedicated to this topic (Pecci and Balduini 2014).

A small group of ITs is characterized by the absence or a severely reduced amount of megakaryocytes (Mks) in the bone marrow due to defective commitment–differentiation of multipotent stem cells to the Mk lineage. Defects of THPO, its receptor (MPL), or the signaling pathways stimulated by the binding of THPO to MPL have been hypothesized or proven as the causes of these disorders. Of note, while CAMT always evolves into bone marrow aplasia, different degrees of bone marrow hypoplasia may be observed in RUSAT and *THPO*-RD. This indicates that the THPO-MPL pathway is important not only for megakaryocytic differentiation but also for maintenance of the multipotent hematopoietic progenitor compartment.

Defective Mk maturation is the main pathogenetic mechanism of thrombocytopenia in many ITs, although in some forms other mechanisms, as shortened platelet survival or impaired proplatelet formation, contribute to the low platelet count. The genes affected in these ITs are in most cases transcription factors responsible for the fine-tuning of activation and inactivation of specific genes that must be expressed at some stages of megakaryocytic maturation and silenced in others phases. Three of these forms (FPD/AML, *ANKRD26*-RT, and *ETV6*-RT) are characterized by dysmegakaryopoiesis and predisposition to hematological malignancies. Based on this observation, these ITs can be considered as inherited forms of the unilineage myelodysplastic syndrome affecting the Mk lineage (refractory thrombocytopenia) (Gyan et al. 2015).

In another large group of ITs, platelet deficiency derives from a defect in the complex mechanisms that allow mature Mks to release platelets into the lumen of bone marrow sinusoids. In most cases, mature Mks fail to extend properly the long cytoplasmic protrusions from which platelets detach. Less frequently, a premature and/or ectopic release of platelets within the bone marrow results in ineffective thrombopoiesis. ITs deriving from altered platelet release are mainly caused by mutations in cytoskeleton components or membrane integrins.

Finally, shortened platelet survival is the main cause of thrombocytopenia in three ITs. In WAS/XLT, platelets are intrinsically fragile and are prematurely destroyed by the spleen. This is the reason why splenectomy increases or even normalizes platelet count in this condition (see below "Therapy"). In platelet-type von Willebrand disease (PT-VWD), the affinity of platelet GPIbα for the von Willebrand factor (VWF) is increased, and platelets bind spontaneously large circulating multimers of this molecule. It has been suggested that the removal from circulation of

platelet-VWF complexes is the cause of thrombocytopenia, but that there is no experimental evidence of this in humans. At variance, platelets are intrinsically normal in thrombocytopenia associated with STSL, but the high blood levels of phytosterols that characterize this disorder have a toxic effect on their membrane and shorten their survival.

Diagnosis

Two major difficulties are encountered in the diagnostic process of ITs: recognition of patients with a genetic form among individuals with thrombocytopenia and identification of the specific disorder of each patient.

Recognize that Thrombocytopenia Has a Genetic Cause

As a matter of fact, a large proportion of patients are diagnosed as affected by an IT only after a previous misdiagnosis of ITP. The risk of misdiagnosis is well illustrated by the finding that 57 of 181 consecutive women with ITs had a previous diagnosis of ITP (Noris et al. 2014b). For this reason, 44 of them had received treatments that are not only useless, but even dangerous, such as immunosuppressive agents and splenectomy. In many IT patients, the low platelet count is found incidentally in adult life, and the genetic origin of thrombocytopenia is frequently overlooked (Balduini et al. 2013). To avoid this oversight, it is recommended to consider the possibility that every unexplained thrombocytopenia has a genetic origin whenever it is not possible to ascertain that platelet count was normal in the past. In this case, medical history, physical examination, and microscopy examination of peripheral blood films are crucial to identify symptoms and signs that are suggestive of ITs.

Medical History

The finding that other family members of the proband have low platelet counts clearly supports the hypothesis of an IT. However, a negative family history does not exclude this possibility, because some ITs are transmitted in a recessive manner or derive from de novo mutations. For instance, near 40 % of probands with *MYH9*-RD have sporadic forms arising from de novo mutational events (Balduini et al 2011a). Also the presence of bleeding tendency since birth or on the occasion of the first hemostatic challenges, as trauma, menarche, or surgery, supports the hypothesis of a genetic defect. Another finding suggestive for ITs is bleeding tendency more severe than expected based on platelet count, since defective platelet function characterizes many IT forms (Table 2).

As some ITs are associated with other congenital defects or predispose to other illnesses, medical history should not be limited to bleeding diathesis; moreover, the search for associated manifestations should be performed not only in the proband but in all the family members. Indeed, the associated defects may have variable expressivity within the same families and/or may occur late in life. In the latter case, they may be absent in young individuals but present in older affected relatives. For instance, young patients with *MYH9*-RD usually do not present with kidney damage, deafness, and/or cataracts, which are instead frequently found in older family members with this disorder. It is recommended that family history includes also the search for leukemias or myelodysplastic syndromes, which occur with high frequency in many pedigrees with FDP-AML, *ANKRD26*-RT, and *ETV6*-RT.

Physical Examination

Physical examination aims to identify the abnormalities possibly associated with thrombocytopenia in syndromic ITs. As schematized in Fig. 1, these defects may affect all body districts, and examination should be therefore as complete as possible. The list of defects described in this figure is not exhaustive, and many other rarer abnormalities have been reported. Some defects are easily detected by general examination, while others are less evident, and their identification requires a targeted search. For instance, visual inspection is sufficient to detect the bilateral radial aplasia of TAR, while the radioulnar synostosis of RUSAT is suspected by the limited supination of the forearm. A few laboratory tests can complement the physical examination when searching for specific organ dysfunctions: urinalysis, to show proteinuria as the first sign of renal involvement in *MYH9*-RD, and dosage of liver enzymes, which are elevated in approximately 50 % of patients with this disease.

Blood Film Evaluation

Microscope evaluation of blood cells is a powerful tool for suspecting ITs since most of them are characterized by morphological anomalies of platelets, leukocytes, and/or erythrocytes (Table 3).

Platelets The most common abnormality of platelets is enlarged size with remarkable anisocytosis. Examples of giant platelets, large platelets, and platelets with normal size are given in Figs. 3 and 4. Table 4 reports a classification of ITs according to platelet diameters based on the analysis of 376 patients with 19 different disorders (Noris et al. 2014a). Depending on platelet diameters and the percentage of platelets larger than 3.9 μm (nearly half the diameter of normal erythrocytes), this classification distinguishes ITs with giant platelets, with large platelets, with normal or slightly increased platelet size, and with normal or slightly

Table 3 Morphological abnormalities of blood cells at examination of peripheral blood slides raising the suspicion that thrombocytopenia has a genetic cause

Blood cell abnormality	Inherited thrombocytopenia
Platelets	
Platelet anisocytosis	Most inherited thrombocytopenias
Giant platelets and >40 % of platelets larger than half a red blood cell	*MYH9*-RD, biallelic BSS, *PRKACG*-RT
Small platelets and/or <10 % of platelets larger than half a red blood cell	WAS, XLT, CAMT, *CYCS*-RT
Agranular ("pale") platelets (with large platelets)	GPS, *GFI1b*-RT
Hypo-granular platelets (with normal-sized platelets)	*ANKRD26*-RT
Some platelets with one single giant granule	TCPT/JBS, *FLI1*-RT
Vacuolated platelets	XLTT
Leukocytes	
"Döhle-like" inclusions in neutrophils	*MYH9*-RD
Red blood cells	
Anisopoikilocytosis or anisocytosis	*GATA1*-related disorders, *GFI1b*-RT
Stomatocytosis	STSL
Anisopoikilocytosis with dacryocytosis	GPS

For abbreviations of disorders, see Table 1

decreased platelet size. Platelet size in ITP is largely overlapping with that observed in ITs with large platelets and with normal or slightly increased platelet size, so that peripheral blood films evaluation has little utility in distinguishing these conditions. At variance, the percentage of large platelets has good sensitivity and specificity in differentiating ITs with giant platelets or with normal/reduced platelet size from ITP: the finding of more than 40 % or less than 10 % of platelets larger than half an erythrocyte strongly supports the diagnosis of the former conditions and makes the diagnosis of the latter unlikely. Cell counters are less effective than peripheral blood film evaluation in distinguishing ITs from ITP because, as already discussed, they often fail to recognize very large platelets and therefore underestimate MPV in ITs with giant platelets. However, it has been shown that a MPV value 50 % higher than the average value in healthy subjects has good diagnostic accuracy in recognizing ITs with very large platelets (Noris et al. 2009). Conversely, the finding of a normal or slightly increased MPV does not exclude the presence of giant platelets, and examination of blood films is required.

Abnormality of platelet granules is another finding suggesting the genetic origin of thrombocytopenia (Fig. 3d–h). Reduced or absent granules associated with platelet macrocytosis are typical of GPS and *GFI1b*-RT, while a reduced number of granules in normal-sized platelets may be observed in *ANKRD26*-RT (Noris et al. 2011). Identification of even a very small proportion of platelets with one single giant granule supports the diagnosis of TCPT/JCB (Penny et al. 1995).

Finally, a large number of vacuolated platelets support the diagnostic hypothesis of XLTT (Fig. 3i) (Balduini et al. 2004).

Leukocytes Blood film evaluation may be diagnostic in *MYH9*-RD, because the presence of faint, light-blue inclusion bodies (Döhle-like bodies) in polymorphonuclear leukocytes associated with very large platelets is pathognomonic of this disorder (Fig. 4) (Savoia et al. 2010). Döhle-like bodies consist of aggregates of wild-type and mutant MYH9 protein, MYH9 mRNA, and ribosomes. Conventional, panoptic staining reveals only the largest aggregates, which are identified in 42–84 % of patients. However, immunolabeling for MYH9 protein (Fig. 4e–g) discloses that these inclusions are present in all neutrophils of all patients (with the only exception of the very rare patients with mosaicisms) (Kunishima et al. 2005). The finding of aggregates at immunofluorescence assay for MYH9 is specific for *MYH9*-RD and is currently used as a screening test for this disorder (Savoia et al. 2010).

Erythrocytes The morphology of red blood cells deserves to be considered since abnormalities of their shape and size are observed in *GATA1*-related disorders, *GFI1b*-RT, sitosterolemia, and GPS.

Identification of the Specific Disorder of Each Patient

Identification of the specific form of IT affecting each patient is traditionally a two-step process: first, analysis of clinical data and a few simple tests to raise a diagnostic suspicion and then, second, targeted sequencing of the candidate gene(s) to confirm the diagnostic hypothesis. Figure 5 reports a diagnostic algorithm used in many centers (Balduini et al. 2003; Noris et al. 2004) that has been now updated to include the newly discovered diseases.

Syndromic Forms

Medical history and physical examination are used to recognize the defects possibly associated with thrombocytopenia in syndromic ITs and therefore to raise a diagnostic suspicion to be confirmed by genetic analysis. A few instrumental or laboratory tests may be required to identify and/or characterize certain defects. For instance, radiological examination is needed to characterize the bone defects of some ITs (Thompson et al. 2001). If *MYH9*-RD is suspected, audiometric and ophthalmological evaluation are required to confirm the presence of sensorineural deafness and cataracts

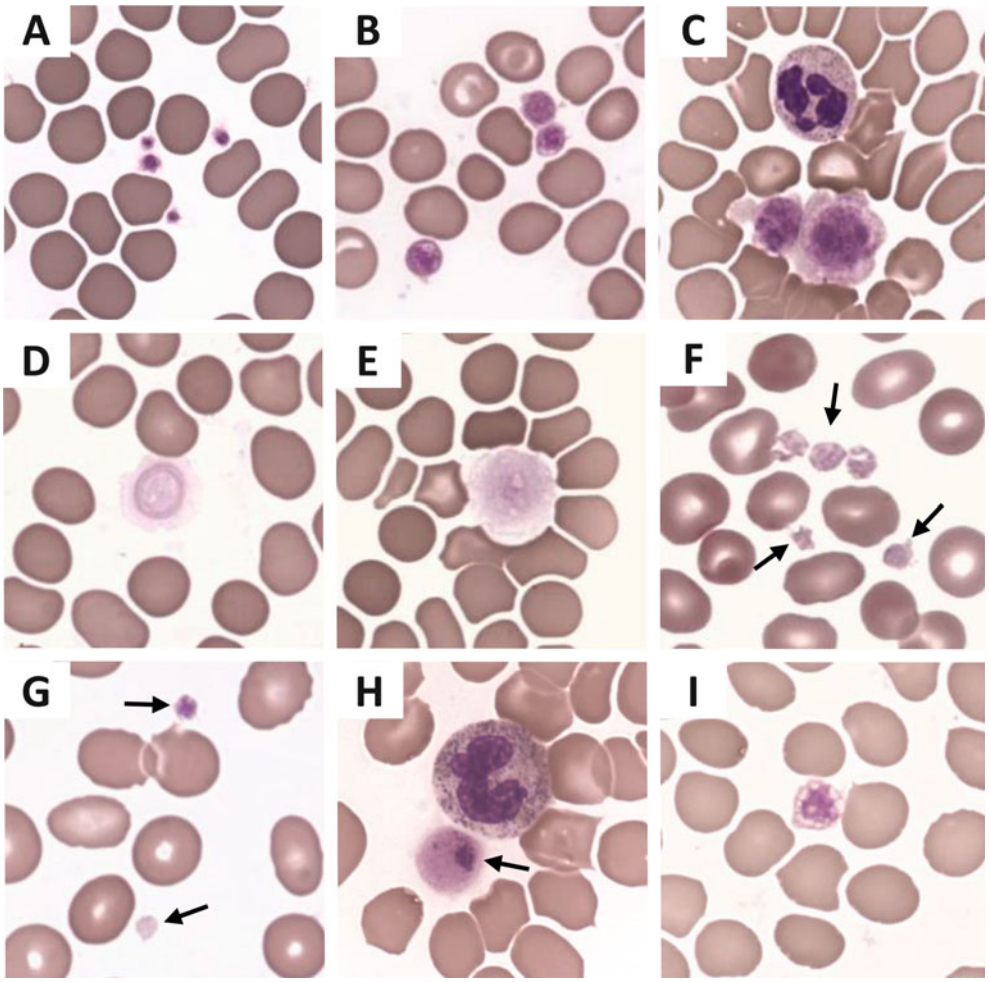

Fig. 3 Morphological abnormalities of platelets in inherited thrombocytopenias. Platelet size distinguishes forms with normal or nearly normal platelet size (**a**), with large platelets (**b**) and with giant platelets (**c**). The finding of large platelets that look "pale" in May–Grünwald–Giemsa-stained blood films is due to the absence of azurophilic granules (α-granules) and is highly suggestive of gray platelet syndrome (**d**, **e**), while a milder granule deficiency indicates *GF1Ib*-related thrombocytopenia (**f**). Granule deficiency in a variable proportion of platelets with normal or slightly increased size may be observed in *ANKRD26*-related thrombocytopenia (**g**, *arrows* indicate one platelet with normal α-granule content and one platelet without granules). The finding of platelets with a single giant granule is indicative of Paris–Trousseau thrombocytopenia/Jacobsen syndrome (**h**) even when only a very small percentage of platelets has this feature. Finally, large and vacuolated platelets have been described in *GATA1*-related diseases (**i**)

(Verver et al. 2016), respectively, while urinalysis is recommended to demonstrate proteinuria, which is the first sign of kidney damage (Pecci et al. 2008).

Non-syndromic Forms

After exclusion of syndromic forms, platelet size guides subsequent investigation (Pecci 2015).

Normal or Nearly Normal Platelet Size In case of normal, slightly increased, or slightly decreased platelet size, infants or children require bone marrow examination, because the absence/severe reduction of megakaryocytes indicates CAMT (Ballmaier and Germeshausen 2011). Regardless of age, bone marrow examination is due also in subjects with varying degrees of leukopenia and/or anemia, because the finding of bone marrow hypoplasia suggests *THPO*-RD. Once these two forms have been excluded, eight diagnoses are possible, and the transmission mode of thrombocytopenia in the family can help to narrow the diagnostic possibilities. However, the penetrance of mutations for thrombocytopenia may be incomplete in some dominant disorders, and normal platelet counts have been observed in few subjects with mutations that usually cause thrombocytopenia in *ANKRD26*-RT, FPD-AML, or *CYCS*-RT (Liew and Owen 2011; Noris et al. 2011).

Platelet Macrocytosis The diagnostic possibilities for subjects with large platelets are numerous. The diagnostic algorithm suggests to examine a peripheral blood film as the initial test. The finding of Döhle-like inclusion bodies in granulocytes of a patient with giant platelets is pathognomonic for *MYH9*-RD (Balduini et al. 2011a). Identification of platelet macrocytosis with most platelets looking "pale" due to a severe reduction in platelet azurophilic granules (α-granules) suggests GPS. A variable deficiency of granules in a proportion of platelets is compatible with *GFI1b*-RT (Stevenson et al. 2013, 2015b). The finding of red cell anisopoikilocytosis, often associated with anemia, indicates the ITs deriving from *GATA1* mutations (Millikan et al. 2011), while stomatocytosis associated with hemolytic anemia indicates sitosterolemia (Rees et al. 2005).

In case blood film evaluation does not identify abnormalities of blood cells other than platelet macrocytosis, three rather simple and inexpensive tests are used to further

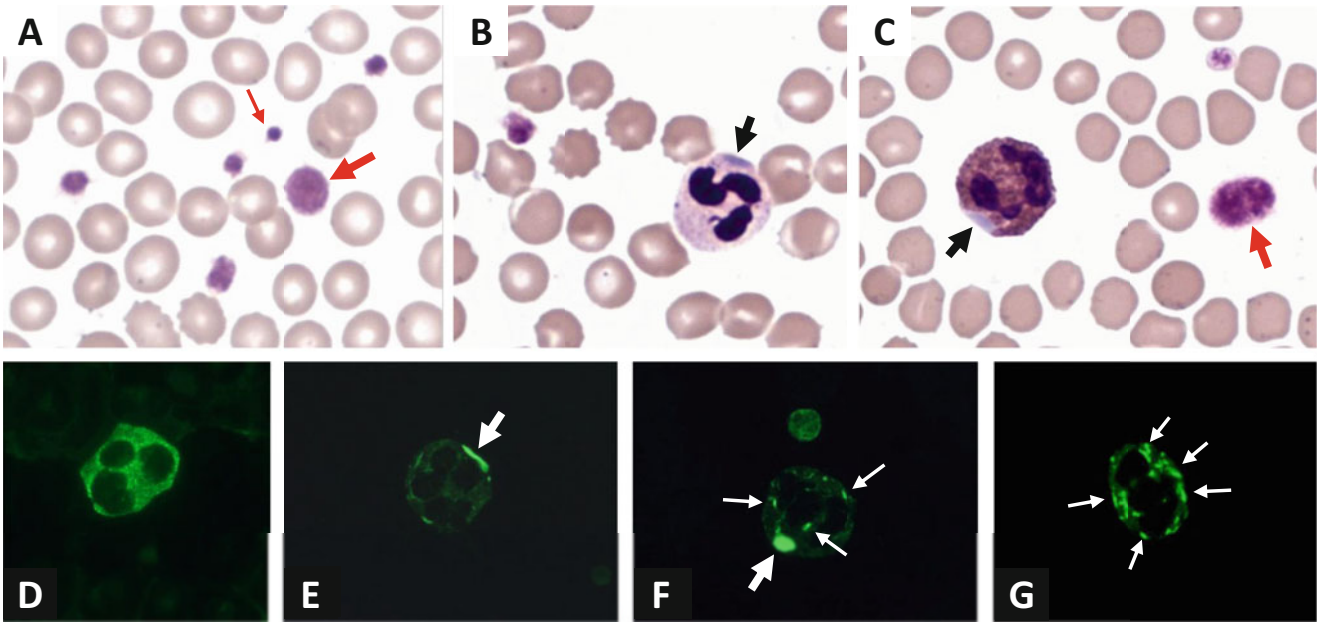

Fig. 4 Blood films in *MYH9*-related disease. (**a**–**c**) May–Grünwald–Giemsa-stained blood films; (**d**–**g**) immunofluorescence with antibodies against MYH9 protein. Platelet size in *MYH9*-related disease ranges from elements as large as red cells (*red*, *bold arrows* in **a** and **c**) to normal-sized elements (*thin arrow* in **a**). The faint, light blue, round-, or spindle-shaped inclusion bodies (Döhle-like bodies) located at the periphery of neutrophils and eosinophils shown (*black arrow*) in **b** and **c**, respectively, are typical of *MYH9*-related disease and are identified in about 50 % of patients. Immunofluorescence shows that these inclusions contain the *MYH9* protein clumped in a limited number of large or small spots (*bold* and *thin arrows*, respectively, in **e**–**g**) instead of being distributed homogeneously in the cytoplasm as in controls (**d**). Immunofluorescence analysis recognizes these inclusion bodies in almost all patients with *MYH9*-related disease and is therefore an excellent screening test for this condition

drive the diagnostic process. In vitro platelet aggregation after stimulation with ristocetin is markedly reduced or absent in patients with biallelic BSS: this diagnosis is confirmed by flow cytometric demonstration of severely reduced or undetectable GPIb/IX/V complex on the surface of platelets (see below) (Savoia et al. 2011; Berndt and Andrews 2011). Conversely, platelet aggregation in response to low ristocetin concentrations (0.3–0.4 mg/mL) that do not produce any effect in normal platelets suggests PT-VWD. In this condition, platelets often aggregate spontaneously in vitro upon stirring (Othman and Emsley 2014; Federici 2009). Of note, these abnormalities of in vitro platelet aggregation are observed also in type 2B von Willebrand disease (2B-VWD), which is clinically indistinguishable from PT-VWD. For differentiating these two conditions, we have to consider that in PT-VWD the abnormal platelet response to ristocetin derives from a defect of GPIbα that increases its affinity for VWF, while in 2B-VWD it is the consequence of mutations in VWF that increase the affinity of this molecule for GPIbα. Thus, plasma of subjects with 2B-VWD increases the response of normal platelets to ristocetin, while platelets of subjects with PT-VWD aggregate in response to low ristocetin concentration also when resuspended in normal plasma. Flow cytometry instead of platelet aggregation can be used to differentiate these two conditions by mixing tests (Giannini et al. 2010).

As discussed, immunomorphologic analysis for the MYH9 protein on blood slides is a powerful tool for diagnosing *MYH9*-RD, with sensitivity and specificity near to 100 % (Savoia et al. 2010).

Finally, flow cytometry for platelet surface glycoproteins is useful to confirm the diagnostic suspicion of biallelic BSS aroused from the study of platelet aggregation, as well as to raise the suspicion of monoallelic BSS or *ITGA2B*/*ITGB3*-RT. A reduction by about 50 % of the GPIb/IX/V complex in a subject with mild macrothrombocytopenia suggests a diagnosis of monoallelic BSS, while a reduced expression of the $\alpha_{IIb}\beta_3$ complex is compatible with *ITGA2B*/*ITGB3*-RT (Gresele et al. 2009).

New Diagnostic Approaches for Inherited Thrombocytopenias

The rapid advances in genetic techniques make currently feasible the targeted analysis of many different genes or even of the whole exome at once. Thus, it is now possible to search for mutations in all the genes whose mutations are

Table 4 Tentative classification of inherited thrombocytopenias based on platelet size. Most of inherited thrombocytopenias are classified according to the findings of Noris et al. (2014a)

ITs with giant platelets (mean platelet diameter >4 μm, more than 50 % of platelets larger than 4 μm)	*MYH9*-RD Biallelic BSS *PRKACG*-RT STSL
ITs with large platelets (mean platelet diameter >3.2 μm, more than 20 % of platelets larger than 4 μm)	*TUBB1*-RT GPS *FLNA*-RT *GFI1b*-RT Monoallelic BSS *ITGA2B/ITGB3*-RT *ACTN1*-RT *GATA1*-RD *SLFN14*-RT
ITs with normal/slightly increased platelet size (mean platelet diameter >2.6 μm, more than 5 % of platelets larger than 4 μm)	FDP-AML TCPT/JBS *FLI1*-RT *ANKRD26*-RT RUSAT *ETV6*-RT
ITs with normal/reduced platelet size (mean platelet diameter <2.6 μm, less than 5 % of platelets larger than 4 μm)	CAMT *CYCS*-RT WAS XLT TAR *THPO*-RT *FYB*-RT

For the forms discovered after publication of this study, data from literature have been used. For abbreviations of different disorders, see Table 1

known to result in ITs as a single-step diagnostic procedure instead of using a diagnostic algorithm to identify and prioritize one or a few genes to be sequenced. The single-step diagnostic approach might seem more convenient in terms of simplicity and, given the decreasing cost of massive parallel sequencing, even in terms of affordability. However, massive sequencing always finds a number of changes in a number of genes in each patient, and discriminating between nonpathogenic variants and variants that are causative of ITs may be a major problem. Thus, the best diagnostic approach to ITs is still a matter of investigation, and the skills available locally can influence the choice whether to use the multi- or the single-step methodology.

Another important question is whether the identification of the causative mutations is required in all cases. In fact, the number of known ITs and that of involved genes are continuously increasing, and, as discussed above, identifying the specific defect of each patient entails a considerable use of resources. In general, making a definite diagnosis is due whenever this translates into an advantage for the patient because this information assists physicians in defining prognosis and choosing the best treatment or follow-up regimen. On this basis, it is mandatory to make a definite, molecular diagnosis in patients with FDP/AML, *ANKRD26*-RT, and *ETV6*-RT because of their risk of developing hematological malignancies, in subjects with CAMT because of their constant evolution into bone marrow aplasia, in WAS/XLT because of the efficacy of specific treatments (see below), and in *MYH9*-RD because of the risk of developing kidney failure. Moreover, the identification of the causative mutation in *MYH9*-RD is important for defining the risk of non-congenital manifestations based on the well-established genotype–phenotype correlations (Pecci et al. 2014a; Verver et al. 2016). Finally, it has been shown that the THPO mimetic eltrombopag increases platelet count in this condition. Since FDP/AML, *ANKRD26*-RT, *ETV6*-RT, CAMT, and WAS are among the few ITs without platelet macrocytosis, it is recommended to diagnose at the molecular level subjects with an IT with normal or nearly normal platelet size. Moreover, it is recommended that patients with inherited macrothrombocytopenias receive the screening immunofluorescence test for *MYH9*-RD and, in case of positivity, undergo mutation screening in *MYH9*. The need for a molecular diagnosis is less stringent for the other forms of IT, although the identification of the causative mutations enables prenatal diagnosis and makes genetic consultation more effective.

Therapy

A comprehensive management of patients with ITs aims not only to prevent bleedings and stop hemorrhages once they occurred but also to take care of the other congenital and acquired defects possibly associated with thrombocytopenia.

General Measures for Preventing Bleeding

Patients must be informed that many drugs, as aspirin and other nonsteroidal anti-inflammatory drugs, some antidepressants, antibiotics, and anesthetics, impair platelet function and therefore increase the risk of bleeding. These medications should be administered only after a careful evaluation of the risks/benefits balance (George and Shattil 1991). Subjects with the most severe forms of IT should avoid activities at high risk of trauma, such as contact sports. Another important measure is to advise patients to perform accurate oral hygiene and to make regular dental visits to prevent future invasive dental procedures. Administration of oral contraceptives is usually effective in preventing or controlling menorrhagia.

It is important to emphasize that even patients with ITs are at risk of developing thrombotic events (Girolami et al. 2013). The decision to use antithrombotic prophylaxis must

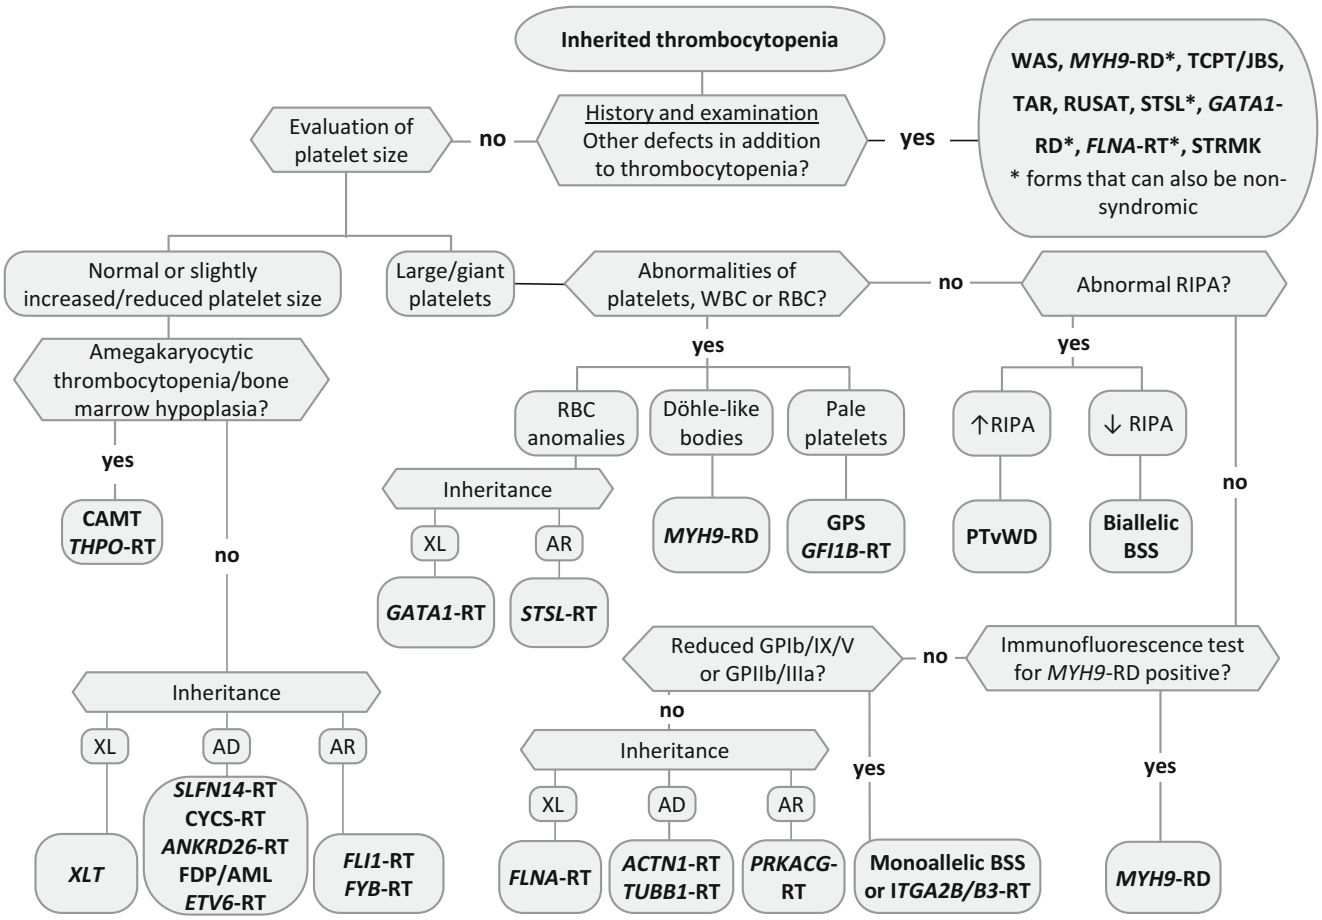

Fig. 5 Diagnostic algorithm for inherited thrombocytopenias. History and examination are used for diagnosis of patients with syndromic forms, whereas morphological evaluation of blood films and three laboratory tests guides the diagnostic process in non-syndromic forms. Definitive confirmation of the diagnostic hypotheses requires sequencing of candidate genes. For abbreviations of disorders, see Table 1; *RIPA* ristocetin induced platelet aggregation

be taken after a careful evaluation of the risk/benefit ratio based on the overall clinical picture of each patient.

Preparation to Hemostatic Challenges

Platelet count and bleeding history are the elements to be considered to decide how to prepare patients to hemostatic challenges. Subjects with more than 100×10^9 platelets/L do not need any precautionary treatment if their platelet function is not severely defective, while those with less than 50×10^9 platelets/L need prophylactic treatment. Bleeding history and typology of the hemostatic challenge direct the management of patients with $50–100 \times 10^9$ platelets/L (Tosetto et al. 2009). For instance, subjects with no or very mild previous bleeding events can undergo surgery or delivery without any support, while those with previous hemorrhages require prophylactic treatments. Prophylactic treatments should be considered also in all patients who need major surgeries, especially at critical sites as eye or nervous system.

Platelet Transfusions

Prophylactic platelet transfusions are effective in reducing the risk of bleeding, even if their administration does not ensure that the patient will not bleed. Platelets from HLA-matched donors should be used whenever possible to prevent or overcome alloimmunization and refractoriness to subsequent platelet infusions. Subjects with biallelic BSS who completely lack the platelet GPIb/IX/V complex can develop isoimmunization against the components of this complex. In this case, immunosuppression and/or plasmapheresis to clear antibodies can restore the efficacy of platelet transfusion (Liumbruno et al. 2009).

Antifibrinolytic Drugs

Successful systemic administration of antifibrinolytic agents, such as tranexamic or epsilon-aminocaproic acid, has been

reported for covering minor surgery in a few patients with ITs (Althaus and Greinacher 2009; Pecci et al. 2014b). However, no clinical study on the effectiveness of these drugs in ITs has been performed, and this treatment should be considered as empirical. Antifibrinolytics are contraindicated in hematuria given the risk of clots formation in the renal collecting system (Kumar et al. 2013).

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP) is an approved treatment for mild hemophilia A and type 1 von Willebrand disease due to its ability to stimulate the release of VWF from endothelial cells. DDAVP also enhances the procoagulant activity of platelets (Colucci et al. 2014), and this observation could provide a possible explanation for the successful use of the drug for covering minor surgery in some patients with mild ITs (Tosetto et al. 2009; Sehbai et al. 2005). However, clinical studies on the efficacy of DDAVP in these conditions are still lacking. Though rarely, DDAVP is associated to important side effects, such as hypotension, tachycardia, fluid retention, and hyponatremia, and for this reason it should be used with caution in patients with ischemic or congestive heart disease or heart failure, as well as in infants.

Activated Recombinant Factor VIIa

Activated recombinant Factor VIIa (rFVIIa) promotes thrombin generation by both tissue factor-dependent and tissue factor-independent mechanisms and is currently approved for treating patients with Glanzmann thrombasthenia (Poon 2007). In the setting of ITs, it has been successfully used for preparing to invasive procedures a few subjects with biallelic BSS (Tefre et al. 2009; Hacihanefioglu et al. 2007) and one girl with TAR (Coppola et al. 2007). Thromboembolic events are potentially severe side effects of rFVIIa.

Short-Term Eltrombopag

The thrombopoietin mimetic eltrombopag is licensed for therapy of chronic ITP and chronic hepatitis C, as well as treatment of severe aplastic anemia refractory to immunosuppressive drugs. A short-term course of eltrombopag has proved effective in transiently increasing platelet count in patients with *MYH9*-RD and less than 50×10^9 platelets/L (Pecci et al. 2010). Eltrombopag increased platelet concentration to values around or above 100×10^9/L in 8 of 12 patients, with minor increases in the remaining subjects. Importantly, eight of the ten patients with spontaneous bleeding at baseline achieved complete remission of hemorrhages. Based on these findings, short-term eltrombopag administration has been successfully used for preparing to surgery one adult and one pediatric patient with *MYH9*-RD (Pecci et al. 2012; Favier et al. 2013). It is presently unknown whether short-term eltrombopag is effective for preparing to surgery patients with ITs other than *MYH9*-RD.

Stopping Hemorrhages

Local measures are first-line treatment for mild or moderate mucocutaneous bleedings. Endoscopic electrocautery and nasal packing are recommended for stopping epistaxis. Compression and application of gelatin sponges or gauzes soaked in tranexamic acid can be effective in controlling bleeding from superficial wounds. Suturing can stop hemorrhages from accidental or surgical wounds (for instance, bleeding after tooth extraction). Mouthwash with tranexamic acid may be useful for gingival bleeding.

In case local measures are not possible or do not work, platelet transfusion (see above) is the measure to be used first. In case of refractoriness to platelet transfusions, rFVIIa has been proved effective in a small number of patients with BSS (Tefre et al. 2009; Hacihanefioglu et al. 2007). There is no experience with the use of this drug in other ITs. The role of antifibrinolytic drugs and DDAVP for stopping hemorrhages remains to be ascertained.

Treatments to Stably Increase Platelet Count

Allogeneic hematopoietic stem cell transplantation (HSCT) and gene therapy can potentially cure ITs, while splenectomy and long-term administration of TPO mimetics have the potential to stably increase platelet count in some disorders.

Allogeneic Hematopoietic Stem Cell Transplantation

The median life expectancy of patients with WAS is about 15 years, and all CAMT patients die for bone marrow aplasia during infancy. HSCT is the treatment of choice for both WAS and CAMT as it can cure all the aspects of these severe disorders.

Concerning WAS, 5-year overall survival of 122 patients who underwent HSCT after the year 2000 was 100 % for children transplanted from HLA-matched siblings and 90 % for those transplanted from HLA-matched unrelated or mismatched related donors (Moratto et al. 2011). Patients transplanted from unrelated donor after the age of 5 years had the worse outcome, with a 5-year survival around 75 %. Thus, even if early transplantation is desirable, treatment from unrelated donors should be offered also to older patients.

HSTC should be considered also for patients with severe, syndromic forms of XLT, in that a retrospective study of 24 patients revealed that 20 of them were alive without

serious posttransplantation events after a median follow-up of 50 months. However, four deaths for infections were reported (Oshima et al. 2015).

For what it concerns CAMT, near 60 children treated by HSCT have been reported in the literature. The overall long-term survival rate was 80 %, with 72 % of patients having normal donor hematopoiesis and good quality of life (Ballmaier and Germeshausen 2011). HSCT-related mortality was 8 % in children transplanted from related donors and 23 % in those transplanted from unrelated donors (Woods et al. 2014).

HSCT may be considered also in patients with severe forms of biallelic BSS with spontaneous, life-threatening hemorrhages, especially when they developed refractoriness to platelet transfusions. Two children and one adult received HSCT from HLA-identical siblings (Locatelli et al. 2003; Rieger et al. 2006), and all of them were cured.

Gene Therapy

Transplantation of autologous, gene-corrected hematopoietic stem cells is in principle an effective alternative to HSCT in patients with severe ITs. Gene therapy has been utilized so far only in patients with WAS. The first clinical trial used retroviral-transduced hematopoietic stem cell and obtained partial or complete resolution of immunodeficiency, autoimmunity, and bleeding diathesis. However, it was associated with a very high risk of insertional mutagenesis, with activation of several proto-oncogenes leading to leukemia in seven of the nine evaluable patients (Braun et al. 2014). Much better results have been obtained with lentiviral-based gene therapy. A total of 11 patients were treated at three European centers: ten of them obtained stable engraftment with improvement in platelet count and complete reconstitution of the immune function, while one patient died of infectious disease. Importantly, no evidence of vector-related toxicity was observed (Aiuti et al. 2013; Hacein-Bey Abina et al. 2015; Pala et al. 2015).

Splenectomy

Splenectomy does not induce any stable benefit in ITs, with the notable exception of WAS/XLT.

Analysis of the outcome of spleen removal in 41 XLT patients revealed that the cumulative incidence rate of serious bleedings was reduced, but there was a significantly higher incidence of severe infectious events (two fatal) (Albert et al. 2010). Overall survival in splenectomized patients was not significantly different from that of subjects not undergoing splenectomy. Thus, the risk–benefit balance of splenectomy should be weighed in each patient, taking care to administer anti-infective prophylaxis to subjects receiving this treatment.

In WAS, splenectomy should be avoided in patients candidate to HSCT, as it increases the risk of severe infection after transplantation (Ozsahin et al. 2008). The risk–benefit balance seems to favor splenectomy in WAS patients who cannot be transplanted. Thirty-nine patients with no suitable bone marrow donors underwent splenectomy, with most of them receiving prophylactic antibiotics to minimize the risk of sepsis (Mullen et al. 1993). Almost all patients achieved normal platelet counts, and the rate of serious bleeding was reduced nearly sevenfold. However, five patients died of sepsis. Median survival in the non-transplanted splenectomy group was 25 years, compared with less than 5 years in non-transplanted and non-splenectomized patients.

Long-Term Eltrombopag

Long-term eltrombopag administration for achieving stable increase of platelet count has been tested in a series of eight patients with WAS/XLT and severe thrombocytopenia (Gerrits et al. 2015). Five subjects responded (achievement of at least one on-treatment platelet count higher than 50×10^9/L). More importantly, all the five responders obtained improvement of baseline spontaneous bleeding. No major adverse events have been recorded. However, the safety profile of prolonged administration of eltrombopag in WAS/XLT requires further studies, and chronic administration of this drug cannot yet be recommended.

Treatments for the Other Defects or Illnesses that Add to Thrombocytopenia

Patients with FPD/AML, *ANKRD26*-RT, and *ETV6*-RT are at risk of developing acute leukemias and myelodysplastic syndromes. When this happens, HSCT is an important part of the therapeutic armamentarium. In case a related donor is available, it is important to exclude that he too is affected by the same IT, because transplanting hematopoietic cells of affected relatives exposes patients to the risk of developing again a new hematological malignancy (Buijs et al. 2001).

Concerning the extra-hematological defects of *MYH9*-RD, four patients with renal involvement had their proteinuria stably reduced by angiotensin receptor blockers and/or angiotensin-converting enzyme inhibitors (Pecci et al. 2008). The possible, favorable effect of this treatment was confirmed by more recent observations (Sekine et al. 2010; Oh et al. 2015). However, it is premature to conclude that these drugs prevent or delays deterioration of renal function. Dialysis or kidney transplantation is required in individuals with end-stage renal disease. Cochlear implantation is effective in restoring hearing capacity when deafness severely affects the quality of life: restoration of an excellent hearing function was obtained by eight of ten subjects receiving this treatment, while one patient had a slightly worse performance that could be explained by the very long duration of severe deafness. Only one patient did not significantly

improve (Pecci et al. 2014a, b). Patients with *MYH9*-RD should be monitored for the possible development of cataract, and the standard surgery should be carried out when indicated.

In patients with ITs associated with congenital limb deformities, reconstructive orthopedic surgery allows children to return to most activities of daily living (Al Kaissi et al. 2015).

Take Home Message

- Inherited thrombocytopenias are more frequent than previously thought. Since bleeding tendency is often mild or even absent, thrombocytopenia may be identified incidentally in childhood or adult life, and affected patients are at risk of misdiagnosis with ITP.
- Medical history (to identify other affected family members), physical examination (to recognize the additional defects of syndromic forms), and blood film examination (to detect the characteristic abnormalities of blood cell morphology) are the most important tools to suspect the genetic origin of thrombocytopenia.
- Making a definite diagnosis is important to recognize the forms of inherited thrombocytopenias that predispose to the acquisition of additional diseases, like hematological malignancies and renal failure.
- Specific treatments for some forms of syndromic and non-syndromic inherited thrombocytopenias have been identified.

Immune Thrombocytopenia: Where Are We Now?

Nichola Cooper and James Bussel

Abstract

This review focuses on megakaryocyte development, regulation of platelet production, and the role of thrombopoietin (TPO) in relation to thrombocytopenia and correction of thrombocytopenia in immune thrombocytopenia (ITP). It appears that molecules (antibodies) and cells (T cells) that attack platelets are also directed against megakaryocytes and, thus, ITP is characterized by not only by accelerated platelet destruction but also by inhibition of platelet production. There is also a relative TPO deficiency, meaning that correction can often be achieved by administration of TPO receptor agonists. Current understanding of the pathology of ITP is extremely complicated. It seems that T helper cells (CD4) are required, even to make antibodies to platelets. However, initial studies of plasma infusion from ITP patients into normal subjects suggested that, in 10 of 26 cases, infusion of such plasma does not result in thrombocytopenia. It is possible that, in some of these outliers, all the antiplatelet antibody is on the platelets themselves and there is no free antibody in the plasma. However, clinical experience indicates that cytotoxic and other T cells are heavily involved and that there are almost no functions (receptors, cell to cell interactions, cytokine releases) of T cells that have not been demonstrated to be abnormal in ITP. Several studies with the beta T cell receptor, demonstrating important olioclonal and clonal abnormalities, have reinforced this.

Treatment of ITP remains very complicated and uncertain after a course of steroids (even there, the choice of dexamethasone versus prednisone has not been settled). Rituximab-based treatment and use of TPO receptor agonists have strong studies favoring their use, but other studies show limited likelihood of a good response in patients. It is easier to increase the platelet count in the short term than to achieve the "Holy Grail" of a cure.

Introduction

Definition of ITP

ITP initially stood for idiopathic thrombocytopenic purpura. After being called immune thrombocytopenic purpura as a result of the studies by Shulman et al. (1965), ITP now stands for immune thrombocytopenia. The purpura was dropped when it was recognized that some thrombocytopenic patients did not have manifestations of bleeding. Other abbreviations included AITP (autoimmune thrombocytopenic purpura).

The current definition (unlike the initial one) excludes non-immune thrombocytopenias such as the inherited thrombocytopenias. Although the concept of autoimmune

(autoantibody-mediated) thrombocytopenia is very clear and unanimously agreed upon, ITP remains a diagnosis of exclusion because of the lack of utility of platelet antibody testing. This is complicated because, for example, the only way to know that an apparent case of ITP is primary and not, for example, secondary to hepatitis C, CMV, *H. Pylori*, CVID, or CLL is to run tests to exclude these possibilities. However, such extensive testing is far from the standard of care. Which epidemiologic, clinical, or laboratory features to use as the basis for performing certain additional tests has never been thoroughly explored or validated.

The only way to confirm ITP positively is by a good response to ITP-specific therapy. The classic example is a dramatic but transient overnight platelet increase in response to intravenous gamma globulin (IVIG), but even a rapid and substantial response to steroids is very suggestive of ITP. These responses, if present, are believed to be useful if there is a response but do not distinguish primary from secondary ITP.

At present, there is clear consensus that there is little benefit of anti-platelet antibody testing to include or exclude the diagnosis of ITP. In the future, if preliminary findings are confirmed and the consensus shifts, then distinction of types of ITP between those with predominant anti-platelet antibodies directed against GPIb-IX-V and those with antibodies primarily directed against $\alpha_{IIb}\beta_3$ may become clinically important; or those with antibodies compared with those lacking antibodies.

Platelet Production and Regulation of Thrombopoietin Levels

Megakaryocyte development is driven by many different transcription factors (as shown in Fig. 1), a process further complicated by migration of megakaryocyte progenitors, which start in the stem cell niche and must get to the vascular niche. Migration is dependent on SDF1α and relies on collagen, von Willebrand factor, and fibrinogen interacting with the platelet and megakaryocyte counter-receptors GPIb-IX-V and $\alpha_{IIb}\beta_3$. Once the pro-platelets are extended into the blood vessel, shear forces from blood flow cause them to fragment off (see Italiano (2017) for more details). Even if they are still platelet aggregates, they become single platelets after they arrive at the pulmonary capillaries.

Traditionally, antibodies to platelets have been thought to be directed to $\alpha_{IIb}\beta_3$ and GPIb-IX-V. However, an interesting feature is that the Ashwell–Morell receptor in hepatocytes might play a role in platelet regulation. Antibodies to GPIb-IX-V can cause externalization of neuraminidase, which then desialylates GPIb on platelets. These desialylated platelets, like aged platelets, are cleared in the liver by interaction with the Ashwell–Morell receptor. Data from Karen Hoffmeister's group suggests that, via a receptor that is similar to that of interleukin(IL)-6, these platelets then stimulate production of thrombopoietin (TPO) via the JAK2–STAT3 signaling cascade (Grozovsky et al. 2015). However, whether this happens rarely, all the time, or somewhere in between remains to be clarified (Fig. 2).

There is no correlation between platelet counts and TPO levels. Instead, the TPO levels seem to depend on the numbers of megakaryocytes in the bone marrow (Fig. 3). This is similar to the regulation of granulocyte colony-stimulating factor but not erythropoietin levels (Corbacioglu et al. 2000). Thrombocytopenic patients with aplastic anemia have very high TPO levels, whereas patients with ITP and very low platelet counts have only slightly elevated or normal circulating TPO (Kuter et al. 1994). This is the so-called Kuter hypothesis. What is less clear are the mechanisms of regulation, up or down, of TPO

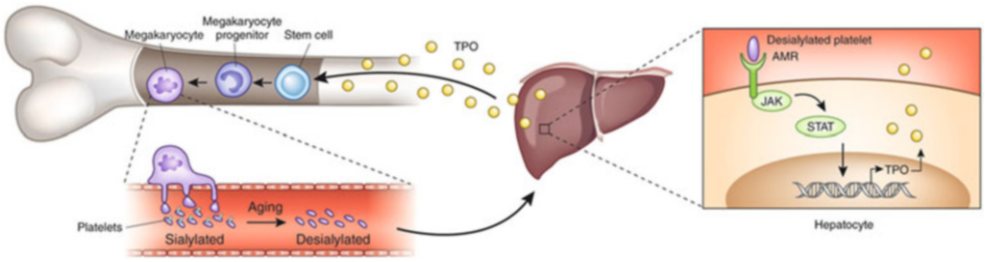

Fig. 2 Old and desialated platelets are recognized by the Ashwell–Morell receptors (*AMR*) in hepatocytes, causing thrombopoietin production. Physiology of the Ashwell–Morell receptor and its role in TPO production via the JAK-STAT pathway. Taken from Kile BT (2015) Nat Med 21:11–12

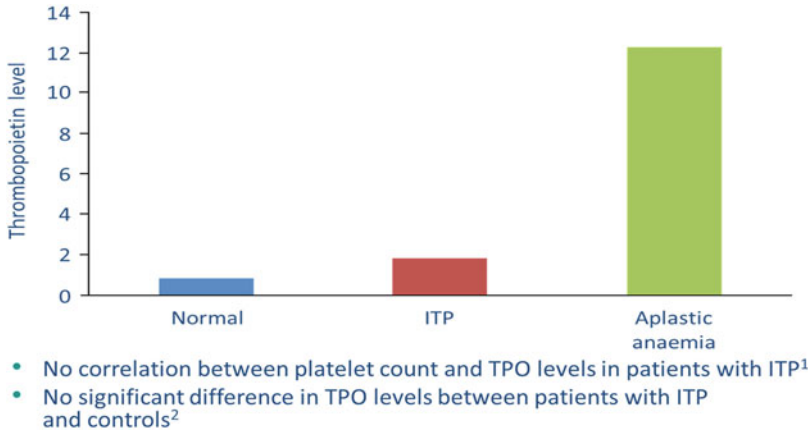

Fig. 3 Kuter hypothesis of TPO regulation. The role of platelet count and marrow megakaryocyte number in determining thrombopoietin level: low platelet count in ITP (in which there are ample numbers of megakaryocytes in the marrow) is consistent with TPO binding to TPO receptors and thus a reduction in the level of TPO to normal or near normal. Adapted from Kosugi S et al (2003) Br J Haematol 93:704–706; Aledort LM et al (2004) Am J Hematol 76:205–213

production. Current studies suggest that the role of inflammation is mediated primarily by IL-6 in the liver.

Autoimmunity in ITP

How do we know that ITP is an autoimmune disease? The classic studies of Harrington (Fig. 4a) showed that infusion of ITP patient's plasma into normal controls mostly (but not always) causes thrombocytopenia in the recipients (Harrington et al. 1951). Follow-up studies have shown that this effect appears to be antibody mediated. Bob McMillan's group and Mei Chang in Diane Nugent's group (Fig. 4b) showed that plasma from ITP patients inhibited growth and development of megakaryocytes to variable extents; the plasma from different patients had different degrees of effect in both studies (Chang et al. 2003; McMillan et al. 2004). It thus appears clear that antiplatelet antibodies react not only with platelets but also with megakaryocytes. Whether this is important to the pathogenesis of ITP in all, most, or some cases is not clear.

What do we know about T cells in ITP? There have been a multitude of studies demonstrating a multitude of abnormalities of T cells (Semple et al. 1991, 1996). One

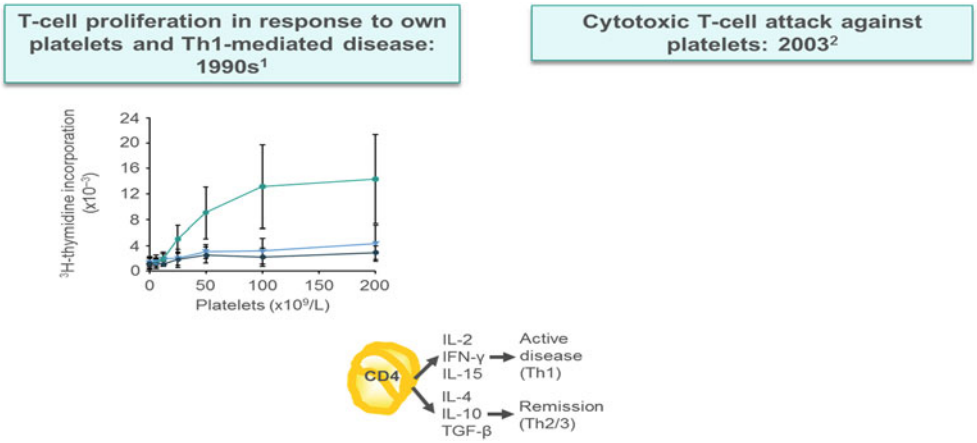

Fig. 5 Role of T-cell-mediated platelet destruction in the immune pathology in ITP. (**a**) T cell proliferation in response to a patient's own platelets (Semple et al. 1991). (**b**) Cytotoxic T cells play a role in destruction of platelets in active ITP (Olsson et al. 2003) (CD4 skewing to Th1 should be figure C, and comes from Semple JW and Provan D (2012) Curr Opin Hematol 19:357–362)

set involves the abnormalities of T cells as complex immune regulators of the immune response. The most sophisticated involve analyses of newly discovered cytokines or of cell populations such as follicular B cells in the spleen and their role in anti-platelet antibody regulation and/or production. Other studies have similar levels of sophistication and are very complicated.

Perhaps the clearest and most uniform findings have involved T regulatory cells (Tregs). Evidence for their deficiency in both number and function has been confirmed in a number of studies (Bao et al. 2010). Similarly, their restoration in response to therapy has been invoked not only with TPO agents but also using several different therapies (e.g., rituximab) (Stasi et al. 2007). Tregs can suppress the interaction of dendritic cells with T helper cells and prevent T helper cells from interacting with B cells to make antiplatelet antibodies by reducing their proliferation.

A different case is investigation of cytotoxic T cells to determine their role in direct destruction of platelets and megakaryocytes. A classic study of cytotoxic T cells was carried out by Wadenvik's group. In a small number of patients with ITP, an in vitro natural killer-type assay showed that there was cytotoxicity to platelets, with lysis. Furthermore, the study pinpointed the mechanism (e.g., granzyme levels were increased) and showed that not only was there more lysis in patients with ITP than in controls but also more cytotoxicity with active ITP than for ITP in remission (Fig. 4b) (Olsson et al. 2003). Additional studies of this topic have been very limited.

In the 1990s, there were studies showing T cell proliferation in response to patients' own platelets and studies consistent with an active TH1-mediated disease driven by IL-2, interferon γ, and perhaps even IL-15 (Fig. 4a). To date, hundreds of studies have been performed demonstrating a confusing variety of abnormalities of T cells and their cytokines (Fig. 5).

The role of CD8 cells seems more complicated than just to attack platelets and megakaryocytes in patients with ITP. It appears that CD8 cells are necessary for megakaryocyte proliferation and, when CD8-positive T cells are co-cultured with megakaryocyte progenitors, more megakaryocytes develop, there is less apotosis, and fewer platelets, which is somewhat surprising (Li et al. 2007; Fig. 6). Similarly, it appears that dexamethasone can increase the number of CD8-positive T cells and increase Tregs, which is a surprising finding given the expected immunosuppressive effect of steroids.

Some of the complexities of the pathogenesis of ITP, in addition to those mentioned, include epitope spreading (presentation of new epitopes of the platelet glycoproteins so that there is a broader spectrum of anti-platelet antibodies) in macrophages, which may contribute to chronicity and failure to respond to ITP therapies; the role of anti-platelet antibodies; and the role of these antibodies in impairing megakaryocyte production and maturation and in reducing platelet production. In addition, there are many co-stimulatory molecules involved between macrophages as antigen-presenting cells, helper T cells, and B cells including CD40, CD40 ligand (CD154), CD80, and CD28. These and other interactions could help determine whether the disorder is serious or not so serious and whether the patient is likely to get better over time (Cines and Blanchette 2002).

Management of ITP

There are many challenges in managing ITP. Diagnosis can be complicated, although not most of the time. Classic diagnostic practice involves excluding all other causes and having a normal complete blood count, except for thrombocytopenia, and no findings such as hepatosplenomegaly or lymphadenopathy on physical examination. Response to

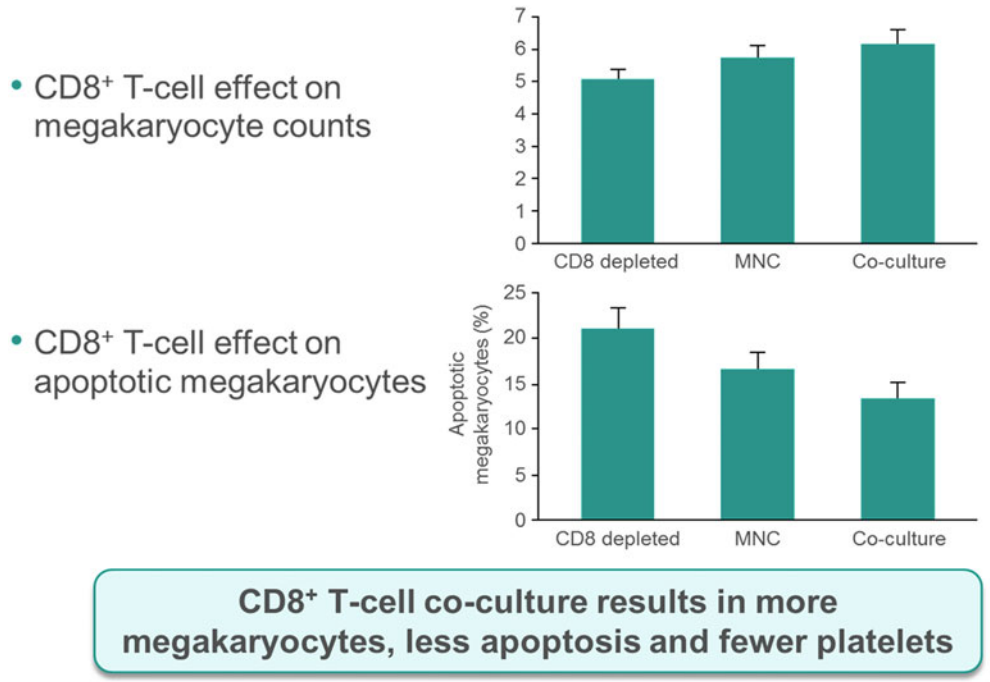

Fig. 6 The role of $CD8^+$ T cells in the bone marrow. Figure taken from Li S et al (2007) Br J Haematol 139:605–611

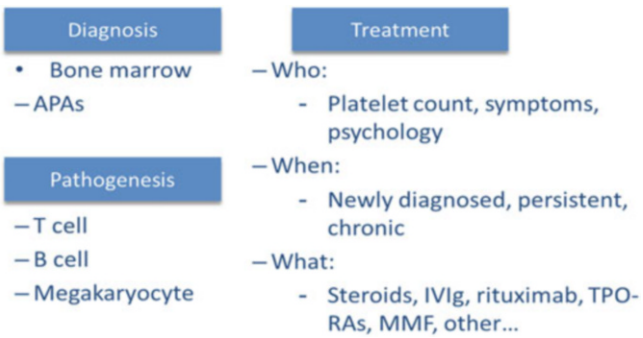

Fig. 7 Management of ITP. Diagnosis, pathogenesis, and treatment of ITP

treatment can also affect the diagnosis; for example, if a patient receives IVIG (or steroids) and the platelets increase dramatically, albeit transiently, then that strongly suggests that this is a case of ITP. It should be noted, however, that such a response (as mentioned in Sect. "Introduction: Definition of ITP") does not differentiate secondary from primary ITP (Fig. 7).

Pathogenesis can be very complicated and treatment decisions involve many different factors. These factors include the platelet count, the degree of symptoms especially bleeding and fatigue, and how the patient feels about treatment in general and a given treatment in particular. The risk of bleeding is an important factor for some patients (e.g., construction workers or athletes), as is travel (e.g., consideration of what to do when a patient does not have their usual source of emergency back-up available). Patients may be treated differently depending on the duration of their disease (newly diagnosed, persistent, or chronic) and can be treated with a wide variety of agents, as listed in the 2010 consensus document (Provan et al. 2010).

Decisions about treatment are not clearly defined. For adults, most are either asymptomatic or have minor bruising and perhaps a few scattered petechiae, despite relatively low platelet counts. Treatment is mostly given for platelet counts below 30,000/μL. There is increased mortality in elderly patients with persistently low counts (Cohen et al. 2000). Certain studies in the past have demonstrated that morbidity and mortality can derive from complications of immunosuppressive treatment given at too high a dose for too long, especially too much prednisone for months or years (Portielje et al. 2001).

The primary goal of treatment is to avoid intracranial hemorrhage, although improving health-related quality of life (HRQoL) is now recognized as very important and is more relevant for many patients. Data from Cortellazzo et al. (1991), summarized by Cohen et al. (2000), show that the rate of fatal hemorrhage per year for patients aged 40–60 years is 0.012 per year (i.e., just over 1 in 1000); for those aged over 60 years, the mortality is 0.13 per patient year (13 per 1000), which is thought to be driven to a large extent by comorbidities and other medications (Cortelazzo et al. 1991). In addition, patients with ITP have an increased risk of venous thromboembolism. In a long-term study of romiplostim, it was demonstrated that strokes

Clinical situation	Therapy option
First line (initial treatment for newly diagnosed ITP)	Anti-D Corticosteroids: Dexamethasone, methylprednisolone, prednis(ol)one IVIg
Second line	Azathioprine Cyclosporin A Cyclophosphamide Danazol Dapsone MMF Rituximab Splenectomy TPO-RAs Vinca alkaloids
Treatment for patients failing first- and second-line therapies	**Category A: Treatment options with sufficient data** TPO-RAs **Category B: Treatment options with minimal data and considered to have potential for considerable toxicity** Campath-1H Combination of first- and second-line therapies Combination chemotherapy HSCT

Fig. 8 First and second line treatments in the consensus document. Treatments listed alphabetically (also by category for third line) divided by first, second, and third line from the 2010 consensus document (Provan et al. 2010)

occurred particularly in the over 70 year olds (Kuter et al. 2013).

For children, and possibly younger adults, treatment is required if the count is over 30,000/μL only in cases where there is bleeding, the patient requires surgery, the patient is on anticoagulation or antiplatelet agents, and possibly if other factors such fatigue and access to care are involved. In the 10,000–30,000/μL range, the issue is whether treatment is needed and, if so, what to treat. Factors to take into consideration are age, comorbidities, and past treatment, including how well it worked or did not work. For guidelines or information as of early June 2016, there is the international consensus report that was published in 2010 (Provan et al. 2010) and the second version of the American Society of Hematology (ASH) evidenced-based guidelines for ITP (Neunert et al. 2011). Both the consensus report and the ASH guidelines are under revision and new versions should appear within the next year (Fig. 8).

The consensus report lists front line treatments, which everybody agrees with although there are differences about which treatments to use and when. The most recent study showed that the platelet count went up quicker with dexamethasone than with prednisone, but long-term outcome (the current Holy Grail of ITP treatment) was not significantly different between dexamethasone and prednisone treatments (Wei et al. 2016). The choice of second line treatments is more complicated because there is not much evidence other than some randomized trials of thrombopoeitic agents compared with placebo and a very large amount of open-label, single-arm data for splenectomy. A "How I Treat" article in 2012 focused on the selection of second line agents (Ghanima et al. 2012). For other agents, the issues are their efficacy and the side effects. For third line treatment, the only option that has sufficient data and category A evidence is use of thrombopoietic agents (Bussel et al. 2006, 2007; Saleh et al. 2013; Kuter et al. 2013).

For second line treatments, common morbidity for persistent ITP is caused by infection or other steroid-related complications and the most prominent steroid-sparing agents are rituximab; immunosuppression with danazol, azathioprine, or mycophenolate mofetil; TPO receptor agonists (TPO-RAs; romiplostim or eltrombopag); and splenectomy.

Looking at rituximab, the only study that assessed long-term outcome looked at responders 1 year after the initial rituximab infusion (Patel et al. 2012) and showed that the long-term outcome (more than 3 years) was only a 21 % persistent complete response. All other responding patients (approximately another 20–30 %), whether the response was partial or complete, relapse and require additional treatment (Patel et al. 2012). This number (21 %) could represent the percentage of people who would have improved over time anyway.

As this result became more evident, efforts were made to supplement rituximab treatment, the choice being high-dose dexamethasone. The initial concept was that rituximab would deplete intravascular B cells and plasma cells would die off. However, plasma cells lived longer than had hitherto been believed to be the case and, therefore, rituximab alone did not result in full depletion of antibody-making cells . This was consistent with the lack of development of hypogammaglobulinemia with rituximab alone (Cooper et al. 2004). Borrowing from experience with myeloma treatment, it was thought that dexamethasone would affect the plasma cells and rituximab would affect the B cells and, thus, there would be a better response to combined therapy. Two initial studies explored the addition of one 4-day cycle of dexamethasone to the standard dose of rituximab, but both compared this combination to one cycle of dexamethasone alone rather than to rituximab alone (Zaja et al. 2010; Gudbrandsdottir et al. 2013). The results were good, but only newly diagnosed patients (the easiest to treat patients) were entered in the studies and long-term follow up is not

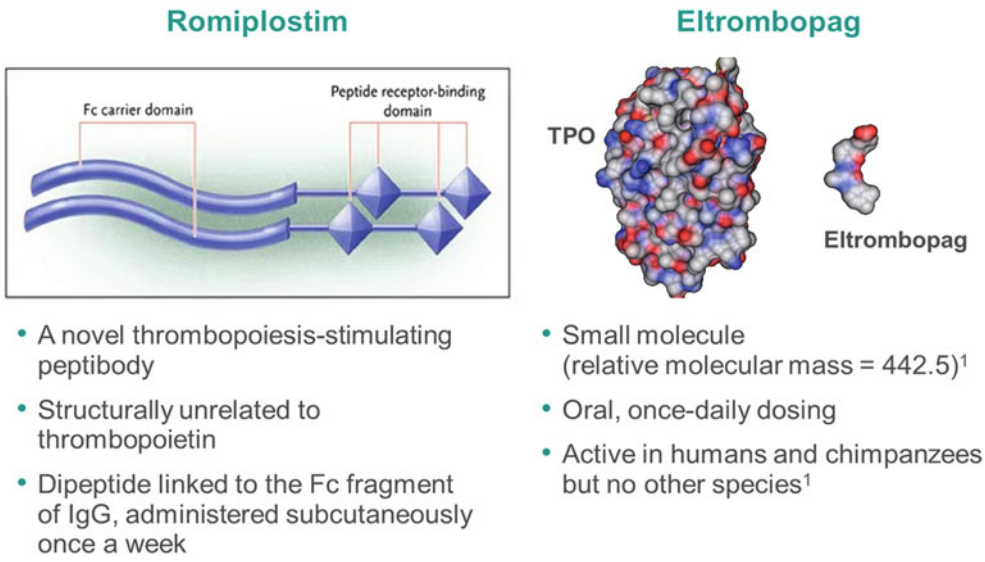

Fig. 9 Licensed TPO receptor agonists. The properties and physical attributes of the two licensed TPO agents, romiplostim and eltrombopag

available. More recent results using three cycles of dexamethasone and standard treatment of four doses of rituximab demonstrate that the only subset of patients with a very good cure rate(>70 %) are women with duration of their ITP of less than 1 year. This finding in women with ITP was supported by an identical result in adolescent girls (Chapin et al. 2016). It is, however, important to realize that, even in the groups that eventually relapse, as many as 50 % are in continuing response more than 2 years after the initial rituximab treatment. This combination provides good results at a high short-term (1–3 year) rate but the eventual relapse lessens the positive impact of this treatment scheme.

The next consideration was to use mycophenolate mofetil (MMF) as a second line treatment option. There are at least 11 ITP studies of MMF treatment, none of which are very large in size or randomized (Taylor et al. 2015). Overall, the response rates are about 50 % and MMF is well tolerated. Whether MMF is better than azathioprine is not clear. A newly issued "black box warning" (package insert for the USA) is that MMF can alter the levels of oral contraceptive hormones and therefore result in their failing to prevent pregnancy. MMF is best used in either mild to moderate disease or as a sequel to dexamethasone–rituximab to enhance cure rates (Chapin et al. 2016).

Splenectomy has become a very infrequently used treatment (Boyle et al. 2013). Over the period 1991–2009, in a US population, the rate of splenectomy fell from 30 to <10 % and is probably even lower today. Note that splenectomy offers the greatest chance for clinical remission and is potentially the most cost-effective treatment. Taking all comers with splenectomy, approximately 60 % of patients have durable remissions if the operation is not performed too late in the course of the disease (Kojouri et al. 2004). Currently, many patients refuse splenectomy if it is only going to work 60 % of the time. There are perioperative complications including infection, bleeding, and thrombosis (post-op anticoagulation treatment may be appropriate) and the long-term complications of infection with overwhelming post-splenectomy sepsis and thrombotic complications (Thomsen et al. 2010). A recent study presented at the European Hematology Association (EHA) congress in June 2016 by the group of Waleed Ghanima suggested that there was no increase in myocardial infarctions or pulmonary hypertension in patients with ITP who underwent splenectomy. However, there was a significant approximately 50 % increase in venous thrombosis and this translated into a significant increase in the incidence of stroke (Rørholt et al. 2016).

Turning to the thrombopoietic agents, we know that TPO drives the pathway from stem cells all the way to megakaryocyte proliferation (Kaushansky 1998). Its role in platelet release from megakaryocytes is uncertain. As discussed above, we do not know what fraction of TPO production is constitutive and how much it can be upregulated (e.g., by binding of desialated platelets to the Ashwell–Morell receptor) (Fig. 9).

Both romiplostim and eltrombopag were developed by screening of compounds. Romiplostim is composed of four small dipeptides attached to each other by disulfide bridges and to an Fc portion of an IgG_1 molecule to increase the half-life by allowing recirculation via FcRn. It is given once a week subcutaneously. In the USA, although not in Europe, it is still not approved for self-administration by the patient at home. Eltrombopag is given daily by mouth. Although there have been recent changes to the US package insert, we believe it should be taken on an empty stomach at least 2 h after eating and without eating for another 2 h afterwards. Furthermore, there should be no divalent cation intake (i.e.,

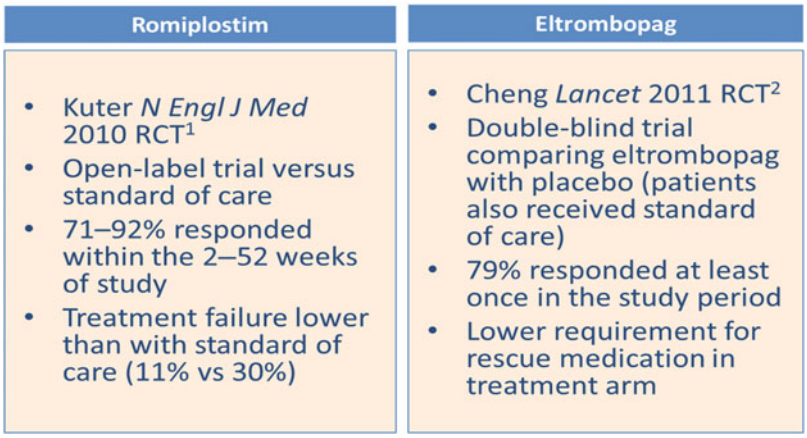

Fig. 10 Responses with TPO receptor agonists in adults (platelets $>50 \times 10^9$/L): Results from two randomized controlled trials (Kuter et al. 2010; Cheng et al. 2011). Description of two of the five large randomized controlled trials with these agents in adults with ITP (there are three large randomized trials in children with ITP)

calcium in milk or other dairy or other supplements for 4 h before and 4 h after). Most people therefore take it at bedtime, do not eat after dinner, and do not have dairy with dinner, but this is not always possible. Both romiplostim and eltrombopag are expected to cross the placenta and thereby affect fetal bone marrow, so their use in pregnancy is strongly discouraged. Both agents have been used at the very end of pregnancy to increase the platelet count in either refractory ITP patients or in those with inherited thrombocytopenias so that the platelet count is good enough for delivery and, hopefully, for epidural anesthesia (personal experience).

Both molecules share similar mechanisms of action although it is thought that they bind at different places, with romiplostim binding at the TPO binding site and eltrombopag potentially binding in the intramembranous portion. The difference in binding could underlie anecdotal findings in patients who respond to one agent but not the other (Khellaf et al. 2013). A theoretical advantage of the lack of eltrombopag binding at the TPO receptor site is that TPO can bind there, creating an additive or even synergistic effect, but this remains theoretical. Eltrombopag is a chelator and is inactive when it has chelated a cation, which is why calcium, magnesium, and iron inactivate it if ingested in proximity to the drug.

Figure 10 compares two randomized controlled trials (Kuter et al. 2010; Cheng et al. 2011). There are also a number of other randomized controlled trials with each agent. Adult ITP patients appear to respond 60–90 % of the time with either treatment and often can either discontinue or reduce the use of rescue treatments (i.e., platelet transfusion, steroids, IVIG, etc.) and/or discontinue or reduce the dose of concomitant medications (e.g., prednisone) after starting the thrombopoietic agent. Patients usually reduce bleeding in proportion to their platelet count increase and, overall, at least some of them have an improvement in their level of energy and/or HRQoL. Some of the latter may experience less bleeding and therefore less fear of bleeding but, in addition, thrombocytopenia has reversible organic effects on energy levels and vitality that have been amply demonstrated in a number of studies (McMillan et al. 2008).

Long-term results from both treatments have been collected and published or presented. The overall thromboembolic event rate was approximately 6 % for both agents over 6–8 years of treatment (Kuter et al. 2013; Saleh et al. 2013). There is still debate over the exact cause of the thromboembolisms. They appear to be a combination of the underlying disease, predisposition of certain individuals who have been "protected" by their thrombocytopenia, and the availability of an increased number of younger platelets. Bone marrow reticulin fibrosis, which raised considerable concern early on, seems to occur infrequently and does not cause any major issues (Ghanima et al. 2014). In addition, in patients who have discontinued treatment, the reticulin fibrosis has regressed in almost all cases (Ghanima et al. 2014). With eltrombopag, it seems that approximately 3 % of patients are unable to take it because of increases in transaminases and/or bilirubin, but most people with increased transaminases who discontinue eltrombopag can successfully resume it (Saleh et al. 2013). If eltrombopag can indeed cause cataracts, it appears to be a very small effect. Determination of a specific rate has been confounded by the many people with ITP who take steroids for prolonged periods of time, who are elderly, who may have smoked cigarettes, and who potentially have other risk factors for cataracts. There

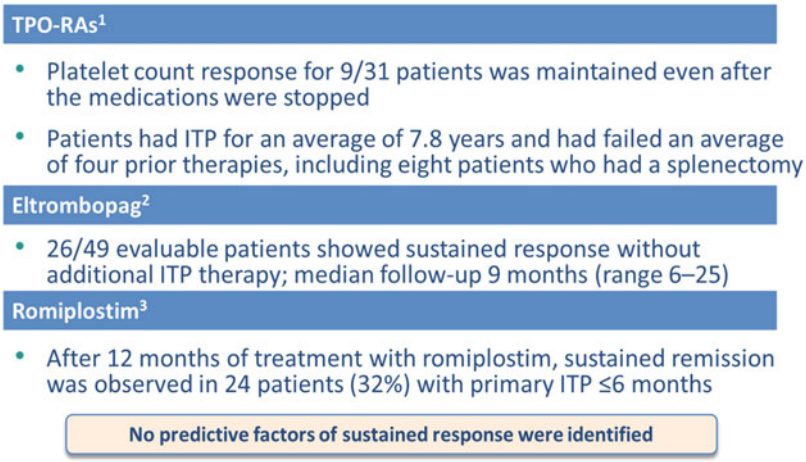

Fig. 11 Sustained remissions of ITP associated with the use of TPO receptor agonists

does not appear to be in ITP per se any induction of malignancy. If, however, a patient has myelodysplastic syndrome instead of ITP, there could be induction of blasts, which usually regress with discontinuation of medication (Bryan et al. 2010).

For both therapies, there are patients who, after a variable duration of treatment, can successfully discontinue a TPO agent and yet maintain an adequate count. What fraction of patients this is, how long they have had ITP, and how long they were on medication remains unknown. There is a weak tendency for patients who have been able to discontinue medication not to have been on TPO agents for a long time and not to have had ITP for a long time. Furthermore, even in adults, there can be spontaneous improvement over a number of years. This continues to be studied without clear resolution at this time, although one could hazard an estimate of 20–40 % improvement within 3 years of starting thrombopoietic agents (Fig. 11).

There is also the question of why remission should occur. Possibly, it occurs as a result of spontaneous improvement over time and the TPO agent is merely supporting the platelet count until "spontaneous remission or improvement" does occur. Alternatively, thrombopoietic agents may not be as immunologically inert as originally thought. This is consistent with platelets being part of the innate immune response (see Slaba and Kubes 2017). At least one study has showed the induction of Tregs, not just by number but also by function (Bao et al. 2010).

Figure 12 outlines one possible schema for an approach to ITP. Clearly, the great majority of the decisions in this setting are not informed by randomized controlled trials. However, an unequivocal issue here is not to overly prolong the use of steroids. If there is no early remission, the side effects of prolonged use of steroids outweigh their benefit. IVIG as a rescue medicine (i.e., to bring the count up quickly) is a reasonable early approach but has relatively little curative effect, although there may be a small amount with repeated use as demonstrated in children with ITP. In persistent ITP, MMF has been widely used. Other treatments are TPO agents or rituximab. The latter is more likely to work with dexamethasone and if used closer to diagnosis rather than further from it. Whether the benefit of adding three cycles of dexamethasone to rituximab outweighs the side effects is not clear. However, at this time, for women within 1 year of diagnosis, especially those who are early persistent, it seems very useful (Chapin et al. 2016). Other agents for chronic patients, in addition to splenectomy, include danazol, dapsone, azathioprine, and possibly even hydroxychloroquine if there are lupus-like features (Provan et al. 2010).

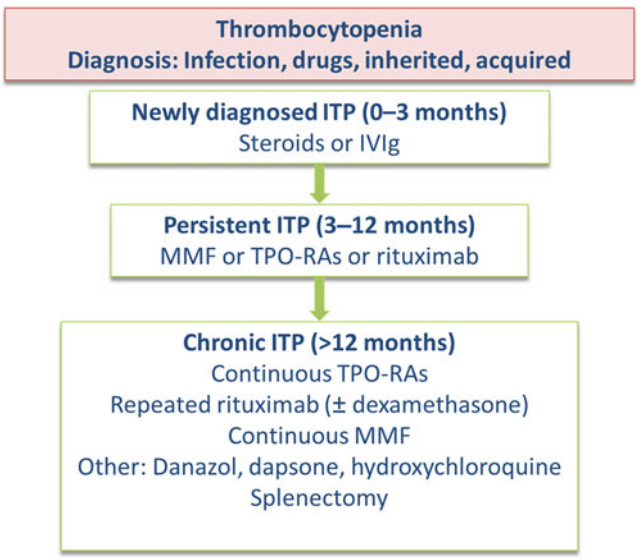

Fig. 12 A possible approach to ITP diagnosis and treatment

Pediatric ITP

Children with ITP are thought to have the "same" disease as adults. This may be most true for children with very persistent and chronic disease in which no spontaneous improvement occurs and standard treatments are sometimes ineffective. However, for most children with ITP, the ITP resolves spontaneously within 3–6 months. It is thought that many of these cases reflect "virally induced" ITP with antibodies to an infective agent that cross-reacts with platelets. As the infection clears and antibody titers fall, the platelet count returns to normal. For these patients, the major debate is whom to treat and with what. Some physicians prefer treatment when patients have very low platelet counts, whereas others prefer to "watch and wait" if there is no major ongoing bleeding.

Reduced quality of life is probably overlooked more often in this population than in adults because children do not express it as well as adults. It may be expressed as increased irritability, poor performance, or greater fatigue.

Serious bleeding is primarily intracranial hemorrage (ICH), which is estimated to occur in approximately 1 in 200–500 cases (Psaila et al. 2009). It may occur at presentation or at any time during the course of the disease. It is slightly over-represented in those with chronic disease.

Treatment effects are similar to those seen in adults. The major issue is that the patient can improve at any time up to the end of the first year so there is less need than with adults to provide a "definitive" therapy. Splenectomy is avoided whenever possible and is ideally reserved for those who have had ITP for more than 1 year, are older than 5 years, have very low platelet counts, bleeding, and are not doing well with other therapies. The effects of rituximab are similar to those seen in adults, with younger children not doing so well and adolescent girls within 1 year of ITP diagnosis responding best when rituximab is combined with dexamethasone (Chapin et al. 2016). TPO agents have recently been studied in children, with one small and three large randomized controlled studies completed (Bussel et al. 2011, 2015a, b; Tarantino et al. 2016; Grainger et al. 2015). All studies have shown good efficacy and good safety and resulted in eltrombopag being licensed for children with ITP down to the age of 1 by the FDA in the USA and by the EMA in Europe. Similar licensure is expected for romiplostim in the near future. More data demonstrating long-term safety and persistent efficacy is available for romiplostim than for eltrombopag at this time (Bussel et al. 2015a, b). One retrospective study has investigated bone marrow and not seen problems (e.g., high grades of fibrosis or abnormal cells) (Ramaswamy et al. 2014). An ongoing romiplostim study is prospectively exploring marrow findings.

Other treatments (e.g., immunosuppressive agents such as 6-MP and azathioprin) have also been studied in single-arm trials (Grace et al. 2012). In the 1980s, long-term IVIG was also tried but caused post-infusion headaches and was cumbersome because of the time needed for infusion. Similarly, intravenous anti-D was tried (Andrew et al. 1992) but its use declined with the discovery of serious intravascular hemolysis occurring for 1 in 1115 infusions (Gaines 2000). This was carefully reviewed after a "black box" warning was issued by the FDA (Despotovic et al. 2012).

Overall, the good news is that ITP in children mostly resolves spontaneously and the rate of serious bleeding is rare. The bad news is that it is not currently possible to predict the advent of chronic disease or of serious bleeding. Furthermore, chronic disease in children is not easier to treat than chronic disease in adults.

Conclusion

In summary, this is a very exciting time for ITP as newer treatments are better studied and additional treatments continue to be developed. Furthermore, other considerations are also being taken into account (e.g., HRQoL), but this is just one example of the "whole patient" approach. Molecular studies may allow separating patients into different groups and directing treatment choices; unfortunately this is still not possible.

We now know that, although there are many factors that influence megakaryocyte development and the regulation of platelet production, the role of TPO is key. It remains to be clarified whether aging platelets are cleared in the liver and stimulate synthesis of additional TPO, and what other factors are important and operative in this system to up- or downregulate endogenous TPO production. The more the autoimmune response is studied, the more complex it seems. The good news is that there are more targets for intervention; the bad news is that it is impossible to test them all. Although antibody-mediated platelet destruction (and impaired platelet production) is certainly central to the pathogenesis of ITP, the role of cell-mediated immunity has been studied on many levels and it seems that autoreactive T cells drive the disease in more difficult or more chronic ITP patients. Even though TPO receptor agonists are not the "be all and end all," if a patient responds to them they usually provide a good quality of life even if patients do not improve enough to be able to discontinue treatment. Because cure is the goal, perhaps additional rituximab combinations or better prediction of splenectomy outcome will allow us to take care of at least a sizeable fraction of our patients.

Take-Home Message Boxes

The diagnosis and management of ITP is still a work in progress. Although novel treatments have improved the management strategy in ITP, many questions remain to be answered and some patients continue to be refractory to treatment. A better understanding of the pathology of ITP, biomarkers to direct treatment and new therapeutics for refractory patients is needed.

Fetal and Neonatal Alloimmune Thrombocytopenia

Gérald Bertrand and Cécile Kaplan

Abstract

Fetal and neonatal alloimmune thrombocytopenia (FNAIT) results from the maternal immune response against fetal-specific antigens inherited from the father. FNAIT is the most common cause of severe fetal and neonatal thrombocytopenia in maternity wards. The most feared complication of FNAIT is the occurrence of intracranial hemorrhage. Since the first description of this condition in the 1950s, significant progress has been made in the understanding of the pathology and management of patients with alloimmune thrombocytopenia, but some questions remain unresolved. This chapter addresses the pathophysiology of FNAIT and discusses advances in the diagnosis and management of at-risk pregnancies.

Key Discoveries

- Progress in laboratory diagnosis has led up to now to the description of 28 platelet antigen systems involved in this pathology.
- Syncytiotrophoblastic microparticles expressing β_3 integrin spreading into the maternal blood circulation may be the cause of maternal immunization.
- Antenatal management is offered for subsequent pregnancies, preventing the occurrence of fetal/neonatal intracranial hemorrhages.
- With the development of noninvasive strategies for antenatal management, follow-up of the maternal alloantibody concentration during IVIG-treated pregnancies may be helpful for identifying therapy failure and managing delivery.
- Alternative therapies to maternal antenatal management with IVIG are under study, focusing on the transplacental passage of the maternal alloantibodies, the interaction with the fetal FcγRs, and prevention of immunization.

Introduction

Thrombocytopenia, defined by a platelet count below 150×10^9/L, is the most common hematologic disorder observed in the fetus or neonate. Fetal/neonatal alloimmune thrombocytopenia (FNAIT) is the commonest cause of severe fetal (Hohlfeld et al. 1994) and neonatal thrombocytopenia in maternity wards (Dreyfus et al. 1997). It is considered to be the counterpart of hemolytic disease of the fetus and newborn (HDFN), but in contrast to HDFN, FNAIT frequently occurs during the first pregnancy. The most feared complication is the occurrence of intracranial hemorrhage (ICH) leading to death or neurologic sequelae. FNAIT, a potentially devastating disease, is not a rare event; its incidence has been estimated to be about 1/800 to 1/1200 live births in Caucasians.

Clinical Presentation

FNAIT is a diagnosis of exclusion after considering other causes of fetal or neonatal thrombocytopenia. Fetal thrombocytopenia has been defined as a platelet count $<150 \times 10^9$/L, irrespective of the gestational age. Fetal thrombocytopenia may be suspected in a variety of circumstances: e.g., congenital infection, chromosomal abnormalities, congenital/inherited

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_51

platelet disorders (Wiskott-Aldrich syndrome), immune thrombocytopenia.

Unfortunately fetal alloimmune thrombocytopenia is more often discovered when ICH has occurred. Sonography reveals ventriculomegaly or fetal hydrocephalus. ICH has been documented regardless of implicated platelet alloantigens. With the development of imaging, ICH has been documented as early as 20 weeks gestation, and 80 % of ICH has occurred before 30 weeks gestation (Spencer and Burrows 2001). The deleterious consequences are death or neurologic sequelae.

It is very important to consider the onset of neonatal thrombocytopenia. Before 72 h of life, thrombocytopenia is almost always related to complications of pregnancy and/or delivery: placental insufficiency, hypoxia, perinatal infection, disseminated intravascular coagulation, and immune thrombocytopenia (alloimmune, autoimmune). After 72 h, it generally results from postnatal acquired bacterial infection or necrotizing enterocolitis.

Most commonly, neonatal alloimmune thrombocytopenia is suspected in an otherwise well-appearing, full-term infant with unexplained bruising and purpura at birth, or a few hours afterwards born to a pregnant healthy mother. In some circumstances, severe bleeding such as ICH, a large cephalohematoma, and gastrointestinal or genitourinary hemorrhage is observed. In any case, a platelet count should be obtained revealing isolated thrombocytopenia. Nonetheless, associations with other disorders do occur and should not be ignored (infection, chromosomal abnormality, maternal autoimmune thrombocytopenia). FNAIT may be suspected when the thrombocytopenia is more severe than anticipated for the diagnosis. A history of neonatal thrombocytopenia in prior pregnancies is also important to consider.

In the case of severe thrombocytopenia, the risks of life-threatening hemorrhage necessitate prompt diagnosis and effective therapy. It should be noted that neonatal thrombocytopenia may be asymptomatic when the platelet count is above 50×10^9/L and may be discovered by chance when performing a blood cell count for some other reason. The diagnosis is important for the management of index cases and for subsequent pregnancies. In all cases, raising the possibility of FNAIT should guide investigations accordingly.

Pathophysiology

FNAIT results from the production of maternal alloantibodies against fetal platelet antigens which are inherited from the father [human platelet antigen: HPA nomenclature (von dem Borne et al. 1995)].

The mechanisms of maternal immunization are partly understood. In contrast with HDN, platelet alloimmunization may occur during the first pregnancy (Bertrand et al. 2011). Findings have shown that fetal syncytiotrophoblasts express the integrin β_3 on their cell surfaces. Syncytiotrophoblastic microparticles spreading into the maternal circulation may possibly be the cause of immunization during pregnancy (Kumpel et al. 2008). The maternal immunogenic background is involved in HPA-1a alloimmunization. It has been shown that HPA-1a immunization is initiated by the binding of HPA-1a peptides to HLA-DRB3*01:01 and HLA-DRB4*01:01 molecules (Delbos et al. 2016; Loewenthal et al. 2013; Valentin et al. 1990). The immune response to the HPA-5b antigen has also been shown to be HLA associated, but studies of maternal immunization due to other HPA specificities are too small to draw conclusions in this regard.

The intensity of the thrombocytopenia may result from several factors:

- The active transfer of IgG through the placenta, from 13 weeks of gestation and the full expression of fetal platelet alloantigens as early as 18 weeks of gestation (Kaplan et al. 1985). This process depends on fetal Fc (FcRn) receptors. These receptors have various affinities according to IgG subclasses, due to several polymorphisms located on their genes (Einarsdottir et al. 2014).
- Adherence, phagocytosis and lysis of IgG-coated cells by IgG Fc receptors on macrophages may be modulated by glycosylation. Kapur et al. reported that anti-HPA IgG with a low amount of fucose displayed higher binding affinity to FcγRIIIa and FcγRIIIb, but not to FcγRIIa, as compared to antibodies with a high amount of Fc fucose. Moreover, the degree of anti-HPA-1a fucosylation has been correlated with the neonatal platelet count in FNAIT (Kapur et al. 2014).

Platelet Antigens Implicated in FNAIT

HPA Antigens

Platelet alloantigens are present on the platelet glycoproteins (GPs) GPIb-V-IX (von Willebrand receptor), $\alpha_{IIb}\beta_3$ complex (fibrinogen receptor), $\alpha_2\beta_1$ complex (collagen receptor), and CD109. Platelet antigens result from single amino acid substitutions. An international nomenclature was set up: HPA antigens are classified in the order of their discovery. Twenty eight HPA systems have been described up to now (Table 1). In each system, the most frequent allele is called "a," and the less frequent "b." Antigen frequencies vary among the populations studied so far.

Table 1 HPA nomenclature (human platelet antigen)

System	Antigen	Glycoprotein	Nucleotide change	Amino-acid change (mature protein)
HPA-1	HPA-1a HPA-1b	GPIIIa	176T>C	L33P

[a]w: Workshop, no antithetic antigen discovered

In persons of European origin, the HPA-1a antigen is responsible for the majority of cases of FNAIT [85 % cases of alloimmunizations (Davoren et al. 2004)], followed by HPA-5b (Kaplan et al. 1991) and -3a alloimmunizations (Glade-Bender et al. 2001) with a lower frequency. In East Asians, FNAIT is mainly linked to HPA-4b (Feng et al. 2006).

During recent years FNAIT has been reported involving rare or private antigens, most of them located in the $\alpha_{IIb}\beta_3$ complex. Recent studies have shown these low-frequency antigens as not being restricted to single families (Bertrand et al. 2007, 2013a; Kaplan et al. 2005). Consequently, during laboratory investigations, in the absence of fetomaternal incompatibility for the most frequent antigens according to ethnicity, a search for the presence of these low-frequency antigens is recommended.

The relevance of the anti-HPA-15a or HPA-15b alloantibodies in FNAIT requires further evaluation, due to technical difficulties to detect these antibodies.

HPA-2, located on platelet GPIbα, has not been considered as an important alloantigen implicated in FNAIT, since reported cases caused by this antigen are rare. It is currently unknown whether the paucity of reported cases of FNAIT mediated by HPA-2 is due to less immunogenicity of this antigen or due to a difference in pathology caused by HPA-2 antibodies. Recent data from a murine model suggest that antibodies against GPIbα may cause nonclassical signs of FNAIT [i.e., earlier spontaneous miscarriage but not neonatal bleeding (Li et al. 2011)], which may mask the severity and frequency of human anti-HPA-2-mediated FNAIT, thus reducing the observed number of cases.

It has been suggested that antibodies against GPIbα may cause platelet activation and thrombus formation in the placenta, which may impair placental function and lead to spontaneous miscarriage (Li et al. 2011).

Although platelet destruction is thought to be the major contributor to bleeding in affected patients, the effect of antiplatelet antibodies on vascular injury may affect bleeding and fetal growth. Several HPA antigens are expressed on the β3 integrin of the $\alpha_{IIb}\beta_3$ complex, which is also part of the integrin αvβ3 expressed on other cell types, such as angiogenic endothelial cells and invasive trophoblasts. It is therefore conceivable that maternal antibodies against HPA-1a may affect fetal angiogenesis, contributing to intrauterine growth restriction. Recently, reports suggest that impairment of angiogenesis, but not platelet or fibrin clots, may be the major cause of fetal embryonic hemorrhage (Yougbare et al. 2015).

HLA (Human Leukocyte Antigen) Molecules

Feto-maternal anti-HLA class I alloimmunization is common, as about one-third of multiparous women are sensitized to HLA class I. As platelets express both HLA-A and HLA-B antigens, antibodies may be responsible for thrombocytopenia. However, no systematic study has established a clear correlation between neonatal alloimmune thrombocytopenia and the presence of anti-HLA alloantibodies, except a few cases reported in the literature (Moncharmont et al. 2004; Thude et al. 2006).

Thrombocytopenia and Alloimmunization Anti-blood Groups Anti-A or Anti-B

In most individuals, platelets express only weakly A and B antigens of the ABO blood group on their surface. However, a low proportion of normal subjects unusually expresses strongly A and B antigens on the surface of their platelets. Few cases of anti-A or anti-B fetomaternal alloimmunizations have been published (Curtis et al. 2008).

Anti-GP Isoimmunizations

Isoantibodies occurring in mothers deficient in platelet CD36 [3–5 % of Asian or African ancestry (Ohto et al. 2004)] or deficient in the platelet $\alpha_{IIb}\beta_3$ complex (as observed in Glanzmann thrombasthenia) may also be involved in FNAIT (Curtis et al. 2002; Ohto et al. 2004; Leticee et al. 2005). The same situation may also be observed in patients suffering from Bernard-Soulier syndrome (absence of GPIb: Peitsidis et al. 2010).

Diagnosis and Therapeutic Strategies

When fetal ICH is suspected through imaging, it is important to establish the diagnosis of fetomaternal immunization (Fig. 1). Positive cases will be managed by close collaboration between obstetricians and neonatologists.

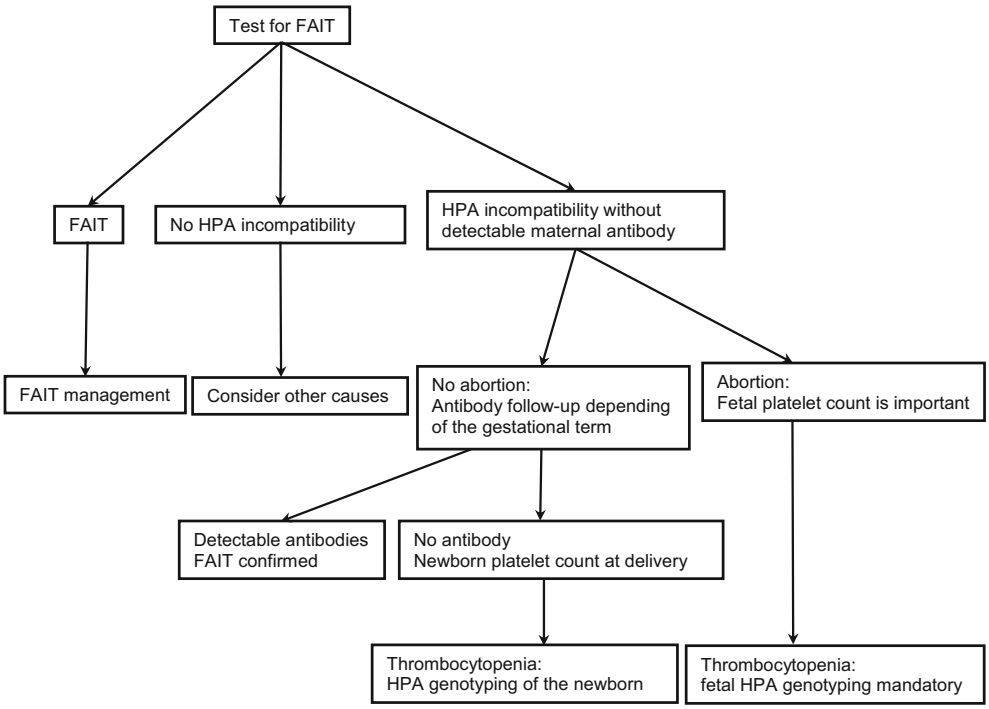

Fig. 1 Algorithm for laboratory investigations when a fetal alloimmune thrombocytopenia (FAIT) is suspected

Any severe or isolated neonatal thrombocytopenia should be explored.

The diagnosis of alloimmune thrombocytopenia will be ascertained only when the maternal alloantibody and the offending antigen present in the fetus or newborn are identified.

Investigations should be performed in a specialized laboratory that has the capacity to perform antigen-capture assays for antibody testing, and typing of common HPAs, and even rare or new platelet alloantigens.

Serology

The screening and identification of antiplatelet antibodies are currently performed by antigen-capture methods. The MAIPA (monoclonal antibody-specific immobilization of platelet antigens) is considered as the gold-standard reference method (Kiefel et al. 1987). This method is an antigen-capture assay, performed with two monoclonal antibodies (Mab), one targeting human IgG and the other targeting platelet glycoproteins. However, false-negative results might be observed resulting from competition between anti-GP Mab and human antibodies. The use of a panel of anti-GP Mab directed against the same GP with distinct epitopes may solve this problem. Maternal alloantibody detection is performed on the serum and tested (1) against a panel of group O donor platelets and (2) against the father's platelets. When alloimmunization involves a low-frequency platelet antigen, the MAIPA will only be positive with the paternal platelets.

Alternatively, the modified antigen-capture ELISA or MACE may be used (Fig. 2). In this technique, platelet GPs are precoated onto the microtiter plate, preventing disruption of the formed immune complexes during the lysis phase. Nevertheless, the conformational structure of the antigens may be modified.

The mixed passive hemagglutination, or MPHA, method bypasses the major pitfalls of the MAIPA and the MACE. However, antibody quantification cannot be done with this method, as the detection system is not colorimetric.

Some antibodies with a weak affinity are detected only by surface plasmon resonance (SPR) technology (Bakchoul et al. 2013; Peterson et al. 2013). Their clinical relevance remains to be determined.

Recently, the Luminex technology has been adapted to identify anti-HPA alloantibodies, which saves time and requires fewer biological samples (Porcelijn et al. 2014).

When a maternal alloantibody is not detectable despite parental antigenic incompatibility, it may be necessary to obtain new samples in the postnatal period and at the beginning of a new pregnancy.

Maternal autoimmunity should also be investigated; anti-GP autoantibodies may cross the placental barrier and cause fetal/neonatal thrombocytopenia, which is generally less severe when observed with alloantibodies. It has been reported that association with maternal alloimmunization is

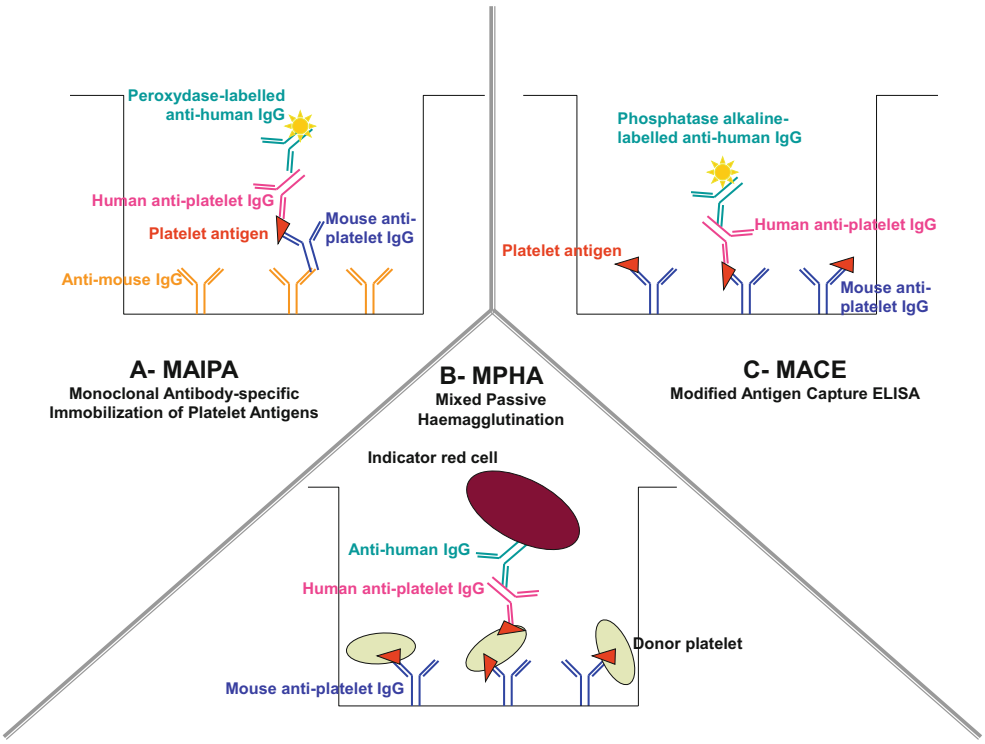

Fig. 2 Detection of antiplatelet antibodies using the MAIPA (*A*), MPHA (*B*), and MACE (*C*) methods. The final molecular architecture of antibodies and antigens is shown

not a rare event (Dreyfus et al. 1997). In that condition, thrombocytopenia can last for a longer time.

Platelet Typing

Platelet phenotyping is the best way to identify potentially immunogenic peptides. The main limitation for platelet phenotyping is the scarcity of specific, good-quality typing sera, especially for rare platelet antigens. Consequently, genotyping is the routine method for platelet typing. This approach obviates the need for patient platelets and suitable typing sera.

For appropriate counseling for subsequent pregnancies, the father's genotype should be performed whenever possible.

Unfortunately, genotype is not always representative of true phenotype. Discrepancies between phenotyping and genotyping may be observed when a genetic mutation hampers the technique itself [silent mutation located under one of the polymerase chain reaction primers, impairing DNA amplification (Bertrand et al. 2006a, 2010, 2013b; Conti et al. 2014; Nogues et al. 2013)].

Therapeutic Strategies

Postnatal Therapy

Therapeutic options will depend on the severity of thrombocytopenia.

In case of hemorrhage or a platelet count below 30×10^9/L during the first 24 h of life, the severely affected newborn should be promptly transfused with platelets, even without the results of laboratory investigations. Follow-up is important to maintain the platelet count above 50×10^9/L.

If the platelet count is above 30×10^9/L, usually no treatment is required in the absence of ICH.

For a premature infant, or in the case of an associated pathology, respiratory distress, or infection, platelet transfusion is required to maintain the platelet count above 50×10^9/L.

In any case, the platelet count should be monitored for at least 1 week to detect any fall in the platelet count.

Platelet Transfusion Therapy

In the context of FNAIT, the ideal platelets to be transfused are those that will not be destroyed by the maternal alloantibodies present in the newborn. Consequently, maternal platelets are the best product. They must be washed to remove the alloantibody and irradiated (to avoid graft versus host disease). However, due to logistical difficulties, maternal platelet transfusions are not often available.

To circumvent these problems, a national registry of HPA-typed donors has been developed in different countries (Allen et al. 2004); in addition frozen platelets may be used, as in France (Lee et al. 2002). However in an emergency, random platelet transfusion is an appropriate strategy pending the availability of compatible platelets later on (Kiefel et al. 2006). In order to limit the destruction of transfused random platelets, it is recommended to add IVIG (daily dose of 1 g/kg; 2 days). A recent report on a limited number of cases has shown that platelet transfusion alone was effective (Bakchoul et al. 2014). IVIG alone is not indicated as the sole therapy. It does not prevent hemorrhage; the lag-time efficacy is about 20 h.

Outcome

Cerebral imaging should be performed as part of a careful neurological examination before the newborn is discharged from hospital. A normal platelet count is usually obtained with or without treatment in 8–10 days, and in the absence of ICH, the outcome is favorable.

In case of ICH, death has been reported as affecting 10–15 % of the cases, or there are neurologic sequelae in 20 % of cases.

Management of Subsequent Pregnancies

Due to the recurrence of this condition in successive pregnancies with an incompatible fetus, usually implying an increasingly severe condition, antenatal therapy has been offered since 1984 (Daffos et al. 1984; Kaplan et al. 1988; Bussel et al. 1988).

The important questions are the evaluation of the fetal status, identification of fetuses requiring therapy, and monitoring the response to therapy.

Antenatal therapy nowadays is offered to women with a past history of an affected infant.

The pregnant women should be monitored in referral centers offering genetic counseling.

The determination of the fetal status is a prerequisite. In the case of paternal heterozygosity for the offending antigen or an unidentified father, fetal platelet genotyping is necessary. This may be performed on amniotic cells. However, amniotic liquid puncture is an invasive method with adverse side effects, premature labor, or even in utero death. New developments in fetal DNA isolated from maternal plasma are promising. A protocol is already in use for antenatal diagnosis of HPA-1 incompatibility (Le et al. 2013).

Due to ethical reasons, randomized controlled trials on the efficacy of different protocols have not been done. There is a general consensus on maternal therapy with IVIG with or without steroids as a first-line treatment while minimizing invasive procedures. Therefore, fetal blood sampling is becoming less frequent. Delivery by elective C-section is usually proposed when the fetal status is unknown. Compatible platelets are prepared to be available if necessary for transfusion immediately after birth.

Dosing and timing of maternal therapy depend on the strategy in use by the team, and protocols may differ. Therapy stratification depending on the sibling status, with or without ICH, has been advocated (Bussel et al. 2010). Between 1992 and 2015, 16 retrospective studies on IVIG antenatal therapy were published (582 newborns). Only 13 cases of ICH were reported (2.2 %).

In our experience for the standard risk, i.e., a sibling without ICH, we recommend IVIG 1 g/kg/week, from 20 to 22 weeks of gestation until delivery by C-section at 39 weeks of gestation (Bertrand et al. 2011). In the case of high-risk pregnancy, siblings with ICH, the therapy will start at 16–18 weeks of gestation. With this strategy, no ICH was observed in our retrospective study on 75 HPA-1bb pregnant women treated with IVIG. Addition of steroids (prednisone 0.5 mg/kg/day) from 30 to 32 weeks of gestation significantly increased the mean newborn platelet count: 135×10^9/L (54 newborns) with IVIG and steroids versus 89×10^9/L (27 newborns) with IVIG only (Bertrand et al. 2011).

For the most severely affected fetuses, recent studies have suggested that IVIG $\times$ 2 infusions of 1 g/kg/week combined with 0.5–1.0 mg/kg/day prednisone is the most effective medical regimen (Vinograd and Bussel 2010).

No side effect of maternal therapy with IVIG has been reported in the children on long-term follow-up (Radder et al. 2004).

In the absence of fetal blood sampling to assess the fetal platelet count, searching for maternal parameters predictive of therapy effectiveness is challenging. We have shown that the maternal anti-HPA-1a alloantibody concentration is a predictive variable for severe fetal thrombocytopenia when the test is performed early in the pregnancy and before any treatment (Bertrand et al. 2006b). Follow-up of the antibody concentration during IVIG-treated pregnancies appears to be helpful for identifying therapy failure and managing delivery (Bertrand et al. 2014; Killie et al. 2007a; Sainio et al. 2013).

The sisters of the homozygous women who gave birth to an affected infant should be aware, and counseling offered to detect high-risk pregnancies.

Other Therapeutic Approaches

Alternative therapies to maternal IVIG are focused on the transplacental passage of the maternal alloantibodies, the interaction with the fetal FcγRs, and prevention of immunization.

Anti-FcγR immunoglobulins may have the capacity to reduce platelet destruction (Li et al. 2011). Another approach in preventing platelet destruction is the use of recombinant HPA-1a-specific antibodies with abrogated Fcγ receptor binding (Ghevaert et al. 2013). These antibodies have the capacity to saturate available HPA-1a-binding sites from fetal platelets without activating FcγR signaling. These strategies have been studied using murine FNAIT models. Due to physiological differences between mouse and human placentation, transposition to human FNAIT therapy is still under discussion.

Very recently, Ni and colleagues suggested a new treatment option for thrombocytopenia, based on sialidase inhibition (Jansen et al. 2015). This option relies on the observation that platelets normally gradually loose surface sialic acid as they circulate and age through cleavage by sialidases (Grozovsky et al. 2015). It has been shown in vitro that desialylation of the platelet von Willebrand factor receptor complex triggers platelet destruction, which could be circumvented with a sialidase inhibitor. In vivo, they performed a retrospective observational study on patients treated with oseltamivir (sialidase inhibitor) and found a significant increase in platelet count in treated patients, proof of the principle that sialidase inhibition increases platelet count in humans, probably by decreasing clearance of platelets (Jansen et al. 2015).

A study in the Norwegian population suggests the possibility of a prophylactic treatment similar to the prevention of HDN (Kjeldsen-Kragh et al. 2012). This relies on the hypothesis that in the majority of cases, maternal immunization occurs at the first delivery and not during pregnancy, despite reports showing immunization during the first pregnancy (Mueller-Eckhardt et al. 1989; Durand-Zaleski et al. 1996; Bertrand et al. 2011). To examine the validity of the hypothesis, a proof-of-concept study on a murine model has been reported (Tiller et al. 2012).

Cost-Effectiveness of a Screening Strategy of High-Risk Pregnancies

As the first pregnancy may be affected by FNAIT, screening at-risk pregnancies for prevention of deleterious consequences is of the utmost interest. This strategy is still a subject of debate, despite studies from European countries showing that the implementation of such screening is cost-effective given the damage caused by ICH (Killie et al. 2007b). Several screening strategies have been reported in the literature, screening pregnant women or newborns and counseling for the next pregnancy (Durand-Zaleski et al. 1996).

The main issues are:

- The detection of maternal alloantibodies with the potential difficulties as mentioned above.
- The evaluation of the fetal risk during the pregnancy under consideration, without invasive procedure. Quantification of alloantibodies (concentration below a threshold) may be considered, but a gray zone does exist.
- The protocol to be proposed for antenatal management, especially in the case of first pregnancies.

Conclusion

In conclusion, FNAIT first described in the early 1950s is still a matter of interest for immunologists, obstetricians, and neonatologists. Progress has been made in diagnosis and management for a better quality of life. However, larger collaborative studies are still needed for improvement in diagnosis and for specific therapies.

Take Home Messages

- Fetal and neonatal alloimmune thrombocytopenia is not a rare event: Incidence of 1/800 to 1/1000 live births in persons of European origin.
- Any severe isolated fetal or neonatal thrombocytopenia should be explored.
- Laboratory diagnosis relies on the identification of maternal antiplatelet alloantibodies directed against fetal platelet antigens inherited from the father.
- The most feared complication is intracranial hemorrhage resulting in death or long-term disability.
- In emergency, in case of severe neonatal thrombocytopenia or hemorrhage, platelet transfusion therapy should be done promptly.
- Management of subsequent high-risk pregnancy is offered in referral centers due to recurrence for incompatible fetuses.

Drug-Induced Thrombocytopenia: Pathogenesis, Diagnosis and Management

Beng H. Chong and James J.-H. Chong

Abstract

A large number of drugs have been reported to cause immune thrombocytopenia. Recent research has considerably increased our knowledge of the cellular mechanisms that drive this immune reaction to drugs. The diagnosis is usually made clinically after considering the causal relationship with the suspected drug and the occurrence of the thrombocytopenia. The mainstay of treatment is essentially cessation of the suspected drug or drugs. The platelet count usually returns to normal limits within 1–2 weeks. However, high-dose glucocorticosteroid and IVIg are often administered because of the high risk of bleeding associated with severe thrombocytopenia. This review will focus on the various cellular mechanisms that cause drug-induced immune thrombocytopenia and will also discuss its diagnosis and management.

Introduction

Hippocrates used the term "purpura" to describe the purple spots on the skin of patients with pestilential fever without knowing its association with bleeding or thrombocytopenia (Jones and Tocantins 1933). "Purpura" comes from the Latin word "'*ρэrpэrə*" meaning purple. In the sixteenth century, Lusitanus observed that purpura could occur in the absence of fever. Three centuries later, Krauss in 1883 and Denys in 1887 recognized "purpura" as bleeding under the skin, "purpura haemorrhagica" caused by a decrease of blood platelets (Jones and Tocantins 1933). In 1883, Vipan described the association of purpura with quinine ingestion (Vipan 1865). In 1928, Rosenthal provided the first evidence that drug ingestion could lead to thrombocytopenia by showing prompt decrease in platelets when a patient with quinine-induced thrombocytopenia was re-challenged with quinine (Leach et al. 1997).

Many drugs have been implicated to cause thrombocytopenia (Chong 1991; Aster et al. 2009; Aster and Bougie 2007; George et al. 2006; Chong et al. 2013). Drug-induced thrombocytopenia is common because it is caused by a large number of drugs, many of which are commonly used medications (see below). However, it is difficult to diagnose and is often unsuspected and under-recognized. Yet it is potentially serious as it can cause severe bleeding and even fatal haemorrhage such as an intracranial bleed (Freiman 1990; Fireman et al. 1981; Samaranayake and Yap 2014).

Mechanisms of Drug-Induced Thrombocytopenia

Although drug-induced thrombocytopenia has been identified for more than a century, it is only in recent years that its mechanisms have been characterized, and even now

some aspects of its pathophysiology remain unclear. Drugs cause thrombocytopenia by two broad mechanisms:

(a) Suppression of platelet production (non-immune and immune)
(b) Increased platelet clearance (non-immune and immune)

Mechanisms of Non-immune Drug-Induced Thrombocytopenia

(a) *Suppression of platelet production (non-immune)*. Drugs involved in this mechanism are usually antineoplastic/cytotoxic drugs such as alkylating agents (cyclophosphamide, adriamycin, melphalan) and antimetabolites (methotrexate) which cause predictable, dose-dependent myelosuppression leading to pancytopenia. However, some non-cytotoxic drugs also suppress platelet production, but they usually cause isolated mild but sometimes severe thrombocytopenia. These drugs include histone deacetylase inhibitors (HDIs) such as panobinostat (used in treatment of cancer) (Iancu-Rubin et al. 2012; Matuoka et al. 2007; Bishton et al. 2011) and valproate (used as an anticonvulsive and in psychiatry treatment) (Eastham and Jancar 1980; Kaufman and Gerner 1998; Trannel et al. 2001; Gesundheit et al. 2002; Proulle et al. 2000; Sleiman et al. 2000), anagrelide (used in treatment of essential thrombocythaemia) (Wang et al. 2005; McCune et al. 1997), linezolid (an oxazolidinone antibiotic used in treatment of drug-resistant bacterial infection) (Attassi et al. 2002; Orrick et al. 2002; Minson and Gentry 2010; Matsumoto et al. 2010; Pascoalinho et al. 2011; Cossu et al. 2014), interferon-α (used in hepatitis B treatment) (Li et al. 2010; Sata et al. 1997), imatinib mesylate (a -tyrosine-kinase inhibitor used in treatment of chronic myeloid leukaemia) (Sashida et al. 2003; Rajappa et al. 2007) and bortezomib (a proteasome inhibitor used in multiple myeloma treatment) (Lonial et al. 2005). HDIs suppress megakaryocyte maturation by inhibiting proplatelet formation and platelet release from megakaryocytes (Iancu-Rubin et al. 2012; Bishton et al. 2011). With regard to other drugs, the mechanism whereby they inhibit megakaryocytes is still unclear. With valproate, linezolid and imatinib, if the thrombocytopenia is profound, there may be an additional reason such as an immune mechanism (Proulle et al. 2000; Pascoalinho et al. 2011; Rajappa et al. 2007) or renal dysfunction (Matsumoto et al. 2010; Cossu et al. 2014).

(b) *Increased platelet clearance (non-immune)*. Drugs can increase platelet clearance by either an immune or non-immune mechanism. Drugs that induce thrombocytopenia by a non-immune mechanism include interleukin-2, growth factors such as granulocyte (G)-monocyte (M) colony stimulating factor (CSF), G-CSF and M-CSF (Nash et al. 1995; Minelli et al. 2009; Baker and Levin 1998), cytokines such as tumour necrosis factor (TNF)-α/interferon (IFN)-γ (Michelmann et al. 1997) and amrinone (Kinney et al. 1983; Ross et al. 2009). The mechanism whereby these drugs cause thrombocytopenia is still largely unknown, but the growth factors are believed to induce thrombocytopenia by macrophage activation (Nash et al. 1995; Baker and Levin, 1998) and TNF-α and IFN-γ by endothelial activation (Michelmann et al. 1997).

Drug-Induced Thrombotic Thrombocytopenic Purpura (TTP)

Drugs can also cause TTP, but the mechanism for the thrombocytopenia is different from that of the "conventional" drug-induced immune thrombocytopenia (DITP), a term usually reserved for thrombocytopenia caused by drug-dependent antibodies directed against platelets and/or megakaryocytes.

In a systemic review of published reports before March 2014, 78 drugs have been implicated to cause TTP. Only 22 drugs had evidence of a definite causal relationship with TTP (Al-Nouri et al. 2015). Of these, three drugs (quinine, cyclosporine and tacrolimus) accounted for the majority of the patient reports with definite evidence. On the other hand, the Food and Drug Administration (FDA) safety databases reveal that ticlopidine and clopidogrel (thienpyridine-derived anti-platelet agents) are the two most common drugs associated with TTP (Zakrija et al. 2009). Other drugs with definite evidence of association with TTP are bevacizumab, cocaine, docetaxel, everolimus, gemcitabine, interferon-α, interferon-β, mitomycin, muromonab-CD3, oxaliplatin, penicillin, pentostatin, quetiapine, sirolimus, sulfisoxazole, sunitinib, tacrolimus, trielina and vancomycin and vincristine (Al-Nouri et al. 2015).

The mechanisms whereby drugs induce TTP are largely unknown. The microvascular endothelial cell (EC) injury may be caused by the direct toxic effect of the drug itself (e.g. cyclosporine and tacrolimus) or a drug-related autoantibody (e.g. quinine-, oxaliplatin- and vancomycin-induced TTP) (Reese et al. 2015; Al-Nouri et al. 2015). EC damage leads to deficiency of ADAMTS13 which may be exacerbated by anti-ADAMTS13 autoantibodies such as in thienopyridine-associated TTP (Zakrija et al. 2009). EC injury also induces the release of extra-large von Willebrand factor multimers which cause platelet aggregation and microvascular thrombosis which in turn induces microangiopathic haemolysis and end-organ damage (e.g. renal impairment). In thienopyridine-associated TTP,

Zakrija et al. (2009)) revealed that the majority of patients have ADAMTS13 autoantibodies and severe thrombocytopenia, and they response well to therapeutic plasma exchange, but the minority have severe renal impairment and direct EC injury by drug, and they respond less well to plasma exchange. TTP will not be further discussed in this chapter as it is out of the scope of this review.

This review will focus on DITP which is mediated by drug-dependent platelet antibodies. Thrombocytopenias due to myelosuppression, megakaryocyte suppression and accelerated platelet clearance by non-immune mechanisms will also not be discussed further in this chapter. Heparin-induced thrombocytopenia (HIT) which has distinctly different clinical features, mechanism, diagnostic approach and treatment (Chong and Isaacs 2009) will be discussed in another chapter.

Drug-Induced Immune Thrombocytopenia (DITP)

Drugs that Cause DITP

Reese et al. (2010) investigated 1468 drugs suspected of causing DITP using three sources, namely, (1) previous case reports (253 drugs); (2) laboratory data from the Blood Centre of Wisconsin, USA (202 drugs); and (3) the Adverse Event Reporting System (AERS) of the US Food and Drug Administration (1444 drugs). However, only 102 drugs were listed in all three sources and these drugs probably represent the drugs most commonly suspected to cause DITP. Of these 102 drugs, 24 had definitive evidence that they cause DITP, namely, clinical data showing a causal relationship and the detection of drug-dependent anti-platelet antibodies. Of these 24, 12 drugs had drug-dependent antibodies identified in ten or more patients, providing strong and definitive evidence of DITP. These 12 drugs are commonly used in clinical practice such as antibiotics/antituberculotics (ampicillin, piperacillin, rifampicin, ethambutol, sulfisoxazole, trimethoprim/sulfamethoxazole and vancomycin), anti-platelets/$\alpha_{IIb}\beta_3$ inhibitors (abciximab, eptifibatide, tirofiban), non-steroidal anti-inflammatory agents (ibuprofen, naproxen), anticonvulsants (carbamazepine, phenytoin, valproic acid) and quinine/quinidine. Arnold et al. (2013) compiled a similar list of 36 drugs which satisfied all clinical criteria of DITP plus detection of drug-dependent antibodies, but only 16 of these drugs had positive test results by two of more laboratories. There are 24–36 drugs that satisfy clinical and laboratory criteria for DITP reported by multiple sources but 12–16 drugs with very strong evidence of DITP (Reese et al. 2010; Arnold et al. 2013). With time, more and stronger evidence will emerge for more drugs, and the list of drugs with definite/strong evidence of DITP will increase.

In addition, "DITP" may also occur with ingestion of beverages (e.g. tonic water which contains quinine) (Korbitz and Eisner 1973; Brasic 2001), herbal medicines (e.g. *Jui*, a Chinese herbal tea) (Azuno et al. 1999; Ohmori et al. 2004) and certain foods (e.g. *tahini*, pulped sesame seeds) (Arnold et al. 1998).

In some instances, DITP occurs in the presence of two drugs. This may happen when two concomitant drugs each induce an immune response and produce a drug-specific anti-platelet antibody. Alternatively, a drug increases the blood concentration of another drug or its metabolite(s). An example of the former is a patient, receiving both piperacillin and vancomycin, who developed a piperacillin- and vancomycin-dependent antibody resulting in severe thrombocytopenia which resolved only when both drugs were withdrawn (Anand and Chauhan 2011). An example of the latter is dexamethasone and phenytoin (Pandey and Yarlagadda 2012). Dexamethasone inhibits epoxide hydralase increasing the concentration of phenytoin epoxide which is responsible for the thrombocytopenia. Awareness of this drug interaction may help to prevent DITP with these drugs.

Incidence of DITP

The incidence of DITP varies with the drug implicated. Studies based mainly on national surveillance and hospital records reported incidences between 0.6 and 1.8 per 100,000 (Bottiger and Westerholm 1972; Bottiger and Bottiger 1981; Pedersen-Bjergaard et al. 1996, 1997, 1998; Danielson et al. 1984). For drugs such as quinine and trimethoprim/sulfamethoxazole, the reported incidence is higher, 36 and 28 per 1,000,000 per week of drug exposure, respectively (Kaufman et al. 1993). These studies may have underestimated the true incidences as diagnoses of DITP are difficult (George et al. 2006; George and Aster 2009). However, the frequencies with drugs such as heparin and $\alpha_{IIb}\beta_3$ inhibitors are higher. As many as 1–2 % of patients develop thrombocytopenia with their first exposure to $\alpha_{IIb}\beta_3$ inhibitors (abciximab, tirofiban and eptifibatide) and 10–12 % on re-exposure to abciximab (Curtis 2014). About 0.5–5 % of patients receiving unfractionated heparin develop thrombocytopenia (Shantsila et al. 2009), with a lower frequency with low molecular weight heparin, ~0.2 %.

Pathophysiology of DITP

As in non-immune drug-induced thrombocytopenia, the drug-dependent antibodies and drugs cause thrombocytopenia by cellular processes that (1) increase platelet clearance and/or (2) suppress platelet production. Before these

processes can occur, the drug-dependent antibodies and the inducing drugs will have to bind to platelets and/or megakaryocytes. The mechanisms whereby the antibodies and drugs interact with platelets/megakaryocytes will be discussed first.

How Does the Drug-Dependent Antibody Bind to Platelets in the Presence of the Drug?

DITP is mediated by a drug-dependent antibody (usually IgG) that binds to platelets and/or megakaryocytes in the presence of the sensitizing drug. Several mechanisms for the antibody-platelet-drug or antibody-megakaryocyte-drug interactions have been proposed. These proposed mechanisms will be discussed below:

1. *Hapten mechanism*. This was the mechanism believed to cause all DITP in the 1940s based mainly on evidence from animal studies (Ackroyd 1953; Shuman 1958, 1964). Drugs were thought to be too small by themselves to become immunogenic. It was postulated that they covalently bind to a macromolecule such as a protein and act as haptens to elicit an immune response inducing the formation of hapten-dependent antibodies. These antibodies recognize the macromolecule only when the hapten is attached. Subsequently, studies of patients with DITP show no evidence of drugs acting as haptens except perhaps penicillin and its derivatives (Garratty and Petz 1975; Murphy et al. 1983).
   Penicillin if administered to patients in large doses can covalently bind to proteins on red cell surface via its reactive β-lactam ring. Penicillin acting as a hapten can induce the generation of hapten-dependent antibodies which induce destruction of red cells causing autoimmune haemolytic anaemia (Garratty and Petz 1975). A recent study reported that penicillin derivative piperacillin can also induce the formation of hapten-dependent antibodies that target piperacillin-coated red cells and may possibly cause piperacillin-induced autoimmune haemolytic anaemia (Garratty 1993). It has been postulated that the hapten mechanism may also account for the thrombocytopenia occasionally seen in patients receiving penicillin and piperacillin (Murphy et al. 1983). However there is no convincing experimental evidence to support this hypothesis.
2. "*Quinine-type*" *immune thrombocytopenia, the prototype DITP*. The mechanism whereby quinine or its isomer (quinidine) induces thrombocytopenia has been extensively studied. Most other drugs cause immune thrombocytopenia by a similar or slightly modified mechanism. In the 1940s–1980s, it was believed that quinine, quinidine and most drugs induced thrombocytopenia by the hapten mechanism (Fig. 2a). The drug-dependent antibody reacts with quinine (attached to a plasma protein [macromolecule]), and the antibody-antigen complex then binds via Fc domain to platelet which is then destroyed as "an innocent bystander" as the antibody has no specificity for platelets ("innocent-bystander mechanism").
   (a) *Target antigen*. In 1983, we provided the first evidence that the drug-dependent antibody in a patient with quinidine-induced thrombocytopenia recognized a specific platelet surface protein. We immunoprecipitated GPIb-IX complex from platelet lysate with the patient's quinidine-dependent antibody using staphylococcal protein A (Chong et al. 1983). This observation not only indicates that the platelet antigen is GPIb-IX complex but it also suggests indirectly that the antibody binds to platelets via its Fab domain and not its Fc domain. This was a radical finding that challenged the dogma of that time, i.e. the "innocent-bystander" mechanism (Shuman 1958, 1964). This finding led subsequently to studies which directly showed that drug-dependent antibodies bind to platelets with their Fab domain in the presence of drugs (Smith et al. 1987; Christie et al. 1985). Later, another platelet drug-related antigen, $\alpha_{IIb}\beta_3$, was also identified (Chong et al. 1991; Visentin et al. 1991). $\alpha_{IIb}\beta_3$ complex and/or GPIb-IX complex are now known to be target antigens in DITP caused not only by quinine/quinidine but also most other drugs (Gentilini et al. 1998; Burgess et al. 1998, 2000; Asvadi et al. 2001; Peterson et al. 2008). One report suggested PECAM-1 as the target antigen for patients with thrombocytopenia induced by carbimazole (Kroll et al. 2000).
   In 2015, there is debate as to the exact mechanism by which the quinine-dependent antibody binds to platelets in the presence of the drug despite our knowledge of the precise platelet location of the antibody binding sites. There are at least two proposed hypotheses and they are discussed below:
   - *Hybrid paratope mechanism*. Recently, Zhu et al. (2015) and Bougie et al. (2015) proposed a *hybrid paratope* mechanism of drug-dependent antibody binding to the platelet antigen. Their hypothesis was based on the findings of their studies of two quinine-dependent monoclonal antibodies (moAbs), 314.1 and 314.3, which resembled human quinine-dependent antibodies. These moAbs recognized an epitope on platelet GPIIbβ and bound to the target epitope with low affinity in the absence of quinine. They found that quinine did not bind GPIIbβ but instead bound with high affinity and specificity the Fab domain of the

moAbs, 314.1 and 314.3, in a ratio of roughly 2:1 (quinine to moAb). These investigators also showed by crystallography strong drug binding to the complementarity-determining regions (CDRs) of the antibodies. Drug binding induced conformational changes in the CDRs resulting in the moAbs binding with enhanced affinity to GPIIbβ (Fig. 1a). *Hybrid paratope* was suggested as an appropriate name for their proposed mechanism. This is because (1) quinine combines with the CDR loop of the antibody to form *a paratope* which then binds to the epitope on platelet GPIIbβ, and (2) the paratope is a hybrid comprising the antibody CDR loop and quinine (Zhu et al. 2015). The *hybrid paratope* is an unconventional but novel mechanism. As the hypothesis is a departure from the conventional concept of drug sensitization, a relevant question is how does the patient become sensitive to quinine? These investigators suggested that quinine fortuitously binds to the B cell receptor and thus induces the production of quinine-dependent antibodies (Zhu et al. 2015).

However, there are additional unanswered questions: (1) Do the moAbs, 314.1 and 314.3, resemble exactly the quinine-dependent antibodies of patients with DITP? For example, does quinine also bind with high affinity to the CDR of the human drug-dependent antibodies? (2) Is the *hybrid paratope* mechanism also applicable to the human quinine-dependent antibodies that recognize other platelet antigens such as GPIIIa, GPIX and GPIbα? (3) How does the specific B

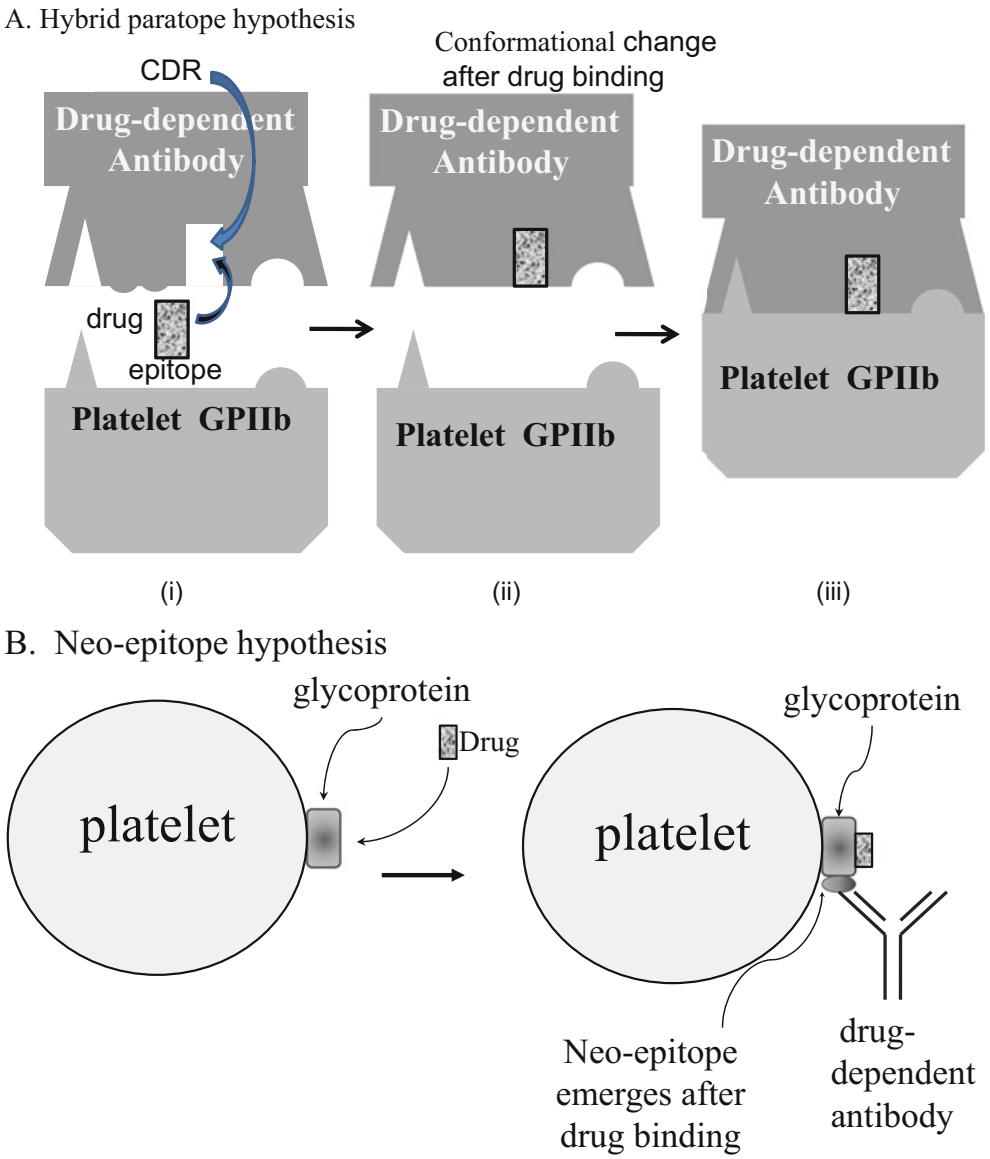

Fig. 1 Quinine-type drug-induced thrombocytopenia—hypotheses of antibody-drug-glycoprotein interaction. (**a**) *Hybrid paratope hypothesis*: Drug binds to the CDR of the drug-dependent antibody which has rough specificity and binds with low affinity to the target antigen, GPIIb, in the absence of the drug. Drug binding induces a conformational change in the CDR such that the antibody now has high specificity for and binds with high affinity to GPIIb. (**b**) *Neoepitope hypothesis*: The drug binds to target glycoprotein (antigen), GPIX or GPIIIa, inducing a conformational change such that a neoepitope, otherwise cryptic, is exposed so that the drug-dependent antibody can bind with high specificity and affinity

cell that recognizes quinine come into existence since quinine is too small a molecule to be antigenic? Do they occur in response to the weak non-covalent binding of quinine to the target antigen (GPIIbβ)?

- *The neoepitope hypothesis*. The conventional concept of drug sensitization is that the drug binds to an autologous protein, usually non-covalently, and induces a conformational change in the protein giving rise to a neoepitope that is previously unseen by the immune system. This leads to the production of an antibody that binds drug dependently to the neoepitope (Fig. 1b). In the case of quinine-induced thrombocytopenia, the autologous protein is GPIb, GPIX or GPIIIa. The antibody-binding domain has been fine mapped to the membrane-proximal ectodomain of GPIX (R110–Q115) (Asvadi et al. 2001), the N-terminal domain of GPIbα (residues 283–293) (Burgess et al. 1998) and the hybrid and plexin/semaphorin/integrin (PSI) domains of GPIIIa (A50–D66) (Peterson et al. 2008). GPIX (R110–Q115) and GPIIIa (A50–D66) are located in the regions of the platelet receptors that are highly hyperflexible (Xiong et al. 2001; Zhu et al. 2008; Mo et al. 2009; Dill 1991). Li (2010) suggested that as a result of the protein hyperflexibility, the drug binds to and stabilizes different non-native conformations of the receptors; some are recognized as foreign and induce an immune response (Li 2010). Heterogeneous drug-dependent antibodies are thus generated, and they recognize heterogeneous epitopes that cluster around a specific site of the platelet receptor. Hyperflexibility of GPIX domain, R110–Q115, may also explain why it is the binding site of at least four human drug-induced antibodies, namely, quinine-, quinidine-, rifampicin- and ranitidine-dependent antibodies (Asvadi et al. 2001; Burgess et al. 1998; Peterson et al. 2008). Hyperflexibility of the protein may allow drugs of different chemical structures (quinine, quinidine, rifampicin and ranitidine) to bind to this domain of GPIX (Li 2010).

  One weakness of this hypothesis is that the drug binds only weakly and non-covalently to the platelet receptor. As Li (2010) explained above, non-covalent drug binding to a hyperflexible protein may still permit induction of an immune response.

3. *Thrombocytopenia induced by $\alpha_{IIb}\beta_3$ inhibitors* (*fibans*). Fibans (tirofiban and eptifibatide) are synthetic small molecules that bind tightly to the arginine-glycine-aspartic acid (RGD) recognition site on $\alpha_{IIb}\beta_3$. They block fibrinogen binding, platelet aggregation and platelet thrombus formation (Topol et al. 1999). The fibans are used to treat acute coronary syndrome and to prevent stent thrombosis after percutaneous transluminal coronary angioplasty and stenting (Topol et al. 1999). Clinical trials (The RESTORE Investigators 1997; The PURSUIT Trial Investigators 1998) and subsequent clinical experience revealed that 0.1–2.0 % of patients who received fibans developed severe thrombocytopenia within 24 h of the first drug exposure (Patel et al. 2005; Coons et al. 2003; Rezkalla et al. 2003; Billheimer et al. 2002; Bougie et al. 2002; Seiffert et al. 2003). The incidence of severe thrombocytopenia in large clinical trials was lower than that observed in smaller studies. In the large trials, the thrombocytopenia might have been under-recognized. In contrast, smaller studies often included selected patient populations and hence there is a tendency to overestimate the incidence of thrombocytopenia.

   Thrombocytopenia is mediated by drug-dependent antibodies against $\alpha_{IIb}\beta_3$ that can occur naturally. This may explain the rapid onset of the thrombocytopenia (Bougie et al. 2002). These antibodies have also been detected in healthy individuals with no previous drug exposure (Aster et al. 2009; Aster and Bougie 2007; Bougie et al. 2002). Previous research has shown that RGD peptide can induce changes in $\alpha_{IIb}\beta_3$ resulting in the emergence of cryptic epitopes which are recognized by certain moAbs (Frelinger et al. 1991; Kouns et al. 1991; Jennings et al. 2000). These epitopes are known as "ligand-induced binding sites (LIBS)". The LIBS were expected to be also the epitopes of the fiban-dependent antibodies, but a recent study by Bougie et al. (2012) showed conclusively that they are not. They used the term MIBS (mimetic-induced binding sites) to denote the domains that emerge after fiban binding to $\alpha_{IIb}\beta_3$ (Fig. 2c). MIBS were located in the head region of $\alpha_{IIb}\beta_3$, near the RGD recognition site, probably on the β-propeller domain of GPIIb or the βA domain of GPIIIa (Bougie et al. 2012). The fiban-dependent antibodies were specific to the inducing drug (tirofiban or eptifibatide) in the majority of patients, but in the minority the antibodies cross-reacted with other fibans (Bougie et al. 2012; Chong 2012).

4. *Abciximab-induced thrombocytopenia*. Abciximab is a chimeric (mouse/human) monoclonal antibody (Fab fragment) that binds to the βA domain of GPIIIa and inhibits fibrinogen binding and thrombus formation. About 2 % of patients receiving the drug suffer acute, severe thrombocytopenia within 2–48 h within the first exposure to the drug (Kilickiran et al. 2008; Jubelirer et al. 1999; Curtis et al. 2002, 2004). The incidence is increased to 12 % when the drug is given again within 30 days (Bougie et al. 2012; Mascelli et al. 1998). In a subgroup of patients, the

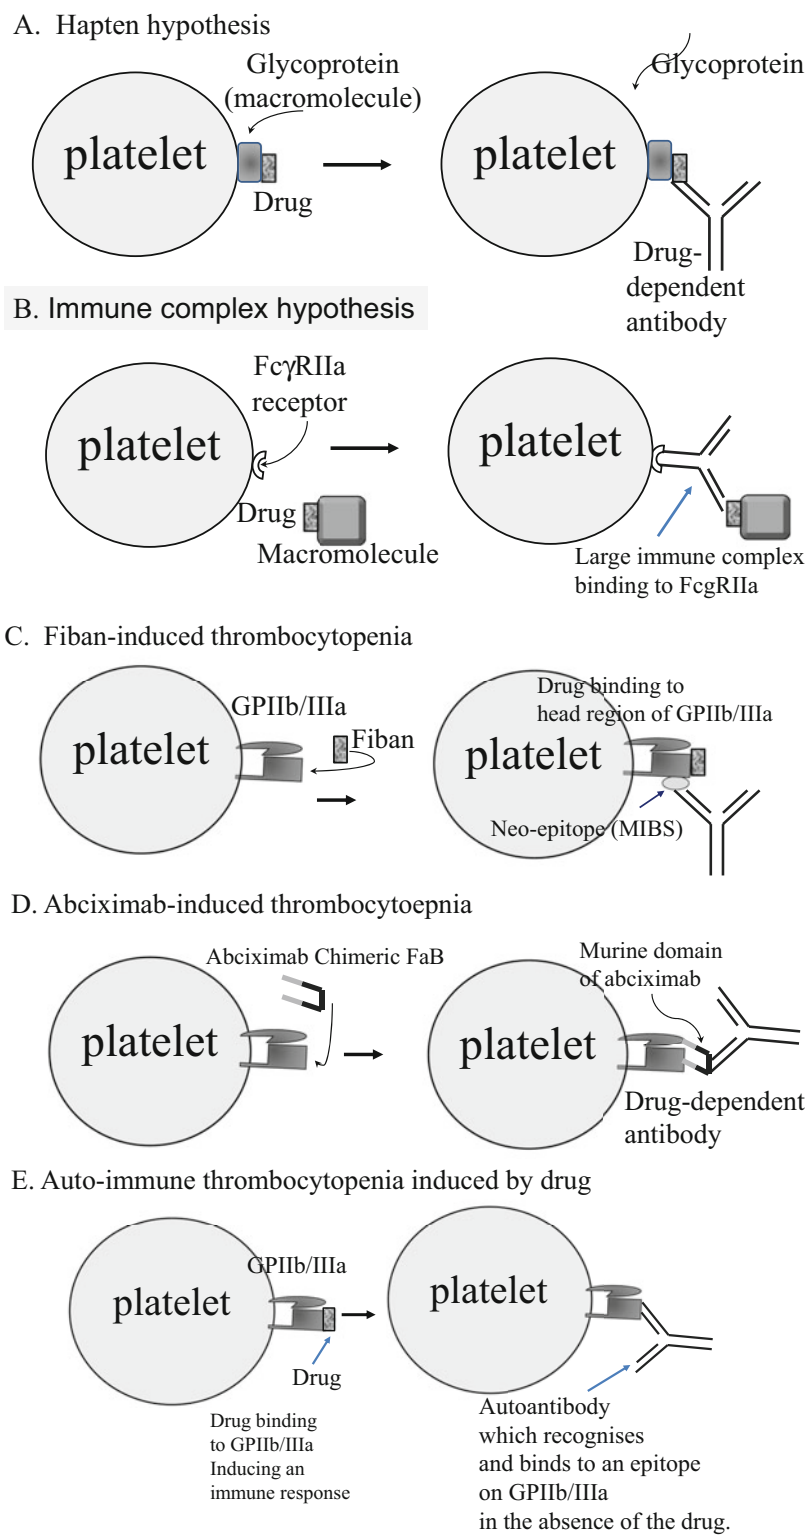

Fig. 2 Hypotheses of antibody-drug-glycoprotein interaction (continued). (**a**) *Hapten hypothesis:* Drug (so small to be immunogenic) binds to a macromolecule and induces an immune reaction resulting in the production of an antibody that binds strongly to the macromolecule only in the presence of the drug. (**b**) *Immune complex or* "*innocent-bystander*" *hypothesis*: As in the hapten hypothesis, the drug binds to a macromolecule and induces an immune response leading to the production of an antibody that the binds to the macromolecule-drug complex to form a large immune complex which then binds to platelet via its FcγRIIa receptor. (**c**) *Fiban-induced thrombocytopenia*: Fiban (drug) binds to the RGD site in the head region of platelet $\alpha_{IIb}\beta_3$ and induces a conformational change resulting in the emergence of a neoepitope (also known as MIBS) to which the drug-dependent antibody binds. (**d**) Abciximab-induced thrombocytopenia: Abciximab (a human-murine chimeric Fab) binds to the RGD recognition site at the head region of platelet $\alpha_{IIb}\beta_3$. The abciximab-dependent antibody has specificity for the murine domain of abciximab and it binds to this domain of the drug. (**e**) Drug-induced autoimmune thrombocytopenia. Anti-platelet autoimmune antibody binds to platelets in the absence of the drug

onset of thrombocytopenia is delayed till 5–8 days after drug administration (Jenkins et al. 1998).

The acute thrombocytopenia is believed to be due to natural occurring antibodies which have specificity for the murine sequences in the chimeric Fab (Curtis et al. 2002, 2004) (Fig. 2d). The delayed thrombocytopenia is mediated by an induced antibody that reacts with the platelet-bound drug which can persist for weeks (Curtis et al. 2004; Mascelli et al. 1998). Some of these antibodies may also cause platelet activation. However,

the antibody has also been found in healthy volunteers without previous drug exposure, but the antibody specificity is different as this antibody recognizes the papain cleavage site introduced during the manufacture of the drug (Curtis et al. 2002).

The thrombocytopenia caused by abciximab and other $\alpha_{IIb}\beta_3$ inhibitors can be severe and the potential bleeding risk is high, particularly in the clinical setting when patients also receive other anti-platelet agents (aspirin and clopidogrel) and frequently have undergone invasive revascularization procedures. However, the actual incidence of bleeding is surprisingly low. Nevertheless, thrombocytopenia in this cardiovascular setting is associated with unfavourable clinical outcomes including increased mortality rate, higher incidence of acute myocardial infarction and increased frequency of blood transfusions (Sinkovic and Majal 2015).

5. *Autoimmune thrombocytopenia induced by drugs*. Autoimmune haemolytic anaemia induced by drugs such as alpha methyldopa, procainamide and levodopa is well described (Petz 1993), but autoimmune thrombocytopenia caused by these and other drugs is less well characterized (Giner et al. 2003; Aster 2000; Landrum et al. 1994). Besides the three drugs, a number of other drugs have also been reported to induce autoimmune thrombocytopenia. These other drugs include (1) gold salts used previously to treat rheumatoid arthritis (Adachi et al. 1987; von dem Borne et al. 1986; Garner et al. 2002; Griem and Gleichmann 1995), (2) sulfamethoxazole (Aster 2000) and (3) monoclonal antibodies used to treat cancers such as rituximab (Ram et al. 2009), efalizumab (Warkentin and Kwon 2005) and trastuzumab (Drudi et al. 2010).

   In contrast to other DITPs, the platelet-specific antibodies produced react with platelets in the absence of the drug (Fig. 2e), similar to the autoantibodies in primary immune thrombocytopenia (ITP). In gold-induced thrombocytopenia, the antibodies were reported to have specificity for $\alpha_{IIb}\beta_3$ (von dem Borne et al. 1986), but one study found that antibodies in this condition are predominantly GPV specific (Garner et al. 2002). The mechanism whereby the drugs induce production of platelet-specific autoantibodies is still unclear although heavy metals have been shown to trigger autoimmunity in animal models (Griem and Gleichmann 1995). There is also a hypothesis that suggests that gold might interfere with macrophage processing of platelet membrane glycoproteins in such a way that "cryptic peptides" normally not seen by the immune system are generated and they trigger an immune response.
6. *Immune complex mechanism*. Before the 1980s, this mechanism, previously known as "innocent-bystander" mechanism, was thought to be the pathogenic process causing immune thrombocytopenia induced by quinine and most other drugs (Ackroyd 1953; Shuman 1958, 1964). Since the 1980s, however, there has been a large body of evidence against this mechanism being the cause of thrombocytopenia induced by quinine (Chong et al. 1983, 1991; Smith et al. 1987; Christie et al. 1985) and other drugs (Visentin et al. 1991; Gentilini et al. 1998). In the immune complex mechanism, the drug attached to a macromolecule (a plasma protein) and the antibody produced following drug sensitization reacts with the drug and macromolecule to form an immune complex which binds to platelets via their FcγRIIa receptors (Fig. 2b). Cross-linking platelet FcγRIIa receptors leads to platelet activation and adverse clinical consequences such as thrombosis (Chong and Isaacs 2009; Shantsila et al. 2009).

   The *immune complex mechanism* is applicable to thrombocytopenia induced by only a very small number of drugs, most notably heparin and similar drugs like pentosan polysulphate and protamine sulphate (Singla et al. 2013; Bakchoul et al. 2013; Goad et al. 1994; Schwartsmann et al. 1996; Pluda et al. 1993; Tardy-Poncet et al. 1994). The drug-dependent antibodies in protamine-induced thrombocytopenia have recently been characterized. Unlike the antibodies in HIT, the protamine-dependent antibodies appear to recognize a neoepitope on protamine (positively charged) after the drug has complexed with heparin or platelet surface glycosaminoglycan (both negatively charged); no plasma protein-like platelet factor 4 (PF4) is involved (Singla et al. 2013; Bakchoul et al. 2013). The immune complex formed induces platelet activation (e.g. serotonin release) via its binding to and cross-linking of platelet FcγRIIa receptors. This can be blocked by anti-FcγRIIa receptor monoclonal antibody, IV.3. Similarly, pentosan polysulphate (Goad et al. 1994), a negatively charged heparinoid, used in clinical trials for treatment of advanced malignancies such as human immunodeficiency virus-associated Kaposi's sarcoma has been reported to cause thrombocytopenia and thrombosis via the immune complex mechanism (Schwartsmann et al. 1996; Pluda et al. 1993; Tardy-Poncet et al. 1994).

HIT specifically will not be discussed in this chapter but will be covered in Greinacher et al. (2017).

Immune Processes that Increase in Platelet Clearance and Suppression of Platelet Production Resulting in Thrombocytopenia

1. *Increase in platelet clearance by drug-dependent antibodies and drug*

   It is widely believed that antibody-coated platelets are cleared rapidly by macrophages in the spleen and/or liver

by phagocytosis via Fc receptors. This notion probably arises from platelet kinetic studies in patients with ITP in the 1970s and 1980s which showed shortened platelet survival in ITP patients, increased platelet clearance and platelet turnover (Branehog et al. 1974; Harker 1970). The increased platelet turnover was believed to be a compensation for the increased platelet loss. However, there is no similar human data for DITP. We and Bougie et al. have provided data from murine DITP models (Bougie et al. 2010; Liang et al. 2010). Both groups showed rapid platelet clearance mediated by quinine-dependent antibodies in NOD-SCID mice. Human platelets injected immediately after administration of DITP serum/IgG and quinine were rapidly cleared from the circulation in these mice. The profound and rapid platelet clearance was seen uniformly with sera/IgG of seven patients with quinine-induced thrombocytopenia (Liang et al. 2010). This is consistent with the classical clinical picture of severe thrombocytopenia of rapid onset in patients with thrombocytopenia induced by quinine. In contrast, platelet clearance mediated by sera/IgG of primary immune thrombocytopenia (ITP) was more variable and gradual and less marked, in keeping with the heterogeneous nature of chronic ITP.

Platelet lysis by complement, T cells and radical oxygen species (ROS) and platelet clearance via hepatic Ashwell-Morrell receptors have been demonstrated in ITP (Najaoui et al. 2012; Olsson et al. 2003; Nardi et al. 2001, 2004; Li et al. 2015), but there is no evidence that these mechanisms also cause platelet destruction or clearance in DITP.

2. *Inhibition of platelet production by drug-dependent antibodies and drug*

Platelet kinetic/turnover study by Ballem et al. (1987) has shown decreased platelet production in a significant number of patients with chronic ITP, and this was attributed to megakaryocyte immuno-injury induced by anti-platelet antibodies (Piguet and Vesin 2002). These autoantibodies have specificity of GPIb-IX and/or $\alpha_{IIb}\beta_3$ which are present not only on platelets but also on megakaryocytes. It is not unexpected that these antibodies bind and inflict immuno-injury to megakaryocytes. Hoffman et al. (1985), Takahashi et al. (1999), McMillan et al. (2004) and Chang et al. (2003) demonstrated that ITP autoantibodies and monoclonal antibodies against platelet glycoproteins impaired proliferation and maturation of megakaryocytes in in vitro culture. ITP autoantibodies also blocked proplatelet formation and platelet release by cultured megakaryocytes (Li and Kuter 2001; Iraqi et al. 2015). However there are only limited number of studies on the effects of drug-dependent antibodies on megakaryocytes and platelet production. Greinacher et al. (2009) found that epifibatide-induced antibodies enhanced megakaryocyte apoptosis and impaired their proliferation and consequently prolonged the thrombocytopenia. We provided further evidence of immuno-injury to megakaryocytes by drug-dependent antibodies (Perdomo et al. 2013). We also demonstrated that the quinine-induced antibodies not only bound in the presence of quinine to megakaryocytes but they led to cell apoptosis, decreased cell vitality and increased cell death. Quinine-induced antibody binding also decreased significantly GPIX/GPIbα-bearing megakaryocytes (mature megakaryocytes) suggesting that antibodies impaired terminal megakaryocyte differentiation. Furthermore, when megakaryocytes were cultured in vitro with quinine-dependent antibody and quinine, proplatelet formation and platelet production were significantly inhibited (Perdomo et al. 2013).

Diagnosis of DITP

Clinical History of Drug Taking

A patient with an unexpected severe thrombocytopenia of sudden onset should prompt the clinician to consider the possibility of DITP. The patient should be asked about taking not only drugs that commonly cause thrombocytopenia but also herbal medicine, certain foods and tonics that may cause the same side effect. Quinine is present in some beverages such as tonic water and Schweppes Bitter Lemon (Korbitz and Eisner 1973; Brasic 2001). *Jui*, a Chinese herbal medicine, and food items such as tahini have also been reported to induce significant reduction in blood platelets (Arnold et al. 1998; Azuno et al. 1999; Ohmori et al. 2004).

Clinical Picture

The clinical picture varies with the inducing drug and the severity of the thrombocytopenia. For most DITP, the thrombocytopenia is severe and patients often present with extensive petechiae and bruises and oral blood blisters. Mucosal bleeding and occasionally intracranial haemorrhage may also occur. Fatal bleeding may happen but fortunately only infrequently. The onset is often abrupt, usually occurring 5–14 days after drug commencement, but early onset can occur if there is a previous drug exposure. In contrast, DITP caused by $\alpha_{IIb}\beta_3$ inhibitors (fibans and abciximab) presents with severe thrombocytopenia of sudden onset usually within 2–48 h of drug administration (Jubelirer et al. 1999; Curtis et al. 2002, 2004; Kilickiran et al. 2008). This often happens in patients with no previous exposure to the drug. However, in some patients the onset of

thrombocytopenia may be delayed until 5–8 days after abciximab administration (Jenkins et al. 1998).

For diagnosis of DITP, two sets of clinical data should be considered:

(a) Patient-specific data
(b) Information regarding the capacity of the drug to cause DITP

(a) *Patient-specific data*. The clinician should consider whether the temporal relationship of the drug commencement or the onset of thrombocytopenia is consistent with the drug causing DITP. The caring physician should also be aware of drug interactions that may cause DITP. A drug may increase in the plasma concentration of the metabolite of another drug which induces thrombocytopenia (Pandey and Yarlagadda 2012). This is particularly important in patients with impaired renal or liver functions. An example is dexamethasone and phenytoin (see above, Sect. "Drugs that Cause DITP"). Other drugs and co-morbid conditions that may cause thrombocytopenia should be excluded. Exclusion of other causes, particularly other concomitant drugs, may be difficult. Each suspected drug may be stopped one at a time, but this may take too long. It may be more practical to stop all suspected drugs until the offending drug is identified by a laboratory assay (see below) or a re-challenge with the suspected drug is carefully undertaken. Drug re-challenge is seldom carried out nowadays as it incurs too high a risk to the patient. Except for those drugs that cause autoimmune thrombocytopenia such as gold salts, procainamide and rituximab (von dem Borne et al. 1986; Ram et al. 2009; Singla et al. 2013), the return of the platelet to normal levels or baseline after cessation of the suspected drug provides direct confirmation of the diagnosis of DITP. Clinical criteria for diagnosis of DITP listed in Table 1 may be helpful.

(b) *Capacity of the suspected drug to cause DITP*. The potential of a suspected drug to cause thrombocytopenia should be sought from previous published studies (George et al. 1998) and certain websites, in particular the strength of evidence and the frequency of the drug causing DITP. A helpful website is http://www.ouhsc.edu/platelets. This website provides up-to-date information regarding all case reports of DITP and objective assessment of the level of evidence for a particular drug to cause DITP.

Table 1 General mechanisms of drug-induced immune thrombocytopenia

Major mechanisms	Hypotheses
Increase in platelet clearance	• Increased platelet clearance by *splenic and *hepatic macrophages • *Increased platelet clearance via hepatic Ashwell-Morrell receptors • *Platelet lysis by complements in circulation • #Platelet lysis by free oxygen radicals in circulation
Suppression of platelet production	• Suppression by megakaryocyte differentiation • Increase in megakaryocyte apoptosis • Inhibition of proplatelet production

Some evidence in *ITP or #thrombocytopenia associated with HIV but no direct evidence yet in DITP

Laboratory Diagnosis

The clinical diagnosis of DITP should be confirmed whenever possible by the detection of specific drug-dependent antibody using a laboratory assay. Before testing of drug-dependent antibodies, it is important to exclude the possibility of pseudothrombocytopenia (Barton and Stack 2009). Pseudothrombocytopenia is an in vitro artefact due to platelet clumping, leading to falsely low automated platelet counts with blood samples anticoagulated with ethylenediaminetetraacetic acid (EDTA). The incidence of pseudothrombocytopenia is increased from a baseline of 0.1–1.1 % in patients receiving abciximab. If pseudothrombocytopenia is confirmed by observation of platelet clumping on blood smear examination, the platelet count should be repeated by retaking of blood sample using a different anticoagulant such as citrate. In the absence of EDTA, the EDTA-dependent anti-platelet antibody does not induce platelet clumping.

There are two approaches to detect anti-platelet antibodies: (1) direct test and (2) indirect test (Chong and Keng 2000; Chong 2008; Heikal and Smock 2013).

1. *Direct test* detects antibody (IgG) on or associated with the patients' platelets. For this approach, the patient platelets are used and a fluorescence-labelled or enzyme-linked anti-human IgG or IgG/IgA/IgM secondary antibody is then used to detect the antibody on patient platelets often with flow cytometry or enzyme-linked immunosorbent assay (ELISA). Isotope-based assay such as the ^{51}Cr platelet lysis test is rarely used nowadays (Cimo et al. 1977) because of its lack of sensitivity and also the hazard of radioactivity it imposes.

   Normal platelets are used as a negative control. This method is suitable for detecting autoantibodies in primary ITP or DITP caused by drugs which induced autoimmune thrombocytopenia such as gold salt, methyldopa and rituximab (see Sect. "How Does the Drug-Dependent Antibody Bind to Platelets in the

Presence of the Drug?"). It has disadvantages of (a) being unable to determine the drug dependency of drug-related anti-platelet antibodies and thus unable to identify the offending drug and (b) the difficulty of obtaining enough patient platelets for testing if the thrombocytopenia is severe. This test is not usually used in DITP unless the patient has drug-induced autoimmune thrombocytopenia. One should however be aware that in some patients with DITP, a weak autoantibody is sometimes present in addition to the stronger drug-dependent antibody (Lerner et al. 1985; Bougie et al. 2006).

2. *Indirect test* detects antibody in the patient's serum. In the indirect test, patient serum is incubated with normal group O platelets in the presence or absence of the suspected drug (Heikal and Smock 2013). The antibody bound drug dependently to normal platelets is then detected using a fluorescence-labelled or enzyme-linked anti-human IgG or IgG/IgA/IgM secondary antibody as in the direct test. The indirect test is usually used for DITP. The blood sample should be collected after drug withdrawal when the suspect drug is no longer present in the patient serum. The assay can be repeated with each suspected drug to identify the offending drug. This is often dubbed as the "in vitro drug re-challenge". In some instances, the inducing agent is the drug metabolite, in which case the drug metabolite should be used instead of the parent drug. Positive result of the sample with normal platelets and patient serum in the absence of the suspected drug suggests that the antibody detected is an autoantibody. Another negative control used is normal platelets, plus normal serum and suspected drug; this is to exclude non-specific reactions such as drug autoflourescence.

The common methods commonly used to detect the drug-dependent antibody either by the direct or indirect test are:

1. Flow cytometry
2. ELISA
3. Monoclonal antibody-specific immobilization of platelet antigen (MAIPA) assay

The *MAIPA assay* has the advantage of being able to identify the platelet glycoprotein which is the target of the drug-dependent antibody. Each assay can be designed to detect IgG, IgM or IgA antibody separately or altogether.

Unlike autoantibody assays for diagnosis of ITP, drug-dependent antibody assays are often very helpful in the diagnosis of DITP, particularly for thrombocytopenia caused by quinine, quinidine, rifampicin, vancomycin, fiban and abciximab (Chong et al. 1983, 1991; Burgess et al. 2000; Asvadi et al. 2001; Bougie et al. 2002; Curtis et al. 2004). In our experience, these assays have high sensitivity and specificity. Flow cytometry is available in most clinical laboratories although MAIPA may be technically demanding and its availability may be somewhat restricted.

Management

The immediate step in the management of DITP is the cessation of the suspected inducing drug or in some cases the herbal medicine, tonic or food item. It must be noted that sometimes two drugs may cause DITP at the same time and both drugs should be withdrawn (Anand and Chauhan 2011). After drug withdrawal, the drug-dependent antibody does not bind to platelets or megakaryocytes even though the antibody may persist for several months thereafter. High-dose corticosteroid such as prednisone (1–2 mg/kg) and IVIg (2 g/kg over 2–5 days) is often administered when the thrombocytopenia is severe and risk of bleeding high (Chong 1991; Aster et al. 2009; George et al. 2006). The thrombocytopenia invariably resolves in 1–2 weeks or longer if the drug has a prolonged plasma half-life or there is impaired renal function. Therefore it is difficult to know if these treatments are efficacious. However, Liang et al. (2010) provided evidence in a murine model of DITP that IVIg was partially effective in preventing rapid platelet clearance by drug-dependent antibodies and improving platelet survival. The mechanism whereby IVIg exerts its effect is unclear in DITP; it may induce Fc receptor blockage or may impair antigen-presenting cell processing (Chong and Chong 2010).

It should be noted that if serious bleeding such as intracranial haemorrhage occurs when the platelet count is markedly low within the first few days after drug withdrawal, there is no effective treatment that will increase the platelet count. Nevertheless, platelet transfusion is usually given, preferably after Fc receptor blockage by IVIg infusion, but the transfused platelets are often rapidly cleared. Red cell transfusion should also be administered if the Hb level is 80 g/L or lower. Anti-fibrinolytic therapy such as tranexamic acid is helpful. Dialysis or plasma exchange to remove the offending drug may be needed in the case of a drug with very long plasma half-life or in patients with severely impaired renal function. In patients with DITP, in contrast to ITP, corticosteroid should be abruptly stopped when the thrombocytopenia has resolved.

In patients with DITP due to $\alpha_{IIb}\beta_3$ inhibitors, there may be other management issues. These drugs are frequently administered to patients with high-risk acute coronary syndrome or with incipient/overt heart failure. Thrombocytopenia in these patients is associated with increased mortality

Table 2 Hypotheses of platelet-antibody-drug interactions in DITP

Hypotheses	Descriptions
Hapten mechanism	The drug is too small to be immunogenic. It binds covalently to an autologous protein and elicits an immune response. The antibody produced recognizes the specific protein only when the hapten is attached. A possible example is penicillin-induced thrombocytopenia (Fig. 2a)
Quinine-type DITP	1. *Hybrid paratope* mechanism. The drug binds to the CDR domain of a naturally occurring antibody that has a weak affinity to the platelet GPIIbβ. It induces a conformational change in the CDR of the antibody transforming the antibody to one that binds to platelet GPIIbβ with high affinity and specificity (Fig. 1a) 2. *Neoepitope* mechanism. The drug binds weakly and non-covalently to a hyperflexible domain of a platelet receptor (GPIX or GPIIIa), inducing emergence a cryptic or new epitope never before seen by the immune system and eliciting an immune response. The antibody produced recognizes the neoepitope and binds with high affinity and specificity (Fig. 1b)
Fiban-induced DITP	Fiban (drug) binds platelet $\alpha_{IIb}\beta_3$ near the RGD binding site, inducing a conformational change and formation of a neoepitope (MIBS) (see text) to which antibody binds (Fig. 2c)
Abciximab-induced DITP	The patient's naturally occurring antibody recognizes and binds to a mouse sequence of abciximab chimeric Fab which is attached to platelets (Fig. 2d)
Autoimmune thrombocytopenia induced by drugs	Drug ingestion affects the immune system in such a way that autoimmunity results. Anti-platelet autoantibody produced reacts with platelets in the absence of the drug (Fig. 2e)
Immune complex mechanism	The antibody binds to a plasma protein-drug complex and the immune complex binds to the platelet via its FcγRIIIa receptor, and the platelet is destroyed/activated as an innocent bystander (Fig. 2b)

and other complications. Red cell transfusion should be considered at Hb levels lower than 80 g/L to improve tissue oxygen delivery, particularly in the setting of coronary ischaemia. In addition to the management described above, withdrawal of anti-platelet agents and anticoagulants, if clinically appropriate, should be considered in the event of serious bleeding (Tables 2 and 3).

Future Directions

Quinine-induced thrombocytopenia is the prototype of DITP caused by most drugs. Hybrid paratope hypothesis is the proposed mechanism supported by strong experimental evidence. Yet, there are still unanswered questions regarding this hypothesis such as:

(1) How does quinine sensitization occur? (2) Is the immunogen a complex resulting from weak, non-covalent binding of quinine to GPIIb? (3) Does the hybrid paratope hypothesis also apply to quinine-dependent antibodies that have specificity for GPIbα, GPIX and GPIIIa?

Answers to these questions await future studies. Further studies are also required to confirm the hypothesis of fortuitous binding of quinine to the B cell receptor as the initiating event for the production of quinine-induced anti-platelet antibodies.

There is an unmet clinical need for an effective treatment when serious bleeding occurs before platelet recovery in patients with DITP, particularly when the offending drug has a prolonged plasma half-life or drug clearance is delayed due to impaired renal or liver functions. Future research may lead to development of efficacious treatments that will rapidly increase circulating platelets during the thrombocytopenic phase of DITP.

The two lists of drugs overlap with a number of drugs appearing on both lists, but some drugs appear in one but not in the other

Conclusion

In recent years, there has been considerable new knowledge of DITP pathogenesis, particularly thrombocytopenia caused by quinine (the prototype drug) and $\alpha_{IIb}\beta_3$ inhibitors (fibans and abciximab). Recent research has shown that the drug-dependent antibody binds not only to platelets inducing their rapid clearance but also to megakaryocytes causing apoptosis, inhibiting their maturation and platelet production. The binding sites of human drug-dependent antibodies, particularly quinine-dependent antibodies, have been fine mapped to a hyperflexible region in the membrane-proximal domain of GPIX (R110–Q115) and PSI domain of GPIIIa (A50–D66). However, the most exciting recent advance in DITP research is the finding of structural changes in the CDRs of the murine monoclonal quinine-dependent antibodies induced by quinine binding converting them to the antibodies that bind with high affinity and specificity to their target platelet glycoprotein (GPIIb). This finding leads to the unconventional hybrid paratope hypothesis. The challenge in future research is to reconcile this finding to previous observations in DITP.

Diagnosis of DITP is usually made clinically based on clinical diagnostic criteria. Whenever possible, the clinical diagnosis of DITP should be confirmed by detection of the drug-dependent antibodies. The crucial immediate step in DITP treatment is prompt cessation of the suspected drug (s) and thrombocytopenia invariably resolves within 1–2 weeks. Even though their efficacy is still unclear, high-dose prednisone and IVIg are usually administered during the period of severe thrombocytopenia because of the high risk of potentially catastrophic bleeding. Glucocorticosteroid is stopped abruptly once thrombocytopenia resolves.

Take-Home Message Boxes

Diagnosis of Drug-Induced Immune Thrombocytopenia (DITP)

- Clinical diagnosis:
  - Patient-specific data
    History of drug taking consistent with diagnosis of DITP
    History that satisfies one or more clinical diagnostic criteria (Table 4)
  - Consider the capacity of the drug to cause DITP.
- Laboratory diagnosis:
  - Detection of drug-dependent antibody or autoantibody

Table 4 Clinical diagnostic criteria

Criteria	Description
1	Suspected drug is commenced 5–14 days before the onset of thrombocytopenia. After suspected drug withdrawal, platelet count returns to normal or baseline levels
2	Suspected drug is the only drug administered before the onset of thrombocytopenia or other drugs are continued/reintroduced after withdrawal of suspected drug. Continuation/reintroduction of other drugs does not hinder platelet recovery after cessation of the suspected drug
3	Other causes of thrombocytopenia are excluded clinically
4	Re-challenge with the suspected drug results in prompt recurrence of thrombocytopenia or the offending drug is identified by detection of the specific drug-dependent antibody by a laboratory assay
	Level of evidence Definite: Criteria 1, 2, 3 and 4 met Probable: Criteria 1, 2 and 3 met Possible: Criteria 1 met Unlikely. Criteria 1 not met

Management of Drug-Induced Immune Thrombocytopenia (DITP)

- Cease the offending drug.
- If thrombocytopenia is severe and bleed risk is high/bleeding has occurred, commence high-dose corticosteroid therapy and/or IVIg.
- If bleeding is severe,
  - Give platelet transfusion preferably after IVIg has provided Fc receptor blockade.
  - Start anti-fibrinolyitc agent such as tranexamic acid.
- Give red cell transfusion if Hb drops below 80 g/L.

Heparin-Induced Thrombocytopenia

Andreas Greinacher, Tamam Bakchoul, Adam Cuker, and Theodore (Ted) E. Warkentin

Abstract

Heparin-induced thrombocytopenia (HIT) is an adverse prothrombotic disorder caused by an immune response to complexes of platelet factor 4 and polyanions. The clinical relevance of HIT results from the wide use of heparin, which is the reason that the absolute number of patients affected by HIT is high. HIT is currently the most frequent immune-mediated adverse drug reaction affecting blood cells.

This chapter will address the clinical presentation of HIT and summarize recent findings on its pathogenesis including the concept that HIT is likely a misdirected bacterial host-defense mechanism. Description of laboratory tests for HIT and an outline on current recommendations for management of affected patients provide information relevant for daily clinical practice.

Introduction

Thrombocytopenia is relatively common in hospitalized patients, especially in the critically ill. Although a falsely low platelet count can be caused by laboratory artifact ("pseudothrombocytopenia"), true thrombocytopenia has multiple potential explanations that can be classified in five general ways (Table 1). Timing of the onset of thrombocytopenia and its severity differ considerably among different causes (Table 2). Most immune-mediated thrombocytopenias are associated with an increased risk for bleeding, while thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia (HIT) increase the risk for thrombotic complications (although patients with TTP often present with bruising and mucosal bleeding). Table 3 summarizes the main features of immune thrombocytopenias.

Nonimmune Heparin-Associated Thrombocytopenia

Heparin binds to platelets, resulting in mild platelet activation (Salzman et al. 1980; Chong and Ismail 1989) and an enhanced aggregation response to several agonists (Chong

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_53

Table 1 Six general explanations for thrombocytopenia, including pseudothrombocytopenia

Explanation	Comment	Examples
Pseudothrombocytopenia	Antibody-mediated platelet clumping that occurs ex vivo, i.e., spurious thrombocytopenia	EDTA-induced pseudothrombocytopenia; platelet satellitism (platelet binding to leukocytes)
Hemodilution	Abrupt platelet count fall due to administration of fluids or blood products	Early postoperative thrombocytopenia
Hypersplenism	Splenomegaly may require imaging studies to detect; concomitant leukopenia and (to lesser extent) anemia are usually present	Cirrhosis-associated portal hypertension
Decreased platelet production	Usually there is concomitant leukopenia and anemia (a notable exception is certain types of hereditary thrombocytopenia)	Myelodysplasia; aplastic anemia; marrow infiltration by metastatic cancer; alcohol-induced thrombocytopenia
Platelet consumption	Accelerated platelet clearance due to pathologically increased platelet activation or other poorly defined mechanisms of increased platelet clearance	Disseminated intravascular coagulation; septicemia; multiorgan system failure; hemophagocytic syndrome
Platelet destruction	Accelerated platelet clearance due to pathological mechanisms that target platelets, especially due to platelet-reactive antibodies	Autoimmune thrombocytopenic purpura; HIT; drug-induced immune thrombocytopenia; TTP/HUS

EDTA ethylenediaminetetraacetic acid, *HIT* heparin-induced thrombocytopenia, *TTP/HUS* thrombotic thrombocytopenic purpura/hemolytic uremic syndrome

and Castaldi 1986; Holmer et al. 1980). This effect is pronounced in patients with infection and peripheral vascular disease (Mikhailidis et al. 1985; Burgess and Chong 1997). Unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), and fondaparinux induce outside-in signaling via the glycoprotein (GP) IIb-IIIa complex (Gao et al. 2011), which potentiates the effect of low-dose adenosine diphosphate (Gao et al. 2011). Whereas UFH and fondaparinux had similar proactivating effects in one study (Gao et al. 2011), another observed much less pronounced effects of LMWH compared to UFH (Barradas et al. 1987).

In vivo these proaggregatory effects can explain a moderate decrease in platelet count after therapeutic-dose UFH, less with LMWH (Horne III 2007), most likely due to mild platelet aggregation in vivo, with platelet aggregates cleared by the reticuloendothelial system (Balduini et al. 1993; Blauhut et al. 1985). This phenomenon might explain why an overall lower frequency of thrombocytopenia was seen in critically ill patients who received LMWH versus UFH in a randomized trial (Williamson et al. 2013). However, the frequency of nonimmune heparin-associated thrombocytopenia is difficult to discern, as there is no diagnostic test and hospitalized patients usually have alternative explanations for an early platelet count fall.

Immune HIT

Clinical Features

Thrombocytopenia

Typical- vs. Rapid-Onset HIT The platelet count usually falls beginning 5–10 days after the start of an immunizing exposure to heparin, most often intra/perioperative heparin (Fig. 1) (Warkentin and Greinacher 2003). The platelet count then declines substantially (usually >50 %) over the next 2–3 days. This pattern ("typical-onset" HIT) is seen in approximately 60–70 % of patients (Warkentin and Kelton 2001b). In 25–30 % of cases, onset of thrombocytopenia occurs within 24 h of starting heparin ("rapid-onset HIT") (Warkentin and Kelton 2001b); these patients have been previously exposed to heparin within the recent past (usually within the last month but sometimes up to 3 months). This profile is explained by heparin being restarted in a patient who already has circulating HIT antibodies, accounting for the abrupt platelet count fall. The strong association with recent prior heparin exposure reflects the striking transience of HIT antibodies (Warkentin and Kelton 2001b).

Delayed-Onset HIT Sometimes, thrombocytopenia begins several days after stopping the immunizing course of heparin or worsens in spite of stopping heparin ("delayed-onset HIT" or "autoimmune-like" HIT) (Warkentin and Kelton 2001a; Rice et al. 2002; Greinacher 2014). These patients have high-titer HIT antibodies that are somewhat heparin-"independent", i.e., the patient serum activates platelets strongly in vitro without requiring pharmacologic heparin.

Persisting HIT Rarely, thrombocytopenia persists for at least 1 month after stopping heparin (~1 % of patients) (Kopolovic and Warkentin 2014); in contrast, instances of platelet count recovery in spite of continued heparin have also been reported (Warkentin et al. 2013). These clinical extremes reflect differences in persistence of HIT antibodies with and without heparin-independent platelet-activating properties. In general, the median time to platelet count

Table 2 Thrombocytopenia (TP) in in-hospital patients in relation to the time course of platelet count

	Thrombocytopenia at admission	Normal platelet count at admission with initial platelet count fall and persistent thrombocytopenia for more than 4 days	New *rapid* platelet count fall after platelet recovery from on day 4 with no new major intervention	New *slow* platelet count fall after platelet recovery after day 4

Bleeding risk: ⇧⇧—strongly increased, ⇧—moderately increased, ⇔—not increased, ⇩—prothrombotic risk)

recovery ($>150 \times 10^9$/L) is 4 days, with 90 % showing platelet count recovery within 1 week (Warkentin 2013a; Greinacher et al. 2009; Warkentin et al. 2013).

Spontaneous HIT Rarely, a disorder occurs that clinically and serologically resembles HIT, except that there is no proximate heparin exposure; patients often have preceding infection or knee replacement surgery, suggesting that bacterial or knee cartilage-derived polyanions or free DNA/RNA rarely can trigger a strong HIT-mimicking immune response (Warkentin et al. 2008a, 2014).

Table 3 Immune thrombocytopenias

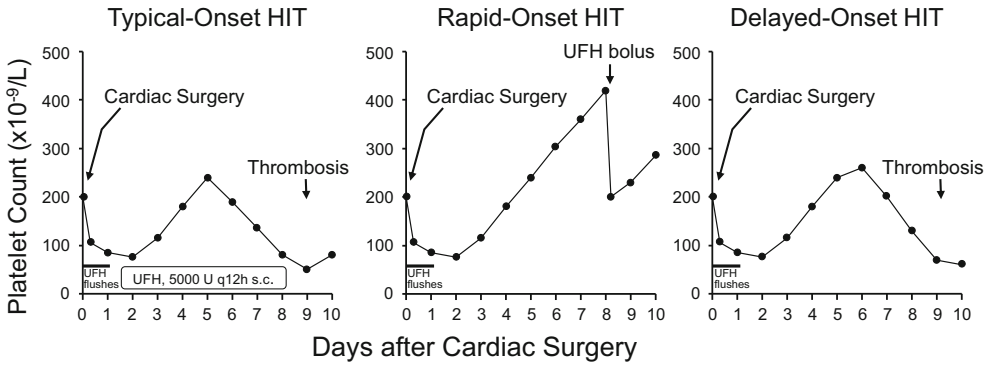

Fig. 1 Timing of onset of HIT. Temporal profiles of onset of HIT. Cardiac surgery patients are shown; thus, day of surgery = day 0, reflecting (immunizing) intraoperative exposure to UFH (unfractionated heparin). Modified from Warkentin TE and Greinacher A. Heparin-induced thrombocytopenia and cardiac surgery. *Ann Thorac Surg* 2003; 76 (6): 2121–2131 (Warkentin and Greinacher 2003)

Severity of Thrombocytopenia The thrombocytopenia of HIT is usually moderately severe (median platelet count nadir, ~60 × 10^9/L; Fig. 2) (Warkentin 2006), only rarely falling to <10 × 10^9/L; this contrasts from classic drug-induced immune thrombocytopenia (e.g., quinine, vancomycin), where the platelet count nadir is usually <20 × 10^9/L (Warkentin 2003, 2007). Sometimes, the platelet count falls by >50 %, but because of postoperative thrombocytosis, the platelet count nadir remains >150 × 10^9/L (Warkentin 2004).

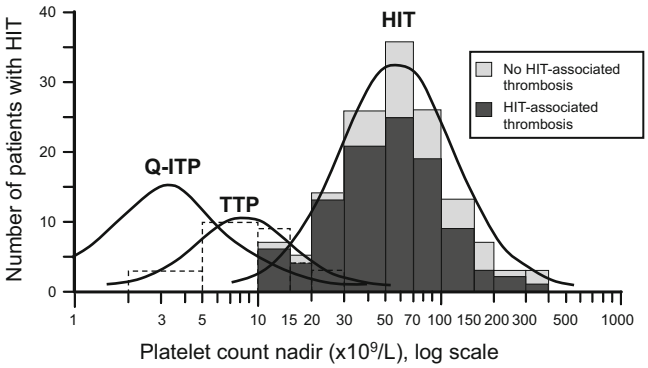

Fig. 2 Distribution of platelet count values in different disorders. HIT (with or without associated thrombosis), quinine-induced immune thrombocytopenia (Q-ITP), and thrombotic thrombocytopenic purpura (TTP) with absent ADAMTS-13 activity (dITP, TTP). Thrombotic Complications

Thrombotic complications occur in 50–70 % of patients with serologically confirmed HIT (Warkentin 2003; Warkentin et al. 2013). Thrombosis can be venous, arterial, and/or microcirculatory. The overall ratio of venous/arterial thrombosis is ~4:1. Bleeding is uncommon.

Venous Thrombosis

Lower-limb deep-vein thrombosis (DVT), sometimes bilateral, is the most common HIT-associated thrombotic complication; pulmonary embolus is also relatively common (Warkentin 2013a). When microvascular thrombosis occurs in a limb with DVT, *phlegmasia cerulea dolens* (severe venous limb ischemia) can progress to *venous limb gangrene* (the most common cause of limb amputation in HIT) (Warkentin et al. 1997; Warkentin 2015c). Progression of DVT to venous limb gangrene typically occurs after stopping heparin and is strongly associated with vitamin K antagonist (VKA) therapy; patients have a characteristic "supratherapeutic" INR (>4) (Warkentin et al. 1997; Srinivasan et al. 2004). The pathogenesis is VKA-induced protein C depletion, with continuing HIT-associated thrombin generation, leading to microthrombosis.

Venous thrombosis can also occur in upper limb veins (at central venous catheter sites) (Hong et al. 2003), cerebral veins/dural sinuses (Meyer-Lindenberg et al. 1997), mesenteric veins, and adrenal veins (Arthur et al. 1985; Warkentin et al. 2015a); this last complication results in adrenal hemorrhage which—when bilateral—can cause life-threatening adrenal failure.

Arterial Thrombosis

Arterial thrombosis in HIT usually involves large arteries such as the distal aorta and lower-limb arteries (acute limb ischemia with absent pulses) (Rhodes et al. 1973); stroke, myocardial infarction, upper limb ischemia, and bowel infarction are other frequent events (Warkentin 2013a).

Microthrombosis

Overt (decompensated) DIC occurs in 10–20 % of patients with HIT (Warkentin 2013a) usually with severe thrombocytopenia and coagulopathy (e.g., elevated INR). Fibrin D-dimer levels are typically very high, but overt hypofibrinogenemia is uncommon, probably because fibrinogen levels are expected to be elevated in the postoperative patient who gets HIT. DIC is a risk factor for microthrombosis and limb ischemic necrosis, partly because of inappropriate direct thrombin inhibitor dose reduction or interruption because of falsely high APTT values (Warkentin 2015c) ("APTT confounding").

Other HIT-Associated Thrombotic Complications

Thrombosis of intravascular prostheses and hemodialysis circuit clotting can indicate HIT (Warkentin 2015a) as do necrotizing skin lesions at UFH or LMWH injection sites (Warkentin 1996a). Rarely, HIT is associated with skin necrosis in the absence of subcutaneous injections or VKA therapy (Tassava and Warkentin 2015).

Acute Systemic (Anaphylactoid) Reactions

Acute systemic (or anaphylactoid) reactions present as fever/chills, tachycardia, flushing, blood pressure changes, headache, chest pain, and dyspnea, beginning 5–30 min after an IV bolus of heparin or 30–120 min post-subcutaneous LMWH injection. Patients have circulating HIT antibodies, and there is a concomitant abrupt platelet count fall (Warkentin and Greinacher 2009) postinjection. Transient global amnesia has also been reported (Warkentin et al. 1994b).

Pathogenesis

HIT is mediated by platelet-activating IgG antibodies induced by polyanions, most often heparin (Fig. 3). Neoepitopes are formed on the cationic chemokine, platelet factor 4 (PF4; CXCL4), when PF4 forms complexes with polyanions (Amiral et al. 1992). PF4 is a positively charged tetrameric 35 kDa protein stored in platelet α-granules and secreted during platelet activation. PF4 binds to endothelial cell heparan sulfate, from which it detaches with heparin infusion.

The HIT Antigen and Antibodies

PF4 PF4 binds to platelets, e.g., via chondroitin sulfate. PF4 binding to heparin is greatest at an optimal stoichiometric ratio (PF4/heparin ~2:1 (Greinacher et al. 2008)). Binding of heparin to PF4 neutralizes its strong positive charge (Rauova et al. 2006), allowing two PF4 tetramers to come into close proximity (Greinacher et al. 2006). Besides the stoichiometric considerations, polyanion composition, chain length, and degree of sulfation also affect binding to PF4 (Horne and Chao 1990; Greinacher et al. 1995). In most clinical settings, plasma UFH and especially LMWH concentrations are in excess to the optimal concentration (Greinacher et al. 2008); this changes when a large number of activated platelets release PF4, helping explain why anti-PF4/heparin antibodies are more frequently produced in patients undergoing major surgery (Warkentin et al. 1995; Visentin et al. 1996) compared to medical patients.

The neoepitopes to which anti-PF4/heparin antibodies bind are only exposed on PF4 in its tetrameric form (Sachais et al. 2012), probably requiring at least three PF4 monomers (Block et al. 2014). A crucial requirement for a PF4/polyanion complex to expose neoepitopes is formation of at least three bonds between PF4 and polyanion. This induces a structural change in PF4, increasing to >30 % the content of antiparallel β-sheets (Brandt et al. 2014). Further, the reaction must release enough energy to support a further conformational change in PF4. Only heparin molecules with chain length ≥10 monosaccharides fulfill these requirements. Short heparins bind to only one PF4 tetramer, whereas long heparins bind to at least two PF4 tetramers. When two PF4 tetramers are brought closely together, the individual clouds of positive charge around each single PF4 tetramer fuse into one large cloud surrounding all of the PF4 molecules within the cluster (Nguyen et al. 2015). This charge redistribution provides the additional energy needed to expose the neoantigens. Formation of ultralarge PF4-polyanion complexes occurs especially with UFH (vs. LMWH), and does not occur with the

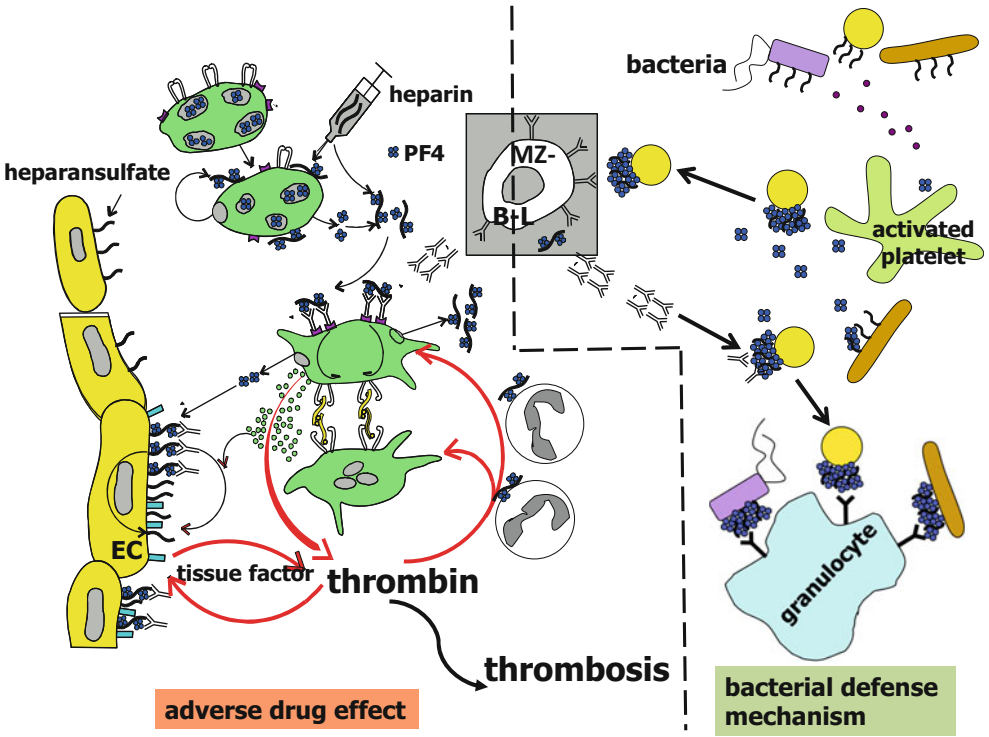

Fig. 3 Pathogenesis of heparin-induced thrombocytopenia: *left side*, in HIT the combination of anticoagulant treatment and thrombocytopenia paradoxically results in thrombosis and not in bleeding. Platelet factor 4 (PF4) released from platelet α-granules forms immunogenic PF4/heparin complexes. (*Marginal zone*) B lymphocytes generate IgG that recognize the PF4/heparin complexes; the Fc-parts of the IgG bind to platelet FcγIIa receptors, resulting in Fc receptor clustering and consequent strong platelet activation and aggregation. Platelet-derived microparticles that accelerate thrombin generation are produced. In addition, HIT antibodies directly or indirectly activate endothelial cells, and can also activate monocytes, resulting in additional tissue factor expression. Resulting increased thrombin generation leads to increased risk for thrombosis in HIT, providing a rationale for treatment that reduces thrombin generation. *Right side*: PF4 also binds to negatively charged molecules on bacteria, forming PF4/polyanion complexes, which express the same neoepitopes as on PF4/heparin complexes. PF4-coated bacteria also trigger PF4/polyanion antibody production. By the resulting antibodies, bacteria are opsonized and phagocytosed from granulocytes. The evolutionary advantage of this immune defense mechanism is that PF4 binds to different bacteria and PF4/polyanion antibodies can thereby bind to and opsonize pathogens the immune system has not seen before. Misdirection of this bacterial host-defense mechanism, in which heparin-coated platelets mimic bacteria, may underlie the development of HIT. Taken with modifications from Greinacher A, New England Journal Medicine 2015 (Greinacher 2015)

pentasaccharide, fondaparinux (Rauova et al. 2005). Nevertheless, fondaparinux can bind to PF4 (Greinacher et al. 2006) and induces anti-PF4/heparin antibodies to a similar extent as LMWH (Warkentin et al. 2005a). Potentially, fondaparinux interacts with PF4 synergistically with endothelial cell heparan sulfate or platelet membrane chondroitin sulfate, thereby inducing the immunogenic antigen. However, as multimolecular PF4/fondaparinux complexes do not form, fondaparinux only rarely causes HIT.

PF4 has been crystallized with fondaparinux and the Fab fragments of the HIT-antibody like monoclonal antibody KKO. The information obtained from these complexes further indicates that PF4 undergoes a certain structural change after binding to polyanions (Cai et al. 2015).

Other polyanions can also bind PF4 and induce the same conformational changes (Visentin et al. 1997; Greinacher et al. 1992). Especially relevant are PF4 interactions with nucleic acids (DNA, RNA) (Jaax et al. 2013). First, this could explain spontaneous HIT syndrome after knee replacement surgery (RNA release) (Warkentin et al. 2014). Second, nucleic acid-based drugs (aptamers, siRNAs) can bind to PF4 and induce thrombocytopenia, although it remains unresolved whether this reflects direct platelet activation by nucleic acids (Flierl et al. 2015) or in some situations a secondary immune mechanism.

Other Autoantigens Besides PF4 In virtually all patients with HIT, anti-PF4/heparin antibodies are detected. It has been suggested that non-PF4 antigens, such as interleukin-8 (IL-8) or neutrophil-activating peptide 2 (NAP-2), could be also involved (Amiral et al. 1996a; Regnault et al. 2003), but this remains unproven. Unlike anti-PF4/heparin antibodies, binding of anti-IL-8 and anti-NAP-2 antibodies to their respective antigens occurs even without heparin, but is enhanced by heparin. These antibodies tend to occur in patients with autoimmunity, cancer, infection, and trauma.

HIT as Misdirected Host Pathogen Defense Mechanism (Fig. 3) PF4 has a role in labeling pathogens for the immune system, as it binds in a charge-dependent fashion to gram-positive and gram-negative bacteria. Hereby, PF4 exposes the same antigenic complexes on bacteria as are formed with heparin on the platelet surface (Krauel et al. 2011). In a mouse model of *polymicrobial* bacterial sepsis, mice generated PF4/heparin-reactive antibodies (Krauel et al. 2011) without addition of heparin. Furthermore, an association between periodontal disease (frequently associated with bacteremia) and anti-PF4/heparin antibodies has been observed (Greinacher et al. 2011). Due to the ability of PF4 to bind to anionic cell walls of diverse bacterial species, anti-PF4/polyanion antibodies can even bind to bacteria not previously encountered by the host immune system.

Heparin-dependent antibodies are polyclonal and bind to multiple epitopes on PF4/heparin complexes (Li et al. 2002; Ziporen et al. 1998). Not all antibodies are able to activate platelets, however, and those features characterizing "pathogenic" (platelet-activating) antibodies remain largely uncertain. Platelet activation by anti-PF4/polyanion antibodies depends on the Fc part of the antibodies and can only be mediated by IgG, which bind through their Fc moieties to platelet FcγIIa receptors (FcγRIIa) (Kelton et al. 1988; Chong et al. 1989; Newman and Chong 2000). Cross-linking of the Fc receptors triggers platelet activation, release of platelet granules (containing PF4) and formation of platelet-derived microparticles, and ultimately platelet aggregation (Fig. 3) (Chong et al. 1981, 1982; Warkentin et al. 1994a). IgM antibodies might cause thrombocytopenia (although this is unproven), but most studies indicate they lack procoagulant effects (Juhl et al. 2006; Lindhoff-Last et al. 2001; Greinacher et al. 2007; Warkentin 2003; Amiral et al. 1996b). Some subclasses of anti-PF4/heparin IgG are more common ($IgG_1 > IgG_3 > IgG_2 > IgG_4$) (Amiral et al. 1996c). For induction of HIT, the quantity of IgG antibodies is more important than their subclass. Once the process of HIT-antibody-induced platelet activation begins, more PF4/heparin complexes are formed and bind to the platelet surfaces, thereby allowing more heparin-dependent antibodies to bind (Newman and Chong 2000). This self-enhancing chain reaction produces intense platelet activation (Chong et al. 1981). Generation of platelet-derived microparticles and other procoagulant materials leads to activation of blood coagulation pathways, thrombin generation, and thrombus formation ("hypercoagulability" of HIT) (Warkentin et al. 1994a; Warkentin 1996b).

Role of Endothelial Cells and Monocytes

Anti-PF4/polyanion antibodies also recognize PF4 bound to endothelial cell heparan sulfate, causing immunoinjury (Cines et al. 1987; Visentin et al. 1994). This occurs independent of FcγRIIa and exogenous heparin (Cines et al. 1987; Visentin et al. 1994). As human PF4 (hPF4) transgenic mice (expressing hPF4 on their endothelial cells, but lacking FcγRIIa receptors on their platelets) do not develop thrombosis after anti-hPF4/heparin antibodies are administered, direct endothelial cell activation alone is likely not a major mechanism of thrombosis in HIT. However, anti-PF4/polyanion antibodies also bind to PF4/thrombomodulin, thereby inhibiting activation of protein C, further increasing prothrombotic imbalance in HIT (Kowalska et al. 2011).

Anti-PF4/polyanion antibodies also bind to PF4/proteoglycan (chrondroitin sulfate) complexes on monocytes (Rauova et al. 2010), inducing monocyte activation via FcγRI (Kasthuri et al. 2012), resulting in expression of tissue factor and enhanced procoagulant activity (Arepally and Mayer 2001).

FcγRIIA Polymorphism

The only Fc receptor expressed by platelets is FcγRIIA, which has an Arg/His_{131} polymorphism. The role of this polymorphism as a risk factor for HIT is controversial (Brandt et al. 1995; Burgess et al. 1995; Denomme et al. 1997; Arepally et al. 1997; Bachelot-Loza et al. 1998; Carlsson et al. 1998). Two major studies are consistent, however, in showing FcγRIIA 131RR increases risk for thrombosis in HIT. One was a large cohort study (Carlsson et al. 1998), and the other a combination of in vitro studies and a cohort study (Rollin et al. 2015) showing that due to the lower affinity of FcγRIIA 131RR for monomeric IgG (especially IgG_2), the threshold for platelet activation by PF4/polyanion/IgG immune complexes is lower (because monomeric IgG cannot block the receptor).

Immune Response

The immune response of HIT has several atypical features. Anti-PF4/polyanion IgG antibodies are generated as early as 4 days (median, day 6) (Greinacher et al. 2005a; Selleng et al. 2010; Pouplard et al. 1999; Warkentin et al. 2000), even in patients receiving heparin for the first time. Further, IgM and IgA antibodies can be generated contemporaneously (i.e., without IgM precedence), and with IgG being the predominant class of antibodies formed (Greinacher et al. 2009; Warkentin et al. 2009b). Further, antibody titers decrease rapidly within several weeks (Warkentin and Kelton 2001b; Greinacher et al. 2009), which is also unusual for a secondary immune response.

Increasingly, "spontaneous HIT syndrome" (Warkentin et al. 2014) is observed in which patients develop an illness

clinically and serologically mimicking HIT despite no proximate heparin exposure. Patient serum contains strongly reacting anti-PF4/heparin IgG with autoantibody-like features, which recognize platelet-bound PF4 in the absence of pharmacologic heparin (Warkentin and Kelton 2001a; Socher et al. 2008; Prechel et al. 2005; Padmanabhan et al. 2015a). The history of recent bacterial infection or knee replacement surgery points to a pathogenesis involving PF4/bacteria or PF4/nucleotide complexes that induce primary immunization and, when boosted, (rarely) spontaneous HIT.

In mouse models, the immune response after active immunization with PF4/heparin complexes is mediated by marginal zone B-cells (Zheng et al. 2013) and is dependent on the presence of T-cells (Zheng et al. 2015). However, human and murine B-cells can also be stimulated to produce anti-PF4/polyanion antibodies by in vitro stimulation with proinflammatory molecules, such as CpG. Furthermore, mice lacking protein kinase Cδ (PKCδ) that are prone to breakdown of B-cell tolerance produce anti-PF4/heparin antibodies spontaneously. Therefore, breakdown of B-cell tolerance may play a role in HIT pathogenesis (Zheng et al. 2014). Monocytes take up PF4/heparin complexes by an active endocytic pathway and then transport them to late endosomes, where the complexes still express the antigen recognized by HIT antibodies. This raises the intriguing hypothesis that PF4/heparin complexes are seen by the immune system as particulate antigens. Such antigens are especially immunogenic, as they are more resistant to proteolysis and can, in some instances, be recycled to the cell surface, allowing for antigen persistence (Joglekar et al. 2015).

Frequency of HIT

HIT occurrence has several requirements (Warkentin 2011). First, heparin exposure triggers a humoral immune response. This usually occurs when heparin is given in a setting of platelet activation and inflammation (e.g., intra- or perioperatively). Second, the "HIT antibodies" must be able to induce platelet activation in vivo (sufficient plasma levels of platelet-activating IgG antibodies). Finally, these events must occur in a susceptible host (platelets become activated). Therefore, the incidence of HIT varies among different patient populations (Fig. 4 (Greinacher and Warkentin 2008)).

The overall frequency of (immune) HIT in hospitalized patients who receive heparin is ~0.2 % (Smythe et al. 2007), but this includes brief or trivial heparin exposures. Some patient populations have frequencies of HIT as high as ~5 % (e.g., post-orthopedic surgery females receiving prophylactic-dose UFH for at least 10 days (Greinacher et al. 2005a)) or even 10 % (post-ventricular assist device implantation receiving therapeutic-dose UFH) (Warkentin et al. 2009a). Risk factors for HIT include heparin type (UFH > LMWH > fondaparinux), patient type (surgical [major > minor trauma] > medical > obstetrical/pediatric), sex (female > male), and dose and duration of heparin exposure (Warkentin et al. 1995, 2006, 2011a; Lubenow et al. 2010; Linkins and Lee 2013).

The risk of HIT is approximately tenfold less with LMWH versus UFH (Warkentin et al. 2006; Martel et al. 2005), reflecting a lower rate of antibody formation as well as a reduced frequency of thrombocytopenia "breakthrough" among immunized patients for LMWH versus UFH (Warkentin et al. 2013). The frequency of HIT with

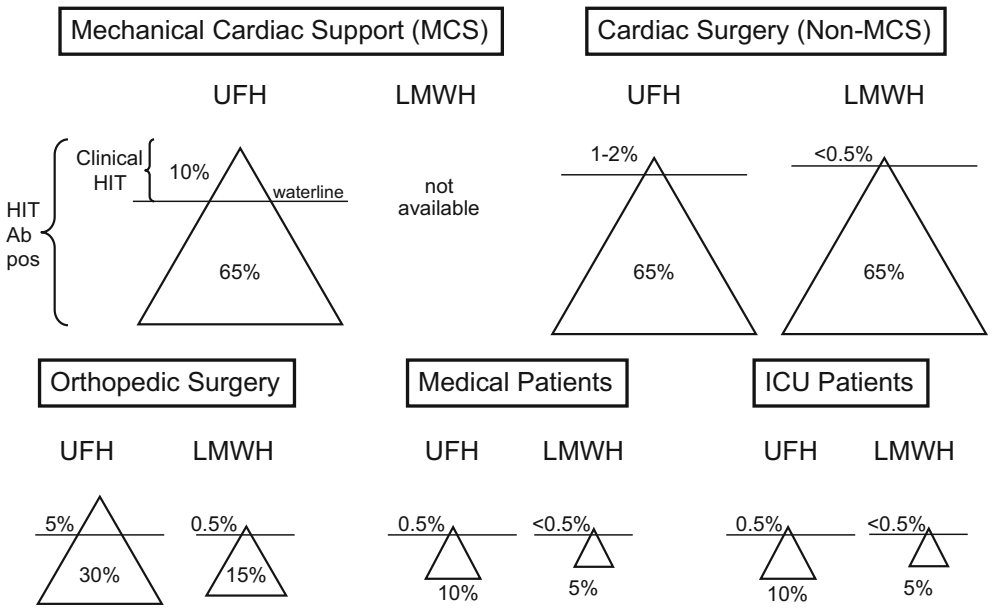

Fig. 4 Multiple iceberg model. The frequency of HIT in different patient populations treated with UFH versus LMWH is shown. The size of the iceberg reflects relative frequencies of anti-PF4/heparin formation, whereas the iceberg tip protruding above the waterline indicates the relative frequency of breakthrough of HIT. Modified from: Greinacher A, Warkentin TE. Risk of heparin-induced thrombocytopenia in patients receiving thromboprophylaxis. Exp Rev Hematol 2008; 1 (1): 75–85 (Greinacher and Warkentin 2008)

fondaparinux (sulfated pentasaccharide) appears negligible (but not zero) (Warkentin et al. 2005a, 2011a).

Anti-PF4/heparin antibodies first become detectable about 4 days (median) after starting an immunizing exposure to heparin, with antibody levels peaking approximately a week later (Greinacher et al. 2009; Warkentin et al. 2009b). Thus, greater duration of heparin (up to about 10 days) increases risk of HIT, with later occurrences (despite prolonged administration) uncommon.

The role of heparin "flushes" or device-bonded heparin in triggering or maintaining HIT is controversial. For example, onset of HIT in a patient receiving heparin flushes or an implanted heparin-bonded device could reflect immunization due to earlier intraoperative administration of UFH as well as the formation of highly pathogenic HIT antibodies that do not require further heparin to cause thrombocytopenia (Warkentin 2013b).

The frequency of HIT is higher if the definition of thrombocytopenia requires a proportional (relative) platelet count fall (e.g., >50 %), rather than a drop below an arbitrary threshold (e.g., 150×10^9/L), as the former definition better accounts for the phenomenon of postoperative thrombocytosis (Warkentin et al. 2003).

HIT is less common in medical than surgical patients (Warkentin et al. 2006), perhaps reflecting lack of perioperative PF4 release as an immunizing trigger. In critically ill patients, HIT is a relatively uncommon cause for thrombocytopenia: less than 1 % of such patients have HIT as the explanation for thrombocytopenia (PROTECT Investigators for the Canadian Critical Care Trials Group and the Australian and New Zealand Intensive Care Society Clinical Trials Group et al. 2011; Selleng et al. 2007; Warkentin 2015b). Indeed, the high frequency of subclinical seroconversion among heparin-treated patients means that early-onset and persisting thrombocytopenia in the intensive care unit rarely indicates HIT even when HIT immunoassays are positive (Selleng et al. 2010).

For unknown reasons, HIT is rare in pregnant women and in children, and does not appear to occur in neonates (Klenner et al. 2004).

The "stoichiometric" requirements for optimal PF4/heparin ratios in triggering immunization could help explain why HIT risk is higher with greater magnitude of trauma (Lubenow et al. 2010) and perhaps also why greater body mass index (BMI) was associated with a greater risk of anti-PF4/heparin antibody formation (since higher BMI predicts for more optimal PF4/heparin ratios when fixed-dose postoperative heparin thromboprophylaxis is given) (Warkentin et al. 2010).

Diagnosis

Clinical Diagnosis

HIT should be suspected whenever an otherwise unexplained drop in platelet count and/or thrombosis *begins* on/after day 5 of heparin administration, usually by day 10 (first day of heparin use = day 0). This is called "typical-onset HIT." The diagnosis should also be considered in patients with unexpected thrombocytopenia, especially when accompanied by new thrombosis that occurs (or worsens) after stopping heparin ("delayed-onset" or "autoimmune-like" HIT). Also, when heparin administration is associated with an abrupt and otherwise unexplained platelet count fall, "rapid-onset HIT" should be considered if patients have received a (presumably immunizing) recent exposure to heparin (see Fig. 1 shown earlier in the chapter).

A clinical scoring system, the "4Ts" (Table 4), is based on the mnemonic, *T*hrombocytopenia, *T*iming, *T*hrombosis (or other sequelae of HIT), and (lack of) o*T*her explanations for thrombocytopenia (Lo et al. 2006) A more recent scoring system is the HIT Expert Probability (HEP) score (Cuker et al. 2010). Scores are helpful in ruling out HIT, because a low score suggests a low (<2 %) probability of having a positive

Table 4 4Ts scoring system for HIT

4Ts category	2 points	1 point	0 point
*T*hrombocytopenia	Platelet count fall >50 % and platelet count nadir ≥20	Platelet count fall 30–50 % or platelet count nadir 10–19 (maximum, 1 point, for >50 % platelet count fall that directly results from surgery)	Platelet count fall <30 % or platelet count nadir <10
*T*iming (of onset of platelet count fall)	Clear onset day 5–10 or platelet fall ≤1 day (prior heparin exposure within 30 days)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts); onset after day 10; or fall ≤1 day (prior heparin exposure 30–100 days ago)	Platelet count fall ≤4 days without recent heparin exposure
*T*hrombosis (or other sequelae)	New thrombosis (confirmed); necrotizing skin lesion(s) at heparin injection site(s); post-heparin anaphylactoid reaction	Progressive or recurrent thrombosis; non-necrotizing (erythematous) skin lesions at heparin injection sites; suspected thrombosis (not proven)	None
o*T*her causes of thrombocytopenia	None apparent	Possible	Definite

The 4Ts score is the sum of the values for each of the four categories. Scores of 1–3, 4–5, and 6–8 correspond to low, intermediate, and high probability of HIT, respectively

platelet activation assay; however, even a high score suggests a probability of HIT of only ~50 % (Cuker et al. 2012).

Laboratory Investigations

HIT can be difficult to exclude or confirm based on clinical information alone. Laboratory testing for heparin-dependent antibodies is therefore a mainstay of diagnosis. Two classes of assays are available: functional (platelet activation) assays and (PF4-dependent) immunoassays (Table 5). In general, testing should only be performed when HIT is reasonably suspected (e.g., 4Ts score of 4 points or greater, Table 4), given their low diagnostic specificity, especially for the immunoassays (Greinacher et al. 2007).

Functional Assays

The presence of platelet-activating antibodies can be established only by using functional assays. There are

Table 5 Laboratory tests for HIT

Test system	Principle	Detected antibodies	Sensitivity	Specificity	NPV	PPV	Advantages	Drawbacks
PaGIA	Beads, gel centrifugation	Polyspecific	91–94	81–88	99.5–99.1	35.1–36.6	One sample, short turnaround time	Visual interpretation, Difficult to quantify
HealthTEST	Beads, membrane filter	Polyspecific	Non-informative	30–35			One sample, easy to perform, no special equipment	Non-informative
LFI-HIT Melinea	Beads, lateral flow technology	IgG	Visual: 100 Scanner: 97	93 93	100 99.7	54.0 52.4	One sample, short turnaround time, no special equipment	Serum samples are required
HemosIL® HIT-Ab	Beads, agglutination	Polyspecific	100	76	100	45.5	Automated and quantifiable, standardization makes results comparable between laboratories	
HemosIL® AcuStar HIT-Ab	Beads, chemiluminescent detection	Polyspecific	98	82	99.7	41.8	Automated and quantifiable, standardization makes results comparable between laboratories	
HemosIL® AcuStar HIT-IgG	Beads, chemiluminescent detection	IgG	96.2	96.5	99.5	78.1	Automated and quantifiable, standardization makes results comparable between laboratories	
Stago Diagnostica	Enzyme-linked immunosorbent assays	IgG (polyspecific)	98	90				Time and cost intensive
Immucor GTI Diagnostics	Enzyme-linked immunosorbent assays	IgG (polyspecific)	100 100	89 81	100 100	43 28		Time and cost intensive
HYPHEN BioMed	Enzyme-linked immunosorbent assays	IgG (polyspecific)	100	87	100	39	Detects heparin-dependent antigens other than PF4	Time and cost intensive
In-house ELISAs	Enzyme-linked immunosorbent assays	Separately IgG, IgM, IgA	98–100	86–88	99.7	47.2	Require in-house quality control measures	

Althaus et al. (2013), Arepally et al. (1995), Bakchoul et al. (2009, 2011), Lindhoff-Last et al. (2001), Morel-Kopp et al. (2012), Pouplard et al. (2007), Sachs et al. (2011), Warkentin et al. (2007), Whitlatch et al. (2008)

(1) assays that use whole blood or platelet-rich plasma (PRP) and (2) assays that use washed platelets.

Whole Blood Assay

The whole blood impedance analyzer (Multiplate®, multiple electrode platelet aggregometry) detects platelet activation in the presence of heparin and patient plasma. Blood from a selected donor is collected in hirudin-containing tubes. UFH is then added (0.5 or 100 IU/mL final concentration) and the suspension incubated with patient-citrated platelet-poor plasma (PPP) or heat-inactivated serum. Changes in impedance are then recorded over a 15 min period. This assay, which does not require platelet preparation, may have similar sensitivity as the serotonin-release assay (SRA) when performed using blood from a donor whose platelets are known to react well to HIT antibodies (Morel-Kopp et al. 2012).

Platelet-Rich Plasma Assay

In the platelet aggregation test (PAT), platelet aggregometry is performed with citrated PRP isolated from one selected donor. Platelet activation (aggregation) is investigated in the presence of patient PPP (or serum) and heparin in two concentrations (0.5 and 100 IU/mL). Although this assay is easier to perform compared with washed platelet assays, its sensitivity is inferior to the SRA even when good platelet donors are selected (Chong et al. 1993).

Washed Platelet Assays

In the heparin-induced platelet activation (HIPA) assay and the serotonin-release assay (SRA) (Greinacher et al. 1991; Warkentin et al. 1992), washed platelets are used to investigate platelet activation by heparin-dependent antibodies, either by visually observing formation of platelet aggregates or measuring release of radiolabeled serotonin, respectively.

In the HIPA assay, washed platelets from four healthy unselected donors are used. Washed platelets are incubated with patient serum in the presence of buffer or heparin (0.2 and 100 IU/mL). Incubation takes place in a round-bottom microtiter plate, with spinning magnetic spheres used as source of shear force. Platelet aggregate formation is determined visually at 5-min intervals; the test is positive if aggregation is observed within 30 min (at 0.2 but not at 100 IU/mL heparin) using the platelet suspensions of least two out of four donors.

In the SRA, platelets obtained from a selected donor are preincubated with radioactive ^{14}C-serotonin. After washing, platelets are incubated with patient serum and heparin in flat-bottomed microtiter wells in duplicate on a plate shaker. After incubation for 60 min and centrifugation, supernatants of each reaction mixture are collected and radioactivity measured. Test results are expressed as percentage of serotonin release (compared to 100 % value determined by detergent-induced platelet lysis). The test is considered positive if there is >20 % release at low heparin concentrations (0.1–0.3 IU/mL) and <20 % release at supratherapeutic heparin (100 IU/mL) levels (although sera from patients with clinical HIT usually cause >50 % serotonin release (Warkentin et al. 2013)).

Both functional assays are considered the "gold standard" for diagnosing HIT. However, these assays are difficult to perform, require selected healthy platelet donors, and are restricted to few reference laboratories. Moreover, the SRA requires the use of the radioisotope, [^{14}C]-serotonin, which most laboratories try to avoid due to regulatory and safety issues.

PF4-Dependent Immunoassays

Antibody binding can be detected by enzyme-linked immunosorbent assays (ELISAs) and particle-based immunoassays.

In ELISAs, the target antigen (PF4/polyanion complex) is bound onto a solid phase, e.g., microtiter plate wells. Patient serum or plasma is added, and an enzyme-labeled secondary antibody is used to detect anti-PF4/heparin antibodies binding in a semiquantitative fashion. The intensity of color change, measured as optical density (OD), is proportional to the amount of bound antibodies.

At least three ELISAs are commercially available. They differ in source of PF4 and type of polyanion: (1) Diagnostica Stago (Asnières-sur-Seine, France) utilizes recombinant PF4 bound to heparin (Arepally et al. 1995); (2) Immucor GTI Diagnostics (Waukesha, WI, USA) makes use of purified PF4 (obtained from outdated platelets) bound to the non-heparin polyanion, polyvinyl sulfonate (Visentin et al. 1994); and (3) HYPHEN BioMed (Neuville-sur-Oise, France) uses platelet lysate (source of PF4 and, possibly, other heparin-binding proteins) to bind to surface-immobilized heparin.

Although ELISAs have an excellent negative predictive value (NPV) to rule out HIT, their specificity is low (40–80 %, depending on the assay). A minor drawback of most immunoassays is that they only detect PF4/polyanion-dependent antibodies, but whether the ELISA that uses platelet lysate has advantages is uncertain (Regnault et al. 2003; Bounameaux et al. 2007).

Particle-based immunoassays detect anti-PF4/heparin antibodies through agglutination of particles coated with PF4/heparin complexes. Several assays are available. In the particle gel immunoassay (PaGIA, DiaMed division of Bio-Rad Laboratories, Cressier sur Morat, Switzerland), red-colored, agglutinated beads are unable to migrate through the sephacryl gel, which is detected visually (Meyer et al. 1999). The major advantage of the PaGIA is its rapid turnaround time (15 min). Although occasional

false-negative test results have been reported (Bakchoul et al. 2009; Pouplard et al. 2007), a recent prospective management study showed high NPV even when the pretest probability of HIT seemed high (Linkins et al. 2015).

Another rapid assay is the "HealthTEST Heparin/Platelet factor 4 Antibody Assay" (Akers Biosciences, Inc., Thorofare, NJ, USA). Here, a membrane filter is used to separate non-agglutinated blue-colored particles from agglutinated ones. However, this assay fared poorly in comparative studies (Warkentin et al. 2007).

Recently, lateral flow technology was used as a point-of-care test for anti-PF4/heparin antibodies (Sachs et al. 2011). HIT antibodies are detected using the principle of capillary action which induces a flow of the test sample along a solid phase. This test system is designed to investigate one patient sample and can be performed in <15 min without the need for special equipment. Interestingly, not only a high NPV but also a satisfactory positive predictive value (PPV) was found.

Automated immunoassays have been recently introduced: one is based on the agglutination of latex particles (HemosIL® HIT-Ab (PF4-H)) and two are based on chemiluminescent detection system (HemosIL® AcuStar HIT-Ab (PF4-H) and HemosIL® AcuStar HIT-IgG (PF4-H), respectively). In the latex agglutination assay, the (expected) agglutination of PF4/polyvinyl sulfonate-coated beads by a monoclonal anti-PF4/heparin antibody is inhibited in the presence of anti-PF4/heparin antibodies (Legnani et al. 2010). These assays have high NPV and informative PPVs (Althaus et al. 2013).

Strategies to Reduce Overdiagnosis

Most laboratories perform immunoassays in their algorithm to diagnose HIT. However, as few as 10–15 % of sera from patients suspected for HIT, and only up to 50 %, of ELISA-positive patient sera additionally contain the clinically relevant, platelet-activating antibodies characteristic of HIT. Several approaches may increase the diagnostic specificity of ELISAs: selective detection of IgG antibodies, analyzing the magnitude of the OD, and use of a high heparin inhibition step.

Exclusive Detection of IgG

Detection of anti-PF4/heparin antibodies of IgM and IgA classes reduces diagnostic specificity of immunoassays (Lindhoff-Last et al. 2001; Warkentin et al. 2005b), and exclusive detection of anti-PF4/heparin IgG improves operating characteristics without loss of sensitivity (Bakchoul et al. 2009) provided that the manufacturer's recommended cutoff is used (Nagler et al. 2015).

Optical Density

The magnitude of the OD value corresponds strongly with the likelihood of a positive functional test and hence a diagnosis of HIT (Warkentin 2008; Greinacher et al. 2010). Weak positive test results (OD <1.0), especially with a polyspecific ELISA (i.e., detecting IgG, IgA, and/or IgM), are in fact strong evidence *against* the diagnosis of HIT. Laboratory cutoffs should be individualized, however, because OD values are arbitrary units and can differ considerably between photometers (Greinacher et al. 2010).

High Heparin Inhibition Step

The specificity of HIT immunoassays can be improved by the implementation of a confirmation step using supratherapeutic concentrations of heparin. This is because a persistently positive test despite high heparin concentrations can indicate an antibody that reacts against PF4 but not to the PF4/heparin complex. Such antibodies usually do not indicate HIT. While some studies support the use of this step (Warkentin et al. 2008b; Whitlatch et al. 2008), especially for weakly positive OD values <1.0 units (Althaus et al. 2011, 2013), some of the clinically most relevant high-titer antibodies with strong platelet-activating capacity are not inhibited (Warkentin et al. 2008b; Bakchoul et al. 2011). A recent meta-analysis did not find this maneuver to be helpful (Nagler et al. 2015).

Suggested Algorithm to Diagnose HIT

Diagnostic algorithms that combine clinical features and results of laboratory testing are available for diagnosis of HIT (Fig. 5). Screening PF4-dependent immunoassays are indicated for patients with at least intermediate probability of HIT. If the ELISA is positive, a functional assay should be also performed to confirm or refute a diagnosis of HIT (Warkentin et al. 2011b).

Future Assays

A transgenic B-cell line expressing FcγRIIa coupled to a luciferase reporter, to which patient serum and PF4/heparin is added, can detect platelet-activating IgG that bind to PF4/heparin complexes on the B-cells, thereby cross-linking the FcγRIIa, activating the coupled luciferase, and producing a luminescence signal (Cuker et al. 2013). The other

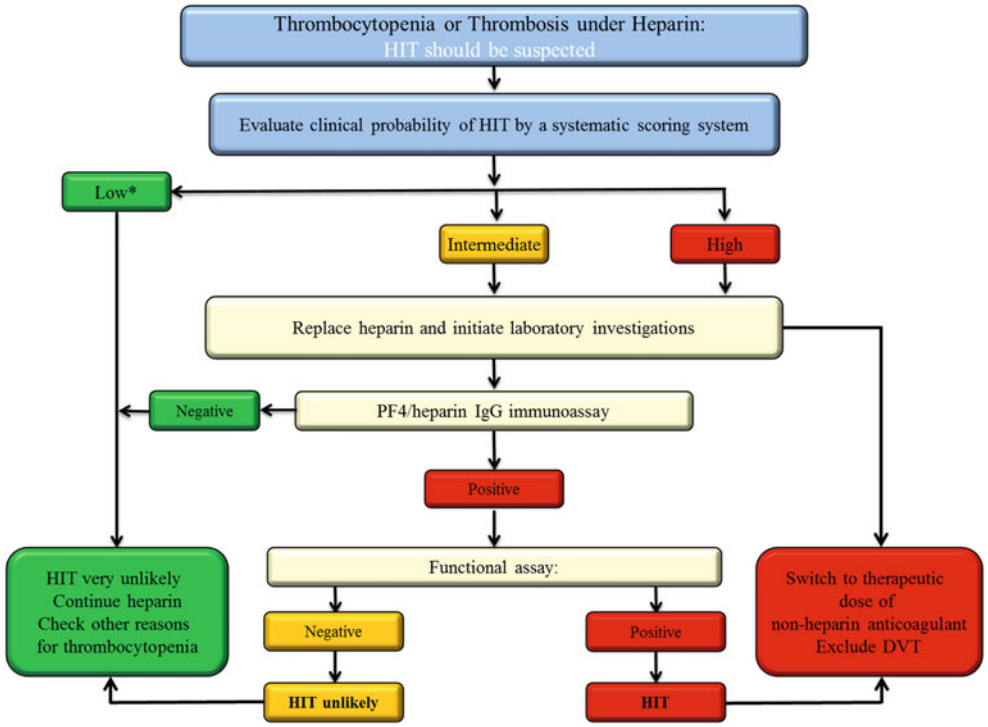

Fig. 5 Diagnostic flow chart for HIT. The flow chart provides a guide on decision making in a patient suspected to have HIT. Antigen assays for PF4/heparin antibodies are widely available, while functional assays using washed platelets such as the serotonin-release assay or the HIPA test are restricted to specialized laboratories. In centers where a functional assay is unavailable or cannot be obtained promptly, other options include using high reactivity of the antigen test (e.g., an OD >1.0) as a surrogate marker for clinically relevant antibodies or incorporating the 4T score in interpretation (indicated by the *gray*, *hatched arrows*), although overdiagnosis of HIT remains possible. Even if acute management decisions are made without confirmation of platelet-activating, heparin-dependent antibodies, effort should be made to rule out or confirm the presence of these antibodies to guide future patient management

assay measures proteolysis of FcγRIIa (Nazi et al. 2013). Both assays require further evaluation.

Recently, it has been suggested that supplementation of PF4 to functional assays increases sensitivity for detecting platelet-activating antibodies (Nazi et al. 2015; Padmanabhan et al. 2015a, b), but whether this improves overall diagnostic performance is unclear.

HIT Management

Treatment of suspected HIT involves cessation of heparin (including low-molecular-weight heparin, heparin flushes, and heparin-bonded catheters) and initiation of a parenteral non-heparin anticoagulant. Laboratory studies should be ordered to confirm the diagnosis of HIT, but treatment should not be withheld pending results if HIT is strongly suspected. Our suggestions for management of HIT are summarized in Table 6 and described in detail below.

Parenteral Anticoagulants for the Treatment of HIT

Parenteral anticoagulants for use in treating HIT are detailed below. The mechanism of action, dosing, monitoring, and metabolism of these agents are summarized in Table 7. Choice of anticoagulant should be based on the patient's hepatic and renal function, clinical stability, drug availability, and physician experience.

Argatroban

Argatroban is a hepatically metabolized direct inhibitor of thrombin. It is the only FDA-approved agent for the treatment of HIT available in the USA. The pivotal studies leading to its approval (ARG-911 and ARG-915) were single-arm open-label studies in which argatroban-treated subjects were compared to historical untreated controls (Lewis et al. 2001, 2003). In a pooled analysis of ARG-911 and ARG-915, argatroban reduced the risk of new thrombosis by approximately 70 % compared with controls. The rate of major bleeding was 0.99 %/day (Lewis et al. 2006). A shortcoming of these studies is that serologic confirmation of HIT was not required for enrollment (but was required for the control subjects). Post hoc laboratory testing

demonstrated that approximately one-third of subjects were antibody-negative and likely did not have HIT, a limitation that may have biased the results in favor of argatroban (Walenga et al. 1999). Argatroban is administered as a continuous intravenous infusion. Treatment is monitored with the APTT or, less commonly, the dilute thrombin time or ecarin clotting time. Dose reduction is advised in patients with hepatic dysfunction, heart failure, anasarca, and after cardiac surgery (Table 7) (Linkins et al. 2012).

Bivalirudin

Bivalirudin, another direct thrombin inhibitor, is less reliant on liver and kidney function for clearance and has a shorter half-life than argatroban (25 vs. 40–50 min). Thus, it is a potentially attractive option for situations where rapid dose titration is desired, e.g., cardiac surgery, percutaneous coronary intervention (PCI), and critical illness with multiorgan failure. Bivalirudin has been studied for PCI in large clinical trials and is approved for anticoagulation during PCI for both HIT and routine (non-HIT) settings (Lehman and Chew 2006). Protocols have also been established for patients undergoing cardiac surgery with or without cardiopulmonary bypass (Dyke et al. 2006; Koster et al. 2006). Assessment of bivalirudin in hospitalized patients, including patients with combined hepatic and renal dysfunction, is limited to retrospective studies (Kiser and Fish 2006; Joseph et al. 2014). Bivalirudin is administered as a continuous intravenous infusion. In the operating room and catheterization suite, it is monitored by activated clotting time. Elsewhere, the APTT is used (Table 7).

Danaparoid

Danaparoid is an antithrombin-dependent inhibitor of factor Xa; inhibition of thrombin is also mediated by heparin cofactor II. It is approved for the treatment of HIT in multiple jurisdictions, but not in the USA, where it has been withdrawn from the marketplace. In an open-label trial, patients with HIT and thrombosis were randomized to danaparoid or dextran-70. Recovery from thrombosis was greater in the danaparoid arm (56 % vs. 14 %, $p = 0.02$) (Chong et al. 2001). Danaparoid is given intravenously as a bolus followed by accelerated initial infusion and then maintenance infusion (Table 7). Low (prophylactic-)-dose danaparoid (e.g., 750 U twice or thrice daily by subcutaneous injection) should be avoided in patients with HIT because of a relatively high rate of breakthrough thrombosis (Farner et al. 2001). In vitro cross-reactivity of HIT antibodies with danaparoid occurs in a minority of patients, but is rarely clinically significant, and routine testing for in vitro cross-reactivity is not recommended (Magnani and Gallus 2006).

Fondaparinux

Fondaparinux, a synthetic pentasaccharide, is an antithrombin-dependent inhibitor of factor Xa. It is approved for the treatment and prevention of venous thromboembolism, but is not approved for treatment of HIT. However, it is widely used for treatment of HIT and appears to have similar efficacy and safety to approved agents (Warkentin et al. 2011c; Schindewolf et al. 2014; Kang et al. 2015). Although anti-PF4/heparin antibody formation is common in postoperative patients receiving thromboprophylaxis with fondaparinux, and a small number of cases of HIT possibly caused by fondaparinux in this setting have been reported, the risk of fondaparinux causing further thrombocytopenia when used to treat HIT appears to be negligible (Motokawa et al. 2011; Warkentin et al. 2011a). Fondaparinux is administered by once-daily subcutaneous injection, does not require routine monitoring (Table 7), and may therefore facilitate transition to the outpatient setting. Because of these advantages, we frequently use fondaparinux for management of stable patients with acceptable renal function.

Limitations of Approved Agents and Investigational Therapies

Argatroban and danaparoid, the only agents licensed for management of HIT, are associated with important limitations. Both drugs are expensive. Management is complex, involving continuous intravenous infusion, frequent laboratory monitoring, and dose adjustment. The therapeutic indices for these agents are narrow. They carry a ~1 % daily risk of major hemorrhage and do not reduce frequency of limb amputation or death (Lewis et al. 2006; Hursting and Verme-Gibboney 2008; Chong et al. 2001; Magnani and Gallus 2006). The availability of danaparoid has been limited by worldwide shortages. Monitoring of argatroban by APTT may be confounded by HIT-associated consumptive coagulopathy and result in underdosing (Warkentin 2014). Argatroban also raises the international normalized ratio (INR), complicating transition to VKAs (Sheth et al. 2001).

Fondaparinux greatly reduces the complexity of HIT management. It does not require routine monitoring or dose adjustment, is administered subcutaneously, and has a negligible effect on the INR, thereby facilitating transition to outpatient therapy. Direct oral inhibitors of thrombin (e.g., dabigatran) and factor Xa (e.g., rivaroxaban, apixaban, edoxaban) do not cross-react with HIT antibodies (Krauel et al. 2012) and carry similar practical advantages, but published experience with these agents in patients with HIT is limited (Linkins et al. 2014), and low trough levels may not provide adequate protection for highly prothrombotic states such as HIT. Accordingly, use is not recommended outside of a clinical trial (Linkins et al. 2016). Other novel therapies for HIT including PF4 antagonists, FcγRIIA blockers, and splenic tyrosine kinase inhibitors are in preclinical development (Cuker 2012).

Transitioning to Oral Anticoagulants

Patients with HIT who are treated with a VKA are at risk for venous limb gangrene, a potentially catastrophic thrombotic

Table 6 Summary of suggestions for management of patients with acute HIT

Topic	Suggestion(s)
Parenteral anticoagulation	• In patient with strongly suspected or confirmed acute HIT, heparin should be discontinued, and a parenteral non-heparin anticoagulant (e.g., argatroban, bivalirudin, danaparoid, fondaparinux) should be initiated in therapeutic intensity • We prefer fondaparinux in stable patients with acceptable renal function
Screening for lower extremity deep-vein thrombosis	• We request compression ultrasonography of the bilateral lower extremities in patients with isolated HIT to screen for silent deep-vein thrombosis
Platelet transfusion	• We recommend avoidance of routine prophylactic platelet transfusion in patients with suspected or confirmed HIT • Platelet transfusion may be considered in patients with or at risk for serious bleeding
Transition to oral anticoagulation	• Patients may be transitioned to an oral anticoagulant after the platelet count recovers to a stable plateau • If a VKA is used, it should be overlapped with a parenteral anticoagulant for $\geq$5 days and until the INR reaches the intended target • If a DOAC is used, overlap with a parenteral anticoagulant is not required
Duration of anticoagulation	• In patients with HIT and thrombosis, we suggest 3–6 months of anticoagulation • In patients with autoimmune HIT and thrombosis, we suggest to continue anticoagulation until the platelet count recovers to a stable plateau and until the results of the functional assay revealed no further activation in the absence of heparin, but in case of thrombosis at least for 3–6 months • In patients with isolated HIT and negative compression ultrasonography of the lower extremities, we continue anticoagulation until the platelet count recovers to a stable plateau

Table 7 Parenteral anticoagulants for the treatment of HIT

Drug	Clearance (half-life)	Initial dosing	Monitoring
Direct thrombin inhibitors			
Argatroban	Hepatobiliary (40–50 min)	Bolus: none Continuous infusion: normal organ function → 2 μg/kg/min Liver dysfunction (bilirubin > 1.5 mg/dL) → 0.5–1.2 μg/kg/min Heart failure, anasarca, post-cardiac surgery → 0.5–1.2 μg/kg/min	Adjust to APTT 1.5–3.0 times baseline
Bivalirudin[a]	Enzymatic/renal (25 min)	Bolus: none Continuous infusion: normal organ function → 0.15 mg/kg/h Renal or liver dysfunction → dose reduction may be appropriate	Adjust to APTT 1.5–2.5 times baseline
Indirect factor Xa inhibitors			
Danaparoid	Renal (24 h)	Bolus: <60 kg → 1500 units 60–75 kg → 2250 units 75–90 kg → 3000 units >90 kg → 3750 units Accelerated initial infusion: 400 units/h × 4 h, then 300 units/h × 4 h Maintenance infusion: normal renal function → 200 units/h Renal dysfunction → 150 units/h The daily dose can also given as s.c. injection, after the acute phase of HIT, i.e., platelet counts normalized	Adjust to danaparoid-specific anti-Xa activity of 0.5–0.8 units/mL
Fondaparinux[a]	Renal (17–24 h)	<50 kg → 5 mg SC daily 50–100 kg → 7.5 mg SC daily >100 kg → 10 mg SC daily Cl_{Cr} 30–50 mL/min → use caution Cl_{Cr} <30 mL/min → avoid use	None[b]

APTT activated partial thromboplastin time, Cl_{Cr} creatinine clearance

[a]Not approved for treatment of HIT

[b]Some authorities monitor using fondaparinux-specific anti-Xa activity

complication of the microvasculature secondary to depletion of protein C (Warkentin et al. 1997). Thus, warfarin should be avoided in patients with HIT until the platelet count recovers to a stable plateau within the normal range. When a VKA is initiated, large loading doses (e.g., warfarin >5 mg/day) should be avoided, and the VKA should be overlapped with a parenteral anticoagulant for at least 5 days and until the INR has reached the intended target. If a patient happens to be on a VKA when HIT is newly diagnosed, it should be discontinued, reversed with vitamin K, while at the same time an alternative anticoagulant is started in therapeutic dose (Linkins et al. 2012).

Transitioning from argatroban to a VKA is challenging because argatroban prolongs the INR. Algorithms have been developed to guide this transition and avoid under-anticoagulation (Sheth et al. 2001).

Duration of Anticoagulation

As with other thromboembolic events secondary to a transient provoking factor, 3–6 months of anticoagulation is generally sufficient for patients with HIT and thrombosis. For patients with isolated HIT, the optimal duration of anticoagulation is controversial. In a historical series of 62 untreated patients with isolated HIT, the cumulative incidence of thromboembolism at 30 days was 52 %. The majority of events occurred within 10 days of heparin cessation, a period corresponding to platelet recovery (Warkentin and Kelton 1996). At a minimum, anticoagulation should therefore be continued in patients with isolated HIT until platelet recovery. Some experts recommend a longer course of treatment (4–6 weeks) (Linkins et al. 2012).

Also controversial is whether asymptomatic patients with HIT should undergo screening lower-limb compression ultrasonography. Silent DVT is common in patients with HIT (Tardy et al. 1999), but whether its identification should influence duration of anticoagulation is uncertain. We perform leg vein ultrasound in all patients with serologically confirmed isolated HIT and continue anticoagulation for at least 3 months in those with proximal DVT.

Platelet Transfusion

There is a theoretical concern that platelet transfusion may precipitate thrombosis in patients with HIT, though published evidence is conflicting (Goel et al. 2015; Hopkins and Goldfinger 2008; Refaai et al. 2010). Because HIT generally manifests as a prothrombotic rather than a hemorrhagic diathesis, prophylactic platelet transfusion is rarely indicated. However, transfusion may be appropriate in the setting of significant bleeding, high bleeding risk (e.g., during alternative anticoagulation with severe thrombocytopenia or an invasive procedure), or diagnostic uncertainty.

Vascular Access Devices and Inferior Vena Cava Filters

HIT-associated thrombosis demonstrates a propensity to occur at sites of vessel injury (Greinacher et al. 2005b; Hong et al. 2003). We therefore recommend against insertion of central venous catheters and arterial lines unless absolutely necessary. Inferior vena cava filters may have serious consequences including caval thrombosis and progression of DVT to ischemic limb gangrene (Ishibashi et al. 2005). Moreover, their use does not obviate the need for anticoagulation. Thus, they should generally be avoided in patients with HIT.

Heparin Reexposure for Cardiovascular Procedures and Hemodialysis in Patients with a History of HIT

HIT antibodies are transient and generally resolve within several weeks or a few months in a predictable sequence: functional assays become negative first (median, 50 days post-heparin cessation), followed by immunoassays (median, 80 days) (Warkentin and Kelton 2001b). HIT laboratory testing will determine where a patient is along this sequence, guiding timing of heparin reexposure, if required (e.g., intraoperative anticoagulation for cardiovascular surgery) (Table 8).

The safety of intraoperative heparin in remote HIT (negative functional and immunologic assays) was first

Table 8 Recommendations for intraoperative anticoagulation in patients with a history of HIT

Phase	Functional assay	Immunoassay	Recommendation
Acute	+	+	1. Delay surgery 2. If surgery cannot be delayed, use an alternative anticoagulant (e.g., bivalirudin), or treat with preoperative plasma exchange until functional assay becomes negative
Subacute[a]	–	+	1. Delay surgery 2. If surgery cannot be delayed, consider heparin
Remote	–	–	1. Heparin

[a]Defined as patients with recent HIT whose platelet count has recovered but who remain antibody-positive; heparin reexposure can be considered if the functional test is negative even if the PF4-dependent immunoassay is still positive

established in a series of ten patients undergoing cardiac surgery. None developed recurrent HIT or recrudescence of HIT antibodies (Potzsch et al. 2000). Intraoperative anticoagulation in patients with subacute HIT (negative functional assay, positive immunoassay) is more controversial. In three patients with subacute HIT who required urgent heart transplantation, exposure to intraoperative heparin did not result in clinical recurrence (Selleng et al. 2008). Even a brief course of heparin should be avoided in patients with a persistently positive functional assay (acute HIT). If surgery cannot be delayed, an alternative anticoagulant such as bivalirudin may be used (Kiser and Fish 2006; Joseph et al. 2014). An alternative approach involves preoperative plasma exchange to remove platelet-activating antibodies and enable intraoperative heparin. This approach appears to be safe, but has not been extensively studied (Warkentin et al. 2015b; Welsby et al. 2010). Whenever a patient with a history of HIT is reexposed to heparin, exposure should be limited to the intra- and early postoperative period (HIT antibodies cannot recur for at least 5 days (Warkentin and Sheppard 2014)). If pre- or postoperative anticoagulation is indicated, a non-heparin anticoagulant should usually be used.

In light of its documented efficacy and safety in large coronary angiography trials (Lehman and Chew 2006), we recommend bivalirudin for heart catheterization including PCI in all patients with a history of HIT. If bivalirudin is not available, heparin is an acceptable alternative in patients with remote HIT, provided that its use is limited to the procedure itself.

Although anti-PF4/heparin antibodies are present in ~10 % of patients on chronic hemodialysis (Carrier et al. 2007; Asmis et al. 2008), HIT is uncommon (<1 %) in this population (Hutchison and Dasgupta 2007). In patients with a history of HIT, treatment with heparin during hemodialysis is contraindicated. Alternative strategies for prevention of dialysis circuit thrombosis, including saline flushing, regional citrate, danaparoid, argatroban, and VKA, have been reported but not systematically investigated.

Take Home Messages

- HIT is one of the most frequent adverse drug effects due to the widespread use of heparin. The clinical features of HIT are summarized in the 4 Ts score, which can be used to determine the clinical likelihood of HIT in the individual patient. Antigen assays such as EIAs have a high negative predictive value and can therefore be used to rule out HIT, while only functional assays differentiate non-platelet-activating antibodies from clinically relevant platelet-activating antibodies. The direct thrombin inhibitors argatroban and bivalirudin, and the factor Xa inhibitors danaparoid and fondaparinux, are established options for treatment of HIT (although approval status differs between jurisdictions). The oral direct anticoagulants are promising options for treatment of HIT, but experience is still anecdotal. The pathogenesis of HIT depends on an immune response towards the endogenous protein PF4, which undergoes a conformational change after binding to polyanions. Likely, HIT is a misdirected antibacterial host defense response. Better understanding of the immunopathology of HIT may provide information on the pathogenesis of other antibody-mediated autoimmune disorders.
