APP23 transgenic mice are known to exhibit vascular and parenchymal Aβ plaques (Winkler et al. 2001), whereas APP Dutch mice show only vascular pathology (Herzig et al. 2004). Analysis of aged APP23 transgenic mice revealed that these mice exhibit pre-activated platelets in the circulation (Fig. 2b). In vitro, platelet activation induced a strong increase in integrin activation and P-selectin exposure compared with age-matched control mice (Jarre et al. 2014). Enhanced platelet activation translated into almost unlimited thrombus formation on collagen under flow ex vivo and accelerated vessel occlusion in vivo. Platelets localized to vascular Aβ deposits in cerebral vessel walls of the AD transgenic mice APP Dutch and APP23. Full occlusion of vessels in APP23 and APP Dutch mice suggests sustained platelet recruitment to vascular Aβ deposits by activated platelets (Gowert et al. 2014) (Fig. 3a). Accordingly, injury of the carotid artery by topical application of $FeCl_3$ led to significantly reduced occlusion times in APP23 mice. Moreover, the infusion of Aβ-stimulated platelets in wild-type mice resulted in enhanced platelet adhesion at the injured carotid artery, suggesting that Aβ-mediated alterations in platelet activation are crucial for cardiovascular and cerebrovascular events in AD (Gowert et al. 2014; Jarre et al. 2014).

Platelets, Coagulation, and Cerebral Amyloid Angiopathy

Different groups have provided strong evidence that platelets are able to process APP and release Aβ upon activation with physiological agonists such as collagen (Smith 1997) and soluble synthetic Aβ(1-40) (Gowert et al. 2014). Aβ(1-40) is the major Aβ peptide released from platelets and is the major component of Aβ deposits in cerebral vessels (Gravina et al. 1995), suggesting that platelets actively contribute to cerebral amyloid angiopathy (CAA).

The reason for increased Aβ accumulation within cerebral vessels is still not well understood. CAA might be the result of altered clearance of Aβ or increased production of Aβ. In 1995, Wisniewski and colleagues observed that smooth muscle cells in the medium supported the deposition of Aβ in the vessel wall (Wisniewski et al. 1995). However, the onset of CAA occurs at the outer basement membrane, suggesting that circulating platelets might trigger CAA. This hypothesis is further supported by the fact that platelets adhere to immobilized Aβ in vitro and to Aβ deposits in cerebral vessels of AD transgenic mice (Fig. 3a).

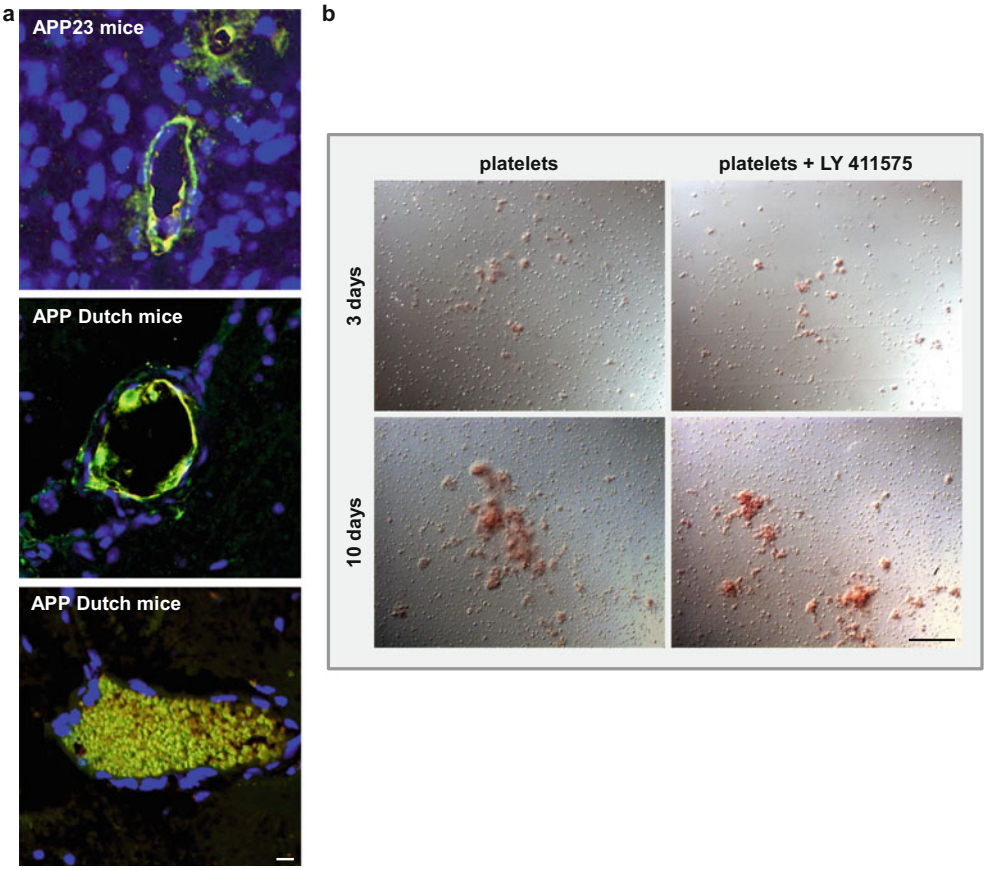

Fig. 3 Platelets adhere to Aβ deposits in cerebral vessels of AD transgenic mice and modulate soluble Aβ into fibrillaraggregates. (**a**) Platelets are recruited to vascular Aβ deposits in cerebral vessels of APP23 (*upper panel*) and APP Dutch mice (*middle* and *lower panels*). Brains were immunohistochemically analyzed for Aβ deposition (6E10, Covance; *red*) and the presence of platelets using the platelet-specific marker GPIb (CD42b, US Biological; *green*). Nuclei staining was performed using 4′,6-diamidine-2-phenylindole (DAPI). Full occlusion of cerebral vessels after sustained platelet recruitment to vascular Aβ deposits (*lower panel*). *Scale bar* 10 μm. (**b**) Congo-Red-positive platelets and Aβ deposits in platelet cell culture following stimulation with 50 μg/mL soluble Aβ after 3 days (*upper panel*) and 10 days (*lower panel*) in culture. To exclude Aβ production by platelets, the γ-secretase inhibitor LY 411575 was used

Interestingly, apoptotic platelets are able to absorb soluble and oligomerized Aβ(1-42), a mechanism that could trigger local accumulation of Aβ at the cerebral vessel wall. Moreover, platelets are able to modulate the conversion of soluble Aβ peptides into fibrillar structures that might also accelerate CAA (Gowert et al. 2014) (Fig. 3b). It is noteworthy that Glanzmann's thrombasthenia (GT) patients whose platelets fail to aggregate in response to stimuli, because they lack or have nonfunctional αIIβ3 integrin, do not suffer from neurodegenerative diseases, suggesting that platelets are markedly involved in the pathology of AD (Nurden et al. 2011).

Studies have confirmed the involvement of fibrinogen in the generation of CAA. Depletion of fibrinogen successfully reduced CAA in AD mice (Cortes-Canteli et al. 2010). Mechanistically, the authors observed oligomerization of fibrinogen in response to Aβ stimulation, which might play a crucial role in AD (Ahn et al. 2010). The newly designed inhibitor RU-505 prevents the Aβ–fibrinogen interaction, leading to restored Aβ-induced alterations in fibrin clot formation and degradation in vitro, and inhibits vessel occlusion in AD mice (Ahn et al. 2014). In a transgenic mouse model of AD (Tg6799 mice), long-term treatment (4 months) with RU-505 resulted in reduced vascular Aβ deposition in the cortex and improved cognitive impairment. Improved neuronal health and attenuated Aβ deposition was also observed with a modest decrease in fibrinogen levels in TgCRND8 mice expressing a double mutant form of APP695, suggesting that blockade of the interaction between fibrinogen and Aβ might be a promising therapeutic strategy in AD (Cortes-Canteli et al. 2015). In AD patients, alteration in the blood–brain barrier could promote the deposition of fibrinogen in cerebral blood vessels and parenchyma and its accumulation in CAA (Paul et al. 2007).

Targeting Platelets in AD

Antiplatelet Therapy

Increasing evidence from studies in AD patients and in AD transgenic mice shows enhanced platelet activation in AD pathology. Thus, anti-platelet therapy might have an effect on the progression of AD. Epidemiological studies in the past suggested that treatment of AD with NSAIDs or aspirin might slow the progression of either vascular or Alzheimer-type pathology. A randomized placebo-controlled clinical trial provided evidence that treatment of AD patients with celecoxib, a selective cyclooxygenase (COX)-2 inhibitor, does not prevent Alzheimer dementia (Lyketsos et al. 2007). A randomized, double-blind study of patients taking rofecoxib, a selective COX-2 inhibitor, also showed that

inhibition of COX-2 is not a useful therapeutic strategy (Thal et al. 2005). In contrast, Broe and colleagues provided evidence for a protective role of anti-inflammatory drugs and aspirin in AD (Broe et al. 2000). However, results obtained from a two-wave longitudinal study over 3.6 years do not support the hypothesis that aspirin or NSAIDs have a protective effect in AD (Henderson et al. 1997).

Aspirin is the most common anticoagulant drug used for the prevention of stroke and myocardial infarction (Yeung and Holinstat 2012). Aspirin irreversibly inhibits COX-1, thus blocking the generation of thromboxane A2 (Loll et al. 1995). High doses of aspirin display anti-inflammatory effects because the production of prostaglandins by white blood cells is inhibited; low doses of aspirin are mainly used for antithrombotic therapy. As shown in the AD2000 randomized open-label trial, treatment of AD patients with aspirin for 2 years has no worthwhile benefit, whereas it increases bleeding risk (Bentham et al. 2008). Cognition and functional ability were evaluated in 156 AD patients who received daily low doses of aspirin and compared with those of 154 AD patients not on aspirin. The results showed no benefit of aspirin therapy on the progression of AD in these subjects, with bleeding complications in 8 % of patients.

Platelets as Biomarker for AD

Peripherial biomarkers play an important role in providing reliable, quick and safe diagnoses. The number of subjects suffering from age-related diseases such as AD is increasing dramatically; therefore, the identification of molecules that can serve as biomarkers is needed. Currently, the definitive diagnosis of AD is possible only post mortem, and the identification of molecular characteristics ante mortem are problematic because of the restricted availability of appropriate sample material. To date, available biomarkers originate from cerebrospinal fluid and are therefore not convenient for routine diagnostics because of the invasiveness of the procedure (Veitinger et al. 2014b). There is a compelling need to develop objective diagnostic and prognostic biomarkers in AD involving easily available tissue, such as blood cells and in particular platelets. Platelets were considered a good model for study of the metabolic changes occurring in AD that might be relevant for the identification of reliable biomarkers (Catricala et al. 2012; Evin and Li 2012; Veitinger et al. 2014b). The alteration in APP processing with altered ratio of APP isoforms (APPr) in AD patients is promising (Evin and Li 2012; Tang et al. 2006; Veitinger et al. 2014b). Determination of APPr might also be relevant for monitoring the outcome of therapies in patients with AD (Evin and Li 2012). Patients with mild to moderate AD were treated with the acetylcholinesterase inhibitor donepezil. After 30 days, an increase in platelet APPr was measured, suggesting that donepezil influences APP metabolism in platelets (Borroni et al. 2002). Zainaghi and colleagues found a decreased ratio of APP130/110 kDa isoforms in patients with AD compared with healthy subjects. Determination of the APPr might also be a promising tool for detection of the conversion from mild cognitive impairment (MCI) to AD, because the baseline levels of the APP130/110 isoform ratio are significantly lower in platelets from patients with MCI who converted to AD compared with patients who remained with stable MCI (Zainaghi et al. 2012). Thus, the measurement of APP isoforms could provide a tool for diagnosis of AD at early stages, for monitoring the progression of AD, and for analysis of a patient's responsiveness to therapeutic intervention (Evin and Li 2012).

Because the balance between non-amyloidogenic and amyloidogenic processing of APP is altered in AD, the sAPPα, ADAM10, and BACE levels in platelets are also promising potential biomarkers (Tang et al. 2006; Veitinger et al. 2014b). Recent studies provide evidence that analysis of platelet activation might have predictive value for the rate of cognitive decline in AD patients (Prodan et al. 2011; Stellos et al. 2010). Significantly higher expression of P-selectin and activated integrin $\alpha_{IIb}\beta_3$ in circulating platelets were observed in patients with AD and fast cognitive decline compared with AD patients showing slow cognitive decline (Stellos et al. 2010). Prodan and coworkers found a relationship between the level of coated platelets and the progression of MCI to AD (Prodan et al. 2011).

In 2014, Veitinger and colleagues presented a platelet protein biochip that can detect an AD specific phenotype (Veitinger et al. 2014a). This array combines protein quantification of monoamine oxidase B and tropomyosin 1 with protein-based genotyping for single nucleotide polymorphisms in the genes encoding apolipoprotein E and glutathione S-transferase omega 1. Although only minimally invasive blood withdrawal is necessary, this biochip enables the identification of AD in patients with a precision of 92 % and could therefore be a promising new tool for the diagnosis of AD.

Interestingly, animal models for studying the molecular mechanisms of AD including platelets are rare, although animal models are known to be a valuable tool in basic and biomedical research. Analysis of brain sections from AD transgenic mice such as APP23 or APP Dutch showed that platelets are recruited to vascular Aβ plaques, where they form aggregates leading to vessel occlusion (Gowert et al. 2014). Increased activation of platelets from AD patients has been described by Stellos and colleagues (Stellos et al. 2010). The analysis of platelet activation in APP23 mice also revealed changes in platelet activation in AD transgenic mice. Activated platelets circulate in these AD transgenic mice (Fig. 2b) and platelet activation with standard platelet agonists induced strongly enhanced platelet activation

compared with age-matched control mice. These results emphasize the need for animal models in the search for new diagnostic tools and to gain more insight into APP–Aβ metabolism in AD (Jarre et al. 2014).

AD and the Risk of Cardio- and Cerebrovascular Diseases

There is a strong relationship between AD, the vascular system, and (cerebro-) vascular diseases such as stroke, atherosclerosis, and hypertension (Catricala et al. 2012; Honig et al. 2003; Mielke et al. 2007). It is now recognized that, on the one hand, vascular risk factors enhance the risk of AD but, on the other hand, AD is related to cerebrovascular dysfunction with blood flow abnormalities that might also interfere with AD pathology (Hardy 2007; Iadecola 2004; Luchsinger et al. 2005; Smith and Greenberg 2009; Staffen et al. 2009). Diabetes and current smoking are the main risk factors; however, hypertension and heart disease can also increase the risk of AD (Luchsinger et al. 2005). Atrial fibrillation, hypertension, and angina are associated with a greater rate of decline and might play a role in secondary prevention of AD (Mielke et al. 2007). The presence of brain infarction influences the course of AD, and increasing evidence suggests that vascular Aβ deposition can impair blood vessel function (Smith and Greenberg 2009). Subcortical infarcts add to the effects of AD pathology by increasing dementia and impaired memory function (Schneider et al. 2007). Importantly, higher platelet activation markers were found in patients with fast cognitive decline compared with patients showing slow cognitive decline. The rate of decline was related to age, platelet activation markers, and a history of myocardial infarction (Stellos et al. 2010).

Vascular Aβ deposition is a common pathology in elderly individuals and is associated with AD. Vascular Aβ is toxic for smooth muscle cells (Mok et al. 2006; Shin et al. 2007) and leads to platelet adhesion and activation, which could induce vessel occlusion, as shown in a transgenic AD mouse model (Gowert et al. 2014) (Fig. 3a). Moreover, toxic Aβ in cerebral vessels causes vascular rupture with intracerebral hemorrhage and reduced blood flow, pointing to a second effect of Aβ in the brain in addition to its direct neurotoxic effects (Smith and Greenberg 2009; Thal et al. 2008). This could represent a mechanism by which CAA is associated with microinfarction and small cortical infarcts. Different studies in the past have analyzed the relationship between vascular function, brain lesions, and clinical symptoms in CAA and AD patients with impaired cognition. Given the fact that more than 90 % of patients with AD display cerebrovascular deposition of Aβ (Attems 2005), studies in mice and humans are needed to determine whether CAA is actively implemented in cognitive decline and is a cause of brain infarction in AD patients. To date, the reason for an increase in Aβ within the cerebral vessel is still unclear. Increased production (Li et al. 2004) or altered clearance of Aβ (Zlokovic 2005) might cause CAA. Moreover, smooth muscle cells in the medium support the deposition of Aβ in the vessel wall (Wisniewski et al. 1995), but the onset of Aβ deposition occurs at the outer basement membrane (Thal et al. 2008). However, platelets adhere to vascular Aβ deposits and might be responsible for the onset of CAA (Fig. 3a). According to the study of Gowert and colleagues, platelet adhesion, activation, and aggregation at Aβ deposits of cerebral vessels might be responsible for complete occlusion of these vessels, as observed in AD transgenic mice known to develop CAA. Moreover, platelets become activated by soluble Aβ (Fig. 2a) and are able to modulate soluble Aβ into fibrillar structures that might contribute to CAA (Gowert et al. 2014). However, the molecular mechanisms and the relation between (cerebro-) vascular pathology and Aβ plaque formation in AD are not yet fully understood. There is a clear indication that cerebral hypoperfusion augments CAA and promotes cortical microinfarcts. In post-mortem human brains, the severity of CAA was a significant predictor of cortical infarcts. Concomitant with human data, AD transgenic mice with CAA showed accelerated vascular Aβ deposition after chronic cerebral hypoperfusion as a result of bilateral carotid artery stenosis (Okamoto et al. 2012). Another study from Garcia-Alloza and colleagues documented that experimental stroke in mice can trigger vascular Aβ deposition and the authors proposed a mechanism that involves interference with amyloid clearance pathways (Garcia-Alloza et al. 2011).

In addition to the association of CAA with cerebral infarcts, the analysis of platelet activation in APP23 mice revealed an enhanced activation profile in these AD transgenic mice compared with age-matched control mice, leading to virtually unlimited thrombus formation under flow ex vivo. In vivo, accelerated vessel occlusion in APP23 mice provided evidence that mice (at least) are at high risk of arterial thrombosis, leading to vascular complications not only in the brain (Jarre et al. 2014). A retrospective study provided evidence for association of Aβ(1-40) levels with progression of arterial stiffness, incident atherosclerosis, and incident coronary heart disease. The study concluded a direct correlation between Aβ(1-40) plasma levels and high risk of cardiovascular mortality in patients with coronary heart disease (Stamatelopoulos et al. 2015). Further studies

are needed to shed light on the relationship between CAA, blood vessels, the risk of cerebro- and cardiovascular complications, and AD.

Other Neurodegenerative Diseases

In the late 1970s, platelets were considered to be an appropriate tool for diagnosis and research in psychiatric and neurologic disorders (Stahl 1977). Platelets can serve as a good model for the transport, metabolism, and release of serotonin (5-HT). It was suggested that the study of 5-HT in blood and platelets might indicate possible abnormalities of 5-HT in neurons of patients suffering from different neurologic diseases such as schizophrenia, Parkinson's disease, and Huntington's chorea. At present, the analysis of platelets and their impact in neurological disorders apart from AD is rare and often descriptive.

Parkinson's disease (PD) is a degenerative disorder of the central nervous system and mainly affects the motor system (Shulman et al. 2011). Mean platelet volume (MPV) was measured in patients with PD and shown to be higher than in AD patients and controls. The authors concluded that MPV could be an indicator of platelet dysfunction (Kocer et al. 2013). To date, platelet activation abnormalities have not been described in PD. Different studies have reported that platelet mitochondrial activity as well as mitochondrial membrane potential in platelets is not altered in PD (Antony et al. 2015).

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease with glutamate excitotoxicity (Bos et al. 2006). Platelets were analyzed for alterations in glutamate uptake to assess whether platelets could be a potential peripheral marker for the disease. Platelets from ALS patients showed a significant increase in the expression of glutamine synthetase but normal expression of the glutamate transporter excitatory amino acid transporter 2 (EAAT2). Interestingly, glutamate uptake following thrombin stimulation, as well as under basal conditions, did not differ between platelets from ALS patients and controls (Bos et al. 2006). Dupuis and colleagues analyzed platelet and plasma levels of serotonin and the major serotonin derivate 5-HIAA and found a significant decrease in ALS patients. The levels of platelet serotonin did not correlate with disease duration but were positively correlated with patient survival, suggesting that serotonin influences the progression of ALS (Dupuis et al. 2010).

Huntington's disease (HD) is a neurodegenerative genetic disorder that affects muscle coordination and provokes mental decline and behavioral symptoms (Walker 2007). Several studies have analyzed platelet alterations in HD. In the early 1980s, a few reports described no significant differences in platelet glutamate and aspartate uptake, whereas others found abnormal platelet aggregation in HD compared with controls (Mangano and Schwarcz 1981). In more recent studies, mitochondrial activity was investigated in HD patients. Although normal platelet mitochondrial complex I activity was observed in early HD, when neuronal degeneration is already present (Powers et al. 2007), differences in mitochondrial respiratory chain complex activity and bioenergetic alterations were observed in human platelets before the onset of HD clinical symptoms (Silva et al. 2013). A study from Carrizzo and coworkers provides evidence for nitric oxide dysregulation in platelets from patients with advanced HD, leading to decreased NO levels in platelets from HD subjects (Carrizzo et al. 2014).

Conclusions

For many years, platelets have been deemed a good model for study of the pathogenesis of AD and to serve as a valuable biomarker because they are easily accessible and display the complete machinery for processing Aβ. However, it has become increasingly evident that platelets not only mirror the disease but actively contribute to the progression of AD. Moreover, alterations in platelet activation and thrombus formation suggest that AD patients might be at high risk of cerebro- and cardiovascular complications. Further studies are needed to gain more insight into the molecular mechanisms and the impact of platelets in AD. Our understanding of platelet function and its contribution to other neurodegenerative diseases is still far from complete.

Take Home Messages

- Platelets express the amyloid precursor protein and possess the complete enzymatic machinery for processing amyloid-β
- For decades, platelets were thought to be a valuable model for study of amyloid-β pathology and to serve as a biomarker
- Studies in mice and humans show a strong relation between abnormal platelet activation and generation of reactive oxygen species and the incidence of cerebro- and cardiovascular disease and AD
- Platelets are directly involved in the progression of AD by modulating cerebral amyloid angiopathy
- The impact of platelets with platelet serotonin (5-HT) release, nitric oxide regulation, and mitochondrial activity in psychiatric and neurologic disorders remains an open question

Platelets and Diabetes

Francesca Santilli, Paola Simeone, Rossella Liani, and Giovanni Davì

Abstract

It is increasingly recognized that platelets are the culprit cells implicated in the propensity to atherothrombosis in the setting of both type 1 and type 2 diabetes mellitus, making the study of platelet pathophysiology and platelet activation/inhibition some of the most intriguing fields of research related to diabetes vascular complications. Indeed, a platelet hyperreactive phenotype with biochemical evidence of persistent in vivo platelet activation, with enhanced thromboxane (TX) biosynthesis, has been described in diabetic patients in different stages along the natural history of the impairment of glucose metabolism, even in the preclinical phases.

This chapter highlights several issues within this field: (1) the variable contribution of sustained and acute hyperglycemia, glycemic instability, and insulin resistance to the observed changes in the platelet pathophysiology; (2) the role of oxidative stress and inflammation and namely of platelet-derived inflammatory molecules and microparticles, as secondary mediators of diabetes-induced platelet activation; and (3) the complex intertwining between the described pathophysiology and the anticipated epidemiological burden in terms of high risk of vascular events and lower protection from antithrombotic prophylaxis, with particular reference to aspirin.

Availability of high-throughput techniques is rapidly changing the way we address the problem, with a deeper insight on transcriptomics and posttranscriptional regulation of platelets as a consequence of the above-described metabolic abnormalities.

Diabetes and Accelerated Atherothrombosis

Type 2 diabetes mellitus (T2DM) is a chronic metabolic disorder characterized by hyperglycemia with disturbances of carbohydrate, fat, and protein metabolism. People with diabetes are at an increased risk of coronary artery disease (CAD), peripheral vascular disease, and cerebrovascular disease (American Diabetes Association 2015a). Although the mortality from CAD in patients without DM has declined since the 1990s, the mortality in men with T2DM has not changed significantly (Roffi et al. 2001). In fact, people with diabetes have a poorer long-term prognosis after myocardial infarction (MI), including an increased risk for congestive heart failure and death.

Diabetes is a strong independent predictor of short- and long-term recurrent ischemic events, in acute coronary syndrome (ACS) (Roffi et al. 2001), including unstable angina and non-ST-elevation MI (Yusuf et al. 2001), ST-elevation MI treated medically (Mak et al. 1997), and ACS undergoing percutaneous coronary intervention (Stuckey et al. 2005). Finally, the concomitant presence of cardiovascular risk factors and comorbidities that negatively affect the outcomes of ACS is higher in this setting (Brogan Jr et al. 2006).

Platelet Activation in Diabetes

Accelerated atherosclerosis in DM may be explained by the fact that the altered metabolic state that accompanies DM is responsible for abnormalities in endothelial and platelet function, which may contribute to the cellular events that cause atherosclerosis and subsequently increase the risk of adverse cardiovascular events.

Alterations in platelet function occur early in the diabetic state and enhanced platelet aggregation predates vessel wall change (Colwell et al. 1983). Moreover, increased platelet aggregation and thromboxane (TX) A_2 synthesis are apparent within days of making rats diabetic with streptozotocin (Gerrard et al. 1980).

Several functional alterations of platelet activity have been observed in DM. Diabetic platelets respond more frequently to subthreshold stimuli, becoming consumed more rapidly, which brings forth to an accelerated thrombopoiesis of more reactive platelets. Thus, platelets from DM subjects are hyperreactive, with enhanced adhesion, aggregation, and thrombin generation (Arjomand et al. 2003), associated with increased platelet generation of thromboxane A_2. Hence, due to such peculiar, disease-related dysregulation of several signaling pathways, leading to a hyperreactive phenotype (Davì and Patrono 2007; Ferreiro et al. 2010), they are regarded as "diabetic" platelets (Fig. 1).

Since 1965, increased platelet aggregation was recognized in DM (Bridges et al. 1965). From then on, augmented platelet degranulation and thromboxane synthesis, mediating further platelet activation, have been demonstrated in DM (D'Angelo et al. 1984). Enhanced platelet activation in DM has also been demonstrated by increased numbers of P-selectin (CD62P)—and CD63-positive platelets, by flow cytometry (Stratmann and Tschoepe 2009). Increased circulating activated platelets can be found even in T1DM, and P-selectin positive platelets can be detected in their metabolically healthy first-degree relatives (Stratmann and Tschoepe 2009). Moreover, thromboxane-dependent platelet activation and endothelial perturbation represent early events in T1DM that are possibly related to an acute inflammatory response (Davì et al. 2003; Romano et al. 2001).

The platelet adenosine diphosphate (ADP) $P2Y_{12}$ receptor signaling pathway is upregulated in diabetic platelets (Matsuno et al. 2005), thus reducing cAMP concentration and enhancing platelet adhesion and aggregation (Ferreira et al. 2006). Moreover, arachidonic acid-stimulated TXA_2 synthesis, determined via its stable metabolite TXB_2, was significantly greater in platelet-rich plasma from diabetic patients than in controls and was positively correlated with the fasting plasma glucose (Matsuno et al. 2005).

Biochemical evidence of increased platelet thromboxane-dependent activation in vivo can be obtained through noninvasive measurements of thromboxane metabolite excretion (Ciabattoni et al. 1989) that avoid artifactual platelet activation during and after blood sampling (FitzGerald et al. 1983). Our group firstly demonstrated that thromboxane A_2 biosynthesis, evaluated in vivo through the urinary excretion of 11-dehydro-TXB_2, is enhanced in patients with T2DM (Davì et al. 1990).

A major issue is whether enhanced platelet activation in DM is merely a consequence of more prevalent atherosclerotic lesions (relevant to the thrombosis risk complicating plaque rupture) or reflects the influence of the accompanying metabolic disturbances on platelet biochemistry and function (Davì et al. 1997). Patients with diabetes and peripheral arterial disease (PAD) had higher TX biosynthesis than age- and sex-matched control subjects (Davì et al. 1990). However, platelet activation has been shown to be rather related to the presence of DM per se, but not to macrovascular disease (Davì et al. 1990). Moreover, alterations in platelet function have been associated with the progression of diabetic microangiopathy, but their role in the prediction of microvascular disease has not been defined (Sobol and Watala 2000; Tarnow et al. 2009). Biochemical evidence

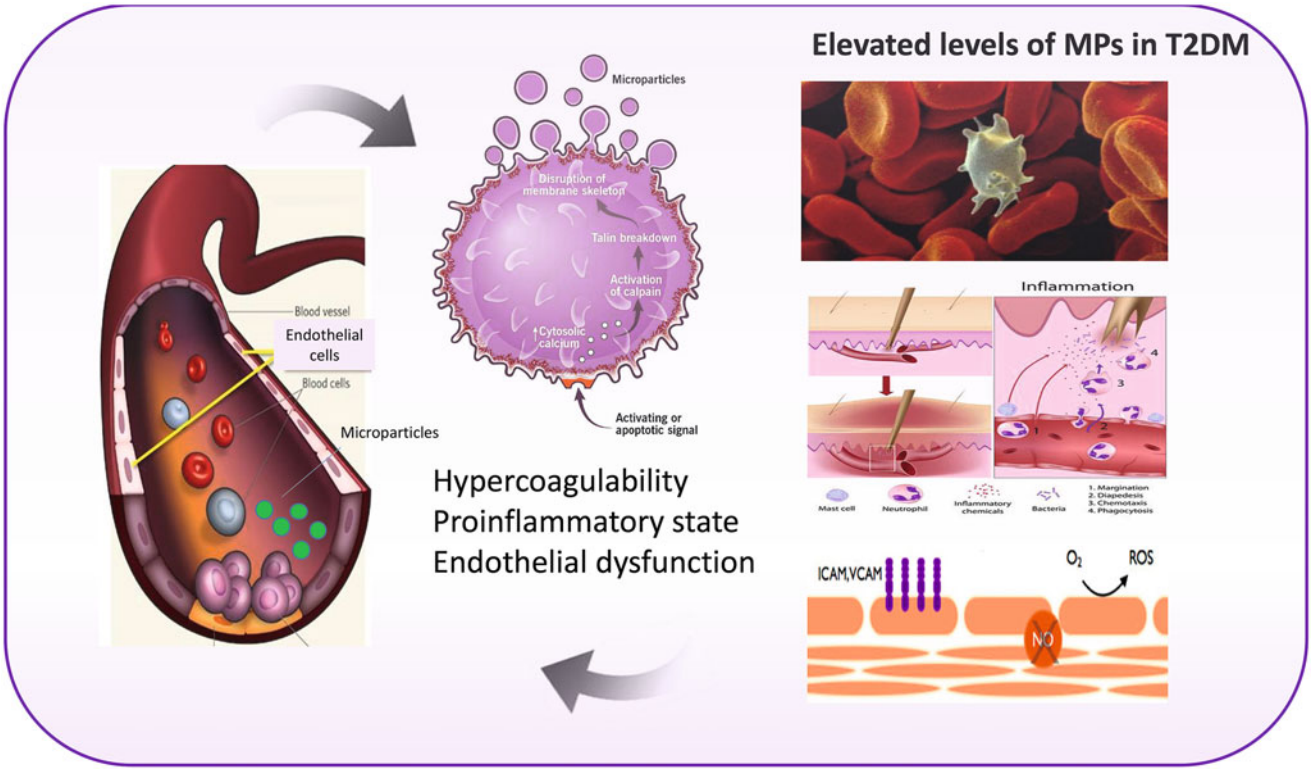

Fig. 1 Metabolic abnormalities in T2DM. The metabolic abnormalities associated with type 2 diabetes may affect platelet transcriptome and/or posttranscriptional regulation through intermediate mediators, such as oxidative stress with isoprostane formation, inflammatory molecule production, endothelial dysfunction with circulating endothelial cells and microparticle release, and cross talk between cells with miRNA exchange through circulating microparticles. The variable contribution and still poorly characterized interaction among these mechanisms eventually result in enhanced platelet hyperreactivity, as reflected by enhanced platelet tissue factor expression and expression of TF-positive platelet–leukocyte complexes; increased expression of activation-dependent adhesion molecules (e.g., $\alpha_{IIb}\beta_3$, P-selectin), reflecting increased aggregability and the cross talk with leukocytes; and increased in vivo arachidonic acid metabolism and increased thromboxane $(TX)A_2$ biosynthesis

of TX-dependent platelet activation in patients with newly diagnosed T2DM, without micro- or macrovascular complications, would support the hypothesis of a primary role of metabolic abnormalities on platelet phenotype (Santilli et al. 2010).

The understanding that platelet activation is not merely the final step of atherothrombosis but takes part in the earlier stages of metabolic diseases, including diabetes, was paralleled by the identification of an additional function for platelets, acting as powerful activators and amplifiers of inflammation and eliciting further platelet activation. Circulating levels of inflammatory mediators derived from platelets, such as soluble CD40 ligand, soluble CD36, Dickkopf-1, and soluble receptor for advanced glycation end products (sRAGE), are higher in patients with diabetes as compared to controls and able to elicit the release of cytokines and chemokines, cell activation, and cell–cell interactions. Their properties make these soluble mediators potential biomarkers of ongoing low-grade inflammation possibly predicting future atherothrombotic events.

Platelets from DM patients may frequently exhibit accelerated turnover, as reflected by the presence of a higher number of reticulated platelets. These circulating cells represent young, mRNA-rich platelets with enhanced proaggregating potential. Reticulated platelets are larger and more reactive platelets, as platelet size correlates with greater platelet reactivity and total release of granular content (Tschoepe et al. 1991). Moreover, larger platelets produce more TXA_2 than smaller platelets. Thus, the increased potential for aggregation of such platelets lowers their threshold for activation, possibly contributing to increased incidence of cardiovascular events in the diabetic setting. Furthermore, these larger platelets of DM patients show a lower response to antiplatelet therapies with aspirin or clopidogrel (Guthikonda et al. 2007, 2008). Hence, mean platelet volume (MPV), a parameter that mirrors in vivo platelet turnover (Bath and Butterworth 1996) and is considered as an independent predictor of vascular events (Vizioli et al. 2009), is increased in diabetes (Hekimsoy et al. 2004), without any correlation between MPV and fasting blood

glucose, HbA1c, and duration of diabetes. MPV increase occurs at the beginning of the disease and persists for its duration, suggesting that the increase in MPV may be due to the diabetic state per se. The mechanisms underlying increased platelet volume in diabetes may be osmotic swelling due to raised levels of some glucose metabolites (Martyn et al. 1986), or, more likely, an increased MPV may reflect higher platelet turnover, as suggested by a high proportion of reticulated platelets found in T2DM (Rocca et al. 2012). It has been suggested that insulin may induce megakaryocytes to produce larger platelets (Watanabe et al. 1987). Whether an increased volume may also mirror functional differences among platelets released by megakaryocytes is still under study. Larger platelets are equipped with a higher content of proteins relevant to hemostasis and thrombosis. Tissue factor (TF), a 47-kDa glycoprotein, is the main activator of the coagulation cascade occurring in physiologic and pathologic conditions (Camera et al. 2003). Platelets can be a source of active TF, the so-called "blood-borne" TF or "circulating" TF, which can sustain activation of the blood coagulation on the edge of a growing thrombus (Camera et al. 2012). Megakaryocytes are committed to release into the circulation a well-characterized number of TF-carrying platelets, representing a fraction of the total platelet population (Camera et al. 2015). If this fraction would coincide with platelets with a larger platelet volume, MPV may also reflect the extent of platelet hyperreactivity and possibly the likelihood to atherothrombosis. Whether TF-containing platelets are more common in the setting of diabetes is currently under deep investigation.

Microparticles (MPs) of platelet origin may promote inflammatory cell recruitment, inducing cell adhesiveness through upregulation of cytokines (RANTES) both in endothelial cells and monocytes (Nomura 2009). MPs may drive vascular inflammation, endothelial dysfunction, leukocyte adhesion, and recruitment (Fig. 2). MPs are increased in a wide range of thrombotic disorders, with an interesting relationship between their levels and disease pathophysiology, activity, or progression. PMPs are also shown to be involved in the progressive formation of atherosclerotic plaque and development of arterial thrombosis, especially in diabetic patients (Santilli et al. 2016). Enhanced levels of TF-bearing MPs have been found in T2DM patients (Ueba et al. 2008). The procoagulant potential of MPs in diabetes (Camera et al. 2003) is increased and related to glycemic control. Thus, several lines of experimental and clinical evidence support a role of MPs as markers of cardiovascular risk and drivers of atherothrombosis in diabetes (Santilli et al. 2016).

This chapter will focus on the strong body of evidence indicating a platelet hyperreactivity phenotype in diabetes, fostered by the variable contribution of a number of mechanisms driven by the metabolic abnormalities associated with T2DM and eventually affecting the platelet transcriptome and/or posttranscriptional regulation. These would include oxidative stress with isoprostane formation, inflammatory molecule production, endothelial dysfunction with circulating endothelial cells and microparticle release, and cross talk between cells with miRNA exchange through circulating microparticles (Fig. 1).

Metabolic Changes and Platelet Activation

Hyperglycemia

The abnormal metabolic state that accompanies diabetes renders arteries susceptible to atherosclerosis, being capable of altering the functional properties of multiple cell types,

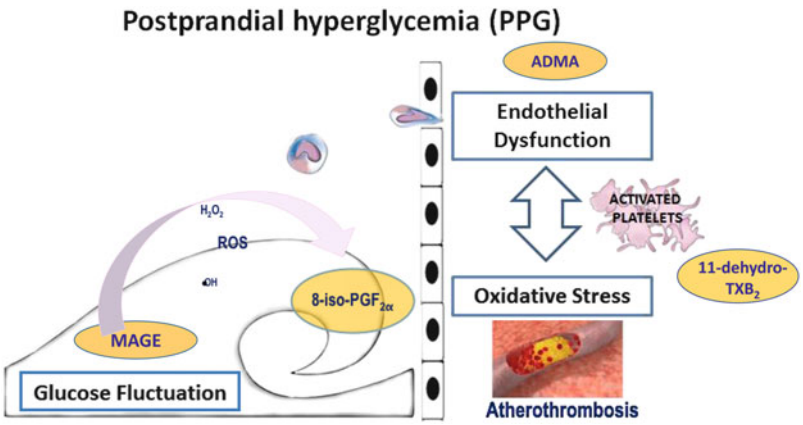

Fig. 2 Microparticles. Platelets are a major source of microvesicles, membrane-coated vesicles that emerge by budding upon apoptosis. Microparticles are both biomarkers and effectors of disease. They expose negatively charged phospholipids, which provide binding sites for activated coagulation factors. Elevated levels of MPs may also promote inflammatory cell recruitment, via their influence on cell–cell interactions and cytokine release. Finally, platelet-derived MPs may promote inflammatory cell recruitment, inducing cell adhesiveness through upregulation of cytokines both in endothelial cells and monocytes

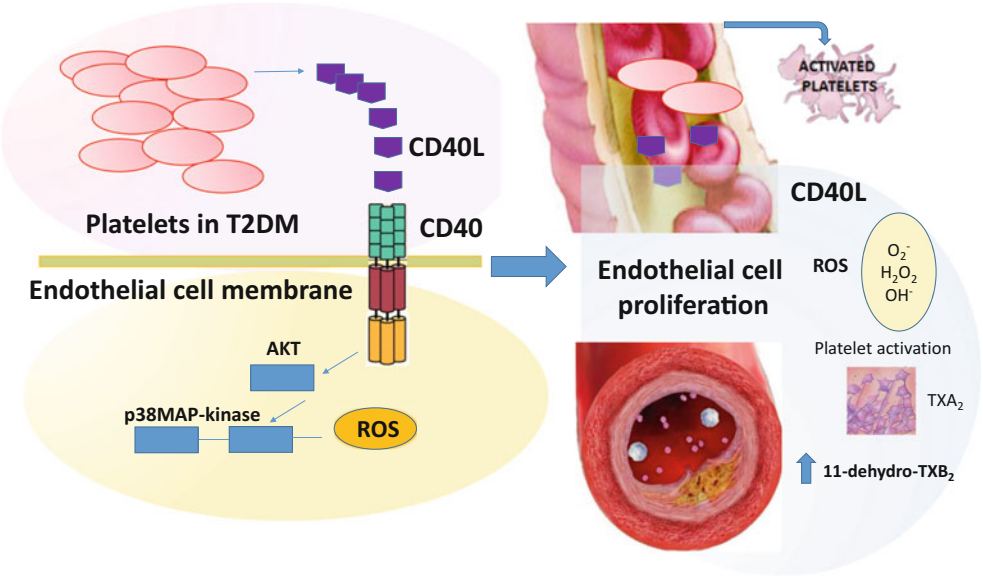

Fig. 3 Glucose fluctuations in diabetes. Glucose postprandial swings exert detrimental effects by increasing oxidative stress and endothelial dysfunction, as mirrored in vivo by circulating levels of asymmetric dimethylarginine (ADMA), with subsequent lipid peroxidation and TX-dependent platelet activation. These abnormalities favor the occurrence of atherothrombosis. Acute glucose fluctuations, as reflected by mean amplitude of glycemic excursions (MAGE), are strongly correlated in vivo with isoprostane generation and thromboxane biosynthesis, as reflected by the urinary 8-iso-$PGF_{2\alpha}$ and 11-dehydro-TXB_2 excretion rates, respectively, both cross-sectionally and during interventions aimed at reducing glucose excursions

including platelets. An altered platelet metabolism and changes in intraplatelet signaling pathways may contribute to the pathogenesis of atherothrombotic complications of diabetes.

A variety of mechanisms may be responsible for enhanced platelet aggregation. Among them, hyperglycemia may represent a causal factor for in vivo platelet activation and may be responsible for nonenzymatic glycation of platelet glycoproteins, causing changes in their structure and conformation, as well as alterations of membrane lipid dynamics. Intraplatelet glucose concentration mirrors the extracellular concentration, since glucose entry into the platelet does not depend on insulin (Vinik et al. 2001). Chronic hyperglycemia upregulates the expression of platelet activation markers (CD31, CD62P, CD63) and platelet surface receptors (GPIb and $\alpha_{IIb}\beta_3$) (Eibl et al. 2004), significantly related to HbA1c levels, suggesting that improvement of metabolic control may be beneficial on platelet activation.

Impaired fasting glucose (IFG)—a prediabetic state—is a frequent glycemic disorder in the general population. MPV is significantly higher both in diabetics and in IFG subjects than in controls (Coban et al. 2006). MPV is positively related to fasting glucose and HbA1c in both diabetics and IFG. This may be a potential mechanism by which subjects with IFG are at increased cardiovascular risk (Santilli et al. 2010).

Postprandial hyperglycemia—an early metabolic abnormality often preceding the clinical diagnosis of diabetes and an independent risk factor for CVD in T2DM (Balkau 2000)—is characterized by postprandial glucose (PPG) deterioration, preceding impairment in fasting glucose level (Cavalot et al. 2006). Thus, impaired glucose tolerance (IGT) reflects the progression from normoglycemia to T2DM. The mechanism(s) by which glucose fluctuations during the postprandial period exert their deleterious effects may include enhanced oxidative stress and endothelial dysfunction (Monnier et al. 2009), both contributing to platelet activation (Fig. 3). Persistent in vivo TX-dependent platelet activation and enhanced lipid peroxidation in response to postprandial hyperglycemic spikes have been demonstrated in patients with early T2DM—with HbA1c levels <7 %—and free of detectable microvascular and macrovascular complications (Coban et al. 2006). Furthermore, only PPG (upward glycemic spikes) predicts TX biosynthesis, consistent with the finding that acute, short-term hyperglycemia, induced by hyperglycemic clamping, enhances thromboxane biosynthesis in T2DM (Ha and Lee 2001). Consistently, other factors, largely reflecting the underlying primary metabolic abnormality, have been reported to predict TX biosynthesis in other clinical settings, such as cholesterol levels in hypercholesterolemia and homocysteine or folate concentration in hyperhomocysteinemia (Davì and Patrono 2007). A moderate decrease in PPG achieved with the α-glucosidase inhibitor acarbose causes time-dependent downregulation of both urinary TX metabolite

excretion, suggesting a causal link between early metabolic abnormalities and platelet activation in this setting (Balkau 2000). A recent study from our group, comparing the extent of TX-dependent platelet activation in IGT, DM patients with a diagnosis documented either <12 months or ≥ 12 months, demonstrated that thromboxane biosynthesis—at study entry—was comparably enhanced in the three groups, with limited intra-subject variability over time (Ciaffardini et al. 2014).

Insulin Resistance

T2DM is frequently associated with insulin resistance and, consequently, with increased levels of circulating insulin, especially at the beginning of the natural history of diabetes.

Insulin resistance or its associated hyperinsulinemia are independent risk factors for CAD, with a level of risk similar to that of hyperlipidemia (Despres et al. 1996). Increased insulin resistance rather than decreased insulin secretion are related to inflammation (Blake and Ridker 2001) even in the prediabetic state (Festa et al. 2003). Insulin resistance per se contributes to increased platelet activation, independently of underlying inflammation. Platelets retain a functional insulin receptor capable of insulin binding and autophosphorylation (Falcon et al. 1988). After receptor binding, insulin inhibits $P2Y_{12}$ signaling and thereby reduces platelet reactivity (Ferreira et al. 2004). Thus, insulin is generally thought to reduce platelet responses to various agonists (Abrahm et al. 1986). Insulin also increases the surface expression of PGI_2 receptors, thus exerting an antiplatelet action by maintaining platelet sensitivity to PGI_2 (Abrahm et al. 1986). Decreased platelet insulin receptor number and affinity (Udvardy et al. 1985) might account for platelet hyperactivity in T2DM. Alteration of insulin action enables platelet dysfunction (Kahn 1998).

Insulin resistance increases intraplatelet calcium concentration that leads to augmented degranulation and aggregation. Moreover, insulin resistance reduces platelet sensitivity to NO and PGI_2, both released by the endothelium with an inhibitory effect on platelet function (Nissen et al. 2008).

Thus, the finding that human platelets have insulin receptors that participate in the regulation of platelet function (Falcon et al. 1988) led to the hypothesis that in clinical settings characterized by decreased insulin sensitivity, platelets are potential sites of insulin resistance and that the latter is associated with impairment in the physiological antiaggregating action exerted by insulin (Trovati and Anfossi 2002). Whereas insulin inhibits platelet aggregation in healthy non-obese subjects, this effect is blunted in obese individuals (Trovati et al. 1995; Monnier et al. 2006). Thus, an impaired platelet response to insulin could be another feature of the insulin resistance syndrome.

Oxidative Stress

DM is strictly linked with oxidative stress, with overproduction of reactive oxygen species (ROS), as well as with reduced antioxidant levels, in both type 1 (Chiarelli et al. 2004, 2005) and type 2 diabetes (Jardin et al. 2006; Davì et al. 2010). Enhanced generation of oxidants, such as superoxide anions and hydrogen peroxide, is able to increase platelet activation (Freedman 2008).

Hyperglycemic spikes may advise ROS production directly via glucose metabolism and auto-oxidation and indirectly through the formation of AGE and their receptor binding. ROS, in turn, may activate other signaling molecules, such as PKC and NF-kB, leading to transcription of redox-sensitive genes (Gresele et al. 2003). These glycated proteins may contribute to the development of atherosclerotic complications by activation of the receptor for AGEs (RAGE) (Santilli et al. 2009a). Due to increased ROS production, plasma from patients whose diabetes is poorly controlled has less antioxidant capacity (Tsai et al. 1994) and contains increased levels of lipid hydroperoxides (Nourooz-Zadeh et al. 1995) and F_2-isoprostanes, such as 8-iso-prostaglandin (PG) $F_{2\alpha}$ (Davì et al. 1999), only partially reversible in association with improved glycemic control. 8-iso-$PGF_{2\alpha}$ is considered a nonenzymatic oxidation product of arachidonic acid in circulating LDL and is a marker of lipid peroxidation both in vitro and in vivo (Ciaffardini et al. 2014).

Increased urinary excretion of 8-iso-$PGF_{2\alpha}$ has been depicted in association with diabetes (Patrono and FitzGerald 1997). Moreover, improvement of metabolic setting and vitamin E supplementation in T2DM patients are both accompanied by a significant reduction in the urinary excretion of 8-iso-$PGF_{2\alpha}$ and of 11-dehydro-TXB_2 (a stable metabolite of TXB_2) (Blake and Ridker 2001; Formoso et al. 2008). Thus, changes in the rate of arachidonate peroxidation to form biologically active isoeicosanoids, such as 8-iso-$PGF_{2\alpha}$, may represent an important biochemical link between altered glycemic control, oxidant stress, and platelet activation in T2DM (Blake and Ridker 2001).

Of interest, increased lipid peroxidation and platelet activation denote early events in the development of T1DM subjects (Davì et al. 2003). Subjects with newly diagnosed diabetes had significantly increased urinary excretion of both 8-iso-$PGF_{2\alpha}$ and 11-dehydro-TXB_2 and higher plasma levels of a number of inflammatory markers such as IL-6 and TNF-α. They were reduced after 1 year from the onset of diabetes. Thus, biochemical signals of oxidative stress and platelet activation can be appreciated early at the onset of diabetes, and their variable intensity is driven, at least in part, by IL-6 production and disease duration (Davì et al. 2003).

Moreover, both lipid and protein oxidation are significantly elevated in patients with T2DM (De Cristofaro et al. 2003). The association of F_2-isoprostane formation with both urinary 11-dehydro-TXB_2 excretion and plasma prothrombin fragment F1 + 2 levels argues that lipid peroxidation can influence platelet as well as coagulative activation, thus contributing to a prothrombotic state in T2DM (Falcon et al. 1988). Oxidized lipids put on activated platelets may give a better surface for the assembly and activation of prothrombinase complex. This may promote a vicious cycle that, together with the oxidation linked depression of the anticoagulant pathway, may predispose to a prothrombotic state in diabetes mellitus (Davì et al. 2002).

Lastly, oxidative modifications of circulating proteins have been involved in the increased platelet hyperactivity seen in diabetic patients. Glycoxidation of albumin, with glycated albumin generation, blunts the nonesterified fatty acid-fixing ability of albumin, thus supporting enhanced arachidonate oxygenation made eligible for the production of TXA_2 (Blache et al. 2015).

Several pathways are involved in hyperglycemia-induced vascular damages: (1) enhanced polyol activity, causing sorbitol and fructose accumulation; (2) increased formation of advanced glycation end products (AGEs); (3) activation of protein kinase C and nuclear factor kB; and (4) increased hexosamine pathway flux (Brownlee 2001). Hyperglycemia triggers these deleterious metabolic events through a single process: overproduction of superoxide by the mitochondrial electron-transport chain.

Glucose swings reveal a triggering effect on oxidative stress (Monnier et al. 2006). In the postprandial phase, glucose variations induce oxidative stress more than chronic hyperglycemia. The MAGE, obtained by measuring the arithmetic mean of the differences between consecutive peaks and nadirs (Service et al. 1970), is used for assessing glucose fluctuations during the day, as a marker of glycemic instability (Service et al. 1987; Tschoepe et al. 1991). Acute glucose fluctuations are strongly correlated with isoprostane generation, while no relationship was observed when urinary 8-iso-$PGF_{2\alpha}$ excretion rates were plotted against main markers of sustained hyperglycemia (HbA1c and mean daily glucose concentrations) (Basili et al. 2006).

Diabetes and Platelet-Derived Inflammation

Platelets represent an important linkage between inflammation, thrombosis, and atherogenesis. Platelet-induced chronic inflammatory processes at the vascular wall result in development of atherosclerotic lesions and atherothrombosis (May et al. 2007).

Hyperglycemia, glycemic variability, and insulin resistance are determinants and predictors of platelet activation and consequently also of the release of inflammatory mediators such as CD40 ligand, CD36, Dickkopf-1, and presumably soluble receptor for advanced glycation end products (sRAGE), which amplify the inflammatory status further promoting the release of cytokines and chemokines.

CD40 signaling mediates many inflammatory responses in atherosclerosis. A wide variety of inflammatory cells express CD40 ligand (**CD40L**), and stimulation by other pro-inflammatory cytokines increases endothelial cell expression of CD40L (Fig. 4). Upregulation of CD40L at baseline prospectively predicts cardiovascular events among apparently healthy women. Elevated soluble CD40L (sCD40L) levels have been found in both type 1 and 2 diabetes, further supporting the idea of a common basis for both diabetes and atherosclerosis (Santilli et al. 2006).

Soluble **CD36** (sCD36) has been proposed to early identify diabetics at risk of accelerated atherothrombosis. CD36 is believed to play a critical role in the initiation of atherosclerotic lesions through its ability to bind and internalize modified LDL trapped in the arterial wall, facilitating the formation of lipid-engorged macrophage foam cells (Libby 2002). Additionally, CD36 has been proposed as a marker of macrophage activation and inflammation (Tuomisto et al. 2005). Thus, monocyte CD36 seems to be upregulated under conditions that follow T2DM and the metabolic syndrome (Nakata et al. 1999). Platelet CD36 is associated with nonreceptor tyrosine kinases of the Src family (Huang et al. 1991) implicated in platelet activation by ox-LDL. LDL cholesterol can be oxidatively modified by monocytes via the MPO-H_2O_2-NO_2 system, to form ligands with high affinity for CD36 ($oxPC_{CD36}$). $oxPC_{CD36}$ interaction with platelet CD36 results in increased platelet activation and enhanced thrombus formation at sites of vascular injury in vivo (Jackson and Calkin 2007). Increased plasma CD36 levels have been described not only in overt T2DM (Koonen et al. 2011) but also in prediabetic conditions such as polycystic ovary syndrome and in patients with IGT (Glintborg et al. 2008). sCD36 levels may be predicted by chronic low-grade inflammatory state (CRP and IL-6), low insulin sensitivity, and higher BMI (Handberg et al. 2009) all involved in the pathogenesis of DM and metabolic syndrome. We have provided in vivo evidence that persistently increased levels of sCD36 in T2DM patients are related to impaired metabolic control and to diabetes duration (Liani et al. 2012). Furthermore, we have observed a highly significant correlation between sCD36 and the urinary excretion rate of 11-dehydro-TxB_2, supporting the likelihood of CD36 release during TxA_2-dependent platelet activation in T2DM. Interestingly, a linear and direct correlation has been reported between plasma CD36 levels and the urinary excretion rate of 8-iso-$PGF_{2\alpha}$, marker of in vivo ongoing lipid peroxidation (Patrono et al. 2005) related to circulating ox-LDL levels (Liu et al. 2004). This is in agreement with

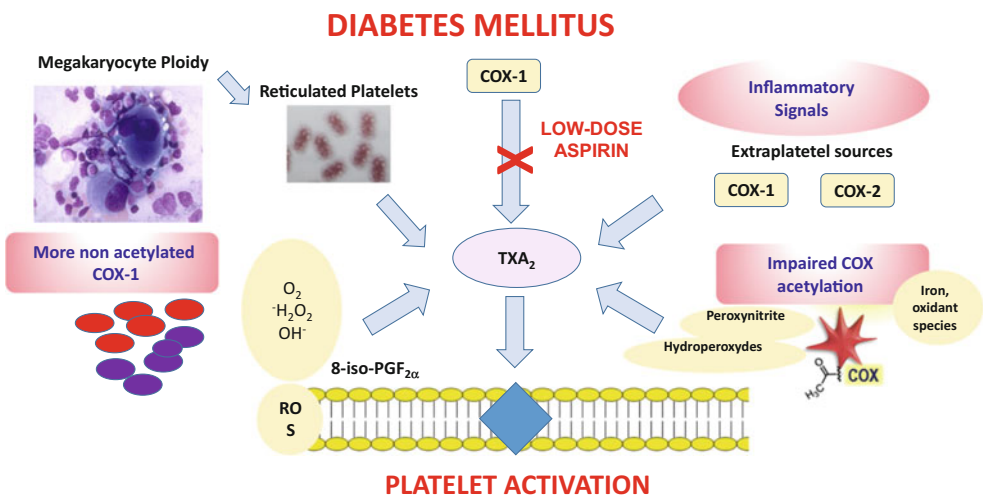

Fig. 4 CD40 signaling. CD40L is a 39-kD transmembrane glycoprotein structurally related to tumor necrosis factor (TNF)-α. More than 95 % of the circulating CD40L derives from platelets. This mediator is stored in the cytoplasm of resting platelets, exposed on the surface upon platelet activation, cleaved, and released into the extracellular environment. This product of cleavage, soluble CD40L, in turn induces inflammatory responses in the endothelium by binding CD40 on endothelial cells. CD40L also increases platelet release of ROS through activation of Akt and p38 MAP kinase signaling pathways. The linear correlation between plasma CD40L levels and the urinary excretion rate of the enzymatic metabolite of TXB_2, 11-dehydro-TXB_2, supports the likelihood of CD40L release during TXA_2-dependent platelet activation in T2DM

the evidence that a specific CD36-dependent, ox-LDL-mediated signaling pathway is required for platelet activation (Chen et al. 2008).

Dickkopf-1 (DKK-1) is the pivotal regulator of the wingless (Wnt) signaling pathway, involved in inflammation, atherogenesis, and control of glucose metabolism (Chien and Moon 2011). Wnt signaling modulates atherosclerosis, regulating endothelial function, vascular smooth muscle cell proliferation, angiogenesis, and inflammation, mediating both inflammatory and anti-inflammatory effects. Wnt pathways are directed by multiple antagonists or modulators including dickkopfs (DKK). Platelets are major sources of circulating levels of DKK-1 in several clinical settings (Lattanzio et al. 2014). Based on the evidence of enhanced DKK-1 expression in platelets (Voorzanger-Rousselot et al. 2009), we supposed that diabetic subjects with higher platelet activation in vivo may exhibit increased circulating DKK-1. Thereafter, we speculated that the increased concentrations of DKK-1 in T2DM may derive, at least in part, from TX-dependent platelet activation. Thus, for the first time, we reported that in diabetic patients enhanced circulating levels of the Wnt antagonist DKK-1 are deeply associated with 11-dehydro-TXB_2, ADMA, and CD40L levels. Indeed, DKK-1 levels in T2DM may mirror interactions between inflammation, endothelial dysfunction, and platelet activation (Voorzanger-Rousselot et al. 2009). As a matter of fact, we revealed in vivo that in T2DM patients, DKK-1 is enhanced since the earlier stages of the disease (Vazzana et al. 2012), and amelioration of glycemic control, exerted for instance by acarbose, downregulates plasma DKK-1 levels. Such considerable reduction of DKK-1 after glycemic control improvement and the positive link between changes in the two parameters suggest that hyperglycemia may be a significant driver of soluble DKK-1. In addition, the detected downregulation of plasma DKK-1 in low-dose ASA-treated subjects vs untreated patients makes platelets a likely source of its release (Aukrust et al. 1999).

RAGE (receptor for advanced glycation end products, AGEs) initiates the intracellular signaling that disrupts the cellular function through its recognition and binding of AGEs (Goldin et al. 2006). AGEs contribute to several microvascular and macrovascular complications through formation of cross-links between molecules in the basement membrane of extracellular matrix. AGEs are prevalent in the diabetic vasculature and contribute to the development of atherosclerosis. Soluble forms of RAGE (sRAGE), including the splice variant endogenous secretory (esRAGE), have been found in blood and tissues (Schmidt et al. 2001). Ligand engagement of RAGE triggers cell-specific signaling, resulting in enhanced generation of ROS and activation of NF-kB (Hasan et al. 2003). By occupying the ligand-binding domain, sRAGE might act as an endogenous competitive inhibitor of RAGE, thus influencing the modulatory network of the ligand–RAGE axis (Santilli et al. 2009a) that plays a critical role in the interplay between hyperglycemia and vascular homeostasis (Basta et al. 2006). We described lower plasma sRAGE in subjects with T2DM as compared to nondiabetic subjects, with a significant inverse correlation between circulating sRAGE and HbA_{1c}, insulin resistance

index, S100A12, and CRP. Moreover, in diabetic patients, in vivo oxidative stress and endothelial dysfunction were associated with low sRAGE, as reflected by urinary 8-iso-$PGF_{2\alpha}$ and plasma asymmetric dimethylarginine (ADMA), respectively (Devangelio et al. 2007). These findings suggest that the ligand–RAGE hyperactivity, supported by poor metabolic control, increases in vivo ROS generation, thus promoting systemic inflammation, endothelial dysfunction, and platelet activation (Ferreiro et al. 2010). AGEs strongly activate platelets, increasing RAGE expression at the platelet surface membrane (Gawlowski et al. 2009). As in diabetes, sRAGE levels are reduced in hypercholesterolemic patients and are inversely correlated with oxidative stress and endothelial dysfunction (Yilmaz et al. 2009). Regardless of the underlying metabolic abnormality (familial combined hyperlipidemia or metabolic syndrome), circulating esRAGE discriminates also patients with NAFLD, suggesting that activation of the AGE/RAGE pathway may contribute to the progression of both liver and cardiovascular disease (Santilli et al. 2015a).

Despite no formal demonstration that platelets are a source of soluble RAGE, this hypothesis is suggested by indirect in vivo data, showing that low endogenous secretory RAGE (esRAGE) levels are significant predictors of urinary 11-dehydro-TXB_2 excretion rate in several clinical settings (Santilli et al. 2015a).

Aspirin in T2DM

Platelets are primary targets of antithrombotic therapy in diabetic cardiovascular disease (Jennings 2009).

Aspirin (**ASA**) exerts its platelet action mainly by irreversibly acetylating a serine residue of platelet cyclooxygenase (COX)-1 (Roth et al. 1975), thus inhibiting the formation of thromboxane (TX) A_2. This effect is irreversible because platelets are enucleate and, thus, unable to resynthesize COX-1.

Aspirin is the pivotal agent for secondary prevention among patients with diabetes (Kumbhani et al. 2015) significantly reducing the risk for ACS, stroke, and cardiovascular death (Kumbhani and Bhatt 2010). ADA recommends the use of low-dose ASA (75–162 mg/day) for secondary prevention of cerebrovascular and cardiovascular events in all diabetic patients with history of CVD (American Diabetes Association 2015b).

In primary prevention, the most recent ACCF/AHA guidelines recommend low-dose ASA in people who are at increased CVD risk (10-year risk of CVD events over 10 %) and who are not at increased risk of bleeding, whereas ASA is not recommended for diabetic subjects with low CVD risk (10-year CVD risk under 5 %) as the potential adverse effects from bleeding offset the potential benefits. ADA recommends ASA therapy (75–162 mg/day) as a primary prevention strategy at increased cardiovascular risk such as men aged >50 years or women aged >60 years who have at least one additional major risk factor (family history of CVD, hypertension, smoking, dyslipidemia, or albuminuria) (American Diabetes Association 2015b). Ongoing trials will provide further insights into the appropriateness of ASA prescription in the primary prevention setting in diabetic subjects. These include A Study of Cardiovascular Events iN Diabetes (ASCEND) and Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trial in Diabetes (ACCEPT-D).

ASA Resistance or Hyporesponsiveness?

Among the different antiplatelet strategies, over the past years, the term "aspirin resistance" has been largely abused and inappropriately applied to define both the occurrence of vascular events despite ongoing treatment (clinical definition) and the residual platelet reactivity or impaired platelet response in aspirin-treated individuals (laboratory definition). While clinical failure is an anticipated event for any preventive strategy, given the multifactorial nature of atherothrombosis, laboratory failure is often biased by the variable accuracy of methods employed to assess the response to aspirin.

Although largely inappropriate, the term aspirin resistance has prospered for long, in particular in the setting of diabetes, driven both by the pathophysiological evidence of enhanced platelet hyperreactivity/activation in this setting and by the epidemiological evidence of suboptimal response to aspirin in patients with diabetes, as emerged in metanalyses of clinical trials in this setting (Pignone et al. 2010). Heterogeneity among evaluated studies, low event rate, different aspirin regimens tested, and high rate of aspirin discontinuation may have biased the available results.

While acknowledging the multiple limitations related to the epidemiological evidence fostering the aspirin failure hypothesis, there is compelling pathophysiological evidence for a residual platelet hyperreactivity, variably assessed among studies, despite ongoing low-dose aspirin treatment, at least in a fraction of diabetic patients, leading to a slow shift from the term "aspirin resistance" into "variability of aspirin response."

In this regard, a number of questions arise, whose solution may help in substantiating and providing clinical relevance to the whole story: first, whether methods used to assess platelet inhibition by aspirin are accurate and reliable;

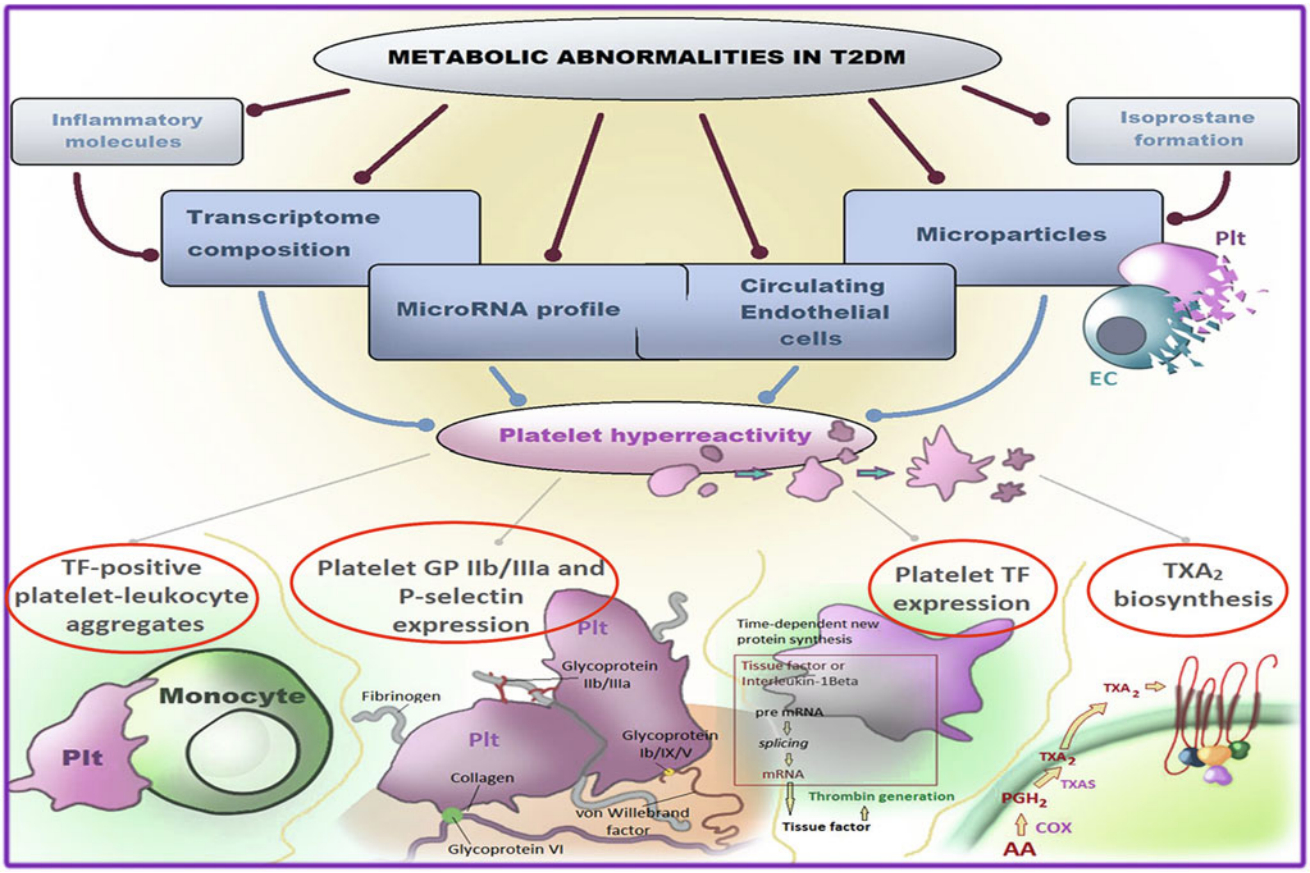

Fig. 5 Less-than expected response to ASA. Diabetic patients may have a lower response to aspirin probably due to an increased megakaryocyte ploidy and accelerated platelet turnover, with an excess of newly released, non-acetylated COX-1 over the 24-h dosing interval that is not inhibited by the once-daily low-dose ASA prescription; low-grade inflammation with increased TXA_2 generation by extraplatelet sources of COX-1 and COX-2; oxidative stress, with increasing reactive oxygen species (ROS) production, nonenzymatic lipid peroxidation leading to formation of biologically active compounds, such as 8-iso-$PGF_{2\alpha}$, able to bind TP receptor, thus contributing to TX-dependent platelet activation; and impaired COX-1 inhibition, by a number of mechanisms, the most likely in this clinical setting being enhanced lipid hydroperoxide ambient

second, whether there is evidence that the presence of diabetes may modulate the inhibitory effect of low-dose aspirin on platelet function; and third, which, if any, easily detectable clinical or biochemical characteristics may identify individuals who would gain inadequate response to aspirin.

Serum TXB_2 and urinary 11-dehydro-TXB_2 are biochemical endpoints targeting aspirin mechanism of action and provide reliable information on the maximal biosynthetic capacity of circulating platelets ex vivo and on the actual rate of TXA_2 biosynthesis in vivo, respectively (Davì and Patrono 2007). In contrast, while platelet COX-1, as reflected by serum TXB_2 levels, is uniformly and persistently suppressed by ASA treatment, the effect of ASA is variably detected by functional assays, potentially leading to misclassification of "responder" as "resistant" phenotypes owing to poor reproducibility of functional measurements on repeated measurements (Santilli et al. 2008, 2009b).

In addition to common causes of suboptimal response to aspirin, such as poor compliance, pharmacodynamic interaction with NSAIDs, as well as pharmacokinetic issues such as prescription of enteric-coated formulations of aspirin, the evidence that the inhibitory effect of low-dose aspirin on platelet function may be modified by the presence of diabetes is mounting.

Excess fat, which is largely prevalent in the diabetic population, may affect aspirin pharmacokinetics due to a larger distribution volume. Adequate bioavailability may be restored by weight loss and/or avoidance of enteric-coated formulations.

In diabetes, lower response to aspirin may be related to (a) enhanced platelet turnover, through increased reactivity of younger platelets; (b) increased TXA_2 formation by platelet COX-2 expression or extraplatelet, cellular COX-1, and/or COX-2, during low-grade inflammation; and (c) incomplete inhibition of COX-1 (Fig. 5). Furthermore, oxidative stress, characterizing diabetes, may favor the escape of platelets from aspirin effects, with multiple mechanisms (Santilli et al. 2015b):

1. Mechanisms impairing the effects of endogenous antiaggregant agents, i.e., reduced platelet sensitivity to the antiaggregating effects of nitric oxide, due to high glucose-mediated oxidative stress
2. Mechanisms interfering with platelet COX acetylation, e.g., COX-1 polymorphisms (Pettinella et al. 2009) and lipid hydroperoxide-dependent impaired acetylating effects of aspirin
3. Mechanisms favoring platelet priming (lipid hydroperoxides) or activation (F2-isoprostanes, acting as partial agonists of thromboxane receptor) or aldose-reductase pathway-mediated oxidative stress, leading to enhanced platelet TXA_2 biosynthesis or TX receptor activation.
4. Mechanisms favoring platelet recruitment, promoted by aspirin-triggered platelet isoprostane formation (Cangemi et al. 2012).

Among all described mechanisms, one of the most convincing is attributable to increased platelet turnover. Unacetylated COX-1 and COX-2 in newly generated platelets may provide a possible explanation for ASA-insensitive TXA_2 biosynthesis: one daily dose of low-dose ASA may be inadequate because of the large capability of bone marrow to accelerate platelet production, even tenfold of basal rate. Several circulating platelets entering the bloodstream after ASA washout will have their COX-1 activity uninhibited and may be responsible for accelerated recovery of TX generation in the 12–24-h dosing interval. Several groups, including ours, have reported that a twice-daily dosing in diabetic patients may overcome this issue (Rocca/Santilli/Pitocco et al. 2012). In our diabetic population (Rocca/Santilli/Pitocco et al. 2012), the shorter duration of COX-1 suppression in about one-third of the studied population was unrelated to glycemic control or diabetes duration, but was likely to be due to abnormal megakaryopoiesis, obesity, or both. Indeed, on multiple regression analysis, higher MPV and body mass index (BMI) were the only independent predictors of accelerated COX-1 recovery. Thus, BMI and MPV may be regarded as candidate and easily measured biomarkers to be tested in larger population, to identify DM patients who may achieve less antithrombotic protection by aspirin and for whom personalized dosing regimens may be tested to overcome interindividual variability.

Conclusions

It is apparent, we would say, lapalissian, that platelets, despite being small, anucleated cells, are the major players and address the propensity to atherothrombosis of the patients with diabetes mellitus.

More recent evidence shows that platelets have the capacity of protein synthesis through translation of megakaryocyte-derived mRNAs and may change their mRNA/protein composition and thus their functions, upon stimulation and/or disease. Thus, in the last years, availability of high-throughput techniques is allowing testing the hypothesis that the metabolic abnormalities associated with T2DM may affect PLT transcriptome and/or posttranscriptional regulation through intermediate mediators, such as oxidative stress with isoprostane formation, inflammatory molecule production, endothelial dysfunction with release of circulating endothelial cell or microparticles, and cross talk between cells with miRNA exchange through circulating microparticles (Fig. 1). Such "molecularly (re)programmed" platelets might influence the development and progression of atherothrombosis in diabetes. Concurrently, molecules produced by platelets will have the potential to serve as biomarkers of the thrombotic risk or the response to antiplatelet treatment.

Take Home Messages

- Platelets are the culprit cells implicated in the propensity to atherothrombosis in the setting of both type 1 and type 2 diabetes mellitus, and are related to diabetes vascular complications.
- A persistent in vivo platelet activation, with enhanced thromboxane (TX) biosynthesis, has been described in diabetic patients, even in the preclinical phases of the natural history of the disease.
- Acute hyperglycemia, glycemic instability, and insulin resistance affect platelet pathophysiology.
- Platelet-derived inflammatory molecules, markers of oxidative stress and inflammation, are secondary mediators of diabetes-induced platelet activation.
- Molecules produced by platelets have the potential to serve as biomarkers of the thrombotic risk or the response to antiplatelet treatment.
- The metabolic abnormalities associated with type 2 diabetes may affect platelet transcriptome and/or posttranscriptional regulation through intermediate mediators, such as oxidative stress with isoprostane formation, inflammatory molecule production, endothelial dysfunction with circulating endothelial cells and microparticles release, cross-talk between cells with miRNA exchange through circulating microparticles.

Acknowledgments The expert editorial assistance of Dr. Stefano Lattanzio is gratefully acknowledged.

Part VI

Pharmacology

Aspirin

Carlo Patrono

Abstract

The last 35 years of clinical research on aspirin have proven its value as a lifesaving drug for the treatment and prevention of atherothrombosis. The place of low-dose aspirin in the therapeutic armamentarium has not been substantially altered by the successful development of new antiplatelet agents, including $P2Y_{12}$ and PAR-1 receptor blockers. The demonstration of additive beneficial effects resulting from effective blockade of the platelet ADP and/or thrombin receptor combined with thromboxane suppression in high-risk patients is consistent with the multifactorial nature of atherothrombosis. Besides becoming an essential component of the antithrombotic strategy in high-risk settings, low-dose aspirin has also provided a mechanistic insight into the participation of platelets in other pathophysiologic processes, including colorectal cancer. The aim of this chapter is to review the mechanism of action and clinical pharmacology of aspirin as an antiplatelet agent, as well as the randomized trial evidence supporting its efficacy and safety. Moreover, more recent findings on additional long-term benefits of aspirin therapy will be discussed and new developments put into perspective.

Historical Perspective

Although synthesized in an industrial environment in 1897 and marketed in 1899, acetylsalicylic acid (aspirin) remains a cornerstone of antiplatelet therapy for the treatment of acute ischemic syndromes, both coronary and cerebrovascular, as well as for their secondary prevention (Amsterdam et al. 2014; Lansberg et al. 2012; Parekh et al. 2013; Roffi et al. 2016; Vandvik et al. 2012). In contrast, its role in the primary prevention of atherothrombosis has been the subject of debate during the past 10 years and remains highly controversial (Patrono 2013). Historically, aspirin has evolved from a prototypic nonsteroidal anti-inflammatory drug (NSAID) to a highly targeted antiplatelet drug (Born and Patrono 2006), largely as a consequence of fundamental discoveries on its mechanism of action in the early seventies (Vane 1971; Hamberg et al. 1975; Roth et al. 1975) (Fig. 1). These include the discovery by J. Vane (1971) that aspirin inhibits prostaglandin (PG) synthesis, the discovery by M. Hamberg and B. Samuelsson (1975) of thromboxane (TX) A_2 as the major arachidonic acid (AA) metabolite in human platelets responsible for the pro-aggregating effect of AA, and the characterization by P. Majerus and his colleagues (1975) of acetylation of platelet PG-synthase as the molecular mechanism responsible for permanent inactivation of its cyclooxygenase (COX) activity. These pivotal studies provided the basis for the development of mechanism-based biomarkers of TXA_2 inhibition in man, i.e., serum TXB_2 (Patrono et al. 1980) and urinary TX metabolite (TXM) excretion (Roberts et al. 1981). The availability of these biomarkers allowed characterizing the dose and time dependence of the inhibitory effects of aspirin on platelet TXA_2 production in healthy subjects (Patrignani et al. 1982; FitzGerald et al. 1983). The consistent demonstration of saturability of the platelet-inhibiting effect of

aspirin at low doses given once daily and the characterization of its biochemical selectivity in sparing prostacyclin (PGI_2) biosynthesis (Patrignani et al. 1982; FitzGerald et al. 1983) provided the rationale for testing the clinical efficacy and safety of a low-dose aspirin regimen in a variety of high cardiovascular (CV) risk settings (Patrono 1994) including acute myocardial infarction (MI) (ISIS-2-Collaborative Group, 1988). The publication of the International Study of Infarct Survival (ISIS)-2 (1988), demonstrating a remarkable protective effect of low-dose aspirin against vascular mortality at 5 weeks after a suspected acute MI (Fig. 2), represented the turning point for the use of aspirin as an antithrombotic agent and provided perhaps the most convincing evidence for an important role of platelet TXA_2 in the pathophysiology of coronary atherothrombosis (Davì and Patrono 2007).

Pharmacokinetics

Aspirin is rapidly absorbed in the stomach and upper small intestine, primarily by passive diffusion of non-dissociated acetylsalicylic acid across gastrointestinal (GI) membranes. Drug plasma levels peak at 30–40 min after the ingestion of uncoated aspirin (Pedersen and FitzGerald 1984). In contrast, it can take up to 4 or 5 h for plasma aspirin levels to peak after the administration of enteric-coated formulations (Patrignani et al. 2014). Orally administered aspirin undergoes substantial presystemic hydrolysis to salicylic acid in the gut content, the gut wall, and the liver (Pedersen and FitzGerald 1984). The systemic bioavailability of regular aspirin tablets is approximately 45–50 % over a wide range of doses (20–1300 mg) (Pedersen and FitzGerald

1984). However, lower bioavailability of enteric-coated preparations due to poor absorption from the higher pH environment of the small intestine may result in inadequate platelet inhibition (Cox et al. 2006; Grosser et al. 2013), particularly in obese subjects (Cox et al. 2006). Aspirin first comes into contact with platelets in the gut capillaries during absorption, and, as a consequence, platelets are exposed to higher drug levels than are present in the systemic circulation (Pedersen and FitzGerald 1984). This may explain, at least in part, the relative biochemical selectivity of low-dose aspirin (75–100 mg once daily) in sparing vascular PGI_2 production (Pedersen and FitzGerald 1984).

Aspirin has a half-life of 15–20 min in the bloodstream (Pedersen and FitzGerald 1984; Patrignani et al. 2014). Despite the rapid clearance of aspirin from the circulation, its antiplatelet effect lasts for the platelet life-span (8–10 days) owing to the permanent inactivation of platelet PGH-synthase (PGHS)-1, an effect that can be reversed only through the generation of new platelets. Given the short half-life of aspirin in the systemic circulation, the long-lasting duration of its antiplatelet effect is ensured by acetylation of PGHS-1 in the bone marrow megakaryocytes and limited new protein synthesis in anucleate platelets. Thus, there is a complete dissociation between the pharmacokinetics and pharmacodynamics of aspirin, allowing the use of a once-a-day regimen for antiplatelet therapy. However, reduced systemic bioavailability of the drug or faster renewal of the drug target may reduce the duration of its full antiplatelet effect and require a different (e.g., twice daily) dosing regimen (Rocca et al. 2012; Pascale et al. 2012) (see below).

Mechanism of Action

Aspirin inhibits platelet function through a molecularly sophisticated mechanism of action that appears ideally suited to target anucleate cell fragments, i.e., by rapidly inducing an irreversible modification in a critical platelet protein that cannot be repaired during the 24-h dosing interval. The limited systemic bioavailability of the active moiety, acetylsalicylic acid, and its short half-life contribute to restraining the extent and duration of any extra-platelet effects of the drug.

Aspirin exerts its unique antiplatelet effects by selectively acetylating a single serine residue (Ser-529) of PGHS-1 (DeWitt et al. 1990). This causes permanent inactivation of the COX activity of the enzyme, which catalyzes the conversion of AA to PGG_2, but does not appreciably affect its peroxidase activity responsible for reducing PGG_2 to PGH_2. Aspirin inhibits the COX activity of PGHS-1 by placing a larger than normal side chain at position 529 thereby interfering with arachidonate binding to the COX active site (DeWitt et al. 1990). Acetylation of the PGHS-1 and PGHS-2 by aspirin is regulated by the catalytic activity of the peroxidase which yields a higher oxidative state of the enzyme (Bala et al. 2008). In cells with high levels of hydroperoxy-fatty acids, the efficacy of aspirin in acetylating PGHS-2 is markedly decreased as compared to cells with low levels of hydroperoxides (Bala et al. 2008). This finding may explain, at least in part, the differential dose requirements for the anti-inflammatory effects (largely dependent on PGHS-2 inhibition, as with other NSAIDs) as compared to the antiplatelet effects of aspirin (entirely dependent on PGHS-1 inhibition), despite comparable potency in inhibiting the two purified enzymes in vitro (Bala et al. 2008). Presystemic acetylation of platelet PGHS-1 (Pedersen and FitzGerald 1984), as noted above, as well as the cumulative nature of inactivation of platelet COX-1 activity upon repeated daily dosing (Patrignani et al. 1982) may also contribute to the relative biochemical selectivity of low-dose aspirin in vivo (Patrignani et al. 1982; FitzGerald et al. 1983).

PGHS-1 and PGHS-2 are homodimers composed of identical subunits, but it has been shown that only one subunit is active at a time during catalysis; moreover, many NSAIDs bind to a single subunit of a PGHS dimer to inhibit the COX activity of the entire dimer (Shimokawa and Smith 1992). However, 50 % acetylation of platelet PGHS-1 is not sufficient to fully suppress the maximal capacity to synthesize TXA_2, and partial acetylation of the second subunit is required in order to suppress platelet COX-1 activity completely (Patrignani et al. 2014; Li et al. 2014).

Permanent inactivation of platelet COX-1 by low-dose aspirin represents the best characterized mechanism of action to explain its clinical efficacy as an antithrombotic agent (Patrono 1994). The finding that the acetylation of platelet PGHS-1 (Patrignani et al. 2014), the inhibition of TXA2 production (Patrignani et al. 1982), and the clinical efficacy of aspirin in reducing the risk of major vascular events in high-risk patients (ATT Collaboration 2002) are saturable at low doses (i.e., even much higher doses are not more effective) allows establishing a cause-effect relationship between this selective acetylation process and its clinical readout (s) (Patrono 2015). Although aspirin can acetylate a number of plasma proteins (e.g., fibrinogen or prothrombin), enzymes, and DNA in vitro (Patrono 2015), this usually requires millimolar concentrations that are approximately 100–1000 times higher than those achievable after oral dosing of low-dose aspirin (Patrignani et al. 2014). Thus, the apparently heterogeneous therapeutic effects of low-dose aspirin may well reflect the multifaceted consequences of platelet COX-1 inhibition on pathophysiological processes (e.g., response to injury and tissue repair) that participate in such diverse diseases as coronary atherothrombosis and colorectal cancer, rather than "pleiotropic" effects on different drug targets (Patrono 2015).

Pharmacodynamics

The pharmacodynamics of aspirin as an antiplatelet agent can be adequately described by serum TXB_2 measurements (Patrono et al. 1980, 1985; Patrignani et al. 1982). Platelet TXA_2 production during whole blood clotting, as reflected by serum TXB_2, represents a highly specific and sensitive index of the maximal biosynthetic capacity of circulating platelets in response to endogenously formed thrombin (Patrono et al. 1980). This biomarker is ideally suited to characterize the pharmacological inhibition of platelet COX-1 activity, when the inhibitor is added in vitro or administered in vivo (Patrono et al. 1980; Patrignani et al. 1982). After oral dosing of aspirin in healthy subjects, serum TXB_2 concentrations are reduced in a dose-dependent fashion with a maximal inhibitory effect achieved after a single dose of 100 mg (Patrono et al. 1980; Patrignani et al. 1982). However, because of the cumulative nature of platelet COX-1 inactivation upon repeated daily dosing (Patrignani et al. 1982), the same ceiling effect of virtually 100 % suppression of serum TXB_2 can be obtained with daily doses as low as 30 mg (Patrignani et al. 1982). Earlier studies using the ability of ingested aspirin to inhibit subsequent in vitro acetylation of PGHS-1 in washed platelets by [^{3}H-acetyl]-aspirin (Burch et al. 1978) underestimated the potency of aspirin in inhibiting COX-1 activity because full acetylation of the enzyme is not required in order to inhibit completely TXA_2 production (Patrignani et al. 2014; Li et al. 2014). Burch et al (1978) reported that a daily dose of 325 mg was required to inhibit by >95 % subsequent acetylation of the platelet enzyme by [^{3}H-acetyl]-aspirin but acknowledged that "the degree to which cyclooxygenase must be inhibited to alter thrombosis is unknown." Similarly, in the study of FitzGerald et al (1983), urinary TXM excretion was maximally inhibited at doses of 325 mg daily and above, most likely because extraplatelet sources contribute appreciably to TXM excretion and are less sensitive to the inhibitory effect of aspirin.

Upon discontinuing aspirin after a brief course of 325 mg per day, no new enzyme appeared in circulating platelets for approximately 2 days (Burch et al. 1978). The authors interpreted the "lag" in the return of unacetylated enzyme to the circulation as evidence that aspirin acetylates PGHS-1 in the bone marrow megakaryocyte (Burch et al. 1978). In fact, human megakaryocytes express both PGHS-1 and PGHS-2 (Rocca et al. 2002). Similarly, Patrignani et al (1982) observed a 2-day lag in the recovery of serum TXB_2 following discontinuation of a 30-day regimen of 30 mg daily. Thereafter, both the unacetylated enzyme (Burch et al. 1978) and serum TXB_2 (Patrignani et al. 1982) returned toward pre-aspirin levels with a linear time course consistent with platelet turnover (life-span 8.2±2 days). Therefore, bone marrow megakaryocytes represent an important drug target contributing to the long-lasting antiplatelet effect of aspirin, inasmuch as the new platelets released during 24–48 h after dosing most likely carry PGHS-1 that has been acetylated in their progenitors. However, substantial interindividual variability in the rate of recovery of platelet COX-1 activity has been described in aspirin-treated patients with vascular disease (Rocca et al. 2012). Accelerated platelet turnover, as seen in association with type 2 diabetes mellitus (T2DM) and following coronary artery bypass graft (CABG) surgery, as well as reduced systemic bioavailability of enteric-coated aspirin in obese subjects, may shorten the duration of the full inhibitory effect on platelet TXA_2 production to less than 24 h and require more frequent dosing (Rocca et al. 2012; Pascale et al. 2012; Patrono et al. 2013; Paikin et al. 2015) (Fig. 3). Variable duration of the antiplatelet effect of aspirin, noncompliance, or a pharmacodynamic interaction with other NSAIDs (see below) may all be responsible for less than complete inhibition of serum TXB_2 and TXA_2-dependent platelet function measured 24 h after dosing. However, these phenomena should not be erroneously labeled as aspirin "resistance," because they all have a plausible explanation and can be easily diagnosed and corrected (Patrono and Rocca 2007; Grosser et al. 2013). If "resistance" is defined in classical pharmacological terms, i.e., as the failure of actual aspirin intake to fully inactivate platelet COX-1 (Patrono and Rocca 2007), then aspirin resistance is either a very rare phenomenon (Santilli et al. 2009; Grosser et al. 2013) or does not exist. A relatively large study of 400 healthy volunteers failed to identify a single case of true drug resistance (Grosser et al. 2013).

Because of its unique pharmacokinetic and pharmacodynamic features, aspirin has a lesser inhibitory effect on PGI_2 than on TXA_2 biosynthesis at all doses, reaching a ceiling effect on the former at 650–1300 mg daily (FitzGerald et al. 1983). Substantial sparing of in vivo PGI_2 production, as reflected by PGI_2 metabolite (PGIM) excretion, has been reported during administration of aspirin 100 mg daily both in health (Capone et al. 2004) and disease (Cavalca et al. 2014). It is likely that substantial inhibition of PGI_2 biosynthesis at higher aspirin doses reflects dose-dependent acetylation of vascular (both endothelial and smooth muscle cell) PGHS-2 (McAdam et al. 1999; Yu et al. 2012). The clinical significance of a PGI_2-sparing regimen of aspirin administration remained largely hypothetical for about 25 years after the original proposal of endothelium-derived PGI_2 representing an important mediator of vessel-wall thromboresistance (Moncada and Vane 1979). The clinical development of the coxibs as selective inhibitors of COX-2 (FitzGerald and Patrono 2001) and their placebo-controlled, long-term trials have provided convincing evidence that inhibition of vascular PGI_2 biosynthesis unaccompanied by adequate inhibition of platelet TXA_2 production is associated with a doubling of the risk of major coronary events (Kearney et al. 2006; CNT

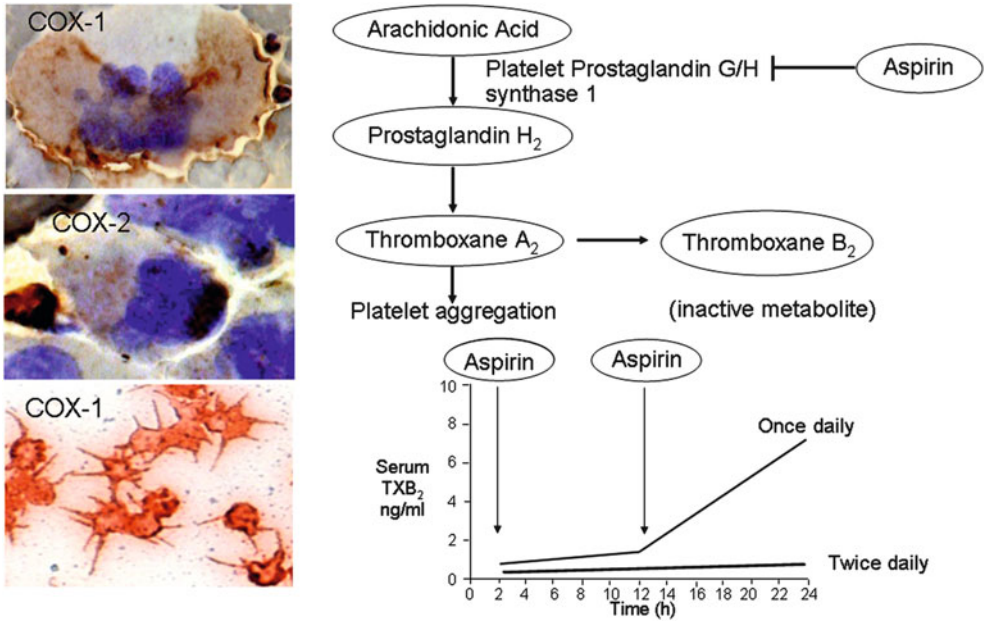

Fig. 3 Model of altered aspirin pharmacodynamics in type 2 diabetes mellitus. Under conditions of normal megakaryopoiesis, low-dose aspirin acetylates COX isozymes in both circulating platelets and bone marrow megakaryocytes, and only negligible amounts of unacetylated enzymes are resynthesized within the 24-h dosing interval. This pharmacodynamic pattern is associated with virtually complete suppression of platelet TXA_2 production in peripheral blood, as reflected by serum TXB_2, throughout the dosing interval. Under conditions of abnormal megakaryopoiesis, an accelerated rate of COX-isozyme resynthesis is biologically plausible in bone marrow megakaryocytes, accompanied by faster release of immature platelets with unacetylated enzyme(s) during the aspirin dosing interval, and in particular between 12 and 24 h after dosing. This pharmacodynamic pattern is associated with incomplete suppression of platelet TXA_2 production in peripheral blood and time-dependent recovery of TXA_2-dependent platelet function during the 24-h dosing interval. Twice daily administration of low-dose aspirin can reverse this abnormal biochemical phenotype. Immunohistochemistry panels depict megakaryocytes stained for COX-1 and COX-2, and peripheral washed platelets stained for COX-1

Collaboration 2013). Meta-analyses of the coxib trials have also provided evidence that some traditional COX-2 inhibitors (e.g., diclofenac and ibuprofen), which only incompletely and transiently inhibit platelet COX-1 activity because of their reversible mechanism of action and short half-life, may increase the risk of major vascular events to a similar extent as the coxibs (Kearney et al. 2006; CNT Collaboration 2013), thereby reinforcing the importance of virtually complete and persistent blockade of platelet COX-1 activity throughout the dosing interval in order to exert cardioprotective effects. In fact, the relationship between inhibition of serum TXB_2 and suppression of TXA_2-dependent platelet activation in vivo is strikingly nonlinear (Reilly and FitzGerald 1987; Santilli et al. 2009), with >97 % inhibition of the former being required for full suppression of the latter (Santilli et al. 2009) (Fig. 4).

Drug–Drug Interactions

Aspirin has been reported to interfere with the antihypertensive effect of blood pressure-lowering drugs, particularly angiotensin-converting enzyme (ACE) inhibitors (Patrono et al. 2008).

This represents a mechanism-based pharmacodynamic interaction that is shared by all NSAIDs and is largely attributed to COX-2 inhibition in the renal cortex and medulla, resulting in increased vascular resistance and sodium retention, respectively (Patrono et al. 2008). This pro-hypertensive effect was not apparent with once daily administration of low-dose (75 mg) aspirin in intensively treated hypertensive patients, in whom this antiplatelet regimen did not impair blood pressure control or the need for antihypertensive therapy as compared to placebo (Hansson et al. 1998).

A subgroup analysis of the PLATO trial, a randomized comparison of ticagrelor vs. clopidogrel in aspirin-treated patients with acute coronary syndromes (ACS) (Wallentin et al. 2009), revealed a potential interaction between aspirin and ticagrelor (Mahaffey et al. 2011). Thus, the higher the daily dose of aspirin (allowed range, 75–325 mg), the lower the benefit of ticagrelor vs. clopidogrel. Although the mechanism of this apparent interaction remains elusive, the FDA has approved ticagrelor for aspirin-treated ACS patients with a warning to maintain the daily aspirin dose at/or lower than 100 mg.

Some NSAIDs, i.e., ibuprofen (Catella-Lawson et al. 2001; Renda et al. 2006) and naproxen (Capone et al. 2005; Li et al. 2014), interfere with the antiplatelet effect

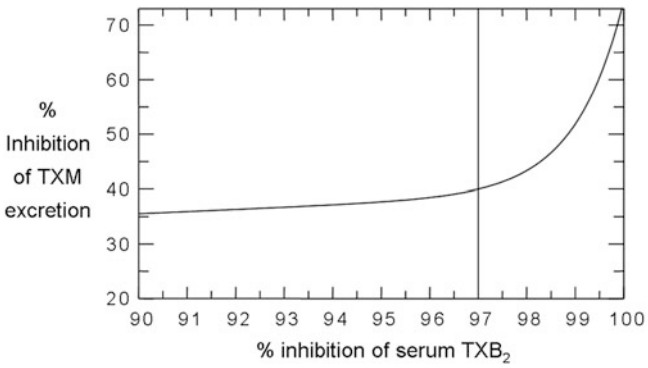

Fig. 4 Nonlinear relationship between inhibition of platelet COX-1 activity, as reflected by serum TXB_2, and inhibition of TXA_2 biosynthesis in vivo, as reflected by urinary 11-dehydro-TXB_2 excretion. Reproduced from Santilli et al. (2009) with permission from the American College of Cardiology

of low-dose aspirin by competing for a common docking site (Arginine-120) within the COX-channel of PGHS-1, to which aspirin binds reversibly with low affinity prior to acetylating Ser-529. Analgesic drugs which have been reported not to share this pharmacodynamic interaction with low-dose aspirin include paracetamol (Catella-Lawson et al. 2001), diclofenac (Catella-Lawson et al. 2001), and celecoxib (Renda et al. 2006), i.e., COX-2 inhibitors with some degree of COX-2 selectivity (FitzGerald and Patrono 2001). The use of these NSAIDs in high-risk patients treated with low-dose aspirin should be restricted to the lowest effective dose for the shortest duration necessary for arthritic symptom control, or else aspirin should be replaced with clopidogrel if the patient is not on dual antiplatelet therapy (Patrono and Baigent 2014).

Clinical Efficacy and Safety

The efficacy and safety of aspirin have been evaluated in several populations, ranging from patients presenting with an acute MI or an acute ischemic stroke to apparently healthy persons at low risk of CV events (Patrono et al. 2005). The highly variable benefit/risk profile of the same antiplatelet strategy in different clinical settings reflects the variable incidence of ischemic vs. hemorrhagic complications in the treated population, as well as the relative importance of TXA_2-dependent platelet activation in coronary vs. cerebrovascular atherothrombosis and in primary hemostasis of the GI tract vs. the brain (Davì and Patrono 2007).

In patients with acute MI, low-dose aspirin (162.5 mg daily) started within 24 h after the onset of symptoms reduced vascular mortality (primary endpoint) by 23 %, as well as recurrent MI or stroke by 50 % (ISIS-2 Collaborative Group 1988). Treatment of 1000 such patients for about 5 weeks resulted in 40 fewer major vascular events with no statistically significant increase in major bleeding complications. In patients with acute ischemic stroke, aspirin (160–300 mg daily) started within 48 h after the onset of symptoms reduced overall mortality by approximately 10 % and improved functional outcome at 30 days (Lansberg et al. 2012). Treatment of 1000 such patients for about 3 weeks resulted in 9 fewer deaths and 7 more patients with a good functional outcome at the expense of 4 more major (nonfatal) extracranial bleeds (Lansberg et al. 2012). Despite the development of newer antiplatelet agents, low-dose aspirin is still recommended with the highest grade and level of evidence (1A) as initial treatment and long-term therapy of patients with ACS (Roffi et al. 2016) or acute ischemic stroke (Lansberg et al. 2012).

In stable patients with atherothrombotic vascular disease, both individual studies (Patrono et al. 2008) and meta-analyses of randomized trials of antiplatelet therapy (ATT Collaboration 2002) indicate that low-dose aspirin reduces the risk of recurrence of a serious vascular event by approximately 25 %. Indirect comparisons of the results of these high-risk trials provide no evidence of a dose-dependent effect within a wide range of aspirin daily doses (30–1500 mg) (ATT Collaboration 2002). Moreover, a limited number of direct, randomized comparisons of higher vs. lower doses of aspirin in patients with cerebrovascular disease or ACS showed no evidence of superiority of higher vs. lower doses, consistent with saturability of the antiplatelet effect at low doses (Patrono 2015) (Fig. 5).

Among a wide range of high-risk patients, in whom the annual rate of a serious vascular event ranges between 4 and 6 %, low-dose aspirin may prevent approximately 10–15 fatal and nonfatal ischemic events for every 1000 patients treated for 1 year (number needed to treat [NNT]: 67–100) (Patrono et al. 2005). This substantial benefit is obtained at the expense of causing 1–2 major extracranial (mostly GI) bleeding complications per 1000 patients (number needed to harm [NNH]: 500–1000) and 1–2 hemorrhagic strokes per 10,000 patients (NNH: 5000–10,000) (Patrono et al. 2005). Therefore, for most patients with a prior vascular event (at average bleeding risk) taking low-dose aspirin, the number in whom the recurrence of a serious vascular event would be avoided clearly outweighs the number in whom aspirin would cause a major bleeding complication (Patrono et al. 2005; Patrono 2015).

In contrast, among asymptomatic subjects without a prior vascular event, the balance of benefits and risks of long-term therapy with low-dose aspirin is substantially uncertain because the risks without aspirin, and hence the absolute benefits of antiplatelet prophylaxis, are about an order of magnitude lower than in secondary prevention (Patrono 2013). Moreover, in contrast to secondary prevention trials, in which a clear benefit of antiplatelet prophylaxis was demonstrated for both fatal and nonfatal coronary and cerebrovascular events, the benefit of aspirin in primary

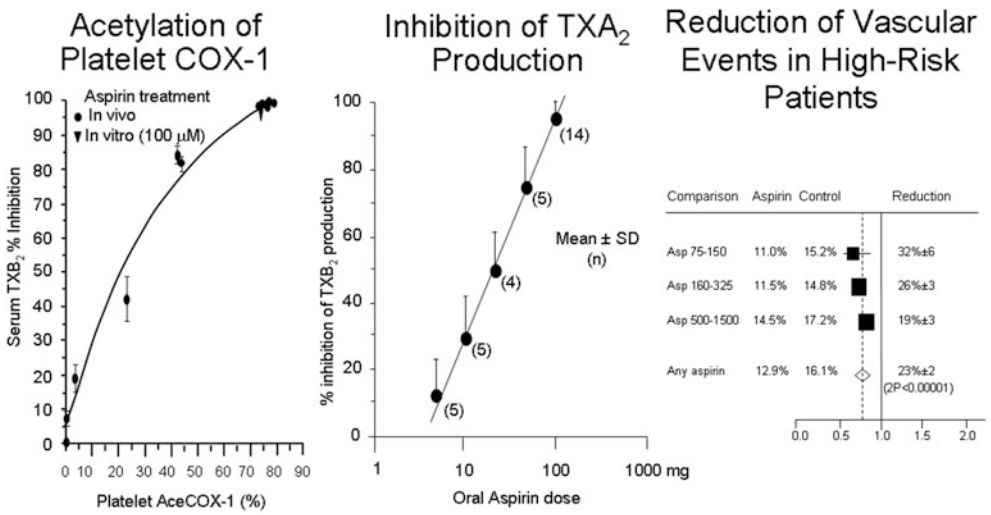

Fig. 5 Acetylation of platelet PGHS-1, inhibition of TXA_2 production, and reduction of vascular events by aspirin. The *left* panel illustrates the saturability of the acetylation process measured in vitro and ex vivo following oral dosing with 100 mg daily in healthy subjects (Patrignani et al. 2014); the *middle* panel depicts saturability of the inhibitory effect on platelet COX-1 activity, as reflected by serum TXB_2 measurements after single oral doses of aspirin in healthy subjects (Patrignani et al. 1982); the *right* panel illustrates saturability of the clinical effect of aspirin in reducing risk of serious vascular events in high-risk patients (ATT Collaboration 2002)

Squares or diamonds to the *left* of the *solid line* indicate benefit. *MI* myocardial infarction, *CHD* coronary heart disease. (asterisk) Myocardial infarction, stroke, or vascular death. Vascular death is coronary heart disease death, stroke death, or other vascular death (which includes sudden death, death from pulmonary embolism, and death from any hemorrhage but in the primary prevention trials excludes death from an unknown cause). Reproduced from ATT Collaboration (2009) with permission from The Lancet

prevention trials was limited to reducing the risk of nonfatal MI (ATT Collaboration 2009) (Fig. 6). On the basis of a meta-analysis of individual participant data from the six largest primary prevention trials of aspirin in approximately 90,000 subjects at relatively low vascular risk (0.6 % per year), the ATT Collaboration (2009) has shown that, irrespective of age or sex, the absolute reduction in serious vascular events would be only about twice as large as the

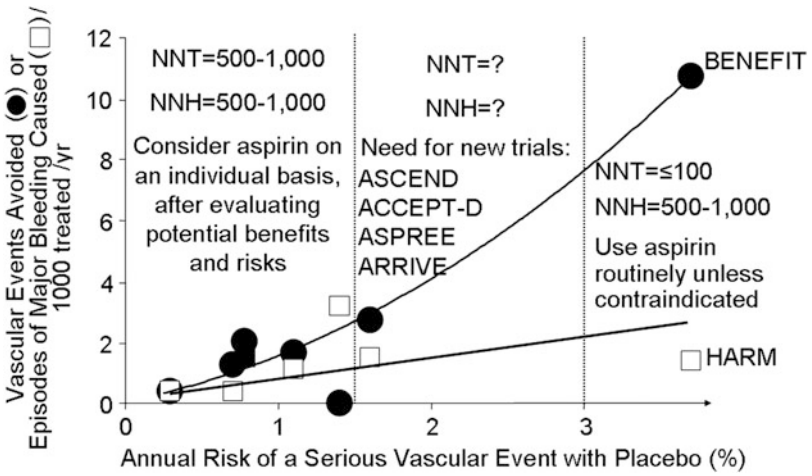

Fig. 7 The numbers of vascular events avoided and episodes of major bleeding caused per 1000 patients treated with aspirin per year are plotted from the results of individual placebo-controlled trials of aspirin in different patient populations characterized by various degrees of cardiovascular risk, as noted on the abscissa. Number needed to treat (NNT) and number needed to harm (NNH) values are given for subjects in three categories of risk on the basis of the presence or absence of randomized controlled trials. *ACCEPT-D* Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trials in Diabetes, *ASCEND* A Study of Cardiovascular Events in Diabetes, *ARRIVE* Aspirin to Reduce Risk of Initial Vascular Events, *ASPREE* ASPirin in Reducing Events in the Elderly, *BDT* British Doctors Trial, *HOT* Hypertension Optimal Treatment Study, *PHS* Physicians' Health Study, *PPP* Primary Prevention Project, *SAPAT* Swedish Angina Pectoris Aspirin Trial, *TPT* Thrombosis Prevention Trial, *WHS* Women's Health Study. absolute increase in nonfatal GI bleeding. Moreover, the predicted 5-year absolute effects of allocation to aspirin in subjects at low to high coronary risk (5-year risk from <5 % to >10 %) would yield a relatively constant ratio between the calculated NNH (from 1000 to 100, respectively) and NNT values (from 500 to 50, respectively) (ATT Collaboration 2009). This is not surprising, as the main risk factors for coronary events (with the exception of hypercholesterolemia) were also associated with bleeding complications (ATT Collaboration 2009). The current uncertainty on the benefit/risk profile is reflected by conflicting guidelines on the use of aspirin in primary prevention, as well as by its heterogeneous regulatory status in different countries (Patrono 2015).

Based on the available results of primary and secondary prevention trials, one can identify three areas of CV risk (Fig. 7): (1) one with an annual risk up to 1.5 %, where evidence from five randomized trials allows a reliable calculation of both NNT and NNH values to guide a personalized approach to antiplatelet prophylaxis; (2) an intermediate zone between 1.5 and 3 % annual CV risk, where evidence from a single trial is insufficient to reliably assess benefit and harm and new trials are needed (see below) to address this knowledge gap; and (3) an area of annual risk >3 %, starting with patients with chronic stable angina, where the evidence from many trials shows that the benefit of aspirin treatment clearly outweighs any potential harm resulting from bleeding complications (Patrono 2015).

Several lines of evidence support a chemopreventive effect of aspirin against cancer of the GI tract, particularly colorectal cancer (Thun et al. 2012), through a mechanism of action possibly related to platelet inhibition (Patrignani and Patrono 2016) (Fig. 8). It has been argued that even a 10 % reduction by low-dose aspirin in overall cancer incidence over 5 years would yield an absolute benefit comparable to the absolute reduction in serious vascular events; these combined benefits would outweigh the absolute excess of major bleeding complications by three- to fivefold, depending on age and gender (Thun et al. 2012). The US Preventive Services Task Force (Bibbins-Domingo et al 2016) has recently published a recommendation statement addressing the possibility that the same antiplatelet regimen of low-dose aspirin may be recommended for the primary prevention of both CV disease and colorectal cancer in adults ages 50–59 years who have a 10 % or greater 10-year CVD risk, are not at increased risk for bleeding, and have a life expectancy of at least 10 years.

Low-dose aspirin has been reported to produce additional benefits in the prevention of venous thromboembolism (Patrono 2015) and preeclampsia (Mol et al. 2015) that may well reflect the participation of TXA_2-dependent platelet activation in their pathophysiology (Fig. 8).

Ongoing Trials

Several ongoing, placebo-controlled trials may help assess the benefit/risk profile of low-dose aspirin in preventing CV complications and other outcomes (including dementia and cancer) in approximately 50,000 participants at higher CV

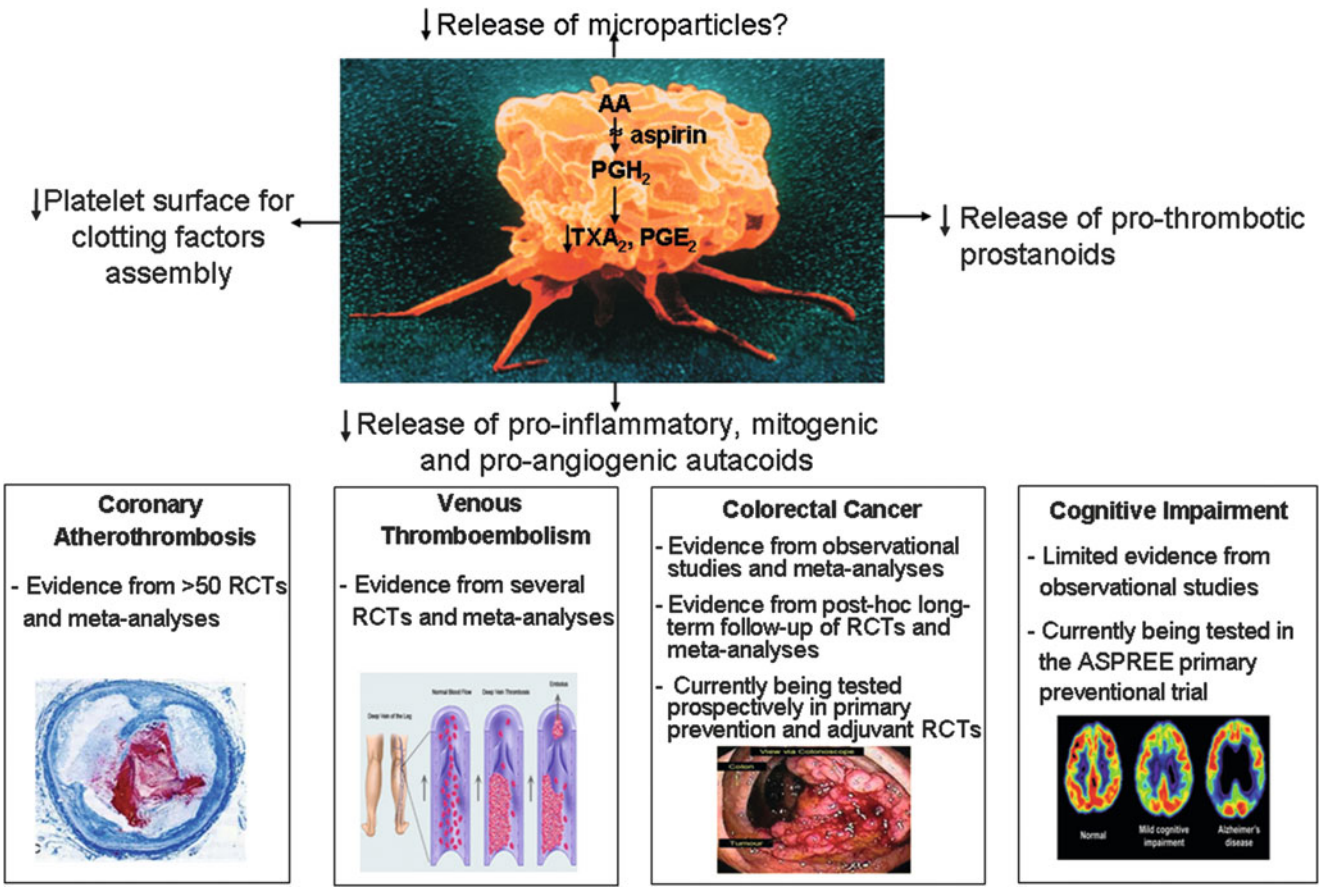

Fig. 8 A wide repertoire of lipid and protein mediators, which may contribute to several clinical syndromes possibly responsive to low-dose aspirin therapy, are released upon platelet activation and aggregation. The figure illustrates inhibition of platelet prostanoid production by aspirin and its functional and clinical consequences. The lines of evidence supporting the protective effects of aspirin are summarized below each panel. *AA* arachidonic acid, *ASPREE* ASPirin in Reducing Events in the Elderly, *RCT* randomized controlled trial(s), PGE_2 prostaglandin E_2, PGH_2 prostaglandin H_2, TXA_2 thromboxane A_2. Reproduced from Patrono (2015) with permission from the American College of Cardiology

risk than in the earlier trials because of diabetes mellitus (ASCEND [A Study of Cardiovascular Events in Diabetes], British Heart Foundation 2015; and ACCEPT-D [Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trials in Diabetes], De Berardis et al. 2007), advanced age (ASPREE [ASPirin in Reducing Events in the Elderly], ASPREE Investigator Group 2013), or a cluster of CV risk factors (not including diabetes) expected to confer a 10-year risk >15 % (ARRIVE [Aspirin to Reduce Risk of Initial Vascular Events], Bayer HealthCare 2015). The inclusion of colorectal cancer as a prespecified secondary endpoint in these trials will allow collecting a large amount of prospective data on the chemopreventive effect of low-dose aspirin during a 5- to 7.5-year follow-up (Patrono 2015). In addition, a number of adjuvant trials in cancer patients (e.g., ADD-Aspirin trial) are currently ongoing or planned in which participants undergone primary treatment with curative intent for an early-stage common solid tumor (e.g., colorectal, gastroesophageal, breast, or prostate) are randomized to receive aspirin (one or two daily doses in the range 100–300 mg) or placebo for 1–8 years and will be assessed for disease-free survival or overall survival (Patrono 2015) (Fig. 9).

Gaps in Knowledge and Future Directions for Research

The last 35 years of clinical research on aspirin have proven its value as a lifesaving drug for the treatment and prevention of atherothrombosis (Patrono et al. 2005). The place of low-dose aspirin in the therapeutic armamentarium has not been substantially altered by the successful development of at least ten new antiplatelet agents, including $P2Y_{12}$ and PAR-1 receptor blockers (Patrono and Rocca 2010). The demonstration of additive beneficial effects resulting from effective blockade of the platelet ADP and/or thrombin receptor on top of TXA_2 suppression in high-risk patients

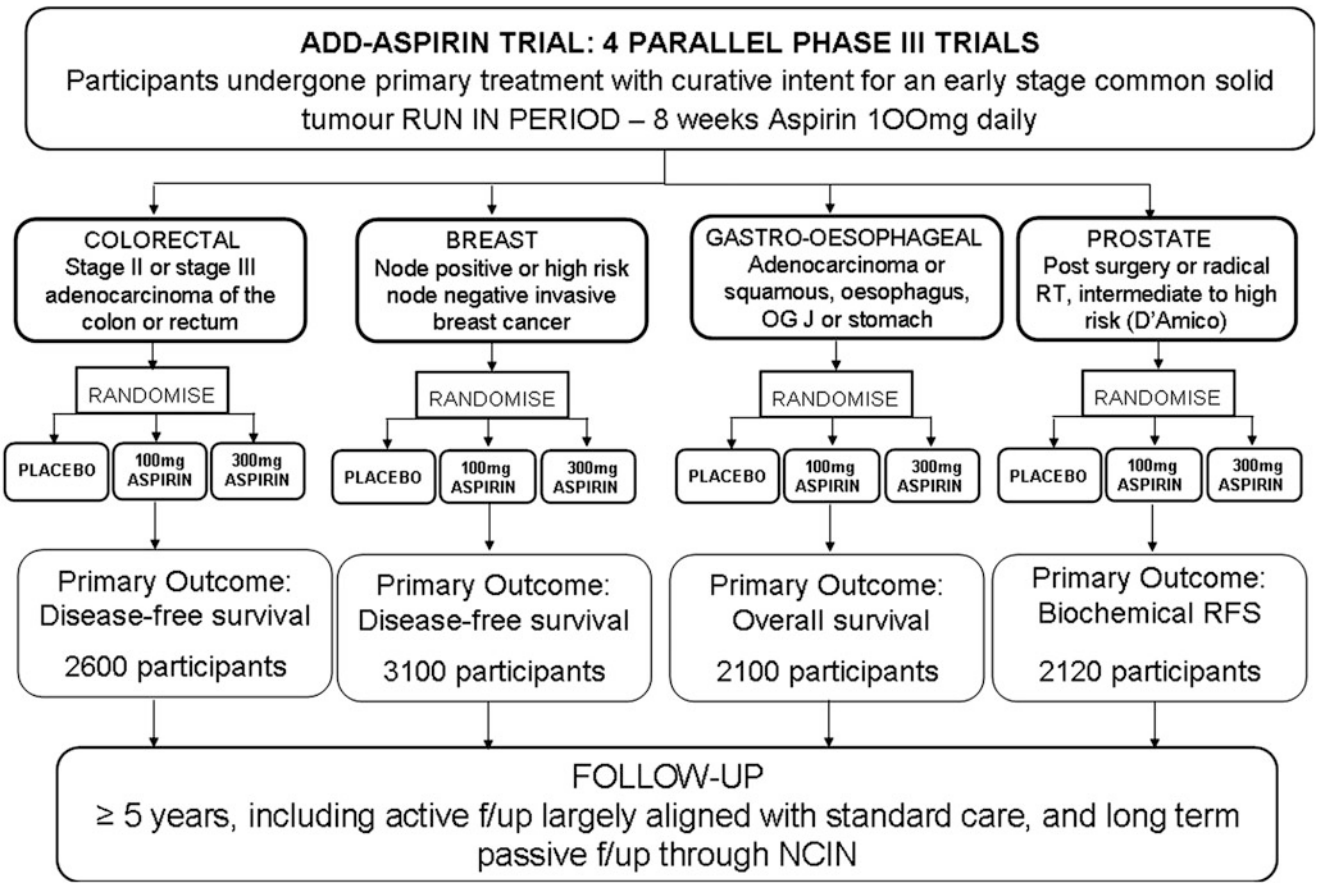

Fig. 9 Design of the ADD-Aspirin trial, four parallel phase-3 trials in patients with colorectal, breast, gastroesophageal, or prostate cancer. Courtesy of Prof. Ruth Langley, University College London, UK

is consistent with the multifactorial nature of atherothrombosis and the nonredundant nature of these different pathways of platelet activation (Davì and Patrono 2007). However, the size of the residual CV risk in patients with ACS (about 10 % experiencing a major vascular event at 1 year) despite optimal pharmacological treatment, including low-dose aspirin, effective $P2Y_{12}$ inhibitors and statins, calls for reappraisal of the pathophysiology of these adverse outcomes and innovative preventive strategies (Roffi et al. 2016). Furthermore, several randomized trials are underway to determine whether aspirin can be dropped from combined antiplatelet regimens for the long-term management of patients who are treated with one of the new antiplatelet drugs (Vranckx et al. 2015).

Besides becoming an essential component of the antithrombotic strategy in high-risk settings, low-dose aspirin has also provided a mechanistic insight into the participation of platelets in other pathophysiologic processes. The hypothesis that platelet activation during the repair process of intestinal mucosal lesions may trigger an early event in colorectal carcinogenesis, i.e., COX-2 induction in adjacent nucleated cells and increased PGE_2 production, was formulated on the basis of the lack of a dose effect in the apparent protection against cancer development and death associated with aspirin use in observational studies (Patrono et al. 2001), a finding supported by post hoc analyses of CV prevention trials of aspirin showing saturability of the apparent chemopreventive effect at low doses (Thun et al. 2012). This hypothesis is being tested prospectively in the ongoing primary prevention and adjuvant trials mentioned above (Patrono 2015).

Similarly, the potential role of platelet-derived inflammatory mediators in neurodegeneration and cognitive decline is currently being explored by the ASPREE Investigator Group (2013) in a placebo-controlled aspirin trial of 19,000 elderly subjects with no diabetes or CVD who are being followed for 5 years with death, dementia, or significant disability as the primary endpoint. Measurement of noninvasive biomarkers of platelet activation in substudies of the ongoing trials may allow further characterization of the role of

platelet activation and inhibition in atherothrombotic and other important disorders sharing common mechanisms of disease.

Take-Home Messages

- Low-dose aspirin remains the cornerstone of antiplatelet therapy in the treatment of acute ischemic syndromes and in the secondary prevention of atherothrombosis.
- The place of aspirin in primary prevention remains controversial because of the uncertain balance of benefits vs risks, requiring a personalized approach to therapy that takes into consideration current knowledge as well as patient's values and preferences.
- Additional research is needed to characterize the mechanism of action and optimal dose of aspirin in the chemoprevention of colorectal cancer, a potential additional benefit of long-term antiplatelet therapy.

Acknowledgments Dr. Patrono's studies were supported by grants from the European Commission (FP6 EICOSANOX Consortium and FP7 SUMMIT Consortium) and from the Italian Ministry of University and Research (PRIN Project 2013). The expert editorial assistance of Ms. Daniela Basilico and Ms. Patrizia Barbi is gratefully acknowledged. Dr. Patrono has received consulting fees and an institutional grant from Bayer AG for investigator-initiated research on platelet activation in diabetes mellitus and is a member of the scientific advisory board of the Aspirin Foundation.

Pharmacology: Inhibitors of $P2Y_{12}$

Lisa Gross, Dániel Aradi, and Dirk Sibbing

Abstract

Dual antiplatelet treatment consisting of aspirin and a $P2Y_{12}$ inhibitor represents the cornerstone of treatment in patients with acute coronary syndrome (ACS) and those undergoing percutaneous coronary intervention. $P2Y_{12}$ inhibitors are broadly used worldwide to prevent and treat ischemic events in cardiac patients; however, understanding their pharmacokinetic and pharmacodynamic properties is important for accurate use in daily practice.

Within the group of $P2Y_{12}$ inhibitors, thienopyridines such as ticlopidine, clopidogrel, and prasugrel are prodrugs that require hepatic metabolization and conversion to a pharmacologically active metabolite to exert the antiplatelet effect. Their active metabolites covalently and irreversibly bind to the $P2Y_{12}$ receptor for the entire life span of the platelet. Contrary, the cyclopentyltriazolopyrimidine-type $P2Y_{12}$ inhibitor, ticagrelor, and the intravenous $P2Y_{12}$ receptor inhibitor cangrelor are direct-acting $P2Y_{12}$ inhibitors that do not require metabolic activation and noncompetitively inhibit the $P2Y_{12}$ receptor by inducing a conformational change.

Due to lower risk of hematological side effects, faster onset of action, and once-daily administration, ticlopidine was soon replaced by clopidogrel that has become the $P2Y_{12}$ inhibitor of choice for many years in patients with cardiovascular disease. However, the onset of the antiplatelet effect of clopidogrel was still relatively delayed for many ACS patients requiring urgent PCI. In addition, a relatively high rate (15–40 %) of patients did not reach adequately low levels of platelet reactivity with clopidogrel—as evaluated by ADP-induced platelet function testing—and was exposed to an increased risk of stent thrombosis, myocardial infarction, and mortality. Thus, novel oral $P2Y_{12}$ receptor inhibitors prasugrel and ticagrelor were developed to provide faster, more predictable,

and more potent antiplatelet effect than clopidogrel. Approved by the FDA in 2009 and 2011, respectively, both prasugrel and ticagrelor showed improved thrombo-ischemic outcomes in patients with ACS, albeit at an expense of increased risk for bleeding. Despite being a reversibly binding agent, 5 days is required for the recovery of normal platelet function after discontinuation of ticagrelor. With this regard, cangrelor, the first intravenous $P2Y_{12}$ inhibitor, has a unique pharmacokinetic profile with a 5–10-min plasma half-life resulting in immediate, potent $P2Y_{12}$ inhibition with a complete offset of action within 30–60 min after discontinuation.

This book chapter aims to provide further insights regarding the pharmacokinetic and pharmacodynamic properties of available $P2Y_{12}$ inhibitors assisting their everyday use in clinical practice.

Introduction

Platelet activation and aggregation are fundamental steps in the development of acute coronary events, and platelets also play a key role in the progression of atherosclerosis (Davi and Patrono 2007). Therefore, antiplatelet agents represent some of the most commonly prescribed drugs worldwide to prevent and treat cardiovascular events.

Platelet adhesion and subsequent activation may occur at sites of vascular injury, rupture of atherosclerotic plaques, or in the vicinity of exposed struts of implanted coronary stents. The activation process is triggered and amplified by three major agonists: thrombin, adenosine diphosphate (ADP), and thromboxane A_2 leading to the formation of platelet-rich thrombus (see Fig. 1) (Wallentin 2009).

ADP, released from the dense granules of all activated platelets, is a major driver of thrombus formation. ADP stimulates platelet activation through two G-protein-coupled receptors, $P2Y_1$ and $P2Y_{12}$. $P2Y_1$ is a Gq-coupled receptor that initiates ADP-induced platelet aggregation through the stimulation of phospholipase C and phosphatidylinositol-signaling pathway (Kalantzi et al. 2012). $P2Y_1$ receptor activation initiates shape change and early, slight, and reversible aggregation, without stable thrombus formation. Binding of ADP to the $P2Y_{12}$ receptor results in signaling cascades that amplify and sustain platelet aggregation, as well as strongly increase platelet degranulation and procoagulant activity, which culminates in thrombus growth and stabilization (Wallentin 2009; Daniel et al. 1999; Davi and Patrono 2007; Dorsam and Kunapuli 2004). $P2Y_{12}$ is a Gi-coupled seven-transmembrane domain receptor (see Fig. 2), which mediates platelet activation by inhibiting the adenylate cyclase-mediated signaling pathway and decreasing intracellular cAMP levels. The intercellular signaling pathways triggered by $P2Y_1$ receptor and $P2Y_{12}$ receptor activation and their physiological effects are illustrated in Fig. 5. The overall fold of the P2Y12R structure consists of a canonical seven-transmembrane (7TM) bundle of α-helices and a carboxy-terminal helix VIII that is parallel to the membrane bilayer (Zhang et al. 2014). The $P2Y_{12}$ receptor couples primarily to $G\alpha_{i2}$ and less prominently to other members of the Gi family, resulting in the inhibition of adenylyl cyclase. Rap1b, Akt, and potassium channels are important functional effectors downstream of $P2Y_{12}$ receptor stimulation (Wallentin 2009; Kalantzi et al. 2012; Kim et al. 2004). The decrease in intracellular cAMP levels reduces the rate of phosphorylation of the vasodilator-stimulated phosphoprotein, thus inducing activation of the $\alpha_{IIb}\beta_3$ receptor and platelet aggregation. Thus, $P2Y_{12}$ plays a central role in amplification and stabilization of ADP-induced platelet aggregation (Kalantzi et al. 2012).

Thienopyridines, such as ticlopidine, clopidogrel, and prasugrel, are inactive prodrugs and need to undergo hepatic metabolism to generate an active metabolite that binds covalently and irreversibly to the ADP-binding site on the $P2Y_{12}$ receptor for the entire life span of the platelet (Wallentin 2009; Michelson 2008). Contrary, ticagrelor and cangrelor do not belong to the thienopyridine class, but are direct-acting $P2Y_{12}$ inhibitors that reversibly change the conformation of the $P2Y_{12}$ receptor (see Fig. 4).

Differences in absorption, metabolism, receptor binding, and drug interactions all influence the final $P2Y_{12}$ inhibitory effect of the specific agent. This book chapter aims to provide insights into the pharmacokinetic and pharmacodynamic properties of $P2Y_{12}$ inhibitors.

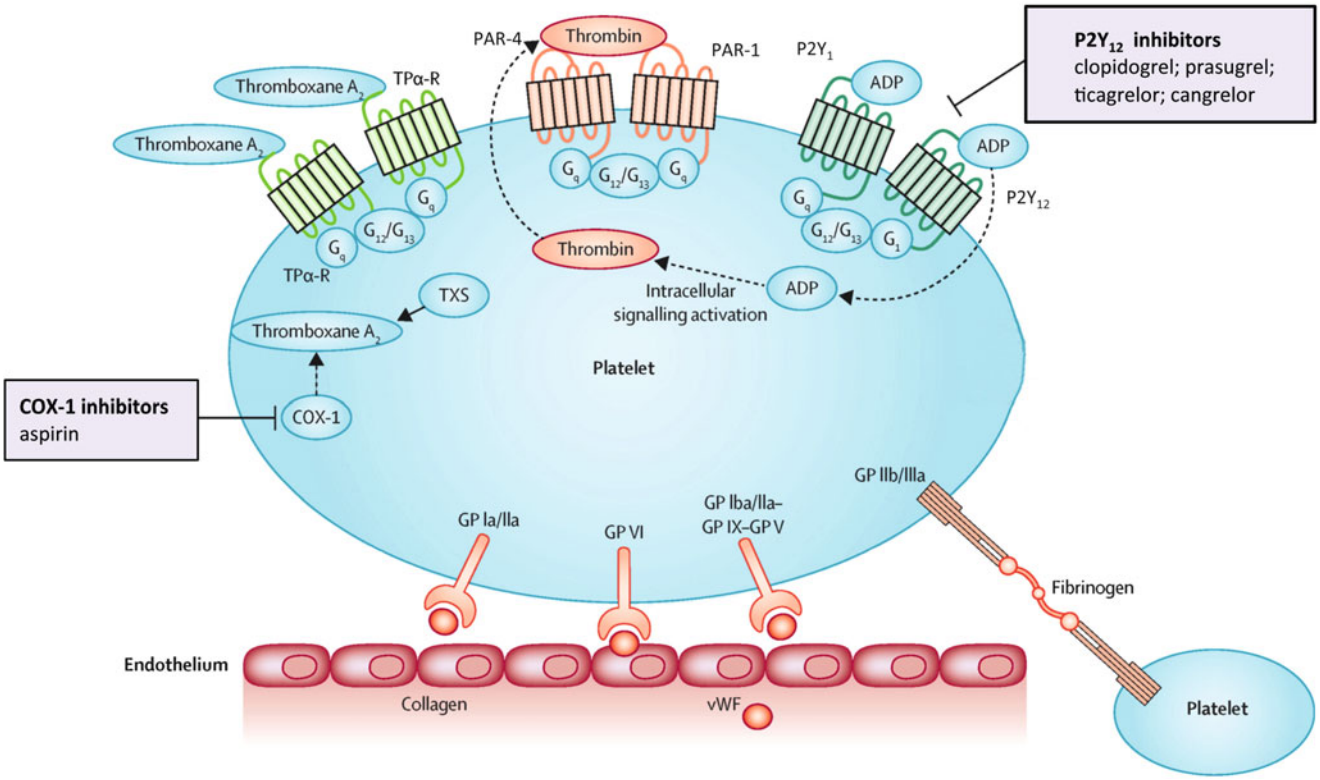

Fig. 1 Platelet pathways targeted by $P2Y_{12}$ inhibitors and aspirin. Platelet adherence to injured vascular endothelium is mediated by binding of glycoprotein receptors to exposed extracellular matrix proteins (collagen and vWF). Complex intracellular signaling processes result in the local production and release of multiple agonists, including thromboxane A2 and ADP. These factors bind to their respective G-protein-coupled receptors, mediating paracrine and autocrine platelet activation. Platelet integrin $\alpha_{IIb}\beta_3$ mediates the final common step of platelet aggregation by undergoing a conformational change, binding fibrinogen and vWF, and leading to platelet-rich thrombus. Dual antiplatelet therapy consisting of aspirin and a $P2Y_{12}$ inhibitor effectively targets pathways associated with thromboxane A2 and ADP-mediated platelet activation. *vWF* von Willebrand factor, *GP* glycoprotein, *COX-1* cyclooxygenase *1, 5-HT2A* serotonin receptor 2A, *PAR* protease-activated receptor, *TP* thromboxane prostanoid receptor, *TXS* thromboxane A synthase. Ticlopidine

Ticlopidine (see Fig. 3) was the first thienopyridine and received US Food and Drug Administration (FDA) approval in 1991 for the prevention of ischemic events in patients with coronary artery disease.

Ticlopidine is administered orally in a dose of 250 mg twice daily. Onset of action occurs between 24 and 48 h after initiation of treatment, with maximal inhibition of ADP-induced platelet aggregation 3–5 days after initial dosing (see Table 1) (Farid et al. 2010; Picard-Fraire 1983; Saltiel and Ward 1987). Eighty-five percent of the drug is absorbed, with peak plasma concentrations (C_{max}) being reached 1–3 h after the oral dose (Farid et al. 2010; Picard-Fraire 1983). The median ticlopidine C_{max} after the first oral dose is approx. 310 ng/mL, increasing to 990 ng/ml after 21 days of treatment (Farid et al. 2010; Knudsen et al. 1992). Pharmacokinetics is nonlinear, with significant decrease in clearance after repeated dosing. The median half-life ($t_{1/2}$) after multiple dosing is 29 h, but may be up to 4–5 days in elderly patients (Farid et al. 2010; Knudsen et al. 1992)—Likewise, steady-state concentrations in plasma are achieved in 14–21 days in elderly patients, but within 5 days in younger patients (Farid et al. 2010; Saltiel and Ward 1987). Ticlopidine is 98 % plasma protein-bound (Ito et al. 1992). It is a prodrug, requiring multistep hepatic CYP P450-dependent bioactivation to form the active metabolite, which was isolated and characterized by Yoneda et al. in 2004 (see Fig. 4) (Yoneda et al. 2004). It shows a rapid hepatic metabolism and is metabolized by at least five main pathways resulting in a minimum of 13, mostly inactive, metabolites (Wallentin 2009; Picard-Fraire 1983). CYP2C19, CYP2B6, and CYP3A pathways have been shown to contribute to the metabolism of ticlopidine (Ha-Duong et al. 2001; Richter et al. 2004; Dalvie and O'Connell 2004). However, the CYPs involved in the formation of the active metabolite from its thiolactone

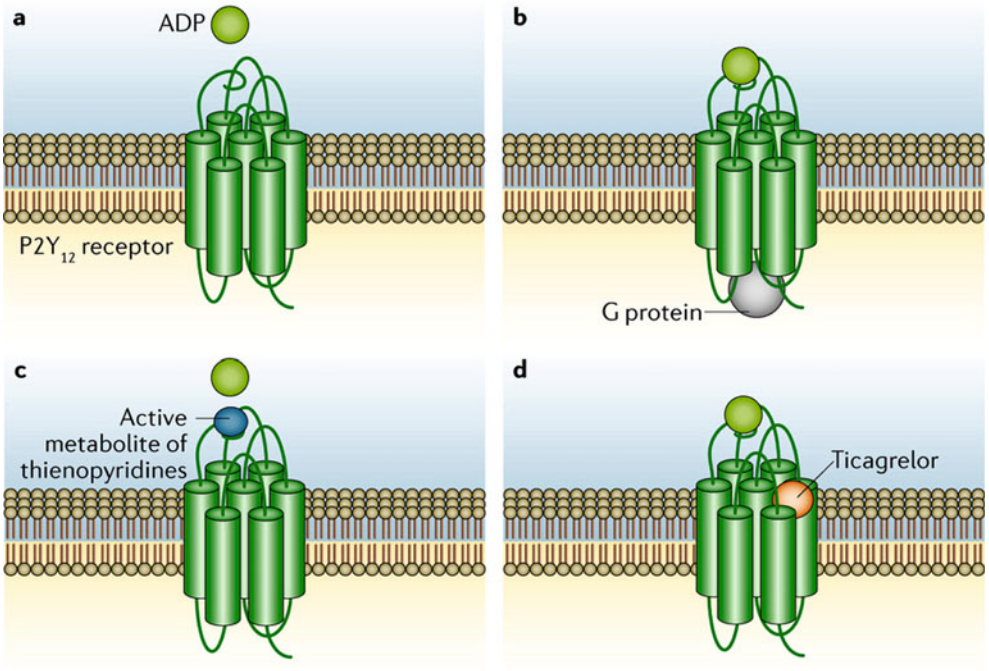

Fig. 2 Binding properties of $P2Y_{12}$ receptor inhibitors. (**a**) ADP binds to the P2Y12 receptor, which (**b**) leads to a conformational change of the receptor and to G-protein activation. (**c**) Competitive binding of the active metabolite of thienopyridines to the $P2Y_{12}$ receptor. Binding is irreversible, which renders the receptor nonfunctional for the life of the platelet. (**d**) Ticagrelor binds reversibly to the $P2Y_{12}$ receptor at a site that is distinct from the ADP-binding site (noncompetitive binding). Ticagrelor inhibits ADP signaling and conformational change of the receptor by "locking" the receptor in an inactive state; the receptor is functional after dissociation of the ticagrelor molecule. ADP can still bind at its binding site, and the degree of receptor inhibition is dependent on the concentration of ticagrelor. intermediate are still unknown (Farid et al. 2010). 60 % of the agent is eliminated in the urine and 23 % in the feces.

The most common side effects observed with ticlopidine included diarrhea, nausea, vomiting, stomach pain, purpura, and skin rashes (Whetsel and Bell 1999). Patients treated with ticlopidone also showed potentially life-threatening side effects including hepatotoxicity (Martinez Perez-Balsa et al. 1998; Takikawa 2005), hyponatremia, nephrotic syndrome, neutropenia, and thrombocytopenia (Steinhubl et al. 1999). Due to these toxic side effects and its slow onset of action, ticlopidine was replaced by clopidogrel (Berger et al. 1999; Muller et al. 2000; Quinn and Fitzgerald 1999; Moussa et al. 1999).

Clopidogrel

Clopidogrel (see Fig. 3) is a second-generation thienopyridine and was approved by the FDA in 1997 to reduce the incidence of ischemic events in patients with atherosclerotic vascular disease. It is a prodrug, and its active metabolite covalently and irreversibly binds to the $P2Y_{12}$ receptor for the entire life span of the platelet (see Figs. 2 and 5).

The pharmacokinetic and pharmacodynamic properties of clopidogrel are summarized in the Table 1. The recommended oral dose is 75 mg once daily. The peak plasma concentrations of the parent carboxylic metabolite as well as the active metabolite (see Fig. 4) occur within 30 min to 1 h following administration of a single oral dose (Small et al. 2008). Administration of a loading dose between 300 and 600 mg leads to a peak platelet inhibition response within 2–5 h (Muller et al. 2001; Wallentin 2009; von Beckerath et al. 2005; Price et al. 2006; Montalescot et al. 2006). The C_{max} of clopidogrel active metabolite after a 300-mg loading dose is approximately 70 ng/mL and approximately 30 ng/mL after a 75-mg maintenance dose (Lenz and Wilson 2003). Bonello et al. showed in 2008 that a 600-mg loading dose was associated with a significant decrease in the rate of post-PCI major adverse cardiovascular events at 1 month compared with a 300-mg loading dose, without any inhospital increase in bleeding complications (95 % confidence interval 0.41–0.95, $p = 0.03$) (Bonello et al. 2008b). Furthermore, it has been shown that loading

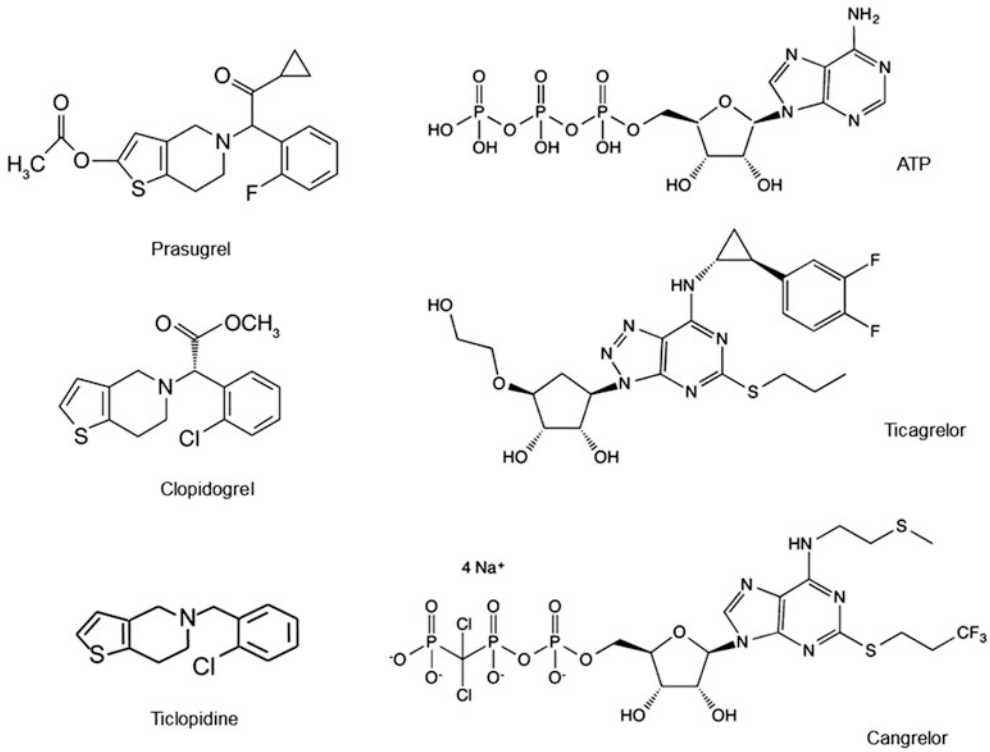

Fig. 3 Chemical structures of prasugrel, clopidogrel, ticlopidine, adenosine triphosphate (ATP), ticagrelor, and cangrelor

doses exceeding 600 mg only slightly, but not significantly, increased platelet inhibitory capacity (von Beckerath et al. 2005). However, in patients who were nonresponders to clopidogrel despite a 600-mg loading dose, adjusting the clopidogrel loading dose according to platelet monitoring using the VASP index has been shown to significantly improve the clinical outcome after PCI (Bonello et al. 2008a, 2009). Gladding et al. showed that in PCI patients a clopidogrel 1200-mg loading dose, given as two 600-mg doses 2 h apart, results in more rapid and complete platelet inhibition than a single 600-mg dose and a maintenance dosage of 150 mg daily produces greater platelet inhibition than 75 mg daily (Gladding et al. 2008). In line, Angiolillo et al. showed that the use of a 150-mg maintenance dose of clopidogrel in patients with type 2 diabetes with <50 % platelet inhibition is associated with enhanced antiplatelet effects. However, the antiplatelet effects achieved were nonuniform, and a considerable number of patients persisted with inadequate platelet inhibition (Angiolillo et al. 2007b, 2008).

The achieved level of platelet inhibition is generally maintained until dosing is discontinued (Jernberg et al. 2006; Wallentin et al. 2008; Savcic et al. 1999; Caplain and Cariou 1999; Thebault et al. 1999). Platelet inhibition decreases to pretreatment levels 5–7 days after treatment is terminated, but the recovery is dependent on the platelet inhibitory effect before discontinuation (Caplain et al. 1999; Caplain and Cariou 1999; Thebault et al. 1999; Weber et al. 2001).

Clopidogrel is rapidly absorbed through adenosine triphosphate binding cassette efflux transporters located in the apical membrane of the intestinal mucosa (Taubert et al. 2006). Both the parent drug and the active metabolite are highly protein bound (~98 % and ~94 %). As a prodrug, clopidogrel requires metabolic transformation to exert its antiplatelet effect (see Table 1) (Angiolillo 2012). Approximately 85 % of clopidogrel is hydrolyzed in the blood by esterases to an inactive carboxyl metabolite. Only about 15 % of the absorbed prodrug is rapidly metabolized by hepatic cytochrome P450 isoenzymes (including CYP 3A4/5, CYP 2C19, CYP 1A2, CYP 2C9, and CYP 2B6) in a two-step oxidation process to a highly unstable active metabolite (see Figs. 4 and 5) (Franchi and Angiolillo 2015). The active metabolite belongs to a family of eight isomers with chemical structure of 2-{1-[1-(2-chlorophenyl)-2-methoxy-2-oxoethyl]-4-sulfanyl-3-piperidinylidene} acetic acid (Pereillo et al. 2002). Approximately 50 % of clopidogrel are excreted in the urine and 46 % in the feces in the form of inactive metabolites, respectively (Lins et al. 1999). Owing to the extreme labile nature of the active metabolite, proper characterization of the elimination kinetics of the active metabolite has not been performed (Mullangi and Srinivas 2009).

Clopidogrel is the most widely used $P2Y_{12}$ inhibitor, recommended in patients with stable coronary artery disease undergoing PCI, in patients after stroke, and in those with peripheral artery disease (Franchi and Angiolillo 2015; Sherwood et al. 2014; Fihn et al. 2014; Task Force et al.

Table 1 Pharmacological properties of $P2Y_{12}$ receptor inhibitors

	Ticlopidine	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Route of administration	Oral	Oral	Oral	Oral	Intravenous
Dose	250 mg twice daily	LD 300/600 mg, MD 75 mg once daily	LD 60 mg, MD 10 mg once daily (5 mg if <60 kg, >75 years)	LD 180 mg, MD 90 mg twice daily	30 μg/kg bolus, 4 μg/kg/min infusion
Receptor blockade	Irreversible	Irreversible	Irreversible	Reversible	Reversible
Metabolism	Prodrug CYP P450 dependent (multistep)	Prodrug CYP P450 dependent (2 steps)	Prodrug Intestinal esterase + CYP P450 dependent (single hepatic step)	Direct-acting No biotransformation needed, CYP P450-dependent active metabolite	Direct-acting No biotransformation
Onset of action (after LD)	24–48 h	2–5 h	30 min–5 h	30 min–5 h	2 min
Offset of action	11–13 days	5–7 days	7–10 days	5–7 days	30–60 min
Time to peak plasma concentration, of AM t_{max}	1–3 h (Yoneda et al. 2004)	30 min–1 h (Small et al. 2008)	30 min (Small et al. 2008)	2 h (Husted et al. 2012)	2 min (Teng et al. 2010)
IPA $_{MD}$, % (LTA-defined)	20–30 % (Sharis et al. 1998; Kereiakes et al. 1997; Farid et al. 2010) (highly variable)	34–52 % (Farid et al. 2008, 2010) (highly variable)	50–71 % (Farid et al. 2008, 2010)	58–93 % (Gurbel et al. 2009; Husted et al. 2006)	>80 % (Franchi and Angiolillo 2015; Storey et al. 2001)

2013; Levine et al. 2015; Task Force on the management of et al. 2012).

An important limitation of clopidogrel is that the generation of active metabolites and consequently the achieved level of platelet inhibition is highly variable after fixed dosing. This is primarily due to single nucleotide polymorphisms in key genes of the CYP system that catalyze clopidogrel activation: patients having loss-of-function copies (most commonly *2 and *3) of the CYP2C19 gene have lower levels of active metabolites and higher levels of platelet reactivity despite treatment. In turn, those with gain-of-function copies (like *17) of the CYP2C19 have higher exposure to clopidogrel active metabolites. In addition to genotype variations, clinical factors such as diabetes have been shown to alter PK profile of clopidogrel, leading to less potent platelet inhibition in diabetic patients (Angiolillo et al. 2014).

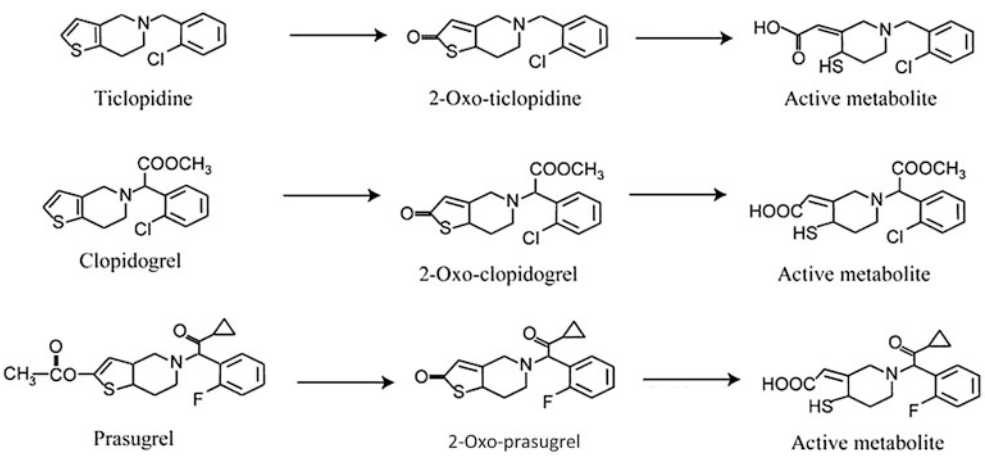

Fig. 4 Thienopyridine active metabolites

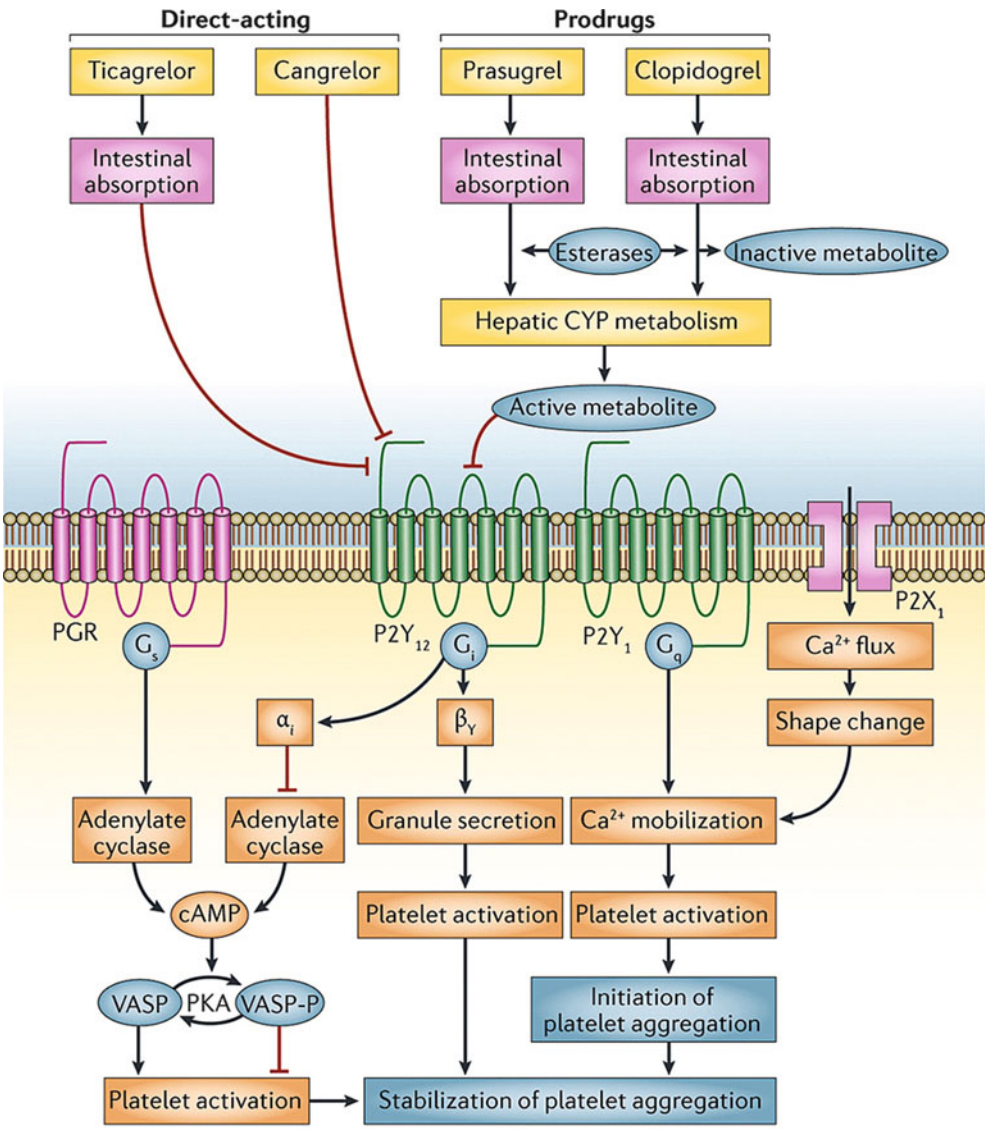

Fig. 5 Mechanisms of action of $P2Y_{12}$ inhibitors. After intestinal absorption, ~85 % of the oral prodrug clopidogrel is hydrolyzed in the blood by esterases to an inactive metabolite; the remaining 15 % is converted to the active metabolite by hepatic CYP isoenzymes, in a two-step oxidation process. By contrast, prasugrel is oxidized more effectively to its active metabolite via a single CYP-dependent step. Cangrelor and ticagrelor do not require hepatic metabolism for pharmacodynamic activity. Ticagrelor is an oral agent that reversibly inhibits platelet activation by allosteric modulation of the $P2Y_{12}$ receptor. Cangrelor is an intravenous ATP analogue, with no need for intestinal absorption, and reversibly inhibits the $P2Y_{12}$ inhibitor (Franchi and Angiolillo 2015). *AC* adenylyl cyclase, *CYP* cytochrome P450, *PGR* prostaglandin receptor, *PKA* cAMP-dependent protein kinase A, *VASP* vasodilator-stimulated phosphoprotein, *P* phosphorylated. As a result of the variability of active metabolite generation, a significant proportion of patients (15–40 %) were described to have inadequate response to standard clopidogrel doses, exposing them to a higher risk for recurrent thrombotic events (Yusuf et al. 2001; Steinhubl et al. 2002; Chen et al. 2005; Angiolillo et al. 2007a; Stone et al. 2013; Tantry et al. 2013; Aradi et al. 2014; Brar et al. 2011).

In addition to the highly variable antiplatelet effect provided by the drug, another important limitation is the relatively slow onset of action of clopidogrel. These limitations urged the development of more potent $P2Y_{12}$ inhibitors with a faster onset of action and more predictable antiplatelet effect.

Prasugrel

The third-generation thienopyridine prasugrel (see Fig. 3) was approved by the FDA in 2009. It is an orally administered prodrug, which requires a two-step metabolism with oxidation to 2-oxo-prasugrel being performed by intestinal esterases just upon absorption, followed by a single hepatic step involving hepatic CYP to generate the active metabolite (see Figs. 4 and 5, Table 1). Although the molar potency of the respective active metabolites of prasugrel and clopidogrel is identical, the metabolic conversion of prasugrel is more efficient, resulting in higher in vivo availability (Sugidachi et al. 2007). These pharmacokinetic properties of prasugrel translate into a faster onset of action, on average more potent platelet inhibitory effect and significantly lower interindividual variability in the active metabolite levels and regarding platelet inhibition compared to clopidogrel (see Table 1) (Franchi and Angiolillo 2015; Wiviott et al. 2007b).

Platelet inhibition is observed 15–30 min after administration of a loading dose of 60 mg, and maximum 60–75 % platelet inhibition is usually achieved within 2–4 h (see Table 1) (Wallentin 2009; Jernberg et al. 2006; Wallentin et al. 2008; Ernest et al. 2008; Asai et al. 2006; Brandt et al. 2007; Jakubowski et al. 2006). After discontinuation of treatment, platelet aggregation returns to pretreatment levels within 7–10 days (Wallentin 2009; Asai et al. 2006; Jakubowski et al. 2006, 2007a; Matsushima et al. 2006). Platelet inhibition is dose dependent, with maximal levels of inhibition (60–75 %) occurring after administration at doses greater than 30 mg (Wallentin 2009; Jernberg et al. 2006; Jakubowski et al. 2007a, b). The C_{max} of prasugrel's pharmacologically active metabolite (see Fig. 3), R-138727, is achieved approximately 30 min after oral administration, with a dose-dependent exposure to prasugrel metabolites in humans (Farid et al. 2008, 2010; Asai et al. 2006; Matsushima et al. 2006). Following a 60-mg loading dose and a 10-mg maintenance dose, the C_{max} values for the active metabolite are about 453 ng/mL and 56 ng/mL, respectively (Farid et al. 2010). Approximately 68 % of the agent is excreted in the urine and 27 % in the feces in the form of inactive metabolites over a period of 10 days, indicating that urinary excretion is the major pathway for the elimination of inactive prasugrel metabolites (Farid et al. 2010).

After oral administration, prasugrel is rapidly and nearly completely (>80 %) absorbed from the intestine (Farid et al. 2007). Prasugrel, like ticlopidine and clopidogrel, is a prodrug and is extensively metabolized. The hydrolysis of prasugrel is mediated by hCE2, an intestinal enzyme, and forms the thiolactone R-95913 through keto-enol tautomerism. R-95913 is metabolized to prasugrel's active metabolite, R-138727 (see Fig. 4). At least half of the dose is rapidly converted to its active metabolite (Farid et al. 2010). Four CYPs are capable of forming prasugrel active metabolite from its thiolactone precursor (CYP3A4, CYP2B6, CYP2C9, CYP2C19) (Rehmel et al. 2006). Administration of maintenance doses or loading doses of prasugrel results in a significantly more rapid onset and more consistent platelet inhibition than observed with clopidogrel in patients with coronary artery disease (Jernberg et al. 2006; Wallentin 2009; Wallentin et al. 2008; Wiviott et al. 2007b; Payne et al. 2007; Brandt et al. 2007; Jakubowski et al. 2007a, b; Weerakkody et al. 2007). In two vulnerable patient groups, i.e., in those weighing less than 60 kg and those above 75 years, the excessive platelet inhibitory effect of prasugrel led to higher risk for bleeding mandating a dose reduction in maintenance dose to 5 mg. Prasugrel is contraindicated in patients with prior history of transient ischemic attack or stroke.

In order to reduce bleeding risk especially in patients in urgent need of surgery, the reversible, direct-acting $P2Y_{12}$ inhibitors ticagrelor and cangrelor were brought into market.

Ticagrelor

Ticagrelor (see Fig. 2) is a noncompetitive, direct-acting $P2Y_{12}$ inhibitor that reversibly binds to the $P2Y_{12}$ receptor (see Figs. 2 and 5). In contrast to clopidogrel and prasugrel, it does not require metabolic activation (see Table 1).

This first-in-class cyclopentyltriazolopyrimidine is an orally administered antiplatelet agent that directly inhibits the $P2Y_{12}$ receptor through allosteric modulation (see Figs. 2 and 5) (Ferreiro and Angiolillo 2012; Franchi and Angiolillo 2015). Unlike the active metabolites of thienopyridines, ticagrelor does not directly block the ADP-binding site; instead, the drug reversibly binds to a distinct site on the $P2Y_{12}$ receptor and prevents ADP from activating the $P2Y_{12}$ pathway, in a noncompetitive fashion (see Fig. 2) (van Giezen et al. 2009; Rollini et al. 2016). As a result, the

$P2Y_{12}$ receptor becomes nonfunctional (locked in inactive state) without losing the capability of ADP binding. Ticagrelor received regulatory approval in Europe and in the United States for the reduction of thrombotic events in patients with acute coronary syndromes in 2011. Due to the reversible nature and the plasma half-life of 8–12 h, it requires a twice-daily dosing regimen (see Table 1) (Teng et al. 2010; Gurbel et al. 2009). Standard loading dose is 180 mg, and standard maintenance dose is 90 mg twice daily.

Ticagrelor is rapidly absorbed with a median time to peak concentration (T_{max}) of 2 h. Although it is a direct-acting agent, approximately 30–40 % of its antiplatelet effects are attributed to an active and approximately equipotent metabolite (AR-C124910XX) generated by hepatic CYP3A4 and CYP3A5 (Teng et al. 2010). After absorption, ticagrelor and AR-C124910XX are highly plasma protein-bound (>99.8 %) (Sillen et al. 2011; Teng et al. 2010). Both exhibit predictable linear pharmacodynamics in patients with atherosclerosis, stable coronary disease, and acute coronary syndromes (Dobesh and Oestreich 2014; Husted et al. 2006, 2012; Teng et al. 2010; Storey et al. 2007). After administration of radiolabeled ticagrelor, mean radioactivity recovery was 58 % in feces and 27 % in urine. However, levels of unchanged ticagrelor and AR-C124910XX in urine were less than 0.05 %, suggesting that renal excretion plays a minor role in the elimination of ticagrelor (Dobesh and Oestreich 2014; Teng et al. 2010).

Ticagrelor achieves rapid (approximately 2 h), dose-dependent, and near-complete (IPA_{MD} ~ 93 %) inhibition of ADP-induced platelet aggregation (see Table 1) that is similar to the potency of prasugrel (Teng and Butler 2010). Consistent with its noncompetitive and reversible mode of $P2Y_{12}$ inhibition, the rate of offset is significantly faster as compared with prasugrel; however, due to the more potent platelet inhibitory effect, the offset is comparable to that of clopidogrel (Gurbel et al. 2009). After discontinuation of treatment, plasma concentrations start to decline after approximately 12 h, and platelet aggregation returns to pretreatment values after 5–7 days (Husted et al. 2006; Teng and Butler 2010; Storey et al. 2010; Gurbel et al. 2009). However, like thienopyridines, ticagrelor is only available orally.

Unlike thienopyridines of which the only known target receptor is $P2Y_{12}$, ticagrelor also blocks equilibrative nucleoside transporter 1 (ENT-1) that is a plasmalemmal transport protein transporting nucleoside substrates such as adenosine. ENT-1 is frequently expressed in many cells, such as on red blood cells. ENT-1 rapidly uptakes adenosine from the plasma that may undergo phosphorylation to form ATP or degradation to uric acid intracellularly. By blocking ENT-1, ticagrelor increases plasma adenosine levels. Although it is thought that elevated plasma levels of adenosine is responsible for the dyspnea after ticagrelor treatment, dipyridamole is even a more potent inhibitor of adenosine reuptake but does not cause dyspnea (Cattaneo and Faioni 2012). Therefore, dyspnea, a common side effect of ticagrelor treatment, is of unknown mechanism.

Cangrelor

All antiplatelet agents discussed so far are limited by their oral distribution, bearing the risk of incomplete absorption in the setting of acute myocardial infarction. Moreover, the currently available data indicate a drug-drug interaction between morphine and oral $P2Y_{12}$ receptor inhibitors, when administered together. First, the CRUSADE registry revealed higher rates of adverse clinical outcomes in non-ST-segment elevation acute coronary syndrome patients treated with clopidogrel who received i.v. morphine, when compared to those who did not (Meine et al. 2005; Kubica et al. 2016). In the ATLANTIC study population, early in-ambulance administration of ticagrelor in patients with ST-segment elevation myocardial infarction improved coronary reperfusion only in patients not receiving morphine (Montalescot et al. 2014). These findings are in line with pharmacodynamics studies (Parodi et al. 2013, 2014, 2015), suggesting that the onset of action of prasugrel and ticagrelor may be delayed by coadministration of morphine in ST-segment elevation myocardial infarction patients (Kubica et al. 2016). Recently, the first randomized, double-blind, placebo-controlled trial featuring three methods of platelet reactivity assessment (vasodilator-stimulated phosphoprotein phosphorylation assay, multiple electrode aggregometry, and VerifyNow) revealed that morphine significantly delays and attenuates ticagrelor exposure and action in patients with myocardial infarction (Kubica et al. 2016). Intravenous administration of $P2Y_{12}$ inhibitors might overcome these shortcomings.

The first and only $P2Y_{12}$ inhibitor with intravenous administration option is cangrelor, that is, an ATP analogue in structure (2-trifluoropropylthio,N-(2-(methylthio)ethyl)-ß,γ-dichloromethylene ATP; see Fig. 3). It was introduced and approved by the FDA in June 2015 for reducing thrombotic events in patients undergoing PCI. As a major advantage compared with oral $P2Y_{12}$ inhibitors, it achieves very potent platelet inhibition and reaches steady-state conditions within a few minutes of initiating administration (see Table 1) (Franchi and Angiolillo 2015; Franchi et al. 2013; Angiolillo et al. 2012b). Cangrelor is an intravenous adenosine triphosphate analogue that directly and reversibly binds to the $P2Y_{12}$ inhibitor in a dose-dependent manner without requiring metabolization (see Fig. 5, Table 1) (Franchi et al. 2013; Angiolillo et al. 2012b). Although the binding site of cangrelor at the $P2Y_{12}$ receptor level is not clearly defined,

cangrelor is associated with high levels of receptor occupancy, preventing ADP signaling (Rollini et al. 2016; van Giezen and Humphries 2005). The modifications in the ATP molecule provide cangrelor with a great affinity for the $P2Y_{12}$ receptor and a higher resistance to ectonucleotidases (Ferreiro et al. 2009). Cangrelor shows a rapid onset of action (2 min) when administration is started with a bolus dose and exhibits a linear dose-response pharmacokinetic profile that leads to very stable pharmacodynamic effects (Franchi and Angiolillo 2015). It also exerts a dose-dependent effect on platelet inhibition with infusions up to 4 μg/kg/min, achieving a high degree (>80 %) of platelet inhibition following 5 and 20 μmol/L ADP stimuli (Storey et al. 2001; Ferreiro et al. 2009; Franchi et al. 2013; Angiolillo et al. 2012b). After discontinuation of infusion, cangrelor shows a very rapid offset of action due to its very short half-life (3–5 min) due to rapid degradation through dephosphorylation, with platelet aggregation returning to pretreatment values within 30–60 min (Franchi and Angiolillo 2015; Franchi et al. 2013; Angiolillo et al. 2012b). These pharmacodynamic properties seem optimal for patients in need of rapid platelet inhibition who are unable to intake oral drugs. Cangrelor might also be a good antiplatelet treatment option for ACS patients requiring CABG surgery. The BRIDGE trial was a pharmacodynamic trial conducted in 210 patients (50 % ACS patients) treated with a thienopyridine and requiring surgery. Cangrelor was associated with high and stable levels of platelet inhibition, with an extremely rapid offset of action after discontinuation before surgery and without increased risk of major bleeding or adverse events before or during CABG surgery (Rollini et al. 2016; Angiolillo et al. 2012a).

An important consideration for the use of cangrelor is how to switch from the intravenous agent to oral $P2Y_{12}$ inhibitors. A pharmacodynamic investigation conducted in healthy volunteers showed that concomitant administration of clopidogrel and cangrelor infusion leads to inadequate clopidogrel-induced antiplatelet effects, because clopidogrel does not bind to the $P2Y_{12}$ receptor while the receptor is occupied by cangrelor (Rollini et al. 2016; Steinhubl et al. 2008). However, clopidogrel-induced antiplatelet effects were not affected when clopidogrel was administered after a cangrelor infusion, given the very rapid offset of action of cangrelor (Steinhubl et al. 2008; Rollini et al. 2016). The transition from cangrelor to prasugrel was associated with transient recovery of platelet reactivity, particularly within 1 h after cangrelor discontinuation, which was attenuated when prasugrel was administered 30 min before stopping cangrelor infusion (Rollini et al. 2016; Schneider et al. 2015). In contrast, a pharmacodynamic study showed that the pharmacodynamic effects of ticagrelor and cangrelor are consistently preserved independently from the sequence in which the drugs are administered. Therefore, ticagrelor can be administered before, during, or after cangrelor infusion without pharmacodynamic interaction (Schneider et al. 2014; Rollini et al. 2016). With this regards, ticagrelor may be beneficial given the distinct $P2Y_{12}$ receptor binding site leading to lack of competition when both drugs are present in the plasma.

Take-Home Messages

- Thienopyridine-type $P2Y_{12}$ inhibitors, such as ticlopidine, clopidogrel, and prasugrel, are prodrugs that require hepatic metabolization and conversion to a pharmacologically active metabolite to exert their antiplatelet effect. Their active metabolites covalently and irreversibly bind to the $P2Y_{12}$ receptor for the entire life span of the platelet; therefore, the offset of the antiplatelet effect is only possible by formation of new platelets.
- Clopidogrel is widely used in various cerebrovascular patients to prevent and treat recurrent thrombotic complications. An important limitation of the drug, however, is the highly variable active metabolite formation leading to unpredictable platelet reactivity inhibition after fixed dosing. Patients with inappropriate platelet reactivity inhibition are exposed to higher risk for stent thrombosis, myocardial infarction, and mortality.
- Prasugrel provides more potent and more predictable antiplatelet effect with a quicker onset of action as compared to clopidogrel, although their active metabolites have similar $P2Y_{12}$ inhibitory effect at equimolar concentrations. The more potent and more predictable antiplatelet effect translated into improved clinical outcomes in patients with ACS undergoing percutaneous coronary intervention, albeit at the expense of an increased bleeding risk.
- Ticagrelor is a cyclopentyltriazolopyrimidine-type, reversible binding, direct-acting $P2Y_{12}$ inhibitor, not requiring metabolic activation. It also provides a rapid and predictable $P2Y_{12}$ inhibition with similar safety and efficacy profile as prasugrel. Importantly, ticagrelor also inhibits adenosine reuptake by blocking ENT-1, causing an elevated level of adenosine with unknown clinical consequences.
- Cangrelor is an intravenous $P2Y_{12}$ inhibitor, with a unique PK profile: it achieves very potent platelet inhibition and reaches steady-state conditions within a few minutes of initiating administration and shows a very rapid offset of action after discontinuation.

Glycoprotein IIb/IIIa Antagonists

Madhan Shanmugasundaram and David J. Moliterno

Abstract

Patients with acute coronary syndrome and who undergo percutaneous coronary intervention are at a high risk for recurrent adverse cardiovascular events. There is a continuous search for an ideal antiplatelet medication that has a favorable risk benefit profile with a quick onset of peak action. Glycoprotein IIb/IIIa inhibitors (GP IIb/IIIa) were introduced with that precise idea in mind, that it is an intravenous antiplatelet agent with a rapid onset of action, which can be used to achieve maximal antiplatelet activity in patients with acute coronary syndrome (ACS) and those undergoing percutaneous coronary intervention (PCI). Abciximab, eptifibatide, and tirofiban are the three available intravenous GP IIb/IIIa inhibitors of which the latter two are small molecules. Initial trials that examined these agents were done in the balloon angioplasty era when $P2Y_{12}$ receptor blocker use was not routine. These trials demonstrated a significant reduction in the composite end point of death, myocardial infarction (MI), and urgent target vessel revascularization predominantly driven by a reduction in recurrent MI that included periprocedural events. There is a definite increase in major and minor bleeding with these agents which needs to be weighed against the potential benefits before initiating the drug. More contemporary trials that were done on patients who were adequately treated with $P2Y_{12}$ inhibitors failed to recreate the initial results, but nevertheless there was still a significant reduction in ischemic events. There is still a role for these agents in patients with high-risk non-ST segment elevation myocardial infarction and ST segment elevation myocardial infarction with heavy thrombus burden, particularly if they have not been adequately pretreated with $P2Y_{12}$ inhibitors.

Platelet Biology

It is well established that platelets play a critical role in normal hemostasis and pathogenesis of thromboembolic disease. Beyond being the primary cellular component of arterial thrombosis, platelets are involved in fibrin formation, inflammation, and fibrinolysis. When an atherosclerotic plaque ruptures, the exposed subendothelial matrix induces platelet activation and aggregation in three phases, initiation, extension, and perpetuation phase, resulting in the formation of platelet plug or white thrombus (Davi and Patrono 2007). In the initiation phase, circulating platelets bind to the exposed subendothelial matrix at the site of endothelial injury via GP Ib-IX receptor complex that binds to the von Willebrand factor (vWF). This triggers platelet activation and release of various platelet-activating agonists such as thromboxane A2 (TxA2), thrombin, serotonin, and adenosine diphosphate (ADP). TxA2 and ADP activate the platelets directly through G-protein-coupled receptors resulting in platelet aggregation (Hughes and Pfaff 1998).

The extension phase thus recruits more platelets to the site of endothelial damage. Platelet aggregation is predominantly mediated by glycoprotein (GP) IIb/IIIa receptors. GP IIb/IIIa receptors undergo a conformational change in activated platelets which allows them to bind with specific ligands such as fibrinogen, fibronectin, and von Willebrand factor (Lefkovits et al. 1995). This step is critical in the formation of platelet plug, thus making the GP IIb/IIIa receptors an attractive pharmaceutical target as it represents the final common pathway in the formation of white thrombus (Angiolillo et al. 2010). In the perpetuation phase the platelet-rich thrombus and coagulation cascades interact with one another by a series of complex mechanisms resulting in the formation of stable platelet-fibrin-rich plug. It is estimated that there are approximately 80,000 GP IIb/IIIa receptors on the surface of each platelet (Wagner et al. 1996). Figure 1 shows the structure of a GP IIb/IIIa receptor.

Glycoprotein IIb/IIIa Inhibitors

It has been shown by in vitro studies that intravenous GP IIb/IIIa inhibitors block 80–90 % of ADP-induced platelet aggregation in a dose-dependent fashion compared to 10 % by aspirin and 30–50 % for thienopyridines. There are three GP IIb/IIIa inhibitors available for routine clinical use: abciximab, eptifibatide, and tirofiban.

Abciximab

Abciximab (ReoPro®) was the first GP IIb/IIIa inhibitor to be approved by FDA for clinical use in 1997. It is an antibody against the GP IIb/IIIa receptor which rapidly and firmly binds the IIb/IIIa receptor (Coller et al. 1983). As such, abciximab has a very short plasma half-life but a long biologic half-life (up to 48 h) (Schror and Weber 2003). Because abciximab near irreversibly binds the receptor, there are no reversal agents. Platelet transfusions provide some, but limited, reversal effect since abciximab can continue to bind to the newly infused platelets (Webb et al. 2011). The recommended bolus dose is 0.25 mg/kg followed by 0.125 mcg/kg/min infusion for up to 12 h in patients with acute coronary syndrome with planned invasive strategy. Bleeding is the most common side effect as reported in various placebo controlled trials (EPIC Investigators. 1994). Although thrombocytopenia is reported in 5–6 % of patients in early abciximab trials, clinically significant thrombocytopenia (platelet count $< 100{,}000/cc^3$) occurred in 2 % of patients. Even though the incidence of thrombocytopenia is higher with abciximab compared to the other GP IIb/IIIa inhibitors, there appears to be no significant increase in bleeding.

Eptifibatide

Eptifibatide (Integrilin®) is a small-molecule cyclic heptapeptide with high specificity for the GP IIb/IIIa receptor but low affinity. Hence it disassociated rapidly from the receptor and has a short biologic half-life (Scarborough et al. 1999). It is cleared mostly by kidneys; hence dose adjustment is necessary based on creatinine clearance and is contraindicated in hemodialysis patients (Alton et al. 1998). It has been shown that in 10–15 min after the bolus dose, there is nearly complete inhibition of ADP-induced platelet aggregation, and effect persists for 2–4 h after the infusion is stopped. The dose of eptifibatide is 180 μg/kg bolus followed by a maintenance infusion of 2 μg/kg/min for 18–24 h. It was shown that the pharmacodynamics of eptifibatide was significantly altered by anticoagulants that chelate calcium, resulting in overestimation of the in vivo effects of this agent. This resulted in the use of lower doses of eptifibatide in some earlier trials which in turn resulted in lower efficacy (Gilchrist et al. 2001). The dosing regimen is different when used in the percutaneous coronary intervention (PCI) setting where a double bolus (180 mcg/kg) 10 min apart followed by

infusion is recommended. This was based on the findings of ESPRIT trial which was terminated prematurely due to superior results compared to placebo (ESPRIT Investigators. 2000). Even though bleeding is the major side effect, it was shown that TIMI major bleeding rates were not statistically different compared to placebo. Thrombocytopenia is also uncommon with eptifibatide.

Tirofiban

Tirofiban (Aggrastat®) is a small-molecule, non-peptide tyrosine derivative that causes reversible GP IIb/IIIa inhibition. Similar to eptifibatide, it also has a high specificity for the GP receptor, but the platelet-bound half-life is extremely short (Barrett et al. 1994). The plasma half-life is about 2 h and platelet function returns to baseline within 6–8 h after cessation of the drug. It is cleared mostly by the kidneys; hence dose adjustment for advanced renal disease is required, and it is contraindicated in patients on dialysis.

Currently recommended dosing is 25 mcg/kg bolus followed by infusion at 0.15 mcg/kg/min for up to 18 h. Earlier tirofiban trials however used a lower dose that resulted in inferior results, but the current dosing recommendations were based on pharmacodynamic trials that established superior platelet inhibition with the higher bolus dose. Bleeding and thrombocytopenia are the most commonly reported adverse events with tirofiban with rates similar to those reported with eptifibatide. Important pharmacokinetic properties of the GP IIb/IIIa inhibitors are summarized in Table 1.

Table 1 Pharmacology of GP IIb/IIIa inhibitors

Characteristic	Abciximab	Eptifibatide	Tirofiban
Size	Large molecule	Small molecule	Small molecule
Nature of drug	Monoclonal antibody	Heptapeptide	Non-peptide
Plasma half-life	10 min	2.5 h	2 h
Platelet half-life	Hours	Seconds	Seconds
Dose	Bolus: 0.25 mg/kg Maintenance: 0.125 mcg/kg/min for 12 h	Bolus: 180 mcg/kg × 2 Maintenance: 2 mcg/kg/min for 12–18 h	Bolus: 25 mcg/kg Maintenance: 0.15 mcg/kg/min for 12–18 h
Time taken for return of platelet function after cessation of drug	24 h	4 h	4 h
Clearance	Spleen	Renal	Renal
Reversal	Platelets infusion	None	None

Role of GP IIb/IIIa Inhibitors

Unstable Angina and Non-ST Elevation Myocardial Infarction

Glycoprotein IIb/IIIa inhibitors were introduced to address the problem of increased major adverse cardiovascular events (MACE) in patients presenting with acute coronary syndrome (ACS) and hence form a class of well-studied medication in this cohort of patients. This is a heterogeneous group to begin with, and not all patients had routine early invasive approach which makes it hard to generalize any data to the contemporary ACS population, but there was still a 10 % relative reduction in the 30-day incidence of death or MI. Most of the benefit from the GP IIb/IIIa inhibitors is from reduction of recurrent MI and periprocedural infarction. It should also be noted that most of these GP IIb/IIIa inhibitor trials were performed in the era of balloon angioplasty and no routine use of thienopyridines.

One of the first major trials examining the use of GP IIb/IIIa inhibitors in unstable angina patients undergoing balloon angioplasty was the EPIC trial. It showed a significant reduction of death, MI, recurrent ischemia, or failed revascularization in patients randomized to abciximab therapy (1994). ISAR REACT 2 trial randomized over 2000 patients with non-ST elevation MI (NSTEMI) undergoing invasive treatment to abciximab or placebo. It showed a significant reduction in major adverse cardiovascular events (death, MI, or urgent revascularization) at 30 days in patients who received abciximab (Kastrati et al. 2006). This trial included patients who were given a loading dose of clopidogrel (600 mg) hence proving that there is role for GP IIb/IIIa inhibitors in these patients. No significant difference in bleeding was noted in either of these two studies. Glycoprotein IIb/IIIa inhibitors were tested as part of upstream therapy in patients planned for early invasive strategy. CAPTURE trial randomized patients with refractory unstable angina (recurrent myocardial ischemia on maximal medical therapy including heparin and nitrates) who were undergoing balloon angioplasty to abciximab or placebo. This trial again showed a significant reduction in MACE at 30 days (CAPTURE Investigators. 1997). The GUSTO IV ACS trial was unique in the fact that it examined the use of abciximab in patients who were not undergoing early intervention. It showed no significant difference in MI or death at 30 days and hence concluded that upstream use of abciximab in patients undergoing medical therapy only for NSTEMI may not be beneficial, thus the class III recommendation in this clinical scenario (Simoons 2001).

PRISM trial showed that in patients with unstable angina receiving heparin and aspirin, tirofiban use reduced death, MI, and refractory ischemia at 48 h compared to placebo at

the expense of increased bleeding (PRISM Investigators. 1998a). PRISM PLUS trial compared the use of tirofiban alone to heparin alone and combination of tirofiban and heparin in patients with unstable angina and NSTEMI. This trial was terminated early due to increased mortality in patients randomized to tirofiban alone but showed a significant reduction in death, MI, or refractory ischemia within 7 days in patients on combination therapy (tirofiban and heparin). About one third of patients underwent balloon angioplasty and the rest were treated conservatively (1998c). ADVANCE trial examined the use of high bolus dose tirofiban in patients with NSTEMI who were pretreated with clopidogrel, undergoing high-risk PCI, and demonstrated a significant reduction of MACE at 180 days (Valgimigli et al. 2004).

The PURSUIT trial was one of the larger trials (over 10,000 patients) to examine the use of eptifibatide in patients presenting with unstable angina or NSTEMI. It showed a significant reduction in death or MI up to 30 days in patients who received eptifibatide at the expense of increased bleeding (PURSUIT Investigators. 1998b). The EARLY ACS trial tested the hypothesis of upstream eptifibatide use in patients with NSTEMI who were planned to undergo PCI. This study showed no significant difference in ischemic outcomes (death or MI) in patients who received the drug early (12 h before angiography) compared to the ones who received it during angiography, and also early GP IIb/IIIa inhibitor use was associated with more bleeding (Giugliano et al. 2009). However it should be noted that EARLY ACS trial was conducted in an era of frequent use of stents and routine early angiography compared to PURSUIT trial. A meta-analysis by Tricoci et al. showed an 11 % reduction in ischemic end points (death or MI) at 30 days with upstream use of small-molecule GP IIb/IIIa inhibitors in patients with NSTEMI, but a 23 % increase in major bleeding was seen in these patients (Tricoci et al. 2011). These trials clearly demonstrate that routine upstream use of GP IIb/IIIa inhibitors in ACS patients may not be beneficial due to the modest ischemic benefit being outweighed by higher bleeding risk. A recently published Cochrane review of GP IIb/IIIA inhibitors that included 60 randomized trials (over 60,000 patients) concluded that with downstream use (during PCI), there was a significant reduction at death or MI at 30 days with significantly increased major bleeding risk (odds ratio 1.39, CI 1.21–1.61) in patients receiving GP IIb/IIIa inhibitors. With upstream use there was a slight decrease in death or MI at 30 days with increased major bleeding (odds ratio 1.29, CI 1.14–1.45). The number needed to treat (death or MI) was 42, and the number needed to harm (major bleeding) was 125. The benefits of GP IIb/IIIa inhibitors appeared to be homogenous across different population subgroups although less marked for patients pretreated with clopidogrel (Bosch et al. 2013).

In the latest ACC/AHA guidelines for management of patients with non-ST elevation acute coronary syndromes, GP IIb/IIIa inhibitors have received a class I recommendation in patients undergoing early invasive approach if they have not been adequately pretreated with a second antiplatelet drug (clopidogrel, prasugrel, or ticagrelor) and class IIa in patients adequately pretreated with two oral antiplatelets if they have a high-risk presentation (Amsterdam et al. 2014). The European Society of Cardiology (ESC) guidelines assign a class IIa recommendation for GP IIb/IIIa inhibitors use during PCI only for bailout situations or thrombotic complications (Roffi et al. 2016). It is very clear in the guidelines that routine upstream use of GP IIb/IIIa inhibitors is generally discouraged.

ST Elevation Myocardial Infarction

Glycoprotein IIb/IIIa inhibitors have been studied extensively in patients with ST elevation myocardial infarction (STEMI) who underwent either thrombolytic therapy or primary PCI. Primary PCI has been established to be superior to thrombolytic therapy in STEMI, but only a minority of patients in the United States present to a PCI-capable hospital. This paved way for a series of studies examining different pharmacologic strategies aimed at achieving comparable results to primary PCI. Facilitated PCI is a strategy of pharmacologic reperfusion therapy delivered prior to a planned PCI. As a part of this strategy, GP IIb/IIIa inhibitors were combined with different fibrinolytics in various doses to achieve reperfusion, but overall, this was shown to be inferior to pharmaco-invasive approach (thrombolytic therapy administered at a non-PCI hospital with intent of transferring to a PCI hospital for early angiography – within 3–24 h) or primary PCI. In earlier trials such as GUSTO V (Topol 2001) and ASSENT-3 (2001), GP IIb/IIIa inhibitors were combined with thrombolytics and were shown to increase bleeding risk without additional ischemic benefit. It should be noted that pre-procedural thienopyridine use was not routine in these earlier trials. Upstream abciximab use with 600 mg of clopidogrel was tested in BRAVE-3 study where it was shown that there was no difference in the infarct size (Tc-99 m sestamibi SPECT imaging) compared to placebo (Mehilli et al. 2009). A sub-study of APEX AMI (Huber et al. 2010) trial supported the idea of upstream GP IIb/IIIa use in STEMI patients, but this finding was refuted in the larger FINESSE study. In FINESSE trial over 1500 patients with STEMI were randomized to one of the three arms of the study: either half-dose reteplase combined with abciximab or abciximab alone or primary PCI in the background of aspirin and heparin therapy. The study failed to show any difference in ischemic end point, but increased bleeding and transfusion requirements were seen (Ellis et al. 2008).

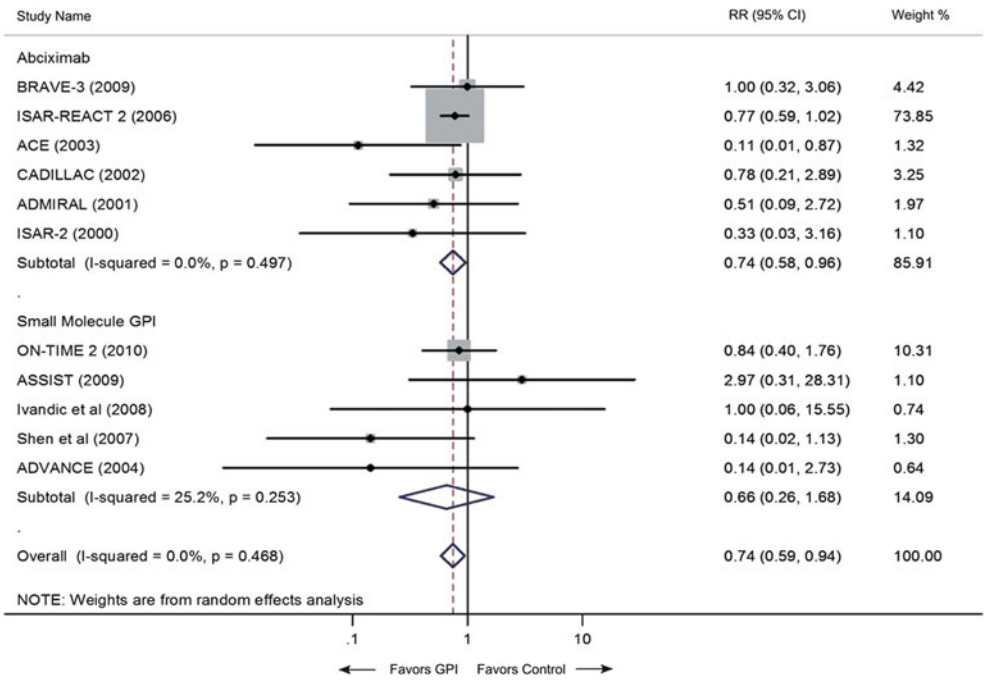

Fig. 2 Risk ratio for myocardial infarction in ACS patients. Reproduced with permission from Winchester, D.E., et al., *Efficacy and safety of unfractionated heparin plus glycoprotein IIb/IIIa inhibitors during revascularization for an acute coronary syndrome: a meta-analysis of randomized trials performed with stents and thienopyridines*. Clin Cardiol, 2012. **35**(2): p. 93–100

Downstream (administered in the catheterization lab at the time of PCI) abciximab use was tested in several small trials in patients undergoing primary PCI and showed some ischemic benefit at the expense of increased bleeding (Brener et al. 1998; Neumann et al. 2000; Montalescot et al. 2001; Stone et al. 2002; Antoniucci et al. 2003). It should however be mentioned that in HORIZONS-AMI trial routine GP IIb/IIIa use with heparin was compared to bivalirudin in patients undergoing primary PCI for STEMI. It was shown that there was no added ischemic benefit from GP IIb/IIIa use; however, there was increased bleeding noted in this group (Stone et al. 2008). A meta-analysis by Dong et al. examined the role of GP IIb/IIIa inhibitors in patients with STEMI undergoing primary PCI after pretreatment with loading dose thienopyridine. They showed that there was no significant difference in 30-day or 6-month death or MI in patients treated with GP IIb/IIIa inhibitors but there was significantly increased bleeding risk (Dong et al. 2013). The Cochrane review also showed slight reduction in 30-day MACE (death, MI, or urgent TVR) with increased major bleeding risk in STEMI patients (Bosch et al. 2013).

A recently published meta-analysis examined the role of GP IIb/IIIa inhibitors in patients with ACS, in the current era of stents and routine thienopyridine use, and the results of this study reflect the practice guidelines. There was a 26 % relative risk reduction in MI at 30 days with GP IIb/IIIa inhibitors use (3.1 % in GP IIb/IIIa inhibitors versus 4.4 % with control, RR = 0.74; 95 % CI 0.59–0.94, $p = 0.014$) (Fig. 1). In regard to safety, it was noted that there was an increase in TIMI minor bleeding, but the incidence of major bleeding at 30 days was 2.5 % with GP IIb/IIIa inhibitors versus 2.1 % with control, hence not different (RR = 1.21; 95 % CI 0.89–1.63, $p = 0.22$) (Fig. 2) (Winchester et al. 2012). In the 2013 ACC/AHA STEMI guidelines, GP IIb/IIIa inhibitors were given a class IIa recommendation in selected patients undergoing primary PCI (heavy thrombus burden and inadequate $P2Y_{12}$ receptor antagonist loading) and class IIb in pre-catheterization setting with no discrimination being made among the three agents (O'Gara et al. 2013). GP IIb/IIIa inhibitors received a class IIa recommendation in the recent ESC STEMI guidelines, as a bailout therapy in the presence of massive thrombus, slow or no-reflow or a thrombotic complication (Steg et al. 2012).

Percutaneous Coronary Intervention

Glycoprotein IIb/IIIa inhibitors were studied in patients undergoing outpatient non-emergent PCI. As previously mentioned most of these trials were done in the era of balloon angioplasty only or bare metal stents and when $P2Y_{12}$ receptor antagonist use was not standard practice. Hence in some initial trials, there was a reduction in MACE events, but a closer look at these trials showed that most of the benefit

was from reduction of recurrent MI, likely related to reduction of periprocedural infarction. Also some of the earlier trials used a different dose of these medications as the appropriate dose that achieved maximal inhibition of platelet aggregation had not been identified. Over 2000 patients who were scheduled to undergo elective PCI were randomized to eptifibatide therapy or placebo in the ESPIRIT trial, which was terminated early due to efficacy. This study showed significant reduction in death, MI, or urgent TVR in patients randomized to eptifibatide therapy.

ISAR REACT trial randomized patients undergoing elective PCI who were preloaded on clopidogrel to abciximab or placebo and demonstrated that addition of GP IIb/IIIa inhibitor did not provide any significant ischemic benefit in this population. This trial is more similar to our current day PCI practice pattern and hence convincingly showed that routine use of GP IIb/IIIa inhibitors for elective PCI in patients preloaded on $P2Y_{12}$ antagonists is not beneficial (Kastrati et al. 2004). Winchester et al. published a meta-analysis of 22 trials that included over 10,000 patients undergoing elective PCI with stents adequately preloaded on $P2Y_{12}$ inhibitors, comparing the utility of GP IIb/IIIa inhibitors. There was a 31 % relative risk reduction in nonfatal MI in patients receiving GP IIb/IIIa inhibitors compared to placebo (5.1 % vs. 8.3 %, RR 0.69, 95 % CI 0.55–0.86, $p = 0.001$) (Fig. 3) with no difference among the type of GP IIb/IIIa inhibitors used. There was no reduction in all-cause mortality with GP IIb/IIIa inhibitors use. Even though there was an increase in TIMI minor bleeding with GP IIb/IIIa inhibitors use 3.0 % versus 1.7 % with control (RR: 1.70, 95 % CI 1.28–2.26, $p < 0.0001$), there was no increase in TIMI major bleeding. The incidence of major bleeding was 1.2 % with GP IIb/IIIa inhibitors versus 0.9 % with placebo (RR 1.37, 95 % CI 0.83–2.25, $p = 0.22$) (Fig. 4) (Winchester et al. 2011). According to the 2011 PCI guidelines, routine use of GP IIb/IIIa inhibitors in patients undergoing elective PCI (treated with heparin and adequately preloaded on clopidogrel) is a class IIb recommendation if adequately pretreated with clopidogrel and class IIa recommendation if not pretreated (Levine et al. 2011) (Fig. 5).

Intracoronary Use of Glycoprotein IIb/IIIa Inhibitors

Optimizing outcomes and minimizing complications in patients undergoing PCI are critical. During PCI there is often distal micro- or macroembolization which contributes to periprocedural MI that has been shown to increase mortality. It was proposed that if GP IIb/IIIa inhibitors could be delivered locally via intracoronary administration, myocardial perfusion could be maintained during PCI.

Clinical scenario	Elective or urgent PCI	NSTEMI	STEMI (abciximab vs. reteplase + abciximab)	Unstable angina (refractory)	NSTEMI (placebo vs. 24 h abciximab vs. 48 h abciximab)
Number of patients	2399	2022	800	1265	7800
Timing of drug	Downstream	Downstream	Downstream	Upstream	Upstream
Dose	0.25 mg/kg bolus 0.125 mcg/kg/min for 12 h	0.25 mg/kg bolus 0.125 mcg/kg/min for 12 h	0.25 mg/kg bolus 0.125 mcg/kg/min for 12 h	0.25 mg/kg bolus 0.125 mcg/kg/min for 18–24 h	0.25 mg/kg bolus 0.125 mcg/kg/min for 24–48 h
Other anticoagulants or antiplatelets	Heparin, ASA ± ticlopidine	Heparin, ASA, clopidogrel	Heparin, ASA, clopidogrel	Heparin, ASA ± ticlopidine	Heparin or LMWH, ASA
Invasive treatment arm	100 % PTCA > BMS	100 % DES > BMS ≫ PTCA	100 % BMS ≫ PTCA	100 % PTCA	Conservative therapy only
Primary outcome	Death or MI at 1 year	Death, MI, or urgent TVR	Infarct size (SPECT)	Death, MI, or urgent TVR	Death or MI at 30 days
Results	5.3 % vs. 10.8 % ($p < 0.001$)	8.9 % vs. 11.9 % ($p = 0.03$)	15.7 % vs. 16.6 % (ns)	11.3 % vs. 15.9 % ($p = 0.012$)	8.2 % vs. 8 % (ns) (24 h group) 9.1 % vs. 8 % (ns) (48 h group)

PCI percutaneous coronary intervention, *NSTEMI* non-ST elevation myocardial infarction, downstream: after angiography or at the time of PCI, upstream: at the time of admission or before angiography, *PTCA* percutaneous transluminal coronary angioplasty, *BMS* bare metal stent, *DES* drug-eluting stent, *MI* myocardial infarction, *TVR* target vessel revascularization, *SPECT* single photon emission computed tomography, *ASA* aspirin, *LMWH* low molecular weight heparin

Intracoronary administration of eptifibatide was shown to increase localized platelet GP IIb/IIIa receptor occupancy and microvascular perfusion (measured by corrected TIMI frame count) in patients undergoing PCI for ACS (Deibele et al. 2010). Intracoronary tirofiban was shown to be similar to intravenous bolus and infusion of tirofiban in patients undergoing primary PCI, in a small study, in regard to microvascular perfusion and ST segment resolution (Kirma et al. 2012). Abciximab was the most studied GP IIb/IIIa inhibitor for intracoronary use with conflicting evidence from different trials. One study showed intracoronary abciximab significantly reduced 30-day mortality and targeted vessel revascularization (TVR) in STEMI patients undergoing primary PCI compared to intravenous administration (Iversen et al. 2011). Another study that compared intracoronary to intravenous abciximab in STEMI patients undergoing primary PCI showed a significant reduction in the infarct size and extent of microvascular obstruction in the intracoronary arm (Thiele et al. 2008). These findings were however refuted by the CICERO trial that showed no improvement in myocardial reperfusion as assessed by ST segment resolution with intracoronary abciximab in STEMI patients undergoing primary PCI (Gu et al. 2010). Finally a large multicenter randomized trial that compared intracoronary to intravenous abciximab in STEMI patients undergoing primary PCI showed no difference in all-cause mortality, MI, or congestive heart failure at 90 days (Thiele et al. 2012). A meta-analysis of four randomized trials that included over 1000 patients undergoing primary PCI for STEMI treated with IC or IV abciximab showed a significant reduction in overall mortality with IC abciximab but no reduction in MACE (Shimada et al. 2012). Hence even though it has been confirmed that intracoronary administration of GP IIb/IIIa inhibitors has more platelet receptor occupancy, there appears to be no significant clinical benefit with this strategy. Consequently IC abciximab received a class IIb recommendation for use in select patients with STEMI in the recent ACC/AHA STEMI guidelines (O'Gara et al. 2013). Important trials are summarized in Tables 2, 3, and 4 according to the agent and clinical scenario in which it was tested.

Adverse Events

The most obvious side effect of GP IIb/IIIa use is bleeding. There is increased major and minor bleeding with GP IIb/IIIa use, but due to the different definitions used in clinical trials (TIMI and GUSTO), it is difficult to estimate an exact percentage risk. Also in the older GP IIb/IIIa trials where excess bleeding was identified, the dose of heparin used was higher with a higher activated clotting time (ACT) target. Now the recommended therapeutic ACT range for patients receiving GP IIb/IIIa inhibitors

Table 3 Trials examining the use of eptifibatide in different clinical scenarios

	ESPRIT (2000)	IMPACT (Tcheng et al. 1995)	PURSUIT (1998b)	EARLY ACS (Giugliano et al. 2009)
Clinical scenario	Elective and urgent PCI	Elective PCI (placebo vs. 4 h vs. 12 h infusion)	NSTEMI	NSTEMI (early vs. delayed eptifibatide)
Number of patients	2064	150	10,948	9492
Timing of drug	Downstream	Downstream	Upstream	Upstream

ACS acute coronary syndrome, *ASA* aspirin, *MI* myocardial infarction, *TVR* target vessel revascularization, *PTCA* percutaneous coronary transluminal angioplasty

is 200–250 s. The more contemporary trials performed with these new recommendations showed lower bleeding rates comparable to heparin alone. None of the GP IIb/IIIa trials showed increase in intracranial or fatal bleeding. The incidence of clinically significant thrombocytopenia is approximately 2 % with abciximab and 1 % with tirofiban and eptifibatide.

Role of GP IIb/IIIa Inhibitors in the Current Practice

Antiplatelet and antithrombotic therapy forms the cornerstone of ACS therapy. In the current practice with an early invasive approach and routine potent $P2Y_{12}$ inhibitors

(clopidogrel, prasugrel, and ticagrelor), one may question the need for additional IV antiplatelet therapy. It is important to remember that even though aspirin and $P2Y_{12}$ inhibitors block one pathway of platelet activation, platelets continue to activate via various other pathways. In fact, the most potent platelet activator thrombin remains unchecked in patients with ACS. Hence GP IIb/IIIa inhibitors, which block the final common pathway of platelet activation, make it a more potent antiplatelet agent. With increasing use of newer oral $P2Y_{12}$ inhibitors (prasugrel and ticagrelor), which have a shorter time to peak antiplatelet effect, one may question the need for GP IIb/IIIa inhibitors. However, it should be noted that in the landmark trials that resulted in the approval of these drugs (TRITON TIMI 38 and PLATO), there was a 44 % and 64 % use of GP IIb/IIIa inhibitor, respectively, and hence the degree to which GP IIb/IIIa inhibitors contributed to reduction of events in these patients is unclear. Until recently GP IIb/IIIa inhibitors were the only intravenous antiplatelet agent available to cardiologists, but now cangrelor which is an IV $P2Y_{12}$ inhibitor is an alternative option for achieving rapid inhibition of platelet activation. The CHAMPION group of trials examined the use of cangrelor in patients undergoing PCI for various reasons (chronic stable CAD and ACS). CHAMPION PCI trial tested IV cangrelor use as an upstream strategy in patients undergoing PCI, and CHAMPION PLATFORM tested it as a downstream therapy that was initiated at the time of PCI. Both these trials compared cangrelor to clopidogrel and showed no benefit with cangrelor in terms of death, nonfatal MI, or urgent revascularization within 48 h of PCI, but there was a small reduction in stent thrombosis events (Bhatt et al. 2009; Harrington et al. 2009). CHAMPION PHOENIX trial then compared cangrelor to clopidogrel in patients undergoing elective or emergent PCI, and the drug was initiated at the time of PCI. This trial showed a significant reduction in the composite end point of death, MI, urgent revascularization, or stent thrombosis (Bhatt et al. 2013). Cangrelor was just approved by the FDA but its clinical role in daily interventional practice remains to be seen. Platelet thrombin receptor antagonist vorapaxar was studied in combination with GP IIb/IIIa inhibitors in patients with NSTEMI on dual antiplatelet therapy undergoing planned PCI in the TRACER trial. It was demonstrated that the combination of vorapaxar and GP IIb/IIIa inhibitors did not confer any ischemic benefit but increased bleeding (GUSTO moderate to severe) (Cornel et al. 2015). Even with all the new potent $P2Y_{12}$ inhibitors and bivalirudin, there continues to be a role for use of GP IIb/IIIa inhibitors in a carefully selected patient population such as high-risk ACS patient not adequately preloaded on $P2Y_{12}$ inhibitors, patient with peri-PCI complications such as side branch occlusion, STEMI patients with large thrombus burden particularly if the $P2Y_{12}$ inhibitor was just administered, and patients undergoing ad hoc PCI for stable CAD not adequately pretreated.

Conclusion

Glycoprotein IIb/IIIa inhibitors form an important class of medication in patients undergoing PCI for acute coronary syndromes to reduce recurrent MI and procedural complications. Although they were largely studied in the pre-$P2Y_{12}$ receptor inhibitor and balloon angioplasty era, there is still a role for GP IIb/IIIa inhibitors in current cardiology practice. There is no doubt that these medications have ischemic benefit but the associated increased bleeding risk warrants a careful patient selection to achieve a net clinical benefit.

Take Home Messages

- Glycoprotein (GP) IIb/IIIa inhibitors form an important class of medication in patients undergoing PCI for acute coronary syndromes to reduce recurrent myocardial infarctinon and procedural complications.
- Oral thienopyridines have replaced intravenous inhibitors of GP IIb/IIIa inhibotrs in many situations.
- Ischemic event reduction has been offset by an increased frequency of bleeding events.

Dipyridamole and PDE Inhibitors

Paolo Gresele, Stefania Momi, and Emanuela Falcinelli

Abstract

Inhibition of platelet aggregation can be achieved either by the blockade of membrane receptors or by interaction with intracellular signaling pathways. Cyclic adenosine 3′,5′-monophosphate (cAMP) and cyclic guanosine 3′,5-monophosphate (cGMP) are two critical intracellular second messengers provided with strong inhibitory activity on fundamental platelet function. Phosphodiesterases (PDEs), by catalyzing the hydrolysis of cAMP and cGMP, limit the intracellular levels of cyclic nucleotides thus regulating platelet function. The inhibition of PDEs may therefore exert a strong platelet inhibitory effect. In mammalian tissues, 11 structurally related but functionally distinct PDE gene families (PDE1–PDE11) have been described. Platelets possess three PDE isoforms, PDE2, PDE3, and PDE5, with different selectivity for cAMP and cGMP. Several nonselective or isoenzyme-selective PDE inhibitors have been developed, and some of them have entered clinical use as antiplatelet agents. This review will focus on the effect of PDE2, PDE3, and PDE5 inhibitors on platelet function and on the evidence for an antithrombotic action of some of them and in particular of dipyridamole and cilostazol.

Introduction

Inhibition of platelet aggregation is the cornerstone of treatment for the prevention of recurrent ischemic cardiovascular events. Platelet inhibition can be achieved either by blockade of membrane receptors or by interaction with intracellular signaling pathways. While receptor antagonism may provide high specificity, the inhibition of platelet signal transduction may display broader effects suppressing platelet activation regardless of the initial stimulus. Inhibition of signaling can be obtained either by interfering with platelet-activating second messengers or by amplifying the action of physiologic regulator of platelet function, like endothelial-derived nitric oxide (NO) and prostacyclin (PGI_2) which act by activating adenylyl and guanylyl cyclases, respectively, thus increasing intraplatelet cyclic adenosine 3′,5′-monophosphate (cAMP) and cyclic guanosine 3′,5′-monophosphate (cGMP). cAMP and cGMP are two critical inhibitory intracellular second messengers regulating fundamental platelet processes. In fact, elevation of platelet cyclic nucleotides interferes with almost all known platelet activation signaling pathways and thus blocks cytoskeletal rearrangement, fibrinogen receptor activation, degranulation, and expression of pro-inflammatory mediators. Indeed, cAMP and cGMP activate protein kinases that phosphorylate specific substrates (i.e., Rap1, MLCK, VASP, etc.), thus interfering with receptor/G protein activation and phospholipase C, protein kinase C, and MAP kinase activation and blocking cytosolic Ca^{2+} elevation and the reorganization of cytoskeleton (Daniel et al. 2002).

Phosphodiesterases and Platelets

PDEs by catalyzing the hydrolysis of cAMP and cGMP to inactive 5′AMP and 5′GMP limit intracellular levels of cyclic nucleotides and thus regulate the amplitude, duration, and compartmentation of cyclic nucleotide signaling (Bender and Beavo 2006).

To date, more than 60 different isoforms of PDE have been described in mammalian tissues, grouped into 11 broad families (PDE1–PDE11) based on differences in their structure (Fig. 1), kinetics, regulatory properties, and sensitivity to chemical inhibitors (Maurice, Nat Rev Drug Discov 13:290-314, 2014). Alternative splicing and transcription start sites also contribute to the multiplicity of the different isoforms, many of which possess species-specific tissue and/or cellular distribution. Current data suggest that individual isozymes modulate distinct regulatory pathways in cells.

Given that PDEs are associated with many different functions, targeting pathological conditions by modulating individual PDEs has been the object of intense study (Table 1).

Functionally, PDEs can be classified in terms of their affinity for and rates of degradation of cAMP and cGMP. PDE1, PDE2, and PDE3 hydrolyze both cAMP and cGMP, and PDE4 and PDE8 specifically hydrolyze cAMP, whereas PDE5 specifically hydrolyzes cGMP. Concerning affinity for cyclic nucleotides, PDE3 isoforms are high-affinity enzymes, with KD's <150 nM, while other families, such as PDE1 and PDE5, have affinities in the μM range. For many PDEs, affinity for one substrate is so much higher than for the other as to render them functionally monospecific. PDE3 has a relatively high affinity for both cAMP and cGMP but a much lower efficacy of hydrolysis for cGMP, behaving essentially as a pure cAMP PDEs; it has also been referred to as cGMP-inhibited cAMP PDE because cGMP may competitively inhibit AMP hydrolysis (Grant and Colman 1984). Thus, in platelets, agents that activate guanylyl cyclase potentiate the effects of activators of adenylyl cyclase (Maurice and Haslam 1990).

Platelets express three PDE isoenzymes: PDE2, PDE3, and PDE5. Hidaka and Asano (Hidaka and Asano 1976) were the first to resolve the PDE activity of platelets into three distinct peaks: The first prefers cGMP as a substrate, with a Km of about 1 μM and is selectively inhibited by PDE5 inhibitors. The second hydrolyzes equally well cAMP and cGMP (Haslam et al. 1999) and is selectively inhibited by PDE2 inhibitors. The third has a high affinity for both cAMP and cGMP but hydrolyzes cAMP much more rapidly than cGMP and is selectively inhibited by PDE3 inhibitors. Thus, in platelets, cAMP is hydrolyzed by PDE3 and PDE2, and cGMP is hydrolyzed by PDE5 and PDE2 (Fig. 2); these isozymes account for at least 90 % of platelet PDE activity. Moreover, high concentrations of cGMP stimulate PDE2 (Bender and Beavo 2006). PDE2 inhibitors have been used mainly as research tools, but ongoing studies investigate their effectiveness for memory impairment and prevention of endothelial permeability in inflammation (Bender and Beavo 2006). PDE3 comprises two subfamilies, PDE3A and PDE3B, showing distinct and overlapping tissue and subcellular distributions. In situ hybridization studies have shown that PDE3A is highly expressed in the cardiovascular system, including the myocardium, VSMCs, and megakaryocytes, while PDE3B mRNA is detected in adipocytes (Park et al. 2007). It has been shown that PDE3A is the

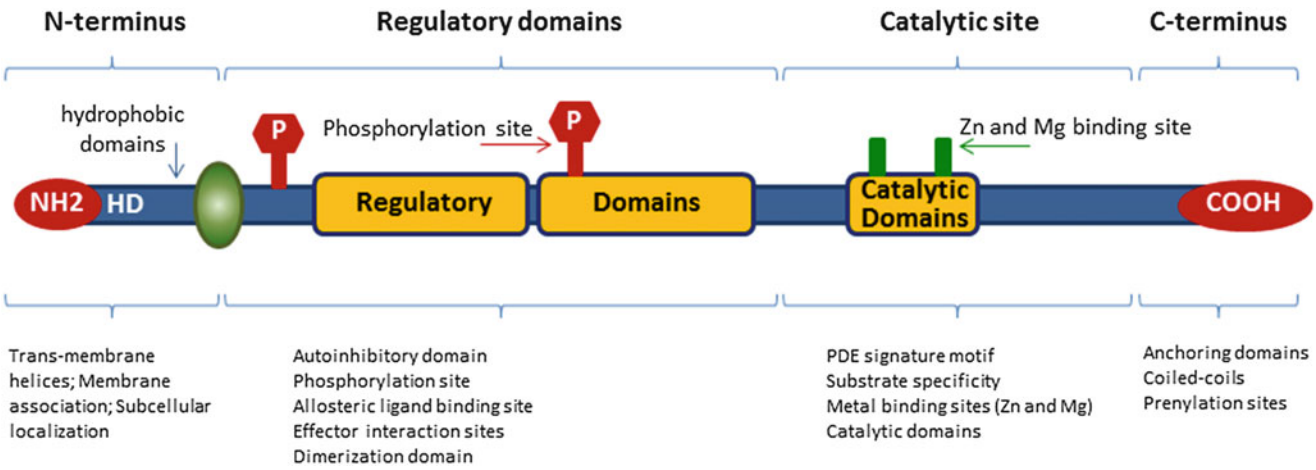

Fig. 1 General structure of PDE enzyme molecules

Table 1 Phosphodiesterase (PDE) families

Family	Substrate	Intracellular localization	Tissue expression	Specific inhibitors
PDE1	cGMP > cAMP	Cytosolic	Cardiac muscle, vascular smooth muscle, brain	Vinpocetine, IC86340, 8-MM-IBMX
PDE2	cGMP = cAMP	Membrane bound or cytosolic	*Platelets*, cardiac muscle, endothelial cells	EHNA, BAY 60-7550, PDP
PDE3	cAMP/cGMP	Membrane bound or cytosolic	*Platelets*, vascular smooth muscle	*Cilostazol*, milrinone, vesnarinone, lixazinone, anagrelide, olprinone, trequinsin, OPC-33540, dihydropyridazinone, siguazodan, SK&F 94120, CI 930, KCA-1490
PDE4	cAMP	Membrane bound or cytosolic	Cardiac muscle, vascular smooth muscle, brain, inflammatory and immune cells	Rolipram, etazolate, zardaverine
PDE5	cGMP	Cytosolic	*Platelets*, vascular smooth muscle	*Sildenafil*, E4021, DMPPO, CP461, MY-5445, NCX 911, DA-8159, zaprinast, *dipyridamole*, udenafil, lodenafil, avanafil
PDE6	cGMP > cAMP	Cytosolic	Retinal rods and cones	Sildenafil, zaprinast, dipyridamole
PDE7	cAMP>cGMP	Cytosolic	T-lymphocytes, B-lymphocyte, skeletal muscle, cardiac muscle	Dipyridamole
PDE8	cAMP	Membrane bound or cytosolic	Testis, eye, liver, kidney, skeletal muscle, embryo, ovary, brain	Zaprinast
PDE9	cGMP	Cytosolic or nuclear	Small intestinal smooth muscle, liver, kidney, lung, brain, testis, skeletal muscle, hearth, thymus	Methylxanthine, theophylline,
PDE10	cGMP > cAMP	Cytosolic or particulate	Testis and brain	None
PDE11	cAMP = cGMP	Cytosolic	Skeletal muscle, prostate, kidney, liver, pituitary and, salivary glands, testis	None

main subtype of PDE3 expressed in platelets (Sun et al. 2007).

PDE Inhibitors

Soon after the discovery of PDEs, it was found that caffeine is an effective inhibitor of PDE activity and a number of nonselective PDE inhibitors, including the caffeine analogue theophylline, entered clinical use. Later, several isoenzyme-selective PDE inhibitors have been developed as medicines or are currently under investigation for various disorders (Maurice et al. 2014).

This review will focus on the effects of PDE2, PDE3, and PDE5 inhibitors on platelet function and on their potential as antithrombotic agents (Table 2).

Dipyridamole

Dipyridamole (2,6-bis(diethanolamino)-4,8-dipiperidino-pyrimido-(5,4-d)-pyrimidine) was synthesized more than 50 years ago and initially used as a coronary vasodilator. However, it was soon shown that dipyridamole inhibited platelet aggregation (Born and Cross 1963; Elkeles et al. 1968) and thrombus formation in rabbits (Ahn et al. 1989), opening the way to the use of dipyridamole as an antithrombotic agent (Schwartz et al. 1988).

Mechanisms of Action

Dipyridamole affects platelet function by acting on different targets: it inhibits the reuptake of adenosine by red blood cells, in this way enhancing plasma levels of this vasodilator and platelet inhibitory nucleoside; it also acts as an inhibitor of PDE5 and PDE3, thus increasing intraplatelet cAMP and/or cGMP; it also acts as an antioxidant by scavenging free radicals that inactivate cyclooxygenase, thus enhancing PGI_2 biosynthesis.

Adenosine is released by tissues into the extracellular space as a breakdown product of ATP during ischemia, or by erythrocytes stressed by elevated shear forces, and is then taken up avidly by erythrocytes to keep plasma levels low. Inhibition of adenosine reuptake by dipyridamole is concentration dependent and reaches 90 % at 1 μM of dipyridamole

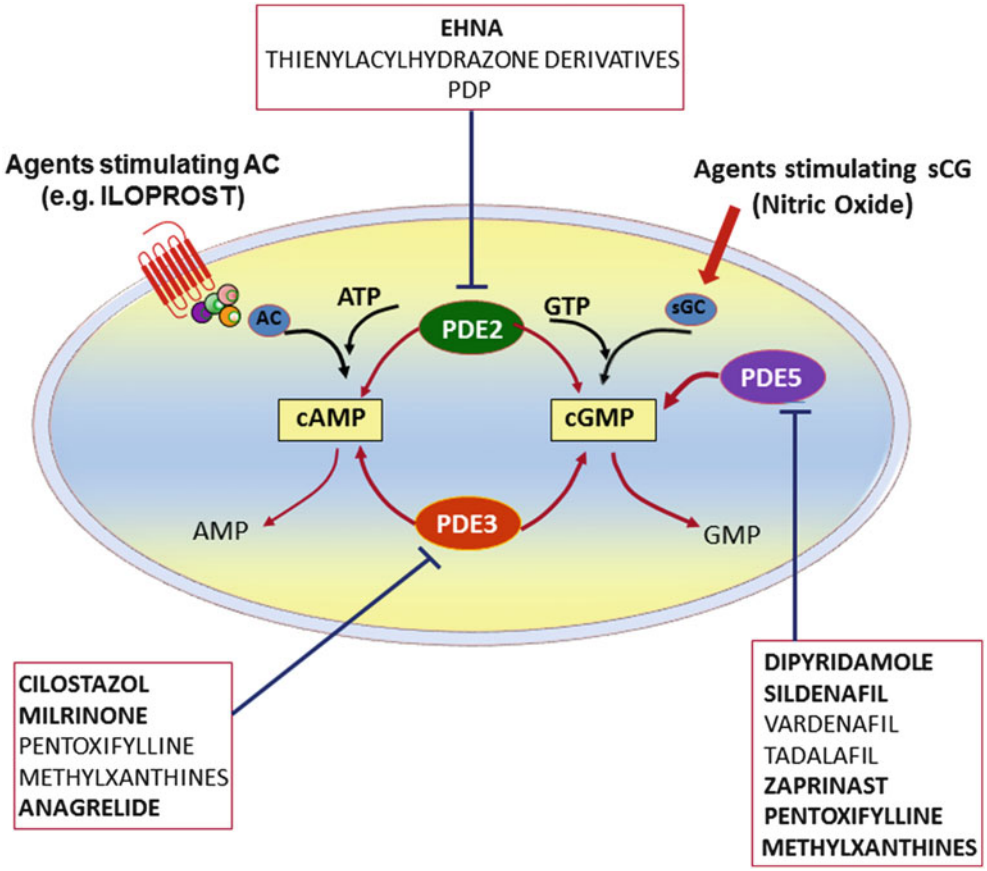

Fig. 2 Schematic representation of a platelet and the mechanisms regulating intraplatelet levels of cyclic nucleotides (cAMP and cGMP), the three isoforms of PDEs so far described in platelets, and their pharmacological inhibitors. In bold are the drugs discussed in the review

Table 2 PDE inhibitors and their clinical use

Family	Specific inhibitor	Use in clinical trial
PDE2	EHNA, BAY 60-7550, PDP, IC933, oxindole, ND7001, Aptosyn	No
PDE3	Cilostazol	Cerebrovascular disorders, peripheral vascular disease, intermittent claudication, prevention of stroke, peripheral arterial disease, diabetes mellitus
	Olprinone	Gastric acidosis, systemic inflammation after cardiopulmonary bypass
	Milrinone, cilostamide, amrinone, enoximone	Valvular disease, pulmonary hypertension, cardiac surgery
	Anagrelide	Essential thrombocythemia
	Vesnarinone, lixazinone	No
	Trequinsin, OPC-33540, dihydropyridazinone, siguazodan, SK&F 94120, CI 930, KCA-1490	No
PDE5	*Sildenafil*	Pulmonary hypertension, diabetes mellitus, endothelial dysfunction, ischemic stroke, schizophrenia, active digital ulcers, erectile dysfunction, gastroparesis, sickle cell anemia
	Tadalafil	Benign prostatic hyperplasia, erectile dysfunction, pulmonary hypertension, prostate cancer
	Vardenafil, lodenafil, avanafil	Erectile dysfunction
	Dipyridamole	Erectile dysfunction, ischemia-reperfusion injury, atherosclerosis, stroke, breast cancer, rheumatoid arthritis
	Udenafil	Erectile dysfunction, chronic obstructive pulmonary disease
	E4021, DMPPO, CP461, MY-5445, NCX 911, DA-8159, zaprinast	No

in whole blood (Klabunde 1993), a concentration in the range of those attained after oral administration to humans (0.5–6 μM). Dipyridamole inhibits platelet aggregation in whole blood, as assessed by impedance aggregometry, but not in PRP, both in vitro and ex vivo, by blocking the reuptake of adenosine (Gresele et al. 1983, 1986).

A stronger antiplatelet effect of dipyridamole in whole blood than in plasma was confirmed using different laboratory methods (De La Cruz et al. 1992; Perez Requeio et al. 1988; Muller et al. 1990; Saniabadi et al. 1991).

The modest PDE3-inhibitory action of dipyridamole increases the effects of adenosine and PGI_2, both stimulators of adenylyl cyclase, leading to inhibition of platelet activation (Soderback et al. 1991; Harker and Kadatz 1983).

Dipyridamole potentiates the inhibitory effects of NO on human and rabbit platelets (Sakuma et al. 1990) by inhibiting PDE5 and thus increasing vasodilator-stimulated phosphoprotein (VASP) production, an established marker of the NO/cGMP effects (Aktas et al. 2003), both in vitro and in vivo (Utz et al. 2001). However, the inhibition of PDE5 is detectable in vitro only at concentrations (100–200 μM) much higher than those attainable after oral administration.

The antioxidant properties of dipyridamole may contribute to its antithrombotic effect. In fact, not only dipyridamole enhances extracellular adenosine, which reduces superoxide anion generation by human neutrophils and directly scavenges oxygen and hydroxyl radicals, but it has direct antioxidant effects. In fact, dipyridamole has better antioxidant properties than ascorbic acid, α-tocopherol, and probucol (Iuliano et al. 1996; Pascual and Romay 1992).

The antioxidant activity of dipyridamole leads to the inhibition of leukotriene B4 production in vitro by stimulated white blood cells (Gresele et al. 1987). Moreover, based on its antioxidant properties, dipyridamole was shown to prolong prostacyclin production by "exhausted" vessel walls, preventing the autoinactivation of cyclooxygenase caused by enhanced peroxide formation (Deckmyn et al. 1984), an activity similar to the so-called physiological prostacyclin-regulating plasma factor (Deckmyn et al. 1985).

The redox state of dipyridamole regulates its antioxidant properties which appear to be mediated in vascular cells by suppression of NF-kB signaling (Chakrabarti and Freedman 2008).

Additional pharmacologic effects of dipyridamole that may be of relevance for prevention of atherothrombosis are the inhibition of vascular smooth muscle cell proliferation, the prevention of endothelium-leukocyte interactions (Kim and Liao 2008), the increase of antithrombotic properties of endothelial cells (Eisert 2001), the interference with leukocytes interaction with endothelium, the enhancement of IL-1-stimulated NO production by smooth muscle cells (Iimura et al. 1996), and the inhibition of inflammatory gene expression in platelet-monocyte aggregates (Weyrich et al. 2005). Very recently an additional interesting observation has shown that inhibition of multidrug resistance protein-4 (MRP-4)-mediated transport by dipyridamole increases aspirin entrapment in platelets and its in vitro effect on COX-1 activity (Mattiello et al. 2011), thus explaining in part the pharmacodynamic (Gresele et al. 1985) and therapeutic (Diener et al. 1996; Halkes et al. 2006) synergism with aspirin.

Antithrombotic Properties

The antithrombotic effects of dipyridamole have been evaluated in several animal models. Thrombus formation on air-injured carotid arteries of rabbits was reduced by dipyridamole, while salicylate increased it (Weber et al. 1990). In rabbits, the accumulation of radioactive fibrinogen at balloon angioplasty-treated carotid arteries was significantly reduced by dipyridamole (0.45 mg/kg/h for 4 h) as compared to heparin (Van Ryn et al. 2003).

More recently, in a model of chronic hind limb ischemia induced by the ligation of the common femoral artery branches in mice, dipyridamole (200 mg/kg b.i.d. for 7 days) was shown to enhance ischemia-induced arteriogenesis, thereby quickly restoring blood flow through a PKA-dependent NO pathway (Venkatesh et al. 2010).

Moreover, in a model of $FeCl_3$-induced femoral artery thrombosis in rats, the administration of dipyridamole (40 mg/kg), ineffective by itself, potentiated the antithrombotic effect of AICAR, an activator of the AMP-activated protein kinase (AMPK), suggesting that the combination of AMPK activators with PDE inhibitors could magnify their antiplatelet effect through a synergistic elevation of cGMP (Liu et al. 2013).

Clinical Studies

There is little clinical evidence that dipyridamole alone exerts an antithrombotic effect. Several studies instead have been carried out in combination with aspirin. Dipyridamole in combination with low-dose aspirin is associated with greater stroke risk reduction in patients with ischemic cerebrovascular disease. This was confirmed in two large clinical studies: the ESPS2 (Diener et al. 1996), in which 6602 patients with prior stroke or transient ischemic attack (TIA) were randomized to aspirin (50 mg daily), slow release dipyridamole (200 mg twice a day), the two agents in a combined formulation, or placebo, and the ESPRIT trial (Halkes et al. 2006), in which 2739 patients with previous TIA were randomized to aspirin (30–325 mg day) with or without dipyridamole (200 mg twice daily). A recent meta-analysis supports the higher efficacy of combination therapy

over aspirin alone (Verro et al. 2008). Based on these findings, the 2012 ACCP guidelines suggest dual therapy with extended-release dipyridamole plus aspirin (or clopidogrel) over aspirin monotherapy for stroke prevention after a first TIA or stroke (Lansberg et al. 2012). More recently, a meta-analysis including data from five clinical studies carried out in 4318 patients with previous TIA or stroke allocated to aspirin + dipyridamole and 4304 to aspirin alone concluded that the combination reduces the risk of stroke recurrence by 17 % with no rise of bleeding (Li et al. 2013). In addition, in patients with acute ischemic stroke or TIA, treatment with dipyridamole plus aspirin significantly lowered long-term mortality as compared with aspirin alone (Arnarsdottir et al. 2012). A large clinical trial, the PRoFESS study, was carried out to investigate whether aspirin 25 mg or extended-release dipyridamole 200 mg twice a day was not inferior to clopidogrel 75 mg once a day in 20,332 patients with previous stroke and did not meet predefined criteria for noninferiority but showed similar rates of recurrent stroke with the two treatments. Moreover, there were more hemorrhagic strokes with aspirin plus extended-release dipyridamole than with clopidogrel (Sacco et al. 2008). The degree of functional impairment (disability and cognitive decline) at 3 months after stroke was similar across treatment arms (Diener et al. 2008). The results of this large study are substantially inconclusive due to serious limitations in design, like the end point of noninferiority, the extremely stringent noninferiority margins, and the possible statistical fluke (Kent and Thaler 2008), and the considerable resources and effort that went into the study are unlikely to translate into any meaningful change in clinical practice (Anderson 2008).

Another condition for which there is evidence of efficacy of dipyridamole is secondary prophylaxis of thromboembolic events in patients with mechanical heart valves in combination with warfarin (Stein et al. 2001). Concerning the effects in other clinical indications, a recent overview of 27 randomized long-term secondary prevention trials involving 23,019 patients presenting with an arterial vascular disease (cardiac disease, cerebral ischemia, thrombosis of hemodialysis fistula, patients prone to develop atherosclerosis) comparing dipyridamole, alone or in combination with an antiplatelet drug other than dipyridamole (chiefly aspirin), with placebo found that there was no evidence that dipyridamole reduced the risk of vascular death, while it significantly reduced the risk of further vascular events (RR 0.88, 95 % CI 0.81–0.95). However, this benefit was statistically significant only in patients presenting after cerebral ischemia (De Schryver et al. 2006). Finally, among stented patients with high on-treatment platelet reactivity (HTPR), adding dipyridamole to clopidogrel does not

Table 3 Ongoing trials with cilostazol

Cilostazol vs. placebo	Peripheral arterial disease, claudication	Difference in quality of life	30	Phase 4	NCT02374957
Cilostazol + simvastatin vs. cilostazol + pravastatin	Dyslipidemias, peripheral artery disease	AUC of simvastatin	20	Phase 1	NCT02431013
Cilostazol plus aspirin plus clopidogrel vs. aspirin or clopidogrel	Noncardioembolic cerebral infarction	Recurrence of symptomatic ischemic stroke	4000	Phase 3	NCT01995370
Probucol plus cilostazol vs. atorvastatin vs. atorvastatin plus probucol plus cilostazol	Severe hypercholesterolemia	Effect on mean Achilles tendon thickness	250	Phase 4	NCT02098460
Cilostazol vs. aspirin	Peripheral arterial disease	MACE—MALE	200	Phase 3	NCT02770274
Cilostazol vs. placebo	Coronary artery disease	Circulating EPC number	300	Phase 4	NCT02174939
Cilostazol vs. aspirin	Coronary artery disease	Severity of coronary artery stenosis	100	Phase 3	NCT02266030
Cilostazol vs. placebo	Mild cognitive impairment	Changes in MMSE	200	Phase 2	NCT02491268
Dual antiplatelet vs. triple antiplatelet	Acute myocardial infarction	MACCE	951	Phase 4	NCT01261832
Isosorbide mononitrate vs. cilostazol	Cerebral small vessel diseases, cognitive impairment stroke	Tolerability	60	Phase 2	NCT02481323
Cilostazol vs. placebo	Vasospastic angina	Chest pain frequency	100	Phase 3	NCT02087007
Ticagrelor or clopidogrel vs. cilostazol	Coronary artery disease	IPA	1350	Phase 4	NCT01955200
Triple antiplatelet therapy (TAT) vs. double-dose clopidogrel antiplatelet therapy (DDAT)	Coronary heart disease	TLF	3750	Phase 4	NCT01267734
Clopidogrel, ticagrelor, cilostazol	HTPR	MACE	70		NCT02101411

MACE major adverse cardiovascular events, *MALE* major adverse limb events, *MMSE* Mini-Mental State Examination, *MACCE* major adverse cardiovascular and cerebral events, *IPA* inhibition of platelet aggregation, *TLF* target lesion frequency, *HTPR* high on-treatment platelet reactivity

reduce platelet reactivity more than double-dose clopidogrel, and both strategies proved to be inadequate to overcome HTPR (Park et al. 2014).

Table 3 reports the ongoing trials with dipyridamole, alone or in combination with other antiplatelet drugs, registered in ClinicalTrials.gov.

Cilostazol

Cilostazol, a 2-oxo-quinoline derivative (6-(4-(1-cyclohexyl-1H-tetrazol-5-yl)butoxy)-3,4-dihydro-2(1H)-quinolinone), was registered in Japan and other Asiatic countries in 1988 and approved in the USA in 1999 for the treatment of intermittent claudication (Faxon et al. 2004).

Cilostazol is a specific and strong inhibitor of PDE3 in platelets ($IC_{50} = 0.2$ μM) and smooth muscle cells (SMC) where it diminishes intracellular calcium causing SMCs relaxation and inhibition of platelet activation (Shrör 2002). Cilostazol also inhibits adenosine uptake, thus enhancing adenosine levels that in turn enhance intracellular cAMP resulting in additional increases in cAMP (Shrör 2002).

Platelet Inhibition

Cilostazol inhibits both primary and secondary platelet aggregation induced by collagen, ADP, arachidonic acid, and epinephrine with IC_{50} values ranging from 3.6 to 15.0 μM, depending on the agonist (Kimura et al. 1985; Yasunaga and Mase 1985). It also suppresses the expression of P-selectin (IC_{50} 25 μM) (Kariyazono et al. 2001), TxB2 production, and PF4 and PDGF release and enhances the antiplatelet effects of PGI_2 (Igawa et al. 1990). Cilostazol inhibits shear stress-induced platelet activation in vitro, with an IC50 of 15.0 μM (Minami et al. 1997), and ex vivo not dissimilar to that exhibited by ticlopidine plus aspirin (Tanigawa et al. 2000). Among patients with acute myocardial infarction (AMI) undergoing coronary stenting, the association of cilostazol with clopidogrel plus aspirin resulted in a greater antiplatelet effect as compared with clopidogrel plus aspirin (Jeong et al. 2010). Moreover, the addition of cilostazol to clopidogrel gives greater inhibition of platelet aggregation than clopidogrel, either at the standard or at double dose, in clopidogrel low responders (Lee et al. 2010).

One potential benefit of the use of cilostazol over conventional antiplatelet therapy is the relatively short recovery time of platelet function (Iwamoto et al. 2003).

Cilostazol inhibits the expression of monocyte chemoattractant protein-1 (MCP-1), an initial trigger in the development of atherosclerosis and in human umbilical vein endothelial cells (HUVECs) by increasing intracellular cAMP (Nishio et al. 1997).

Cilostazol is rapidly absorbed and reaches peak plasma concentrations (775 ng/ml = 2.09 μM) at about 2.4 h after oral administration. In plasma cilostazol is largely bound to proteins (95–98 %), primarily albumin (Bramer et al. 1999; Suri et al. 1998). Specifically, metabolism of cilostazol occurs primarily via CYP3A5 and, to a lesser extent, CYP2C19, while <1 % of the administered dose is excreted unchanged in urine (Akiyama et al. 1985). CYP3A5 and CYP2C19 polymorphisms explain the substantial interindividual variability in the metabolism of cilostazol, with a coefficient of variation of about 40–60 % (Bramer et al. 1999; Yoo et al. 2010).

After oral administration, cilostazol and its metabolites, 3,4-dehydrocilostazol (OPC-13015) and 4-trans-hydroxy-cilostazol (OPC-13213), show a half-life of approximately 10 h, with a twofold accumulation during repeated administration (Shrör 2002).

Effect on the Bleeding Time

There is no evidence that cilostazol prolongs the bleeding time when compared to aspirin, clopidogrel, or ticlopidine (Tamai et al. 1999; Wilhite et al. 2003), even when used in combination with these antiplatelet drugs (Wilhite et al. 2003).

In a study in healthy men comparing ticlopidine, aspirin, and cilostazol, bleeding time was significantly prolonged by aspirin and ticlopidine, but not by cilostazol (Ikeda et al. 1987).

In patients with peripheral arterial disease (PAD), aspirin and clopidogrel alone significantly prolonged the bleeding time and even more when used in combination. In contrast, no prolongation of the bleeding time was observed with cilostazol alone, neither a further prolongation was seen when it was added to aspirin or clopidogrel (Comerota 2005).

Thus, unlike other antiplatelet drugs, cilostazol seems unique because patients receiving this drug do not show a significant prolongation of the bleeding time, but the reasons for this difference are still unknown. A recent in vitro study examining mural platelet thrombus growth on a collagen surface under high shear rate conditions in the absence of ADAMTS13 activity, i.e., mimicking blood flow in patients with thrombotic thrombocytopenic purpura, showed that cilostazol downregulates the size of mural platelet thrombi

without affecting their initial formation. This has been suggested as a reason why cilostazol does not significantly prolong bleeding time despite its strong antiplatelet activity (Yagi et al. 2012).

Animal Models

Cilostazol exerts antithrombotic activity in different animal models. Pulmonary thromboembolism induced by ADP and collagen in mice was reduced by cilostazol at 3 and 10 mg/kg per os, more effectively than by aspirin and pentoxifylline (Kimura et al. 1985). Cerebral infarction induced by the injection of arachidonic acid into the internal carotid artery of rabbits was reduced by 1 mg/kg cilostazol (Watanabe et al. 1986).

In a porcine model of totally occlusive thrombosis of the carotid artery induced by electrical injury, cilostazol significantly prolonged the time to occlusion and decreased thrombus weight more than ticlopidine (Kohda et al. 1999). In $FeCl_3$ venous thrombosis model in rats, oral administration of cilostazol 50 mg/kg significantly decreased venous thrombus weight (Kim et al. 2011).

Finally, the effects of clopidogrel, ticlopidine, and cilostazol on gastric bleeding induced by intraluminal perfusion of acidified ASA (25 mM aspirin acidified with 25 mM HCl) were studied in rats. Clopidogrel and ticlopidine (both 30 mg/kg), two $P2Y_{12}$ receptor inhibitors, increased gastric bleeding and ulcerogenic responses to acidified ASA, while cilostazol (30 mg/kg) suppressed them, making it a suitable candidate for combined use in dual antiplatelet therapy (Takeuchi et al. 2014).

Clinical Studies

Several studies have shown the superiority of cilostazol vs. placebo and also vs. pentoxifylline in increasing the walking distance (Thompson et al. 2002; Benedis et al. 2014) and quality of life of peripheral arterial disease (PAD) patients (Regensteiner et al. 2002).

Cilostazol was tested for secondary prevention of stroke in a randomized, placebo-controlled, double-blind trial in 1052 patients in Japan (Gotoh et al. 2000). Cilostazol reduced significantly the recurrence of ischemic stroke (−41.7 %, CI −9.2–62.5 %) as compared with placebo and the incidence of the combined end point MI, TIA, and intracranial hemorrhage. The benefits were achieved without a significant increase of bleeding (2.8 vs. 2.1 %) and with no fatal intracranial hemorrhages (Gotoh et al. 2000). These data seem to confirm a low bleeding risk with cilostazol. In the second Cilostazol Stroke Prevention Study (CSPS 2), in 2757 patients with a noncardioembolic cerebral infarction within the previous 26 weeks, cilostazol 100 mg twice daily was shown to be noninferior, and possibly superior, to aspirin 81 mg once daily, in preventing stroke recurrence (yearly rate of 2.76 %) ($n = 82$) in the cilostazol group and (3.71 %) ($n = 119$) in the aspirin group (HR 0.743, 95 % CI 0.564–0.981; $p = 0.0357$), and was associated with fewer hemorrhagic events (Shinohara et al. 2010). A meta-analysis of 12 double-bind, placebo-controlled trials in patients with atherothrombotic disease concluded that cilostazol is associated with a significant risk reduction of cerebrovascular events [relative risk (RR), 0.86; 95 % confidence intervals (CI), 0.74–0.99; $p = 0.038$] with no associated increase of bleeding (Uchiyama et al. 2009) and with no significant difference in the incidence of cardiac events (RR, 0.99; 95 % CI, 0.83–1.17; $p = 0.908$) (Uchiyama et al. 2009). Moreover, a more recent meta-analysis of nine studies (6328 patients) compared the efficacy and safety of cilostazol with other antiplatelet therapies in the prevention of recurrent cerebral ischemic events after an initial ischemic stroke. The study concluded that cilostazol, alone or in combination with aspirin, significantly reduced stroke recurrence (RR, 0.63; 95 % CI 0.52–0.76), poststroke intracranial hemorrhage (RR, 0.36; 95 % CI 0.21–0.63), and extracranial bleeding (RR, 0.62; 95 % CI 0.46–0.83) in patients with a prior ischemic stroke as compared with other antiplatelet therapies (Tan et al. 2015). A recent network meta-analysis of 24 randomized controlled trials for a total of 85,667 patients compared 11 antiplatelet therapies in patients with ischemic stroke or transient ischemic attacks treated for at least 1 year, concluding that long-term monotherapy was a better choice than long-term dual therapy and that cilostazol had the best risk-benefit profile for long-term secondary prevention after stroke or transient ischemic attack (Xie et al. 2015).

In a study in 1212 patients with acute coronary syndromes (ACS) undergoing percutaneous coronary intervention (PCI), cilostazol added to aspirin plus clopidogrel reduced the composite end point cardiac death, myocardial infarction, and stroke as compared to aspirin plus clopidogrel (Han et al. 2009). In agreement, a recent randomized trial in 514 patients undergoing percutaneous coronary intervention concluded that the addition of cilostazol to aspirin lowered the rates of cardiovascular and cerebrovascular events at 2 years compared to aspirin monotherapy (hazard ratio 0.61, 95 % CI 0.40–0.93, $p = 0.021$) (Ueda et al. 2016).

Recently, however, a multicenter randomized trial in 960 patients undergoing coronary drug-eluting stent implantation showed that the addition of cilostazol to aspirin and clopidogrel for 6 months did not reduce the composite adverse outcome of cardiac death, nonfatal myocardial infarction, ischemic stroke, or target lesion revascularization (Suh et al. 2011).

Table 4 Ongoing trial with dipyridamole

Intervention	Condition	Primary end-point	Estimated enrollment	Phase	Clinical trial.gov identifier
Dipyridamole vs. placebo	HIV infection	Changes in plasma levels of sCD14, sCD63, and IL-6	40	Phase 1 Phase 2	NCT02121756
Warfarin plus dipyridamole vs. aspirin plus dipyridamole on top of low molecular weight heparin	Cirrhosis, hypertension, splenectomy, venous thrombosis	PVT or spleno-mesenteric thrombosis	60	Phase 4	NCT02247414
Dipyridamole vs. placebo, dipyridamole + antihypertensives	Hypertension	Supine SBP	160	Phase 1 Phase 2	NCT00223717
Apixaban vs. any of aspirin, dipyridamole, carbasalate calcium, clopidogrel, no antithrombotic treatment	Cerebral hemorrhage, atrial fibrillation	Vascular death or nonfatal stroke	100	Phase 2	NCT02565693
Aspirin + dipyridamole + clopidogrel vs. DAPT	Stroke	Ordinal stroke severity at 90 days	4100	Phase 3	NCT01661322

SBP systolic blood pressure, *DAPT* dual antiplatelet therapy

Cilostazol has also been suggested to prevent post-stent restenosis (Weintraub et al. 2004). Cilostazol was compared with ticlopidine, both in addition to aspirin, in 397 patients undergoing elective coronary stenting for the rate of restenosis: restenosis tended to be lower with cilostazol, but not significantly (Ge et al. 2005). A recent study investigated whether periprocedural cilostazol affects the incidence of in-stent restenosis or target vessel revascularization after carotid artery stenting (CAS). The study group included 553 patients undergoing CAS, 207 of which (37.4 %) were treated with cilostazol, followed for 30 months. The incidence of ISR or TVR was significantly lower in the cilostazol-treated group than in the untreated group (1.4 vs. 6.4 %; log-rank $p = 0.006$) (Yamagami et al. 2010). A meta-analysis of five randomized controlled trials comparing triple therapy (cilostazol plus aspirin plus thienopyridines) with aspirin plus clopidogrel in 1597 patients undergoing coronary stenting showed that triple therapy reduced significantly more the 6-month restenosis rate (12.7 vs. 21.9 %; odds ratio 0.5; 95 % CI, 0.38–0.66; $p < 0.001$) (Jennings and Kalus 2010). A recent meta-analysis of 19 randomized trials involving 7464 patients undergoing coronary stent implantation showed that triple antiplatelet therapy (cilostazol plus aspirin plus clopidogrel) was associated with similar rates of death, nonfatal MI, ischemic stroke, and ST compared with dual therapy (aspirin plus clopidogrel), but with lower rates of target lesion revascularization (RR 0.67, 95 % CI 0.56–0.82, $p < 0.0001$) and target vessel revascularization (RR 0.65, 95 % CI 0.55–0.77, $p < 0.00001$), as well as less late loss of minimal lumen diameter (mean difference −0.14, 95 % CI −0.17 to −0.11, $p < 0.00001$) and less binary angiographic restenosis (RR 0.54, 95 % CI 0.45–0.65, $p < 0.00001$) (Chen et al. 2015). Both regimens had similar rates of bleeding, but triple therapy had significantly higher rates of headache, palpitations and tachycardia, rash, and gastrointestinal side effects, the most common side effects associated with cilostazol (Sorkin and Markham 1999). However, cilostazol-based triple antiplatelet therapy compared with dual therapy did not reduce major cardiovascular events and was associated with an increase in minor adverse events (Chen et al. 2015).

Finally, in a small study, cilostazol administration improved long-term patency after carotid artery stenting in 97 patients with high-grade carotid stenosis monitored for a 12-month period (0 vs. 15.7 %, $p = 0.03$) (Takigawa et al. 2010). In conclusion, several findings show promising effects of cilostazol, alone or even more in combination with other antiplatelet agents, but most studies are insufficiently sized, and further clinical research is warranted.

Table 4 reports the ongoing trials with cilostazol, alone or in combination with other antiplatelet drugs, registered in ClinicalTrials.gov.

Methylxanthines and Pentoxifylline

Naturally occurring methylxanthines were the earliest PDE inhibitors to be discovered, and among them caffeine (1,3,7-trimethylxanthine) was the first (Sutherland and Rall 1958). Some years later, theophylline (1,3-dimethylxanthine) and theobromine, more effective PDE inhibitors, were characterized (Butcher and Sutherland 1962). Ardlie and coworkers documented inhibition of platelet aggregation by caffeine and theophylline in 1967 (Ardlie et al. 1967). In a milestone study in 1971, Mills and Smith showed that adenosine increases cAMP in platelets and that methylxanthines prevent the conversion of cAMP to AMP, acting as PDE inhibitors, thus greatly increasing the inhibitory effects of adenosine on platelet aggregation (Mills and Smith 1971). Caffeine and theophylline act also as nonselective adenosine receptor antagonists (Evoniuk et al. 1987). In healthy

volunteers, 250 mg caffeine orally three times a day for 7 days reduced platelet aggregation, increased intracellular cAMP, and upregulated the platelet adenosine A_{2A} receptors (Varani et al. 1999). Recently, a 7-week pilot intervention study in healthy volunteers has shown that caffeine is not the only coffee constituent that contributes significantly to PDE inhibition in human platelet lysates and that other roasting-associated compounds, such as chlorogenic acid, polyphenols 5-CQA, and caffeic acid, play a role in the modulation of platelet cAMP (Montoya et al. 2014).

Pentoxifylline (3,7-dimethyl-1-(5-oxohexyl)-xanthine), a vasoactive drug used in patients with intermittent claudication (Jackson and Clagett 2001) and reported to reduce whole blood viscosity and to improve erythrocyte deformability, was shown to inhibit platelet aggregation in vitro in platelet-rich plasma (PRP) but at concentrations higher than those attainable in vivo (Nenci et al. 1981). However, given that the platelet inhibitory effect was potentiated by PGI2, it was suggested that the in vivo antiplatelet activity could be stronger (Weithmann 1980); moreover, pentoxifylline was found to inhibit platelet aggregation in whole blood more effectively than in PRP, due to the contribution of an adenosine uptake inhibitory effect on erythrocytes (Manrique and Manrique 1987). So far, there is no evidence that pentoxifylline reduces ischemic cardiovascular events (Jackson and Clagett 2001) neither that it enhances platelet inhibition in diabetic patients treated with dual antiplatelet therapy (Ueno et al. 2011).

Anagrelide

Anagrelide (Agrylin/Xagrid) (BL-4162A, 6,7-dichloro-1,5-dihydroimidazo[2, 1-6] quinazolin-2[3H]one monohydrochloride hydrate) is a potent inhibitor of PDE3 and a potent and broad spectrum inhibitor of platelet aggregation (IC_{50} = 36 nM) (Seiler et al. 1987).

During studies in humans, however, anagrelide was found to produce thrombocytopenia (Thiele et al. 2006); although the mechanisms through which anagrelide inhibits the megakaryocyte maturation are not completely understood, the drug has entered clinical use for patients with essential thrombocythemia (Silverstein et al. 1988).

Erythro-9-(2-hydroxy-3-nonyl) adenine (EHNA), an inhibitor of adenosine deaminase (ADA), was shown to act as a selective PDE2 inhibitor with an IC50 of 3 μM and at least 50-fold selectivity over other PDEs (Dickinson et al. 1997). EHNA (20 μM) has no direct effect on platelet aggregation, but it potentiates the inhibition of thrombin-induced platelet aggregation by nitroprusside, a guanylyl cyclase stimulator (Dickinson et al. 1997). The use of EHNA as a tool to assess the role of PDE2 in platelets is limited by the low PDE2-inhibitory potency and by the concomitant adenosine deaminase inhibitory action.

Furthermore, a novel series of *thienylacylhydrazone derivatives* synthesized from natural safrole (4-allyl-1,2-methyldioxybenzene), a Brazilian natural product obtained from *Ocotea pretiosa*, have been studied as PDE2 inhibitors for their antiplatelet activity (Lima et al. 1999). The most potent of these inhibited platelet aggregation induced by arachidonic acid (IC50 0.2–3.1 μM) and collagen (IC50 0.9–3.4 μM) and effects enhanced by sodium nitroprusside without interference with ADP-induced aggregation, ATP release, and thromboxane (Tx)B2 production (Brito et al. 2010). Moreover, one of these induced a concentration-dependent relaxation of intact rat aortic rings (IC50=74 μM) (Silva et al. 2002).

Novel selective PDE2 inhibitors with nanomolar potency, such as 9-(6-phenyl-2-oxohex-3-yl)-2-(3,4-dimethoxybenzyl)-purin-6one (PDP), have recently been developed but not tested on platelets (Diebold et al. 2009).

Milrinone, a specific PDE3A inhibitor, inhibits arachidonic acid-induced platelet shape change and platelet aggregation induced by ADP, U46619, collagen, and calcium ionophore, both in whole blood and in platelet-rich plasma (Barradas et al. 1993), with IC50s as low as 1 μmol/l, a concentration lower than the concentration achievable after therapeutic administration (1.5 μmol/l), indicating that an antiaggregating effect milrinone can occur in vivo (Anfossi et al. 1996). Milrinone induces an elevation of intraplatelet cAMP in a dose-dependent way resulting in the inhibition of platelet aggregation (Manns et al. 2002).

Milrinone is currently in clinical use for congestive heart failure (Colucci 1991).

To date, only one family of PDE5, PDE5A, has been described. Three splice variants of PDE5A, PDE5A1/PDE5A2/PDE5A3, have been found in humans differing in their N-terminal region, but with similar Km for cGMP (Hidaka and Asano 1976).

Three *PDE5 inhibitors*, sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis), are currently in clinical use for erectile dysfunction.

Actually the first developed PDE5 inhibitor to be used in humans was zaprinast (M&B22948), originally designed as a mast cell-stabilizing drug for the treatment of allergic diseases (Murray 1993). The observation that cGMP elevation induced by zaprinast was associated with smooth muscle cell relaxation opened the possibility to use PDE5 inhibitors in cardiovascular diseases (Rudd et al. 1983). Zaprinast inhibits human platelet PDE5 with an IC_{50} of 0.3 μM and PDE2A with an IC_{50} of 42 μM. In association with SNP (1 μM), zaprinast led to a complete concentration-

dependent inhibition of serotonin release in washed platelets (IC_{50} ~ 1.6 μM) (Dunkern and Hatzelmann 2005). This compound was an unsuccessful clinical drug candidate, turned out to be weak and poor selective for PDE5. Consequently, a variety of compounds with key variations in the heterocyclic ring system of zaprinast were prepared leading to the identification in 1989 of sildenafil as a PDE5 inhibitor, which was 100 times as potent as zaprinast and highly specific in its action.

Sildenafil (1-[4-ethoxy-3-(6,7-dihydro-1-methyl-7-oxo-3-propyl-1H-pyrazolo[4,3-d]pyrimidin-5-yl)phenylsulfonyl]-4-methylpiperazine) is a potent PDE5 inhibitor, with high selectivity for human PDE5 over PDE2, PDE3, and PDE4 (>1000-fold) and moderate selectivity (>80-fold) over PDE1 (Schwartz and Kloner 2010). Sildenafil instead is only approximately tenfold more potent for PDE5 than for PDE6 (an enzyme found in the photoreceptors of the human retina), and this explains the frequent side effect of flashes of blue light with its use. Platelet PDE5 is inhibited by sildenafil with an IC_{50} of 6.3 nM (Wallis et al. 1999). While sildenafil alone had no effect on platelet function, it potentiated the inhibition by sodium nitroprusside of rabbit and human platelets (Wallis et al. 1999).

Sildenafil is rapidly absorbed after oral administration, with ~40 % bioavailability. Plasma concentrations peak within 30–120 min (median, 60 min), and the drug is primarily metabolized by hepatic cytochrome P450 3A4 (major route) and 2C9 (minor route) which convert it to an active N-desmethyl metabolite that possesses 50 % of the parent drug's potency for PDE5 (Cheitlin et al. 1999).

The administration of sildenafil (100 and 50 mg in healthy volunteers) inhibited collagen-induced aggregation (100 mg), with an additive effect when combined with nitrates (ISDN, 10 mg) (Berkels et al. 2001). Moreover, ADP-stimulated $\alpha_{IIb}\beta_3$ receptor activation was inhibited by sildenafil (100 mg) (Halcox et al. 2002). A study in healthy men showed that bleeding time was significantly prolonged (+72 %) 1 h after sildenafil intake (100 mg), with recovery after 4 h, whereas a lower dose (50 mg) did not alter the bleeding time (Berkels et al. 2001). Sildenafil was also reported to increase the incidence of epistaxis in patients on concomitant vitamin K antagonists and in combination with heparin had an additive effect on bleeding time in rabbits (Galie et al. 2010). Given the relatively low selectivity of sildenafil for PDE5, other more selective PDE5 inhibitors have been developed: vardenafil (Kd of 0.6–0.7 nM; selectivity over PDE6, approximately 16-fold) (Young 2002) and tadalafil (Kd range of 0.9–6.7 nM, 200–700 times more selective for PDE5 than PDE6) (Corbin and Francis 2002). In patients with erectile dysfunction associated with cardiovascular risk factors (dyslipidemia, hypertension, and smoke), tadalafil enhanced cGMP and significantly reduces P-selectin expression in platelets (De Bon et al. 2010).

Summary

Antiplatelet therapy is the mainstay of treatment of patients with acute cardiovascular ischemic events and of secondary prophylaxis of patients with a previous ischemic event. Despite great progress, even optimal antithrombotic therapy still does not offer satisfactory protection against cardiovascular events and is associated with serious risk of hemorrhagic side effects. Agents targeting thromboxane production or activity, ADP, and fibrinogen binding to platelets have proven of benefit but have also shown limitations.

An alternative, appealing strategy is to develop agents interfering with intracellular signaling pathways (Gresele et al. 2008). PDE inhibitors by increasing crucial intraplatelet second messengers, such as cGMP and cAMP, have great potential for platelet inhibition. In fact, differently from aspirin or clopidogrel, not only do they inhibit platelet activation induced by all stimuli, they also exert beneficial cardiovascular effects through their capacity to regulate the interaction of platelet with vascular smooth muscle cells in the setting of ischemic cardiovascular disease. However, the widespread distribution of PDE in the body renders it difficult that an effective antiplatelet action be achieved without significant unwanted effects. Moreover, the reversibility of the effect of most clinically available PDE inhibitors on their target may represent a serious limitation for their antithrombotic effectiveness in long-term secondary prophylaxis. It is now established that continuous platelet inhibition is required in order to obtain an effective antithrombotic protection and the reversibility of the blockade of the target with temporary restoration of platelet function in patients at high cardiovascular risk may be associated with enhanced ischemic events, as shown by the negative experience with orally active $\alpha_{IIb}\beta_3$ antagonists (Curtin and FitzGerald 2000). It is not a chance that antiplatelet agents currently used in secondary prevention of ischemic events, i.e., aspirin and thienopyridines, act both by irreversibly blocking their target. A deeper understanding of the physiology of PDEs in platelets and other tissues, the development of techniques allowing to target PDE inhibition to platelets, and the development of irreversible or long-acting isoenzyme-selective PDE inhibitors may potentially lead to advances in antiplatelet therapy.

Take Home Messages

- Continuous platelet inhibition is required to obtain an effective antithrombotic protection.

(continued)

- PDE inhibitors by increasing crucial intraplatelet second messengers, such as cGMP and cAMP, have great potential for platelet inhibition.
- PDE inhibition in platelets and the development of irreversible or long acting isoenzyme-selective PDE inhibitors may potentially lead to advances in antiplatelet therapy.

PAR Antagonists

Patrícia O. Guimarães and Pierluigi Tricoci

Abstract

Thrombin is a potent platelet agonist that acts through protease-activated receptors (PARs) on platelet surface. PAR-1 is considered the main thrombin receptor in human platelets, while the roles of PAR-4 are not completely understood. Vorapaxar is the most widely studied PAR-1 antagonist and is the first in its class to be approved for clinical use, with indication for secondary prevention of recurrent ischemic events in patients with previous myocardial infarction or peripheral artery disease. In the chapter we will review the peculiar mechanism of action of PARs, their roles in hemostasis and thrombosis, and the pharmacology of vorapaxar. We will also review the main clinical data with special attention on the delicate balance between prevention of thrombosis and risk of bleeding.

Protease-Activated Receptors

Platelets have central role in maintaining hemostasis at sites of vascular injury and at the same time are responsible for thrombotic disease, especially in the context of ruptured atherosclerotic plaques or endothelial damage. Platelets are activated by multiple pathways, and their inner mechanism of amplification leads to growth of initial platelet aggregates (Jennings 2009).

The primary mechanism for in vivo activation at site of vascular damage, and thus key for hemostasis, is the adhesion to the extracellular collagen matrix, leading to platelet activation and the formation of an activated platelet monolayer (Jennings 2009). The interaction between collagen and platelets occurs through von Willebrand factor linked on collagen platelets and glycoprotein (GP) Ib/V/IX complex on platelets and the direct binding of the GP VI, the major platelet-collagen receptor, and collagen (Jennings 2009; Roberts et al. 2004). The collagen-induced platelet activation is thought to be central in maintaining normal hemostasis (Farndale et al. 2004).

Activated platelets release other factors leading to the amplification of platelet activation. In particular activated platelets secrete ADP, which is stored at high concentrations in dense granules, and contribute to the expansion of the platelet activation process (Jennings 2009). Similarly, release of thromboxane A2 from activated platelets contributes to the amplification of platelet-mediated thrombus formation. These amplification mechanisms are important in both normal hemostasis and pathologic thrombus formation. In addition to collagen, thrombin can trigger platelet activation. Thrombin is the most potent platelet activator known as it acts at very low, nanomolar concentrations (Jennings 2009). The interaction between thrombin and platelet in humans is mediated by the PAR-1 and the PAR-4 receptors (Coughlin 2000; Macfarlane et al. 2001). Both receptors can independently mediate thrombin signaling, and PAR-1 is activated at low concentration of thrombin, while PAR-4 becomes active at high concentration (Coughlin 2000). Thus, PAR-1 is thought to be the main thrombin receptor on human platelet. The roles of PAR-4 are not well understood. It may serve as a "backup" receptor in an important system or act in conditions with high thrombin concentrations (Coughlin 2000). Alternatively it could mediate responses to proteases other than

thrombin or provide other unknown contributions to platelet function. Nonetheless both receptors appear to contribute to intracellular signaling in response to thrombin. In fact, PAR-4 is activated and shut off more slowly than PAR-1, and release of calcium signaling in response to thrombin in human platelets is given by the contribution of both receptors (Coughlin 2000). What roles PAR-4 plays with PAR-1 antagonist pharmacology strategies are also unknown and important to understand. Is concomitant PAR-4 blockade needed to achieve a full efficacy of antagonism of thrombin-mediated platelet activation? Is the efficacy and safety of PAR-1 antagonist modified by variability in PAR-4 activity?

PAR-1 is a seven-transmembrane-span G-protein-coupled receptor, which is activated through a unique mechanism (Fig. 1) (Zhang et al. 2012). In fact the interaction of PAR-1 with thrombin is not a typical "ligand-receptor" interaction. Instead, PAR-1 acts as a protease substrate for thrombin. In turn thrombin binds the receptor transiently and removes the N-terminus unmasking a tethered ligand (SFLLRN), prior to dissociating (Chen et al. 1994). The tethered ligand in turn activates the PAR-1. Unlike "typical" receptors that can go through many rounds of activation by diffusible agonists, each PAR undergoes a single activation cycle (Zhang et al. 2012). The identification of PAR antagonists has been challenging because compounds must compete with high local concentration of the tethered agonist. PARs are ubiquitous in the human body with a variety of functions in different tissues and have roles in cell proliferation and inflammation (Macfarlane et al. 2001). A detailed review of these functions is outside the scopes of this chapter. Intracellular signaling of PAR-1 occurs through G proteins $G_{\alpha q}$, $G_{\alpha 12/13}$, $G_{\alpha i}$, and $G_{\beta\gamma}$ that mediate intracellular response (Angiolillo et al. 2010) (Fig. 2).

Activated PAR-1 is rapidly desensitized by phosphorylation and arrestin binding, which uncouples the receptor from G proteins. PAR-1 is then internalized through endocytosis and degraded by lysosomes, without being recycled (Arora et al. 2007; Trejo et al. 1998; Zhang et al. 2012).

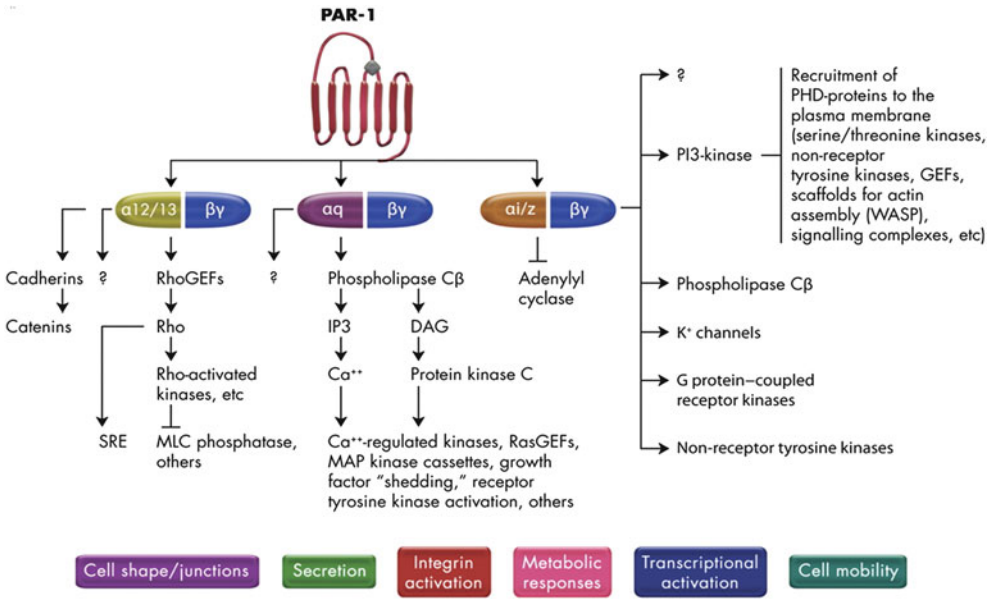

Fig. 2 Intracellular PAR-1 signaling pathway (From Angiolillo DJ, EHJ 2010)

Roles of PARs in Hemostasis

A lot of what we know about the roles of PARs in hemostasis comes from the work of Coughlin in mice (Cornelissen et al. 2010; Coughlin 2000). Mouse platelets express PAR-3 and PAR-4. PAR-3 is necessary for thrombin-mediated platelet activation at low thrombin concentrations; however, it is not associated with intracellular signaling but serves as cofactor to PAR-4. The thrombin signaling in mouse depends on PAR-4 (Coughlin 2005). The mouse dual receptor PAR-3/PAR-4 system provides a good dual receptor model like in humans, with PAR-3 resembling human PAR-1 given its high affinity for thrombin. PAR-3 -/- mice are a good model for human PAR-1 inhibition as higher thrombin concentration is needed to activate platelet (through PAR-4). PAR-4 -/- mice are totally unresponsive to thrombin and thus resemble concomitant PAR-1/PAR-4 inhibition in humans. The mouse models provide insights on what is the role of thrombin-mediated platelet activation in normal hemostasis. Complete thrombin deficiency is not compatible with life, and completely thrombin-deficient mice die during gestation. Fibrin (Fib -/-)-deficient mice show significant hemorrhagic tendency, but they can survive to old age. Combined fib -/- and PAR-4 -/- genetic makeup is also incompatible with life and mimics complete thrombin deficiency (Coughlin 2005). As expected, platelets of PAR-4 (-/-)-deficient mice are totally unresponsive to thrombin. However, they appear healthy and have no evidence of anemia or spontaneous bleeding. PAR-4 (-/-) female can support pregnancies, and platelets are normal in number and morphology (Coughlin 2005). In mice blood loss model PAR-3 (-/-) was not associated with increased bleeding time, unless concomitant $P2Y_{12}$ (-/-) genetic deficiency was present concomitantly (Coughlin 2005). A mild hemostatic defect can be detected from prolonged bleeding times only for high degree of injury (Hamilton et al. 2004). Similar results were observed with infusion of an intravenous PAR-1 antagonist SCH 530348 (analogue of vorapaxar), which did not cause increase in bleeding time in a cynomolgus monkey surgical blood loss model, unless a $P2Y_{12}$ inhibitor was administered concomitantly (Chintala et al. 2010). Overall these animal models support the concept that thrombin-mediated platelet activation is not critical to normal hemostasis. A clue on why thrombin-mediated platelet activation may be not as impactful on normal hemostasis comes again from PAR-4 -/- mice (Vandendries et al. 2007). A study with laser-induced thrombus formation and real-time digital fluorescence microscopy (Fig. 3) shows that compared to wild-type mouse, the PAR-4 (-/-) deficiency did not affect the formation of initial juxtamural thrombi at site of vascular injury, thus allowing hemostasis, but impaired the further propagation of platelet thrombus (Vandendries et al. 2007). So whenever the injury is small enough that significant growth of thrombus is not needed, PAR-mediated platelet activation may not be critical. In terms of therapeutic applications, blocking growth of thrombi without impairing the initial formation of a hemostatic plug may result in desirable effect, i.e., preventing formation of large occlusive thrombus, without losing hemostatic properties.

Even if impaired thrombin-mediated platelet activation does not significantly affect normal hemostasis in mice, it does appear to provide protection against thrombosis. PAR-4 (-/-) mice, whose platelet does not respond to thrombin, have been shown to have a reduced thrombotic response on a variety of arterial injury models (i.e., thromboplastin-induced pulmonary embolism, $FeCl_3$-induced thrombosis,

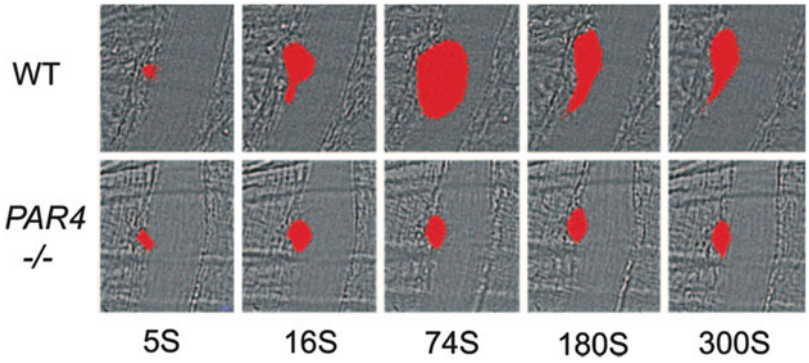

Fig. 3 Thrombus propagation in PAR-4 -/- mice (Vandendries ER, Proc Natl Acad Sci USA 2007)

laser injury-induced thrombosis of the cremasteric artery), supporting the hypothesis that blocking thrombin receptors on platelet may protect against thrombosis (Cornelissen et al. 2010). Data on protection against thrombosis derived from partial inhibition of thrombin-induced platelet activation were also derived from mice model. As described above PAR-3 (-/-) mice only respond to high concentration of thrombin, thus mimicking PAR-1 inhibition in human, where platelets only respond to high thrombin concentration through the PAR-4 receptor (Cornelissen et al. 2010). At low level of vascular injury (4 % $FeCl_3$), PAR-3 (-/-) mice were as protected from thrombosis as PAR-4 (-/-) mice and more protected than $P2Y_{12}$ (-/-) mice. At higher level of vascular injury (8 and 20 % $FeCl_3$), PAR-3 (-/-) mice did not show significant reduction in thrombus formation, unlike PAR-4 and PY12 (-/-) mice (Cornelissen et al. 2010). Taken together these results suggest that partial thrombin-mediated platelet activation (such as with PAR-1 antagonism) may be effective at low level of injury (which may correspond to spontaneous plaque rupture). At high level of arterial injury, such as during PCI, partial PAR blockade becomes less effective than complete PAR inactivation or $P2Y_{12}$ inhibition.

The totality of the animal model supported the hypothesis that blocking thrombin-mediated platelet activation can reduce thrombosis without impairing normal hemostasis.

Vorapaxar

Pharmacodynamics and Pharmacokinetics

Vorapaxar (Zontivity, Aralez) is a synthetic derived of himbacine, a compound found in barks of Australian magnolias (*Galbulimima baccata*) (Chackalamannil et al. 2005). Vorapaxar is an oral, potent, selective, competitive PAR-1 antagonist, with high affinity for the receptor (Chackalamannil et al. 2005). Vorapaxar does not interfere with other functions of thrombin, such as fibrinogen cleavage and fibrin generation, and the coagulation cascade is not affected. Vorapaxar is highly selective for the PAR-1 receptors (compared to others PARs) (Zhang et al. 2012). The binding pockets of vorapaxar on the receptor are very superficial, which is unusual for G-protein-coupled receptors (Zhang et al. 2012). There are three openings in the binding pocket that are narrower than vorapaxar. Thus, it remains unclear how the drug reaches the binding pocket, possibly through the membrane given the molecule is highly lipophilic (Zhang et al. 2012). The binding of vorapaxar with PAR-1 is reversible; however, after the drug attaches the binding pockets, those "close" resulting in a very slow off rate and a virtually nonreversible interaction (Zhang et al. 2012). Vorapaxar does not have significant on PAR-4-mediated response to thrombin (Judge et al. 2015).

Pharmacokinetics

Vorapaxar is rapidly absorbed following oral administration, and peak plasma concentration is achieved at 1–2 h after administration under fasting condition and a 45 min delay in peak concentration with a highly fat meal, but no changes in the area under the curve of concentration and a small change in peak concentration (https://www.merck.com/product/usa/pi_circulars/z/zontivity/zontivity_pi.pdf). The bioavailability of vorapaxar is nearly 100 %.

Vorapaxar is eliminated after liver metabolism mediated by CYP3A4 and CYP2J2 (Kosoglou et al. 2012). Coadministration with potent CYP3A4 inhibitors or inducers has been shown to increase (inhibitors) or decrease (inducers) exposure by approximately 50 %. The terminal elimination half-life is 8 days, resulting in a long persistent duration of platelet inhibition, and 50 % platelet inhibition is still seen after 4 weeks (https://www.merck.com/product/usa/pi_circulars/z/zontivity/zontivity_pi.pdf). Vorapaxar's metabolites are mainly eliminated through feces (58 %), with a smaller proportion of renal excretion (25 %). The major active circulating metabolite is the monohydroxy metabolite M20 (https://www.merck.com/product/usa/pi_circulars/z/zontivity/zontivity_pi.pdf). Vorapaxar and the

M20 are all virtually bound (≥99 %) to plasma proteins. Vorapaxar is highly lipophilic and the volume of distribution is >400 l.

Antiplatelet Effect

Vorapaxar inhibits ex vivo platelet aggregation induced by the thrombin receptor-activating peptide (TRAP), while it has no significant effect on ADP-induced platelet aggregation. In healthy volunteers, vorapaxar in 20 or 40 mg single loading doses promoted a >80 % inhibition of thrombin receptor-activating peptide (TRAP)-induced platelet aggregation within 1 h, and this effect was sustained for 72 h (Kosoglou et al. 2012). Multiple maintenance doses of 1 and 3 mg/day achieved nearly complete inhibition of 15 mcg TRAP-induced platelet aggregation at Day 7, while with 5 mg/day, complete inhibition was observed at Day 1. One interesting aspect of the antiplatelet effect of vorapaxar is that with increasing concentration, there is not a progressive decrease in platelet function. No antiplatelet effect is seen until the drug reaches a critical plasma concentration, and at that point an "on-switch" effect is seen, and >80 % platelet aggregation inhibition is reached (personal communication, Dr. John Strony). Studies on drug effect on platelet aggregation were also performed in the setting of the phase II among subjects undergoing PCI and in phase III (TRACER) among patients with non-ST-segment elevation acute coronary syndromes. In the phase II Thrombin Receptor Antagonist (TRA)-PCI trial, single loading dose of vorapaxar 40 mg yielded >80 % inhibition of TRAP (15 mcg)-induced platelet aggregation in almost 30 % of patients in 30 min, 70 % in 1 h, and 96 % in 2 h (Becker et al. 2009). At 2 h this effect was seen in 43 % and 53 % of patients in the vorapaxar 10 mg and 20 mg loading dose groups, respectively. At 30 days and 60 days, maintenance doses of 1 mg and 2.5 mg daily yielded >80 % platelet inhibition to TRAP in all patients. The TRACER Pharmacodynamic Substudy assessed the effect of vorapaxar at the doses used in the trial (40 mg loading, 2.5 mg maintenance dose), in NSTE-ACS patients largely (>90 %) treated with concomitant clopidogrel (Storey et al. 2014). Vorapaxar achieved a 97 % (94–98 % IQR) inhibition of maximum platelet aggregation to TRAP at 2 h after administration. This level of platelet inhibition was maintained with the 2.5 mg loading dose until the end of treatment. The study also suggested that platelet aggregation induced by TRAP in TRACER subjects at baseline (i.e., prior to vorapaxar administration) was lower compared to a group of healthy volunteers, suggesting that concomitant treatment with clopidogrel may have some effect on TRAP-induced platelet aggregation (Storey et al. 2014). At the same time, measurable decreases in ADP-induced platelet aggregation measured with VASP were seen with vorapaxar. These data, which need to be confirmed and may have been due to chance, suggest a possible interplay between $P2Y_{12}$ blockade and PAR-1 antagonism which may play a role in the antiplatelet effect when PAR-1 antagonists and $P2Y_{12}$ inhibitors are used concomitantly. A notable observation from the current study is that treatment with vorapaxar leads to reduced expression of PAR-1 after 1 month. The implication of this finding, i.e., a decreased sensitivity to thrombin-mediated platelet aggregation with consequent excessive inhibitory response to vorapaxar over time, needs to be further investigated.

Clinical Trials of Vorapaxar

Phase II Trials

The Thrombin Receptor Antagonist (TRA)-PCI trial assessed safety of vorapaxar which included patients undergoing elective coronary angiography with the intention to perform a PCI (Becker et al. 2009). Aspirin was given on the day of PCI, and patients were randomized to receive either a vorapaxar loading dose (10, 20, or 40 mg) or placebo before the coronary angiography. In cases of scheduled PCI, a loading dose of clopidogrel was given. Patients in the vorapaxar group who went ahead to receive a PCI were randomized in a blinded fashion to receive one of the three maintenance doses (0.5, 1.0, or 2.5 mg) for 60 days, and patients in the placebo group remained under treatment with placebo. Maintenance dose was not given for patients who did not undergo PCI, and those were followed in a separate cohort. A total of 1030 patients were enrolled: 573 underwent PCI and represented the primary cohort of the study, and 457 did not. The primary outcome, thrombolysis in myocardial infarction (TIMI) major or minor bleeding, occurred in similar rates among vorapaxar-treated and placebo-treated patients (3.3 % placebo vs. 2.8 % vorapaxar, OR 0.86, 95 % CI 0.30–2.47). However, there was a numerical trend toward higher bleeding rates with higher loading dose of vorapaxar (4.0 % with 40 mg). The rate of the composite outcome of death, major cardiac event, or stroke was numerically lower in the combined vorapaxar group, when compared with placebo (6 % in the combined vorapaxar group and 9 % in the placebo group, OR 0.67, 95 % CI 0.33–1.34). Myocardial infarction (MI) occurred in 4 % of the combined vorapaxar group and in 7 % of the placebo group.

Another phase II study with vorapaxar was conducted in Japan in patients with NSTE-ACS undergoing PCI (Goto et al. 2010). Participants were randomized to receive a vorapaxar 20 or 40 mg loading dose (followed by a 1.0 or 2.5 mg maintenance dose), or placebo, on top of standard care. The maintenance dose was given until completion of 60 days. PCI was performed in 92 patients, and the rates of TIMI major or minor bleeding were similar between the

pooled vorapaxar group and the placebo group (14 % in the pooled vorapaxar group and 10 % in the placebo group). Moreover, the occurrence of MIs was lower among vorapaxar-treated patients in comparison with placebo-treated patients (16.9 % in the vorapaxar group vs. 42.9 % in the placebo group; $p = 0.013$).

In trial with 90 Japanese patients with previous stroke, the use of vorapaxar (1.0 or 2.5 mg) on top of aspirin for 60 days did not increase the rates of adverse events in comparison with placebo (Shinohara et al. 2012). No TIMI major or minor bleeding was observed in vorapaxar-treated patients, whereas only one participant experienced a TIMI minor hemorrhage during study period. In addition, no MIs occurred.

The TRACER Trial

The Thrombin Receptor Antagonist for Clinical Event Reduction in Acute Coronary Syndrome (TRACER) trial is a phase III, double-blind, multicenter clinical trial which investigates vorapaxar versus placebo on top of standard antiplatelet therapy in preventing ischemic events in patients with NSTE-ACS (Table 1) (Tricoci et al. 2012). A total of 12,944 NSTE-ACS patients were included presenting with symptoms of ischemia within 24 h prior to hospitalization in addition to elevation of troponin/CKMB or high-risk electrocardiogram changes and at least one of the following: age greater or equal to 55 years, diabetes, peripheral arterial disease, previous MI, PCI, or coronary artery bypass graft (CABG). Key exclusion criteria were patients under the use of anticoagulants or inducers/inhibitors of CYP3A4 isoenzymes, history of bleeding diathesis, any previous intracranial bleeding, and severe valve heart disease. Participants were randomized to receive either vorapaxar, 40 mg loading dose at least 1 h before any revascularization procedure followed by 2.5 mg once-daily maintenance dose, or placebo. The duration of the treatment was for the entire duration of the study and a minimum of 1 year. Almost all of the participants received aspirin, and 91.8 % received clopidogrel. The median follow-up period was 502 days. Seven months after the completion of enrollment and 5 months before the planned conclusion of the follow-up, the study was terminated prematurely following a Data Safety Monitoring Board (DSMB). The DSMB, after that the minimum number of primary endpoint events were already achieved, detected an increase rate of intracranial hemorrhages (ICH) with vorapaxar and recommended interruption of the study.

The primary endpoint, composite of cardiovascular death, MI, stroke, rehospitalization for ischemia, or urgent coronary revascularization, occurred in a 2-year rate of 18.5 % in the vorapaxar group and 19.9 % in the placebo group (HR 0.92, 95 % CI 0.85–0.98; $p = 0.07$) (Table 2). Vorapaxar reduced the rate of the key secondary endpoint of cardiovascular death, MI, or stroke, in comparison with placebo (14.7 % vs. 16.4 % at 2 years, HR 0.89, 95 % CI 0.81–0.98; $p = 0.02$), mostly driven by a reduction in the

Table 1 Phase III clinical trials with vorapaxar

rate of MI (11.1 % vs. 12.5 %, HR 0.88, 95 % CI 0.79–0.98; $p = 0.02$), especially spontaneous (type 1) MI. Because the primary endpoint did not meet statistical significance, the trial failed to prove superiority of vorapaxar, despite the nominal statistical significance of the triple endpoint.

Vorapaxar, added to standard of care with common use of dual antiplatelet therapy, increased the rate of Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) moderate or severe bleeding in comparison with placebo (7.2 % vorapaxar vs. 5.2 % placebo, 95 % CI 1.16–1.58; $p < 0.001$), as well as clinically significant bleeding by TIMI criteria (20.2 % vorapaxar vs. 14.6 % placebo, HR 1.43, 95 % CI 1.31–1.57; $p < 0.001$). The rates of intracranial bleeding and hemorrhagic stroke were significantly higher among patients in the vorapaxar group, as compared with placebo (1.1 % vs. 0.2 %, HR 3.39, 95 % CI 1.78–6.45, $p < 0.0001$; 0.3 % vs. 0.1 %, HR 2.73, 95 % CI 1.22–6.14, $p = 0.02$, respectively).

The results of TRACER suggest an overall modest benefit of vorapaxar when used largely in the setting of triple therapy with aspirin and thienopyridine. In fact even if the choice of the quintuple endpoint has likely caused the trial to be "neutral" and accepting a best-case scenario with an 11 % significant reduction of CV death, MI, or stroke, the benefit observed is largely offset by significant increase in bleeding. Nonetheless in our opinion the results of TRACER support the biological efficacy of PAR-1 blockade in ACS patients, as suggested by a reduction of the triple endpoint and the reduction observed in myocardial infarction, especially type 1. Interestingly no substantial effects of vorapaxar were seen in PCI-related MI. These results support the hypothesis, derived from mice studies and discussed before in this chapter, that PAR-1 antagonism may be protective when limited extension of vascular injury occur (i.e., spontaneous plaque rupture) and less with more extensive vascular damage (i.e., during coronary intervention). The significant increase in bleeding, including severe bleeding and ICH, should be interpreted in the context of triple therapy use, and it is similar to other trials where triple therapies were used, such as ATLAS-2 with rivaroxaban or APPRAISE-2 with apixaban (Alexander et al. 2011; Mega et al. 2012). Additionally, in TRACER, patients received a loading dose of 40 mg and concomitant use during the acute phase of parenteral antithrombin agents and about 20 % of patients concomitant GPIIb/IIIa inhibitors. Future studies are needed to establish whether vorapaxar can reduce ischemic events with an acceptable safety profile in ACS when used in the context of single or dual antiplatelet therapy, for example, by replacing aspirin.

The TRA 2P-TIMI 50 Trial

The Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events (TRA 2P-TIMI 50) trial compared vorapaxar versus placebo in addition to standard-of-care antiplatelet therapy in secondary prevention setting of patients with stable, chronic atherosclerotic disease (Table 1) (Dutta et al. 2012). A total of 26,449 participants were randomized which included three populations. The first, and largest (about 67 % of the population), included patients with recent myocardial infarction (2 weeks–12 months post-MI). The second (approximately 18 % of the population) was composed of patients with documented peripheral arterial disease (PAD). The remaining third included patients with recent stroke (2 weeks–12 months post-MI). Patients were randomized to receive 2.5 mg daily of vorapaxar, or placebo. No loading dose was used. Patients were treated concomitantly with aspirin and/or thienopyridine as per treating physician choice. Randomization was stratified by population and planned use of thienopyridine. After a median follow-up of 24 months, a high occurrence of intracranial bleeding events was observed with vorapaxar among patients in the vorapaxar group with previous stroke, including those who had a stroke during the study. The study treatment was interrupted in this group, while post-MI and PAD patients continued the trial to completion. The primary endpoint of the TRA 2P-TIMI 50 trial was revised after the completion of the TRACER trial and defined as the composite of cardiovascular death, MI, or stroke. This protocol modification was made before unblinding and trial termination.

Nearly all participants in the TRA 2P-TIMI 50 trial were treated with aspirin, 78 % of patients post-MI had concomitant thienopyridine, and 37 % of PAD patients had concomitant thienopyridine use.

At 3 years, vorapaxar significantly reduced the rate of the primary outcome in comparison with placebo (9.3 % in the vorapaxar group vs. 10.5 % in the placebo group, HR 0.87, 95 % CI 0.80–0.94; $p < 0.001$) (Table 3). The occurrence of the secondary outcome (composite of cardiovascular death, MI, stroke, or urgent coronary revascularization) was also reduced by vorapaxar, when compared with placebo (11.2 % in the vorapaxar group vs. 12.4 % in the placebo group, HR 0.88, 95 % CI 0.82–0.95; $p = 0.001$). Similar to TRACER, this result was mainly driven by a lower rate of MIs in the vorapaxar group (5.2 % vs. 6.1 %, HR 0.83, 95 % CI 0.74–0.93; $p = 0.001$ for vorapaxar vs. placebo). The rates of all-cause death (5.0 % in the vorapaxar group vs. 5.3 % in the placebo group; $p = 0.41$) and cardiovascular death (2.7 % in the vorapaxar group vs. 3.0 % in the placebo group; $p = 0.15$) were similar between study groups.

A significant increase in the rate of GUSTO moderate or severe bleeding events was observed with vorapaxar, in comparison with placebo (4.2 % in the vorapaxar group vs. 2.5 % in the placebo group, HR 1.66, 95 % CI 1.43–1.93; $p < 0.001$). Vorapaxar also increased the risk of clinically significant TIMI bleeding (15.8 % in the vorapaxar group vs. 11.1 % in the placebo group, HR 1.46, 95 % CI 1.36–1.57; $p < 0.001$) and intracranial bleeding (1.0 % in the vorapaxar group vs. 0.5 % in the placebo group, HR 1.94, 95 % CI 1.39–2.70; $p < 0.001$). The risk of ICH was mainly confined among those with prior stroke (2.4 % in the vorapaxar group vs. 0.9 % in the placebo group, HR 2.55, 95 % CI 1.52–4.28; $p < 0.001$). The excess seeing in ICH in those without stroke was more contained (0.6 % vs. 0.4 %, vorapaxar and placebo, respectively; $p = 0.049$). The rate of the net clinical outcome of cardiovascular death, MI, stroke, or GUSTO moderate or severe bleeding did not differ between study groups (11.7 % in the vorapaxar group vs. 12.1 % in the placebo group, HR 0.97, 95 % CI 0.90–1.04; $p = 0.40$).

The results of the TRA 2P-TIMI 50 trial demonstrated a benefit of vorapaxar in the secondary prevention setting in patients without history of stroke. While bleeding was also increased, the liability of vorapaxar on ICH was more limited in those without stroke. The population that appeared to have the highest benefit was the post-MI (Scirica et al. 2012). Among the 17,779 of 26,449 patients who were included based on a recent MI, the triple endpoint occurred at 3 years in 8.1 % with vorapaxar and 9.7 % with placebo (HR 0.80, 95 % CI 0.72–0.89; $p < 0.0001$). Moderate or severe bleeding were increased with vorapaxar (HR 1.61, 95 % CI 1.31–1.97; $p < 0.0001$), and a trend toward higher ICH rates was observed (0.6 vs. 0.4 %, $p = 0.076$). The benefit on CV death, MI, or stroke was more modest in the PAD population (HR 0.94, 95 % CI 0.78–1.14). No benefit was observed in the prior stroke population (HR 1.03, 95 % CI 0.85–1.25) (Scirica et al. 2012).

In 2014 vorapaxar received market approval in the USA by the Food and Drug Administration (FDA). A 2.5 mg once-daily regimen was approved for secondary prevention in patients with history of MI or with PAD (i.e., the TRA 2P population minus the stroke group). The drug is contraindicated in patients with previous stroke or transient ischemic attack due to increased risk of intracranial bleeding. Similarly, the drug has been approved in the European Union by the European Medicines Agency, for the post-MI indication. The difference was due to variation in procedural regulations between FDA and EMA in drug approval process.

The TRA 2P-TIMI 50 investigators have examined the efficacy and safety of vorapaxar in the trial population reflecting the FDA label (Magnani et al. 2015). A total of 20,170 patients randomized in TRA 2P-TIMI 50 trial met the current FDA label requirement (16,897 with a history of MI and 3273 with PAD). CV death, MI, or stroke at 3 years was significantly reduced with vorapaxar compared with placebo (7.9 vs. 9.5 %; HR, 0.80; 95 % CI 0.73–0.89; $p < 0.001$). GUSTO moderate or severe bleeding was higher in the vorapaxar group (3.7 vs. 2.4; HR, 1.55; 95 % CI 1.30–1.86; $p < 0.001$). ICH was 0.6 % with vorapaxar and 0.4 % with placebo, $p = 0.10$. For every 1000 patients treated for 3 years, vorapaxar prevented 16 CV death, MI, or stroke, at the expense of three more GUSTO severe bleeding and 13 GUSTO moderate or severe bleeding (Magnani et al. 2015).

Table 3 Clinical outcomes in the TRA 2P-TIMI 50 trial

TRA 2P-TIMI 50 endpoints	Vorapaxar event rate at 3 years (%)	Placebo event rate at 3 years (%)	HR (95 % CI); *p*-value
Primary efficacy endpoint	9.3	10.5	0.87 (0.80–0.94); <0.001
Secondary efficacy endpoint	11.2	12.4	0.88 (0.82–0.95); 0.001
MI	5.2	6.1	0.83 (0.74–0.93); 0.001
CV death	2.7	3.0	0.89 (0.76–1.04); 0.15
Stroke	2.8	2.8	0.97 (0.83–1.14); 0.73
Primary safety endpoint	4.2	2.5	1.66 (1.43–1.93); <0.001
TIMI clinically significant bleeding	15.8	11.1	1.46 (1.36–1.57); <0.001
Intracranial bleeding	1.0	0.5	1.94 (1.39–2.70); <0.001

Subgroup Analysis of Special Interest from TRACER and TRA 2P-TIMI 50

Secondary analyses from the two large phase III trials of vorapaxar have provided some very interesting insights on the effect of vorapaxar in certain subgroup, leading the way to possible future development on the drug.

Of great interest are the data from the TRA 2P-TIMI 50 on efficacy of vorapaxar or peripheral vascular outcomes. Clinical trials data supporting use of antiplatelet therapies in PAD are rather scant, and current guidelines recommend use of monotherapy with aspirin or clopidogrel (Rooke et al. 2011). Moreover PAD studies have generally focused on cardiac outcomes, rather than peripheral vascular/limb outcomes. In the TRA 2P-TIMI 50, peripheral vascular outcomes were adjudicated centrally by the clinical event committee. In an analysis among 3787 patients with PAD from the TRA 2P-TIMI 50, rates of hospitalization for acute limb ischemia were significantly reduced with vorapaxar (2.3 vs. 3.9 %; HR, 0.58; 95 % CI, 0.39–0.86; $p = 0.006$) (Bonaca et al. 2013). Also peripheral artery revascularization was significantly lower with vorapaxar (18.4 % vs. 22.2 %; HR, 0.84; 95 % CI, 0.73–0.97; $p = 0.017$). Numerical reduction was observed with vorapaxar on all indication for peripheral revascularization (acute limb ischemia, asymptomatic severe stenosis, chronic critical limb ischemia, claudication) and for all methods of revascularization (surgical or endovascular) (Gilchrist et al. 2015). These data suggest a possible role of vorapaxar in reducing peripheral vascular event and call for future trials comparing vorapaxar with standard of care (currently antiplatelet monotherapy) in the reduction of limb outcomes.

An interesting secondary analysis from the TRACER trial assessed the efficacy and safety of vorapaxar among patients who underwent coronary artery bypass surgery (CABG). In TRACER 1301 of 12,944 patients underwent CABG surgery during the index ACS hospitalization, and 1510 patients underwent CABG during the first 30 days after presentation (Whellan et al. 2014). The protocol recommended the continuation of the study drug before surgery and during the perioperative period. Among patients who underwent CABG, vorapaxar was associated with a 45 % reduction in the primary endpoint (HR, 0.55; 95 % CI, 0.36–0.83; $p = 0.005$), with a significant interaction ($p = 0.012$) between CABG and vorapaxar treatment. CABG-related TIMI major bleeding and chest tube drainage were not significantly different between vorapaxar and placebo. There was no increase in fatal bleeding, or need for reoperation with vorapaxar (Whellan et al. 2014). These results suggest that PAR-1 antagonism with vorapaxar could be an effective and safe strategy to prevent recurrent cardiovascular events following CABG surgery. The results of this study generate the hypothesis that vorapaxar may be effective in preventing ischemic events that are caused by graft failure. Future studies are required to prove this hypothesis and to establish if vorapaxar has a role in the treatment of patients undergoing CABG. One interesting aspect of the CABG analysis is the relatively good safety profile on CABG-related bleeding. It is possible that during CABG, when high concentrations of thrombin are generated, PAR-4-mediated platelet activation serves as effective backup mechanism in the presence of PAR-1 antagonist (Judge et al. 2015).

Both TRACER and TRA 2P-TIMI 50 have explored whether the efficacy and safety of vorapaxar were influenced by the concomitant treatment with thienopyridine (Bohula et al. 2015; Tricoci et al. 2014). Both studies came to the same conclusion that the concomitant treatment with thienopyridine does not affect the efficacy and safety of vorapaxar. In TRACER no significant interaction was found between concomitant long-term treatment with thienopyridine and the efficacy and safety of vorapaxar (Tricoci et al. 2014). Similarly in TRA 2P-TIMI 50, in which patients were stratified at randomization based on planned use of thienopyridine, vorapaxar reduced the CV death, MI, and stroke in patients who had planned thienopyridine use (HR 0.80, 95 % CI 0.70–0.91) and those who had no planned thienopyridine (HR, 0.75; 95 % CI 0.60–0.94) and negative interaction (interaction $p = 0.67$) (Bohula et al. 2015). GUSTO moderate or severe bleeding were increased with vorapaxar regardless of planned use of thienopyridine (interaction $p = 0.37$).

A total of 14,042 patients in the TRA 2P-TIMI 50 had a history of a coronary stent implantation before randomization, with 449 patients receiving a coronary stent during the trial (Bonaca et al. 2014). Vorapaxar was associated with lower rate of definite stent thrombosis (according to Academic Research Consortium definition) (1.1 vs. 1.4 %, HR 0.71, 95 % CI 0.51–0.98; $p = 0.037$). The majority (92 %) of stent thrombosis observed in the study occurred late or very late. In TRACER no significant reduction in ARC definite stent thrombosis was observed with vorapaxar (Tricoci et al. 2012). However, an angiographic core lab evaluation of stent thrombosis from TRACER suggested a low level of concordance in the adjudication of stent thrombosis between the adjudication committee (which based the adjudication mostly on cath lab reports) and an angiographic core lab (with independent, expert assessment of angiographies for the detection of stent thrombosis).

Atopaxar

Atopaxar is another potent PAR-1 antagonist, with a slower onset of action (3.5 h) than vorapaxar. It is metabolized by the liver (CYP3A4), with a shorter terminal half-life (23 h), and primarily fecal excretion.

Two randomized phase II trials were performed in Japan to assess safety of atopaxar in patients with coronary disease. A total of 241 participants with NSTE-ACS were included in the ACS trial (treated for 12 weeks), whereas 263 participants with high-risk stable coronary artery disease were included in the CAD trial (treated for 24 weeks). Patients were randomized to receive one of three dosing regimens of atopaxar (50, 100, or 200 mg), or placebo. In the ACS study, a 400 mg atopaxar loading dose or placebo was given after randomization. More than 90 % of the ACS patients and approximately 40 % of the CAD participants received dual antiplatelet therapy with aspirin and a thienopyridine. Overall, the rates of bleeding events defined by the Clopidogrel in Unstable angina to Prevent Recurrent Events (CURE) criteria were low. In the ACS study, only two major bleeding events occurred in the placebo arm, and one minor bleeding was seen in the atopaxar 200 mg group. In the CAD patients, one major bleeding occurred in the atopaxar 100 mg group, and one minor hemorrhage was observed in the atopaxar 200 mg arm. Numerically higher rates of TIMI-defined bleeding events were seen with atopaxar 200 mg, in comparison with placebo (23.0 % atopaxar 200 mg vs. 16.4 % placebo, $p = 0.398$, in the ACS study, and 13.2 % atopaxar 200 mg vs. 4.5 % placebo, $p = 0.08$, in the CAD study). No TIMI major hemorrhage was observed. The occurrence of major cardiac adverse events (MACE) was similar among atopaxar-treated and placebo-treated patients in the ACS study (5.0 % combined atopaxar group vs. 6.6 % placebo group, RR 0.76, 95 % CI 0.26–2.6; $p = 0.73$). In the CAD trial, the rate of MACE was numerically lower among atopaxar-treated patients (1.0 % in the combined atopaxar group vs. 4.5 % in the placebo group, RR 0.22, 95 % CI 0.04–1.11; $p = 0.07$).

The Lessons From Antagonizing the Cellular Effect of Thrombin-Acute Coronary Syndromes (LANCELOT-ACS) trial included 603 patients with NSTE-ACS within 72 h, to assess safety of atopaxar (O'Donoghue et al. 2011). Participants were randomized to receive atopaxar (all received a 400 mg loading dose and were assigned to receive 50, 100, or 200 mg as a maintenance dose) or placebo. The mean age was 62 years old, and 96 % were treated with aspirin, and 82 % with clopidogrel or ticlopidine. After 12 weeks of treatment, the occurrence of CURE-defined bleeding events was similar among study groups (3.1 % in the combined atopaxar group vs. 2.2 % in the placebo group; $p = 0.63$) (Table 4). The rate of CURE major bleeding was numerically higher in the atopaxar-treated patients (1.8 vs. 0 %; $p = 0.12$). No difference was observed in the rates of TIMI-defined hemorrhages between groups (9.2 % in the combined atopaxar group vs. 10.1 % in the placebo group, $p = 0.77$). The efficacy outcome (MACE) occurred in 8.0 % of the atopaxar-treated patients and in 7.8 % of the placebo-treated patients ($p = 0.93$).

The Lessons From Antagonizing the Cellular Effect of Thrombin-Coronary Artery Disease (LANCELOT-CAD) trial aimed to investigate the safety of atopaxar on a background of aspirin or dual antiplatelet therapy with aspirin and a thienopyridine for patients with high-risk stable CAD (Wiviott et al. 2011). A total of 720 participants were randomized to receive one of the three dosing regimens of atopaxar (50, 100, or 200 mg daily) or placebo for 24 weeks, with an additional follow-up period of 4 weeks. The primary endpoint was bleeding by CURE or TIMI criteria, and the secondary endpoint was the occurrence of MACE, both through week 24. The median age was 64 years, nearly all patients were using aspirin, and approximately 40 % were under dual antiplatelet therapy with aspirin and a thienopyridine. Atopaxar increased significantly the rates of bleeding by CURE criteria when compared with placebo (3.9 % in the combined atopaxar groups vs. 0.6 % in the placebo group, HR 6.82, 95 % CI 1.17–94.0; $p = 0.03$), in a dose-dependent fashion (Table 4). A numerically higher rate of hemorrhages by TIMI definition was also observed with vorapaxar, in comparison with placebo (10.3 % atopaxar vs. 6.8 % placebo, HR 1.52, 95 % CI 0.85–2.76; $p = 0.17$), mostly due to TIMI minimal bleeding. No difference was seen regarding the rates of MACE between study arms (2.6 % atopaxar vs. 4.6 % placebo, HR 0.57, 95 % CI 0.25–1.35; $p = 0.20$).

Transient elevation of hepatic enzymes and QTc interval prolongation were observed more frequently in the atopaxar groups when compared with placebo, especially with higher

Table 4 Clinical outcomes in the LANCELOT-ACS and LANCELOT-CAD trials

Endpoints	LANCELOT-ACS		LANCELOT-CAD	
Groups	Atopaxar combined ($N = 455$) (%)	Placebo ($N = 138$) (%)	Atopaxar combined ($N = 542$) (%)	Placebo ($N = 176$) (%)
Any CURE-defined bleeding	3.1	2.2	3.9	0.6
CURE-defined major bleeding	1.8	0	0.9	0
Any TIMI-defined bleeding	9.2	10.1	10.3	6.8
MACE	8.0	7.8	2.6	4.6

doses. There are no further studies ongoing or planned for atopaxar (source ClinicalTrials.gov).

PZ-128

As we have described earlier in this chapter, PAR-1 is a G-coupled receptor. The basic mechanism of activation of G-coupled receptors is based upon intracellular domains of receptors transmitting signaling to G protein. Therefore, intracellular domains of receptors may represent targets for drugs. Pepducins are synthetic compounds aimed at modulating the interactions between intracellular portion of the receptor and G protein (O'Callaghan et al. 2012).

Pepducins are made of a lipid component attached to a peptide that resembles one of the cytoplasmic loops or the C-terminal of the G-coupled receptor (O'Callaghan et al. 2012). The lipid component of the pepducin allows the molecule to cross the cell membrane and anchors it to cytosolic side (O'Callaghan et al. 2012). The peptidic component mediates the interactions with G proteins (O'Callaghan et al. 2012). The advantage of the pepducin technology is that libraries can be produced with different sequences in order to target the receptor of interest (O'Callaghan et al. 2012). Additionally, depending on the sequences, pepducin can act as agonist or antagonist (O'Callaghan et al. 2012). Different types of pepducins targeting a wide spectrum of receptors have been developed, including PAR-1, PAR-2, and PAR-4 (O'Callaghan et al. 2012). PZ-128 is a cell-penetrating lipopeptide pepducin that targets selectively the G protein associated with the PAR-1 on the inner side of the cellular membrane (Gurbel et al. 2015). Thus, ultimately PZ-128 uncouples the activated PAR-1 with intracellular signaling leading to inhibition of PAR-1-mediated platelet activation (Gurbel et al. 2015). PZ-128 is the first-in-class intracellular PAR-1 antagonist and is being developed as intravenous drug for prevention of acute thrombotic complications of PCI. PZ-128 was studied in a recent phase I study among patients with coronary artery disease or multiple coronary artery disease risk factors (Gurbel et al. 2015). The drug was administered as 1–2 h intravenous infusion, and inhibition of PAR-1-mediated platelet aggregation was studied using the agonist SFLLRN. The inhibitory effects of PZ-128 on platelet aggregation stimulated by SFLLRN were dose dependent with doses between 0.5 and 2 mg/kg. At 30 min 50–84 % inhibition of platelet aggregation was observed and was sustained to 6 h. At 24 h a 50 % recovery of platelet aggregation to SFLLRN was observed. Concomitant aspirin use greatly enhanced inhibition of platelet aggregation to SFLLRN, at the 0.5 mg/kg dose group. No significant effects on aggregation stimulated by a PAR-4 agonist, ADP, or collagen were seen, and no effects on bleeding time, PTT, international normalized ratio, and activated clotting time were observed. The plasma half-life of PZ-128 was 1.3–1.8 h, and no drug was detected in the urine. Given the fast onset of action and relatively short duration of action, PZ-128 represents an interesting intravenous antiplatelet agent, which warrants further investigation. A study of PZ-128 in subjects undergoing non-emergent PCI is currently planned (ClinicalTrials.gov NCT02561000).

PAR-4 Antagonists

Selective PAR-4 antagonists are being developed. The oral PAR-4 antagonist BMS-986141 (Bristol-Myers Squibb) will be investigated in a phase II trial in additional to aspirin for the prevention of brain infarction in patients with recent (<48 h) stroke or TIA (ClinicalTrials.gov NCT02671461). The study is currently planned to complete in mid-2018.

Conclusion

Thrombin is a known potent platelet activator, and inhibition of thrombin-mediated platelet activation thorough PAR-1 receptor antagonism is a novel mechanism to inhibit platelet aggregation and reduce thrombotic-mediated cardiovascular events. Data from large phase III clinical trials, in particular the TRA 2P-TIMI 50 trial, have confirmed that PAR-1 antagonisms with vorapaxar translate in the reduction of clinical events. This trial demonstrated a significant reduction in the rates of ischemic outcomes with vorapaxar in the secondary prevention among patients with recent MI or PAD, but without prior stroke or TIA, at the expense of an increase in major bleeding. The post-MI population appeared to benefit the most in terms of reduced cardiovascular outcomes, but intriguing effects on reduction in acute limb ischemia and need for peripheral revascularization were observed in patients with PAD treated with vorapaxar. The results of the TRA 2P study lead to the approval of vorapaxar for secondary prevention in patients with previous MI (USA and EU) or PAD (USA only) and without history of stroke or intracranial bleeding. Further research may address the role of vorapaxar in the setting of different antiplatelet strategies and different populations. Furthermore new PAR-1 antagonists are in development, and we will learn more about those drugs as new clinical studies are completed.

Take-Home Messages

Thrombin is the most potent platelet activator, and it acts through protease-activated receptors (PARs).

PAR-1 and PAR-4 are the thrombin receptors on human platelets, and PAR-1 is considered the main receptor because it is activated by low concentrations of thrombin, while the role of PAR-4 is not fully understood.

Animal studies suggested that impairment of PAR pathways did not result in significant bleeding tendency, thus supporting the hypothesis that PAR antagonism could result in antithrombotic effects and reduced bleeding liability.

Vorapaxar is an oral, highly selective, potent PAR-1 antagonist which significantly inhibits ex vivo platelet aggregation mediated to TRAP.

Vorapaxar was compared to placebo in two large phase III clinical trials, the TRACER trial in NSTE-ACS and the TRA 2P-TIMI 50, in secondary prevention among patients with recent MI, stroke, or PAD.

In both trials vorapaxar was studied in addition to standard of care, which largely included dual antiplatelet therapy with aspirin and clopidogrel.

The TRACER trial did not meet the primary endpoint, and a reduction in myocardial infarction was observed at the expense of increased risk in major bleeding and ICH.

The TRA 2P-TIMI 50 trial demonstrated that vorapaxar significantly reduced cardiovascular death, myocardial infarction, or stroke, in patients with prior MI or PAD and without history of stroke/TIA, at the expense of increased risk in major bleeding.

Vorapaxar (2.08 mg once daily equivalent to 2.5 mg vorapaxar sulfate) is approved for secondary prevention in patients with history of MI (USA and EU) or with PAD (USA only) and without history of stroke or TIA.

Atopaxar, another oral PAR-1, has been studied in phase II trials and has not been further developed.

Other PAR antagonists are currently in early-phase investigation, including the intravenous PAR-1 antagonist pepducin PZ-128 and the oral PAR-4 antagonist BMS-986141.

Inhibitors of Platelet Adhesion to VWF and Collagen

Claudia Tersteeg, Simon F. De Meyer, and Hans Deckmyn

Abstract

Platelets play an essential role in thrombotic and hemostatic processes. Upon injury, platelets first adhere to the exposed extracellular matrix, predominantly via interactions with collagen and von Willebrand factor (VWF), resulting in hemostatic plug formation. Uncontrolled thrombus formation however results in occlusive complications leading to, e.g., myocardial infarction and ischemic stroke. New and more targeted antiplatelet therapies are essential to prevent such thrombotic complications. In this chapter, we describe different compounds that inhibit initial platelet adhesion. These include compounds that interfere with binding of VWF to collagen or platelet glycoprotein (GP) Ib and molecules that prevent platelet adhesion to collagen via blockade of either GPVI or integrin $\alpha_2\beta_1$. Results from the different preclinical animal and clinical patient studies demonstrate that inhibition of these interactions holds great promise as an antithrombotic strategy without significant increase of the bleeding risk.

Introduction

Vascular injury recruits platelets toward the exposed subendothelial extracellular matrix, of which collagen is the main thrombogenic component. Stable platelet adhesion to the extracellular matrix occurs in the order of tethering, rolling, activation, and firm adhesion and is depending on different platelet receptors. After immobilization of plasma VWF to exposed collagen fibers via the collagen-binding sites in the VWF A1 and A3 domains (Lankhof et al. 1996; Hoylaerts et al. 1997), high shear forces expose the cryptic platelet-binding epitope in the VWF A1 domain (structure of VWF illustrated in Fig. 1). As a result, VWF captures platelets via interaction of the A1 domain and the platelet glycoprotein (GP) Ibα receptor (Siedlecki et al. 1996). This induces tethering and rolling of platelets over the damaged vessel wall, but is not sufficient for stable platelet adhesion. Interaction with VWF brings platelets into close contact with exposed collagen allowing firm adhesion and subsequent activation by collagen via the two major platelet collagen receptors GPVI and integrin $\alpha_2\beta_1$. Thrombus formation is further propagated via α- and dense granule release, activation of integrin $\alpha_{IIb}\beta_3$, and facilitating a procoagulant surface for activation of the coagulation cascade. In healthy individuals, this controlled process results in the repair of the vascular injury, with maintenance of the normal blood flow through the vessel. However, uncontrolled thrombus formation might result in complete occlusion of the vessel, resulting in downstream tissue becoming ischemic. Myocardial infarction and ischemic strokes are examples of consequences of uncontrolled thrombus formation and are a major cause of death in the Western society. In this chapter, we focus on preclinical animal studies and clinical patient studies using inhibitors targeting the major platelet adhesion receptors GPIb, GPVI, and integrin $\alpha_2\beta_1$, as well as the main proteins involved in primary platelet adhesion, collagen and VWF.

The VWF–Collagen Interaction

VWF binds to collagen mainly via its A3 domain. Additionally, collagen, especially types IV and VI, can bind to the VWF A1 domain, which in addition is the domain responsible for platelet GPIb binding. A number of patients have been described with mutations in either the A3 or A1 domain that affect the binding to collagen (Flood et al. 2015). Interestingly, these mutations are not associated with a severe bleeding phenotype, suggesting that targeting this interaction might be relatively safe in terms of bleeding risk. Similarly, expression of a nonfunctional VWF A3 mutant in *Vwf*$^{-/-}$ mice resulted in delayed thrombus growth without affecting the bleeding time (Marx et al. 2008). Also in a mouse model of ischemic stroke, reconstitution of *Vwf*$^{-/-}$ mice with a VWF mutant defective in binding to collagen resulted in less ischemic stroke damage than in mice reconstituted with fully functional VWF, again without increase of bleeding (De Meyer et al. 2010). All these findings strongly suggest that interfering with VWF–collagen interaction might have a beneficial effect on thrombosis with little effect on bleeding. Hence, a number of inhibitory antibodies against the human VWF A3 domain have been tested in animal models.

Inhibitors of the Collagen–VWF Interaction that Bind to VWF

To overcome the problem that some inhibitory anti-VWF antibodies do not cross-react with murine VWF, Navarrete et al. expressed a mutant human VWF that can interact with murine GPIb in *Vwf*$^{-/-}$ mice (Navarrete et al. 2012). In this setup, inhibitory antihuman VWF A3 monoclonal antibodies (mAb), mAb505 and mAb203, significantly delayed vessel occlusion in arterioles, whereas no effect was seen in veins. This highlights the role of VWF A3 in arterial thrombosis and the antithrombotic potential of inhibiting the interaction between VWF A3 and collagen.

The antihuman VWF A3 mAb 82D6A3 was tested in a modified Folts model in baboons, where cyclic flow reductions due to thrombus formation were induced by mechanical injury followed by stenosis applied to the femoral artery (Wu et al. 2002b). An intravenous bolus injection did result in abolition of thrombus formation, without a marked effect on the bleeding time. The same antibody however did not have an effect on in-stent stenosis in baboons, pointing out that collagen–VWF binding has little impact on this process (De Meyer et al. 2007). 82D6A3 was humanized by variable domain resurfacing and grafting on the constant region of human IgG4, resulting in an antibody with similar in vitro affinities and activities as the murine one (Staelens et al. 2006). Also the antihuman VWF mAb SZ-123 was tested for its effects on cyclic flow reductions in the femoral artery of rhesus monkeys where injection of SZ-123 resulted in 100 % prevention of cyclic flow reductions without significant prolongation of bleeding time (Zhao et al. 2013). SZ-123 however is an antibody with dual action since in vitro and ex vivo experiments revealed that SZ-123 also indirectly inhibits ristocetin-induced VWF A1 binding to GPIbα.

Inhibitors of the Collagen–VWF Interaction that Bind to Collagen

Apart from compounds that inhibit VWF–collagen interaction by blocking VWF, also a number of collagen binders have been tested in vivo. In collagen III, a single high-affinity binding site for VWF was identified with RGQOGVMGF (O is hydroxyproline) as the minimal VWF-binding sequence (Lisman et al. 2006). So far, and somewhat surprisingly, inhibitory collagen binders were essentially isolated from hematophagous animals such as leeches, mosquitos, and blackflies. And as collagen binders, they usually have multiple effects, as most of them tend to inhibit both VWF and platelet integrin $\alpha_2\beta_1$ and/or GPVI binding. Simplagrin was derived from the salivary glands of the blackfly *Simulium nigrimanum* and binds to collagen (types I–VI) with high affinity (2–15 nM) (Chagas et al. 2014). In contrast to the other collagen binders, Simplagrin specifically inhibits VWF interaction with collagen type III and indeed binds to the RGQOGVMGF peptide with a similar affinity (11 nM) as to collagen. It furthermore

completely blocks platelet adhesion to collagen under flow conditions at high shear rates, without blocking GPVI or integrin $\alpha_2\beta_1$ interaction to collagen (Chagas et al. 2014). In mice, Simplagrin prevented laser-induced carotid thrombus formation without significant bleeding (Chagas et al. 2014).

Also aegyptin, a mosquito salivary gland protein, binds with high affinity (5 nM) to RGQOGVMGF and with lower affinity (μM range) to the peptides $(GPO)_{10}$ and GFOGER which, respectively, represent GPVI and $\alpha_2\beta_1$-binding sites in collagen (Calvo et al. 2010). Aegyptin prevents photochemically laser-induced carotid artery thrombus formation in the presence of Rose Bengal in rats, without significant bleeding, and protects mice from collagen- and epinephrine-induced (VWF-independent) thromboembolism (Mizurini et al. 2013).

The collagen-binding leech antiplatelet protein (LAPP) was isolated (Connolly et al. 1992) and cloned (Keller et al. 1992) from the leech *Haementeria officinalis* and inhibits both VWF and integrin $\alpha_2\beta_1$ binding to collagens I, III, and IV (van Zanten et al. 1995). However, LAPP had no effect in vivo on either collagen graft thrombosis in baboons (Schaffer et al. 1993) or on platelet deposition in an atherosclerotic rabbit model of angioplastic injury (Lyle et al. 1995).

Calin on the other hand was extracted from the saliva of the medicinal leech *Hirudo medicinalis* as a collagen binder (Munro et al. 1991). This compound also prevents both VWF and platelet $\alpha_2\beta_1$ binding to collagen (Harsfalvi et al. 1995; Depraetere et al. 1999) but, in contrast to LAPP, did have antithrombotic effects in vivo, as it prevented platelet deposition in the traumatized femoral vein of hamsters. No effects were seen on the skin bleeding time in the treated hamsters and also not when calin was applied topically in a standardized skin incision in hamsters or baboons (Deckmyn et al. 1995). By a direct comparison between LAPP and calin, it was suggested that the difference could maybe be ascribed to calin actually still consisting of two different inhibitors (Depraetere et al. 1999), and indeed later on saratin was isolated from the *H. medicinalis* saliva, cloned and expressed as a specific inhibitor of the VWF–collagen interaction (Barnes et al. 2001) although somewhat conflicting evidence was provided that saratin also is able to inhibit $\alpha_2\beta_1$ binding to collagen (White et al. 2007). Whatever the exact mechanism, topical application of saratin reduced platelet deposition and intimal hyperplasia in a rat carotid endarterectomy model (Cruz et al. 2001).

Interfering with the Interaction Between VWF and GPIb

As described above, the interaction between the VWF A1 domain and platelet GPIb is crucial for initial platelet adhesion at sites of vascular injury. As a result, the GPIb–VWF axis has become an attractive target for the development of new antithrombotic compounds. During the last decade, several agents that interfere with the GPIb–VWF interaction have been characterized, and some of these have already entered the first clinical trials.

Blocking the GPIb-Binding Site in the VWF A1 Domain

Back in 1997, Kageyama et al. prepared antihuman VWF antibodies in mice and selected the IgG AJvW2 with a conformational epitope in the VWF A1 domain (Kageyama et al. 1997). AJvW2 exerts a strong inhibitory effect on the interaction between VWF and GIPb as shown by impaired ex vivo VWF-mediated platelet adhesion and agglutination (Kageyama et al. 1997; Yamamoto et al. 1998). When used in canine and guinea pig models, AJvW2 abolished thrombus formation and showed a superior bleeding safety profile compared to antagonists of integrin $\alpha_{IIb}\beta_3$ (Kageyama et al. 1997, 2001). A humanized version of AJvW2 (AJVW200) was next generated, which also effectively inhibited thrombus formation in dogs, again with a safer bleeding profile than integrin $\alpha_{IIb}\beta_3$ inhibitors (Kageyama et al. 2002a, b). More recently, AJW200 was shown to reduce also venous thrombus formation and pulmonary thromboembolism in a rabbit model of venous thromboembolism (Takahashi et al. 2009). Moreover, in a rabbit embolic stroke model, administration of AJW200 with low-dose tPA was synergistic and resulted in significantly improved behavioral function following embolic stroke, showing the potential of VWF–GPIb inhibitors in thrombolytic therapy (Lapchack et al. 2013). In a first clinical study in 2003, AJW200 was well tolerated in human volunteers without bleeding complications (Machin et al. 2003), but no new clinical follow-up studies have been reported since then.

A second inhibitor that binds to the VWF A1 domain is GPG-290, a homodimeric recombinant fragment of human GPIbα. It is composed of the first 290 amino acids and conjugated to human IgG1Fc to form a homodimer. Two gain-of-function mutations (G233V/M239V) give GPG-290 an enhanced affinity for the VWF A1 domain. Because binding of GPG-290 to VWF inhibits the VWF–GPIb interaction, GPG-290 has been shown to exert antithrombotic activity in preclinical murine and canine models of arterial and venous thrombosis with a bleeding safety profile that was superior to clopidogrel (Hennan et al. 2006; Wadanoli et al. 2007; Brill et al. 2011).

Aptamers are nucleic acid macromolecules with a high affinity for a specific molecular target. The aptamer ARC1779 is a 40-nucleotide DNA/RNA aptamer that binds to the VWF A1 domain, thereby inhibiting the interaction between VWF and GPIb. The antithrombotic activity of

ARC1779 was demonstrated in several preclinical settings. ARC1779 reduced adhesion of platelets to collagen-coated matrices, formation of platelet thrombi on denuded porcine arteries, and formation of occlusive thrombi in cynomolgus monkeys (Diener et al. 2009). In a Phase I trial, ARC1779 was well tolerated in healthy volunteers. In a subsequent Phase II trial, ARC1779 effectively increased platelet counts in critically ill patients with thrombotic thrombocytopenic purpura by blocking spontaneous VWF-mediated platelet aggregation (Knobl et al. 2009; Jilma-Stohlawetz et al. 2011; Cataland et al. 2012). Since desmopressin aggravates thrombocytopenia in type 2B von Willebrand disease by the release of large and hyper-adhesive VWF multimers, Jilma et al. investigated whether ARC1779 can prevent desmopressin-induced thrombocytopenia in these patients, which was indeed the case (Jilma et al. 2010). Administration of ARC1779 led to reduced cerebral emboli signals in patients undergoing carotid endarterectomy (Markus et al. 2011).

Nanobodies are a novel class of therapeutic proteins, based on the smallest functional fragments of single-chain antibodies derived from the Camelidae family. They combine the advantages of conventional antibodies with important features of small-molecule drugs and are being developed for a range of diseases. ALX-0081 (later named caplacizumab) is a bivalent nanobody directed toward the A1 domain of VWF that specifically blocks the interaction of VWF with GPIb. ALX-0081 exerts potent activity in vitro and in vivo. Perfusion experiments with blood from patients with acute coronary syndrome demonstrated complete inhibition of platelet adhesion after addition of ALX-0081 (Ulrichts et al. 2011). In a modified Folts model in the baboon femoral artery, the in vivo efficacy and safety, reflected by the inhibition of thrombus formation and surgical bleeding, respectively, were assessed, and ALX-0081 showed a superior therapeutic window compared to clopidogrel and abciximab. The addition of a standard therapeutic combination of heparin, aspirin, and clopidogrel to ALX-0081 did not further enhance efficacy as compared to ALX-0081 monotherapy, but also did not increase surgical bleeding tendency (Ulrichts et al. 2011). Interestingly, ALX-0081 prevented thrombosis in the middle cerebral artery of guinea pigs and induced cerebral reperfusion when given immediately after or 15 min after complete occlusion, thereby reducing brain damage without inducing hemorrhage (Momi et al. 2013). In a Phase I single-center, double-blind, randomized, placebo-controlled study, the nanobody was well tolerated and safe in healthy volunteers (Bartunek et al. 2008). In a subsequent Phase I double-blind, randomized, placebo-controlled study, ALX-0081 was further evaluated in patients with stable angina undergoing PCI. In this study, multiple dosing of ALX-0081 resulted in sustained inhibition of VWF-mediated platelet aggregation without increasing the bleeding risk albeit that patients received standard therapy consisting of aspirin, clopidogrel, and heparin (Bartunek et al. 2010).

In the recent TITAN trial, a randomized, placebo-controlled, single-blind, parallel design study, caplacizumab improved standard of care of patients affected with acquired thrombotic thrombocytopenic purpura by a more rapid normalization of platelet numbers and lower occurrence of exacerbations with manageable side effects and bleeding episodes (Peyvandi et al. 2015). A Phase III "HERCULES" study has been initiated, which will further evaluate the efficacy and safety of caplacizumab in patients with acquired thrombotic thrombocytopenic purpura when administered in addition to the standard of care (ClinicalTrials.gov identifier: NCT02553317).

ADAMTS13: Reducing the Size and Activity of VWF

Besides blocking the platelet-binding site on VWF, another way to limit VWF activity is decreasing its size as indeed VWF activity is positively correlated with multimer size. Ultralarge VWF multimers are hyperactive and particularly thrombogenic and are released from endothelial cells and platelets upon stimulation with various secretagogues. To prevent spontaneous thrombosis, ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin type 1 repeats, member 13) cleaves the Y1605–M1606 bond in the VWF A2 domain, resulting in digestion of ultralarge VWF into smaller, less reactive molecules. Somewhat unexpected, also the carboxyl terminal domains of ADAMTS13 on their own, in the absence of the proteolytic metalloproteinase domain, were shown to directly inhibit thrombus formation (Bao et al. 2014). A deficiency of ADAMTS13 is associated with the devastating disease thrombotic thrombocytopenic purpura caused by VWF-mediated microvascular thrombosis. The antithrombotic potential of ADAMTS13 was demonstrated in various settings. Chauhan et al. showed that ADAMTS13 downregulates both platelet adhesion to exposed subendothelium and thrombus formation in injured murine arterioles and venules, demonstrating the natural antithrombotic activity of ADAMTS13 (Chauhan et al. 2006). The antithrombotic role of ADAMTS13 in venous thrombosis was recently confirmed as mice deficient for ADAMTS13 formed larger venous thrombi than wild-type mice (Tashima et al. 2015). Recombinant ADAMTS13 is being developed as a new therapeutic agent and has been shown to exert a protective role in mouse models of ischemic stroke (Zhao et al. 2009; Fujioka et al. 2010) and myocardial infarction (De Meyer et al. 2012; Gandhi et al. 2012).

Blocking the VWF-Binding Site on GPIbα

A recombinant fragment of VWF, VCL, was made with the intention to compete with VWF for binding to GPIb, and thereby decrease thrombus formation. VLC consists of VWF Leu-504–Lys-728, with a single intrachain disulfide bond linking residues Cys-509–Cys-695 (Gralnick et al. 1992). In an electrical injury-induced thrombosis model in dogs, it was demonstrated that VLC increased time to occlusion in coronary arteries (Yao et al. 1994). In a baboon model, VLC effectively abolished cyclic flow variations in stenosed, endothelium-injured coronary arteries (McGhie et al. 1994).

Our group generated and characterized the antihuman GPIb mAb 6B4 (Cauwenberghs et al. 2001), which has an epitope in GPIbα that consists of two sets of peptide sequences aligning within Lys-230–Val-242 and Tyr-259–Gly-262 resulting in an efficient inhibition of the VWF–GPIb interaction (Cauwenberghs et al. 2001). When injected into baboons, intact 6B4 IgG and its F(ab′)2 fragments caused almost immediate thrombocytopenia, whereas injection of the Fab fragments alone did not. Baboons pretreated with 6B4 Fab fragments showed significantly reduced platelet deposition onto the collagen-rich bovine pericardium (Cauwenberghs et al. 2000). These findings were extended by investigating the efficacy of 6B4 Fab fragments in high shear conditions using a modified Folts model in baboons, in comparison with an integrin $\alpha_{IIb}\beta_3$ antagonist (Wu et al. 2002a). Administration of lower doses of 6B4 Fab significantly reduced the cyclic flow reductions, whereas higher doses completely abolished the cyclic flow reductions without prolongation of the bleeding time. In this study, an anti-$\alpha_{IIb}\beta_3$ antibody also inhibited occlusive thrombus formation but induced a significant prolongation of the bleeding time. Later, a fully recombinant and humanized version of 6B4 Fab fragment was generated and characterized (Fontayne et al. 2006) and maintained its inhibitory capacities in vitro and in vivo in baboons (Fontayne et al. 2008).

Additionally, anfibatide, purified from the venom of the snake *Agkistrodon acutus*, was found to be able to bind GPIb, thereby inhibiting VWF binding. Anfibatide prevented thrombosis and vessel occlusion in murine laser-injured cremaster arteries and $FeCl_3$-injured mesenteric arteries (Lei et al. 2014). Moreover, in a murine model of ischemic stroke, anfibatide had a protective effect on cerebral ischemia and reperfusion injury (Li et al. 2015), confirming earlier studies that highlight the importance of the VWF–GPIb interaction in ischemic stroke (Kleinschnitz et al. 2007; De Meyer et al. 2010; Verhenne et al. 2015).

Inhibition of the GPVI–Collagen Interaction

Glycoprotein VI is a receptor only present on platelets and megakaryocytes, hence making it a very specific target for antithrombotic therapy. The transmembrane region of GPVI is constitutively associated with the Fc receptor γ (FcRγ) chain. This FcRγ chain is essential for the function of GPVI as it is required for GPVI expression, as well as for signal transduction via the immunoreceptor tyrosine-based activation motif (ITAM) and subsequent activation of tyrosine kinase Syk which initiates the downstream signaling cascade (Berlanga et al. 2002). GPVI is present on the platelet in both a monomeric as well as a dimeric form (Dütting et al. 2012). The ligand for GPVI is collagen, with only the dimeric form of GPVI having a high binding affinity. Recent literature however demonstrated that GPVI is also a receptor for polymerized fibrin and that it plays an important role in the thrombus growth and stability by enhancing thrombin generation and the recruitment of new platelets (Mammadova-Bach et al. 2015; Alshehri et al. 2015). Downregulation of platelet reactivity is mediated by GPVI shedding, thus limiting platelet activation during prothrombotic conditions. Shedding of the GPVI ectodomain is mediated by proteolytic activity of ADAM10, a.o. following GPVI cross-linking with and activation of FcRIIa by (auto)antibodies and elevated shear stress (Gardiner and Andrews 2014).

A deficiency in GPVI does not induce a high bleeding risk, again emphasizing its potential as an efficient antithrombotic target. Patients with GPVI deficiency due to genetic mutations or receptor loss via autoantibodies (Moroi et al. 1989; Boylan et al. 2004) only have a mild bleeding disorder; however, platelet aggregation using collagen as an agonist is impaired. Accordingly, mice, in which GPVI function was blocked, present with only a moderately increased tail bleeding time but do have a diminished arterial thrombus formation (Nieswandt et al. 2001; Kato et al. 2003; Bender et al. 2011). These results demonstrate an essential role for GPVI in arterial thrombus formation, however, less so in hemostasis. Additionally, GPVI depletion in mice resulted in reduced brain infarct volume in a transient middle cerebral artery occlusion model for transient ischemic stroke (Kleinschnitz et al. 2007; Kraft et al. 2015). Based on these results, it is expected that targeting GPVI in patients would give a minor bleeding risk, but a strong inhibition of thrombotic processes.

Blockade of GPVI

Targeting of GPVI was done by monoclonal antibodies, Fab fragments, and fusion proteins. Some antibodies can shed

GPVI from the surface of platelets, whereas others only block the interaction with collagen. Monoclonal antibodies from the JAQ family are capable of removing GPVI from the surface of murine platelets, resulting in a GPVI knockout phenotype, associated with protection against lethal thromboembolism with only a mild increased bleeding time (Nieswandt et al. 2001). The antibodies induce a temporary decrease in platelet count at day 1 postinjection, which is completely recovered at day 3 (Nieswandt et al. 2001). The monoclonal antibody F1232 also depletes GPVI from monkey platelets, however, without causing thrombocytopenia (Takayama et al. 2008). This is promising as GPVI apparently can be depleted without the unwanted decrease in platelet count, which is important indeed, as depletion of GPVI by monoclonal antibodies in combination with the absence of integrin $\alpha_2\beta_1$ or with aspirin treatment severely prolonged the bleeding time in mice (Grüner et al. 2004). It might therefore be indicated to monitor the functioning of other receptors before depletion of GPVI as a therapeutic strategy.

Next, Fab fragments were generated from anti-GPVI antibodies. Fab fragments cannot cross-link GPVI receptors or GPVI with the platelet Fc receptor FcRIIa, and hence no longer induce GPVI shedding, but only block its binding site. Administration of Fab fragments OM2 and OM4 inhibited ex vivo aggregation in cynomolgus monkeys and decreased the number of occlusions in a model of cyclic reduction of carotid flow in rats, whereas no increase in bleeding time was observed (Matsumoto et al. 2006; Li et al. 2007). The Fab fragment of mAb 9O12.2 equally inhibited platelet responses toward collagen ex vivo after administration to cynomolgus monkeys (Ohlmann et al. 2008). In a humanized GPVI mouse model, this Fab fragment furthermore prevented lethal thromboembolism and arterial thrombosis (Mangin et al. 2012).

The most advanced GPVI blocking strategy at present is based on the use of a soluble dimeric GPVI-Fc fusion protein. These fusion proteins mimic the dimeric structure of GPVI and therefore compete with platelet GPVI for collagen binding. In vivo, dimeric GPVI-Fc decreased thrombus formation in injured mouse carotid arteries (Massberg et al. 2004; Bültmann et al. 2006) and prevented occlusive thrombus formation and reduced infarct size after ischemic stroke in mice (Goebel et al. 2013), without influencing the bleeding time (Ungerer et al. 2013). Furthermore, the fusion protein reduced myocardial infarct size and resulted in an increased cardiac function after myocardial infarction in mice (Schönberger et al. 2012). The fusion protein was taken to clinical trial as revacept and demonstrated safety and tolerability in a Phase I clinical trial (Ungerer et al. 2011). Currently, a Phase II clinical trial is ongoing where patients with carotid artery stenosis, transient ischemic attacks, amaurosis fugax, and stroke are treated with either revacept plus antiplatelet monotherapy or monotherapy alone (ClinicalTrials.gov identifier: NCT01645306). Readouts include the incidence of microembolic signals, cerebral lesion analysis, clinical end point, and cardiovascular outcomes, and the study is expected to be finalized at the end of 2017. One aspect that might influence the study outcome might be the dosing, as the amount of exposed collagen is not known and not equal in each patient. Even though revacept seems very promising as a future antithrombotic drug, conflicting results were obtained with another dimeric GPVI-Fc fusion protein, where no antithrombotic effects were observed following vigorous ligation injury of the right common carotid artery in the mice (Grüner et al. 2005).

GPVI was also targeted by using EXP3179, an active metabolite of the angiotensin II type 1 receptor antagonist losartan. This drug inhibited GPVI-dependent platelet aggregation and reduced platelet adhesion after acute vessel injury in mice (Grothusen et al. 2007). This effect was achieved by preventing GPVI clustering (Jiang et al. 2015). However, when the drug was administered to patients, no effect on GPVI-dependent platelet aggregation was observed between treated and controls (Jiang et al. 2015). Further targeting the downstream signaling pathway of GPVI is also a possible way of inhibiting GPVI. Syk inhibitor PRT318 targets the GPVI/FcRγ-chain signaling that activates the tyrosine kinase Syk and by this prevents thrombosis in mice (Reilly et al. 2011). However, this inhibitor is not platelet specific as Syk and other components of the downstream signaling are clearly also important in other cells and cellular processes.

Inhibition of Integrin α2β1

Next to GPVI, the other major platelet collagen receptor integrin $\alpha_2\beta_1$ has been investigated as a target for antiplatelet treatment. Integrin $\alpha_2\beta_1$, also known as GPIa/IIa, very late (activation) antigen (VLA)-2/beta, or CD49b/CD29, is a receptor for a number of matrix and non-matrix ligands, including collagens, laminins, tenascins, decorin, E-cadherin, matrix metalloproteinase-1, endorepellin, and several viruses. The $\alpha_2\beta_1$ integrin is expressed on a whole series of cell types, including epithelial and endothelial cells, fibroblasts, specific subsets of leukocytes, and indeed platelets (Madamanchi et al. 2014). It is clear from this list that inhibition of integrin $\alpha_2\beta_1$ might have a considerable number of effects other than merely inhibition of platelet interaction with collagen.

A series of direct and allosteric inhibitors of integrin $\alpha_2\beta_1$ were isolated from snake venoms, hookworms, or herbs (Deckmyn et al. 2012). Also monoclonal antibodies were raised, and peptidomimetics and small molecules were developed (Käpylä et al. 2007; Choi et al. 2007; Nissinen

et al. 2010; Momic et al. 2015). And indeed, in animal models where integrin $\alpha_2\beta_1$ has been inhibited using specific inhibitory monoclonal antibodies or small molecules, a variety of effects was observed including dampening of inflammation responses in wound healing and fibrosis, acceleration of (cancer-related) angiogenesis, or defects in innate immunity (Madamanchi et al. 2014). Vatelizumab, a monoclonal antibody against integrin $\alpha_2\beta_1$, finally is in Phase II clinical trials for acute relapse in multiple sclerosis (ClinicalTrials.gov identifier: NCT02222948).

Nevertheless, targeting $\alpha_2\beta_1$ as an antithrombotic strategy remains attractive, as on the one hand overexpression of $\alpha_2\beta_1$ on human platelets is associated with enhanced thrombotic risk (Moshfegh et al. 1999; Santoso et al. 1999; Carlsson et al. 1999) and, on the other hand, as $\alpha 2\beta 1^{-/-}$ mice have reduced thrombus size in experimental models (He et al. 2003; Kuijpers et al. 2007) with only a mild bleeding tendency (Holtkötter et al. 2002), which was also observed in a patient with an inhibitory autoantibody (Deckmyn et al. 1990). In vivo, evidence for an antithrombotic potential of inhibitors of $\alpha_2\beta_1$ was demonstrated by using small-molecule "compound 15," consisting of a structurally optimized 2,3-diaminoproprionic acid (DAP) moiety combined with benzenesulfonyl-propyl-phenylalanine that significantly reduced thrombus formation in the $FeCl_3$-damaged right carotid artery in mice (Miller et al. 2009). Similarly, BTT-3016, a sulfonamide derivative, was antithrombotic in a mouse model of laser-induced injury to the common carotid artery, with the tail bleeding time prolonged comparable to the effect seen with aspirin (Nissinen et al. 2010).

Discussion and Conclusion

An ideal antiplatelet drug should be able to inhibit platelet adhesion and/or subsequent activation, without inducing major bleeding complications. Blockade of the VWF and/or collagen axis is therefore an attractive therapy, as this would prevent the initial steps of platelet tethering, rolling, and adhesion on the injured vessel wall. The search for clinically applicable compounds has led to the identification of several interesting and promising therapeutic opportunities, from inhibitory antibodies, soluble receptor fragments, and proteins from snake venoms or hematophagous animals to small molecules (summarized in Fig. 2).

The first step of the primary hemostatic response includes the adhesion of plasma VWF to subendothelial collagen, and all available evidence indicates that inhibiting the VWF–collagen interaction represents an effective target to prevent thrombosis without inducing bleeding. However, the inhibitory antibodies did not enter clinical trials, and inhibitory collagen binders isolated from hematophagous animals are not always specific enough for targeted inhibition. These compounds might therefore be less prone for direct clinical application; however, their encouraging effect on preventing experimental thrombosis supports further study.

Next, circulating platelets are captured by immobilized VWF via their GPIbα receptor resulting in tethering and rolling of the platelets. Several interesting compounds have been tested and again showed promising results. With ALX-0081 (caplacizumab) in a clinical trial for thrombotic thrombocytopenic purpura, it will soon become clear whether inhibition of the GPIb–VWF interaction can live

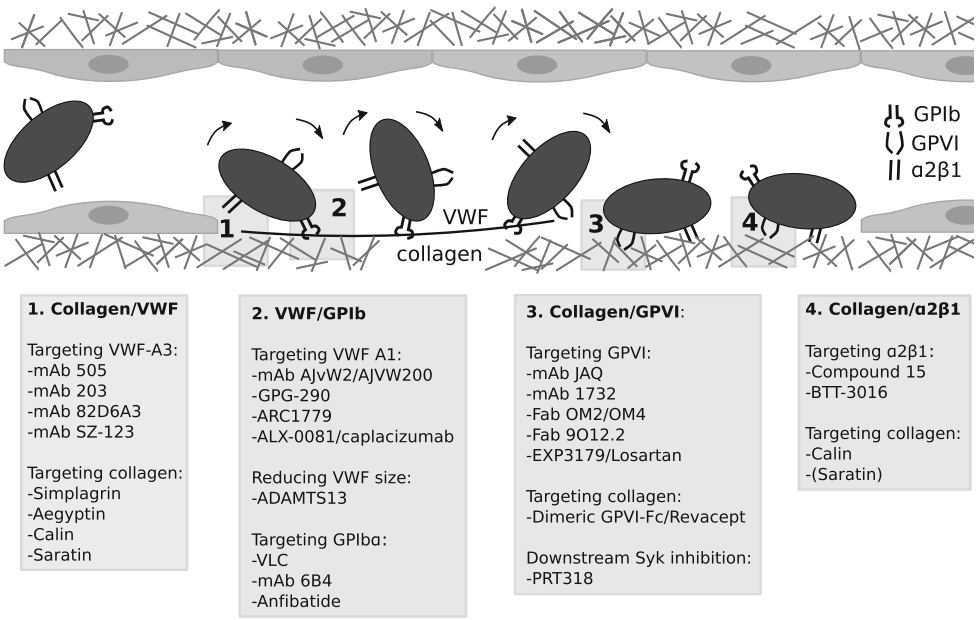

Fig. 2 Overview of inhibitors of platelet adhesion to VWF and collagen for which evidence for in vivo antithrombotic effect is available

up to the expectations with hopeful opportunities for future antithrombotic therapy.

Subsequently, tethering and rolling platelets firmly adhere to collagen via mainly GPVI and integrin $\alpha_2\beta_1$. Based on the results of (pre)clinical studies, GPVI is a promising target for patients with thrombotic complications. The specificity of the GPVI receptor toward the megakaryocyte lineage, the positive results obtained in different studies blocking the GPVI–collagen interaction, and the minimal impact on hemostasis make this an excellent antiplatelet target. With the soluble dimeric GPVI-Fc fusion protein revacept currently in Phase II clinical trial, a future new treatment strategy based on inhibition GPVI–collagen binding might be clinically available soon. As far as integrin $\alpha_2\beta_1$ is concerned, however, relatively limited research has been performed on the potential of targeting this integrin in vivo as an antithrombotic therapy. Nevertheless, even though this receptor is not specific for platelets, it remains an attractive strategy for future research as also here antagonists were able to inhibit thrombus formation without inducing major bleeding complications.

In conclusion, the interactions of VWF and/or collagen with platelets are promising targets for antithrombotic therapy. From preclinical animal studies and clinical patient studies, the accumulated evidence clearly indicates that inhibiting these interactions results in a potent antithrombotic effect without major bleeding episodes. Many of the discussed strategies therefore have the potential to improve the treatment of vascular disease and thrombotic complications in the future.

Take-Home Messages

1. *Inhibition of the VWF–collagen interaction*:
   - The use of monoclonal antibodies inhibiting the VWF–collagen interaction, decreased experimental thrombus formation in vivo; however, they did not enter clinical trials yet.
   - Inhibitors derived from hematophagous animals have potential as antithrombotic medication but sometimes lack specificity.
2. *Inhibition of the VWF–GPIb binding*:
   - Blocking the VWF–GPIb binding using the aptamer ARC1779 or the nanobody ALX-0081 (caplacizumab) shows promising results in the treatment of thrombotic thrombocytopenic purpura.
   - Recombinant ADAMTS13 exerts a protective role in in vivo models of ischemic stroke, myocardial infarction, and thrombotic thrombocytopenic purpura.
3. *Inhibition of the GPVI–collagen interaction*:
   - The soluble GPVI-Fc fusion protein revacept prevents occlusive thrombus formation and currently is being tested in clinical trials.
4. *Inhibition of integrin $\alpha_2\beta_1$ binding to collagen*:
   - Limited research has been performed on targeting this receptor as an antithrombotic therapy.

Pharmacogenomics of Antiplatelet Drugs

Chiara Cerletti, Benedetta Izzi, Licia Iacoviello, and Giovanni de Gaetano

Abstract

Pharmacogenomics might contribute to the individual response variability to antiplatelet drugs (particularly aspirin and clopidogrel) in patients with ischemic coronary or cerebral vascular disease in terms of both therapeutic and adverse effects. Over the last two decades, a large number of studies and several meta-analyses on the possible genomic regulation of common "polygenic" ischemic cardio- and cerebrovascular diseases have been published. These studies have identified numerous DNA variants as disease or antiplatelet drug susceptibility markers. Some of these DNA variants confer a variable increase in risk for disease, while loss-of-function variants in the hepatic *CYP2C19* system have been reported to be the predominant genetic mediators of clopidogrel and other thienopyridine drug antiplatelet response. However, the overall available data are still somewhat contradictory and do not yet allow to define a clear role for pharmacogenomics in providing effective, reliable, personalized antiplatelet therapy: neither clear conclusions nor definite guidelines are available on the clinical advantages of pharmacogenetic testing before prescribing antiplatelet drugs. In the near future, the relative role of additional rare polymorphisms, structural variants and tissue-specific epigenetic features of the human genome will hopefully be defined as significant contributors to the pathogenesis of cardio- and cerebrovascular disease and of individual patient's response to antiplatelet drugs.

Introduction

Pharmacogenomics is the study of how variations in the human genome affect the response to medications. This term substitutes the older "pharmacogenetics", created from the words "pharmacology" and "genetics", to indicate the intersection of pharmaceuticals and genetics. It describes the possibility to analyze multiple genes simultaneously, rather than one at a time, on a large scale, often by a genome-wide approach, thanks to the availability of new genomic technologies.

Pharmacogenomics has been implicated in the individual response variability to antiplatelet drugs (particularly aspirin and clopidogrel) in patients with ischemic vascular disease, mainly coronary and cerebrovascular disease, such as myocardial infarction and stroke, in terms of both therapeutic and adverse effects. A large number of studies and several meta-analyses have been published on this topic, but, until recently, neither clear conclusions nor definite guidelines are available on the clinical advantages of pharmacogenetic testing before prescribing antiplatelet drugs. In this review, we shall mainly refer to meta-analyses of randomized clinical studies. Some relevant open questions will also be summarized and discussed.

Variability of Functional Platelet Response to Antiplatelet Drugs: Early Observations

Despite the efficacy of antiplatelet therapy in preventing ischemic cardio- and cerebrovascular events, shown by hundreds of randomized controlled clinical trials and confirmed by several large meta-analyses (Antithrombotic Trialists' Collaboration 2002; Antithrombotic Trialists' ATT Collaboration et al. 2009), many patients still experience ischemic events while on standardized antiplatelet treatments. This has spurred a large debate on the variability of platelet response, the optimal monitoring of antiplatelet therapy and the relationship between ex vivo measurements of platelet function and clinical outcomes (de Gaetano and Cerletti 2003, 2007; Michelson et al. 2005; de Gaetano et al. 2008).

The question was addressed whether measuring individual platelet response to antiplatelet therapy could be useful to predict clinical outcomes and to modulate antiplatelet drug treatment for better achieving prevention or treatment of thrombosis in otherwise "nonresponder" subjects (de Gaetano and Cerletti 2003). A widespread effort was thus made to try to predict vascular events, therapeutic response and clinical outcomes by platelet function tests.

During the past decades, indeed, clinical trials on antiplatelet drugs had been (and still are) planned and performed on patients enrolled without any previous measurement of their basal platelet function, or of their platelet response to the drug under trial, as measured by laboratory tests. Thus clinical end points could not be correlated to any laboratory parameter of platelet function.

To contribute to thrombosis—it was argued—platelets do not need to hyper-aggregate; it is sufficient that they simply aggregate. This view was shared by many investigators, as confirmed by the fact that no platelet marker was utilized to monitor or predict the risk of vascular events in different clinical conditions (Patrono et al. 1984; Van de Loo 1989; Cortellaro et al. 1992).

However, a variable platelet response to aspirin had already been reported together with the first observation that this drug could interfere with the haemostatic system (de Gaetano 2001). Indeed, more than half a century ago, Quick (1966) proposed an "aspirin tolerance test" based on his observation that not all patients with von Willebrand disease showed a similar prolongation of the bleeding time after aspirin. When, a few years later, the inhibitory effect of aspirin on platelet aggregation was described, it appeared that only some parameters of platelet function such as the second irreversible wave of aggregation induced by ADP or adrenaline, but not others, such as the aggregating response to thrombin, could be prevented by aspirin (Weiss et al. 1968; O'Brien 1968). Shortly thereafter, Smith and Willis (1971) reported that aspirin suppresses platelet prostaglandin production but not platelet aggregation induced by thrombin. However, the observation that TxA2 generation in platelets could be substantially inhibited by any dose of aspirin and the availability of an easy and reliable method for measuring TxB2 in serum (Patrignani et al. 1982) focused the attention on a biochemical parameter endowed with relatively low variability rather than on the evaluation of the multifaceted and variable platelet function.

Moreover, it was observed already in 1968 that in some subjects single doses of aspirin as low as 150 mg, much lower than the anti-inflammatory doses used at that time, were able to variably suppress platelet aggregation and serotonin release for several days; concomitantly, aspirin, but not salicylate, was found to be active, suggesting a role for the irreversible acetylation of some intra-platelet proteins (later on identified as the enzyme cyclo-oxygenase-1, COX-1) in the mechanism of the long-lasting action of aspirin (de Gaetano et al. 1985).

The observation that other non-steroidal anti-inflammatory drugs, such as indomethacin, were platelet inhibitors comparable to aspirin, though short lasting, suggested the existence of a putative platelet common binding site, different from the acetylation site, accessible on COX-1 to all these anti-inflammatory compounds (Cerletti et al. 1982a, b; Livio et al. 1982). The interaction at the level of the binding site of COX-1 between non-steroidal anti-inflammatory drugs, such as indomethacin or ibuprofen, and aspirin was also documented and confirmed (de Gaetano et al. 1985; Catella-Lawson et al. 2001). The possibility that salicylate, rapidly accumulating in blood during chronic administration of aspirin, could interfere with the antiplatelet effect of the parent compound and induce a variable response to the latter was also proposed and demonstrated by different techniques (Dejana et al. 1981, 1985; Cerletti et al. 1982a, b). Functional and modelling studies recently extended to different plant-derived polyphenols (such as gallic acid, resveratrol, quercetin) that have the capacity to bind to platelet COX-1 and to influence the effect of aspirin on platelet function (Crescente et al. 2009). Nutritional compounds of different chemical nature may thus interfere with antiplatelet drugs and partially explain interindividual variability of inhibition of platelet response; but this interesting approach is at the moment of theoretical interest only.

The existence of "responders" and "nonresponders" to antiplatelet drugs other than aspirin is not a recent finding either. In 1974, indomethacin, a non-steroidal anti-inflammatory drug given at that time to patients with chronic glomerulonephritis, reportedly induced a variable inhibition of platelet aggregation tests: stronger inhibition of platelet function was significantly associated with higher reduction of urinary excretion of protein and fibrinogen-/fibrin-related antigen (de Gaetano et al. 1974). A few years later, variability of functional platelet response to TxA2-synthase

inhibitors was also reported by several groups (Heptinstall and Fox 1983; Bertelé et al. 1984; Gresele et al. 1988).

The apparent discrepancy between studies based on platelet function test measurements reporting "aspirin resistance" and the positive results of clinical trials of aspirin prophylaxis in high-risk patients initially pointed to the limitations and unreliability of platelet function studies (Patrono 2003; Santilli et al. 2009). Such an apparent discrepancy was subsequently reconciled by acknowledging the biological and clinical relevance of platelet function variability and the potential limitations of randomized clinical trials performed on large selected populations when extrapolated to individuals. Clinical trials were compared to a kind of "epidemiological night" where all patients look black, as it was not possible to identify in advance the small number of "responders" in terms of reduced clinical outcomes (de Gaetano et al. 2003).

However, if someone would ask: "Should we treat patients with aspirin or other antiplatelet drugs to prevent coronary heart disease or stroke?" the right answer should still be: "Rely upon the results of randomized controlled clinical trials and meta-analyses on the antithrombotic clinical efficacy of antiplatelet drugs" (de Gaetano and Cerletti 2007).

Residual On-Treatment Platelet Response to Aspirin

In the presence of sufficient aspirin dosing and compliance, failure to inhibit TxA2-dependent platelet activation tests appears to be rather uncommon. During the last years, however, "aspirin resistance", better defined as residual on-treatment platelet response measured by platelet function tests other than TxB2 measurement, was reported to be significantly correlated with the lack of clinical response in patients with cardiovascular disease (Freedman 2006; Crescente et al. 2008; Sofi et al. 2008). Advantage was mainly taken from some newly developed point-of-care tests of platelet function. Different meta-analyses reported high prevalence of residual on-treatment platelet response to aspirin at a population level. Among aspirin-treated subjects, a much lower prevalence of hypo-responsiveness for TxA2-dependent assays was found (approximately 6 % for arachidonic acid stimulation), while a higher number of subjects appeared to be lower responders to stimulation of TxA2-independent pathways (PFA-100, 27–33 %) (Crescente et al. 2008, 2011; Krasopoulos et al. 2008). Data from a meta-analysis of 20 studies, totalling 2930 patients, indicate that in patients with cardiovascular disease taking aspirin at doses 75–325 mg daily, nonfatal or fatal cardiovascular events occurred in 39 % of patients with residual on-treatment platelet response to aspirin (assessed by various assays) compared to 16 % events observed among aspirin-responder patients (OR = 3.85, 95 % CI 3.08–4.80) (Krasopoulos et al. 2008). Residual platelet activation in aspirin-treated patients was associated in other studies with an eightfold excess in the occurrence of future cardiovascular events (Frelinger et al. 2006). In a systematic review of eight studies comprising 847 subjects, aspirin nonresponders, as identified by PFA-100, were more likely to have vascular events than aspirin responders (relative risk (RR) 1.63; 95 % CI 1.16–2.28) (Crescente et al. 2008), a finding confirmed in a large meta-analysis of 19 studies comprising 3003 patients (Crescente et al. 2009).

Genetic Variants and Variability of Functional Platelet Response to Aspirin

The functional response of platelets to aspirin appears to be heritable. Studies on aspirin pharmacogenetics tried to identify individuals with different sensitivity to the drug, allowing the recognition of possible genetic regulation of platelet response variability to aspirin and of the susceptibility to atherothrombotic events during aspirin treatment (Freedman 2007; Fitzgerald and Pirmohamed 2011).

Genetic variation in the molecules responsible for platelet activation might be an important potential contributor to the adequacy of the antiplatelet action of aspirin. Table 1-(A) reports the genes and their polymorphic variants shown to be involved in the response to aspirin. Thus far, however, candidate gene studies have not provided consistent evidence for a critical gene-aspirin response relationship. The *COX-1* gene region appears to be highly polymorphic: in particular, studies on C50T, the most extensively investigated candidate gene polymorphism, gave conflicting results; indeed, some studies showed no association with aspirin response, while studies which have shown an association with lower response to aspirin were not correlated with clinical outcomes (Lepäntalo et al. 2006; Clappers et al. 2008; Voora et al. 2011).

Previous studies had focused on polymorphisms of genes encoding for different platelet membrane glycoproteins in small groups of aspirin "nonresponder" patients in terms of platelet aggregation inhibition: platelets from individuals homozygous for the PlA1 allele, encoding for the glycoprotein (Gp)IIIa, appeared indeed to be less sensitive to the inhibitory action of low-dose (160 mg) aspirin. The relationship between GpIIIa and the antiplatelet mechanism of aspirin is however obscure. Goodman et al. (2008) summarized 31 small observational studies, assessing the association between several genetic polymorphisms of candidate genes and clinical response to aspirin. In that review, 50 polymorphisms in 11 genes were investigated in 2834 subjects, either healthy or with cardiovascular disease: the

Table 1 Gene polymorphisms and functional or clinical responses to antiplatelet drugs from main studies

Gene	Variant allele	Outcome	Conclusion
(A) Aspirin

MACE major adverse cardiovascular events, *ST* stent thrombosis

Reproduced modified with permission from Pharmacogenomics as agreed by Future Medicine Ltd. (Yasmina et al. 2014)

PlA1/A2 SNP present in the GpIIIa receptor expressed on the platelet surface was the most investigated, followed by the C807T polymorphism present on the GpIa receptor gene, the A842G and C50T SNPs in the *COX-1* gene, the H1/H2 SNP in the $P2Y_{12}$ receptor gene and the A1622G SNP in the $P2Y_1$ gene. However, the pharmacogenetic studies reviewed in that meta-analysis only considered aspirin resistance as defined by laboratory tests of platelet function, with large method variations from one study to another. There was a significant association between the PlA1/A2 molecular variant and aspirin resistance in healthy subjects (OR 2.36; 95 % CI 1.24–4.48). Such an association was no more apparent in patients with cardiovascular disease (OR 0.92; 95 % CI 0.65–1.30) and when combining the two subgroups (OR 1.14; 95 % CI 0.84–1.54). In addition, the observed association between platelet response to aspirin and the PlA1/A2 polymorphism was only seen when measuring platelet function by aggregometry but not by PFA-100 (Goodman et al. 2008). In a study not included in the review by Goodman et al. (2008), in patients receiving low-dose aspirin and ticlopidine with successful percutaneous coronary intervention, a significant association with the increased risk of the composite outcome of death or myocardial infarction was shown in carriers of the PlA2/A2 genotype (Kastrati et al. 2000).

Failure to show any consistent association between polymorphisms in platelet protein genes and variability of platelet response to aspirin inhibition is possibly due to inadequate assessment of phenotype or to the fact that the contribution of each single gene variant to the overall phenotypic variance was too low and/or the population size too small.

More recent studies, reviewed by Yasmina et al. (2014), also showed conflicting results: indeed, while the PlA1/A1 genotype was associated with a twofold increased risk of high platelet reactivity as assessed by PFA-100 (Abderrazek et al. 2010), patients with the PlA2/A2 genotype had higher ADP-induced platelet aggregation than patients with PLA1/A1 or PLA1/A2 genotypes (Lordkipanidzé et al. 2011); in the latter study no association with arachidonic acid-induced platelet aggregation or urinary concentration of 11-dehydro TxB2 was observed. Lately, PlA polymorphism associated with in vitro aspirin resistance was unrelated to clinical outcomes, death or myocardial infarction, in patients with coronary artery disease, who reported regular aspirin use (Voora et al. 2011).

Studies of other polymorphisms related to either platelet function (GPIIIa, GPIa, GPIb, GPVI, $P2Y_1$, $P2Y_{12}$, CYP2C19, TBXA2R) or inhibition of the pharmacological targets for aspirin (COX-1, COX-2) failed to show any consistent association with the effect of aspirin or clinical outcomes, with the possible exception of *COX-2* genetic polymorphisms, as the *PTGS2* G765C mutation (rs20417). The latter was more frequent in non-aspirin- compared to aspirin-sensitive patients in a cohort of 674 Chinese hypertensive patients (Xu et al. 2012) and was associated with a reduced risk of myocardial infarction and interaction with aspirin use (P for interaction = 0.03) (Lemaitre et al. 2009). In the genetic sub-study of the International Verapamil SR/Trandolapril Study (INVEST), a genome-wide analysis showed a strong association between SNPs on chromosome 1q23 and post-dual antiplatelet therapy. Moreover, in the presence of clopidogrel, genotyping revealed the rs12041331 A-allele in the platelet endothelial aggregation receptor-1 (*PEAR1*) gene to be a strong determinant of collagen-induced platelet aggregation in response to aspirin. Surprisingly, the same rs12041331 A-allele, which was associated with lower post-aspirin collagen-stimulated platelets, led to increased cardiovascular events in percutaneous coronary intervention patients on dual antiplatelet therapy and in an independent population with stable coronary artery disease treated with aspirin alone (Lewis et al. 2013).

Ten-year follow-up data from the Women's Genome Health Study (WGHS), a large population-based cohort of women randomly allocated to aspirin or vitamin E, compared with placebo, indicated that the common polymorphism rs4680 of catechol-O-methyltransferase (*COMT*), a key enzyme in catecholamine metabolism, is associated with incident cardiovascular disease in placebo-treated women and that this association is abolished by treatment with aspirin (Hall et al. 2014). How aspirin could modify cardiovascular disease protection associated with COMT is not known, but candidate mechanisms include effects on platelet function or homocysteine levels and are in agreement with the observation that the differential response to aspirin therapy in a variety of settings is a heritable trait.

Faraday et al. (2007) performed genome-wide linkage (GWL) and association analyses on the same samples through analysis of 37 agonist-induced platelet phenotypes, collected from 1880 asymptomatic subjects before and 14 days after treatment with 81 mg/day aspirin. Eleven patterns of similar platelet function phenotypes, pooled with a principal component analysis, showed suggestive evidence for linkage across 14 regions in the genome, with post-aspirin treatment phenotypes showing higher linkage than in pre-aspirin samples.

In conclusion, aspirin-induced platelet function inhibition may vary at an individual level due to still undefined genetic control. However, the relevance of such a genetic control still remains to be established and seems in any case to be relatively poor.

Variability of Functional Platelet Response to Clopidogrel

For several years it was believed that the variable individual response to antiplatelet therapy was a prerogative of aspirin and a great boost was given to the use of other molecules with other platelet targets, such as the blockade of the ADP receptor $P2Y_{12}$, by clopidogrel and other thienopyridines.

Clopidogrel, a second-generation thienopyridine, is absorbed as a prodrug and converted to its active thiol metabolite by hepatic cytochrome (CYP) P450 enzymes, encoded by a highly polymorphic gene. The prodrug clopidogrel is absorbed via ATP-binding cassette efflux transporters located in the apical membrane of the intestinal mucosa encoded by the multidrug resistance gene *MDR* (*ABCB1*). The majority of the absorbed prodrug is inactivated by hepatic esterases and lacks any antiplatelet activity. Less than 15 % of the absorbed prodrug is further metabolized by two sequential oxidative steps through the hepatic CYP450 system, to generate the active thiol metabolite, which targets and irreversibly inhibits the ADP $P2Y_{12}$ receptor. Figure 1 summarizes the metabolic pathways of

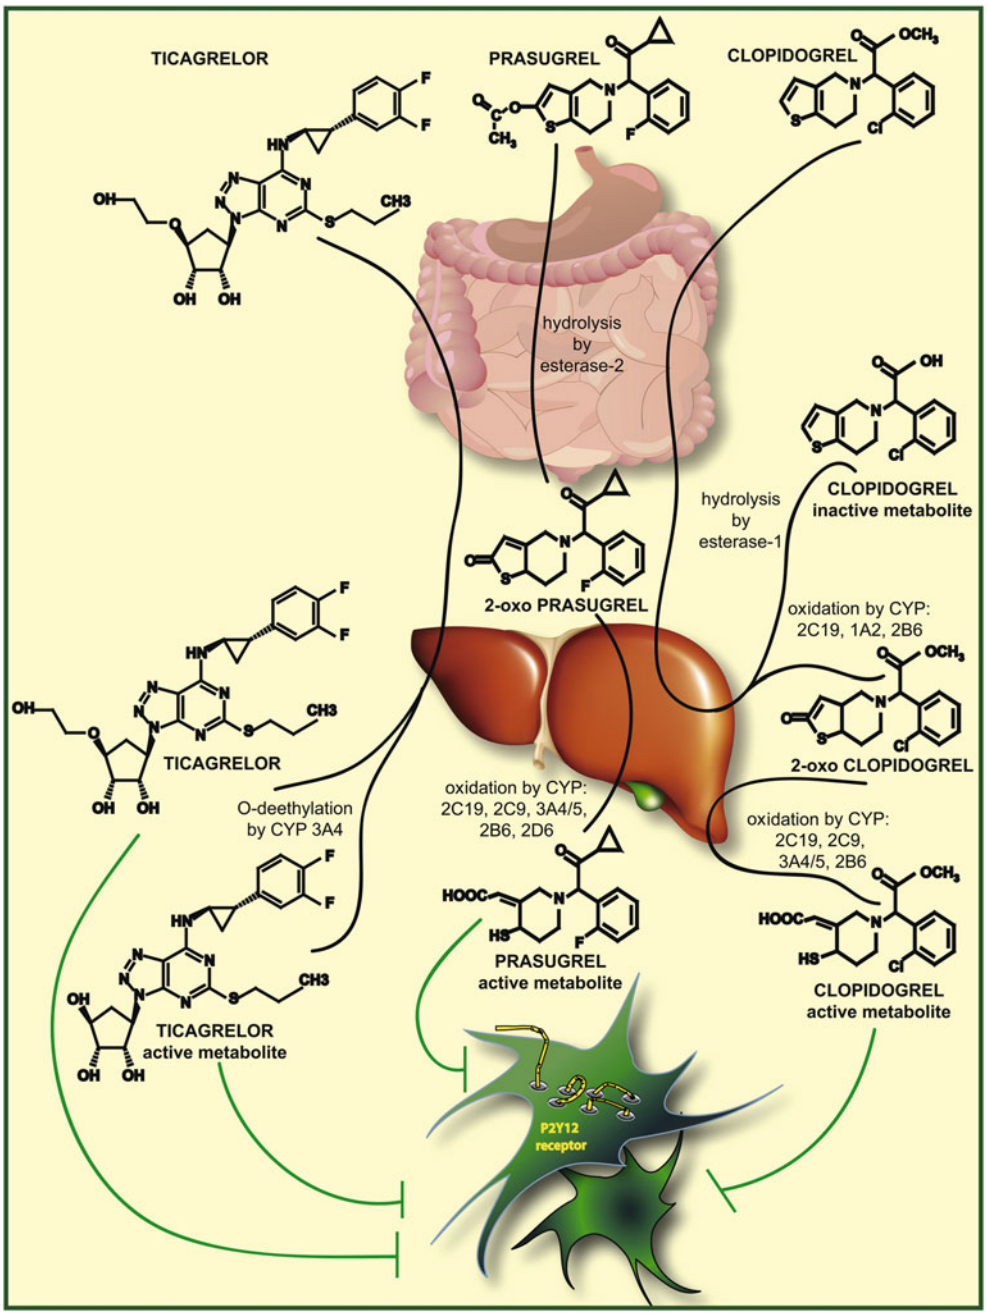

Fig. 1 Chemical structures and schematic metabolic pathways of $P2Y_{12}$ receptor inhibitors. *ADP* adenosine diphosphate, *CYP* cytochrome P450. Reproduced with permission from Siller-Matula et al. (2013)

$P2Y_{12}$ receptor inhibitors (Siller-Matula et al. 2013). Among the CYP isoenzymes, so far identified as having a relevant metabolic role, the polymorphically expressed *CYP2C19* affects both metabolic steps of clopidogrel active metabolite generation and therefore plays a dominant role in this process (Kazui et al. 2010).

The clopidogrel response variability, hypothesized on theoretical grounds (de Gaetano et al. 2002), was first described by Gurbel et al. (2003) followed by several other confirmatory studies, recently reviewed by Cattaneo (2011) and by Bernlochner and Sibbing (2012).

A regimen including both aspirin and clopidogrel has been introduced and extensively used in the secondary prevention of cardio- and cerebrovascular events in patients with previous stroke, myocardial infarction or peripheral arterial disease. The efficacy of clopidogrel in addition to aspirin was shown in the CURE trial, conducted in 12,562 patients with acute coronary syndrome without ST-segment elevation, randomized to aspirin or aspirin plus clopidogrel. The dual therapy reduced the composite end point of cardiovascular death, myocardial infarction or stroke (Yusuf et al. 2001) and is recommended by recent guidelines (Amsterdam et al. 2014; Authors/Task Force Members et al. 2015).

While aspirin variability remains an uncontrolled variable not or only minimally based on genetic polymorphisms, clinical evidence suggests that reduced responsiveness to clopidogrel is the main cause of the reduced efficacy of dual antiplatelet therapy (Peace et al. 2008).

Data from a meta-analysis of 14 studies recruiting 4564 subjects show that among patients with coronary artery disease, who underwent percutaneous coronary intervention, the risk of death and/or thrombotic recurrences increased by about sixfold in those with a poor response to clopidogrel treatment (Sofi et al. 2010).

Criteria to define clopidogrel non-response are numerous and discrepant, some with obvious limits; it is based on either relative or absolute differences in platelet aggregation before and after clopidogrel, or arbitrary cut off points, or two standard deviations from the mean to define low responders. It is therefore often difficult to establish a consensus from literature data on the incidence of clopidogrel non-response (Bonello et al. 2010). The 2013 update of the consensus on the definition of on-treatment platelet reactivity to ADP questioned whether treatment modifications based on the results of current platelet function test platforms can actually influence clinical outcomes. In fact, prospective clinical trials were unable to show any relevant clinical benefit of platelet function tests. In addition, the observation that low-on-treatment platelet reactivity to ADP is associated with a higher risk of bleeding, suggested that a therapeutic window should be considered for $P2Y_{12}$ inhibitor therapy (Tantry et al. 2013).

Genetic Variants and Variability of Functional Platelet Response to Clopidogrel

The primary cause of variability in response to clopidogrel lies in its pharmacokinetics, being largely dependent on the bioavailability of its active metabolite. Multiple candidate gene variants, involved in clopidogrel absorption and activation and in inhibition of the $P2Y_{12}$ receptor, have been shown to correspond to either high or low platelet reactivity. Table 1-(B) reports the genes and their polymorphic variants involved in clopidogrel response. A loss-of-function polymorphism of the *CYP2C19* polymorphism was first demonstrated in acute coronary syndrome patients undergoing percutaneous coronary intervention on clopidogrel: the *2 allele was associated with high residual platelet function, and the *2*2 homozygous subjects had significantly higher platelet aggregation than the *1*2 heterozygotes (Giusti et al. 2007). This finding has been confirmed in other clinical settings (Giusti et al. 2010; Gurbel et al. 2012; Krishna et al. 2012) and most importantly associated with the occurrence of major adverse clinical events (Mega et al. 2009a; Shuldiner et al. 2009; Simon et al. 2009), in particular stent thrombosis in patients treated with clopidogrel (Gurbel et al. 2011).

The results of studies on the association between *CYP2C19* loss-of-function alleles and clinical efficacy of clopidogrel have been reported in several meta-analyses, with apparently discordant conclusions; these have been carefully analysed and critically discussed in a recent systematic review by Osnabrugge et al. (2015): 11 meta-analyses were considered, published in the frame of 2 years, including 30 primary studies, not all included in all meta-analyses (Table 2). Besides several differences among the studies selected for those meta-analyses, such as inclusion or not of conference abstracts, check of quality of primary studies and methods used, all 30 primary studies separately addressed composite clinical end points and stent thrombosis. The results and conclusions of the meta-analyses on the association between *CYP2C19* loss-of-function alleles and clinical efficacy of clopidogrel were discordant: eight out of 11 reported a statistically significant association, with mean effect size ranging from 1.26 to 1.96. Within these positive meta-analyses, five concluded that there was association between loss-of-function alleles and the clinical end point, two stated that the association was possible, and one concluded that this was not proven because of publication bias. Within the other three meta-analyses out of 11, two found no statistically significant pooled effects, and one did not pool the data because of the heterogeneity of the studies analysed. On the other hand, all 11 meta-analyses reported a statistically significant association between *CYP2C19* loss-of-function alleles and stent thrombosis,

Table 2 Characteristics of meta-analyses on CYP2C19 genotype and risk of adverse clinical outcomes in clopidogrel users

	Definitions		Number of studies	
First author, year of publication	Clinical end point	Stent thrombosis	Clinical end point	Stent thrombosis
Hulot, 2010	Death, MI, stroke, urgent vascularization	Definite or probable according to ARC	10	4
Jin, 2011	Clinical adverse events	Not defined	8	5
Mega, 2010b	CV death, MI, stroke	Definite or probable according to ARC	9	6
Sofi, 2011	Death, MI, stroke, unstable angina, stent thrombosis, recurrent ischemia	Not defined	7	4
Zabalza, 2012	CV death, MI, stroke, unstable angina, recurrent ischemia	Definite or probable according to ARC	11	7
Liu, 2011	Major adverse clinical events (not specified)	Not defined	18	9
Bauer, 2011	Death, MI, stroke	Definite: according to ARC Probable: only if reported as composite outcome Possible: not considered	12	9
Holmes, 2011	Death (any cause), CHD, stroke, stent thrombosis, revascularization, hospitalization for ACS	Not defined	26	14
Jang, 2012	Death, MI, stroke, stent thrombosis	Definite or probable according to ARC	16	10
Singh, 2012	Major adverse clinical events (not specified), CV death, MI, stent thrombosis, stroke, major bleedings	Definite or probable	14	6
Yamaguchi, 2013	Death, MI, stroke, stent thrombosis, revascularization	Not defined	7	5

with mean effect size ranging from 1.77 to 3.82. Two meta-analyses downgraded this evidence, one concluding that the association was possible and the other that there was not, due to the presence of heterogeneity and publication bias (Osnabrugge et al. 2015).

In 2010, the US Food and Drug Administration added a boxed warning to the clopidogrel label, with an alert to clinicians on the reduced effectiveness of clopidogrel in patients who are poor metabolizers of the drug, leaving however the decision to use genetic tests to the decision of physicians (FDA Drug Safety Communication 2015).

The authors of the systematic review mentioned above, on the basis of a re-evaluation of all the available meta-analyses, concluded that the FDA recommendation of genotyping for individualized antiplatelet therapy is currently not evidence based.

Similar conclusions were obtained by the results of the GRAVITAS, ARCTIC and TRILOGY-ACS trials, in which bedside-tested platelet reactivity did not result in any clinical benefit (Price et al. 2011; Collet et al. 2012; Gurbel et al. 2012).

The efficacy and safety of intensified antiplatelet therapy (peri-procedural GPIbIIa inhibitor infusions, repeated loading dose or increased maintaining dose of clopidogrel or use of prasugrel) tailored on the basis of individual platelet reactivity tests have been evaluated in prospective studies, reviewed by Aradi et al. (2013a). The conclusions reached by this meta-analysis including ten studies involving 4213 patients undergoing percutaneous coronary intervention are that the intensified protocol was associated with a significant reduction in cardiovascular mortality, stent thrombosis and myocardial infarction, without any difference in major bleeding events. However, the net clinical benefit of the intensified treatment versus the standard one significantly depended on the risk of stent thrombosis with a standard dose of clopidogrel.

A recent prospective proof-of-concept trial randomized 200 patients undergoing percutaneous coronary intervention to either point-of-care genotyping and subsequent personalized treatment or standardized clopidogrel treatment. A significantly lower on-treatment platelet reactivity was observed in the *CYP2C19* loss-of-function allele carriers than in the standard treated patients (Roberts et al. 2012). However, in the subgroup of the ARCTIC study, genotyping the results added little to the pharmacodynamic data to adjust antiplatelet therapy (Collet et al. 2015). These findings support the conclusion that there might still be room for optimization of antiplatelet therapy by genotyping. In fact, negative trials on the use of personalized therapy largely suffer for inappropriate study design, so that the patients who might benefit from personalized antiplatelet therapy on the basis of pharmacogenomics require further classification.

Other genes (*ABCB1, CES1, PON1* and *P2RY12*) encoding for proteins involved in pharmacokinetics and pharmacodynamics of clopidogrel, listed in Table 1-(B),

have been critically discussed elsewhere (Perry and Shuldiner 2013), but understanding their clinical relevance requires further studies.

Variability of Functional Platelet Response to Prasugrel and Non-thienopyridine Derivatives

Prasugrel, a new thienopyridine, is rapidly hydrolysed by carboxylesterases to a thiolactone, further metabolized to an active metabolite via one-step CYP450 metabolism. The active metabolite irreversibly binds to the $P2Y_{12}$ receptor. Prasugrel's active metabolite requires therefore a reduced contribution from CYP2C19 than clopidogrel (see Fig. 1).

The non-thienopyridine derivatives ticagrelor, cangrelor and elinogrel, on the other hand, do not require hepatic conversion and directly and reversibly bind to the $P2Y_{12}$ ADP receptor in a concentration-dependent manner (Cattaneo 2010).

The efficacy of prasugrel was shown to be greater than clopidogrel in the prevention of ischemic events in patients undergoing percutaneous coronary intervention for ST-elevation myocardial infarction (TRITON-TIMI 38) (Montalescot et al. 2009); increased major bleeding compared to clopidogrel was only reported after coronary artery bypass grafting (CABG). The drug use was approved by FDA and EMA in patients with acute coronary syndrome undergoing percutaneous coronary intervention to reduce thrombotic cardiovascular events; it is not generally recommended in elderly patients (>75 years) or in patients with body weight <60 kg or with a history of stroke or transient ischemic attack.

A meta-analysis of randomized, controlled clinical trials comparing the clinical impact of clopidogrel with placebo or prasugrel/ticagrelor versus clopidogrel, comprising a total of 107,473 patients, included cardiovascular death, myocardial infarction, total stroke and intracranial haemorrhage as outcome measures (Aradi et al. 2013b). Clopidogrel reduced the risk of cardiovascular death, myocardial infarction and stroke, without influencing the risk for intracranial haemorrhage. Treatment with prasugrel/ticagrelor provided additional benefit over clopidogrel regarding cardiovascular mortality and myocardial infarction but demonstrated no advantage on stroke and intracranial haemorrhage. Increased potency of $P2Y_{12}$ receptor inhibition is associated with a decreased risk in cardiovascular death and myocardial infarction but not in stroke with respect to clopidogrel.

These results have been confirmed and extended by two recent meta-analyses: Chen et al. (2015) included nine studies involving 25,214 patients and found that the risks of major adverse clinical events outweighed those of major bleeding (OR 7.48, 95 % CI 3.75–14.94, $p < 0.0001$, random effects) and of minor bleeding (OR 3.77, 95 % CI 1.73–8.22, $p = 0.009$, random effects), results corroborated in a standard-dose clopidogrel subgroup analysis (OR 7.46, 95 % CI 3.54–15.68, $p < 0.0001$, and OR 6.44, 95 % CI 2.80–14.80, $p < 0.0001$, random effects, respectively). Despite the increased risk of bleeding associated with prasugrel treatment compared with clopidogrel, the risk of major adverse clinical events far outweighed the risk of bleeding. The meta-analysis by Bavishi et al. (2015) compared the results of randomized clinical trials with newer oral $P2Y_{12}$ inhibitors (prasugrel or ticagrelor) to clopidogrel in 31,470 patients with non-ST-elevation acute coronary syndrome. The primary outcome was a composite of cardiovascular death, myocardial infarction and stroke. Newer oral $P2Y_{12}$ inhibitors significantly decreased major adverse clinical events (RR 0.87, 95 % CI 0.80–0.95) and myocardial infarction (RR 0.85, 95 % CI 0.75–0.96) and showed a trend towards reduction of cardiovascular death (RR 0.89, 95 % CI 0.71–1.01). There was a significant increase in major bleedings (RR 1.27, 95 % CI 1.07–1.50) and major or minor bleedings (RR 1.20, 95 % CI 1.02–1.42). Results were largely similar when stratified by ticagrelor versus prasugrel (p interaction >0.05) except for increased TIMI major/minor bleedings with prasugrel than ticagrelor (p interaction = 0.01).

In conclusion, in patients with non-ST-elevation acute coronary syndrome, newer oral $P2Y_{12}$ inhibitors decrease major adverse clinical events and myocardial infarction at the expense of a significant increase in the risk of bleeding. Treatment of 1000 patients with newer oral $P2Y_{12}$ inhibitors will prevent 16 major adverse clinical events and 13 myocardial infarctions at the expense of increase in six major bleeding events (Aradi et al. 2013b).

In 2014, cangrelor was approved by the Food and Drug Administration for two indications: for the reduction of thrombotic cardiovascular events (including stent thrombosis) in the setting of percutaneous coronary intervention in patients with coronary artery disease and for thrombotic events (such as stent thrombosis) in the setting of bridging therapy in patients with acute coronary syndrome or with stents who are at increased risk when oral $P2Y_{12}$ therapy is interrupted because of surgery (Lhermusier et al. 2015).

Elinogrel is a novel competitive, reversible ADP-receptor antagonist available in oral and intravenous formulation. Additional treatment with elinogrel showed advantages over clopidogrel, including more rapid, less variable and more complete inhibition of platelet function without significantly increased bleeding complications (Müller et al. 2012).

No data are presently available on the pharmacogenetics of these novel inhibitors of $P2Y_{12}$ receptor activation.

Genetic Variants and Prasugrel and Ticagrelor Response

Table 1-(C and D) reports the main genes and their polymorphic variants involved in prasugrel and ticagrelor response, respectively. CYP2C19 is one of the enzymes, which contribute to the metabolism of prasugrel, although to a smaller extent than that seen with clopidogrel. Prasugrel treatment is more effective than clopidogrel in carriers of the loss-of-function allele of *CYP2C19* but has an apparently higher risk of bleeding (Alexopoulos et al. 2011; Grosdidier et al. 2013); on the other hand, carriers of the wild-type genotype of *CYP2C19* show similar efficacy and safety of prasugrel and clopidogrel treatment (Sorich et al. 2010; Cuisset et al. 2012).

No association has been observed between genetic polymorphisms of other metabolizing enzymes (*CYP2C9, CYP2B6, CYP3A5 and CYP1A2*) or efflux transporters (*MDR1*) and pharmacokinetics, pharmacodynamics and clinical outcomes with prasugrel (Mega et al. 2009b, 2010a).

A very recent publication reported the results of *PON1* genotyping of 2922 patients with an acute coronary syndrome undergoing percutaneous coronary intervention, randomized to treatment with clopidogrel or prasugrel in the TRITON-TIMI 38 trial*:* there was no association between the Q192R variant and active drug metabolite levels, change in platelet aggregation or clinical outcomes (cardiovascular death and myocardial infarction) for prasugrel-treated as well as for clopidogrel-treated patients (Mega et al. 2015). A meta-analysis of 13 studies and 16,760 clopidogrel-treated patients in the same publication reinforced the lack of a significant association between Q192R and cardiovascular outcomes in clopidogrel-treated patients (Mega et al. 2015).

Although the CYP2C19 metabolizing enzyme is not involved in ticagrelor pharmacokinetics, there are studies that have evaluated *CYP2C19* genetic polymorphisms and surrogate and clinical outcomes: in stable coronary artery disease patients with *CYP2C19* polymorphism, ticagrelor treatment resulted in lower platelet function than clopidogrel (Tantry et al. 2010); in a sub-study of the PLATO trial, 10,285 acute coronary syndrome patients showed a lower risk of clinical events in the ticagrelor group, compared to clopidogrel. There was no difference in the risk of stent thrombosis and major bleeding compared to clopidogrel in the carriers of the *CYP2C19* loss-of-function allele (Wallentin et al. 2010).

In a recent genome-wide association study in patients of the PLATO trial treated with ticagrelor, the drug pharmacokinetic behaviour was influenced by three genetic loci (*SLCO1B1*, *UGT2B7* and *CYP3A4*). However, the modest genetic effect on ticagrelor plasma levels did not translate into any detectable clinical effect on efficacy or safety during treatment (Varenhorst et al. 2015).

Next Stop: Epigenetics

As already mentioned, a number of candidate gene studies have been designed in the last years to identify possible genetic variants influencing platelet activation and aspirin inhibition. Most of these studies focused on native platelet function and were based on a combination of imputation and genome-wide analysis. With this approach a number of variants, being located in *PEAR1* (rs12041331), *SHH* (rs6943029), *MRVI1* (rs1874445), *ADRA2A* (rs869244), *JMJD1C* (rs2893923) and *GP6* (rs1671152) genes, have been found to be associated to functional-related changes in platelets (Johnson et al. 2010). Interestingly enough, all the variants identified reside in noncoding regions of the genes (either intronic or intragenic), suggesting they may play a role in the expression modulation of these genes rather than influencing their functional properties. In many instances, these noncoding polymorphisms are located in gene regions that are defined as "enhancers" in several pathophysiological conditions but not yet systematically reported in response to antiplatelet therapy variability. Enhancers are important players in gene regulation and could directly link these variants to the changes in gene regulation they might cause in platelets. Three out of the six polymorphisms mentioned above are also introducing a CpG site in the DNA sequence (referred to as "CpG-SNPs"), adding a potential site for methylation to be deposited within the noncoding regions where they are located.

One very interesting example of CpG-SNP is represented by *PEAR1* rs12041331. PEAR1 is highly expressed in platelets and megakaryocytes and participates in both platelet activation and megakaryocyte proliferation (Kauskot et al. 2012, 2013). The minor A-allele of rs12041331 was found to be associated with lower PEAR1 expression in platelets (Faraday et al. 2011). However, in a study involving two independent populations, the minor A-allele was linked to lower platelet function on aspirin but was also found to be a risk factor for cardiovascular events (Lewis et al. 2013). This apparent divergent result still requires further investigations, especially focusing on the molecular mechanisms by which this variant could modulate *PEAR1* expression, eventually through the mediation of DNA methylation. Interestingly, other CpG-SNPs have been recently described for the *CYP2C19* gene (rs12773342, rs12773342, rs12773342) to be associated with coronary heart disease (Ye et al. 2015). However, their mechanism of action still remains elusive.

MicroRNAs (miRNAs) are short noncoding RNAs that work as post-transcriptional regulators of gene expression. Because of their function, miRNAs are present in the circulation via several different mechanisms. miRNAs are cell specific, although some of these molecules are also commonly abundant among some cell types, often when they

contribute to regulate the same pathophysiological processes. One such example is represented by miR-126, abundantly present in both platelets (Landry et al. 2009; Nagalla et al. 2011) and endothelial cells (van Solingen et al. 2009) which has been reported to be altered in various cardiovascular diseases (Corsten et al. 2010; Tijsen et al. 2010; Wang et al. 2010). Plasma levels of this miRNA have been reported to change after treatment with aspirin (de Boer et al. 2013) or aspirin and prasugrel (Zampetaki et al. 2012). Similar observations have also been made for miR-223 (Shi et al. 2013, 2015), while low miR-19b-1-5p expression was linked to aspirin insensitivity in platelets (Kok et al. 2015).

On the other hand, agents like aspirin might play a direct role on the methylation of cells and genes that contribute via effects on platelets to cardiovascular phenotypes. Numerous studies have already shown that aspirin use is associated with a lower incidence of colon neoplasia, metastatic colorectal cancer and death due to colorectal cancer (Algra and Rothwell 2012; Bosetti et al. 2012; Maxwell 2012; Thun et al. 2012). However, few studies are now available on more vascular disease-related cell types such as endothelial cells (Chang et al. 2013). It is hoped that future epigenomic studies in the field might better unravel this possible dual epigenetic-mediated influence of antiplatelet therapy.

Conclusions

Over the last two decades, a number of studies on the possible genomic regulation of common "polygenic" ischemic cardio- and cerebrovascular diseases have been published. These studies have identified numerous DNA variants as disease or antiplatelet drug susceptibility markers. Some of these DNA variants confer a variable increase in risk for disease, while loss-of-function variants in the hepatic *CYP2C19* system have been reported to be the predominant genetic mediators of clopidogrel and other thienopyridine drug antiplatelet response. However, the overall available data are still somewhat contradictory and do not yet allow a clear role for pharmacogenomics in the context of providing effective, reliable, personalized antiplatelet therapy. However, it is anticipated that in the near future, the relative role of additional rare polymorphisms, structural variants and tissue-specific epigenetic features of the human genome (including DNA methylation or acetylation, histone modifications and miRNA post-translational regulation of gene expression) as significant contributors to cardio- and cerebrovascular disease pathogenesis and drug response will hopefully be defined. Future findings will be useful to radically change our practice of cardio- and cerebrovascular medicine.

Pharmacogenomics of Antiplatelet Drugs: Key Concepts

- Pharmacogenomics has been implicated in the individual response variability to antiplatelet drugs in patients with ischemic vascular disease, but no clear conclusions nor definite guidelines are available on the clinical advantages of pharmacogenetic testing before prescribing antiplatelet drugs.
- Residual on-treatment platelet response to aspirin measured by platelet function tests other than TxB2 measurement significantly correlated with the lack of clinical response in patients with cardiovascular disease and with an excess in the occurrence of future cardiovascular events compared to "responder" patients.
- Candidate gene studies have not provided consistent evidence for a critical gene-aspirin response relationship: this is possibly due to inadequate assessment of phenotype or to the fact that the contribution of each single gene variant to the overall phenotypic variance was too low and/or the population size too small.
- Clopidogrel is absorbed as a prodrug and converted to its active thiol metabolite by two sequential oxidative steps through the hepatic cytochrome (CYP) P450 enzymes. Among the CYP isoenzymes having a relevant metabolic role, the polymorphically expressed *CYP2C19* affects both metabolic steps of clopidogrel active metabolite generation and therefore plays a dominant role in this process.
- The results of many studies (and meta-analyses) on the association between *CYP2C19* loss-of-function alleles and clinical efficacy of clopidogrel were discordant; in three large trials (GRAVITAS, ARCTIC and TRILOGY-ACS), bedside-tested platelet reactivity did not result in any clinical benefit.
- In 2010, the US Food and Drug Administration added a boxed warning to the clopidogrel label, with an alert to clinicians on the reduced effectiveness of clopidogrel in patients who are poor metabolizers of the drug, leaving however the decision to use genetic tests to the decision of physicians, a recommendation currently not evidence based.
- Intensified antiplatelet therapy (peri-procedural GPIbIIa inhibitor infusions, repeated loading dose or increased maintaining dose of clopidogrel or use of prasugrel) tailored on the basis of individual platelet reactivity tests in prospective studies was

(continued)

associated with a significant reduction in cardiovascular mortality, stent thrombosis and myocardial infarction, without any difference in major bleeding events. However, the net clinical benefit of the intensified treatment versus the standard one significantly depended on the risk of stent thrombosis with a standard dose of clopidogrel.
- Recent prospective proof-of-concept trials, in which patients undergoing percutaneous coronary intervention were randomized to either point-of-care genotyping and subsequent personalized treatment or to standardized clopidogrel, showed that the genetic clopidogrel profile was a good marker of platelet function response on clopidogrel but was not related to clinical outcome, suggesting that the genetic added little to the pharmacodynamic information used in the study to adjust antiplatelet therapy. These findings support the conclusion that there might still be room for optimization of antiplatelet therapy by genotyping.
- The relative role of additional rare polymorphisms, structural variants and tissue-specific epigenetic features of the human genome will hopefully be defined in the near future as significant contributors to the pathogenesis of cardio- and cerebrovascular disease and of individual patient's response to antiplatelet drugs.

Take Home Messages

- Pharmacogenomics has been implicated in the individual response variability to antiplatelet drugs in patients with ischemic vascular disease, but no clear conclusions nor definite guidelines are presently available on the clinical advantages of pharmacogenetic testing before prescribing antiplatelet drugs.
- In the meantime individual variability can be tested by residual on-treatment functional platelet response to aspirin or other antiplatelet drugs.
- Intensified antiplatelet therapy (peri-procedural GPIbIIa inhibitor infusions, repeated loading dose or increased maintaining dose of clopidogrel or use of prasugrel) can be tailored on the basis of individual platelet reactivity tests to obtain a significant reduction in cardiovascular mortality, stent thrombosis and myocardial infarction, without minor differences in major bleeding events.

- The relative role of additional rare polymorphisms, structural variants and tissue-specific epigenetic features of the human genome will hopefully be defined in the near future as significant contributors to the pathogenesis of cardio- and cerebrovascular disease and of individual patient's response to antiplatelet drugs.

Targeting Intraplatelet Signaling Pathways as Potential Antithrombotic Strategy

Patrick Andre

Abstract

Platelets assume two main functions that lead to opposite outcomes. In one instance, they support hemostatic plug formation and prevent bleeding at sites of vascular breach. Alternatively, their uncontrolled recruitment at sites of plaque erosion/rupture in arteries can lead to ischemic events and death. Antiplatelet agents have been developed to successfully treat or prevent arterial thrombotic events, but their use is inevitably associated with bleeding complications. These agents target platelet receptors (i.e., $P2Y_{12}$, the ADP receptor mediating aggregation and thrombus stability; $\alpha_{IIb}\beta_3$, the fibrinogen and vWF receptor mediating platelet aggregation/thrombus growth; PAR1, the high-affinity platelet thrombin receptor) or the cyclooxygenase 1 (COX1) enzyme that promotes TxA_2 synthesis (another platelet-derived endogenous agonist of platelet aggregation). Evidences have emerged showing that these pathways are complementary as combinations of drugs provide additive protection. Signaling pathways downstream of the glycoprotein receptors have been well characterized and indicate that inhibition of effectors (specific to a pathway or ubiquitous) could provide significant protection from thrombosis. In this chapter, we will review the biology associated with genetic and pharmacologic modulation of platelet effectors and report their effects on thrombosis and primary hemostasis.

Platelet Signaling

Signaling Downstream GPVI-FcRγ and GPIbα

Glycoprotein VI (GPVI), glycoprotein Ib-IX-V (GPIb), and integrins share a common signaling pathway that relies on the engagement of the Src family kinases, the ITAM domain of FcRγ, and the phosphoinositide 3-kinases (PI3K) (Fig. 1). Platelet adhesion to collagen requires GPVI-mediated activation, and deletion or depletion (via use of an antibody) of GPVI in mice is associated with protection from thrombosis and a moderate impairment of the hemostatic response (for review, see Nieswandt and Watson (2003)). GPVI is comprised of two Ig domains followed by a mucin-like region linked to a transmembrane domain possessing an arginine group that allows the association with FcRγ. The FcRγ-chain is a disulfide-linked homodimer with an ITAM sequence in which two tyrosine residues play a critical role in the collagen-FcRγ signaling pathway. The GPVI-FcRγ-chain complex binds to the glycine-proline-hydroxyproline sequence of fibrillar collagen. As both Lyn and Fyn are constitutively bound to the cytoplasmic domain of GPVI via their SH3 domains, cross-linking of GPVI by collagen occurs and brings Fyn and Lyn to the ITAM region in the FcRγ-chain (not represented in this illustration). The Src kinases mediate the phosphorylation of the two YXXL conserved motifs of FcRγ-ITAM. This phosphorylation offers docking sites for the SH2 domains of the spleen tyrosine kinase (Syk), leading to the activation of its kinase function. Syk autophosphorylation happens, allowing it to dissociate from the ITAM domain and to recruit key signaling enzymes. It is believed that such

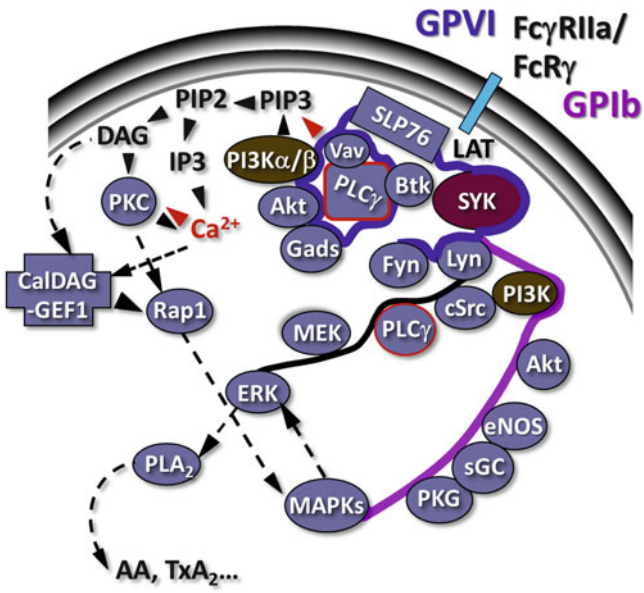

Fig. 1 Platelet signaling pathways downstream ITAM-coupled receptors

activity is driven by its ability to engage the PI3K-Akt-eNOX-sGC-PKG pathway (Li et al. (2010); purple line). The importance of Syk in collagen-dependent platelet activation is illustrated by the fact that neither FcRγ$^{-/-}$ nor Syk$^{-/-}$ platelets respond to collagen-related peptide (CRP) or collagen (Poole et al. 1997). It should be noted that the murine phenotypes associated with these two deficiencies differ substantially as Syk (which is also part of the CLEC2 signaling pathway) deficiency also impacts vasculogenesis, being associated with a severe bleeding diathesis, while FcRγ$^{-/-}$ animals do not show prolonged bleeding time (Poole et al. 1997). Activation of the Syk SH2 domains is at the origin of a signaling cascade involving adapters and effector enzymes (blue line). Activated Syk phosphorylates the transmembrane adapter linker for activated T-cells (LAT) and SLP-76. A complex assembles, comprised of Bruton's tyrosine kinase (Btk), Gads, and phospholipase C (PLC)-γ2. This complex acts as a positive autocrine loop to further enhance the activation PLC-γ2 (Watson et al. 2005). PLC-γ2 hydrolyzes PtdIns (4,5)P_2, cleaving the bond between the glycerol and phosphate moieties, generating the second messengers 1,2-diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3). IP3 is known to release cytosolic calcium from internal stores, while DAG activates protein kinase C (PKC) isoforms α and β that mediate secretion of α-granules, aggregate formation and phosphatidyl serine (PS) expression on the platelet surface (Gilio et al. 2010). The small GTPase Rap1b plays a key role in several of these processes, as it is directly activated by PKC and the calcium-sensing guanine nucleotide exchange factor, CalDAG-GEFI. Activation of PLC-γ2 ultimately leads to activation of PLA_2, release of arachidonic acid followed by the synthesis of thromboxane A_2 (TxA_2), release of granule contents, and activation of $\alpha_{IIb}\beta_3$.

Platelet signaling pathways downstream of GPVI and GPIbα engagement by collagen (CRP/convulxin) and vWF, respectively, have been extensively studied and are well characterized (see above). Figure 2 highlights the defects in enzyme phosphorylation, α- and dense-granule secretion, and $\alpha_{IIb}\beta_3$ activation/aggregation associated with deficiency in key signaling enzymes/effectors involved in the response to collagen/CRP stimulation in mice. The enzymes are shown according to their predicted order in the signaling pathway. Figure 2 also presents the impact of the genetic manipulation (or pharmacological one) on primary hemostasis and reports whether deficiency provides a biological impairment beyond platelet function.

The GPIb-V-IX complex encompasses four subunits. GPIbα and β are disulfide-linked and non-covalently associated with GPV and GPIX. It is commonly believed that the Ibα subunit carries most of the activities as it possesses the binding site for vWF, thrombin, P-selectin, Mac1, and FXI [for review, see Lopez and Dong (1997); Berndt et al. (2001)]. GPIbα interaction with vWF under arterial shear rates facilitates the recruitment of platelets at the vessel wall. This process is initiated by at least two intraplatelet signaling pathways. The cytoplasmic domain of GPIbα associates with Lyn and PI3K. Lyn activates PI3K which in turn leads to the activation of Akt (Angelillo-Scherrer et al. 2005). This triggers the activation of the eNOS/sGC/PKG (cGMP-dependent protein kinase), mitogen-activated protein kinase (p38 MAPK), and extracellular signal-regulated kinase (ERK). GPIbα is also associated with ITAM receptors and, by consequence, shares this signaling pathway with GPVI (Gardiner et al. 2010). Indeed, tyrosine phosphorylation following vWF binding to GPIbα requires the recruitment of Src and Lyn, Lyn activation, followed sequentially by the phosphorylation of Syk, SLP-76, PI3-kinase, Btk, PLCγ2, and PKC, ultimately resulting in elevation of cytosolic Ca^{++} and $\alpha_{IIb}\beta_3$ activation (see Fig. 1). GPIbα also binds thrombin with high affinity, but until recently the functional importance of this interaction was controversial (De Candia et al. 2001; Ramakrishnan et al. 2001). A recent study by Du and colleagues indicates, however, that low concentrations of thrombin induce cooperative signals between GPIbα and PARs (Estevez et al. 2015).

Signaling Downstream Protease-Activated Receptors (PARs) and GPCRs (Fig. 3)

Thrombin activates platelets by cleaving protease-activated receptors (PAR)1 and PAR4 in humans (PAR3 and PAR4 in mice), revealing a new tethered ligand that binds to and activates the receptor. The signaling pathways initiated by the cleavage of PAR1 (high-affinity receptor) and PAR4 (low-affinity receptor) involve heterotrimeric G proteins

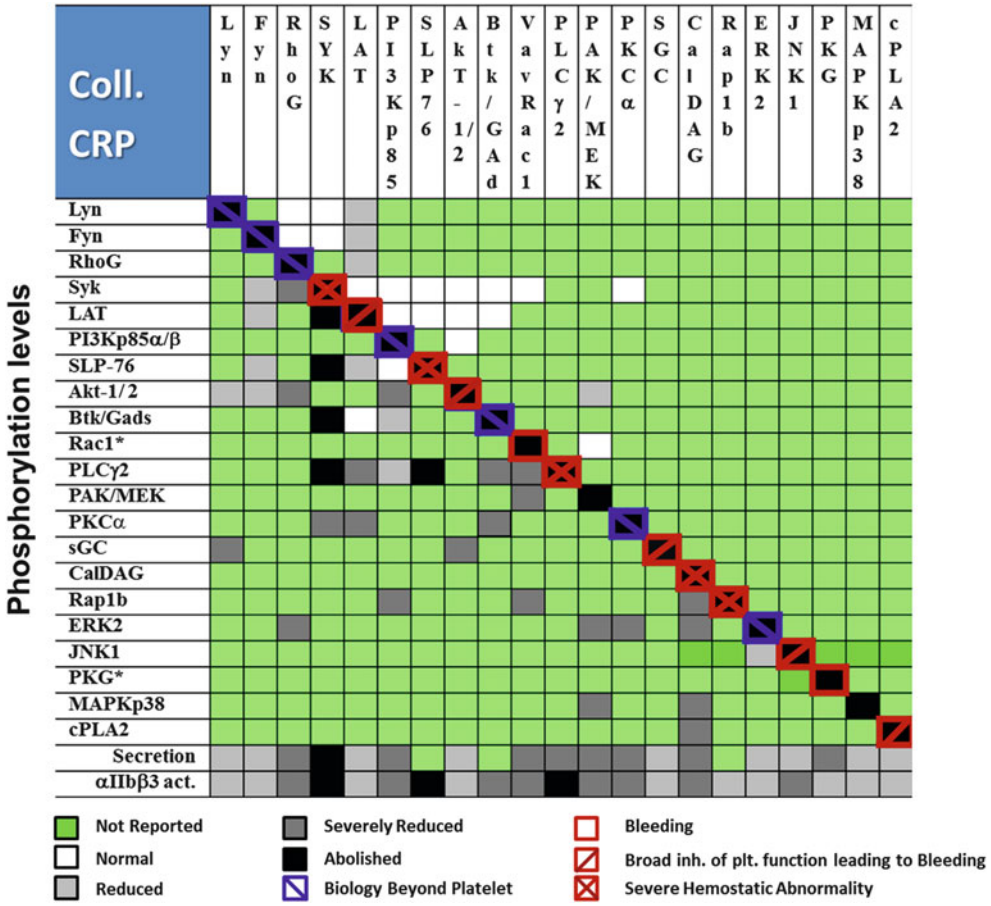

Fig. 2 Impact of genetic deficiency of pharmacological modulation of key platelet effectors on phosphorylation levels, platelet activation, and secretion

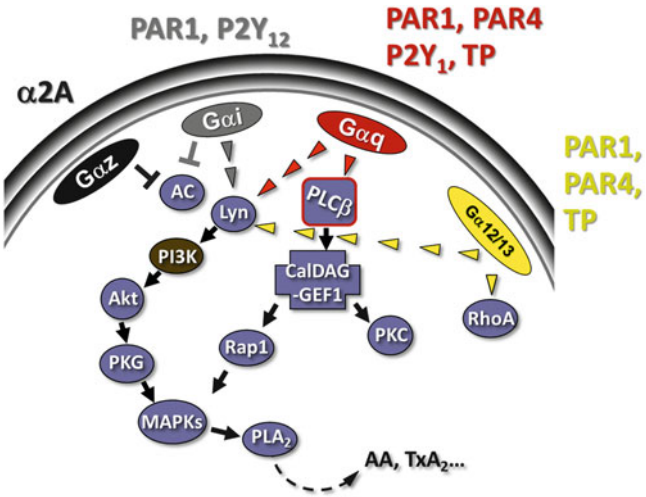

Fig. 3 Platelet signaling pathways downstream PARs and other GPCR receptors

[$G_{\alpha 12/13}$,$G_{\alpha q}$, and $G_{\alpha i/o}$ for PAR1 (Ayoub et al. 2010); $G_{\alpha 12/13}$ and $G_{\alpha q}$ for PAR4] (for review see Russo et al. (2009)). Interestingly, proteases cleave PARs at specific and potentially divergent sites within the extracellular domain, activating the canonical pathways of G proteins and β-arrestin and also different signaling cascade (commonly referred to as biased signaling). It should also be noted that subtle differences exist in signaling pathways between the two receptors as a result of the release of secondary mediators of platelet aggregation (e.g., ADP secretion) and the fact that PAR1 directly activates $G_{\alpha i}$ (Holinstat et al. 2006). In brief, $G_{\alpha q}$ and $G_{\alpha i}$ signaling involving the phospholipase Cβ-CalDAG-GEFI-PKC pathway and the PI3K-Akt-PKG axis or PI3K-Rasa3-Rap1 axis, respectively, converges to induce secretion of the α-granules and dense granules, Rap1 and $\alpha_{IIb}\beta_3$ activation, and platelet aggregation. $G_{\alpha 12/13}$-dependent activation of p115-RhoGEF-RhoA also occurs and leads to platelet shape change. It is believed that thrombin induces activation of Rho and Rac, triggering activation of p21-activated kinase (PAK) at focal adhesion and lamellipodia regions in platelets. PAK plays a key role in platelet filopodia and lamellipodia formation downstream of RhoA, Cdc42, and Rac1, associating with Rac and regulatory proteins such as GEFH1, GIT, and PIX (which also serve as substrate) (Sato et al. 2008). PAK notably

phosphorylates LIMK1 (together with ROCK) resulting in the inactivation of cofilin and, by consequence, in an increase in actin polymerization (Bernard 2007), and activation of Merlin, MAP kinase, and Akt and the release of calcium (Aslan et al. 2013). Finally, Pyk2, a non-receptor tyrosine kinase, interacts with the actin cytoskeleton and gets activated upon thrombin stimulation (and also by ADP and U46619). Interestingly, the $G_{\alpha 12/13}$ signaling cascade is also common to other GPCR receptors such as the TxA_2/PGH_2/isoprostane receptor (TP, which couples with $G_{\alpha q}$ and $G_{\alpha 12/13}$) and the ADP receptors $P2Y_{12}$ (coupled with $G_{\alpha i}$-AC) and $P2Y_1$ (coupled with $G_{\alpha q}$).

$\alpha_{IIb}\beta_3$ Outside-In Signaling

$\alpha_{IIb}\beta_3$ engagement by its ligand promotes platelet adhesion and aggregation and initiates signaling pathways in platelets that lead to cytoskeletal reorganization, spreading, secretion, and clot retraction. It induces the assembly of signaling molecules from which the outside-in signaling originates. c-Src plays a key role in this process via a direct interaction with the β_3 cytoplasmic domain of the receptor (Arias-Salgado et al. 2003; Ablooglu et al. 2009; Wu et al. 2015) and initiation of the PI3K pathway (O'Brien et al. 2012). Its activation follows the coupling of $G_{\alpha 13}$ to the cytoplasmic tail of β_3 (Gong et al. 2010). $\beta_3(\Delta 760–762)$ knock-in mice show reduced tyrosine phosphorylation of c-Src and a defective outside-in signaling pathway in platelets. This platelet function defect is associated with thromboprotection but also prolongation of bleeding time, although the heterozygous animals only displayed moderate prolongation (Ablooglu et al. 2009). Other protein-tyrosine kinases have key functions in mediating outside-in signaling, including FAK (focal adhesion kinase), ILK, Syk, and Src family kinase (SFK). The inhibition of RhoA by c-Src and activation of PI3K mediate platelet spreading on ligands, while PI3K and Syk signaling promotes platelet secretion. Phosphorylation of β3 is also known to control cytoskeletal changes that directly impact platelet function [for review see Estevez et al. (2015)].

Effectors of Platelet Function not Involved in Primary Hemostasis

Lyn

Genetic Modulation and Pathophysiology

Lyn is a non-receptor protein-tyrosine kinase, which belongs to the Src family of tyrosine kinases among Src, Fyn, Hck, Yes, Lck, and Fgr. Lyn associates with the GPVI-FcRγ complex where it sequentially plays stimulatory and inhibitory roles. On the one hand, through its constitutive interaction with the cytoplasmic domain of GPVI, it contributes to the release of platelet granules via the PI3K pathway (Fig. 1, purple line). On the other hand, it promotes the phosphorylation of PECAM-1, which leads to the recruitment of SHP-2 phosphatase (Li et al. 2010; Ming et al. 2011). A similar dichotomy has been reported downstream of the thrombin receptor (Cho et al. 2002; Li et al. 2010). Interestingly, Lyn also plays an important role in the activation of $\alpha_{IIb}\beta_3$ (inside-out signaling) downstream of GPIbα engagement by vWF, a signaling event believed to be mediated by the cGMP signaling pathway, but it does not seem to contribute to outside-in signaling (downstream of $\alpha_{IIb}\beta_3$ engagement by fibrinogen) (Yin et al. 2008). Overall, Lyn deficiency does not lead to bleeding complications but is only associated with moderate inhibition of thrombosis.

Pharmacological Modulation

Based on these findings, one could speculate that monotherapy targeting Lyn would have limited effect on thrombosis. It is possible, however, that modulation of Lyn could synergize with other modulators of platelet function. Development of a selective Lyn inhibitor for the prevention or treatment of thrombosis will necessitate an evaluation of its activity in presence of other platelet antagonists for establishment of target engagement levels and therapeutic windows. This is particularly important as Lyn is also known to control cell cycle, notably in B-cells (Scheuermann et al. 1994), and it works across different cellular signal transduction pathways. In addition, high levels of selectivity would be required against other kinases, notably from the Src family, to prevent effects beyond thrombosis [e.g., see dasatinib mechanism of action and effects in Inge et al. (2013)]. Thus, therapeutic windows would have to be first established in translational preclinical species prior to committing to a full drug discovery program in the thrombosis arena.

Fyn

Genetic Modulation and Pathophysiology

In platelets, Fyn plays a key role in Akt phosphorylation downstream of GPVI and GPIbα engagement (Yin et al. 2008; Kim et al. 2009). It is also involved in outside-in signaling (Kim and Kunapuli 2011). Lack of Fyn is compatible with development and not associated with overt bleeding, although a tendency to rebleed was noticed (Reddy et al. 2008).

Pharmacological Modulation

Fyn kinase inhibitors have been developed but, so far, for non-thrombotic indications. Indeed, Fyn is ubiquitously

expressed across the human body and has been shown to also participate in T-cell signaling, cell growth and survival, adhesion and motility, axon guidance and synaptic function, and myelination [for review see Elias and Ditzel (2015)]. Fyn has been involved in cancer pathogenesis through a direct participation in mechanisms leading to cell growth and death, transformation, and motility, in drug-resistance mechanisms, and in signal transduction pathways in the nervous system. Modulation of Fyn is currently being studied as a potential therapy for the development of Alzheimer disease (Nygaard et al. 2014). As an example, AZD0530, a Fyn kinase inhibitor, showed ability to rescue spatial memory deficits and synaptic depletion (Kaufman et al. 2015). Hence, due to ubiquitous function and distribution and a relatively limited participation to platelet biology (i.e., aggregation), this target does not seem to have triggered development of a specific inhibitor for thrombosis indication.

Rho

Genetic Modulation and Pathophysiology

Rho GTPase such as RhoA, Rac1, and Cdc42 possesses roles in platelet function, cytoskeletal rearrangement, as well as platelet formation (Aslan and McCarty 2013; Pleines et al. 2013). They bind GTP to induce the activation of downstream effectors in a manner relatively similar to that of G_{α} subunits (see Stefanini et al. 2017). Of those GTPases, RhoG regulates microtubule rearrangements, filopodia and lamellipodia formation, spreading and granule trafficking across several cell types (B-cells, T-cells, endothelial cells, platelets (Goggs et al. 2015). $RhoG^{-/-}$ mice have been shown to possess increased levels of IgG1 and two antibodies and a mild defect in B- and T-cell activities (Vigorito et al. 2004). Use of $RhoG^{-/-}$ platelets highlighted a key participation to $\alpha_{IIb}\beta_3$ activation and platelet aggregation upon platelet stimulation by CRP and thrombin, a process initially proposed to be driven by Src and Syk kinases (Goggs et al. 2013). Further work by the group of Dr. Kunapuli demonstrated that RhoG acts upstream of Syk, Akt, and ERK in the GPVI signaling pathway and significantly contributes to thrombus formation in vivo. Interestingly, granule secretion is differentially impaired in $RhoG^{-/-}$ platelets, with normal response observed following thrombin stimulation but not when CRP is the agonist. Such difference may account for the fact that RhoG-deficient animals have defective thrombus formation while presenting normal primary hemostasis (Goggs et al. 2013). This phenotype resembles that of $FcR\gamma^{-/-}$ mice, which too impact Syk phosphorylation, affect thrombosis but are not involved in cessation of bleeding. Since knockdown of RhoG is associated with a relatively mild bleeding phenotype (as opposed to other Rho GTPases), it could constitute a good antiplatelet target.

Pharmacological Modulation

Despite preclinical data indicating that RhoG could constitute a safe antithrombotic target, there is no evidence that its modulation is actively being pursued for thrombotic indications. Rho-kinase inhibitors are being studied for other indications, such as modulation of ocular hypertension. Preclinically, fasudil has been shown to cause increased cerebral blood flow and protect against cerebral death in an endothelium-derived NO manner (Rikitake et al. 2005; Koumura et al. 2011).

PI3K

Genetic Modulation and Pathophysiology

Four class I phosphoinositide 3-kinases (PI3K) have been reported in platelets. PI3Kβ mediates platelet signaling downstream of GPVI engagement by collagen, plays a role in outside-in integrin signaling, and participates in signaling downstream GPCRs (Jackson et al. 2005; Canobbio et al. 2009; Kim et al. 2009; Martin et al. 2010a, b). Signaling downstream of GPVI has been particularly well studied. The p85α subunit coprecipitates with FcRγ and the LAT adaptor protein (Gibbins et al. 1998) and then brings the p110 subunit to the membrane where it is responsible for the generation of the second messengers phosphoinositide (PI) (3,4)P2 and (3,4,5)P3. PI3Kα is key to the GPVI signaling pathway, and its deficiency affects collagen and CRP signaling and aggregation but not that induced by ADP or thrombin (Watanabe et al. 2003). Finally, PI3Kγ is also contributing to ADP-induced platelet aggregation and plays a role in thrombosis (Hirsch et al. 2001; Canobbio et al. 2009).

Pharmacological Modulation

Interestingly, while deficiency in p85α and p85β has been associated with protection from thrombosis at no cost on bleeding, data from experimental studies evaluating activity of pharmacological inhibitors are somehow more controversial. As an example, TGX-221, a PI3Kβ inhibitor that blocks the Rap1b/Akt pathway downstream of ADP-induced activation (see Jackson et al. 2005; Gilio et al. 2009), prolonged bleeding time, a phenomenon likely explained by the fact that PI3Kβ plays a role in collagen, ADP, and also thrombin-induced signaling. Similar findings were also observed by Bird and colleagues with a PI3Kβ antagonist (Bird et al. 2011). A potential explanation could come from the fact that PI3K is ubiquitously expressed and that only highly selective inhibitors should be utilized in and across preclinical species. The requirement for highly selective antagonist is further exemplified by the fact that the different isoforms

have key roles in many processes, such as oncogenesis [α, (Stephens et al. 2005), δ (Sanford et al. 2015)], adaptive immunity, and inflammation [γ, (Ruckle et al. 2006), (δ, (Ali et al. 2004)]. PI3K inhibitors have been developed and tested in human. AZD6482 (ClinicalTrials.gov Identifier: NCT00688714) was notably evaluated vs clopidogrel on bleeding time when taken together with low-dose aspirin (ClinicalTrials.gov Identifier: NCT00853450). Another drug, TG100-115, underwent Phase I/II studies and was designed for heart attack treated with angioplasty (ClinicalTrials.gov Identifier: NCT00103350); however the different findings have not been released yet.

Btk

Genetic Modulation and Pathophysiology

Bruton's family kinases (Btk) are non-receptor tyrosine kinases involved in a multitude of signaling pathways, amplifying signals coming from the cell membrane across a wide variety of cells. They participate in signal transduction downstream of GPCRs, integrins, RTKs, cytokine, and death receptors and interact with nearly all non-receptor tyrosine kinases. They have been reported to activate/phosphorylate PLCγ, PKC, Rho, WASP, actin, BCL-XL, Akt, JNK, Stat3, TFII-I, and NFκB [for review see Qiu and Kung (2000)]. Btk is involved in cell growth, differentiation, and development. As an example, its deficiency prevents proliferation of B-cells upon antigen stimulation, and mutations in human have been linked to immunodeficiency disease, X-linked agammaglobulinemia (XLA), and apoptosis. In platelets, Btk (a member of the Tec family) regulates PLCγ2 activity following engagement of GPVI by collagen and CRP. Btk is regulated by Src kinases, phosphorylated in response to collagen and thrombin stimulation and recruited to the plasma membrane via an interaction with PIP3. Platelets from XLA patients have a defect in activation induced by collagen and CRP (Quek et al. 1998) that can be compensated by high concentrations of platelet agonist.

Pharmacological Modulation

Several compounds targeting Btk (e.g., ibrutinib, acalabrutinib, PCI-32765, HM-71224, CC-292, and ONO-4059) have entered clinical evaluation for the treatment of hematologic malignancies and autoimmune disorders. Interestingly, some bleeding symptoms have been observed in chronic lymphocytic leukemia and mantle cell lymphoma patients treated with ibrutinib, an observation in conflict with preclinical results (Rigg et al. 2015). Furthermore, antithrombotic effects could be observed preclinically with ibrutinib but not with acalabrutinib (Byrd et al. 2016). Thus, selectivity profile of Btk inhibitors will be an area of concern as well as safety and determination of effective thrombosis target engagement levels for long-term chronic use.

PAK

Genetic Modulation and Pathophysiology

PAK (p21-activated kinases) are serine/threonine protein kinases Rho GTPase effectors promoting cytoskeletal rearrangement. PAK2 is activated downstream of PAR receptor engagement (Arias-Romero and Chernoff 2008), where they support activation of the MEK/ERK pathway (Aslan et al. 2013). Nevertheless, there have been no reports on potential involvement in primary hemostasis in preclinical species. Although there is only sparse information relative to the phenotype associated with modulation or deficiency of PAKs, it should be emphasized that mast cell deficiency in PAK1 is associated with decreased allergen-induced degranulation.

Pharmacological Modulation

PAK4 inhibitor (PF-03758309) is currently being tested in human in patients with advanced solid tumors (ClinicalTrials.gov Identifier: NCT00932126). There are no reports on the development of PAK2 inhibitors. Based on its broad involvement in multiple cell signaling pathways, it is likely that highly selective inhibitors would also have to be developed in order to limit the biology to the platelet function.

LIMK1

Genetic Modulation and Pathophysiology

LIMK1 (LIM kinase 1) is expressed in platelets and is activated via phosphorylation of threonine residues (notably through p21-activated kinases) upon platelet activation and is believed to facilitate actin polymerization. Deficiency in LIMK1 is associated with protection from thrombosis without significant effect on primary hemostasis (Estevez et al. 2013). LIMK1 participation to thrombosis is dual as it promotes a GPIbα-dependent TxA_2 synthesis and also integrates responses to low-dose thrombin between GPIb and PAR signaling pathways (Estevez et al. 2015).

Pharmacological Modulation

There are no known modulators of LIMK1 in development.

PKC

Genetic Modulation and Pathophysiology

Human and murine platelets express the PKC isoforms α, β, δ, and θ. PKCα is considered key to platelet degranulation and aggregation in response to collagen and thrombin (human), while PKCβ (mice) supports outside-in signaling (Buensuceso et al. 2005; Konopatskaya et al. 2009; Gilio et al. 2010). Redundancy in isoforms certainly accounts for the lack of bleeding prolongation in PKCα-deficient mice. Perfusion of blood over collagen revealed that while PKCα and β actively contribute to the thrombotic process, the other two isoforms (δ and θ) may act as endogenous inhibitors (Crosby and Poole 2003; Chari et al. 2009). PKCs have broad activities in multiple cell types, being involved in proliferation, differentiation, adhesion, motility, and apoptosis. PKCα expression levels and activity are often increased in tumor tissues [currently the focus of several cancer therapies (Sliva 2004)]. PKCα is also involved in T-cell biology (Pfeifhofer et al. 2006; von Essen et al. 2006) and insulin homeostasis (Leitges et al. 2002), and its modulation has been shown to affect heart failure (Braz et al. 2004).

Pharmacological Modulation

Several PKC inhibitors are currently being tested in clinical studies, notably in the cardiovascular/cardiometabolic area. LY333531, a PKCβ inhibitor has been studied in diabetic patients, notably for reduction in vision loss associated with diabetic retinopathy (ClinicalTrials.gov identifier: NCT00604383). Safety and efficacy studies of KAI-9803 have also been performed in subjects with ST-elevation myocardial infarction (PROTECTION AMI, ClinicalTrials.gov Identifier: NCT00785954), while others are being investigated in multiple transplantation and oncology settings (e.g., AEB071). There are no published reports indicating that such compounds are being developed for thrombosis indications.

Vav1/3

Genetic Modulation and Pathophysiology

Vav1- and Vav3-deficient platelets have a defect in GPVI signaling in response to collagen stimulation, upstream of PLCγ2 (Pearce et al. 2004). Interestingly, Vav has been associated with oxidized LDL-mediated platelet activation, linking thrombosis and hyperlipidemia (Chen et al. 2011).

Pharmacological Modulation

There are no known modulators of Vav1/3 in development.

PLD1

Genetic Modulation and Pathophysiology

Mice deficient in phospholipase D1 have been generated and displayed a defect in GPIbα signaling pathway leading to inhibition of arterial thrombosis at no cost on bleeding. The platelets have an overall impairment of $\alpha_{IIb}\beta_3$ activation in response to most major platelet agonist (Elvers et al. 2010). PLD1 is also involved in other pathologies and has been linked to Alzheimer's disease and tumor angiogenesis and metastasis (Jin et al. 2007; Chen et al. 2012)

Pharmacological Modulation

A PLD1 inhibitor, 5-fluoro-2-indolyl des-chlorohalopemide, has been shown to block the enzyme activity and interfere with granule release and inside-out signaling. It provided protection in an animal model of ischemic stroke with no spontaneous bleeding or prolongation of tail bleeding time, confirming the phenotype of the deficient mice (Stegner et al. 2013).

ERK/p38MAPK

Genetic Modulation and Pathophysiology

Extracellular signal-regulated kinase (ERK) belongs to the mitogen-activated protein (MAP) kinase family involved in cell signaling and adhesion. Genetic inactivation of ERK2 results in early embryonic lethality (Aouadi et al. 2006). In addition, cardiac and craniofacial defects as well as developmental delay and mental retardation have been reported in patients with mutations in the ERK/MAPK pathway (see Samuels et al. 2008). P38 MAPK has also been reported to play a role in models of lung metastasis (Matsuo et al. 2006). In platelets, ERK2 activation downstream of collagen stimulation is Rap1 dependent (Stefanini et al. 2009) and requires TxA_2/TP (mostly G_q) and ADP/$P2Y_{12}$ (G_i signaling) signaling (Roger et al. 2004). Experiments performed under flow conditions revealed that ERK2 and p38 MAPK have complementary roles in adhesion to collagen (Mazharian et al. 2005), that participation of ERK2 requires engagement of GPIbα by vWF and the $P2X_1$ ion channel (via PKC/MEK1/2), while that of p38 involves integrin $\alpha_2\beta_1$. ERK2 is also activated in response to thrombin cleavage of PAR1/4, a phenomenon also attributed to PKC and MEK1/2 (Aharonovitz and Granot 1996). Similarly, thrombosis was delayed in a ferric chloride thrombosis model applied to the carotid artery of $p38MAPK^{+/-}$ mice, a phenotype notably attributed to a defect in $\alpha_{IIb}\beta_3$ activation mediated by inhibition of the TP pathway, likely through a defect in cPLA2 phosphorylation (Borsch-Haubold et al. 1998).

Pharmacological Modulation

Of note, use of a selective MEK1/2 inhibitor in wild-type and transgenic mice overexpressing $P2X_1$ delayed time to occlusion in injured arteries through inhibition of the vWF-GPIbα pathway (Oury et al. 2006). Losmapimod (a p38 MAPK inhibitor, GSK) benefits are currently being tested in a Phase III study in patients with acute coronary syndrome. The hypothesis is that inhibition of p38 MAPK will stabilize atherosclerotic plaques and prevent subsequent thrombosis leading to ischemia. VX-702 (Vertex) has shown an ability to decrease platelet storage lesion in vitro (Wagner et al. 2015) as well as platelet aggregation (Kuliopulos et al. 2004) and has been tested in the setting of rheumatoid arthritis as well as patients with acute coronary syndrome undergoing PCI. p38 MAPK inhibitors are also being developed for indications as diverse as COPD, asthma, rheumatoid arthritis, Alzheimer's, and oncology (Clinicaltrials.gov).

Effectors Involved in Thrombosis and Primary Hemostasis

LAT

Genetic Modulation and Pathophysiology

LAT, or Linker for activation of T-cell, is expressed in T-cells, NK cells, macrophages, mast cells, and platelets. It is found in glycolipid-enriched domains (Zhang et al. 1998a, b) where it associates with several proteins involved in T-cell receptor signaling (Zhang et al. 1998a, b). LAT deficiency in mice is characterized by an absence of mature peripheral T-cells (Zhang et al. 1999). LAT is tyrosine phosphorylated upon collagen stimulation and FcγRIIA cross-linking in platelets (Pasquet et al. 1999). It associates with p85PI3K and the FcRγ-chain but also with SLP-76, PLCγ2, Cbl, and Grb2 (Asazuma et al. 2000). The main consequence of platelet LAT deficiency is a reduced phosphorylation and activation of PLCγ2 that leads to a defect in platelet secretion and aggregation following activation by collagen. LAT deficiency is accompanied by a mild increase in bleeding time similar to that observed in FcRγ-deficient mice and a strong protection from thrombosis (at least similar to that conferred by FcRγ and PLCγ2 deficiency) in models exposing fibrillar collagen to the circulating whole blood (Kalia et al. 2008).

Pharmacological Modulation

There are no known inhibitors of LAT in development for the treatment/prevention of thrombosis.

Akt(s)

Genetic Modulation and Pathophysiology

Akt1 and 2 are serine/threonine kinases found in human and murine platelets. While Yin et al. found that Akt-$1^{-/-}$ mice have a defect in their platelet response to collagen and thrombin accompanied by a decrease in granule release and significantly increased tail bleeding times (Chen et al. 2004; Yin et al. 2008), some have argued that Akt2 is the predominant functional isoform as mice lacking Akt2 present a defect in platelet secretion, aggregation, and thrombus formation. This defect has been attributed to an impairment in the signaling pathway downstream of Gq-coupled receptors (PARs and TP) resulting in reduced secretion of α- and dense granules but without a prolongation of bleeding time values (Woulfe et al. 2004). Interestingly, Akt1 has been linked to organismal growth (Cho et al. 2001a, b), while high expression levels of Akt2 in pancreatic B-cells and brown fat have been related to its involvement in glucose metabolism (Akt$2^{-/-}$ mice are hyperglycemic and hyperinsulinemic and present defects in insulin responses (Cho et al. 2001a, b; Garofalo et al. 2003)).

Pharmacological Modulation

Akt inhibitors are being developed for indications as diverse as relapsed lymphoma, diffuse large B-cell lymphoma, and multiple myeloma. Thus, ubiquitous functions are likely to hamper the development of Akt inhibitors for the treatment or prevention of thrombosis.

Rac

Genetic Modulation and Pathophysiology

Rac GTPase 1 (Rac1) is detected in platelets and its activation following GPCR stimulation or $\alpha_{IIb}\beta_3$ engagement has been well documented (Hartwig et al. 1995; Azim et al. 2000; Soulet et al. 2001). Rac1 deficiency is associated with a severe defect in B-cell development (Walmsley et al. 2003), defective GPVI-mediated platelet activation and aggregation due to impaired PLCγ2 activation (Pleines et al. 2009), and a defect in granule secretion (Akbar et al. 2007). Rac1 was also found to mediate platelet procoagulant response to low-dose agonists (Delaney et al. 2014) and to be at the juncture of cooperative signaling pathways downstream of thrombin activation of GPIbα and PARs (Estevez et al. 2015). According to its platelet pleiotropic effects, it is not a surprise to observe prolonged bleeding time in knockout mice (Akbar et al. 2007).

Pharmacological Modulation

There are no reports related to the development of Rac1 inhibitors for thrombosis or cardiovascular indications.

RhoA

Genetic Modulation and Pathophysiology

Selective deletion of p115-Rho GEF-RhoA in megakaryocyte induces macrothrombocytopenia in mice as well as reduced platelet activation following $G_{\alpha q}$ stimulation, complete inhibition of shape change following $G_{\alpha 12/13}$ stimulation, and defect in granule secretion. RhoA is also important for outside-in mediated signaling as judged by reduced clot retraction. This broad participation to platelet function translates into significant prolongation of the bleeding time and significant protection from thrombosis (Pleines et al. 2012).

Pharmacological Modulation

Development of a RhoA inhibitor has certainly been affected by the bleeding diathesis and macrothrombocytopenia associated with RhoA deletion.

TRPC6

Genetic Modulation and Pathophysiology

Transient receptor potential nonselective calcium channels TRPC6 is an important effector leading to cytosolic Ca^{++}-mediated PS exposure in platelets (Mahaut-Smith 2013) and platelet aggregation (Vemana et al. 2015). Mice deficient in TRPC6 have prolonged tail bleeding time and are protected from arterial thrombosis (Paez Espinosa et al. 2012). This phenotype is believed to stem from a defect in $G_{\alpha q}$ signaling pathway, following thrombin stimulation of platelets. TRPC6 belongs to a class of human transient receptor potential canonical proteins which also contains TRPC1, TRPC3, TRPC4, TRPC5, and TRPC7. These proteins are distributed broadly and are involved in many cellular responses.

Pharmacological Modulation

There have been no reports of drugs targeting TRPC6 for thrombosis indication.

PLCβ

Genetic Modulation and Pathophysiology

Phospholipase Cβ promotes the cleavage of PIP2 into IP3 and DAG following engagement of G protein-coupled receptors. Deficiency in $PLC\beta_2$ in mice is accompanied by defective thrombus stability in vivo (Lian et al. 2005). Interestingly, patients presenting approximately a third of $PLC\beta_2$ have been described and show a mild inherited bleeding disorder together with a defective platelet aggregation process (Lee et al. 1996).

Pharmacological Modulation

Since intermediate levels of $PLC\beta_2$ are associated with bleeding risks, this target may not be suited for development of a safe antithrombotic.

sGC

Genetic Modulation and Pathophysiology

Soluble guanylyl cyclase (sGC) and cGMP-dependent protein kinase (PKG) have been reported to have biphasic effects in platelets, characterized by an initial stimulatory boost followed by inhibitory activities (Li et al. 2003; Zhang et al. 2011). Platelet-specific sGC-deficient mice have prolonged bleeding time (Zhang et al. 2011). PKG inhibitors affect GPIbα and thrombin/PARs signaling pathways leading to $\alpha_{IIb}\beta_3$ activation (Li et al. 2006). Due to its dual activity, development and use of a sGC/PKG inhibitor would have to be carefully evaluated in clinic in order to determine its relative efficacy and safety profiles.

Pharmacological Modulation

Vericiguat has been studied in chronic heart failure patients. Riociguat, a sGC stimulator, is currently being studied in patients with chronic thromboembolic pulmonary hypertension. It has been approved to treat hypertension and chronic thromboembolic pulmonary hypertension and associated with minor or more severe bleeding episodes which could be attributed to its vascular and platelet effects.

JNK1

Genetic Modulation and Pathophysiology

C-Jun aminoterminal kinase (JNK1) belongs to the serine/threonine MAP kinase family, is found in platelets, and is ubiquitously expressed in proliferating cells (Kumar et al. 2015). JNK1 is activated by thrombin, collagen, and vWF (see Adam et al. 2010). JNK1-deficient mice are characterized by a reduction in thrombotic response triggered by fibrillar collagen, unstable thrombi in vivo, decreased secretion, and prolonged bleeding time (with a tendency to rebleed) (Adam et al. 2010). $JNK1^{-/-}$ platelets have a small defect in PKC activation and TxA_2 synthesis (another JNK isoform is believed to contribute to TxA_2 formation). It has been reported that JNK1 and ERK2 possess complementary roles in collagen-induced platelet

signaling, with ERK2 having both JNK1 dependent and independent activities.

Pharmacological Modulation

There have been no reports of drugs targeting JNK1 for thrombosis indication.

$cPLA_2$

Genetic Modulation and Pathophysiology

Platelets possess secretory and cytosolic phospholipase A2 ($cPLA_2$). $cPLA_2$ releases arachidonic acid (AA) from glycerophospholipids, promoting the release of thromboxane A_2 (TxA_2, a potent platelet agonist) via cyclooxygenase 1 (COX1). Deficiency in $cPLA_2$ is associated with decreased granule secretion and platelet aggregation in response to collagen but also with prolonged bleeding time (Wong et al. 2002). Recently, Yoda and colleagues have shown that another PLA_2 ($iPLA_2\gamma$) plays a role in platelet aggregation in response to ADP and hemostasis (Yoda et al. 2014). A direct impact on primary hemostasis is likely explained by the fact that TxA_2 synthesis (like the release of ADP) is key to the platelet feedback loops enhancing the aggregation reaction (Prevost et al. 2009; Estevez et al. 2013). Deficiency of $cPLA_{2\alpha}$ is also responsible for defective fertility (Bonventre et al. 1997) and may protect from experimental autoimmune encephalomyelitis via inhibition of T-cell differentiation (Marusic et al. 2005).

Pharmacological Modulation

A potent, selective inhibitor of $cPLA_2$ has been developed (giripladib) and showed ability to inhibit platelet adhesion and aggregation on fibrillar collagen (Duvernay et al. 2015). Interestingly, under conditions of low collagen-induced activation (that does not involve $cPLA_2$), it is believed that PLC generates diacylglycerol (DG) which is subsequently the subject of the action of diglyceride lipase (DGL), leading to the release of arachidonic acid. A DGL inhibitor has recently been shown to affect platelet aggregation induced by collagen (Jackson et al. 2013).

PAR Intracellular Domain

Pharmacological Modulation

As an alternative to classical orthosteric inhibitor like vorapaxar, inhibition of PAR1 can be achieved via interference with its signaling pathway (O'Callaghan et al. 2012). Recently, Aisiku and colleagues described a class of antiplatelet agents selectively targeting one signaling pathway downstream of PAR1. The agents called parmodulins selectively interfere with $G_{\alpha q}$ signaling, while sparing the believed cytoprotective effect associated with $G_{\alpha 12/13}$ (Aisiku et al. 2015). Thus, it is possible that disease-specific agents could be developed based on the biased signaling properties of PARs.

Effectors Involved Beyond Thrombosis

Syk

Genetic Modulation and Pathophysiology

Syk is a signaling protein with kinase and scaffolding activities. In mice, Syk deficiency is accompanied by embryonic lethality, anemia, petechial hemorrhages throughout the gut, and impairment of B-cell development (Cheng et al. 1995; Turner et al. 1995). Like SLP-76 (see below), it plays a key role in lymphovenous homeostasis where it maintains separation between blood vessels and lymphatic vessels. In platelets, phosphorylation of Syk has been reported downstream of GPVI, GPIbα, and $\alpha_{IIb}\beta_3$ (Law et al. 1999a, b; Watson et al. 2005), following exposure to high shear stress (Speich et al. 2008), after engagement of FcγRIIA, FcRγ, FcαRI, and the C-type lectin receptor-2 (CLEC-2) (Yanaga et al. 1995; Chacko et al. 1996; Suzuki-Inoue et al. 2006). Syk also promotes the recruitment of leukocytes via regulation of leukocyte rolling and adhesion (Mocsai et al. 2002; Frommhold et al. 2007; Zarbock et al. 2007). Interestingly, $Syk^{+/-}$ mice are protected from thrombosis, and pharmacologic modulation of Syk inhibits thrombosis, restenosis, and atherosclerosis while maintaining normal homeostasis (Andre et al. 2011).

Pharmacological Modulation

Syk inhibitors are being developed for the treatment of rheumatoid arthritis (fostamatinib, Rigel), allergic asthma, oncology (fostamatinib, PRT2070), and immune thrombocytopenia (fostamatinib). R406 is notably being developed for the treatment of refractory ITP based on strong preclinical evidence (Podolanczuk et al. 2009; Reilly et al. 2011). Data also showed that modulation of Syk with a selective inhibitor could safely inhibit thrombosis and the progression of atherosclerosis and restenosis in rodents (Andre et al. 2011; Hilgendorf et al. 2011).

SLP-76

Genetic Modulation and Pathophysiology

The adapter protein Src homology 2 domain-containing leukocyte protein 76 (SLP-76) was originally found in T-cells (Jackman et al. 1995). Mice deficient in SLP-76 exhibit a complete block in T-cell development through a defect in pre-TCR signaling and subcutaneous hemorrhages

(Clements et al. 1999). Maintenance of vascular integrity during inflammation is under the critical influence of platelet ITAM signaling as highlighted by the work of Bergmeier and colleagues (Boulaftali et al. 2013). This is to be related to the original observation made in Syk and SLP-76$^{-/-}$ mice in which separation of blood vessels and lymphatic vessels is impaired (Bertozzi et al. 2010; Finney et al. 2012). Despite the presence of hemorrhage, bleeding time is normal in animals with loss of function of SLP-76 (Clements et al. 1999). Furthermore, Bezman and colleagues showed the existence of key tyrosine residues in SLP-76 for the ITAM and integrin receptor signaling leading to platelet function (Bezman et al. 2008).

Pharmacological Modulation

There are no SLP-76 inhibitors undergoing late-stage development for thrombosis indication.

PLCγ2

Genetic Modulation and Pathophysiology

PLCγ2 is mostly expressed in hematopoietic cells (B-cells, platelets, mast cells, and monocytes/macrophages) where it functions as a key signaling player of immunoglobulin superfamily receptors. PLCγ2 knockout mice have normal blood cell counts but impaired BCR-mediated signaling leading to a *xid*-like immunodeficiency phenotype, decreased platelet reactivity, and some levels of subcutaneous, intraperitoneal, and gastrointestinal hemorrhage (Wang et al. 2000). Remarkably, PLCγ2$^{-/-}$ mice have a prolonged bleeding time, but not the PLCγ2$^{+/-}$ animals (Mangin et al. 2003). Importantly, others have shown that knockout animals do not have prolonged bleeding times in spite of a significant protection from thrombosis (Kalia et al. 2008). Platelets deficient in PLCγ2 have a defect in granule release and aggregation following collagen stimulation [in a concentration-dependent manner (Cho et al. 2003)] but do have a normal response to ADP and thrombin.

Pharmacological Modulation

There are no PLCγ inhibitors undergoing late-stage development for thrombosis indication.

CalDAG-GEFI

Genetic Modulation and Pathophysiology

The Ca^{2+} and diacylglycerol-regulated guanine nucleotide exchange factor (CalDAG-GEFI) plays a key role in platelet activation. It activates the small GTPase Rap1, enhancing talin binding to $\alpha_{IIb}\beta_3$ and allowing full activation of the fibrinogen receptor. Mutations in RASGRP2 prevent Rap1 activation, leading to a severe platelet aggregation defect and bleeding diathesis (see Canault et al. 2014; Nurden and Nurden 2015). CalDAG-GEFI deficiency has been shown to protect from ITAM-dependent thrombotic thrombocytopenia (Stolla et al. 2011; Amirkhosravi et al. 2014) and thrombosis (Bergmeier et al. 2007). Defective expression of CalDAG-GEFI was also suggested as the cause of leukocyte adhesion deficiency (LAD-III syndrome), a clinical disorder characterized by impaired activation of integrins in platelets and leukocytes (Bergmeier et al. 2007; Pasvolsky et al. 2007). However, all cases of LAD-III are caused by mutations in the gene Fermt3. CalDAG-GEFI also plays a role in leukocyte rolling and chemotaxis (Carbo et al. 2010; Stadtmann et al. 2011), possibly in the pathology of Huntington's disease (Crittenden et al. 2010) and motor complications (Crittenden et al. 2009).

Pharmacological Modulation

A safe selective inhibitor of CalDAG-GEFI will require that effective target engagement levels (thrombosis) will be different from those leading to bleeding (and other biology). There are no known inhibitors of CalDAG-GEFI in development.

Rap1b

Genetic Modulation and Pathophysiology

Rap1b-deficient mice have 85 % incidence of embryonic and perinatal lethality (with ~40 % having abdominal, cranial, and hepatic bleeding). Generation of Rap1b-null bone marrow chimeras revealed that platelet Rap1b is involved in primary hemostasis, a phenomenon likely to be attributed to its broad role in platelet activation. Indeed, Rap1b$^{-/-}$ platelets exhibit and impaired aggregation response to all platelet agonists (thrombin, collagen, and ADP (including calcium ionophore), independently of the agonist concentration (Chrzanowska-Wodnicka et al. 2005). In addition, Rap1b is also mediating $\alpha_{IIb}\beta_3$ outside-in signaling, explaining the strong protection from thrombosis (Chrzanowska-Wodnicka et al. 2005). Besides a critical role in platelet function, Rap1b has been shown to play major roles in neutrophil chemotaxis (Kumar et al. 2014), B- and T-cell functions (Chu et al. 2008), vascular tone, and blood pressure (Lakshmikanthan et al. 2014).

Pharmacological Modulation

There are no known inhibitors of Rap1b in development for the treatment or prevention of thrombosis.

Pyk2

Genetic Modulation and Pathophysiology

In platelet signaling, Pyk2 (also named the Ca^{++}-dependent tyrosine kinase) promotes Lyn and Fyn activation following thrombin stimulation and acts as a positive feedback loop with/on the Src family kinase (Canobbio et al. 2015). It is also activated downstream of GPIbα and integrins, and its deficiency is associated with prolonged bleeding and protection from thrombosis (Canobbio et al. 2013). Pyk2 biology extends beyond platelet function as it plays an important role in osteoblast and bone formation (Cheng et al. 2013). Pyk2 is also being considered as a target for diverse cancers, including multiple myeloma (Meads et al. 2015).

Pharmacological Modulation

There are no known inhibitors of Pyk2 in development for the treatment or prevention of thrombosis.

Disabled-2

Genetic Modulation and Pathophysiology

Platelet-specific deletion of disabled-2 in mice has revealed a prolonged bleeding time and inhibition of thrombus formation due to a diminished response to thrombin stimulation (Tsai et al. 2014). The inhibition affects $G_{\alpha 12/13}$-mediated RhoA activation and Akt and mTOR phosphorylation and does not seem to interfere with $G_{\alpha q}$ signaling. Pyk2 plays a role in endocytosis, cell surface receptor turnover, and signaling, and its downregulation has been associated with (notably) fibrotic processes, epithelial-to-mesenchymal transition (Martin et al. 2010a, b), and tumorigenesis (Yang et al. 2006).

Pharmacological Modulation

While a disabled-2-derived peptide has been used in perfusion chamber studies in which it demonstrated anti-aggregatory activities, modulation of disabled-2 in vivo has not been tested in the context of thrombosis (Xiao et al. 2012). There are no known inhibitors of Pyk2 in development for the treatment or prevention of thrombosis.

Targets from the Outside-In Signaling Pathway and Their Pharmacological Modulation

The first indication that targeting the $\alpha_{IIb}\beta_3$ outside-in signaling pathway may have an acceptable therapeutic window came from the observation of Law and colleagues who showed that a cytoplasmic tyrosine motif was associated with protection from thrombosis with minor effect on bleeding (Law et al. 1999a, b). Several key effectors have been identified.

$G_{\alpha 13}$

A myristoylated ExE motif peptide inhibiting the $G_{\alpha 13}$-integrin interaction demonstrated the ability to inhibit spreading on the integrin ligand and to inhibit the second wave of platelet aggregation. More importantly, it blocked thrombosis in vivo without prolonging the bleeding time (Shen et al. 2013).

SFK

A peptide derived from the c-Src binding sequence of β_3 has shown selectivity for the outside-in pathway and provided protection from thrombosis although this was accompanied by an increase in bleeding (Su et al. 2008; Ablooglu et al. 2009).

Kindlin-2

Kindlin-2 is a cytoskeletal protein that has been implicated in β_3 integrin signaling pathway (Ma et al. 2008; Liao et al. 2015) and which deficiency is embryonically lethal in mice. Heterozygous mice are protected from thrombosis but also present defect in hemostasis, a phenomenon that has been tentatively related to dysregulation of ADP/AMP catalytic enzymes at the surface of endothelial cells (Pluskota et al. 2013). There are no known inhibitors of Kindlin-2 in development for thrombosis indications.

Lnk

Lnk (lymphocyte adaptor protein) inhibits thrombopoietin-mediated signaling, leading notably to increased platelet production in Lnk-deficient animals. Null mice have a tendency to rebleed and are protected from thrombosis despite presenting a significant increase in platelet count (Takizawa et al. 2010). Lnk main function in thrombosis seems to be in the outside-in signaling pathway where it mediates reorganization of the cytoskeleton. There are no known inhibitors of Lnk in development for thrombosis indications.

PDK1

PDK1 (phosphoinositide-dependent protein kinase 1) is activated by PI3K (via binding to PIP3) and induces

phosphorylation and activation of Akt. Using a platelet-specific PDK1 deletion strategy, PDK1 was demonstrated to enhance thrombin-induced platelet aggregation and outside-in signaling (Chen et al. 2013). PDK1 functions go beyond thrombosis as it participates in multiple cellular functions (cell growth/proliferation/survival), β-adrenergic response and overall cardiac homeostasis (Ito et al. 2009). There are no known inhibitors of PDK1 in development for thrombosis indications.

ILK

Like PDK1, ILK (integrin-linked kinase) regulates multiple cellular functions and associates with β3 (as well as β1) integrin. Mice deficient in ILK have a defect in thrombus formation and α-granule release and exhibited enhanced bleeding time (Tucker et al. 2008). It is also an important contributor to cardiomyocyte homeostasis (like PDK1) and renal homeostasis.

Take Home Message

Comments

1. Some effectors of platelet signaling exist that are involved in thrombosis but not in primary hemostasis.
2. Most effectors possess functions beyond a single signaling pathway inside the platelet or in a different cellular compartment.
3. Some effectors have ubiquitous role in platelet function (i.e., CalDAG-GEFI and Rap1b) and have a major impact on primary hemostasis; intermediate levels of inhibition may provide protection from thrombosis at no cost on bleeding.
4. Some effectors have an impact beyond platelet function. In this category, we can group Syk, SLP-76, and PLCγ2 as their deficiencies are associated with defective platelet function and also vascular defects, but again, pharmacologic modulation at intermediate levels could provide a viable therapeutic window.
5. The severity of the platelet defect (on secretion and $\alpha_{IIb}\beta_3$ activation) is often, but not always, associated with bleeding intensity. For example, deficiency in or modulation of RhoG, PI3Kp85, Btk, PAK, and PKCα severely impairs platelet function at limited or no cost on bleeding.
6. There is a need for selective tool compounds (across animal species) to better characterize and de-risk targets early.
7. Investigators should document the phenotype associated with heterozygous mice, as it would provide valuable information to the industry (related to the validity of the target and efficacious target engagement levels).
8. We encourage investigators to study the signaling pathways in presence of concomitant antithrombotic therapies (antiplatelet and/or anti-coagulants) in order to understand the physiology associated with dual or triple inhibition.

Therapy

Antiplatelet Therapy in Patients with Coronary Artery Disease

Harsh Patel and Neal S. Kleiman

Abstract

Treatment with aspirin has been a cornerstone of acute therapy and of secondary prevention for patients with active coronary artery disease, and in particular those with acute myocardial infarction, acute coronary syndromes, and those undergoing either percutaneous or surgical revascularization. Studies within the past decade have highlighted the added benefit of treatment with antagonists of $P2Y_{12}$ among those with acute coronary syndromes and those undergoing percutaneous revascularization. The optimal duration of treatment appears to be at least 15 months after the onset of the acute coronary syndrome or 30 months for patients who undergo intracoronary implantation of a drug eluting stent, however studies with newer generation stents in selected patients have indicated that shorter durations may well be acceptable. For patients who also have a need for an oral anticoagulant, particularly those with atrial fibrillation or with mechanical prosthetic heart valves, the anti-platelet drug regimen is much less clear. Clinical trials of new regimens in this situation continue to evolve and have indicated that prolonged duration of a triple drug regimen (oral anticoagulant, aspirin, and a $P2Y_{12}$ antagonist) is associated with an increased risk of hemorrhage, and that a regimen that excludes aspirin may be acceptable.

Introduction

Antiplatelet drugs have become a cornerstone of therapy in cardiology. The value of aspirin in reducing thrombotic events in patients with atherosclerotic vascular disease has been noted since the 1950s. Several trials over the past few decades have firmly established its role in both primary and secondary prevention of cardiovascular events resulting from atherosclerotic vascular disease. Several oral $P2Y_{12}$ antagonists have also been proven in randomized studies to provide incremental benefit in addition to aspirin in secondary prevention of thrombotic events in high-risk subgroups. However, the optimal duration of dual antiplatelet therapy is still controversial and remains an area of investigation. Ultimately the optimal duration is likely to be dependent on several patient-specific factors that determine risk of thrombotic events, as well as bleeding. Finally, the role of antiplatelet drugs in non-atherosclerotic disorders such as atrial fibrillation is limited, as most studies have not shown benefit in reducing thrombotic events in comparison to anticoagulants or even placebo.

Antiplatelet Therapy for Secondary Prevention in Stable Coronary Artery Disease

Aspirin

Aspirin is an important cornerstone of therapy in reducing cardiovascular morbidity and mortality in patients with known or established stable coronary artery disease. The mechanisms of aspirin's antiplatelet action are reviewed in Patrono (2017). Several studies have firmly established the role of aspirin in reducing recurrent myocardial infarction, stroke, and vascular death in patients with known symptomatic coronary artery disease. In a meta-analysis by the

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_91

Antithrombotic Trialists' Collaboration of 195 randomized trials including more than 135,000 patients with prior evidence of cardiovascular disease, long-term antiplatelet therapy (primarily with aspirin) in comparison to placebo was found to reduce the combined outcome of nonfatal myocardial infarction, nonfatal stroke, or vascular death by 33 % in patients with stable coronary artery disease and by 53 % in patients who underwent percutaneous coronary intervention (Antithrombotic Trialists' Collaboration 2002). The investigators reported no significant difference in safety or efficacy between doses of 75–150 mg and 160–325 mg. The case for primary prevention is more complex and is still evolving; current guidelines emanating from professional societies provide conflicting recommendations. An interesting potential paradox was reported by the investigators of the Women's Health Study who noted a 24 % relative risk reduction in the frequency of ischemic stroke but not myocardial infarction among women assigned to low-dose aspirin (Ridker et al. 2005), in contradistinction to a reduction in myocardial infarction but not stroke among men enrolled in prior trials of aspirin as secondary prevention, although it is questionable whether this observation can be validated in studies involving large numbers of patients. Given the pathophysiology of atherosclerotic disease (as it is currently understood) and the mechanism of aspirin's action, these reports remain rather vexing. However, the overall clinical consideration in using aspirin for the primary prevention of atherosclerotic-mediated events requires that one understand the balance between event prevention and the risk of bleeding, particularly among patients treated with antiplatelet drugs. As the role of aspirin in primary prevention still remains unsettled, it is interesting to note an analysis reported by the European Society of Cardiology Working Group on Thrombosis, which proposed that given the competing risks, ischemic events, and hemorrhage, aspirin must be given to patients whose 10-year risk of death, myocardial infarction, or stroke exceeds 20 % (Halvorsen et al. 2014).

Clopidogrel

Clopidogrel has also been studied extensively for secondary prevention of cardiovascular events in patients with known stable coronary artery disease. In the CAPRIE trial which randomized 19,185 patients with recent myocardial infarction or recent ischemic stroke or symptomatic peripheral arterial disease to treatment with clopidogrel 75 mg or aspirin 325 mg daily, patients treated with clopidogrel were found to have modest and marginally significant reduction in stroke, myocardial infarction, or vascular death at 2 years (5.32 % versus 5.83 %) as well as lower rates of major gastrointestinal bleeding (CAPRIE Steering Committee 1996). Whether the latter toxicity would have been different between the two treatments had a lower aspirin dose been selected is unknown. Similarly, the Antithrombotic Trialists' Collaboration also reported a small reduction in serious cardiovascular events in patients taking clopidogrel compared to aspirin for secondary prevention (Antithrombotic Trialists' Collaboration 2002). These trials established the value of clopidogrel as an alternative to aspirin (such as in patients with intolerance or allergy to aspirin) for secondary prevention of cardiovascular events.

Other studies have evaluated the incremental benefit of adding clopidogrel to aspirin in reducing cardiovascular events. In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial, 15,603 patients with clinically evident cardiovascular disease (i.e., symptomatic coronary artery disease, peripheral arterial disease, or cerebrovascular disease) or multiple risk factors were randomized to receive clopidogrel 75 mg versus placebo in addition to low-dose aspirin 75–162 mg daily (Bhatt et al. 2006). The study found no difference in composite of myocardial infarction, stroke, or cardiovascular death between the two groups (6.8 % with combination therapy versus 7.3 % with aspirin alone). There was also no significant difference in rates of major bleeding between the two treatment groups in the overall study population. However, in the subgroup of patients with clinically evident cardiovascular disease (12,153 patients), clopidogrel compared to placebo was associated with significant reduction in the primary end point (6.9 % versus 7.9 %, respectively) and no difference in the rate of major bleeding. By contrast, in the subgroup of patients with multiple cardiovascular risk factors but no overt cardiovascular disease, clopidogrel compared to placebo was associated with no difference in primary end point but with increased rates of severe bleeding (2.0 % versus 1.2 %, respectively). Other subsequent post hoc analyses indicated a reduction in events among high-risk patients with diabetes and those with established atherosclerosis (Bhatt et al. 2002, 2007; Ringleb et al. 2004).

Despite the overall negative results of the CHARISMA trial, other studies have clearly shown the benefit of dual antiplatelet therapy for secondary prevention in patients with stable coronary artery disease, especially after percutaneous coronary intervention. The rationale for dual antiplatelet therapy after coronary stent placement relates to the thrombogenicity of exposed metal struts which sit adjacent to mechanically disrupted atheromata. Soon after the adoption of balloon angioplasty, Steele et al. observed in a pig carotid injury model that platelet deposition at the site of injury began within the first hour after balloon injury (Steele et al. 1985). This report was followed by two small clinical studies indicating that aspirin led to reductions in clinical events after balloon angioplasty (Schwartz et al. 1988; Barnathan et al. 1987). Since then, coronary stenting has virtually replaced balloon angioplasty for percutaneous revascularization in patients with coronary artery disease. Several

studies have clearly indicated that adding a $P2Y_{12}$ antagonist to aspirin is mandatory following coronary stent implantation. The first such observation was made with ticlopidine in combination with aspirin (Colombo et al. 1995). Interestingly, although there was no control group and the observations were made in a single center, these observations had a profound effect on the practice of cardiology and are nearly single-handedly responsible for the clinical acceptance of intracoronary stents, even before this report was published. Since that time, the combination of aspirin with a $P2Y_{12}$ antagonist has been referred to as "dual antiplatelet therapy" (DAPT). Multiple studies early after the development of bare-metal stenting showed that rates of stent thrombosis and myocardial infarction in the weeks and months after implantation were significantly lower in patients treated with combination of aspirin and ticlopidine compared to aspirin alone or in combination with oral anticoagulants (Leon et al. 1998; Urban et al. 1998). Thus dual antiplatelet therapy emerged rapidly as the standard of care after coronary stenting. Because of its tolerability and lack of myelosuppresive complications (profound neutropenia), clopidogrel quickly replaced ticlopidine as the second antiplatelet agent (in addition to aspirin) after it was found to have similar efficacy and superior safety/tolerability profile in the CLASSICS trial (Bertrand et al. 2000). No studies have compared dual antiplatelet therapy with aspirin and clopidogrel directly to aspirin monotherapy after drug-eluting stent placement due to the strong evidence favoring dual antiplatelet therapy in patients with bare-metal stents.

Ticagrelor

The newer oral $P2Y_{12}$ antagonist ticagrelor was originally approved in 2011 for use in combination with aspirin in patients with acute coronary syndromes (ACS) based on the results of the PLATO trial. In patients with ACS, ticagrelor compared with clopidogrel led to a 16 % relative risk reduction in a composite end point consisting of cardiovascular death, myocardial infarction, or stroke (9.8 % versus 11.7 %) as well as a significant reduction in stent thrombosis among patients who had been treated with intracoronary stents (Cannon et al. 2010). In addition, the rate of vascular mortality was also reduced (4.0 % versus 5.1 %) in a hierarchical analysis. While many of these effects are explicable on the basis of more potent and more rapid onset of ticagrelor's antiplatelet effect compared with clopidogrel, a possible extra-platelet effect has been postulated, largely as a result of ticagrelor's inhibition of cellular uptake of adenosine leading to higher local levels of the compound (Armstrong et al. 2014). Ticagrelor given prior to angiography has become increasingly popular in patients with ACS given prior to coronary angiography in part because of its rapid onset of action, but also because its more rapid offset of action is more convenient in patients who may ultimately be found to require coronary bypass surgery (Gurbel et al. 2009). Recently, the benefit of dual antiplatelet therapy with aspirin and reduced-dose (60 mg twice daily) ticagrelor in patients with stable coronary artery disease was evaluated in the PEGASUS-TIMI 54 trial (Bonaca et al. 2015). The study enrolled 21,162 high-risk patients who had had a myocardial infarction more than 1 year previously and randomized them to treatment with ticagrelor 90 mg twice daily, 60 mg twice daily, or placebo. All patients were treated with low-dose aspirin. The majority (83 %) of patients had a history of percutaneous coronary intervention. At an average of 3 years of follow-up, the primary composite end point of cardiovascular death, myocardial infarction, or stroke was lower in the patients receiving ticagrelor at either dose compared to placebo (7.85 %, 7.77 %, and 9.04 %, respectively). The reduction in primary end point was driven mainly by lower rates of myocardial infarction and stroke in patients on ticagrelor compared to placebo with no significant difference in rate of death. TIMI major bleeding was also significantly higher in patients receiving ticagrelor compared to placebo (2.6 %, 2.3 %, and 1.06 %, respectively), but there were no differences in rates of fatal bleeding or intracranial hemorrhage.

Antiplatelet Therapy in Patients with Unstable Angina

Plaque disruption followed by platelet deposition and thrombosis is considered to be the pathophysiologic hallmark of the acute coronary syndromes ST segment elevation myocardial infarction, non-ST segment elevation myocardial infarction, and unstable angina. The degree of vascular obstruction can vary from complete arterial obstruction, which results in confluent areas of myocardial necrosis, as seen in ST elevation myocardial infarction; incomplete obstruction, resulting in non-ST elevation myocardial infarction or unstable angina; or embolization of platelet fibrin aggregates resulting in patchy myocardial necrosis. Numerous professional societies have published guidelines for the administration of antiplatelet drugs to patients with acute coronary syndromes (ACS). Those most often cited are products of the European Society of Cardiology and of the American College of Cardiology/American Heart Association. Since the guidelines undergo revision quite frequently as new trial data are published, the reader is referred to either of these two dynamic sources for current specific recommendations on drug dosing in various patient groups. The following section will provide a brief overview on the topic. Considerable attention has been devoted to interdicting the platelet-vascular interaction, for the past five decades. The Veterans Affairs Cooperative Study first studied aspirin 324 mg in a double-blind placebo-controlled trial in 1266 men with unstable angina, whose last

episode of pain had occurred within the prior week, and observed a 51 % reduction in the relative risk of myocardial infarction at 12 weeks, accompanied by a 51 % reduction in mortality (Lewis et al. 1983). Strikingly similar results were observed by Theroux et al. in a study of 479 patients treated at a mean of 7.9 h after the last episode of pain (Theroux et al. 1988). These two studies, along with the ISIS-2 study demonstrating a 23 % reduction in mortality at 5 weeks in patients with ST segment elevation myocardial infarction among those randomized to receive aspirin rather than standard therapy (ISIS-2 1988), firmly established the role of aspirin as first-line therapy among patients with acute coronary syndromes. Additional supporting evidence was provided by the study by Theroux, in which heparin was superior to aspirin, but aspirin was able to prevent the syndrome of disease reactivation that occurred when heparin was withdrawn (Theroux et al. 1992). As $P2Y_{12}$ antagonists were developed, a small trial was performed in which ticlopidine 250 mg twice daily was compared with standard treatment (aspirin was not given) in 652 patients with transient ST segment depression or T-wave inversion within 48 h of admission to the coronary care unit. At 24 weeks, a 46.8 % reduction was observed in the composite of vascular death or fatal myocardial infarction, accompanied by a 46.1 % reduction in nonfatal myocardial infarction (Balsano et al. 1990). However, because of gastrointestinal side effects and the risk of neutropenia, ticlopidine was not commonly used as a standard therapy in unstable angina. Ten years later, the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial enrolled 12,562 patients within 24 h of a non-ST elevation acute coronary syndrome and randomized them to receive either daily clopidogrel 75 mg and aspirin or aspirin alone for 15 months. Treatment with clopidogrel led to a 20 % relative reduction in cardiovascular death, myocardial infarction, or stroke (11.4 % versus 9.3 %) (Yusuf et al. 2001). Subsequent trials with the newer $P2Y_{12}$ antagonists prasugrel (Wiviott et al. 2007) and ticagrelor (Wallentin et al. 2009) have demonstrated that they are superior to clopidogrel at reducing ischemic events in patients with acute coronary syndromes when started soon after hospitalization and continued (for 9 months in the case of ticagrelor or 15 months in that of prasugrel). The increased risk of bleeding when it is given prior to coronary angiography (Montalescot et al. 2013) has limited the indication for prasugrel to patients undergoing emergency angiography for ST segment elevation myocardial infarction and those undergoing percutaneous coronary interventions, while the indication for ticagrelor does not require knowledge of coronary anatomy. While theoretically appealing, prehospital use of ticagrelor in patients with ST segment elevation myocardial infarction was not shown to be superior to in-hospital administration of the drug (Montalescot et al. 2014). It is important to recognize that morphine which is frequently used to provide analgesia to patients with myocardial infarction inhibits gastrointestinal motility and thus may inhibit absorption of antiplatelet medications and thus impair their activity (Parodi et al. 2015). Accordingly, the intravenous adenosine triphosphate (ATP) analog cangrelor was developed to provide rapid $P2Y_{12}$ inhibition, particularly in patients with acute coronary syndromes in whom oral administration is either not feasible or unlikely to be effective. The onset of action of cangrelor occurs within minutes of initiating an intravenous dose and subsides within an hour after terminating it. Cangrelor was studied in the CHAMPION trials in patients with both stable and unstable manifestations of coronary artery disease. Cangrelor was able to reduce periprocedural myocardial infarction in patients undergoing intracoronary stent implants. Although there was no formal statistical interaction between cangrelor treatment and presentation with stable angina versus acute coronary syndromes (Bhatt et al. 2013), intuitively, one would suspect that the utility of the drug is greatest in the latter setting because of limitations in the feasibility of oral drug loading. Caution should be taken when transitioning patients from cangrelor to oral clopidogrel because of competition for the $P2Y_{12}$ binding site between cangrelor and the active metabolite of clopidogrel (Steinhubl et al. 2008). Consequently, the clopidogrel loading dose should be administered at the end of the cangrelor infusion. Similar observations have been made in transitioning patients between cangrelor and prasugrel, but less so in transitioning patients to ticagrelor (Center for Drug Evaluation and Research 2015).

Antagonists of integrin $\alpha_{IIb}\beta_3$ [often referred to as glycoprotein (GP) IIb/IIIa inhibitors] are also used frequently in patients with acute coronary syndromes. The initial studies with abciximab were performed in patients undergoing percutaneous coronary interventions and showed reductions in myocardial infarction, particularly among patients with acute coronary syndromes (ACS) (The EPIC Investigators 1994; The EPISTENT Study Group 1998). Similar findings were reported with the peptide eptifibatide (The IMPACT II Investigators 1997) and the peptidomimetic tirofiban (The RESTORE Investigators 1997). These drugs were used in combination with heparin. An important early finding was that it was necessary to use a reduced dose of heparin (on the order of 60–70 mg/kg rather than the 100 mg/kg dose originally used) in order to minimize the bleeding excess produced by $\alpha_{IIb}\beta_3$ antagonists (The EPILOG Investigators 1997). Extension of these findings to patients treated medically was achieved in broad-based trials of eptifibatide and tirofiban, in which the medication was begun soon after diagnosis (commonly referred to as "upstream" therapy), regardless of whether coronary intervention was planned (The PRISM PLUS Study Group 1998; The PURSUIT Trial Investigators 1998). A similar trial with abciximab did not show a clinical benefit (Simoons 2001). The effect of these treatments when given upstream is often regarded as greatest in patients who subsequently underwent percutaneous coronary interventions (Kleiman et al. 2000), although it

should be noted that such analyses generally represent post-randomization (or "improper") subgroups and should be regarded as statistically unreliable. Based on such observations, a number of oral $\alpha_{IIb}\beta_3$ antagonists were developed but were shown in trials of extended duration of therapy to be associated with both increased bleeding risk and a paradoxical increase in death and myocardial infarction which was believed to be a consequence of platelet activation through outside-in signaling (Chew et al. 2001). The use of $\alpha_{IIb}\beta_3$ antagonists has decreased in recent years, partly based on shortened periods of hospitalization preceding coronary angiography and revascularization, as well as comparisons with the direct thrombin bivalirudin showing less frequent bleeding without an increment in ischemic events when bivalirudin was substituted for the combination of heparin and an $\alpha_{IIb}\beta_3$ antagonist (Stone et al. 2006).

Duration of Dual Antiplatelet Therapy

While it is extremely clear that dual antiplatelet therapy after coronary stenting reduces rates of acute (<24 h) and subacute (<30 days) stent thrombosis and myocardial infarction, the optimal duration of therapy remains unclear. Initial observations after development of coronary stenting consistently showed elevated risk of stent thrombosis for 1 year after stent placement, leading to the general practice of 1 year of dual antiplatelet therapy (Levine et al. 2011). However, in patients with drug-eluting stents, evidence supports the persistence of risk of stent thrombosis even beyond the first year (Mauri et al. 2007). Some observational studies have suggested a possible reduction in rates of myocardial infarction with extended-duration dual antiplatelet therapy after drug-eluting stents (Eisenstein et al. 2007). This was particularly the case in patients who had been treated with first-generation sirolimus-eluting and paclitaxel-eluting stents. Current-generation drug-eluting stents have thinner strut frames and antiproliferative drugs that are embedded in polymers that are less likely to result in vascular inflammation. Several studies indicate that stent thrombosis rates are significantly lower with current-generation drug-eluting stents (Camenzind et al. 2014; Sarno et al. 2014). However, several small open-label randomized trials have shown no significant reduction in rates of myocardial infarction but increased risk of harm due to bleeding with longer therapy (Collet et al. 2014; Park et al. 2010; Valgimigli et al. 2012).

Recently, a large randomized double-blinded trial, the DAPT study, reported continued benefit of dual antiplatelet therapy (with aspirin and either clopidogrel or prasugrel) for up to 30 months after drug-eluting stent in patients who had not had major bleeding in the first 12 months of therapy (Mauri et al. 2014). The study randomized 9961 patients who had undergone percutaneous coronary intervention with drug-eluting stent (38 % for stable coronary disease) 12 months earlier to either continued treatment with aspirin plus thienopyridine or aspirin plus placebo for another 18 months. Notably, patients who needed repeat revascularization or developed recurrent myocardial infarction or bleeding in the first year after index stent placement were excluded. At end of follow-up, the study reported significantly lower rates of stent thrombosis (0.4 % versus 1.4 %) and the composite of death, myocardial infarction, and stroke (4.3 % versus 5.9 %) but higher rates of moderate or severe bleeding (2.5 % versus 1.6 %) in patients receiving extended dual antiplatelet therapy. While cardiovascular mortality was similar in both groups, overall mortality was slightly higher in patients receiving dual antiplatelet therapy (2 % versus 1.5 %) due to higher rates of noncardiac deaths. Prespecified subgroup analysis showed that the benefit of longer-duration dual antiplatelet therapy seemed to be greatest among patients who received first-generation (sirolimus or paclitaxel eluting) stents. Among those who received second-generation (everolimus or zotarolimus eluting) stents, the relative reductions were similar, although the absolute event rates (and therefore absolute reductions) were considerably lower. Notably, there was also evidence of greater benefit of therapy (lower rates of stent thrombosis and major adverse cardiovascular and cerebrovascular events) in patients who underwent stenting for acute coronary syndrome compared to stable coronary artery disease (Yeh et al. 2015). This finding of increased benefit of extended-duration dual antiplatelet therapy in high-risk patients was also corroborated in the recent PEGASUS trial which only enrolled patients with history of myocardial infarction.

Conversely, several smaller trials have also investigated the value of shorter duration (<12 months) of dual antiplatelet therapy after second-generation drug-eluting stents in patients with low-risk features (Feres et al. 2013; Gwon et al. 2012; Kim et al. 2012; Colombo et al. 2014; Gilard et al. 2015; Schulz-Schüpke et al. 2015). All of these abbreviated-term trials had key limitations including low event rates, slow enrollment, and premature termination, tempering their generalizability. A meta-analysis including several of these trials reported no significant difference in rate of major adverse cardiovascular events or mortality but higher rates of bleeding with standard duration (12 months) compared to short duration (3–6 months) of dual antiplatelet therapy (Palmerini et al. 2015a).

Other larger meta-analyses of up to ten trials which evaluated varying durations of dual antiplatelet therapy (from 3 months to 36 months) have been reported, generally with similar conclusions (Palmerini et al. 2015b; Spencer et al. 2015; Giustino et al. 2015). For example, one such meta-analysis including 32,135 patients showed that patients treated with longer-duration dual antiplatelet therapy had lower rates of stent thrombosis and myocardial infarction, though the magnitude of this effect was attenuated in patients

with second-generation drug-eluting stents (Giustino et al. 2015). Risk of clinically significant bleeding was significantly higher in patients taking longer-duration dual antiplatelet therapy. Notably, there was a numerically higher rate of all-cause mortality, which did not reach statistical significance, in patients on long-term dual antiplatelet therapy. The meta-analysis had important limitations including lack of patient-level data, which precludes adjustment for the variable duration and discontinuation regimens of dual antiplatelet therapy in the included trials. Also, risk/benefit analysis of longer-duration dual antiplatelet therapy with regard to the increased risk of bleeding versus decreased risk of stent thrombosis cannot be performed due to lack of information regarding clinical severity of such events. Finally, the significant heterogeneity of the patients in the various trials in terms of baseline risk profile limits generalizability to patients at elevated risk of cardiovascular events.

Udell et al. recently reported a meta-analysis of long-term dual antiplatelet therapy for secondary prevention in patients with prior history of myocardial infarction (Udell et al. 2016). The meta-analysis included 33,435 patients from one trial of patients with prior myocardial infarction (PEGASUS) and five trials with subgroups of patients with prior myocardial infarction (PRODIGY, DAPT, DES-LATE, CHARISMA, and ARCTIC-Interruption). After an average of 31 months of follow-up, patients randomized to longer-duration dual antiplatelet therapy had lower rates of major adverse cardiovascular events including cardiovascular death, myocardial infarction, stroke, and stent thrombosis compared to aspirin alone. There was an increased risk of major bleeding but not fatal bleeding and no difference in all-cause mortality with longer-duration dual antiplatelet therapy.

Thus, the optimal duration of dual antiplatelet therapy for secondary prevention after drug-eluting stents remains controversial. As described above, several trials and meta-analyses have shown a decreased risk of ischemic events but increased risk of bleeding and no clear difference in all-cause mortality with prolongation of dual antiplatelet therapy. Consequently, the decision to continue dual antiplatelet therapy after the first year should probably be individualized and incorporate analysis of patient-specific risk of bleeding as well as risk of ischemic events.

Antiplatelet Therapy for Primary Prevention in Patients with Stable Coronary Artery Disease

Aspirin

Although aspirin has a well-defined role in patients with established cardiovascular disease, its role in primary prevention of coronary events in patients with multiple risk factors is uncertain. A 2009 meta-analysis of six large trials, including more than 95,000 patients without established cardiovascular disease but at elevated risk, showed that aspirin at doses between 75 and 500 mg per day was associated with a significant reduction in rate of first myocardial infarction (0.18 versus 0.23 % per year) but also significant elevation in rate of major bleeding (0.10 versus 0.07 % per year) with no significant difference in stroke or cardiovascular mortality (Antithrombotic Trialists' Collaboration 2009). A more recent analysis, which added patients from three additional trials, also reported similar conclusions (Seshasai et al. 2012). Notably, nearly 80 % of the patients in these meta-analyses came from the Physicians' Health Study, the Women's Health Study, and the Hypertension Optimal Treatment trial, which included patients with low-moderate risk based on an average 10-year risk of a first event of <5 % (Antithrombotic Trialists' Collaboration 2009). Due to the low baseline event rates in these trials, it may not be surprising that in the overall population, the net clinical benefit of aspirin did not outweigh the associated increase in bleeding risk. However, in the small subset of patients with high baseline risk, the net cardiovascular benefit of aspirin did appear to outweigh the bleeding risk (Seshasai et al. 2012).

Thus, given the current evidence, the broad use of aspirin for primary prevention in all patients with cardiovascular risk factors cannot be supported. However, aspirin may be beneficial in certain patients at particularly elevated risk of ischemic events without a high risk of bleeding. Several ongoing randomized trials including ARRIVE and ASPREE which have enrolled patients with moderate to high risk of first cardiovascular event (average 10-year risk of 10–19 %) may help identify subgroups of patients that may benefit from aspirin for primary prevention.

Antiplatelet Therapy for Prevention of Thromboembolism in Patients with Atrial Fibrillation

Aspirin Versus Warfarin

Systemic thromboembolism arising from the left atrium is a major cause of morbidity and mortality in patients with any form of atrial fibrillation. Even though today anticoagulants are considered the standard of care for reducing the risk of thromboembolic complications in patients with atrial fibrillation, the role of antiplatelet agents has also been evaluated in several trials. In the late 1980s–early 1990s, several placebo-controlled trials were conducted to address the clinical equipoise regarding the absolute and comparative effectiveness of warfarin and aspirin in reducing thromboembolic complications in patients with atrial fibrillation. The Stroke Prevention in Atrial Fibrillation (SPAF-I) study randomized 1330 patients with non-valvular atrial fibrillation to either warfarin dose adjusted to INR 2.0–4.5, aspirin 325 mg daily,

or placebo if they were eligible for anticoagulation or if ineligible for anticoagulation to aspirin 325 mg daily or placebo (Stroke Prevention in Atrial Fibrillation Investigators 1991). After mean follow-up of 1.3 years, the study reported that both warfarin and aspirin significantly reduced rate of primary end point (stroke or systemic embolism) compared to placebo (2.3 %, 3.6 %, and 7.4 % respectively). Despite the nominally larger reduction in primary end point with warfarin compared to aspirin, the study was not adequately powered to detect a significant difference between the two therapies. A follow-up study, SPAF-II, compared warfarin dose adjusted to INR 2.0–4.5 with aspirin 325 mg daily in two parallel trials involving 715 patients aged 75 years or less and 385 patients aged >75 years (Stroke Prevention in Atrial Fibrillation Investigators 1994). After a mean follow-up of 2.0 years, warfarin was significantly more effective than aspirin in reducing rate of primary end point in both age groups. However, this benefit of warfarin appeared to be offset by a higher rate of intracranial hemorrhage compared to aspirin, especially in patients aged more than 75 years. By contrast, several other contemporary trials of warfarin in patients with atrial fibrillation (BAATAF, CAFA, and SPINAF) which targeted lower intensity of anticoagulation (INR < 3) reported significantly lower rates of intracranial hemorrhage compared to SPAF-II, despite significant reduction in primary end point compared to placebo (BAATAF Investigators 1990; Connolly et al. 1991; Ezekowitz et al. 1992). These studies lead to the SPAF-III trial in which patients at high risk for thromboembolic complications were randomized to warfarin dose adjusted to INR 2–3 versus fixed low-dose warfarin (initially adjusted to INR 1.2–1.5) plus aspirin 325 mg daily (SPAF Investigators 1996). At end of follow-up, patients treated with dose-adjusted warfarin to INR 2–3 had significantly lower rates of primary end point compared to aspirin + low-dose warfarin (1.9 %/year versus 7.9 %/year, respectively) with no significant difference in major bleeding or intracranial hemorrhage. Importantly, there does appear to be a lower limit to this effect. INR values <2.0 do not appear to confer protection against stroke.

Several meta-analyses including all of the above studies and others have consistently shown that dose-adjusted warfarin is far more efficacious than aspirin in reducing thromboembolic complications as well as mortality in patients with atrial fibrillation (Hart et al. 1999; Cooper et al. 2006). In a 2007 meta-analysis by Hart et al., which included 29 trials with over 28,000 patients, dose-adjusted warfarin was found to produce significantly greater reduction in stroke compared to aspirin (39 % relative risk reduction) (Hart et al. 2007). Rate of major bleeding including intracranial hemorrhage did appear to be higher with dose-adjusted warfarin compared to aspirin, but the absolute risk increase was small (0.2 %/year) (Hart et al. 2007).

Aspirin Monotherapy

Anticoagulant therapy forms the mainstay of treatment in the vast majority of patients with atrial fibrillation based on its clear superiority in efficacy compared to aspirin. However, the value of aspirin as an alternative to anticoagulant therapy in patients with low risk of embolic complications or high risk of bleeding has been debated. Unfortunately, the benefit of aspirin compared even to placebo is also not clear. While several studies (particularly SPAF-I) have suggested a significant reduction in embolic events with aspirin, the 2007 meta-analysis by Hart et al. found that the 22 % reduction in events with aspirin compared to placebo was not statistically significant (Hart et al. 2007). In a meta-analysis of three trials enrolling 1965 patients with atrial fibrillation without prior stroke comparing aspirin at doses ranging from 75 to 325 mg daily to placebo, there was no difference in stroke or all-cause mortality (Aguilar and Hart 2005). Aspirin did reduce the combined end point of stroke, myocardial infarction, and cardiovascular mortality compared to placebo, though this was driven primarily by sensitivity analysis of a fourth trial (SAFT) in which aspirin therapy was combined with warfarin (Aguilar and Hart 2005; Edvardsson et al. 2003). Similarly, the Japanese Atrial Fibrillation Study which randomized 871 patients with atrial fibrillation to aspirin at 150–200 mg daily or no treatment showed that aspirin did not significantly reduce combined end point of stroke, TIA, or cardiovascular death but marginally increased risk of bleeding (Sato et al. 2006).

In summary, in patients with atrial fibrillation who cannot be treated with warfarin, the value of aspirin as an alternative to reduce thromboembolic complications is not clear. Furthermore, several recent studies have shown that patients who are not candidates for warfarin may be more appropriately treated with one of the newer oral anticoagulants instead of aspirin. For example, the AVERROES trial which randomized 5599 patients with atrial fibrillation who were unsuitable for warfarin therapy to apixaban 5 mg twice daily or aspirin 81 mg to 324 mg daily was terminated early due to clear benefit in favor of apixaban (Eikelboom et al. 2010). At mean follow-up of 1.1 years, rate of stroke or systemic embolism was significantly lower in patients receiving apixaban (1.3 %/year versus 3.75 %/year) while rate of major bleeding was no different (1.4 %/year versus 1.2 %/year).

Dual Antiplatelet Therapy with Aspirin and Clopidogrel

While multiple studies showed the superiority of warfarin to aspirin monotherapy in patients with atrial fibrillation, the relative efficacy of warfarin compared to dual antiplatelet therapy with aspirin and clopidogrel remained unanswered

until the ACTIVE W trial (Connolly et al. 2006). This study randomized 6706 patients with atrial fibrillation to dose-adjusted warfarin with INR 2.0–3.0 or clopidogrel 75 mg daily plus aspirin 75–100 mg daily. After mean follow-up of 1.3 years, the study was terminated early due to clear evidence of superiority of warfarin therapy with significantly lower composite outcome of stroke, systemic embolism, myocardial infarction, or vascular death (3.93 %/year versus 5.60 %/year). Severe or fatal bleeding was similar between the two groups, but minor bleeding was significantly higher in patients on dual antiplatelet therapy.

In patients deemed unsuitable for warfarin, the benefit of dual antiplatelet therapy with aspirin and clopidogrel in comparison to aspirin monotherapy was evaluated in the ACTIVE A trial (ACTIVE Investigators 2009). This study randomized 7554 patients with atrial fibrillation to aspirin 75–100 mg daily and clopidogrel 75 mg daily or aspirin alone. After mean of 3.6 years of follow-up, dual antiplatelet therapy was associated with significantly lower composite outcome of stroke, systemic embolism, myocardial infarction, or vascular death (6.8 %/year versus 7.6 %/year) compared to aspirin, but this benefit was offset by a significantly higher rate of major bleeding (2.0 %/year versus 1.3 %/year). However, these results need to be viewed in light of the observation that approximately one third of patients in this trial were ultimately treated with an oral anticoagulant after study withdrawal.

In summary, dual antiplatelet therapy does not seem to improve outcomes in patients with atrial fibrillation compared to aspirin alone and continues to be inferior to anticoagulant therapy. The question of managing patients with atrial fibrillation and stable coronary artery disease remains unanswered. Intuitively, one would expect that oral anticoagulant therapy would be needed to treat the atrial fibrillation, as demonstrated in the trials mentioned above, while antiplatelet therapy would be needed to manage the coronary artery disease. However, data to date have not confirmed this assumption. Based on results from a large Danish registry of atrial fibrillation, adding either aspirin or thienopyridine on top of vitamin K antagonist treatment failed to alter the risk of recurrent coronary events, while the risk of bleeding was increased by 50–84 % (Lamberts et al. 2014).

Triple Antithrombotic Therapy with Dual Antiplatelet Therapy plus an Anticoagulant

The appropriate antithrombotic regimen in patients with atrial fibrillation who also have an acute coronary syndrome or recent stent placement is controversial. The issue becomes more considerably complex among patients with acute coronary syndromes or recent intracoronary stent placement who also have requirements for oral anticoagulants. This population comprises between 5 and 10 % of patients receiving stents. The requirement for three antithrombotic drugs places such patients at elevated risk for hemorrhage. Several studies have indicated that oral anticoagulants are underused in stented patients with atrial fibrillation and that among patients in whom they are used, there is little relation between the perceived bleeding risk and the decision to use oral anticoagulants (Bernard et al. 2013; Ruiz-Nodar et al. 2012). A Danish registry indicated that the lowest bleeding risk and the lowest rate of thrombotic coronary events occurred among patients treated with a combination of oral anticoagulants and clopidogrel without aspirin rather than three drugs (Lamberts et al. 2013). A small randomized trial (WOEST) randomized 573 patients taking an oral anticoagulant to receive either aspirin plus clopidogrel or clopidogrel alone without aspirin for 1 year after stent placement. After 1 year, both the risk of bleeding and that of a composite end point of death, myocardial infarction, stroke, stent thrombosis, or target vessel revascularization were lower in the group treated with double therapy compared to those receiving triple therapy (Dewilde et al. 2013). A second trial (ISAR-TRIPLE) randomized patients who had been on an oral anticoagulant for at least 1 year to either 6 months of triple therapy or 6 weeks of triple therapy followed by therapy with the oral anticoagulant and clopidogrel without aspirin. At the end of 9 months, the rates of ischemic events as well as major bleeding (the primary outcome variable) were identical, although minor bleeding was more commonly seen in the group receiving triple therapy (Fiedler et al. 2015).

Take Home Messages

- Multiple randomized trials and meta-analyses have shown that aspirin reduces cardiovascular events in patients with established atherosclerotic vascular disease, especially in the setting of previous revascularization.
- The value of aspirin for primary prevention of cardiovascular events is unclear. Meta-analyses show that the benefit of aspirin in reducing ischemic events in low-risk patients may be offset by increased risk of bleeding. Ongoing trials aim to evaluate the benefit of aspirin for primary prevention in patients at moderate to high risk of atherosclerotic disease.
- Clopidogrel monotherapy has been shown to be as efficacious as aspirin for secondary prevention of cardiovascular events and therefore can be used as

(continued)

alternative to aspirin in patients with aspirin allergy.

- Dual antiplatelet therapy with aspirin and $P2Y_{12}$ inhibitors has been shown to be superior to aspirin monotherapy for prevention of ischemic events after percutaneous coronary intervention albeit with an increased risk of bleeding.
- The combination of aspirin and prasugrel was found to be superior to aspirin and clopidogrel in reducing ischemic events after percutaneous coronary intervention in the setting of acute coronary syndrome but with an increased risk of bleeding.
- The combination of aspirin and ticagrelor has been found to be superior to aspirin and clopidogrel in reducing cardiovascular death, myocardial infarction, and stroke after percutaneous coronary intervention both in the setting of acute coronary syndrome and stable coronary artery disease.
- The optimal duration of dual antiplatelet therapy after percutaneous coronary intervention is controversial and ultimately likely to depend on patient-specific factors that determine risk of ischemic as well as bleeding events.
- Antiplatelet monotherapy is clearly inferior to anticoagulant therapy in reducing ischemic events in patients with atrial fibrillation.
- Even dual antiplatelet therapy with aspirin and clopidogrel is inferior to anticoagulant therapy in reducing ischemic events in patients with atrial fibrillation.

Antiplatelet Therapy in Cerebrovascular Disorders

Ilana Spokoyny and Gregory Albers

Abstract

Stroke is a preventable public health problem, with widespread effects. Antithrombotic medications are the mainstay of both primary and secondary stroke prevention. This chapter discusses the role of antiplatelet medications such as aspirin, clopidogrel, and dipyridamole in the acute treatment, primary prevention, and secondary prevention of stroke. For acute treatment, the current recommendations are early treatment with aspirin alone for acute ischemic stroke patients who are not receiving thrombolysis. For primary prevention, the recommendations do not generally recommend any antiplatelet unless the patient has atrial fibrillation, in which case anticoagulation is favored. For secondary prevention, the current data favors the use of an antiplatelet agent, either aspirin, clopidogrel, or the combination aspirin-dipyridamole. There is ongoing research into the role of combination aspirin plus clopidogrel, as this may be beneficial in certain subgroups of non-cardioembolic stroke patients. There is also ongoing research on novel antiplatelet agents, with the aim of decreasing recurrent stroke rates as well as bleeding events. This chapter provides a summary of current evidence and recommendations and addresses future possibilities for antiplatelet treatment for ischemic stroke.

Stroke is a worldwide health epidemic with significant public health consequences. Efforts at reducing the burden have focused on both treatment as well as prevention of recurrent events. The majority of strokes are ischemic, caused by insufficient blood flow to an area of brain. The optimal strategy for prevention of recurrent ischemic stroke is dependent on etiology. Decreased blood flow can be caused by emboli from the heart or more proximal arteries, in situ thrombosis of atherosclerotic arteries, global hypoperfusion causing watershed ischemia, or venous clots traveling through a PFO causing a paradoxical stroke. Risk factors for stroke include atrial fibrillation, which predisposes to cardioembolic strokes, as well as vascular risk factors such as hypertension, hyperlipidemia, smoking, and diabetes. Additionally, intrinsic hypercoagulable states place patients at increased risk of both venous thromboembolism and arterial stroke. The prevention strategies are tailored to the etiology of the ischemia, and for this reason, a comprehensive workup is recommended for all patients who suffer a stroke.

Antiplatelet agents have a role in the treatment of acute stroke as well as both the primary and secondary prevention of stroke. Anticoagulation is the treatment of choice for cardioembolic stroke (van Walraven et al. 2002), and it was historically regarded as the best treatment for some subtypes of non-cardioembolic ischemic stroke as well. However, randomized trials of anticoagulation versus antiplatelet therapy for non-cardioembolic stroke subtypes failed to demonstrate superiority of anticoagulation;

P. Gresele et al. (eds.), *Platelets in Thrombotic and Non-Thrombotic Disorders*, DOI 10.1007/978-3-319-47462-5_92

therefore, antiplatelet agents have become the standard antithrombotic approach for secondary prevention of non-cardioembolic stroke. The WARSS trial (Mohr et al. 2001) compared aspirin (325 mg daily) to warfarin dosed to a target INR of 1.4–2.8 among patients with non-cardioembolic ischemic stroke and found no difference in the rates of ischemic stroke, death, or major bleeding between the two groups. The WASID trial (Chimowitz et al. 2005) compared aspirin (1300 mg daily) to warfarin dosed to a target INR of 2–3, among patients with TIA or mild stroke with symptomatic large vessel intracranial artery stenosis. The study was terminated early due to safety concerns in the warfarin arm. There was no difference between the two groups in the combined rate of ischemic stroke, cerebral hemorrhage, or vascular death. There was, however, a significantly decreased rate of death in the aspirin group (4.3 vs. 9.7 %, HR 0.46, 95 % CI 0.23–0.90) and a significantly lower rate of major bleeding (3.2 % vs. 8.3 %, HR 0.39, 95 % CI 0.18–0.84).

In this chapter, we summarize the data on the safety and effectiveness of antiplatelet agents for treatment and prevention of ischemic stroke.

Acute Stroke Treatment with Antiplatelet Agents

The risk of recurrent stroke in the acute period is highest in the first few days after stroke or transient ischemic attack (TIA) and is estimated to be between 3 and 10 % at 2 days (Mozaffarian et al. 2015). Acute treatment of stroke with antiplatelet agents does not reverse the symptoms of stroke, but rather is beneficial due to a reduction in the risk of recurrent stroke in the acute period (Bansal et al. 2013).

Aspirin

The acute use of aspirin for acute ischemic stroke has been studied in two large trials, the Chinese Acute Stroke Trial (CAST) (CAST (Chinese Acute Stroke Trial) Collaborative Group 1997) and the International Stroke Trial (IST) (International Stroke Trial Collaborative Group 1997). A meta-analysis (Sandercock et al. 2014) of the data from these trials and one other (Group 1995) (MAST-I) included patients treated within 48 h with ASA 160–300 mg daily for a duration of 2–4 weeks and demonstrated a 23 % odds reduction of recurrent ischemic stroke in the aspirin-treated patients. For every 1000 people treated with aspirin, seven people would avoid recurrent ischemic stroke, with a number needed to treat (NNT) of 140. There was also a reduction in death or dependency at the end of follow-up. Subgroup analyses did not show a difference in effect among different ages, genders, or ischemic stroke etiologies. Antiplatelet therapy did increase the odds of symptomatic intracranial hemorrhage by 23 %. For every 1000 people treated with aspirin, two would have a symptomatic intracranial hemorrhage, with a number needed to harm (NNH) of 574. Overall, the benefits of aspirin outweigh the risks in the early treatment of acute ischemic stroke, and so the early administration is recommended by multiple society guidelines (Lansberg et al. 2012; Jauch et al. 2013).

Ticagrelor

The SOCRATES clinical trial (Johnston et al. 2016) recently compared the effectiveness of early initiation of aspirin versus ticagrelor in acute ischemic stroke. This large trial included 13,199 patients with a non-severe ischemic stroke or high-risk TIA who had not received IV or IA thrombolysis and were not considered to have had a cardioembolic stroke. Patients were randomized within 24 h after symptom onset, to receive either ticagrelor 90 mg daily (180 mg loading dose on day 1) or aspirin 100 mg daily (300 mg on day 1) for 90 days. The primary end point was the time to the occurrence of stroke, myocardial infarction, or death within 90 days. Based on this primary end point, ticagrelor was not found to be superior to aspirin. The secondary end point was the time of first occurrence of any ischemic stroke, and ticagrelor showed a benefit over aspirin but with a nominal *p*-value because of the negative primary end point. In predefined exploratory analyses, there were indications that ticagrelor may be more effective at reducing ischemic stroke and all stroke. Additionally, ticagrelor seemed to most benefit those patients who were treated within 12 h of symptom onset and those who had been previously taking aspirin. A future direction of study may be aspirin plus ticagrelor within 12 h of stroke onset.

Combination Antiplatelet Therapy

There is ongoing research into the role of early initiation of dual antiplatelet agents after ischemic stroke and TIA. The CHANCE trial studied the combination of aspirin and clopidogrel in a Chinese population treated within 24 h of high-risk TIA or minor ischemic stroke (Wang et al. 2013). The authors compared aspirin 75 mg plus clopidogrel 75 mg for 21 days followed by clopidogrel alone for 90 days to placebo plus aspirin 75 mg for 90 days and demonstrated a significant decrease in the rate of stroke at 90 days. This

study included Chinese patients with high rates of severe intracranial atherosclerosis and was limited to mild stroke or high-risk TIA. Risk factor control (treatment of hypertension, diabetes, and hyperlipidemia) was suboptimal during the study. The results may not be generalizable to non-Chinese patients nor to those with moderate or severe stroke.

The EARLY trial compared treatment within 24 h with aspirin plus dipyridamole to aspirin alone for the first 7 days and then treated all patients with the combination therapy (Dengler et al. 2010). No difference in good outcome was found between the groups at 90 days. The FASTER trial compared early treatment (within 24 h) with aspirin plus clopidogrel to aspirin alone and was terminated early due to slow enrollment, but at 90 days showed no difference in stroke incidence between groups (Kennedy et al. 2007). A meta-analysis combined these studies and patients from 11 other studies who were treated with antiplatelet agents within 72 h, for a total of approximately 9000 patients (Wong et al. 2013). Dual antiplatelet therapy (which varied between trials and included aspirin plus clopidogrel, aspirin plus dipyridamole, and aspirin plus cilostazol) was associated with a 31 % decrease in recurrent stroke, without a significant increase in major bleeding. The results are limited in applicability by the variability in patient population and treatments, as well as the methodology of the trials included.

There are ongoing randomized trials evaluating the benefit of dual antiplatelet therapy compared to aspirin alone (POINT clinical trial; TARDIS clinical trial). In general, current recommendations favor early treatment with aspirin alone for acute ischemic stroke patients who are not receiving thrombolysis; there is insufficient evidence to support the use of alternative antiplatelet agents or dual antiplatelet therapy.

Primary Prevention of Ischemic Stroke

Data on primary stroke prevention with antiplatelet agents have largely come from larger studies which included cardiovascular end points such as myocardial infarction and death from any cardiovascular cause. Because the incidence of stroke is substantially lower in primary prevention studies, absolute risk reductions are small, and even a small increased risk of hemorrhage can neutralize the benefits for prevention of ischemic events. In primary prevention, aspirin has been shown to prevent MI, predominantly in men. Primary prevention of stroke has been demonstrated with aspirin in women with stroke risk factors.

Aspirin

There have been six large randomized trials evaluating the benefits of aspirin in primary prevention of cardiovascular events (Steering Committee of the Physicians' Health Study Research Group 1989; Iso et al. 1999; Collaborative Group of the Primary Prevention Project 2001; ETDRS Investigators 1992; Hansson et al. 1998; Peto et al. 1988). A meta-analysis of these studies showed a benefit of aspirin for MI but not for stroke or mortality (Bartolucci and Howard 2006). Sex differences have been identified with regard to primary prevention—two studies have shown a reduction in ischemic stroke among women taking aspirin for primary prevention (Berger et al. 2006; Ridker et al. 2005). The Antithrombotic Trialists' Collaboration published a large meta-analysis of six studies which included 95,000 patients, comparing antiplatelet agents (mostly aspirin) to placebo in patients with vascular risk factors, and found that primary prevention with aspirin reduced the incidence of serious vascular events by 12 %, but this was driven largely by a reduction in nonfatal MI. The overall effect on stroke was not significant (Baigent et al. 2009).

Clopidogrel

The CHARISMA trial compared combination aspirin and clopidogrel to aspirin alone. Subgroup analysis of patients with vascular risk factors but no prior ischemic event showed that the combination therapy was less effective than aspirin alone at reducing the rate of MI, stroke, or cardiovascular death (Bhatt et al. 2006).

Secondary Prevention of Ischemic Stroke

Antiplatelet therapy is the standard of care for secondary prevention of non-cardioembolic ischemic stroke. The most frequently studied agent has been aspirin; however, a number of trials have focused on either comparing aspirin with an alternative antiplatelet agent or testing a single antiplatelet agent against a combination of aspirin and an alternative antiplatelet agent.

Aspirin

The Antithrombotic Trialists' Collaboration analyzed 16 randomized controlled secondary prevention trials

comprising 17,000 patients and reported that aspirin therapy for secondary prevention reduced ischemic stroke by 22 % compared with placebo and was associated with a nonsignificant increase in hemorrhagic stroke (Baigent et al. 2009). The benefit was independent of age, sex, diabetes, or hypertension. Algra et al. published a large meta-analysis that pooled data from 11 randomized controlled trials comparing aspirin to control in approximately 9500 patients (Algra and van Gijn 1999). Long-term aspirin therapy reduced the risk of all serious vascular events by 13 %, which was mostly driven by a decrease in nonfatal stroke. The dose of aspirin varied between trials, but there was no evidence that higher doses offered better protection. A systematic review reported an increased risk of GI bleeding with doses of aspirin higher than 81 mg (Campbell et al. 2007). However, a large meta-analysis did not show a difference in bleeding rates comparing 75–162 mg to 162–325 mg daily of aspirin (McQuaid and Laine 2006). The 2002 Antithrombotic Trialists' Collaboration reviewed 195 secondary prevention trials and found no differences in effectiveness comparing doses of 75–150 mg daily versus 150–325 mg daily (Antithrombotic Trialists' Collaboration 2002).

Aspirin Atrial Fibrillation

For secondary prevention of stroke in patients with atrial fibrillation, aspirin is significantly less effective than oral anticoagulation. An individual patient meta-analysis of six trials demonstrated that patients treated with warfarin versus aspirin were 45 % less likely (HR 0.55) to have an ischemic stroke, with a small increase of major bleeding (van Walraven et al. 2002).

Clopidogrel

There is fairly limited data comparing clopidogrel to aspirin or placebo. The CAPRIE trial compared clopidogrel 75 mg daily versus aspirin 325 mg daily among patients with recent stroke, MI, or peripheral artery disease to determine which medication was more efficacious at preventing a composite end point of stroke, MI, or vascular death (CAPRIE Steering Committee 1996). Clopidogrel therapy conferred a relative risk reduction of 8.7 % compared with aspirin therapy. Aspirin-treated patients also had a significantly higher rate of GI bleeding. However, most of the benefit of clopidogrel was observed in patients with peripheral artery disease, and analysis of the stroke subgroup (>6300 patients) did not demonstrate a statistically significant benefit of clopidogrel over aspirin.

Combination Antiplatelet Therapy

Clopidogrel plus Aspirin

The MATCH trial compared clopidogrel plus aspirin to clopidogrel alone for the secondary prevention of TIA or stroke in high-risk patients (Diener et al. 2004). Combination therapy did not reduce the rate of recurrent stroke or TIA, or significant vascular events, but was associated with a significant increase in major bleeding complications. The combination of aspirin and clopidogrel was again tested in the CHARISMA trial (Bhatt et al. 2006). This trial evaluated both primary and secondary prevention of cardiovascular and cerebrovascular disease. CHARISMA compared the combination therapy to aspirin alone, rather than to clopidogrel monotherapy. Once again, combination therapy demonstrated no reduction in the risk of composite end point (MI, stroke, or cardiovascular death) while imposing a significantly increased risk of moderate bleeding and a nonsignificant increase in severe bleeding. Based on the results of these trials, the use of combination clopidogrel plus aspirin is not generally recommended for long-term secondary stroke prevention. The combination may have utility for short-term use, for patients with specific stroke subtypes that remain to be clarified (see CHANCE study discussed above and SAMMPRIS discussed below).

Clopidogrel plus Aspirin: Lacunar Stroke

The SPS3 trial evaluated patients with lacunar stroke and compared the combination of aspirin and clopidogrel to aspirin alone (Benavente et al. 2012). However, the study was terminated early due to increased bleeding events and mortality in the dual antiplatelet group. Furthermore, no reduction in recurrent stroke was observed. The MATCH study (Diener et al. 2004) had a large subset of patients with lacunar stroke, and the results of these studies taken together argue against the use of dual antiplatelet therapy for long-term stroke prevention among patients with small-vessel subcortical stroke.

Clopidogrel plus Aspirin: Large Artery Intracranial Atherosclerosis

The SAMMPRIS trial compared angioplasty and stenting plus aggressive medical management to aggressive medical management alone in patients with symptomatic large artery intracranial atherosclerosis (Chimowitz et al. 2011). The medical management consisted of 90 days of dual antiplatelet therapy (aspirin and clopidogrel) along with a high-dose statin. The study demonstrated a lower rate of stroke and death in the medical arm compared to the

intervention arm, as well as compared to historical controls, demonstrating that the short-term use of combination aspirin plus clopidogrel in patients with large artery intracranial atherosclerosis was associated with favorable outcomes.

Clopidogrel plus Aspirin: Embolic Stroke from Aortic Plaque

The ARCH trial compared combination aspirin plus clopidogrel to warfarin with embolism due to aortic plaque and did not show a difference between these two therapies but was terminated early due to slow enrollment (Amarenco et al. 2014).

Clopidogrel plus Aspirin: Embolic Stroke from Atrial Fibrillation

The ACTIVE W (Connolly et al. 2006) and ACTIVE A (Connolly et al. 2009) trials evaluated the safety and efficacy of dual antiplatelet therapy in patients with atrial fibrillation. ACTIVE W compared clopidogrel plus aspirin to warfarin, and ACTIVE A compared clopidogrel plus aspirin to aspirin alone. ACTIVE A included only patients who were not candidates for anticoagulation. The ACTIVE W trial was stopped early because warfarin significantly lowered the rate of the composite end point (stroke, MI, or cardiovascular death) compared to combined antiplatelet therapy. There was also a trend toward less major bleeding with warfarin. The ACTIVE A trial demonstrated that patients treated with clopidogrel plus aspirin had a significantly lower annual rate of the composite end point and that the majority of this effect came from the 27 % reduction in stroke. However, dual antiplatelet therapy had a significantly increased incidence of major bleeding compared to aspirin. Based on the ACTIVE A trial, dual antiplatelet therapy with aspirin plus clopidogrel is an alternative to aspirin monotherapy for secondary stroke prevention in patients with atrial fibrillation patients who are unable to be treated with oral anticoagulation. However, dual antiplatelet therapy and warfarin have similar bleeding rates, and the newer oral anticoagulants likely have lower bleeding risks; therefore, increased bleeding risk is not good reason for selecting dual antiplatelet therapy in a patient with atrial fibrillation.

Dipyridamole plus Aspirin

The ESPS-2 trial compared 200 mg extended-release dipyridamole (ER-DP) twice daily, 25 mg aspirin twice daily, combination aspirin 25 mg and 200 mg ER-DP twice daily, and placebo in a four-armed study (Diener et al. 1996). The combination therapy was the most efficacious at preventing recurrent events (OR 0.59 compared to placebo), followed by aspirin monotherapy (OR 0.81 compared to placebo) and then ER-DP monotherapy (OR 0.79 compared to placebo). The ESPRIT trial compared open-label aspirin plus or minus dipyridamole 200 mg twice daily (Halkes et al. 2006). The composite outcome of stroke, MI, major bleeding, or vascular death was reduced in the dual antiplatelet group by 20 % (HR 0.80) compared to aspirin alone.

Since there was evidence the aspirin plus ER-DP was superior to aspirin alone (ESPS-2 and ESPRIT) and some evidence that clopidogrel was superior to aspirin alone (CAPRIE), the PRoFESS trial (Sacco et al. 2008) sought to compare these two treatments. The trial randomized 20,000 patients to either aspirin/ER-DP (25/200 mg twice daily) or clopidogrel 75 mg daily. No difference was seen in either recurrent stroke or composite end point of stroke, MI, or vascular death. There was a difference in adverse effects—more patients discontinued aspirin/ER-DP due to headache; there was also a trend toward more bleeding on the combination therapy.

Novel Agents

Adjuncts to Acute Therapy

Some antiplatelet medications have been considered for use as adjunct therapy to acute stroke thrombolysis, specifically the glycoprotein IIb/IIIa receptor antagonists such as tirofiban and eptifibatide. These have been evaluated in Phase II trials and were shown to be safe, but Phase III trials are needed to determine their efficacy (Pancioli et al. 2008, 2013; Siebler et al. 2011).

Secondary Prevention

Other antiplatelet agents including ticagrelor, prasugrel, and cangrelor have been recently studied in cardiac patients (Wallentin et al. 2009; Wiviott et al. 2007). The SOCRATES trial (Johnston et al. 2016) failed to show a benefit of ticagrelor over aspirin in the prevention of a composite outcome, but the others are yet to be studied in cerebrovascular disease and represent potential future targets.

Summary and Recommendations

Nonfatal recurrent stroke (ischemic and hemorrhagic) in patients with non-cardioembolic stroke or TIA [Adapted from CHEST Guidelines (Lansberg et al. 2012)]

Comparison	No. of participants (studies) follow-up	Relative effect (95 % CI)	Anticipated absolute effects, time frame of 2 years	
No aspirin vs. aspirin	10,126 (11 studies) 1.5–6 years	RR, 0.81 (0.71–0.92)	**Risk with no aspirin**	**Risk difference with aspirin (95 % CI)**
			130 strokes per 1000	25 fewer strokes per 1000 (from 10 fewer to 38 fewer)
Aspirin vs. clopidogrel	6431 (1 study) 1.9 years	RR, 0.91 (0.78–1.07)	**Risk with aspirin**	**Risk difference with clopidogrel (95 % CI)**
			106 strokes per 1000	10 fewer strokes per 1000 (from 23 fewer to 7 more)
Aspirin vs. aspirin + dipyridamole	7659 (6 studies) 2.6 years	RR, 0.77 (0.67–0.89)	**Risk with aspirin**	**Risk difference with aspirin plus dipyridamole (95 % CI)**
			106 strokes per 1000	24 fewer strokes per 1000 (from 12 fewer to 35 fewer)
Clopidogrel vs. aspirin + dipyridamole	20,332 (1 study) 2.5 years	HR, 0.97 (0.88–1.07)	**Risk with clopidogrel**	**Risk difference with aspirin plus dipyridamole (95 % CI)**
			97 strokes per 1000	3 fewer strokes per 1000 (from 11 fewer to 6 more)
Clopidogrel vs. aspirin + clopidogrel	7599 (1 study) 18 months	RR, 0.95 (0.82–1.1)	**Risk with clopidogrel**	**Risk difference with aspirin plus clopidogrel (95 % CI)**
			97 strokes per 1000	5 fewer strokes per 1000 (from 17 fewer to 10 more)
Antiplatelet vs. oral anticoagulant	5400 (5 studies) 0–5 years	RR, 1.03 (0.88–1.22)	**Risk with antiplatelet**	**Risk difference with oral anticoagulation (95 % CI)**
			106 strokes per 1000	3 more strokes per 1000 (from 13 fewer to 23 more)

Take-Home Messages

- Antiplatelet agents are the standard antithrombotic treatment for secondary prevention of non-cardioembolic stroke.
- For the early treatment of acute ischemic stroke:
  - Aspirin is recommended.
  - There is insufficient evidence to support the use of alternative antiplatelet agents or dual antiplatelet therapy.
- For primary prevention of acute ischemic stroke:
  - The data is mixed and requires further investigation.
  - Aspirin may be effective at preventing strokes in women.
  - Dual antiplatelet therapy is not as safe or effective for primary prevention of vascular events as aspirin.
- For secondary prevention of acute ischemic stroke:
  - Aspirin reduced rates of recurrent ischemic stroke compared with placebo.
  - It is unclear whether clopidogrel outperforms aspirin for secondary prevention—the single study used a combined end point, and clopidogrel's better outcomes were not driven by stroke prevention.
  - There is no difference between the effectiveness of aspirin/ER-DP and clopidogrel, but aspirin/ER-DP had more side effects including headache and bleeding.
  - Use of combination aspirin plus clopidogrel is not recommended for long-term secondary stroke prevention.
  - Short-term use of combination aspirin plus clopidogrel in patients with large artery intracranial atherosclerosis may be beneficial.
  - Aspirin plus clopidogrel is a more effective alternative to aspirin monotherapy for secondary stroke prevention in patients with atrial fibrillation who are unable to be treated with oral anticoagulation. However, dual antiplatelet therapy and warfarin have similar bleeding rates.

Antiplatelet Therapy in Peripheral Artery Disease

Francesco Violi, Stefania Basili, Jeffrey S. Berger, and William R. Hiatt

Abstract

Peripheral artery disease (PAD) is a problem of substantial public health importance and an important hallmark of generalized atherosclerosis involving, in particular, coronary and cerebral circulation. Despite the high prevalence of PAD, in particular in older population, this disease is underdiagnosed because it often presents with atypical symptoms or no ischemic symptoms. Ankle-brachial index (ABI) is a simple, inexpensive noninvasive test, which is widely accepted as a diagnostic test used to evaluate the presence of PAD. The ABI is also demonstrated to be useful in the assessment of vascular risk in asymptomatic and symptomatic patients being correlated with increased risk of coronary heart disease, stroke, and cardiovascular death. The risk factors for PAD are similar to the risk factors for atherosclerosis; thus, smoking should be stopped, and hypertension, diabetes mellitus, and dyslipidemia should be treated. In addition, antiplatelet therapy remains a key intervention to reduce cardiovascular risk in PAD.

In patients with PAD who have clinical evidence of concomitant coronary or cerebrovascular disease, aspirin or clopidogrel would be first-line. However, the data supporting the use of antiplatelet drugs in patients with PAD, who do not have a history of other cardiovascular disorders, are still inconclusive and further study is necessary to explore this issue.

Epidemiology and Classification of PAD

Peripheral artery disease (PAD) is a term that relates to atherosclerosis and narrowing of the arteries in the lower extremities. The spectrum of PAD encompasses acute limb ischemia and chronic limb ischemia, which is further divided into asymptomatic, claudication, and critical limb ischemia (Fig. 1) (Hiatt et al. 2008; McDermott 2015). PAD is a problem of substantial public health importance. It has been estimated that approximately 27 million persons in North America and Europe are afflicted with PAD (Rosamond et al. 2008; Belch et al. 2003). The prevalence of PAD is approximately 12 % of the adult population (Fig. 2), with men being affected slightly more than women (Criqui et al. 1985; Kannel and McGee 1985). PAD is increasingly prevalent in the aging population. Findings from a national cross-sectional survey of PAD Awareness, Risk, and Treatment: New Resources for Survival (PARTNERS) found that PAD afflicts 29 % of patients who are age >70 years or have risk factors of diabetes or smoking (Hirsch et al. 2001).

PAD is an important hallmark of generalized atherosclerosis involving, in particular, coronary and cerebral circulation (Bhatt et al. 2006). Thus, patients with PAD are at high risk of suffering from myocardial infarction, stroke, and vascular death with an annual incidence of about 5 % (Steg et al. 2007). Nevertheless, perception of the specific

risks associated with PAD is generally poor compared with other atherothrombotic settings, such as coronary artery disease or cerebrovascular disease. In fact, PAD represents a growing problem for internists since it is not just a localized disease, but it has serious systemic complications (Stehouwer et al. 2009; Pande et al. 2011).

Despite the strikingly high prevalence of PAD, this disease is underdiagnosed because it often presents with atypical symptoms or no ischemic symptoms related to the legs at all as showed by the Walking and Leg Circulation Study (McDermott et al. 2002). Accordingly, asymptomatic disease may occur in up to 50 % of all patients with PAD (Hirsch et al. 2006) (Fig. 1). In the Rotterdam Study, there was a 19.1 % prevalence of PAD, but claudication was reported in only 6.3 % (Meijer et al. 1998).

Ankle-brachial index (ABI) is the ratio of the ankle to brachial systolic blood pressure. This simple, inexpensive noninvasive test is widely accepted as a diagnostic test used to evaluate the presence of lower extremity peripheral artery disease, defined by an ABI $\leq$ 0.90 in patients with symptoms of claudication or rest ischemia (Fig. 3) (Aboyans et al. 2012; Norgren et al. 2007a, b; Criqui et al. 2008).

The ABI is also demonstrated to be useful in the assessment of vascular risk in asymptomatic and symptomatic patients. Screening for PAD in asymptomatic individuals should be considered in terms of cardiovascular risk and not merely of limb outcomes (Beckman et al. 2006).

Numerous studies have demonstrated that an abnormal ABI correlates with a significantly increased risk of vascular

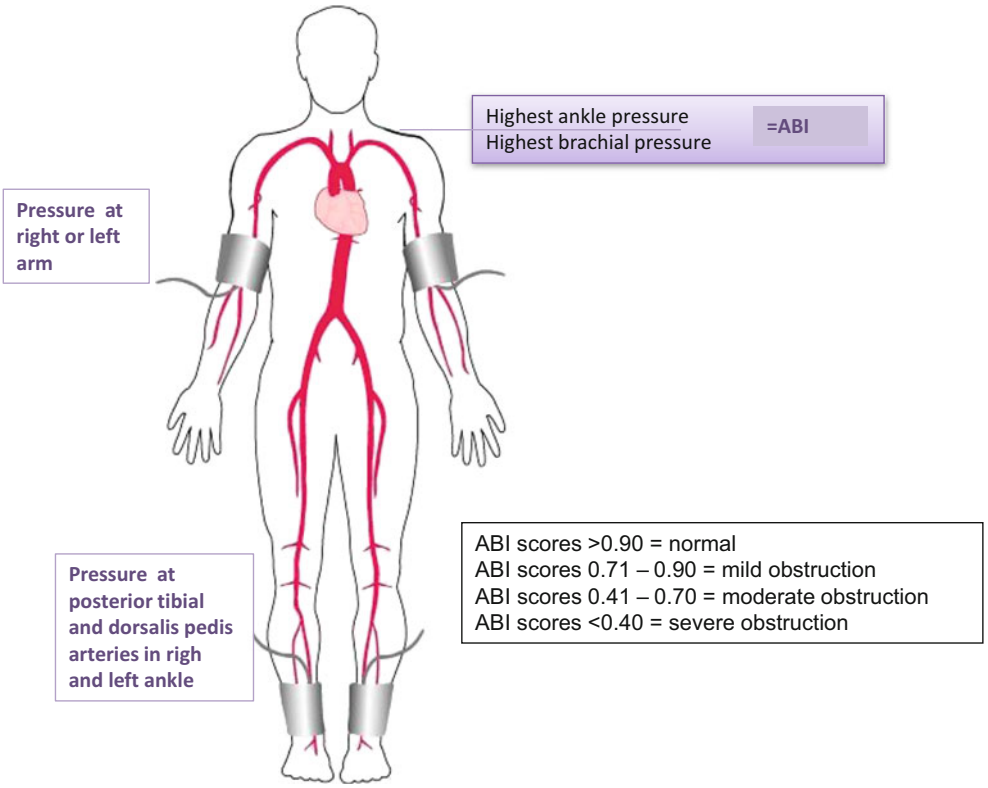

Fig. 3 Ankle-brachial index

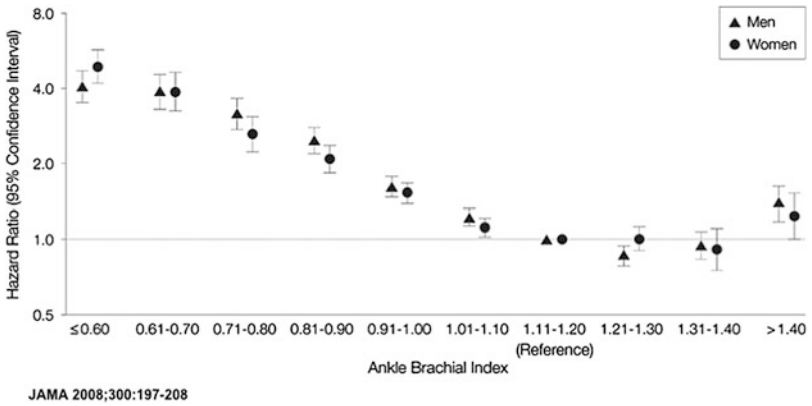

Fig. 4 Hazard ratios for total mortality in men and women by ankle-brachial index at baseline for all studies combined in the ABI collaboration. Pending permission from JAMA

events (Fowkes 2008; Doobay and Anand 2005; Resnick et al. 2004; O'Hare et al. 2006; McDermott et al. 2005).

However, an ABI $\leq$ 0.90 in population-based cohort studies seems to have high specificity but not enough sensitivity for predicting vascular events. Combining the population-based cohorts and the high-risk cohorts, the overall prevalence of ABI $\leq$ 0.90 is 13.2 % (Doobay and Anand 2005). Because of its low sensitivity (yet high specificity), the ABI cannot be used as a generic screening test. Rather, it must be used in a focused manner, choosing individuals for whom the yield of the test is expected to be higher. The sensitivity of a low ABI to predict all-cause mortality is much higher in the high-risk cohorts compared with the population-based cohorts (85.0 % vs. 31.2 %). The sensitivity and specificity of a low ABI to predict incident coronary heart diseases were 16.5 % and 92.7 %, for incident stroke 16.0 % and 92.2 %, and 41.0 % and 87.9 % for cardiovascular mortality, respectively. Furthermore, a meta-analysis of 16 population cohort studies was performed to determine if the ABI provides information on the risk of cardiovascular events and mortality independently of the Framingham Risk Score (FRS) and if it can improve risk prediction (Fowkes 2008). Including ABI in cardiovascular risk stratification using Framingham Risk Score would result in reclassification of the risk category and modification of treatment recommendations in approximately 19 % of men and 36 % of women (Fig. 4). In the hazard ratios (HRs) for death for different levels of ABI compared with an ABI

reference of 1.11–1.20 (low risk), a reverse J-shaped curve for both men and women was detected. For levels of ABI below 1.11, the HRs increased consistently with decreasing ABI as well as for an ABI of greater than 1.40 in both men and women. Conversely, no differences were found for levels of ABI from 1.11 to 1.40. In nearly all the studies in men, the HRs for total mortality were statistically significantly higher in individuals with an ABI of 0.90 or less compared with individuals with normal ABI values of 1.11–1.40. Likewise, significantly increased HRs were found in men and in women both for cardiovascular mortality and for major coronary events. Adjustment of the HRs for individuals with an ABI of 0.90 or less relative to an ABI of 1.11–1.40 for FRS reduced the HRs that, however, were still significantly elevated. Thus, the authors concluded that ABI provided independent risk information compared with the FRS and, when combined with the FRS, low ABI was associated with approximately twice the 10-year total mortality, cardiovascular mortality, and major coronary event rate across all Framingham risk categories. Thus, screening for PAD in asymptomatic individuals should be considered in terms of cardiovascular risk and not merely of limb outcomes.

Management of PAD

The risk factors for PAD are similar to the risk factors for atherosclerosis elsewhere (Fig. 5); the most strongly associated with PAD, in addition to age, are cigarette smoking and diabetes mellitus (DM) (Norgren et al. 2007a, b; Criqui and Aboyans 2015; Aronow 2010). Thus, smoking should be stopped, and hypertension, diabetes mellitus, and dyslipidemia should be treated. In addition, antiplatelet therapy remains a key intervention to reduce cardiovascular risk in PAD. Exercise rehabilitation programs and cilostazol help to relieve symptoms and improve exercise performance (Aronow 2010).

Platelets play an important role in the process of atherothrombosis via release of molecules that are injurious for vascular walls and by precipitating thrombosis at the site of plaque injury. There is evidence indicating that platelets are activated in patients with PAD. Platelet activation as assessed by urinary excretion of 11-dehydro-TxB_2 has been studied in patients with PAD and matched controls (Davì et al. 1997). This study demonstrated enhanced values of urinary 11-dehydro-TxB_2 excretion in PAD patients compared with controls. Such differences, however, seemed to be attributable essentially to the coexistence of risk factors for atherosclerotic disease such as hypercholesterolemia, diabetes, or smoking. Thus, in PAD patients without such risk factors, urinary excretion of 11-dehydro-TxB_2 was similar to that in controls, suggesting that the risk factors rather than atherosclerotic disease, per se, are responsible for enhanced production of TxA_2. Analysis of other markers of

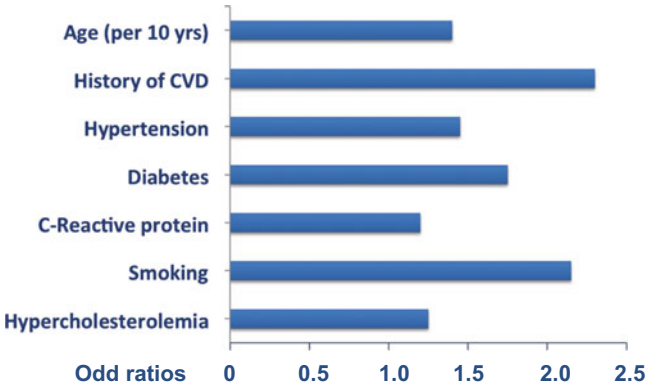

Fig. 5 Risk factors for peripheral artery disease

platelet activation confirmed the existence of platelet activation in PAD. In particular, a significant association between mean platelet volume (MPV) and PAD (as defined by a screening ABI < 0.90 even after multivariable adjustment) and high levels of soluble CD40 ligand and P-selectin have been detected in patients with PAD and critical leg ischemia (Berger et al. 2010; Blann et al. 2005). However, there was no relationship between the severity of arteriopathy, defined as the presence of resting pain, and platelet activation. Therefore, it is still unclear if platelet activation is a reflection of peripheral atherosclerosis or of the coexistence of risk factors such as diabetes, dyslipidemia, and smoking that activate, per se, platelet function.

Antiplatelet Drugs in PAD

Antiplatelet agents are a therapeutic cornerstone in the secondary prevention of cardiovascular events in patients with established atherosclerosis. The essential role of antiplatelet therapy has been well established in serial publications of the Antithrombotic Trialists' Collaboration (ATC) including over 130,000 patients and 50 trials (ATC 2002). This meta-analysis clearly demonstrates a cardioprotective benefit of antiplatelet therapy in a broad population of patients with clinical evidence of atherosclerosis. Specifically, this high-risk population has been defined as those with a history of myocardial infarction, acute coronary syndrome, transient ischemic attacks, or stroke, as well as coronary or carotid revascularization procedures. These are generally patients who have had ischemic events or interventions for symptomatic disease. In the subgroup of patients with stable peripheral arterial disease (PAD), similar benefits of antiplatelet therapy were observed. Thus, antiplatelet treatment was associated with a 23 % risk reduction of vascular events including MI, stroke, and vascular death in overall population with PAD. However, closer scrutiny of these data reveals that

the benefits in the PAD subgroup were largely driven by non-aspirin antiplatelet drugs including ticlopidine, clopidogrel, picotamide, and dipyridamole.

Aspirin and PAD

Aspirin is the most used antiplatelet drug to prevent cardiovascular events in patients with cardiovascular disease. Aspirin inhibits platelet COX1, thereby preventing the formation of thromboxane (Tx) A_2, a potent aggregating and vasoconstrictor molecule (FitzGerald 1991).

At variance with other circulatory territories such as coronary and cerebral trees, the effect of aspirin in peripheral atherosclerosis has been less well investigated, and results are inconclusive. The effect of aspirin has been examined in a post hoc analysis of the Physicians' Health Study where aspirin was ineffective in preventing claudication deterioration, while it seemed to reduce the incidence of peripheral surgical interventions (Goldhaber et al. 1992). However, these data are difficult to interpret due to the retrospective nature of the study. Therefore, evidence for any benefit of aspirin treatment in patients with PAD should be considered insufficient.

The American College of Chest Physicians (Alonso-Coello et al. 2012) practice guidelines recommended aspirin treatment (75–100 mg/day) in patients aged ≥50 years with asymptomatic PAD over no therapy (Grade 2B) for the primary prevention of cardiovascular events. For secondary prevention of cardiovascular disease in patients with symptomatic PAD (including patients before and after peripheral arterial bypass surgery or percutaneous transluminal angioplasty), long-term aspirin (75–100 mg/day) or clopidogrel (75 mg/day) (Grade 1A) were recommended. Moreover, 2011 ACCF/AHA Focused Update of the Guideline for the Management of Patients With Peripheral Artery Disease (Rooke et al. 2011) recommended aspirin, typically in daily doses of 75–325 mg, to reduce the risk of MI, stroke, or vascular death in individuals with symptomatic atherosclerotic lower extremity PAD (Level of evidence: B).

Three RCTs of antiplatelet therapy versus placebo for cardiovascular risk reduction among patients with PAD specifically examined the role of aspirin in PAD.

In the Critical Leg Ischaemia Prevention Study (CLIPS) (Catalano 2007), a study with aspirin in PAD anticipated randomizing 2000 patients, the enrollment was discontinued prematurely after including only 210 PAD patients. The reasons for stopping early were feasibility and not due to encountering any predefined stopping rule. Patients were randomized to placebo or 100 mg aspirin and followed up for 2 years. Throughout the study, major cardiovascular events, including fatal and nonfatal cerebral ischemia and myocardial infarction and critical leg ischemia, were monitored. During the follow-up, there were seven major cardiovascular events in the aspirin-treated group and 20 in the placebo-treated group, with a hazard ratio of 0.35, 95 % confidence interval (CI), 0.15–0.82. However, this benefit was entirely driven by a decrease in nonfatal events, as there were seven deaths on aspirin and four in patients randomized to the control group. Despite such interesting findings, the relatively few number of events and imbalance in deaths did not permit us to reach definite conclusions on the clinical efficacy of aspirin in the PAD population.

In the POPADAD study (Belch et al. 2008), Belch et al. investigated whether aspirin and antioxidants given together or separately can reduce MI and death in patients with diabetes and PAD. In their study, 1276 patients with diabetes and evidence of asymptomatic PAD (as determined by a lower-than-normal ankle-brachial pressure index of 0.99 or less, but no symptoms) over 40 years of age were randomized to receive either aspirin 100 mg or placebo, an antioxidant or placebo, or aspirin and an antioxidant or double placebo and followed over 8 years. There were two hierarchical composite primary end points: death from coronary heart disease or stroke, nonfatal MI or stroke, or amputation above the ankle for critical limb ischemia and death from CHD or stroke. Overall, the researchers found no benefit from either aspirin or antioxidant treatment. Patients in the aspirin groups had 116 primary events compared with 117 in the placebo group [hazard ratio (HR) 0.98 (95 % confidence interval, 0.76–1.26); $p = 0.86$]. There were 43 deaths from CHD or stroke in the aspirin group compared with 35 in the no-aspirin group [HR 1.23 (0.79–1.93); $p = 0.36$].

It is important to recognize that POPADAD is smaller than most of the other aspirin trials, with fewer events and that it is possible that small effects may be shown with larger trials continued for a longer time.

In 2010, the results of Aspirin for Asymptomatic Atherosclerosis (AAA) trial were published (Fowkes et al. 2010). The Aspirin for Asymptomatic Atherosclerosis (AAA) trial, conducted from April 1998 to October 2008, was an intention-to-treat, double-blind, randomized controlled trial of once-daily low-dose enteric-coated aspirin (100 mg) vs. placebo. It involved 28,980 men and women, aged 50–75 years, who were free of clinical cardiovascular disease, recruited from a community Scottish health registry. All recruited patients had an ABI screening test. Of those, 3350 with a low ABI (defined as an ABI value equal to or less than 0.95) entered the trial. The trial was designed for 80 % power to detect 25 % proportional risk reduction in events. Enrolled patients were randomly assigned in 1:1 ratio to low-dose aspirin (100 mg/daily) or to placebo groups. The primary end point of this study was a composite of fatal or nonfatal coronary event or stroke or revascularization. The follow-up had to be extended from the originally planned 5 years to 9.5 years. After a mean (SD) ;follow-up of 8.2 (1.6) years, aspirin was no more effective than placebo in reducing the primary end point (13.7 events per 1000 person-years in the aspirin group vs. 13.3 events

per 1000 person-years in the placebo group; HR, 1.03; 95 % CI, 0.84–1.27). Moreover, aspirin treatment had no significant effect on any of the secondary end points. Aspirin therapy was, however, associated with a nonsignificant increased risk of major hemorrhage (2.0 % vs. 1.2 %; HR = 1.71, 95 % confidence interval, 0.99–2.97). Intracranial hemorrhage occurred in 11 participants (including three fatal subarachnoid/subdural hemorrhages) in the aspirin group and seven in the placebo group. These results are similar to the findings of the aspirin primary prevention trials. Based on these findings, the authors concluded that in asymptomatic PAD patients, aspirin had no clinical benefit and may be harmful.

Additional findings were achieved by a meta-analysis performed by Berger et al. (2009) to assess the benefit of aspirin in treating both symptomatic and asymptomatic PAD patients including 18 prospective, randomized controlled trials of aspirin alone or in combination with other antiplatelet drugs. The meta-analysis was designed to test the null hypothesis that aspirin was not different from placebo or control in reducing the risk of the combined primary end point of nonfatal MI, nonfatal stroke, and cardiovascular death. Among 5269 participants included in the analysis, cardiovascular events were experienced in 251 (8.9 %) of 2823 patients taking aspirin (alone or with dipyridamole) and in 269 (11.0 %) of 2446 in the control group. The pooled RR reduction of 12 % in cardiovascular event rates was not statistically significant. Moreover, in the subset of 1516 participants taking aspirin monotherapy compared to control, aspirin was associated with a nonsignificant reduction in cardiovascular events [8.2 % vs. 9.6 %; RR = 0.75 (95 % CI, 0.48–1.18)] and in all-cause or cardiovascular mortality, MI, or major bleeding.

Almost 20 years ago, the US Food and Drug Administration (FDA) was asked to extend the labeling of aspirin to include PAD patients (FDA 1998). In its deliberations, the FDA could not find substantive evidence to support the role of aspirin for this indication. The implication of this deliberation was that patients with PAD who do not have overt clinical manifestations of atherosclerosis in other arterial beds might not be responsive to aspirin chemoprophylaxis.

With the absence of any new evidence, one should reserve aspirin therapy for PAD patients who have suffered coronary or cerebral ischemic events. This information could be of some importance in the design of additional placebo-controlled trials of aspirin in larger PAD populations.

Non-aspirin Drugs and PAD Drugs Inhibiting the Platelet Arachidonic Acid Pathway

Picotamide, a derivative of methoxyisophthalic acid, is an antiplatelet drug whose pharmacological properties consist in inhibiting both thromboxane A_2 receptors and TxA_2 synthase. As concentrations of the molecule needed to inhibit both pathways are almost equivalent (Modesti et al. 1989, 1994; Violi et al. 1988; Gresele et al. 1989; Berrettini et al. 1990; Cattaneo et al. 1991), picotamide may exert a dual pharmacological action in vivo and be potentially useful in various clinical settings characterized by atherosclerotic disease. Two prospective studies have been performed in PAD populations with different risks for cardiovascular events: the ADEP and DAVID trials.

The first large randomized trial (ADEP trial) on picotamide investigated its clinical usefulness in patients with PAD (Balsano and Violi 1993). For this study, 2304 patients were consecutively enrolled, allocated to either placebo or picotamide (300 mg tid), and followed up for 18 months. End points of the study were major events (i.e., cardiovascular death, myocardial infarction, stroke, or amputation) and minor events (unstable angina, transient ischemic attack, hypertension, renal failure, deterioration of PAD). The "intention-to-treat analysis" showed a risk reduction (18.9 %) in the combined end points, major plus minor events, in the picotamide group compared with the controls which, however, did not reach statistical significance. Conversely, "on-treatment analysis" showed a higher and statistically significant reduction (22.8 %) in the same end points. Side effects such as bleeding were almost identical in the two groups. As the authors suggested, the lack of any beneficial effects of picotamide against major events could have been related to the low occurrence of these events during the follow-up. This phenomenon may be related to a bias in patient selection, which excluded high-risk patients. The capacity of picotamide to prevent vascular complications was, however, magnified when claudicant patients affected by diabetes were taken into account. Thus, a sub-study of the ADEP trial retrospectively analyzed 438 diabetic patients and observed a risk reduction of 45.2 % of combined major and minor events in those treated with picotamide compared with those treated with placebo (Milani et al. 1996). On the basis of this post hoc analysis, another randomized trial (the DAVID trial) was specifically designed for diabetic patients with PAD (Neri Serneri et al. 2004). Thus, 1209 patients were enrolled and randomly assigned to picotamide (600 mg/bid) or aspirin (320 mg/day) and followed up for 2 years. The primary end point was overall mortality, and the secondary one was the combined incidence of death and major cardiovascular events. Mortality was significantly lower in picotamide-treated patients than in those treated with aspirin, showing a relative risk of reduction of 45 %. Furthermore, the incidence of gastrointestinal bleeding was much lower in the picotamide group than in the aspirin group. The secondary end point did not show any significant difference between the two populations, showing only a nonsignificant trend in favor of patients taking picotamide. As pointed out by the authors, a possible bias relative to the high proportion of patients

(about 20 % in each group) who discontinued the trial because of nonfatal events may have underestimated the real incidence of the secondary end points. Moreover, it is possible that the sample size of the study was insufficient to detect any difference in these end points between the two groups. Comparison of the results achieved by the ADEP and DAVID trials also raises the question as to whether the differences seen are dependent on the fact that TxA_2 production is more relevant for atherosclerotic progression in PAD patients with diabetes compared with PAD without diabetes, or whether the different dosage of picotamide (900 mg vs. 1200 mg in ADEP and DAVID, respectively) had a different impact on clinical outcome. Further studies are therefore necessary to explore the relationship between picotamide dosage and TxA_2 inhibition in vivo. In conclusion, activation of platelet arachidonic plays an important role in the pathogenesis of cardiovascular events in PAD, but the clinical trials with picotamide should be considered inconclusive and warrant further investigation.

Non-aspirin Drugs and PAD Drugs Inhibiting Platelet ADP Receptors

Thienopyridine is a drug category that inhibits platelet aggregation by interfering with platelet ADP receptors, i.e., $P2Y_1$ and $P2Y_{12}$.

Ticlopidine was the first drug of this class investigated in patients with PAD with the aim of evaluating the benefit on claudication or the cardiovascular events that complicate the clinical course of PAD. As far as the claudication is concerned, a prospective Italian study performed in 151 patients with claudication demonstrated that ticlopidine (250 mg/bid) increased walking distance compared to placebo-treated patients (Balsano et al. 1989). In the same trial, ticlopidine-treated patients' ABI did not worsen compared to placebo-treated patients, indicating that such antiplatelet treatment may favorably influence atherosclerotic progression. As far as the cardiovascular events are concerned, a Swedish trial (Janzon et al. 1990) investigated if ticlopidine (250 mg/bid), compared to placebo, was able to reduce cerebro- and cardiovascular events in a population with claudication. A total of 687 patients were included in the trial and followed up for 5 years. There was no difference in the clinical end points between the two groups. However, the secondary end point of mortality was lower in the ticlopidine group, and in an on-treatment analysis, there were fewer ischemic events in the ticlopidine-treated group.

The effect of thienopyridine on cardiovascular events was later examined in the CAPRIE trial, which compared the clinical efficacy of clopidogrel (75 mg/day), which is a derivative of ticlopidine, with aspirin (325 mg/day) in a population at different risks of cardiovascular events (CAPRIE 1996). One third of this population was affected by PAD. During 3 years of follow-up, clopidogrel was marginally significantly superior to aspirin in reducing cardiovascular events in the entire population (however the overall difference was insufficient to convince regulatory authorities that clopidogrel was indeed superior to aspirin). A post hoc analysis of the CAPRIE trial performed in the PAD population showed a significant risk reduction of 24 % for cardiovascular events in the clopidogrel-treated group compared to the aspirin group suggesting that the inhibitors of ADP receptors may be particularly efficacious in PAD patients.

In 2007, a publication of a post hoc analysis of Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial (Bhatt et al. 2007) included 2838 patients who had symptomatic PAD. Patients with PAD had a median time from diagnosis to the primary end point [cardiovascular death (including hemorrhagic death), myocardial infarction, or stroke (from any cause)] of 23.6 months in mean. The overall rate of cardiovascular death, MI, or stroke in PAD cohort was 8.7 % in the placebo plus aspirin arm and 7.6 % in the clopidogrel plus aspirin arm (HR = 0.869; 95 % CI: 0.671–1.125). Nevertheless, although the risk reduction in the PAD subgroup appeared similar to that observed in patients with prior MI or prior stroke, it did not reach statistical significance.

Together, these data indicate the clinical usefulness of thienopyridines in PAD to prevent major cardiovascular events. Given the level of evidence from the CAPRIE study, the FDA approved the use of clopidogrel in symptomatic patients with an ABI < 0.85 or PAD patients with a prior history of limb revascularization.

Clopidogrel (75 mg/day) is now recommended as a safe and effective alternative antiplatelet therapy to aspirin to reduce the risk of MI, ischemic stroke, or vascular death in individuals with symptomatic atherosclerotic lower extremity PAD, including those with intermittent claudication or critical limb ischemia, prior lower extremity revascularization, or prior amputation for lower extremity ischemia (Alonso-Coello et al. 2012; Rooke et al. 2011).

Moreover, the use of clopidogrel monotherapy or the use of clopidogrel plus aspirin and in PAD should be further assessed by PAD-specific interventional trials.

Nevertheless, in post hoc analysis of PLatelet inhibition And patienT Outcomes (PLATO) trial, patients with PAD ($n = 1144$) treated with ticagrelor showed numerically lower death from vascular cause, MI, or stroke when compared to treated with clopidogrel ones, but these results did not reach statistical significance (Patel et al. 2015).

The EUCLID (Examining use of tiCagreLor In paD) trial was designed to evaluate the benefit of ticagrelor 90 mg twice daily compared with clopidogrel 75 mg daily in 13,885 patients with symptomatic PAD with a median follow-up of 30 months. The primary efficacy endpoint was a

composite of cardiovascular death, myocardial infarction, or ischemic stroke, and the primary safety endpoint was major bleeding. The primary efficacy endpoint had a hazard ratio of 1.02 [95% confidence interval (CI) 0.92–1.13; $p = 0.65$], and major bleeding had an HR of 1.10 (95% CI 0.84–1.43; $p = 0.49$). Thus, there was no benefit of ticagrelor over clopidogrel in preventing major cardiovascular events indicating that clopidogrel was an active comparator and both drugs had similar results. There were two major subgroups enrolled, and those who had a prior revascularization had a risk of acute limb ischemia of 2.5% compared with 0.6% in patients enrolled based on an abnormal ankle-brachial index. The adjusted hazard ratio was 4.23 for the risk of acute limb ischemia in patients with a prior history of revascularization indicating a substantially increased risk based on a prior limb intervention. Ticagrelor was not superior to clopidogrel in preventing acute limb ischemia (Jones et al. 2016; Hiatt et al. 2016).

Non-aspirin Drugs and PAD Drug Antagonist of Protease-Activated Receptor-1

Vorapaxar is an oral, protease-activated receptor [PAR]-1 antagonist that inhibits thrombin-induced platelet aggregation. It has been recently shown to lower the occurrence of acute limb ischemia and peripheral revascularization in a subset of patients with PAD included in the Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events (TRA2°P)-TIMI 50 study. This is a randomized, double-blind, placebo-controlled trial of vorapaxar in 24,449 patients with stable atherosclerosis (Bonaca et al. 2013). A subgroup analysis of the study showed that in PAD patients ($n = 3787$), vorapaxar did not significantly reduce the risk of cardiovascular death, MI, or stroke, while the occurrence of acute leg ischemia was significantly reduced; vorapaxar therapy was, however, associated with increased risk of bleeding. These findings highlight a potential therapeutic approach to reduce acute limb ischemia and the need for peripheral revascularization in patients with symptomatic PAD. Based on the results of the trial, in May 2014, the US Food and Drug Administration (FDA) approved vorapaxar for the reduction of thrombotic cardiovascular events in patients with PAD.

Comparison of Efficacy of Antiplatelet Treatments in PAD

Although patients with PAD warrant lifelong antiplatelet therapy, an important issue relates to the potentially different impact of antiplatelet drug categories in the clinical progression of PAD. To investigate if specific antiplatelet treatment had a different impact on clinical outcomes, a meta-analysis has been performed in patients with claudication and/or ABI ≤ 0.99 (Basili et al. 2010). Twenty-nine clinical randomized trials on antiplatelet therapy for prevention of vascular death, myocardial infarction, and stroke in 10,735 peripheral artery disease patients have been included in the analysis.

The authors found 1900 (17.70 %) patients in trials with aspirin, 5326 (49.61 %) in those with thienopyridines, 2324 (21.65 %) in those with picotamide, and 1185 (11.04 %) in those with other antiplatelet drugs (including three studies where the active drugs were aspirin and/or dipyridamole). The results of this meta-analysis showed that in patients with claudication, antiplatelet treatment is efficacious in reducing vascular outcomes with a risk reduction of 17 %. Of note, analyzing separately each drug category, conclusive results were achieved by trials with thienopyridines that reduced the risk of cardiovascular events by 22 % ($p = 0.014$); a trend to a reduction was observed with aspirin (−15 %, $p = 0.208$) or picotamide (−21 %, $p = 0.302$), but these changes were not statistically significant. One of the limitations of this meta-analysis included the fact that it has been done in patients with stable PAD and could not, therefore, be extrapolated to nonmedical PAD series. Another limitation of the study was the lack of a direct comparison between two antiplatelet treatments that should require more interventional trials.

Conclusions

Antiplatelet therapy is indicated in patients with PAD to reduce the risk of major cardiovascular events. In patients with PAD who have clinical evidence of concomitant coronary or cerebrovascular disease, aspirin would be first-line.

It remains an open issue if PAD represents an atherosclerotic clinical model where aspirin, differently from coronary heart disease, is less effective in reducing atherosclerotic progression. Based on the reported results, further trials with aspirin should be done in symptomatic PAD patients. In these same patients, clopidogrel would be an acceptable alternative. However, the data supporting the use of antiplatelet drugs in patients with PAD, who do not have a history of other cardiovascular disorders, are still inconclusive, and further study is necessary to explore this issue.

Antiplatelet treatment should be indicated in PAD with clinically evident cardiovascular complication; aspirin or clopidogrel are the first-choice line for antiplatelet treatment. Conversely, the efficacy of antiplatelet treatment for primary prevention in symptomatic or asymptomatic PAD patients is less evident, and, thus, future interventional trials should analyze its cost-effectiveness in this clinical setting.

Take-Home Messages

Aspirin appears to have marginal benefits for reducing initial cardiovascular events when used for PAD patients without clinically evident coronary artery disease.

Clopidogrel significantly reduced cardiovascular events in the setting of peripheral arterial disease and would be an acceptable alternative to aspirin.

Platelet Transfusions

Randolph B. Lyde, Mortimer Poncz, and Michele P. Lambert

Abstract

Platelets clearly have an important role in hemostasis as evident by the increased risk of bleeding noted in severely thrombocytopenic individuals and in those with acquired or inherited defects in platelet function. Therefore, it was reasoned that platelet transfusions to such individuals may alleviate or prevent life-threatening bleeds. This chapter will review the history, the present, and the future of such transfusions as we transition from obtaining platelets from individual donors to growing custom platelets in culture. The opportunities that can arise from this new approach go beyond simply providing functional platelets tailored to meet individual needs and designed to avoid some of the pitfalls of current platelet transfusions and open up a new vista of potential therapeutic products targeted to sites of vascular injury.

History of Platelet Transfusion

Richard Lower performed the first successful blood transfusion in 1665 and kept a dog alive, by infusing blood from one dog into another (Spence and Erhard 2013). Just 2 years later, several people reported transfusing sheep blood into humans, usually with poor outcome and not always for the most ethical reasons so that the medical community initially banned experimentation with transfusion therapy (Spence and Erhard 2013). In 1818, James Blundell completed the first successful human blood transfusion in a series of eight women to manage postpartum hemorrhage (Blundell 1818), and in 1910 transfusions were recognized as successful therapeutic hemostatic interventions when Duke noted that they reduced the bleeding time (Duke 1910). It was not until 1962 that platelet transfusion began to be used more routinely, especially in cancer patients when the relationship between thrombocytopenia and hemorrhage was noted (Gaydos et al. 1962). In the 1970s, the combination of several observational studies identifying a possible role for prophylactic platelet transfusion in hypoproliferative thrombocytopenia and the discovery (Roy et al. 1973; Higby et al. 1974) that platelets were best stored at room temperature with gentle agitation to preserve function (Murphy and Gardner 1969) allowed for the proliferation of platelet transfusions as part of standard management of patients receiving chemotherapy (Blajchman et al. 2008). Further developments included reduction of the risks of bacterial contamination in units and developing strategies to limit platelet sensitization that markedly improved the efficacy of platelet products in individuals.

Indications for Platelet Transfusions

This development of platelet transfusion therapy was driven, in large part, by the observation that hemorrhage due to thrombocytopenia was a leading cause of death in adults and children receiving chemotherapy (Gaydos et al. 1962; Freireich 2011). Today, platelet transfusions have become a routine part of practice in some settings, with the most common indication being prophylactic platelet transfusion in the setting of myelosuppressive chemotherapy. In some studies, 75–80 % of platelet transfusions were performed for this indication (Greeno et al. 2007; Whitaker 2013; Charlton et al. 2014). Critical illness, surgery, and massive trauma are other common indications that result in platelet transfusion. Therefore, platelet needs fall into two broad categories: prophylaxis to prevent bleeding in high-risk settings and interventional where bleeding is ongoing. Thus, one can envision that the ideal product for these two categories might be distinct.

Despite the fact that transfusions have been in use for many years, there is still considerable debate about ideal platelet transfusion triggers, doses, and even the appropriate use of prophylactic versus therapeutic transfusions. The AABB (formerly American Association of Blood Banks) recommends a prophylactic platelet transfusion trigger of $<$10,000/μL in adult inpatients with chemotherapy-induced hypoproliferative thrombocytopenia, with higher thresholds of 20–50,000/μL for patients undergoing procedures (Kaufman et al. 2015). Other sources recommend a platelet transfusion trigger of $<$10,000/μL for stable, non-bleeding patients and $<$20,000/μL for febrile patients (Qureshi et al. 2007; Nahirniak et al. 2015). Higher thresholds have been recommended for neurosurgical patients (Qureshi et al. 2007).

Thrombocytopenia has been associated with increased mortality in critically ill patients (Thiolliere et al. 2013). Most interestingly, the platelet metric associated with poor prognosis in intensive care units is a 30 % decrease in platelet count (irrespective of starting platelet count or development of absolute thrombocytopenia) (Strauss et al. 2002; Moreau et al. 2007). However, in contrast, risk of bleeding is poorly correlated with degree of thrombocytopenia in this patient population (Strauss et al. 2002; Stanworth et al. 2013), and prophylactic platelet transfusions may not significantly alter the risk of bleeding, but may increase thrombotic complications and other problems (Cook et al. 2005). Part of the problem resulting in these seemingly contradictory findings may be the different settings being analyzed, the heterogeneity of platelet efficacy in different individuals, and the differences in platelet biology in various units based not only on the donor, but on the difficulty of maintaining highly reactive platelets ex vivo (Devine and Serrano 2010). Platelet transfusion in the setting of acute, nontraumatic illness is also complicated by increased platelet consumption/turnover, and in this setting, platelet transfusion in a non-bleeding patient may not be effective or necessary (Thiele et al. 2013). Recommended thresholds are not only important to balance the risks of bleeding versus the risks of thrombosis, exposure to potential contaminants and platelet sensitization, but also because of the recognition that provision of donor-based platelet transfusions may be limited in many western world countries that have aging populations with increasing needs for transfusion and a shrinking donor pool (Amrein et al. 2012).

Platelet Preparation

Advances in collection techniques, storage techniques, and additives to decrease platelet reactivity and bacterial contamination have made platelets safer. Today, more than four million units of platelets are transfused per year worldwide (Sullivan et al. 2007). Platelets for transfusion can be derived from whole blood donations or by single-donor apheresis with particular advantages to each technique. Whole blood-derived platelet units are obtained by pooling platelet-rich plasma or buffy coats from multiple donors using differential centrifugation steps. The platelets are then resuspended in plasma or an additive solution plus plasma. These units are relatively cheap to produce as well as optimize use of the entire unit of donated whole blood. However these units do not allow for HLA/HPA matching and result in increased donor exposures to foreign antigens and risk of platelet sensitization (Pietersz 2009). With single-donor apheresis units, the entire unit of platelets is obtained by apheresis from a single donor who needs to undergo a longer and somewhat more invasive procedure (Pietersz 2009). The production of these units is more expensive, and its hemostatic efficacy is dependent on that individual donor, but this method allows for HLA/HPA matching and minimizes the number of donors to which a recipient is exposed. Platelet count specifications for what constitutes an acceptable unit of platelets vary somewhat from country to country, but generally are $2–3 \times 10^{11}$ platelets/unit (e.g., in the United States, minimum platelet specifications are for 3×10^{11}/unit platelets, while Switzerland requires $>2.4 \times 10^{11}$/unit).

Platelet Storage and Its Effects on Platelet Function

In contrast to all other blood components, platelets are stored at room temperature with gentle agitation. They have a short shelf life of 5–7 days due to the risk of bacterial contamination (Perez et al. 2001). Unfortunately, while storage of platelets at room temperature appears to preserve their function, there is still damage to the platelets as a result of their

Table 1 Platelet storage lesion

Factors responsible for the platelet storage lesion	
Intrinsic	Calcium shift
	Signaling (centrifugation)
	Loss of platelet granules
	Cytoskeletal changes
Extrinsic	Metalloproteinase cleavage of receptors
	Hypoxic injury
	Platelet apoptosis

sensitivity to manipulation. This platelet storage lesion is poorly defined and likely multifactorial. Platelet centrifugation during the preparation process results in some degree of platelet activation causing calcium shifts and signaling (Hoffmeister et al. 2003). Also potentially contributing to the platelet storage lesion are metalloproteinase cleavage of the extracellular glycocalicin domain of glycoprotein Ib alpha (Sandgren et al. 2007), degradation of the cytoskeleton (Handigund and Cho 2015), platelet apoptosis (van der Wal et al. 2010), lactic acid accumulation and platelet hypoxia (which are partially ameliorated by agitation of the bag) (Hossien et al. 2014), and platelet degranulation (Handigund and Cho 2015) (Table 1).

Factors Affecting Transfusion Efficacy

Platelet efficacy can be assessed as either the degree of platelet count rise or the effect on bleeding. While assessing bleeding is arguably the most relevant, measuring platelet increment is the easiest in the vast majority of patients who are receiving transfusions because of thrombocytopenia. Intuitively, physicians feel that giving more platelets at a single time should increase the platelet increment and be more effective at preventing bleeding. This was demonstrated not to be true. According to the dose of prophylactic platelet transfusion (PLADO) trial (Slichter et al. 2010), increasing platelet dose from 1×10^{11} platelets/dose to 4×10^{11} platelets/dose did not alter the incidence of bleeding in patients getting prophylactic platelet transfusion, but resulted in more units of platelets being transfused in those patients getting higher platelet doses. A subanalysis showed that this was true even in pediatric patients, but that there was increased bleeding in children in general compared to adults (Josephson et al. 2012). This suggests that giving more platelets at a time in the setting of thrombocytopenia for prophylaxis is not helpful. Most guidelines recommend that platelets transfusions be matched for ABO blood group whenever possible because this increases the platelet recovery after transfusion (Julmy et al. 2009). Other factors that have been shown to decrease platelet increment after transfusion include irradiation of platelets, addition of certain additives, pathogen reduction, and length of time in storage, although most of these factors have not been definitely shown to impact platelet transfusion effectiveness in clinical bleeding (Triulzi et al. 2012). Finally, several patient factors, including gender, height/weight, as well as some clinical conditions and drugs, can also influence the platelet increment posttransfusion (Stanworth et al. 2015).

The greatest cause of platelet transfusion refractoriness is platelet sensitization. Refractoriness is a failure to achieve the expected platelet increment from transfusion (generally for at least two consecutive platelet transfusions of ABO-matched platelets). There are several nonimmune and immune factors that can contribute to platelet refractoriness and should be considered in the assessment of patients. Generally, the nonimmune factors that contribute to platelet refractoriness cause platelet consumption and include bleeding, infection/sepsis, splenomegaly, and graft-versus-host disease (Doughty et al. 1994). Drugs may also contribute to these mechanisms in particular, vancomycin, heparin, and the $\alpha_{IIb}\beta_3$ inhibitors (Stanworth et al. 2015). In approximately 20 % of patients, immune mechanisms play a role, most commonly due to HLA antibodies (Hod and Schwartz 2008). Risk factors for immune refractoriness include a history of prior transfusion, pregnancy, and/or transplantation (Hod and Schwartz 2008).

Platelet Transfusion Risks/Reactions

There are good reasons, beyond conservation of a limited and precious resource, decreasing healthcare costs, and optimizing utilization, to limit the number of transfusions. While platelet transfusions are generally safe, they are not completely without risk. Platelet transfusions account for 10 % of transfusions, but are responsible for 25 % of transfusion-associated adverse events (Harvey et al. 2015).

Febrile nonhemolytic transfusion reactions (FNHTR) to platelet concentrates commonly occur and have been attributed to the presence of cytokines in the plasma from residual leukocytes. These adverse reactions increase in frequency and severity with length of storage (Kelley et al. 2000). The concentration of the cytokines interleukin-6 (IL-6), tissue necrosis factor alpha (TNFα), and interleukin-1 beta (IL-1β) increase with storage, particularly in platelet concentrates containing $>3 \times 10^9$/L leukocytes (Kunz et al. 1998; Kanter et al. 2008). Cytokine accumulation is most marked after day 3 of storage, and levels are highest at day 5 (Kanter et al. 2008). Leukocyte depletion of platelet products using product filtration has been shown to reduce the incidence of FNHTR (Mishima et al. 2015); in the presence of adequate leukocyte depletion of platelet products ($<5 \times 10^6$/unit), the incidence of FNHTR is not affected by platelet storage time. The type of platelet product

(random donor versus apheresis platelet product) has no effect on the incidence of FNHTR.

Platelet products can also potentially be contaminated with infectious agents. Bacterial contamination occurs in ~1 in 2000 platelet units. Despite active and passive surveillance systems to detect bacterial contamination in platelet units, septic transfusion reactions still occur in ~1:50,000 platelet transfusions (Klein 2005) and are associated with a fatality rate of 1.3 deaths per million platelet transfusions (Hong et al. 2016). Viruses are also carried by contaminating leukocytes as in whole blood. Although the risks of viral transmission are fairly low, there are always concerns about transmission of the next new viral infection (Klein 2005). The current discussions of variant Creutzfeldt-Jakob disease suggest that the potential infective agent is carried by platelets (Jones et al. 2005). Finally, as with all blood products, allergic reactions, due to IgE and IgG antibodies in the recipient against plasma proteins in the transfused blood component, or due to transfusion of cytokines, chemokines, and histamine generated in the platelet product during preparation and storage, occur in 0.09–21 % of transfusions and appear to be donor unit and patient specific and should be treated similarly to allergic reactions with any other blood product (Domen and Hoeltge 2003).

Transfusion-associated acute lung injury (TRALI) is the leading cause of transfusion-related mortality in the United States that can occur following a platelet transfusion and has been reported with an incidence of 2.8 per 100,000 apheresis platelets where universal donor restriction policies have not yet been fully adopted (Muller et al. 2015). TRALI involves the appearance of acute respiratory distress, new bilateral pulmonary infiltrates in the absence of circulatory overload within 6 h of transfusion, and can occur with transfusion of any blood component. The rate of TRALI is highest in platelet and plasma transfusions (Stolla et al. 2015). This is generally associated with anti-leukocyte antibodies in the donor, which are most frequently found in donors who have a history of pregnancy, but there may be antibody negative TRALI in about 20 % of cases (Peters et al. 2015a, b). The current leading hypothesis on pathophysiology for TRALI puts forth a "two-hit" or "threshold" model of pathogenesis where the transfusion recipient sustains the "first hit" or reaches a "threshold" of susceptibility to TRALI through critical illness, sepsis, or cardiac surgery, for example, and then receives a transfusion with a product that has requisite characteristics (the "second hit"). These two models are illustrated in Fig. 1 (Bux and Sachs 2007). The screening of at-risk donors has resulted in some countries in dramatic decreases in the frequency of TRALI (Muller et al. 2015); however, there are still cases of nonimmune TRALI and even immune TRALI that are not prevented by screening programs. The risks of platelet transfusions are summarized in Table 2.

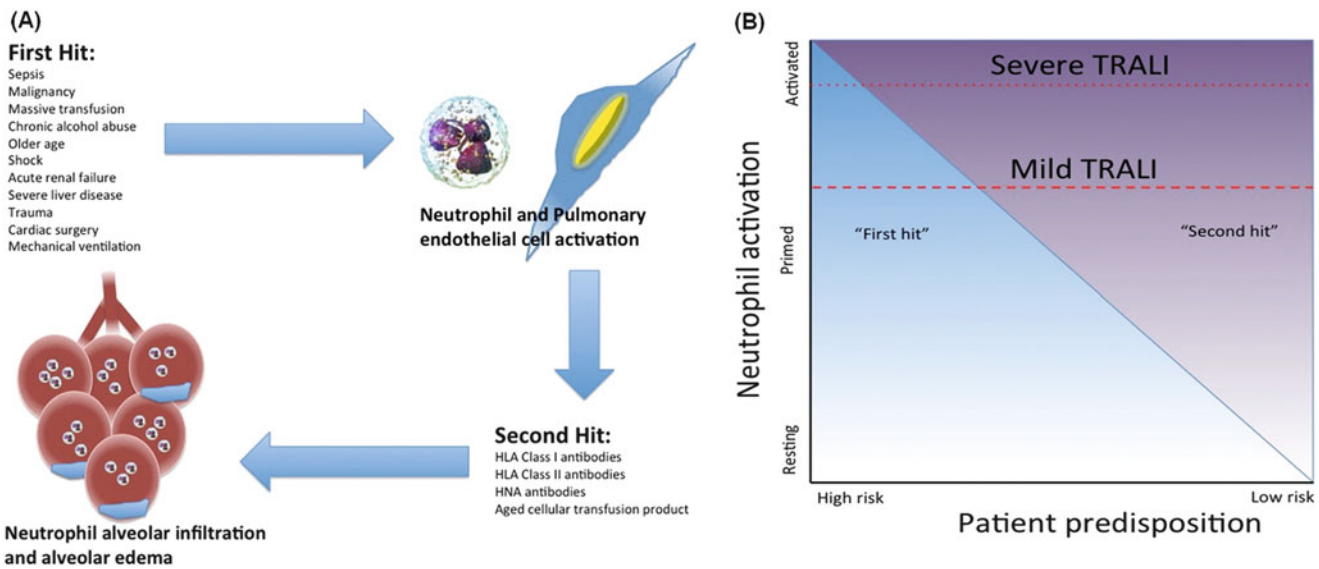

Fig. 1 (**a**) The two-hit model of transfusion-related acute lung injury (TRALI) with hypothesized pathophysiology. A "first hit," an underlying clinical condition of the patient, results in priming of neutrophils and activation of pulmonary endothelial cells. The "second hit," the transfusion of a blood product, causes activation of the neutrophils and coagulation pathways resulting in TRALI. Neutrophil activation results in migration of neutrophils through the interstitium into the alveoli, which are filled with protein-rich edema. The "second hit," the transfusion product, may contain accumulated cytokines, aged cells, human leukocyte antigen (HLA) antibodies or human neutrophil antigen (HNA) antibodies. (**b**) The threshold model of TRALI. In the "threshold model" the threshold is formed by the level of priming of lung neutrophils and the ability of the mediators in the transfusion product to activate these primed neutrophils

Table 2 Risks of platelet transfusion

Risks of platelet transfusions		
Transfusion reaction	Frequency	Postulated mechanism
Febrile nonhemolytic transfusion reaction	1.1–4.6 % of transfusions	Accumulation of cytokines
Allergic reaction	0.09–21 % of transfusions	IgE/EgG antibodies in recipient against plasma proteins in platelet product; transfusion of cytokines, chemokines, and histamine in product during preparation and storage
TRALI	2.8 per 100,000 apheresis units	Multifactorial but includes transfusion of HLA or HNA antibodies
Bacterial contamination	~0.5 %; 1:50,000 transfusions	Due to storage at room temperature

In Vitro Platelet Production

Clearly, donor-based platelet transfusions have made an important contribution to patient care, but have also been limited by the quality and safety of the final product and by the increasing demand for platelets by an aging clinical population and a relatively fixed platelet donor-pool size. One direction to overcome these limitations and to offer personalized platelets has been to produce platelets in vitro from hematopoietic or other stem cells. While there has been important progress made in the area of in vitro platelet production, the technology and methods to produce sufficient quantities of functional platelets in culture have yet to be fully realized. Below, we describe the current status of in vitro platelet production and the remaining challenges that still need to be surmounted to making sufficient quantities of functional platelets in culture. We will also discuss additional application that can come from this alternative source of platelets.

CD34+-Derived Megakaryocytes and Platelets

Thrombopoietin (TPO) was first proposed to be an important regulator of platelet production in 1958, but was not isolated and characterized until 1994, confirming that it is an important regulator of megakaryopoiesis and thrombopoiesis (Kaushansky and Drachman 2002). Recombinant TPO began to be used in culture to produce and expand megakaryocytes and platelets beginning with CD34+ cells isolated from different sources, including mobilized peripheral blood, adult bone marrow, and umbilical cord blood. These sources showed variable yields of large megakaryocytes with polyploid nuclei and also yields of in vitro-released particles that we will term "platelet-like particles" or PLPs (Su et al. 2001; De Bruyn et al. 2005). Choi et al. first showed that these peripheral blood CD34+-derived megakaryocytes in the presence of TPO could produce PLPs after 12 days of culture (Choi et al. 1995). While the size range of these particles was not shown, Choi showed that thrombin or ADP could not only activate a portion of the PLPs but also participate in $\alpha_{IIb}\beta_3$-mediated aggregation. Comparative studies were done with donor-derived platelets, but with at least a portion of the platelets being pre-activated. An additional problem was that it was unclear the amount of PLPs being released per initial CD34+ cell or per derived megakaryocyte and whether these PLPs could potentially be used for transfusions. In 2006, Matsunaga et al. showed that large numbers of PLPs could be produced from cultured umbilical cord blood-derived CD34+ cells (Matsunaga et al. 2006). In their 33-day, three-step protocol, ~3–4 $\times$ 10^4 PLPs could be generated from one umbilical cord CD34+ cell after culture on stromal cells but only a portion were CD41+. In this study, they also showed functionality of these platelets through ADP activation by surface p-selectin binding and proper CD41 integrin function through the monoclonal antibody PAC-1 binding to the activated cells. Experiments were done that compared in vitro-generated PLPs to donor-derived platelets and showed that in vitro PLP production for possible clinical use from CD34+ cells is feasible, but neither paper showed in vivo studies.

Embryonic Stem, Induced Pluripotent Stem (ES/iPS) Cells, and Other Stem Cells Differentiate into Megakaryocytes

Human embryonic stem cells were generated from fetal material, and iPS cells were first derived by Yamanaka et al., from somatic cells in 2006 by transiently expressing four factors in these cells (Takahashi and Yamanaka 2006). ES/iPS cells are appealing in that they can replicate for many generations and can also be differentiated into a variety of different lineages, including the hematopoietic lineage (Holden and Vogel 2008; Osafune et al. 2008; Lim et al. 2013). A number of groups have reported making megakaryocytes from ES/iPS cells using protocols incorporating TPO in the final differentiation process, releasing PLPs (Takayama and Eto 2012; Nakamura et al. 2014). Unlike CD34+ cells that have a limited in vitro life span, ES/iPS cells can theoretically be greatly expanded

prior to differentiation into megakaryocytes, and it was hoped that these stem cells would be a useful resource to obtain clinically relevant numbers of platelets (Nakamura et al. 2014). Initial studies with iPS cell-derived megakaryocytes have shown several limitations: only 1–10 hematopoietic progenitor cells can be produced per initial ES/iPS cell (Lu et al. 2011; Takayama and Eto 2012; Wang et al. 2015), and only 1–10 megakaryocytes can be produced from initial hematopoietic progenitor cell (Lu et al. 2011; Amabile et al. 2013). Finally, these megakaryocytes are small and of low ploidy (Wang et al. 2015), and only 1–10 PLPs could be generated per megakaryocyte. In vitro studies generally focused on individual PLPs to show similar size, shape, and organization of particles to donor-derived platelets and to show functionality. When the full population was examined, only a few percent of the cells were CD41+ and even a smaller percent were CD41+CD42+ (Lev et al. 2011; Lu et al. 2011). Moreover, these PLPs had minimal reactivity to various agonists relative to what one would expect of donor-derived platelets (Gaur et al. 2006). Finally, unlike infused donor-derived platelets, human PLPs infused into immune-compromised NSG mice had a markedly shortened half-life consistent with the fact that most of the CD41+CD42+ PLPs were actually CD42b-, likely due to metalloproteinase cleavage in culture (Fuentes et al. 2010). In vivo functional studies did indicate active incorporation of these PLPs into thrombi in mice (Mishima et al. 2015), but the efficacy of this process relative to donor-derived platelets was not tested.

Other sources of stem cells have also been used in place of ES/iPS cells. These have successfully included endometrial stromal stem cells, fibroblasts, and adipocytes (Mali et al. 2008; Matsubara et al. 2009; Wang et al. 2012). These cells have yielded similar results as ES/iPS cells in terms of efficacy of amplification of megakaryocyte yield per initial stem cell and yield of PLPs per megakaryocyte. The biology of these PLPs in culture and in vivo was also similar to those seen with ES/iPS cell-derived PLPs.

Overcoming the Limitations of In Vitro Megakaryopoiesis and Thrombopoiesis

One clear limitation with ES/iPS cell-derived hematopoietic lineages is that they replicate embryonic hematopoiesis (Sturgeon et al. 2014; Lachmann et al. 2015). There are megakaryocytes in the embryo (Tober et al. 2007), but whether they yield platelets with similar functionally to adult platelets is not clear. Technologies to derive definitive hematopoietic lineages have been described (Lachmann et al. 2015), but whether generating megakaryocytes from these cells would affect yield and/or quality of the final PLPs is unknown.

Another limitation is the yield of PLPs per beginning iPS cell is extremely low. Perhaps if one can establish a self-replicating intermediate cell from iPS cells that can proliferate for multiple rounds before differentiating into megakaryocytes, one can overcome this limitation. In 2014, Nakamura et al. showed that iPS cell-derived megakaryocyte progenitors expressing the proto-oncogene MYC under a doxycycline-inducible promoter and BMI1, a repressor of c-Myc-regulated apoptosis factors, could result in an expandable intermediate lineage (Nakamura et al. 2014). Upon removal of doxycycline, these cells differentiated into megakaryocytes and released PLPs. However, these PLPs had the same limitations as described for PLPs released without this intermediate expansion from iPS cells (Lu et al. 2011). In another approach to accomplish a similar expansion of an intermediate lineage strategy, Noh et al. showed that mouse ES cells expressing *Gata1* shRNA transgene under a doxycycline-inducible promoter could also undergo differential arrest at the megakaryocyte-erythroid progenitor stage, and, following terminal differentiation, these cells could become polyploid megakaryocytes that yielded platelets that were functional both in vitro and in vivo upon infusion (Noh et al. 2015). Whether these studies could be recapitulated in human cells and would yield actual platelets remains unknown.

Bioreactor Systems to Generate Platelets

Several groups have developed bioreactor systems to generate platelets from in vitro-grown megakaryocytes (Nakagawa et al. 2013; Thon et al. 2014; Di Buduo et al. 2015). These systems physically push megakaryocytes using flow through an uncoated plastic sieve in the presence of shear stress and collect the resulting particles as well as whole megakaryocytes at the efferent end. These preparations do contain some PLPs of the size of donor-derived platelets and have some in vitro responsiveness to agonist as well as adherence and spread on fibrinogen-coated surfaces comparable to growth in static cultures. However, the comparative size distribution and range, as well as the relative functionality compared to donor-derived platelets and in vivo half-life and functionality in recipient immunodeficient mice are missing from these reports. Another approach has used silk strands as opposed to a plastic sieve has been pursued and has also met with partial success (Pallotta et al. 2011; Di Buduo et al. 2015).

Infusing Megakaryocytes Rather than Platelets

Most groups assume thrombopoiesis occurs at the endothelial lining of the bone marrow (Machlus and Italiano 2013). The endothelial cells in the marrow sinuses have pores in them that may allow migration of cells in and out of the

intramedullar space. Intravital microscopy of megakaryocytes at these junctions has supported the migration of megakaryocytes across the endothelial cell layer and the immediate release of platelets or larger cytoplasmic fragments (Tavassoli and Aoki 1989; Junt et al. 2007); however, these studies are open to interpretation and can be used to also support the concept that whole megakaryocytes may migrate out of the marrow space intact or in large fragments and lodge in the pulmonary microcirculation and release platelets there (Zucker-Franklin and Philipp 2000). Fuentes et al. documented that both mouse- and human-infused megakaryocytes actually lodge in the lungs and release platelets there over the next few hours (Fuentes et al. 2010). It was also found that unlike in vitro-released PLPs, released human platelets are very similar in half-life, size, size distribution, and functionality in the recipient mice to donor-derived platelets. The mice tolerate these infusions well as only <5 % of the pulmonary vasculature need be occluded. Further larger animal studies will better define the clinical applicability of directly infusing megakaryocytes rather than depending on platelets to be produced ex vivo. Since peak platelet release may take up to 4 h, this approach may be more conducive for prophylactic therapy than for acute bleeding emergencies.

Other Uses of In Vitro-Generated Platelets

Platelet infusion is mostly to treat individuals with thrombocytopenia and rarely to treat patients with inherited defects in platelet function. However, using ES/iPS cells or other stem cells can now be modified by gene editing technologies to knock out or down a particular protein or to express a native or ectopic protein. These modified platelets may have biological and clinical uses that cannot be duplicated by donor-derived platelets.

Decreased Risk of Platelet Sensitization One of the complications of multi-transfusion of platelets is the development of antibodies to HLA markers on the cell and subsequent refractoriness to platelet transfusion. The elimination of the beta2-microglobulin gene in stem cells and their subsequent megakaryocytes and PLPs, after differentiation, has been reported (Riolobos et al. 2013; Feng et al. 2014). If these platelets have normal biology and functionality, they may become another reason to replace donor-derived platelets with a product less likely to lead to sensitization, especially in individuals likely to require multiple platelet transfusions.

Prolonging the Half-Life of Infused Platelets It is possible that overexpression of an antiapoptotic factor such as Bclx (Nakamura et al. 2014) or of the "do-not-eat-me" surface marker CD47 (Olsson et al. 2005) may improve the life span of platelets and reduce the frequency with which individuals need to receive transfusion.

Targeted Delivery of an Ectopic Protein in Platelets Several proteins have been ectopically expressed in megakaryocytes and platelets to achieve targeted delivery vehicle. Urokinase (Kufrin et al. 2003) and ADAMTS13 (Laje et al. 2009) have both been ectopically expressed during megakaryopoiesis, and both are stored in platelet alpha granules. Both can have a targeted and potent antithrombotic effect without causing systemic fibrinolysis for urokinase or von Willebrand factor polymer degradation for ADAMTS13. Ectopic expression of factor VIII (FVIII) has also been achieved in platelets, and it is stored in alpha granules (Yarovoi et al. 2003). This platelet FVIII is not released unless the platelet is activated and has been shown in mice models to significantly correct the bleeding diathesis in hemophilia A mice even in the presence of significant levels of circulating FVIII inhibitors (Shi et al. 2006; Gewirtz et al. 2008). Finally, platelets are known to enhance tumor cell metastasis (Zaslavsky et al. 2010). Platelet transfusions to thrombocytopenic patients with tumors may theoretically enhance hematogenous tumor spread (Lyman and Khorana 2009; Zaslavsky et al. 2010). The ectopic expression and release of an anti-angiogenic agent like a soluble VEGFR may prevent that complication, and it may be useful to incorporate such a modification into platelets being given to cancer patients undergoing chemo- or radiotherapy.

Future Perspective

The clinical need for platelet products continues to expand as our population continues to age and as new therapeutic options are developed that induce thrombocytopenia. The size of the platelet donor pool is likely to shrink concurrently. While alternative therapies that can ameliorate bleeding risk in these patients may develop utilizing TPO mimetic drugs to enhance production (Kuter 2009) or blocking the pathways for platelet clearance (Grozovsky et al. 2015), another potential approach is to generate platelets in cultured megakaryocytes derived from a variety of stem cell sources perhaps ES/iPS cells. Such substitute platelets may overcome other issues related to donor-derived products including high-quality product standardization and ability to avoid sensitization. They also offer the opportunity to develop personalized platelets and targeted drug delivery via platelets to expand the uses of platelet transfusion. It would be anticipated that the advantages of these products would compensate for their likely greater costs of production compared to platelets from volunteer donors.

Technologies to develop a self-proliferating, intermediate cell line in vitro that can give rise to functional megakaryocytes and platelets appear to be an important tool that would allow the scale-up needed to provide a sufficient number of platelets for clinical needs. Limiting or eliminating injury to the megakaryocytes in culture and subsequently to the derived platelets is also important. A way to release functional platelets from these megakaryocytes in vitro or to explore further the clinical applicability of direct megakaryocyte infusions must also be developed. Importantly, a comparative gold standard platelet product that is quiescent prior to being exposed to agonists and is highly responsive to agonists is required to judge any in vitro-generated product. An acceptable in vitro-derived product must be at least comparable to this standard platelet preparation, not only in agonist responsiveness but also in size range and distribution, in the absence of contaminating non-platelet cell fragments, and in circulating half-life. At the moment, none of the in vitro products would meet such criteria or were not tested against such high standards, but with further growth in our understanding of stem cell differentiation to adult hematopoietic progenitor cells, and of the underlying biology of megakaryopoiesis and thrombopoiesis, it would be reasonable to expect that such a clinically applicable product would emerge.

Take-Home Messages

- More than four million platelet units are transfused worldwide on a yearly basis.
- Advances in platelet collection, storage, and additives to decrease platelet activation and bacterial contamination have made platelet products safer.
- Febrile nonhemolytic transfusion reactions are likely reduced by leukodepletion but not by use of single-donor versus random-donor platelet units.
- TRALI has complex pathophysiology and is dependent upon both recipient and donor factors.
- Research to develop other sources of platelets for transfusion is ongoing and may lead to better platelet products in the future.

Platelet-Rich Plasma in Regenerative Medicine

Joseph Alsousou and Paul Harrison

Abstract

The clinical application of platelet-rich plasma (PRP) has been increasing sharply in the last two decades. Its role as a potential regenerative agent and ease of application have allowed it to take huge share in the fast-evolving biological therapy field. The reported effect of PRP on a range of tissue types including bone, cartilage, tendon and muscle has attracted clinical interest in fields such as trauma, orthopaedic, maxillofacial and plastic surgery where effective healing of tissues is critical for successful outcome. The results of in vitro and animal studies that largely report positive effects of PRP on cellular and matrix regeneration have been the main drive for its translation to clinical settings. Despite the lack of appropriately powered trials, PRP administration remains an attractive strategy given its cost-effective, minimally invasive nature and the autologous nature of PRP. In this chapter, the current literature on the use of PRP in regenerative medicine is reviewed highlighting both some of the controversy surrounding this approach and some emerging clinical applications. A new PRP classification system is presented to allow better description of the variable clinical PRP products and their correlated outcome.

Introduction

Platelets are increasingly recognised to play important roles in physiology beyond promotion of haemostasis and thrombosis. Platelet-rich plasma (PRP), an autologous derivative of whole blood that contains a supraphysiological concentration of platelets, has gained increasing attention in both the scientific literature and the wider media for its potential application as a regenerative adjunct therapy (Alsousou et al. 2009; Engebretsen et al. 2010). The regenerative effect of PRP exerted by producing a local environment for tissue regeneration which is rich in growth factors and other cytokines has been supported by in vitro and animal studies that suggest a positive influence on the migration and proliferation of a number of cell types. Furthermore, the full array of potential bioactive growth factors and chemokines released upon platelet activation is becoming well defined (Coppinger et al. 2004; Nurden 2011). These include transforming growth factor (TGF-ß1 and TGF-ß2), platelet-derived growth factor (PDGF-AA, PDGF-AB and PDGF-BB), vascular endothelial growth factor (VEGFs A and C), insulin growth factor (IGF-1) and epidermal growth factor (EGF). These factors can promote local angiogenesis, stem cell homing and local cell migration, proliferation and differentiation, coupled with the deposition of matrix proteins such as collagen which all play a key role in enabling the restoration of normal tissue structure and function (Coppinger et al. 2004; Nurden 2011).

The reported clinical use of PRP is largely confined to the last two decades and initially centred on its application in dental and maxillofacial surgery (Gibble and Ness 1990; Sanchez et al. 2003). More recently, regenerative effects of

PRP in a range of tissue types including bone, cartilage, tendon and muscle have attracted interest in fields such as orthopaedic and plastic surgery where effective restoration of sometimes poorly vascularised and damaged tissue is a critical determinant of successful clinical outcome (Alsousou et al. 2013; Gentile and Cervelli 2010). Despite the lack of appropriately powered trials, PRP administration remains an attractive strategy given its cost-effective, minimally invasive nature and the autologous nature of PRP. The latter eliminates concerns about the potential for disease transmission or immunological reactions. In this chapter, the current literature on the use of PRP in regenerative medicine is reviewed highlighting both some of the controversy surrounding this approach and some emerging clinical applications.

PRP Definition

Platelet-rich plasma (PRP), which is also known as platelet-enriched plasma (PeRP), platelet-rich concentrate (PRC), platelet concentrate, leucocyte-rich PRP (L-PRP), platelet-rich fibrin (PRF), platelet rich in growth factors (PRGF), platelet-rich fibrin matrix (PRFM), autologous concentrated plasma (ACP), platelet gel or platelet releasate, may be defined as a volume of the plasma fraction of autologous blood having a platelet concentration above baseline (Marx et al. 1998). A high concentration of (1,407,640 ± 320,100/μl) of platelets in plasma has been suggested to be a working definition of PRP (Weibrich et al. 2002). Although platelet-rich plasma refers to autologous preparations, the preparation of allogeneic PRP (aPRP) might not be excluded. The use of aPRP may serve as an alternative option in the case of patients who refuse to be subjected to a blood drawing procedure or have contraindications to autologous PRP (Dragica et al. 2007).

In clinical practice, there are a large number of PRP products obtained using different preparation methods. Although they are all labelled as PRP; the content, purity and hence the biological properties of those products all vary widely and could impact upon their potential efficacy. This is causing confusion among clinicians and scientists when it comes to reporting the clinical outcome of PRP applications. Several clinical trials have been conducted without clear quantification of the used PRP biological properties, which may differ significantly leading to varying outcomes. Table 1 shows a list of PRP preparation devices and the related product content. In this chapter, we will describe recently suggested classifications and then suggest a new system to classify PRP based on its biological components.

Cellular Components of PRP

PRP regenerative properties are based on the production and release of bioactive proteins including multiple growth and differentiation factors, following platelet activation. However, the role of other cells that may exist in PRP such as leucocytes and erythrocytes is still under investigation (Alsousou et al. 2010). The presence of leucocytes has a great impact on the biology of these products, not only because of their immune and antibacterial properties but also because they are key players in tissue healing and local factor regulation.

Most PRP products have varying concentrations of blood cells (platelets, leucocytes and erythrocytes) and cell-derived microvesicles, and many of them also have high concentrations of leucocytes. The direct cellular interaction between platelets, leucocytes and target tissues is still largely unknown (Bielecki et al. 2012). Polymorphonuclear leucocyte (PMN) and monocyte adhesion to activated platelets is important for the recruitment of PMN and monocytes at sites of tissue damage. The binding of activated platelets to PMN/monocytes involves P-selectin and the activated β_2-integrin CD11b/CD18 that not only results in transactivation but may cause significant changes in patterns of gene expression to trigger inflammation, e.g. tissue factor expression on monocytes. The effect of PRP components on cells and tissues is a complex process that involves growth factors and cytokines produced by both platelets and leucocytes. In addition, there may be direct cellular interactions that also regulate the intracellular signalling pathways in the resident tissue cells (e.g. ERK and AkT pathways for proliferation) (Franklin et al. 2012).

Bioactive Proteins and Growth Factors in PRP

Researchers have identified hundreds of potentially bioactive proteins either inside platelets or on the plasma membrane (Nurden 2011). The most commonly studied platelet proteins include PDGF, TGF-β, PDEGF, VEGF, IGF-1, FGF and EGF and some cytokines including proteins such as platelet factor 4 (PF4) and CD40L. Chemokines and newly synthesised metabolites are also released during platelet activation. PRP also facilitates the application of autologous plasma along with platelet-derived proteins. In addition, it promotes the development of a fibrin scaffold at the desired location that can act as a temporary matrix for cell growth and differentiation to assist repair in the injured tissue. Studying the role of those bioactive factors is essential to understand the biological activities of PRP.

Table 1 List of PRP preparation devices and their PRP products

Technology	Device name	Product name	Concentration increase[a]	Platelet recovery (%)	Product content
Floating buoy or shelf	Biomet GPS™	PCP	3.2×	70 %	Manual collection of buffy coat which contains platelets, WBC and minimal amount of RBC
	Harvest® SmartPRep2 BMAC™ Depuy Symphony II 3i PCCS	PRP	4.6× 4.0× 4.0×	65–72 %	
Cell saver-based systems	Electa, Haemonetics, CATS, BRAT	PRP	4–6×	75 %	Platelet concentrate only with plasma. No WBC or RBC contamination
Computer-aided system	Sorin Angel	PRP	4.3×	70 %	Automated buffy coat collection, which contains concentrated platelets, WBC fractions and minimal amount of RBC
	Arteriocyte Medical (Magellan™)	PRP	5.1×	76 %	
Standard centrifugation	AutoloGel System SmartPReP	PRP PReP	1–2×	78 %	Platelets in plasma suspension with minimum white cells and low concentration of platelets
	Cascade PRFM Fibrinet system	PRFM	1–2×	78 %	Platelet-rich fibrin membrane
	Choukroun's PRF	PRF	1–2×	70 %	Leucocyte- and platelet-rich fibrin
Direct siphoning	GenesisCS	PRP	6×	68 %	concentrate of platelets and leucocytes through siphoning device
Direct aspiration	Secquire Arthrex ACP	PRP	1.6×	31 %	Manual aspiration of platelet and plasma after centrifuging
Platelet separation	Vivostat	PRF FS	6×	65 %	Platelet-rich fibrin Fibrin sealant without platelet
Platelet filtration	Caption Advanced Tissue Regeneration (ART)-Curasan Set	PC	4.3×	–	Concentrated platelets without plasma

ACP autologous concentrated plasma, *PCP* platelet concentrated plasma, *PRF* platelet-rich fibrin, *PRFM* platelet-rich fibrin matrix, *PRGF* plasma rich in growth factors, *PRP* platelet-rich plasma, *RBC* red blood cells, *WBC* white blood cells

[a]Increase above baseline is based on a collection volume of 50–60 ml whole blood with a single pass (except for the cell saver device that uses 450 ml) (Alsousou 2014)

PRP Preparation

Preparation Methods

Autologous PRP can be prepared in a laboratory or an operating theatre or clinic room from anticoagulated blood collected in the immediate pre-therapeutic period. There are several choices of anticoagulants that can be used for blood collection. Trisodium citrate solution is the most widely used anticoagulant (citrate is a weak chelator of calcium that inhibits coagulation and platelet function) with few negative effects on PRP preparation (Alsousou et al. 2009). ACD (acid citrate dextrose) and CPD (citrate phosphate dextrose), with and without adenine (ACD-A and CPD-A), are also effective anticoagulants. The use of ethylenediaminetetraacetic acid (EDTA) is potentially more harmful in the preparation of PRP, and a large number of damaged/activated platelets have been observed during preparation with this material. Therefore it is not usually recommended for PRP preparation.

Traditionally, a relatively pure preparation and good yield of PRP can be easily obtained in a single step by low g centrifugation (170–200 g) of anticoagulated blood for 10 min at room temperature (Harrison et al. 2011a). A consensus of the working party from the Platelet Physiology Subcommittee of the Scientific and Standardisation Committee (SSC) at the International Society on Thrombosis and Haemostasis (ISTH) provides a g value recommendation for platelet preparation (Cattaneo et al. 2013).

For clinical applications there is no such standardisation, and there are three essential main methods available which can rapidly provide a sterile product suitable for clinical application: the (1) gravitational platelet sequestration (GPS) or centrifugation technique, (2) standard cell separators and (3) autologous selective filtration technology (plateletpheresis).

In the GPS method, three layers become evident: the bottom layer comprised of red blood cells (specific gravity = 1.09), the middle layer comprised of platelets and white blood cells (buffy coat, specific gravity = 1.06) and the top plasma layer (specific gravity = 1.03). Various methods to

collect the platelet layer have been developed, but with varying degrees of red and leucocyte contamination (Table 1). Platelet concentration, yield and recovery are also dependent on the centrifugation protocol and collection method (Kevy and Jacobson 2004). One study evaluated the effect of different centrifugal forces and showed that centrifugation at greater than 800 g may actually decrease the amount of releasable TGF-β from the PRP (Landesberg and Glickman 2000).

Standard cell separators and salvage devices generally operate on a full unit of blood. In general, they use continuous flow centrifuge bowls or continuous flow disc separation technology coupled with hard and soft centrifugation steps. Weibrich et al. described a discontinuous technique with a cell separator that produces a fivefold increase in platelet count (Weibrich et al. 2002). The red blood cells and some, or all, of the platelet-poor plasma (PPP) can also be returned to the patient to maintain circulating volume.

Selective filtration technology or plateletpheresis depends on a single-use proprietary filter designed to concentrate platelets from whole blood. The platelets are captured on the filter and are then harvested to provide a platelet-rich concentrate (PRC). Although this technique reduces platelet lysis, which may be induced during centrifugation, platelet fragmentation and activation have also been shown to occur within filtration-based systems (Schoendorfer et al. 1990; Kevy and Jacobson 2004).

In general, most systems do not concentrate the plasma proteins of the coagulation cascade (Kevy and Jacobson 2004). Plasma protein concentrations above baseline can be achieved through secondary ultrafiltration. The autologous growth factor filter (AGF) is a microporous, hollow, cellulose fibre filtration device with a volume of 8 ml and uses PRP as a baseline product. The device filters water after multiple passes of PRP through the filtration device. As much as two-thirds of the aqueous phase is removed by filtration, thus increasing the concentrations of the retained plasma proteins and formed elements (Everts et al. 2006). Evidently each preparation technique will also result in significant differences in yields, concentration, purity, viability and activation status of the isolated platelets. Each of these variables will therefore not only influence the eventual concentrations of the bioactive proteins released from the platelet granules but also affect the eventual clinical efficacy of each PRP preparation (Whitman et al. 1997).

Handling and Activation of PRP

Once the PRP is prepared, it is claimed that it is stable for clinical use, in the anticoagulated state, for 8 h or longer (Marx et al. 1998). Some authors advocate using PRP within no longer than 6 h if it is kept at room temperature (Ho and Chan 1995). However, Sweeney et al. (2006) suggested using a specific method, which included adding low-pH glucose-containing additive solution with $NaHCO_3$ to platelets within ELX bags, to try and keep PRP viable for up to 7 days by lowering the pH to allow sterilisation and provide energy to maintain platelet viability.

PRP must also be activated for the platelets to release their α-granule contents, with the clot providing a vehicle to capture the secreted proteins and maintain their presence at the application site. Activation with bovine thrombin is no longer recommended as this was reported to cause coagulopathy resulting from cross reactivity of anti-bovine factor V antibodies with human factor V (Cmolik et al. 1993; Landesberg et al. 1998). Calcium chloride is therefore a much safer, but slower, alternative and without any risk of prion or pathogen exposure. Platelet activation via this method takes at least 20 min (Anitua et al. 2004). Recently, autologous thrombin preparation kits have been introduced as a safe and faster activation alternative (Man et al. 2001). Furthermore, injecting inactive PRP into collagen rich tissues may also result in direct platelet activation resulting in degranulation (Fufa et al. 2008; Harrison et al. 2011b). Harrison et al. found that thrombin-activated platelets lead to immediate release of TGF-β1 and PDGF-AB, while the collagen-activated PRP clots resulted in 80 % greater cumulative release of TGF-β1, VEGF and PDGF than thrombin over 7 days (Harrison et al. 2011b).

In Vitro and Animal Studies of PRP

Cell and Tissue Culture Studies

PRP influences the migration, proliferation and differentiation of a number of cell types, although the temporal features and molecular basis of this effect remain unclear. Castelnovo et al. (2000) demonstrated an 80-fold enhancement of porcine retinal cell migration 48 h after the application of human platelet suspension, and PRP has been shown to promote the recruitment of circulation-derived cells for tendon healing in vivo (Kajikawa et al. 2008). PRP can also have a mitogenic effect on endothelial cells (Bertrand-Duchesne et al. 2010), bone (Bertoldi et al. 2009), cartilage (Akeda et al. 2006; Ishida et al. 2007), periodontal ligaments (Pantou et al. 2010) and mesenchymal and dental stem cells (Feng et al. 2010; Huang and Wang 2010). However, there are conflicting reports concerning the effects of PRP on cell differentiation. While several studies indicate a positive influence (Bertoldi et al. 2009; Huang and Wang 2010; Lee et al. 2011; Lucarelli et al. 2005), PRP has been shown to inhibit the osteogenic differentiation of bone marrow-derived pre-osteoblasts in a dose-dependent manner (Arpornmaeklong et al. 2004) and has an inhibitory effect

on mesenchymal stem cell differentiation when applied in isolation, but a stimulatory effect with 1,25(OH)2vitamin D3 co-treatment (Feng et al. 2010).

The effect of PRP on cellular activity appears to be highly time and dose dependent. Soffer et al. (2004) showed that while short-term exposure to human platelet lysate (<24 h) promotes bone cell proliferation and chemotaxis, long-term exposure results in decreased levels of alkaline phosphatase and mineral formation. Other studies indicate that PRP stimulates the growth of bone marrow cells for 4–8 days (Van Den Dolder et al. 2006) and that, beyond 6 days, washed platelet solution has a stronger influence on mesenchymal cell proliferation than PRP (Duan et al. 2011). The concentration of PRP also appears to be critical in determining its effect. Some authors suggest that high concentrations adversely affect fibroblast cell viability and proliferation (Choi et al. 2005; Creeper et al. 2009). Cheng et al. demonstrated the significance of both the platelet and plasma protein constituents of PRP as these fail to significantly enhance gene expression of collagen types 1 and 3 in cultured ligament cells when applied in isolation, but do succeed when in combination (Cheng et al. 2010).

Several studies have confirmed the ability of PRP to induce local gene expression. The growth factors TGF-β1 and PDGF appear to play an important role in tendon and ligament regeneration by promoting expression of proteins including collagen and cartilage oligomeric matrix protein (Cheng et al. 2010; Lyras et al. 2010c; Schnabel et al. 2007). Histologically, PRP has been shown to promote gross ligamentisation of tendons (Sanchez et al. 2010) and increase the maximum breaking strength and stiffness of healing tendons in vitro when used with a bone marrow-derived stromal cell-seeded graft (Morizaki et al. 2010). Activation of the Nrf2-antioxidant response element pathway has been implicated in the increase in tenocyte growth due to addition of platelet-released growth factor (Tohidnezhad et al. 2011). Further, Lyras et al. (2010b, 2011) showed that a single application of PRP to the Achilles and patellar tendon defects significantly enhances IGF-1 protein expression and is associated with a faster healing process confirmed by histology (thicker tendons with organised fibre structure). Anitua et al. demonstrated that PRP application results in increased expression and production of VEGF and HGF in cultured tenocytes (Anitua et al. 2005). Other in vitro studies confirmed that the ability of PRP to promote angiogenesis, which is crucial in acute tissue injury repair, may be an important reason for its regenerative effects (De Mos et al. 2008; Lyras et al. 2010a; Lyras et al. 2009).

It is unclear whether the mitogenic effects of PRP are dependent upon the presence of intact platelets or not. Lysed solutions have been shown to have a positive effect on osteogenic activity (Slater et al. 1995) and bone marrow stem cells (Oprea et al. 2003), but other studies also suggest that unviable or damaged platelets after processing may have impaired growth factor secretion (Marx 2001, 2004).

In Vivo Animal Studies

PRP has been shown to promote bone regeneration in rat and rabbit calvarial defects (Mariano et al. 2010), the alveolar sockets of *Cebus apella* monkeys (Pessoa et al. 2009) and porcine tibial metaphyseal defects (Jungbluth et al. 2010), as well as promote the incorporation of mandibular bone grafts in goats (Fennis et al. 2002). However, other studies suggest that PRP has no effect on bone healing and may actually be detrimental when used as a supplement to bone grafts. In a study looking at craniofacial bone repair in rabbits, PRP-treated grafts were associated with diffuse fibrous tissue deposition that inhibited bone formation when compared with untreated grafts (Giovanini et al. 2011). Broggini et al. also showed that PRP alone, or when used in combination with autogenous bone, failed to promote remodelling in rabbit calvaria, whereas autogenous bone without PRP leads to accelerated remodelling (Broggini et al. 2011).

Transected rat Achilles tendons treated with PRP showed increased callous strength and stiffness by 30 % after 1 week (Aspenberg and Virchenko 2004). Similar effects were observed on lesioned equine superficial digital flexor tendons treated with PRP with significantly higher strength at failure, improved collagen network organisation and increased metabolic activity than saline-treated controls (Bosch et al. 2010). Other animal and in vitro studies have also suggested a key role for angiogenesis as a mechanism underlying the regenerative effects of PRP (Anitua et al. 2005; Bir et al. 2011; De Mos et al. 2008; Li et al. 2009; Lyras et al. 2010a). In a porcine model, Hadad et al. showed that adipose-derived stem cells and PRP significantly enhance healing of perfusion-depleted tissue when applied in combination, but not in isolation, lending support to the hypothesis that the growth factors contained in activated PRP have a permissive effect in enabling regeneration (Hadad et al. 2010).

Animal studies have also shown that PRP application improves left ventricular function following ischaemia reperfusion (Mishra et al. 2011), promotes fat graft survival (Nakamura et al. 2010) and enhances the repair of the cartilage (Milano et al. 2010), skin (Derossi et al. 2009), corneal epithelium (Tanidir et al. 2010), liver (Matsuo et al. 2011), intestine (Yamaguchi et al. 2012) and peripheral nerves (Yu et al. 2011).

Clinical Studies of PRP

Many clinical research studies are either predominantly case studies or limited case series. There have been several randomised trials (RCT) investigating the use of PRP, with a recent systematic review and meta-analysis identifying 23 trials in 13 conditions (Sheth et al. 2012). Pathologies studied include arthroplasty, spinal fusion and a range of tendon pathologies. The 2012 review used the GRADE evaluation method and concluded that the quality of evidence is very low. The authors concluded 'the current literature is complicated by a lack of standardization of study protocols, platelet separation techniques, and outcome measures'. However, despite this uncertainty about the evidence, there is increasing clinical use of PRP within clinical practice in many areas with sports medicine being the most popular.

Bone

There are few clinical studies examining the role of PRP in bone healing after orthopaedic trauma (Alsousou et al. 2009; Pietrzak and Eppley 2005). Most of the published studies are related to the use of PRP in oral and cranial surgery. Currently, it is not uncommon to combine the platelet-rich material with autograft, allograft, demineralised bone matrix or other graft material to fill bony defects in the mandible or cranium (Marx et al. 1998).

In small cohort studies, percutaneous injection of autologous platelet–leucocyte-rich gel has been shown to be an effective and less invasive alternative to bone marrow injection in the treatment of delayed bone union (Bielecki et al. 2012) to promote faster fusion in spinal surgery (Hartmann et al. 2010; Lowery et al. 1999) and healing of clavicle fracture nonunion (a single case) (Seijas et al. 2010).

In bony defects, PRP reduces the time taken for bone regeneration (Nagaveni et al. 2010; Rodrigues et al. 2011) and has been used to treat mandibular osteonecrosis resulting from radiotherapy (Scala et al. 2010) or the use of bisphosphonates (Curi et al. 2007). Cenni et al. recently provided a possible biological explanation for this through the demonstration that growth factor release from platelets is maintained within regions of osteonecrosis (Cenni et al. 2011). In one series, researchers were able to measure levels of PDGF and TGF-β in the fracture haematoma of 24 patients who had fresh fractures of the foot and ankle. However, the investigators were unable to detect these same proteins in the nonunion tissue of seven patients presenting with similar fractures. After PRP application of the nonunion during revision surgery, radiographic union was observed by an average of 8.5 weeks (Gandhi et al. 2005).

The use of PRP in maxillofacial surgery is well supported with recently published level 1 and 2 evidence (meta-analysis or randomised controlled trials). However, there is no level 1 or level 2 evidence showing any cortical bone benefits from PRP. There are just a few anecdotal reports on the effect on a mix of corticocancellous bone or a mixture of PRP and bone substitutes.

Wound Healing

As early as 1990, autologous human platelet-derived wound healing factors (HPDWHF) were proposed to regulate wound healing of recalcitrant skin ulcers by promoting the formation of granulation tissue in the early healing phase (Herouy et al. 2000). PRP and other platelet-rich products have been shown to promote healing in a range of cutaneous lesions (Crovetti et al. 2004; Lacci and Dardik 2010; O'connell et al. 2008) and have therefore attracted interest in fields such as plastic surgery where structured approaches to the use of PRP are beginning to emerge (Gentile and Cervelli 2010). In a randomised controlled trial, diabetic foot ulcers treated with PRP gel showed significantly reduced time to healing compared with controls (Driver et al. 2006). While there have been reports of negative results with the use of platelet-derived wound healing factors in ulceration, most notably in a trial by Krupski et al. (1991), more recent studies using autologous PRP have supported its beneficial role in chronic wound healing and provided evidence that it may actually reverse non-healing trends (Frykberg et al. 2010; Lacci and Dardik 2010).

Post-traumatically, PRP promotes ulcer healing (Cervelli et al. 2011a) and faster re-epithelialisation of lower extremity wounds with bone exposure (Cervelli et al. 2011b) and, in combination with hyaluronic acid, can act as an effective scaffold for cellular growth in covering exposed tendons in acute and chronic open wounds of the foot and ankle (Cervelli et al. 2010). In a 5-year study assessing the effect of applying platelet gel to patients presenting with traumatic loss of finger substance, Balbo et al. reported better aesthetic results and a shorter recovery time in the PRP-treated group (Balbo et al. 2010). However, although an early case report suggested that PRP promotes healing even in the presence of infection (Cieslik-Bielecka et al. 2009), recent randomised studies have shown that it fails to actually prevent infection if administered during inguinal surgery (Lawlor et al. 2011) or during wound closure following venous harvesting (Almdahl et al. 2011).

Marck et al. recently performed a systematic review of the use of PRP in burn injury (Marck et al. 2014). They concluded that the literature on the use of PRP in burns is scarce. Despite this growth factors have been shown to be beneficial, and both animal studies and case reports have

shown that PRP can improve healing times post burn injury. Deep dermal burns may also benefit from the pro-haemostatic effects, antimicrobial properties and well-known positive effects of platelets on wound healing. However, patients with large burns also have profound changes to their physiological state including changes in platelet counts observed post injury, and it is unknown how this may affect the quality of autologous platelet preparations (Marck et al. 2013). Also it is largely unknown how PRP may affect long-term scarring given that platelet growth factors such as TGF-β are implicated. Overall they concluded that further research is required to study the potential efficacy of PRP in burns. One of the obvious problems in burn injury is how to apply activated PRP gel evenly over a large surface area of injury while maintaining biological activity.

Use of PRP in Tendon Disorders

In pilot studies, PRP has been shown to reduce pain in patients with chronic tendinopathy (Gaweda et al. 2010; Kon et al. 2009), with a persisting effect for at least 2 years from the time of treatment despite normalisation of VEGF, EGF and CCL2 blood levels after 24 h (Volpi et al. 2010). More recently, in the 2-year follow-up of a double-blind randomised controlled trial comparing PRP with corticosteroid injection for the treatment of chronic lateral epicondylitis, Gosens et al. reported significantly increased function and reduced pain in the PRP-treated group compared to those treated with steroids (Gosens et al. 2011). The benefit of PRP as a second-line, surgery-sparing therapy in the treatment of elbow tendinopathy resistant to physical therapy has been further demonstrated in a prospective randomised trial reported earlier this year (Creaney et al. 2011). Creaney et al. study showed that injecting PRP in chronic tendinopathy reduced the need for surgery from 20 to 10 % when compared with autologous blood injection alone.

Despite the evidence that PRP may be effective in treating tendinopathy, there is also a growing body of evidence to the contrary. The most significant trial in this regard was a double-blind randomised controlled trial carried out by De Vos et al. which showed no difference in pain or function in patients with chronic Achilles tendinopathy treated with PRP compared with those treated with saline (De Vos et al. 2010b). A recent study identified no significant difference in the degree of neovascularisation or tendon structure (using colour Doppler ultrasonography and ultrasonic tissue characterisation) in patients with chronic Achilles tendinopathy treated with PRP compared with those receiving a saline placebo (De Vos et al. 2011). Another application of PRP that has gained significant attention is its use in anterior cruciate ligament (ACL) reconstruction using hamstring tendon grafting following traumatic injury. In a randomised, double-blind trial, Vogrin et al. used contrast-enhanced MRI to demonstrate that ACL grafts treated with platelet gel had a significantly higher level of vascularisation at the osteoligamentous interface 4–6 weeks postoperatively compared to control grafts (Vogrin et al. 2010b). PRP gel has also been shown to reduce the time taken for a homogenous appearance on MRI following ACL reconstruction by 48 % (Radice et al. 2010), although contrary to this Silva and Sampaio demonstrated a failure of PRP to affect the signal intensity of the fibrous interzone in femoral tunnels following grafting (Silva and Sampaio 2009). Functionally, the application of platelet gel to grafts has been shown to significantly improve anteroposterior knee stability following surgery (Vogrin et al. 2010a).

With regard to the use of PRP in treating rotator cuff tears, a pilot study of patients undergoing arthroscopic rotator cuff repair showed that intraoperative PRP administration was associated with significantly increased function and reduced pain at 6, 12 and 24 months postoperatively with no adverse events (Randelli et al. 2008). However, a recent randomised controlled trial demonstrated that platelet-rich fibrin matrix has no benefit in enhancing healing of small- and medium-sized rotator cuff tears (Castricini et al. 2011): as with tendinopathy, the consensus in the literature is that further trials are needed to determine whether neutral results regarding the benefit of platelet-rich mediums indicate a lack of benefit from having additional growth factors in certain healing environments or whether they reflect suboptimal preparation and administration techniques (Engebretsen et al. 2010; Hamilton et al. 2010). Two recent reviews conclude that the poor methodological quality of trials assessing the use of PRP in treating chronic tendinopathy means the evidence supporting its effectiveness is limited and thus insufficient to recommend its routine clinical use (De Vos et al. 2010a; Kampa and Connell 2010).

A thorough literature search of the application of PRP in Achilles tendon rupture in both animal and human studies was recently conducted. Nine studies present results for the use of platelets in Achilles tendon rupture treatment, seven from animal experiments and two from human trials (Sanchez et al. 2007; Schepull et al. 2011). Six of the animal studies used a rat model, and one used an ovine model. All animal studies, using biomechanical and histological assessments, are in agreement showing a beneficial effect of platelets. Only two human studies have tested the effect of platelets on the treatment of Achilles tendon rupture based on imaging techniques and clinical results. Sanchez et al. (2007) found positive effects in a group of 12 athletes treated with PRP-augmented suture repair at 32 months in a case–control study. In ultrasonographic assessment, there was less tendon thickening and higher concentrations of TFG-beta and other growth factors, and patients regained range of

motion faster and returned to sports (gentle running) earlier. In a randomised study of 30 patients, Schepull et al. (2011) found no effect of platelets on radioisometrical tendon contraction or clinical outcomes. Both of these underpowered clinical studies used PRP as an adjunct to open surgical repair, and this may have obscured any effect of PRP on healing.

There are three other studies that report on the use of platelets in human Achilles tendinopathy although the results of these trials have little bearing on Achilles tendon rupture, which has a very different pathology, regenerative properties and treatment pathways. Therefore there is only one underpowered randomised clinical trial that has assessed PRP in Achilles tendon rupture (Sanchez et al. 2007; Schepull et al. 2011), and the authors of that trial recognised a limitation in their platelet preparation technique and storage (of up to 20 h) resulted in only a 20 % release of growth factors from the platelets. In our own 20-patient pilot study, we achieved an average of 69 % growth factor content release after stimulation.

Recently published systematic reviews (Sadoghi et al. 2012; Taylor et al. 2011) have concluded that there are encouraging signs that PRP could be developed as an effective therapy. Sadoghi et al. (2012) concluded that there is evidence in support of a positive effect of platelet concentrates in the treatment of Achilles tendon ruptures in vivo in animal models and human application, consistent with a medium- to large-sized effect. This effect is most likely attributed to enhanced scar tissue maturation. In another systematic review, Taylor et al. (2011) concluded that PRP use in tendon and ligament injuries has several potential advantages, including faster recovery and, possibly, a reduction in recurrence, with no adverse reactions described. One ongoing randomised trial is studying the effect of PRP on ruptured Achilles tendon (Anonymous 2015); the PATH-2 trial will study the efficacy and mechanism of PRP in pragmatic settings which include clinical, histological and laboratory outcome measures, as well as measurement of platelet quality, purity and growth factor content (Anonymous 2015).

Potential Adverse Risks of PRP

PRP is prepared from autologous blood; therefore it is inherently safe, and any concerns of disease transmission such as HIV, hepatitis or Creutzfeldt–Jakob disease or immunogenic reactions that exist with allograft or xenograft preparations are eliminated (Alsousou et al. 2009). However, using bovine thrombin preparations, which contain bovine factor V to activate the platelets, may lead to immunogenic reactions. The systemic use of bovine thrombin in cardiovascular surgery to promote clotting has been reported to be associated with coagulopathies resulting from cross reactivity of anti-bovine factor V antibodies with human factor V (Cmolik et al. 1993; Landesberg et al. 1998). The bovine thrombin preparations used in those reported cases were high dose (>10,000 units) and were applied directly onto open wounds where absorption into systemic circulation is certain. There have been no similar reports since 1997 due to the use of highly purified bovine thrombin. Conversely, the very small dose of bovine thrombin (<200 units) used to activate PRP before application will be consumed during clot formation and digested by macrophages. Hence, bovine thrombin-activated PRP is unlikely to produce anti-factor V antibodies.

The use of bovine thrombin for activation is therefore now avoided in modern preparation techniques. Some authors proposed that PRP gel formation can be performed only with the addition of calcium chloride, but this usually takes longer to complete (Marlovits et al. 2004). An effective alternative is thrombin receptor agonist peptide (TRAP) that mimics the effect of thrombin on PAR-1 receptors. Most current techniques prefer to use autologous thrombin or calcium chloride to activate PRP.

To date, there is no compelling evidence of any systemic complications of local PRP injection. Furthermore, there are no scientific reports suggesting potential cause–effect relationships between growth factors present in PRP and an increased risk of carcinogenesis. This may be because of the limited need for PRP injections (as PRP is not chronically administered) and because of the short in vivo half-lives and local bioavailability of growth factors produced by PRP.

Clinical Trials

Based on the inconclusive results in the current literature, the authors cannot provide solid evidence in favour of the clinical application of PRP. However, because the majority of the reviewed clinical trials reported encouraging outcomes, further controlled clinical trials are warranted to elucidate where PRP should be used.

However, clinical trials should include a sufficient number of patients and a proper design (randomised controlled trials), including a test group similar to control, except for the application of PRP. Also, proper description of the PRP procurement techniques must be included, including the amount of blood collected, baseline number of platelets, yield, purity, quality and growth factor content of PRP obtained, contaminating cells, concentration factor of platelets above baseline, coagulation promoters, doses and mixing ratio to PRP.

Clinical Study Design

Given the rudimentary knowledge of the mechanism of action of PRP in clinical settings and the limitations of current studies, it is important that any future clinical trial should be carefully designed not only with adequate power to accurately determine the effect of PRP on any particular tendon disorder but also to use disease-specific outcome tools. This has been highlighted by several authors (De Vos et al. 2010a; Maffulli and Del Buono 2012), who have shown that the imprecision in effect size estimates from underpowered studies investigating the use of PRP has led to unsafe conclusions. A study powered to determine if there are clinically important effects while furthering the understanding of PRP mechanism in clinical settings would add significantly to our understanding of the appropriate clinically used PRP. In a consensus paper published recently (Engebretsen et al. 2010), a panel of experts listed important elements of clinical trials of PRP: (1) RCT design, (2) clear inclusion/exclusion criteria, (3) homogenous study population or stratification of variables, (4) standardised clinical assessment, (5) validated PRP production method and delivery, (6) robust outcome measures and (7) standardised post-treatment follow-up protocol.

Currently, we are only aware of one ongoing randomised clinical trial that includes all the above and is adequately powered to measure the efficacy of PRP in clinical settings; the PATH-2 trial has started recruiting patients with acute Achilles tendon rupture and is due to finish in 2018 (Anonymous 2015).

PRP Classification System

'Not all PRP is in fact PRP'

In the field of platelet concentrates, most products are termed PRP. Unfortunately, this term is very general and incomplete, leading to confusion in the scientific literature and misleading conclusions. Currently, there are more than 12 platelet concentrate products available commercially, and although they have varying preparation methods and components (Table 1), they are all labelled PRP.

Accurate use of the terminology to reflect the product properties is required in both clinical and scientific applications. The terminology must be simple, accurate and pragmatic. It also must avoid commercial interests and thus remain scientifically homogeneous (Dohan Ehrenfest et al. 2012). Clinically prepared PRP is in fact a term that includes a wide range of products that have varying biological components (Dohan Ehrenfest et al. 2009). Most of these products have varying concentrations of blood cells (platelets, leucocytes and erythrocytes) and microvesicles. Two authors have tried to classify PRP products according to their biological content, which are described below.

Dohan Ehrenfest et al. (2009) classified the different platelet concentrates into four categories, depending on their leucocyte and fibrin content: pure platelet-rich plasma (P-PRP), leucocyte- and platelet-rich plasma (L-PRP), pure platelet-rich fibrin (P-PRF) and leucocyte- and platelet-rich fibrin (L-PRF) (Table 2). Yet, Mishra et al. (Mishra et al. 2012) used the presence of leucocytes and the method of activation to classify PRP into four types (Table 3).

In addition to the aforementioned factors, platelets are very sensitive to in vitro manipulation and can be easily activated during preparation methods leading to the premature release of their bioactive contents before application to the targeted tissues (Alsousou et al. 2013, 2009; Harrison 2004). Therefore details of the preparation method and ultimate platelet quality (e.g. concentration, viability, activation status and growth factor content) may also be important to potentially stratify any clinical effects.

The authors of this chapter suggest a new classification system, which incorporates the above two classification systems and includes the preparation method technique. This new system will use a combination of numeric and alphabetical characters to identify the class of PRP product. In addition to the two identifiers in the Ehrenfest and Mishra classifications, leucocytes and fibrin, our proposed new system will also include further identifiers activation, platelet concentration and preparation method categories.

Table 2 Ehrenfest classification system of the main available PRP products (Dohan Ehrenfest et al. 2009)

PRP class	Leucocytes	Fibrin content
P-PRP	No	Low
L-PRP	Yes	Low
P-PRF	No	High
L-PRF	Yes	High

Table 3 Mishra classification is divided into four types (1–4) and two subtypes (A and B) (Mishra et al. 2012)

	White cells	Activation	Platelet concentration
Type 1	Increased	No activation	A >5× B <5×
Type 2	Increased	Activated	A >5× B <5×
Type 3	Minimal or no WBC	No activation	A >5× B <5×
Type 4	Minimal or no WBC	Activation	A >5× B <5×

Table 4 The modified PRP classification system. The subcategories of activation, platelet concentration and preparation technique are added after the main class (e.g. L-PRP IB1) (Alsousou 2014)

Class	Leucocytes	Fibrin	Activation	Platelet concentration	Preparation category
P-PRP	–	Low	I II	A B C	1 2 3
L-PRP	+	Low	I II	A B C	1 2 3
P-PRF	–	High	I II	A B C	1 2 3
L-PRF	+	High	I II	A B C	1 2 3

Activation is divided into two subcategories:

I for the use of activation
II for PRP application without activator

Unlike the Mishra classification, platelet concentrates are subdivided into three categories (A, B and C) based on the range of platelet counts in the samples. This is in line with evidence presented previously in this chapter (Weibrich et al. 2004), which states that the most effective platelet count range is 900–1700 $\times$ 10^3/μl. The three categories are:

A. Platelet count $<900 \times 10^3$ /μl
B. Platelet count 900–1700 $\times$ 10^3/μl
C. Platelet count $>1700 \times 10^3$/μl

Furthermore, the preparation methods are classified into three categories:

1. The gravitational platelet sequestration (GPS) technique
2. Standard cell separators
3. Autologous selective filtration technology (plateletpheresis)

This modified classification is presented in Table 4. For example, the PRP used in conducting our PATH-2 trials will be classified as L-PRP IB1, which indicates that this PRP is prepared using the GPS method, which contained leucocytes with a platelet count range of 900–1700, and denotes that the platelets have been activated before application.

Conclusion

The role of PRP in tissue regeneration and its clinical application are a fast-developing field. Although, the effect of PRP on cell lines and tissues has been studied both in vitro and in animal models, clinical applications are still lacking the level of evidence from purposely designed randomised controlled trials. Further controlled clinical trials to elucidate the effects of PRP in pragmatic settings are warranted that need to take into account the quality control of the various PRP preparations utilised to ensure that optimal relationship between the product and outcome is established. Further studies into the mechanism of PRP tissue regeneration may also help elucidate the optimum combination of bioactive factors required to achieve best clinical efficacy.

Take-Home Messages

- The regenerative effect of PRP exerted by producing a local environment for tissue regeneration which is rich in growth factors and other cytokines has been supported by in vitro and animal studies.
- The clinical application of autologous PRP in regenerative medicine has become very popular in many areas of medicine. Despite this, there is a lack of adequately powered trials to provide solid evidence for its clinical use.
- Clinical preparations of PRP are heterogeneous and are often poorly standardised and defined.
- Future trials should be adequately powered to include a sufficient number of patients and controls and include a full description of the PRP preparation methodology utilised as well as the yield, purity, quality and growth factor content of the PRP used.
- We present a new classification system of PRP taking into account the actual content (e.g. with leucocytes and fibrin), the activation methodology, the platelet concentration obtained and the preparation method used.
- Further clinical trials in this area are warranted taking into account the quality of the various PRP preparations utilised to enable a link between sample quality and clinical outcomes, which is also to be established.

Therapeutic Use of Thrombopoietin Receptor Agonists

Michael D. Tarantino and Sarah Chalmers

Abstract

Discoveries throughout the twentieth century have forged our understanding of platelet production and including the variables involved in regulating the growth and maturation of megakaryocytes (Kuter, Br J Haematol 165:248–58, 2014). Thrombopoietin (TPO) is the premier growth factor involved in platelet production. It was first discovered in the early 1990s. TPO binds to the thrombopoietin receptor (TPOr, also termed c-mpl) on platelets, megakaryocytes, and pluripotent stem cells leading to inhibition of apoptosis of stem cells and megakaryocytes; increased megakaryocyte number, size, and ploidy; increased rate of megakaryocyte maturation and platelet count; and decreased platelet threshold for activation by ADP and collagen. Since the discovery of TPO, several TPO or TPO mimetic medications have been developed. Initially, two recombinant human thrombopoietins were developed; however, production was stopped following the discovery of autoantibodies in healthy platelet donors to both the drug and endogenous TPO after trialing the medication. Since then nonrecombinant peptide and non-peptide thrombopoietin receptor agonists (TRAs) have passed several trials in various thrombocytopenia-related disease processes including cirrhosis and/or chronic hepatitis C infection, aplastic anemia, chemotherapy-induced thrombocytopenia (CIT), Wiskott-Aldrich syndrome (WAS), MYH-9 disorders, and, primarily, immune thrombocytopenia (ITP). This chapter will highlight the therapeutic uses of TRAs in thrombocytopenic disorders.

Thrombopoietin

Thrombopoietin is the primary regulator of thrombopoiesis. Throughout the twentieth century, several discoveries lead to the isolation of TPO and the understanding of its role in thrombopoiesis. Megakaryocytes were discovered as the platelet-producing cells in the bone marrow by Wright in 1906 (Wright 1906). In 1958, Professor Endre Kelemen first introduced the concept of TPO as a regulatory factor in thrombopoiesis (Kelemen et al. 1958). Kelemen confirmed his conclusion when he demonstrated a rise in platelet count after injection of sera from patients with myeloproliferative disease into thrombocytopenic mice and humans (Kelemen et al. 1963). Following these discoveries, it would be more than 30 years until TPO was isolated.

In 1994, several research groups simultaneously published results on the successful purification of TPO (Sohma et al. 1994; Lok et al. 1994; Kaushansky 1994; Kato et al. 1995; Bartley et al. 1994; Kuter et al. 1994). Following its purification, the discovery of thrombopoietin as the primary regulator of thrombopoiesis was demonstrated in TPOr or TPO gene knockout mice. The recipient mice had a profound decrease in platelet production and subsequently a precipitous drop in platelet count, proving that TPO stimulates thrombopoiesis (Alexander et al. 1996; Gurney et al. 1994; De Sauvage et al.

1996). TPO is a 353 amino acid precursor protein possibly produced in several organs but predominately in the liver parenchyma. It has two distinct domains separated by a potential cleavage site. The N-terminal region contains the receptor-binding domain and consists of a four-helix structure with 23 % amino acid homology to erythropoietin (EPO). The C-terminus serves to prolong the half-life of the molecule as well as act as a molecular chaperone in the folding of the four-helix structure (Kaushansky 2015).

The TPOr is a dimeric transmembrane receptor found on pluripotent stem cells, immature cells from all cell lines, mature megakaryocytes, and platelets. The binding of TPO to TPOr activates various signal transduction pathways including JAK, STAT, and MAP kinase. The effects of this activation lead to inhibition of hematopoietic stem cells (HSCs) and megakaryocyte apoptosis; HSC differentiation; megakaryocyte maturation; increased megakaryocyte ploidy, number, and size; lower threshold for platelet activation; and involution of the TPO-TPOr complex (Kuter et al. 1994; Li et al. 1999; Zauli et al. 1997).

Early Production of Thrombopoietin Receptor Agonists

Thrombopoietin receptor agonists (TRAs) were first developed in the 1990s. Two recombinant TRAs were initially trialed. One was a recombinant full-length human thrombopoietin (rhTPO) analogous to endogenous TPO. The other was a truncated version of TPO consisting of an analogue of the binding domain of TPO attached to a polyethylene glycol molecule and termed polyethylene glycol (PEG)-ylated-recombinant human megakaryocyte growth and development factor. They were initially trialed for the treatment of chemotherapy-induced thrombocytopenia, myelodysplastic syndrome (MDS), and immune thrombocytopenia with good success (Basser 1996). However, when studied for the use of increasing platelet yields in healthy autologous platelet donors, a small portion of the study group developed neutralizing antibodies to the recombinant TPO as well as endogenous TPO (Li 2001). Production of both recombinant TRAs was discontinued. All study participants eventually recovered. Around the same time, two nonhomologous TRAs, later dubbed "the second-generation" TRAs, were in development.

Second-Generation Thrombopoietin Receptor Agonists (TRAs)

Romiplostim

Romiplostim (Nplate®; Amgen Corporation, California, USA) is a weekly administered parenteral TRA composed of a peptide pair inserted into the arm of an immunoglobulin G heavy-chain molecule. It has no sequence homology to endogenous TPO and therefore is predicted to impart a low risk of cross-reactive neutralizing antibodies. The molecular profile of romiplostim is shown in Table 1. Similar to other IgG fusion molecules, romiplostim binds to the FcRn receptor on endothelial and other cells expressing FcRn and is recycled back into the circulation, producing a circulatory half-life of some 120–140 h (Wang et al. 2004). Romiplostim binds to the extracellular domain of the TPOr, stimulating megakaryocyte growth and platelet production, and lowers the platelet activation threshold (Broudy 2004; Cwirla 1997; Gardiner 2010) (see Fig. 1). Romiplostim is a competitive agonist with endogenous TPO but has not been shown to impair the proliferation response to endogenous TPO. Romiplostim may stimulate alternative pathways leading to an enhanced effect of endogenous TPO in conjunction with romiplostim (Broudy 2004). Romiplostim increases platelet count in a dose-dependent fashion (Bussel et al. 2006). The median peak concentration is achieved in 14 h after a single subcutaneous dose, although the serum concentration is highly variable between patients and does not appear to correlate with dose. The biological half-life of romiplostim is 1–34 days with a median of 3.5 days. The recommended starting dose is 1 mcg/kg actual body weight, given subcutaneously, with dose titration in increments of 1 mcg/kg weekly until a

Table 1 Molecular characteristics of the TRAs

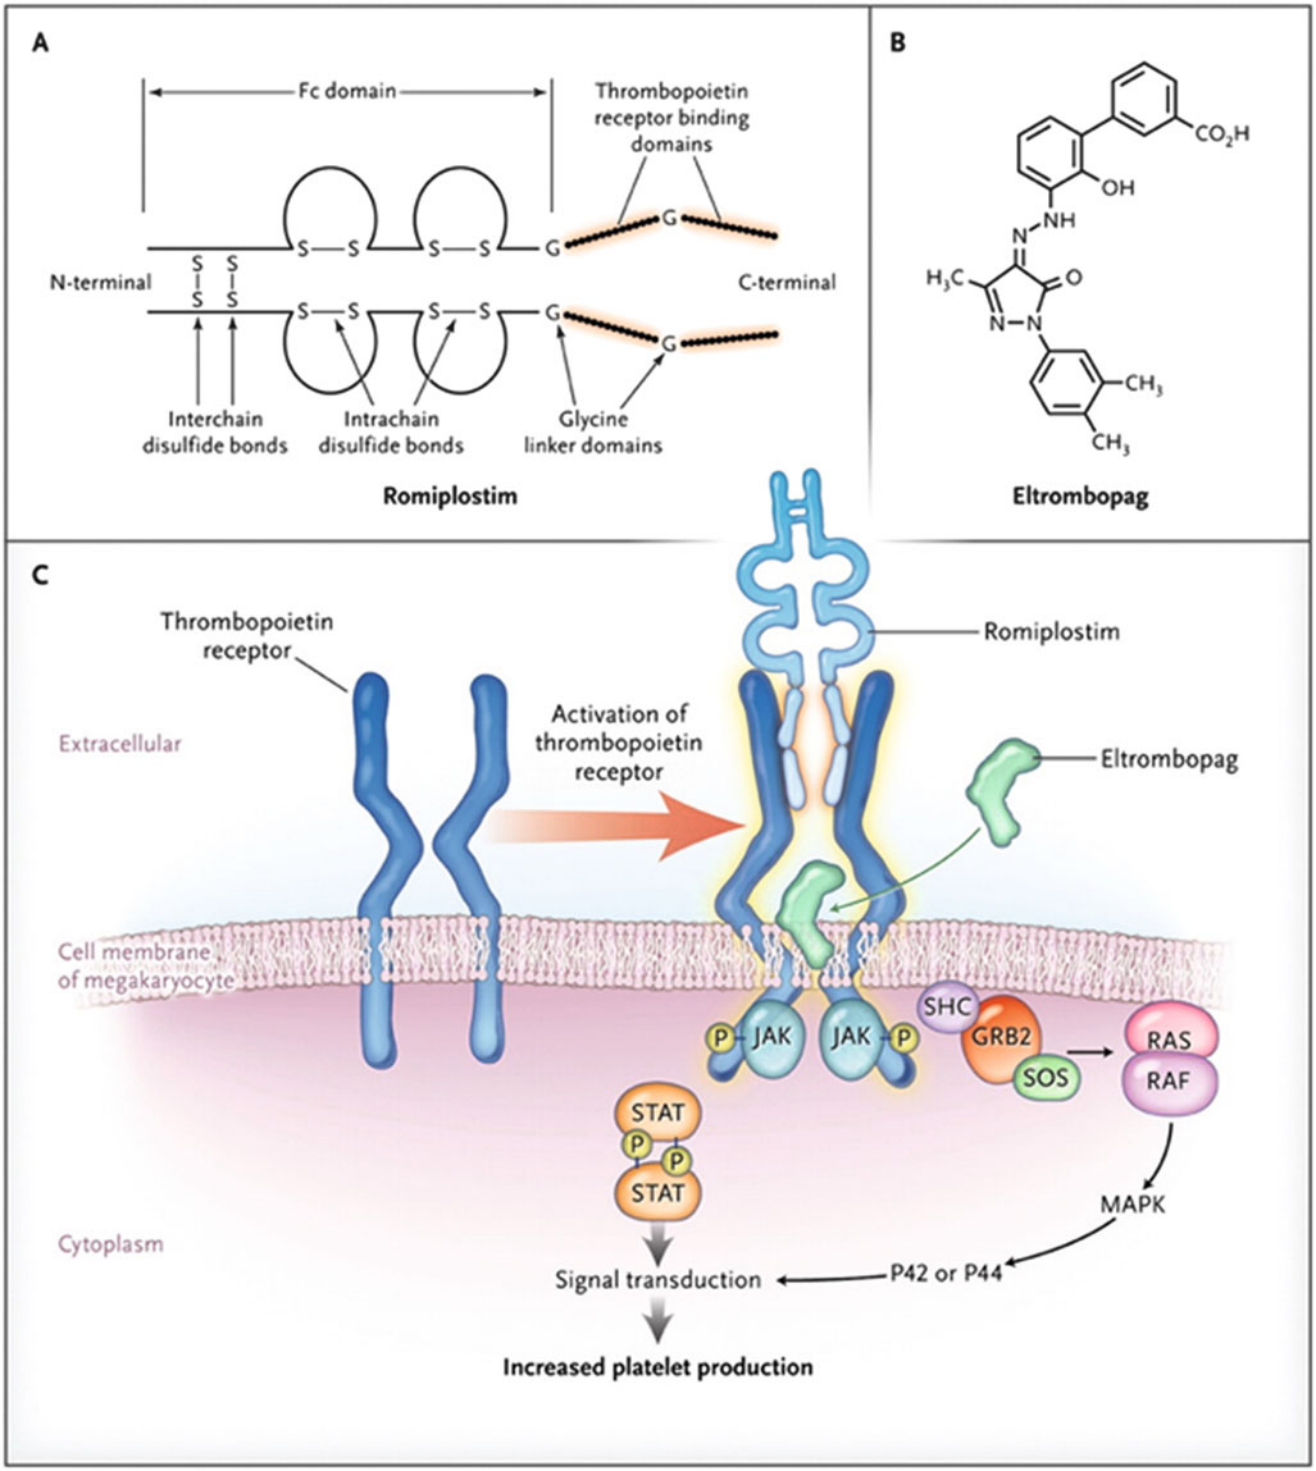

Fig. 1 Schematic of the molecular structure of (**a**) romiplostim and (**b**) eltrombopag. The binding sites on TPOr for romiplostim, to the extracellular domain, and eltrombopag, to the transmembrane domain, are shown in (**c**). From Imbach P, Crowther M. (2011) Thrombopoietin-receptor agonists for primary immune thrombocytopenia. N Engl J Med 365:734–41. Copyright © (2011) Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society

platelet count $>50 \times 10^9$/L is achieved or until maximum dose of 10 mcg/kg is reached. It has been suggested that the initial starting dose of 1 mcg/kg may be inadequate leading to poor initial response and delay in effective dose. In particular, the initial dose may be too low for patients with more severe refractory disease and some advocate for a higher initial starting dose in this patient population (Mitchell and Bussel 2015). Discontinuation is recommended if the platelet count does not exceed $>50 \times 10^9$/L after 4 weeks of treatment with maximum dosing at 10 mcg/kg/week. Weekly monitoring of platelet count is recommended until the platelet count remains stable for at least four weeks, with monthly monitoring thereafter. No drug interactions have been identified, and romiplostim is safe to use in combination with other thrombocytopenia treatment regimens such as corticosteroids or immune globulin.

Eltrombopag

Eltrombopag (Promacta®, Revolade®; Novartis, Malmo, Sweden) is an oral synthetic non-peptide small molecule TRA. It binds to the transmembrane domain of the TPOr at residue 499 leading to differentiation of hematopoietic stem cells into megakaryocyte progenitor cells, stimulates the growth of megakaryocytes, and hence increases the platelet count (see Fig. 1). The molecular profile of eltrombopag is shown in Table 1. In vitro studies have also demonstrated stimulation of multi-lineage hematopoiesis (Erickson-Miller et al. 2005, 2009). The binding site of eltrombopag differs from the binding site of endogenous TPO, therefore potentially allowing for an additive or synergistic effect (Erickson-Miller et al. 2009). Eltrombopag has several unique features, different from recombinant TPOs. It binds to the TPO receptor in the transmembrane domain. Its smaller molecular size theoretically reduces the risk of immunogenicity and allows for oral administration. It has species specificity and is only effective in species with a histidine at the 499 residue of the TPOr (humans and chimpanzees only) (Erickson-Miller et al. 2009; Sellers et al. 2004). Eltrombopag reaches peak concentration in 2–6 h after oral administration and has an oral absorption rate of approximately 52 %. The half-life of eltrombopag is 21–32 h. Greater than 99 % is bound by human plasma proteins. Eltrombopag is metabolized in the liver via CYP1A2, CYP2C8, and UDP-glucoronyltransferase1A1 and 1A3. Eltrombopag and its metabolites have an inhibitory effect on several enzymes of metabolism, specifically OATP1B1 and BRCP, leading to drug-drug interactions with many commonly used medications such as statins, antihyperglycemic agents, angiotensin receptor blockers, imatinib, and methotrexate. It has also been shown to be a chelating agent, and it is therefore recommended that it be taken 4 h before or after ingestion of foods or medications (such as antacids) high in calcium or polyvalent cations. On average, the platelet count increases in the first 1–2 weeks. While eltrombopag has been shown to increase platelet count, it does not appear to have an effect on platelet function (Haselboeck 2013).

The recommended starting dose is 25–50 mg (dependent upon underlying disease state causing the thrombocytopenia) by mouth per day, and the maximum recommended dose is 75 mg/day in patients with thrombocytopenia secondary to chronic ITP, 100 mg/day in patients receiving treatment for thrombocytopenia related to hepatitis C, and 150 mg/day in patients receiving treatment for severe refractory aplastic anemia (Table 2). After initiating eltrombopag, the dose can be increased by 25–50 mg every 2 weeks and titrated to a goal platelet count of $>50 \times 10^9$/L (Jenkins et al. 2007). Lower initial doses are recommended in patients of East Asian descent (due to a 33 % lower clearance rate) and those with hepatic failure (Katsutani et al. 2013). Weekly monitoring of the platelet count is recommended until platelet count has remained stable for at least 4 weeks and then monthly thereafter. In addition, a baseline complete metabolic panel (CMP) including liver function studies should be obtained prior to initiation of treatment and weekly until the platelet count has remained stable for at least 4 weeks. Serum bilirubin as well as alanine aminotransferase concentrations should be closely monitored. Liver function should be assessed by monthly CMPs thereafter.

Table 2 Administration and dosing of the TRAs

Name	Manufacturer	Route of administration	Approved starting dose
Romiplostim[a]	Amgen	Subcutaneous	1 mcg/kg
Eltrombopag[b]	Novartis	Oral	50 mg[c]

TRAs as a Treatment for Immune Thrombocytopenia

Primary immune thrombocytopenia (ITP) is an autoimmune disorder that leads to peripheral destruction, as well as a decreased production of platelets. In ITP, there are a normal or increased number of megakaryocytes and an increase in cell cycling of platelet progenitor cells. However, the platelet turnover is inappropriately normal or decreased suggesting that the effect of the autoantibodies is toward the end of the thrombopoietic cycle (McMillan et al. 1978; Ballem et al. 1987). In children, most often, the disease is self-limited and resolves within 6 months. Often, "watchful waiting" is the chosen treatment in this population though significant bleeding can occur and certainly warrants drug treatment. In adults, ITP is more often a chronic illness and treatment is usually required for platelet count $<30 \times 10^9$/L. Serum concentrations of TPO levels are normal to slightly low in ITP, likely due to removal of platelet-bound TPO as the platelet is cleared in the reticuloendothelial system (Kuter et al. 1994).

The most extensive clinical research in TRAs has been in the treatment of chronic ITP. Both TRAs have demonstrated overall response rates at or above 80 % of study participants (Kuter et al. 2008; Bussel et al. 2007). Response rates have been at least equal to treatment with first-line therapy, and some studies suggest that the response rate is higher (Zeng 2011). Based on placebo-controlled trials, but not head-to-head comparison trials, efficacy rates of romiplostim and eltrombopag have been similar in that both TRAs increase platelet count, decrease rate of bleeding, decrease the need for rescue therapy, decrease splenectomy rates, increase rate of sustained platelet response, and improve quality of life (Bussel et al. 2006; Kuter et al. 2010; Kuter et al. 2013; Khellaf 2011; George 2009; Michel 2011; Gernsheimer 2010; Bussel et al. 2007, 2009; Cheng et al. 2011).

Sustained remission following cessation of romiplostim has also been seen in a portion of study participants with chronic ITP, independent of previous therapy, splenectomy, and disease duration (Červinek et al. 2015). This may be due to induction of tolerance to platelet antigens (Ghadaki 2013; Mahévas 2014). Clinical trials with eltrombopag for the treatment of ITP have yielded similar results with a (on treatment) sustained response rate near 90 % and peak response rate occurring at approximately day 21 (Saleh et al. 2013).

Recent clinical trials of the TRA use in children with persistent or chronic ITP suggest that romiplostim and eltrombopag are useful therapeutic options, to date without reports of the adverse event signals of thrombosis or marrow reticulin accumulation.

In a phase II dose escalation clinical trial of 22 splenectomized and unsplenectomized children with ITP treated with romiplostim vs. placebo, 88 % vs. 0 of study participants achieved a platelet count $>50 \times 10^9$/L for at least two consecutive weeks with a reduction in clinically relevant bleeding and decreased need for rescue therapy. The median time to the goal platelet count was 7 weeks with an effective dose of 5 μg/kg. Splenectomized patients required a slightly higher dose (Bussel et al. 2011).

In another randomized controlled study of 18 children with chronic ITP, nearly 92 % of patients treated with romiplostim achieved the platelet count target of $>50 \times 10^9$/L by the fifth week. The median weekly dose required to reach this target platelet count was again 5 μg/kg. Those in the treatment arm also had a decreased need for rescue therapy (8 vs. 33 %). Participants in the treatment arm had a significant decrease in bleeding severity. No patients developed thrombocytosis and rebound severe thrombocytopenia or had BM fibrosis at 18 week follow-up (Elalfy et al. 2011).

In a retrospective study of 54 children with ITP treated with either romiplostim or eltrombopag for 6–53 months, 82 % reached the target platelet count of $>50 \times 10^9$/L and $\geq 20 \times 10^9$/L above baseline for at least two consecutive weeks (85 % with romiplostim and 75 % with eltrombopag). Forty-eight percent of patients had at least 50 % of their platelet counts within target range. One patient treated with eltrombopag developed a DVT, however, at the site of an ankle fracture. Forty-four patients underwent bone marrow evaluation and none had histology beyond MF-1 (Ramaswamy et al. 2014).

In the PETIT study, a multicenter randomized controlled study which evaluated children with chronic ITP treated with eltrombopag vs. placebo, 62 vs. 32 % of children achieved at least one platelet count $>50 \times 10^9$/L within the first 6 weeks of treatment. No thrombotic events or malignancy were seen. Three percent of participants had to discontinue treatment due to elevated alanine aminotransferase (Bussel et al. 2015).

In a follow-up to PETIT, PETIT2, 63 children with chronic ITP received eltrombopag. Forty percent achieved the primary platelet outcome, 80 % had any platelet response, fewer in the treatment group had clinically relevant bleeding, and two withdrew because of increased liver aminotransferases. No deaths, malignancies, or thromboses occurred during the trial (Grainger et al. 2015):

Preliminary results from a 6-month phase III randomized placebo-controlled trial of romiplostim in 62 children with ITP lasting longer than 6 months revealed similar results with a durable platelet response that was 52 % overall but a slightly lesser rate in 1–6-year-olds. Rates of serious adverse events (AEs) were 5·3 % (1/19) for placebo and 23·8 % (10/42) for romiplostim. No malignancies or thrombotic events occurred during the study period (Tarantino et al. 2015a, b).

Sixty-five pediatric patients from three previous studies received romiplostim in an open-label trial for up to 269 weeks (ongoing at the time of this printing). Three patients in this study achieved remission (platelet counts $\geq 50 \times 10^9$/L for 24 weeks with no ITP treatments). No new adverse event signals were observed. Again, no thrombotic events or malignancies were reported (Tarantino et al. 2015b).

Several studies have demonstrated efficacy in switching from eltrombopag to romiplostim and from romiplostim to eltrombopag for the treatment of chronic ITP. Despite platelet counts of <50 K $\times 10^9$/L at the time of the switch, many achieve platelet counts >100 K $\times 10^9$/L after switching (Kuter 2015; Khellaf 2013; González-Porras 2015). The reason for this response remains unknown but it may be due to the biological action of each in the TPO binding site and/or intracellular signaling (Khellaf 2013).

Other Thrombopoietin Receptor Agonists

Avatrombopag (AKR501, Eisai, Woodcliff Lake, NJ, USA) is an oral non-peptide TRA that is currently in development. It increases the platelet count in a dose-dependent fashion and has a half-life of approximately 16 h. It is similar to eltrombopag in the following ways: (1) it binds to the transmembrane portion of the TPOr, (2) it stimulates megakaryocytopoiesis at multiple stages including differentiation of progenitor cells, (3) it stimulates hematopoietic progenitor cell proliferation, (4) it has an additive effect on platelet count with endogenous TPO, and (5) it appears to have species specificity and is effective in humans and chimpanzees only. The molecular profile of avatrombopag is shown in Table 1. Avatrombopag increases the platelet count at a lower dose than is required with eltrombopag and does not appear to accumulate in the body (Fukushima-Shintani et al. 2008, 2009; Abe et al. 2011). Avatrombopag has predominately been studied in the treatment of chronic ITP. In adults with chronic ITP, studies have demonstrated a response rate (platelet count $>50 \times 10^9$) of 80 % with 20 mg daily dosing, and in the extension study, the durable response rate was 53 % over a 14-week period. In the extension study, 36 % of nonresponders from the randomized study achieved a durable response. Adverse events were similar to profiles seen with other TRAs (Bussel et al. 2014a, b). A phase II trial of 130 patients with thrombocytopenia secondary to chronic hepatitis C undergoing elective procedure demonstrated a 48 % increase in platelet count $>20 \times 10^9$/L and at least one platelet count $>50 \times 10^9$/L. Treatment was, again, well tolerated. No novel adverse events were identified, although one patient in the treatment group did have portal vein thrombosis (Terrault et al. 2014). Avatrombopag remains under investigation and, to date, has not been approved for treatment of any disease processes.

Adverse Effects of TRAs in Patients with ITP (Table 3)

TRAs are generally well-tolerated medications. The most common side effects among patients are mild-moderate in degree, similar in kind and degree across disease states treated with TRAs, and typically not leading to cessation of treatment (Bussel et al. 2006; Bussel et al. 2007; Kuter et al. 2008; Bussel et al. 2009; Kuter et al. 2010, Khellaf 2011, Cheng et al. 2011; Olnes et al. 2012; Saleh et al. 2013; Afdhal et al. 2014; Desmond et al. 2015, Cines 2015).

Concerns for potentially more serious adverse events, including thrombosis, conversion to malignancy, increase in bone marrow reticulin/bone marrow fibrosis, and, particular to eltrombopag, cataracts and transaminitis, prompted a mandatory Risk Evaluation and Mitigation Strategy (REMS) surveillance program in the United States upon regulatory approval of romiplostim and eltrombopag. This surveillance was unrevealing for new or more frequent than predicted adverse events and was eased after approximately 3 years, in 2011 (US Food and Drug Administration 2016).

Emerging evidence suggests that ITP itself is a pro-thrombotic state with a twofold increased risk of venous thromboembolism and 50 % increased risk of arterial thrombosis (Langeberg et al. 2012). Since both romiplostim and eltrombopag have been shown to cause dose-dependent thrombocytosis, the risk of related thromboembolic events might increase. Clinical trials in adults with chronic ITP treated with romiplostim have demonstrated a 2–6.5 % incidence of thromboembolic events (TEE) (Kuter et al. 2008, 2010). In the pivotal clinical trial of romiplostim in adults with chronic ITP, 2/83 in the treatment group developed arterial embolism, while 1/42 patients in the placebo group developed a venous thromboembolism. Both patients with arterial thrombosis had a previous history of vascular disease (Kuter et al. 2008). In long-term follow-up, romiplostim did not demonstrate an increase incidence of thrombosis, and most events were similar to the most common events that occur in the general population (myocardial infarct, transient

Table 3 Adverse events of interest reported in key clinical trials of TRAs in adults with ITP

Adverse event	Romiplostim	Eltrombopag	Avatrombopag
Reticulin fibrosis	6.9 %	8 %	NR
Cataracts	NR	1–2 %	NR
Thrombosis	2–6.5 %	2–5 %	6 %
Hepatic transaminitis	NR	7–10 %	3 %

NR not reported

ischemic attacks, deep vein thrombosis, and pulmonary embolism). There were, however, four cases of portal vein thrombosis in the treatment group vs. no portal vein thrombosis in the placebo treatment group (Cines 2015). In adults with chronic ITP treated with eltrombopag, studies have demonstrated an incidence of 2–5 % for TTE (Cheng et al. 2011; Saleh et al. 2013). In long-term follow-up in which the incidence of TEE was 5 %, all patients who experienced a TEE had at least one preexisting risk factor (smoking, hypertension, obesity, family history, or genetic predisposition), and 3 % had a previous history of TEE. Both venous and arterial thromboses were seen. The occurrence of TEE did not appear to correlate to platelet count, and some of the patients had platelet counts less than the treatment goal when the event occurred (Saleh et al. 2013). Treatment of adults with chronic ITP with avatrombopag has demonstrated a 6 % incidence of TEE. Again, both venous and arterial TEEs were seen. Three of the four patients who had a TEE had at least one preexisting risk factor (Bussel et al. 2014a, b).

Bone marrow fibrosis, mostly characterized by marrow reticulin accumulation, associated with the treatment with TRAs has been a concern in several trials with severity ranging from MF-1 to MF-3 on the European Consensus Scale (Mufti et al. 2006; Ghanima et al. 2014). Reticulin is a normal matrix component in the bone marrow, and up to 81 % of the general population has been shown to have some level of reticulin bone marrow fibrosis as high as MF-1 (Bauermeister 1971; Beckman and Brown 1990). Increased bone marrow reticulin has also been demonstrated in up to 40 % of adults with ITP not treated with TRAs (Ettrup et al. 2010). In the EXTEND study, which assessed long-term follow-up of adults with chronic ITP treated with eltrombopag, 8 % demonstrated MF-2 reticulin levels (Saleh et al. 2013). None demonstrated MF-3. Of the 147 patients who underwent bone marrow biopsy, only 11 received repeat biopsy after >2 years of treatment. Of the 11 patients, 8 showed stable levels of reticulin, 2 had a regression from MF-2 to MF-0, and 1 increased from MF-2 to MF-3 (Saleh et al. 2013). In the most recent report to date, 5-year follow-up data from the EXTEND trial showed none to mild reticulin in 98 % of the study participants. All patients have been asymptomatic and none have demonstrated conversion to a malignant process (Brynes et al. 2015). In a 3-year prospective study of adults with chronic ITP receiving romiplostim, 6.9 % (9 of 131) developed either a ≥2-grade increase in bone marrow reticulin (7 of 131) or collagen fibrosis (2 of 131) (Janssens et al. 2014). Earlier studies of romiplostim in chronic ITP have reported a range of reticulin fibrosis occurrence but lack long-term surveillance. In a single-center, partially retrospective study, using the European Consensus Grading System, 15 of 66 pediatric (24 %) or adult (76 %) patients with chronic ITP developed some degree of marrow fibrosis while receiving one of the three TRAs mentioned above. Interestingly, the outcome of fibrosis did not consistently progress with continuation of the TRA treatment. Data on reticulin or collagen fibrosis associated with TRA use remain limited. Further prospective surveillance is warranted.

Rebound worsening thrombocytopenia has been seen after cessation of therapy in adult patients with chronic ITP, although the rate of rebound is similar to that of placebo. In most cases, the platelet count returned to normal with or without rescue treatment and without sequelae (Bussel et al. 2006; Saleh et al. 2013). Monitoring of platelet counts for 4 weeks after cessation of therapy is recommended.

Eltrombopag is associated with hepatobiliary laboratory abnormalities (HBLA). In a minority of adults with chronic ITP, HBLA occurs at a rate of 7–10 % (Bussel et al. 2007; Cheng et al. 2011; Saleh et al. 2013). The EXTEND trial in adults with chronic ITP demonstrated a 10 % incidence of HBLA that did not correlate with dose or duration of therapy and most recovered with or without cessation of treatment. Those who had HBLA in a previous study that lead to cessation of treatment were retreated with eltrombopag in this follow-up study and did not have reoccurrence of HBLA. The abnormalities that have been seen are mild and reversible, and patients have been asymptomatic. In addition, an association between eltrombopag and hepatic decompensation in patients undergoing treatment for thrombocytopenia secondary to hepatitis C has been observed. Patients who received eltrombopag in addition to antiviral therapy had a higher rate of ascites and encephalopathy as compared to those receiving placebo and antiviral therapy (7 and 4 % in phase III trials and 10 and 5 % in open-label follow-up) (Afdhal et al. 2014). Monthly monitoring of liver function is recommended for all patients undergoing treatment with eltrombopag, with discontinuation of therapy if serum aminotransferase concentrations increase to >3x the upper limit of nomal concentrations, >3x above the patient's baseline concentrations with a progressive increase, sustained elevated aminotransferase concentrations for at least 4 weeks. Discontinuation of eltrombopag is also recommended for those patients with symptoms of chemical hepatitis. (US Food and Drug Administration 2016).

An association between TRAs and immunoblast proliferation is a potential untoward effect of hematologic growth factors. This has been of particular concern when TRAs are used in the treatment of myelodysplastic syndrome (MDS) (Giagounidis et al. 2014). TRAs do not appear to lead to MDS or leukemia in ITP (Saleh et al. 2013).

There has been an observation of cataracts in adults with chronic ITP treated with eltrombopag with an incidence of 0–8 % in the treatment population over a 6–26-week treatment course. Of note, in the RAISE study (a phase III

clinical trial), while 8 % of the treatment population developed cataracts, 10 % of the placebo group was also affected and in long-term follow-up of 3 years. Also, most patients had a history of earlier or concomitant treatment with corticosteroids, which may have contributed to the onset of or progression of the cataracts (Bussel et al. 2009; Cheng et al. 2011; Saleh et al. 2013).

In children, adverse events have been similar to those seen in adults (Elalfy et al. 2011; Ramaswamy et al. 2014). In children with chronic ITP treated with romiplostim, the most common adverse effects were headaches (35–63 %), pyrexia (24–54 %), and oropharyngeal pain (24–50 %) and with eltrombopag, nasopharyngitis (17 %), rhinitis (16 %), and epistaxis (13 %). Thromboembolic events may occur at a lower rate in children than in adults as no cases have been reported in randomized clinical trials of romiplostim or eltrombopag in children (Bussel et al. 2014a, b, 2015; Grainger et al. 2015; Tarantino et al. 2015a, b). Although surveillance bone marrow examination has not been part of the protocol in pediatric trials of the TRAs, the highest level or reticulin seen to date is MF-1, based on a recent retrospective study by Ramaswamy et al. (Ramaswamy et al. 2014). HLAB has been similarly occurring in approximately 6 % of children with ITP treated with eltrombopag. New or progression of existing cataract has occurred in 2 %. Again, all patients were also treated with corticosteroid which is a potentially confounding factor (Grainger et al. 2015).

Second-Generation TRAs in the Treatment of Other Thrombocytopenic Disorders

Liver Cirrhosis and Hepatitis C Infection

In patients with hepatitis C virus (HCV) infection, thrombocytopenia is a complication of chronic liver disease, HCV infection itself, as well as a known side effect of antiviral therapy. Thrombocytopenia in this patient population can lead to reduced or missed dosing of antiviral treatment which can lead to a lower rate of sustained antiviral response. In addition, surgery is often needed, but contraindicated in this population, due to high risk of bleeding secondary to thrombocytopenia. In the treatment of thrombocytopenia secondary to HCV infection and liver cirrhosis, TRAs have been shown to increase platelet count throughout treatment allowing for fewer dose reductions in antiviral therapy, increased sustained viral response rates, and completion of surgery without increase in bleeding or thrombotic events (McHutchison et al. 2007). There has been concern for increase in hepatic decompensation when eltrombopag is used in combination with interferon and ribavirin particularly in those with an albumin <5 g/dL and/or MELD score >10. An increase in thrombotic events such as portal vein thrombosis has also been seen in this study population (Afdhal et al. 2014; Giannini 2015; Moussa and Mowafy 2013).

Severe Aplastic Anemia

Severe aplastic anemia (SAA) is a disorder of pancytopenia and hypocellularity of the bone marrow. It is most often an autoimmune process that affects hematopoietic stem cells (HSCs) and progenitor cells. The complications of severe aplastic anemia are secondary to the cytopenias, primarily infection with neutropenia, and bleeding secondary to thrombocytopenia. Anemia often leads to the need for packed red blood cell transfusion (Desmond et al. 2015). Granulocyte colony-stimulating factor (G-CSF) and erythropoietin (EPO) have not been effective at treating aplastic anemia as they primarily act on their respective committed progenitor cells. Since the defect in SAA is at the HSC level, the ineffectiveness of G-CSF and EPO for the treatment of AA is somewhat expected. On the other hand, EPO binds and stimulates both megakaryocytes and HSCs. Eltrombopag also acts on both HSCs and megakaryocytes. In aplastic anemia, not only has eltrombopag been shown to increase platelet count, but it has also been found to exert a tri-lineage effect with an overall response rate of 44 % in at least one lineage. It also has decreased the need for transfusion in two clinical trials (Olnes et al. 2012; Desmond 2014). Despite the increase in cell counts, no change in bleeding complications or infections has been seen (Desmond 2014). The ultimate role of eltrombopag and other TRAs in the management of SAA is yet to be determined.

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) is a heterogenous group of blood disorders characterized by bone marrow dyscrasia with clonal hematopoiesis, dysplastic bone marrow cells, various combinations of peripheral cytopenias, and increased risk of progression to acute myeloid leukemia. The cause of thrombocytopenia in MDS is multifactorial. Megakaryocytes are affected in several ways including exaggerated apoptosis and production of dysplastic, small, hypolobulated cells leading to impaired platelet production. To a lesser extent, enhanced platelet destruction may contribute to thrombocytopenia (Houwerzijl et al. 2006). MDS-associated thrombocytopenia may also be treatment related that can lead to dose reduction or missed doses of therapy and subsequently poorer outcomes. Thrombocytopenia occurs in approximately 40–80 % of patients with MDS. Currently, prognosis is predicted by the International Prognostic Scoring System Revised (IPSS-R) which uses a point system with higher scores indicating poorer prognosis and a maximum score of 10. The IPSS-R gives 0.5 points for

a platelet count 50–100 $\times$ 10^9/L and 1 point for a platelet count $<50 \times 10^9$/L . Platelet count, the need for platelet transfusion, and possibly the rate of platelet decline to $<50 \times 10^9$/L are independent prognostic indicators (Santini and Fenaux 2015). Currently, risk-based therapy is used and the goal of lower-risk MDS is to decrease the need for transfusion (Garcia-Manero 2015).

Romiplostim has been trialed for the treatment of thrombocytopenia in mild-to-intermediate myelodysplastic syndrome and has demonstrated a reduction in significant bleeding events and need for platelet transfusion per-patient-months, as well as being associated with no increase in thrombotic events. Increase in progression to AML is an obvious concern as this has been a potential adverse effect of interest in patients on TRAs without MDS; however, increase in progression to AML has not been reported. Despite an increase in the platelet count, improvement in mortality rate has not yet been shown with this mode of treatment. Those that have converted to AML while on TRAs have had WHO-defined refractory anemia with excess blasts type 1 or 2. The authors concluded that romiplostim should only be considered for mild-intermediate MDS (Prica 2014).

Romiplostim has also been trialed as an adjunct to other treatments such as lenalidomide, decitabine, and azacitidine. Results have shown a decreased need for reduction in dose of other treatments (Kantarjian et al. 2010; Wang et al. 2012; Greenberg et al. 2013). In vitro studies of eltrombopag in combination with lenalidomide in high-risk cell lines demonstrate inhibition of clonal expansion and inhibition of lenalidomide antiplatelet production effects on megakaryocytes, and eltrombopag alone, and in combination therapy, did not cause progression to leukemia. Eltrombopag alone has been shown to increase megakaryopoiesis at all stages without risk of blast cell formation in vitro (Will et al. 2009; Mavroudi et al. 2011; Tamari 2014).

Cytotoxic Chemotherapy-Induced Thrombocytopenia

Chemotherapy-induced thrombocytopenia (CIT) is dependent upon the type of chemotherapy agent used and occurs via a variety of mechanisms including the inhibition of platelet production, increased platelet destruction, and enhanced platelet clearance. The risk of hemorrhage in patients with CIT is directly related to the degree of thrombocytopenia, which often creates the need for platelet transfusion (which has its own risks), and missed or reduced dosing of chemotherapy (Kuter 2015). First-generation TRA use lead to higher nadir with early peak, reduced platelet transfusions, decreased duration of thrombocytopenia, decreased in missed chemotherapy dose, and possibly even increased survival (Fanucchi et al. 1997; Vadhan-Raj et al. 2000; Moskowitz et al. 2007). Romiplostim and eltrombopag have been shown to stimulate megakaryopoiesis, improve platelet counts (and in some cases, maintain platelet count $>100 \times 10^9$/L), and decrease rate of missed or reduced chemotherapy (Jeong et al. 2015; Winer 2014; Parameswanan 2014). Similar to studies completed in aplastic anemia, eltrombopag has demonstrated decreased anemia and neutropenia as well (Winer 2014). Ongoing studies are investigating novel uses for TRAs including treatment of chemotherapy-induced thrombocytopenia in solid tumors (Kellum et al. 2010), non-Hodgkin's lymphoma, and non-small cell lung cancer, persistent thrombocytopenia following hematopoietic stem cell transplant, and umbilical cord blood transplant. A list of currently approved indications for romiplostim and eltrombopag, at the time of this writing this article, is presented in Table 4.

Table 4 Approved Indications for romiplostim and eltrombopag

Indication	Romiplostim	Eltrombopag/Revolade
Chronic ITP, adults	USA, EU, Australia	USA, EU, Canada, Japan, Canada, Mexico, Brazil, Colombia, Turkey, UAE, Oman, Lebanon, Kuwait, Saudi, Egypt, Morocco
Chronic ITP, children (1–18 years)	–	USA, EU
Thrombocytopenia in HCV infection	–	USA, EU
Severe aplastic anemia	–	USA, EU

Inherited Thrombocytopenias

Among the inherited thrombocytopenias, MYH-9 related disease (MYH-9RD) is an uncommon macrothrombocytopenia characterized, additionally, by the presence of Dohle-like inclusion bodies in leukocytes, normal megakaryocytes, and variable findings of sensorineural hearing loss, presenile cataracts, and a proteinuric nephropathy. The MYH-9 gene codes for nonmuscular myosin IIA, a protein that is responsible for various cytoskeletal elements involved in motility. Thrombocytopenia in this disease is thought to be due to abnormal platelet release (Pecci et al. 2010). Platelet counts are highly variable between individuals, but most have thrombocytopenia, and most often the platelet count remains lower than normal, but stable throughout their lifetime. The most common bleeding abnormalities include epistaxis, menorrhagia, and easy bruising. Serious adverse bleeding events are rare. In premenopausal women, the most common complication is iron deficiency anemia due to menorrhagia. Bleeding risk is directly related to platelet count and spontaneous

bleeding is rare with platelet count $>50 \times 10^9$/L. Treatment is rarely needed; however, given the paucity of prospective studies and the rarity of the disease, the appropriate treatment of spontaneous bleeding and/or pre- and postoperative management is unknown. Eltrombopag has been successfully used in the preoperative period and was successful at raising the platelet count and allowing patients to participate in invasive surgery (Pecci et al. 2010). No bleeding complications were seen in the pre- or postoperative period. Also of interest, no increase in cataracts was seen.

Wiskott-Aldrich/X-Linked Thrombocytopenia

Wiskott-Aldrich syndrome (WAS) and X-linked thrombocytopenia (XLT) are a spectrum of disorders caused by a mutation in the WAS gene. The WAS gene is exclusively expressed in hematopoietic stem cells, and its gene expression product is involved in cell signaling and cytoskeleton reorganization. WAS/XLT-related thrombocytopenia is characterized by small platelet volume, normal megakaryocyte number, and otherwise normal platelet morphology (Haddad et al. 1999; Kajiwara et al. 1999). Patients with WAS/XLT often experience spontaneous hemorrhage including gingival, gastrointestinal, and intracranial hemorrhage. Up to 30 % have a severe hemorrhagic event in their lifetime and 4–10 % of these episodes are fatal (Sullivan et al. 1994; Imai et al. 2004). While thrombocytopenia remains poorly understood in this disease, current hypotheses include increased platelet destruction (immune and nonimmune), decreased platelet size, and a decrease in platelet function (Marathe et al. 2009; Shcherbina et al. 2009; Gerrits 2015). Current palliative treatment options include platelet transfusion and splenectomy, with the only curative therapy being HSC transplantation. Eltrombopag has been shown to increase platelet count but no improvement in platelet function has been seen (consistent with pharmacokinetic studies as noted previously) with a subsequent decrease in bleeding (Gerritis 2015).

Summary

Since the discovery of megakaryocytes in the early 1900s, our understanding of platelet production and the pathophysiology of thrombocytopenia in various disease states has broadened. Despite the positive results seen with the recombinant TRAs, their induction of TRA and endogenous TPO antibodies rendered them useless. However, the development of the nonhomologous, apparently non-immunogenic TRAs, romiplostim and eltrombopag, has created potential treatment options for many thrombocytopenic disorders. Although initial registration studies focused on patients with chronic ITP, the second-generation TRAs, romiplostim and eltrombopag, have potential utility in inherited thrombocytopenias, CIT, MDS, and other secondary thrombocytopenias. As with other hematopoietic growth factors, surveillance for toxicity signals, including reticulin fibrosis and venous and arterial thrombosis, must continue.

Take Home Messages

1. Thrombopoietin (TPO) is the primary regulator of platelet production. Expression of the TPO is relatively constant.
2. Recombinant TPO and second-generation TPO receptor agonists, or TRAs increase the circulating platelet count in patients with a variety of thrombocytopenic conditions.
3. Two TRAs, romiplostim and eltrombopag, are approved in several countries for the treatment of chronic ITP (both), aplastic anemia (eltrombopag), thrombocytopenia related to liver disease (eltrombopag).
4. The safety profile of romiplostim and eltrombopag is largely good, however close monitoring for uncommon drug-specific adverse effects, such as bone marrow reticulin deposition or thromboembolic events, is recommended.

Gene Therapy

Qizhen Shi and Robert R. Montgomery

Abstract

Gene therapy is an attractive approach for disease treatment. Since platelets are the second most abundant cells circulating in blood with the abilities of storage and delivery, it could be a unique target for gene therapy of diseases, e.g., hemophilia, in which platelets are involved. Recent studies have demonstrated that ectopic expression of factor VIII (FVIII) in platelets under control of the platelet-specific promoter results in FVIII storage together with its carrier protein von Willebrand factor (VWF) in α-granules and the phenotypic correction of hemophilia A. Importantly, the storage and sequestration of FVIII in platelets appears not only sufficient to selectively deliver FVIII to sites of hemostatic activation but in addition protects FVIII hemostatic bioactivity from function-blocking inhibitory antibodies. When factor IX (FIX) expression is targeted to platelets, FIX is also stored in α-granules and platelet-derived FIX restores hemostasis in hemophilia B mice, but the clinical efficacy is limited in the presence of anti-FIX inhibitory antibodies. In this chapter, recent studies utilizing platelets as a target for gene therapy of hemophilia A and B are reviewed.

Introduction

Genetically engineering of cells to produce proteins of interest is an appealing approach for disease treatment. The distinct facets of platelet biology (Elzey et al. 2003; Gawaz et al. 2005; Smyth et al. 2009; Semple et al. 2011; Jenne et al. 2013) make platelets a unique target for gene therapy (Yarovoi et al. 2003; Wilcox et al. 2003; Shi et al. 2006, 2007, 2008, 2014, 2015; Kuether et al. 2012; DU et al. 2013; Chen et al. 2014; Greene et al. 2014; Wang et al. 2015). Platelets circulating in blood through the whole body are packed with abundant secretory granules. These granules contain a large number of proteins from both megakaryocyte synthesis and endocytosis. When platelets are activated, the bioactive proteins are released from their granules, participating in a variety of physiologic and pathologic processes. Given the capacities of storage, trafficking, and release, utilizing platelets to deliver therapeutics is an attractive approach for disease treatment. In this chapter, recent studies using platelets as a means to deliver coagulation factors for hemophilia gene therapy are reviewed.

Platelet-Specific Genetic Manipulation

Gene therapy is a cutting-edge promising approach for the treatment of a number of diseases, such as genetic-inherited disorders and certain cancers. Gene therapy is the delivery of

nucleic acid to correct a defective gene or introduce novel therapeutic genes into cells as a means to treat disease, which might lead to a cure. For gene therapy to be successful, a careful choice of the targeted cells for stable transgene expression and an efficient gene delivery vector are critical.

The Target Cell for Gene Transfer for Platelet-Specific Gene Therapy

For platelet-specific gene therapy of hemophilia, platelets are the final target for transgene protein expression and storage. Although platelets have components required for mRNA translation and protein synthesis (Booyse and Rafelson Jr. 1968; Booyse et al. 1968; Ts'ao 1971; Belloc et al. 1982; Kieffer et al. 1987) and de novo proteins are translated in response to cellular activation during physiologic or pathologic processes (Booyse and Rafelson Jr. 1967; Warshaw et al. 1967; Belloc et al. 1982; Kieffer et al. 1987; Weyrich et al. 2004), platelets do not have nuclear transcriptional capacity because they are anucleate cells. In addition, platelets have a limited life span of 8–10 days in humans (Harker et al. 2000; Brown et al. 2000; Scull et al. 2010) and 4–5 days in mice (Harker 1977; Nayak et al. 2013). Thus, direct molecular manipulation of platelets cannot serve as a reliable means for intervention. While megakaryocytes, which are the precursors of platelets, are amenable for genetic manipulation, they also have a limited life span and cannot serve as a means for long-term transgene expression.

In contrast, hematopoietic stem cells (HSCs) are preferable targets for gene transfer to establish in vivo long-term transgene expression in platelets because HSCs have the ability to self-renew and are capable of differentiating into all blood lineages including the megakaryocyte/platelet lineage (Johnson et al. 1982; Srour et al. 1991; Weissman 2000; Lemischka and Moore 2003). Thus, targeting transgene into HSCs may result in transgene protein expression in platelets throughout the lifetime of the recipients. In addition, there are many other aspects that make HSCs a favorable target for gene transfer. For example, HSCs are easily accessible. They can be expanded and genetically manipulated ex vivo followed by reimplantation. HSCs can be obtained not only from natural sources such as bone marrow and umbilical cord blood but also from peripheral blood after mobilization (Indovina et al. 1990; Ings et al. 2006; Ozkan et al. 2015; Karakukcu and Unal 2015). Recent studies showed that induced pluripotent stem (iPS) cells can be differentiated into hematopoietic progenitors (Schenke-Layland et al. 2008; Lengerke et al. 2009; Niwa et al. 2009; Tashiro et al. 2012), suggesting that iPS cells could be a potential source for HSC production. Although efficacy and safety are still issues, with the advanced techniques and increasing knowledge of stem cell biology, generating HSCs from the iPS cells may become possible in the future. Furthermore, from safety point of view, ex vivo transduction followed by transplantation of transduced HSCs to introduce transgene expression should minimize potential antiviral vector immune responses and germ line transmission of vector genomes in contrast to in vivo systematic transduction.

The Promoters Used to Restrict Transgene Expression to the Megakaryocyte/Platelet Lineage

Although both tissue-specific gene promoters and ubiquitous promoters can be used to drive transgene expression in platelets, there are advantages to utilizing tissue-specific promoters to restrict transgene expression to the platelet lineage. Using a tissue-specific promoter, which is a normal cellular gene promoter, rather than a strong viral promoter, to direct therapeutic transgene expression under physiologic regulation may reduce the risks of activation of adjunct cellular genes, thus reducing potential for insertional oncomutagenesis and genome toxicity. In addition, using tissue-specific promoters to restrict transgene expression to the platelet lineage may reduce potential immune response to transgene protein because the platelet-specific promoters will remain inactive in non-platelet lineages, thus reducing potential to activate the immune system. Evidence suggests that immune responses to transgene products are primed by antigen-presenting cells (APC) that are transduced and express transgene antigens (Corr et al. 1996; Doe et al. 1996; Ciesielska et al. 2013). Using tissue-specific promoters to direct transgene expression may avoid transgene expression in APC and thereby abrogate undesired immune responses against transgene product.

To limit transcription of the transgene to the platelet lineage, a megakaryocyte/platelet lineage-specific promoter is required to control the transgene expression. Theoretically, any promoter that directs the transcription of genes encoding a platelet-specific protein can be used to restrict transgene expression to platelets. With a better understanding of the characteristics of promoters, it is becoming more feasible to use a tissue-specific promoter to direct transgene expression to specific tissues. However, we should keep in mind that the efficacy and specificity of transgene expression under control of a manipulated promoter might not be exactly the same as endogenous gene expression because many elements can influence transgene expression. These include the region of the promoter used (DU et al. 2013), the transgene integration site (Clark et al. 1994) and copy number (Garrick et al. 1998; Calero-Nieto et al. 2010), and other gene expression regulators, such as enhancers, silencers, insulators, matrix attachment regions, locus control regions,

and microRNA interactions (Pennacchio and Rubin 2001; Moreno-Moya et al. 2014). Thus, it is very possible to achieve various expression levels of transgene protein among individuals and individual cells within a single recipient even using the same expression cassette with the same promoter.

The promoters that have been used to restrict transcription of transgene to the megakaryocyte/platelet lineage include glycoprotein (GP) Ibα (Yarovoi et al. 2003; Ohmori et al. 2006, 2008; Wang et al. 2015; Arachiche et al. 2014), GPIIb (α_{IIb}) (Berridge et al. 1985; Tronik-Le et al. 1995; Poujol et al. 1998; Tropel et al. 1997; Fang et al. 2005; Shi et al. 2003, 2004, 2006, 2007, 2014; Wilcox et al. 1999, 2000; Rodriguez et al. 2002; Chen et al. 2014; Arachiche et al. 2014; Schroeder et al. 2014; Kanaji et al. 2014), GPV (Sato et al. 2000), GPVI (Ohmori et al. 2006), GPIX (Bastian et al. 1999), platelet factor 4 (PF4) (Ravid et al. 1991; Kufrin et al. 2003; Damon et al. 2008; Siner et al. 2013), and c-mpl (Deveaux et al. 1996; Kaushansky and Drachman 2002). All of these promoters are active in megakaryocytes and expression of transgene continues in their platelet progeny. Most in vivo studies have used either the α_{IIb} promoter or the GPIbα promoter for platelet-/megakaryocyte-targeted transgene expression. The α_{IIb} promoter is a well-characterized promoter that is active throughout megakaryocytopoiesis including in megakaryocyte progenitors as well as multipotent HSCs (Poujol et al. 1998; Prandini et al. 1996; Tronik-Le et al. 1995; Tropel et al. 1997; Uzan et al. 1995; Murray et al. 1996). Evidence shows that the α_{IIb} promoter is also active in primitive HSCs (Debili et al. 2001; Mikkola et al. 2003; Robin et al. 2011) and mast cells (Berlanga et al. 2005). In contrast, the GPIbα promoter is active at relatively later stages of megakaryocytopoiesis (Debili et al. 1992). It has been reported that the GPIbα is also expressed on endothelial cells (Sprandio et al. 1988; Konkle et al. 1990; Wu et al. 1997), dendritic cells (Monteiro et al. 1999), and breast carcinoma cell lines (Oleksowicz et al. 1997). The lineage-specific expression of the endogenous genes regulated by these promoters is summarized in Table 1.

The Vectors Used for Transgene Delivery

Efficient transfection and stable integration of transgene into the genome of HSCs are a key requisite for sustained transgene expression in megakaryocytes/platelets derived from these cells. Since most of the long-term repopulating HSCs are in a quiescent state, only integrating vectors that have the ability to transduce nondividing cells can efficiently introduce transgene into these cells. Although conventional retroviral vectors can integrate into the genome, they are not the best vectors for transgene delivery to HSCs. Retroviral vectors require cell division for integration (Lewis and Emerman 1994; Medin and Karlsson 1997; Purton et al. 2001), and they have a predisposition to integrate in regions close to the transcription start site of cellular genes,

Table 1 The lineage-specific expression of the endogenous gene products

	Hematopoietic progenitors	Megakaryocyte precursors	Mature megakaryocytes	Platelets	Other cells
GPIIb (α_{IIb})	Yes (Murray et al. 1996; Debili et al. 2001; Mikkola et al. 2003; Robin et al. 2011)	Yes (Rabellino et al. 1981)	Yes (Uzan et al. 1995)	Yes (Uzan et al. 1995)	Mast cells (Berlanga et al. 2005)

c-mpl	Yes (Kaushansky and Drachman 2002)	Yes (Kaushansky and Drachman 2002)	Yes (Kaushansky and Drachman 2002)	Yes (Kaushansky and Drachman 2002)	Endothelial cells (Cardier and Dempsey 1998)

increasing risks of insertional mutagenesis (Wu et al. 2003; Mitchell et al. 2004; De et al. 2005; Cattoglio et al. 2010). Lentiviral vectors, which are derived from the human immunodeficiency virus (HIV), have advantages over retroviruses in that they target both dividing and nondividing cells including quiescent HSCs (Miller et al. 1990; Bukrinsky et al. 1993; Sutton et al. 1998; Zennou et al. 2000), and unlike retrovirus, they do not have genomic integration hot spots (Mitchell et al. 2004; Gonzalez-Murillo et al. 2008; Biffi et al. 2011; Ustek et al. 2012). With high transduction efficacy and low genotoxicity, lentiviral vectors represent a promising tool for gene therapy of many disorders via the use of HSCs as a target for genetic manipulation. Utilizing a lentivirus-mediated gene transfer system to introduce a transgene expression cassette under control of a platelet-specific promoter into HSCs could potentially provide patients with a self-replicating pool of stem cells for long-term transgene expression in megakaryocytes and platelets derived from the manipulated HSCs. This will establish an in vivo cellular site for therapeutic protein production. This, together with a preestablished storage capacity and delivery system, makes platelets a unique target for gene therapy.

Platelet-Specific Gene Therapy of Hemophilia A

Hemophilia A is a recessive X-linked bleeding disorder resulting from a factor VIII (FVIII) deficiency (Chavin 1984). Although protein replacement therapy is readily available and effective for patients with hemophilia A, it is expensive and the requirement of frequently accessing blood vessels often limits its universal availability (Wong and Recht 2011; Mannucci et al. 2012). Furthermore, up to 35 % of patients with severe hemophilia A will develop inhibitory antibodies that inactivate FVIII procoagulant activity after protein infusion (Iorio et al. 2010; Mancuso et al. 2012; Franchini et al. 2013). These antibodies, referred to as inhibitors, cause the clinical failure of routine replacement therapy for bleeding episodes (White et al. 1982; Scandella 2000; Furie et al. 1994). Immune tolerance induction by aggressive infusion of FVIII is a treatment option for the eradication of anti-FVIII inhibitors, but it is very expensive, is protracted, and may not always be effective (Astermark 2003; Wight et al. 2003; Knight et al. 2003; Bohn et al. 2004). Gene therapy is an attractive alternative for hemophilia A treatment because it may provide a cure if successful. Substantial progress has been achieved in the last two decades, but immune responses to viral vector or transgene protein are still major concerns (Evans and Morgan 1998; Kootstra et al. 2003; Ye et al. 2004; Gallo-Penn et al. 2001; Matsui et al. 2007, 2011; Zhang et al. 2011; High 2011). Gene therapy of hemophilia A with inhibitors could be more challenging because inhibitory antibodies in the circulation will inactivate functional FVIII if it is constitutively secreted into plasma.

The Impact of VWF on Hemophilia A Gene Therapy

FVIII is a large and relatively unstable plasma glycoprotein that performs an important role in the intrinsic pathway of blood coagulation (Mann et al. 1990). FVIII naturally circulates in an inactive form in plasma in a tightly bound, non-covalently linked complex with its carrier protein VWF (Wagner 1990). Formation of a VWF/FVIII complex is important for FVIII stability and survival. If FVIII does not bind to VWF, it is degraded rapidly by proteases in plasma (Weiss et al. 1977; Chuah et al. 1998; Wise et al. 1991; Kaufman and Pipe 1999). Therefore, it has been thought in the past that for gene therapy to be successful, FVIII must be secreted directly into circulation to allow rapid binding to circulating VWF. The lack of success of previous clinical gene therapy trials (Roth et al. 2001; Powell et al. 2003; Chuah et al. 2004) spurs us to reconsider the target site(s) for FVIII expression and its relationship to VWF biosynthesis.

VWF is a large multimeric glycoprotein that performs multiple functions in hemostasis. Besides chaperoning FVIII as a complex in circulating blood, VWF initiates platelet adhesion at sites of injury, promotes platelet aggregation, and binds to collagen to facilitate clot formation. In a milieu of anti-FVIII antibodies, VWF protects FVIII from inhibitor inactivation (Gawryl and Hoyer 1982; Jacquemin et al. 2000; Shima et al. 1993; Saenko et al. 1994; Jacquemin 2010). Inhibitory antibodies against FVIII are time dependent (Briet et al. 1984; Gadarowski Jr. et al. 1988) because of the association-disassociation interactions between VWF and FVIII and inhibitors. Thus, targeting FVIII expression to cells that synthesize VWF in vivo could be beneficial for gene therapy of hemophilia A and hemophilia A with inhibitors. It is well known that VWF is exclusively produced by megakaryocytes and endothelial cells and stored in the α-granules in megakaryocytes and platelets and Weibel-Palade bodies in endothelial cells (Nachman et al. 1977; Jaffe et al. 1973; Wagner 1993). The cellular site of FVIII synthesis, which had been controversial for decades, has finally become clear in 2014. It is concluded simultaneously by two groups utilizing tissue-specific knockout models that endothelial cells are the primary source of FVIII synthesis in mice (Fahs et al. 2014; Everett et al. 2014), although it is still uncertain which subsets of endothelial cells synthesize FVIII and whether FVIII is synthesized by the same subsets of cells synthesizing VWF. It is known with certainty that FVIII circulates as a complex with VWF in blood (Fig. 1). FVIII is not detected in human (Wilcox et al. 2003; Shi et al. 2014), canine (DU et al. 2013), or murine platelets (Yarovoi et al. 2003; Wilcox et al. 2003; Shi et al. 2014). To date, there is no evidence showing either FVIII synthesis or release from normal platelets.

Early studies of the in vitro production of recombinant FVIII demonstrated enhancement of FVIII synthesis when

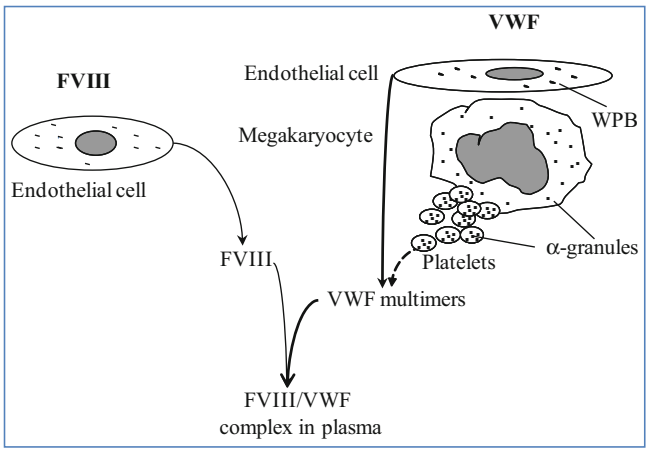

Fig. 1 The cellular sources of VWF and FVIII synthesis. VWF is synthesized by endothelial cells and megakaryocytes and stored in Weibel-Palade bodies in endothelial cells and α-granules in megakaryocyte and platelets. Recent studies demonstrate that FVIII is also synthesized by endothelial cells, but it is still unclear whether FVIII and VWF are produced in different subsets of endothelial cells. FVIII is bound to VWF in a complex circulating in plasma. Figure was used by permission of Q. Shi

performed in a cell that is also synthesizing VWF (Kaufman et al. 1988, 1989). Thus, directing FVIII expression to cells that synthesize VWF (megakaryocytes and endothelial cells) in vivo could potentially result in the formation of an intracellular VWF/FVIII complex and enhance the stability of FVIII compared to cells not synthesizing VWF (hepatocytes, fibroblasts). Targeting FVIII expression to platelets could be especially beneficial for gene therapy of hemophilia A because FVIII will be delivered together with VWF to the right place at the right time, where and when it is needed. This is particularly important for hemophilia A with inhibitors because FVIII would be sequestered by platelets, avoiding inhibitor inactivation in the circulation. Furthermore, a substantial amount of platelet-derived FVIII may be released at hemostatic sites where aggregated platelets become activated at sites of injury, thus circumventing the time-dependent inactivation by antibodies and achieving improved hemostasis (Fig. 2). Additionally, more tightly regulated release by platelets may limit immune exposure to the FVIII gene therapy product, reducing the incidence of inhibitor formation.

Proof of Principle Studies Using Transgenic Mouse Models

The hypothesis motivating platelet gene therapy of hemophilia A is that targeting synthesis of FVIII to megakaryocytes under control of a platelet-specific promoter will direct the storage of FVIII with VWF in the α-granules of platelets derived from these cells. This will establish a pool of FVIII together with VWF in platelets capable of stimulated release at the site of injury, avoiding inhibitor inactivation and achieving hemostasis. Several laboratories have been devoting efforts to develop unique gene therapy approaches using platelets as a target to deliver therapeutics for hemophilia A treatment, which are summarized below.

The αIIb Promoter-Driven Model

To restrict FVIII expression to the platelet lineage, Shi and co-workers have developed a vector, 2bF8, in which human B-domain deleted FVIII expression is driven by the platelet-specific α_{IIb} promoter. In ex vivo studies, Shi et al. found that FVIII expression in Dami cells, a megakaryocyte cell line, is greater when driven by the α_{IIb} promoter compared to the CMV promoter (Shi et al. 2003). When the 2bF8 expression cassette was used to generate transgenic mice on a FVIII knockout background ($2bF8^{tg}$) (Shi et al. 2006), FVIII was specifically expressed in platelets and stored together with endogenous murine VWF in platelet α-granules as determined by confocal microscopy and electron microscopy, and that platelet-derived FVIII is therapeutically effective even in the presence of high titers of anti-FVIII inhibitors. With no detectable plasma FVIII, the level of FVIII in platelets of heterozygous $2bF8^{tg}$ mice corresponded to about 1.4 % of FVIII in normal mouse whole blood. Remarkably, the therapeutic benefit of this platelet FVIII exceeded the benefit of 100 % plasma FVIII in the presence of inhibitors, using a tail-clip model (Shi et al. 2006).

Further studies by Shi et al. using $2bF8^{tg}$ mice have demonstrated that pre-existing immunity does not preclude 2bF8 genetically modified therapeutic engraftment when a sufficient preconditioning regimen is employed (Shi et al. 2008). The studies showed that even with only 1–5 % platelets containing FVIII, the bleeding phenotype was still significantly improved in hemophilia A mice with pre-existing anti-FVIII immunity. To explore the role of VWF in platelet gene therapy of hemophilia A, Shi et al. developed another transgenic mouse model by crossing 2bF8 transgene onto a VWF and FVIII double knockout background ($2bF8^{tg}/VWF^{-/-}$). The level of platelet-FVIII expression was decreased significantly, but the bleeding diathesis is still rescued in $2bF8^{tg}/VWF^{-/-}$ mice in the absence of antibodies in a tail-clipping injury model. However, the clinical efficacy was abrogated in the presence of inhibitors (Shi et al. 2015), demonstrating that VWF is critical in platelet gene therapy of hemophilia A with inhibitors.

The GPIbα Promoter-Driven Model

Yarovoi and co-workers (Yarovoi et al. 2003) have developed a transgenic model in which human B-domain deleted FVIII (hBF8) expression is directed by the platelet-specific

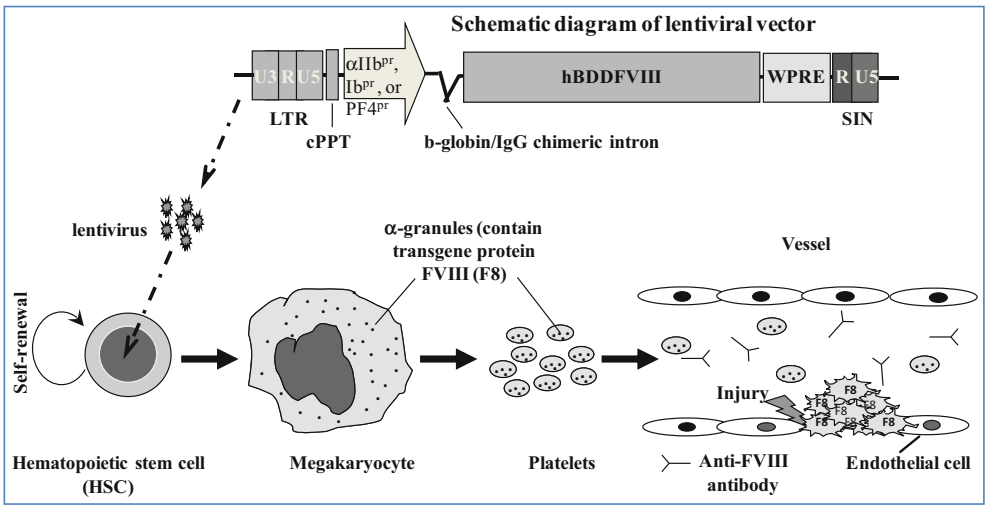

Fig. 2 Schematic diagram of platelet-specific gene therapy of hemophilia A. Lentiviral vectors harboring FVIII expression cassette under control of a platelet-specific promoter (α_{IIb}, Ib, or PF4 promoter) are used to transduce hematopoietic stem cells (HSCs). Transduced HSCs undergo self-renewal as well as differentiation into megakaryocytes where FVIII transgene protein will be made and stored in α-granules which will be shed into platelets circulating in blood. Platelet-sequestered FVIII will be protected from anti-FVIII inhibitory antibody inactivation. At the site of injury, FVIII (together with its carrier protein VWF) will be released from activated platelets, and thus time-dependent inhibitor activation may be circumvented, achieving improved hemostasis. Figure was used by permission of Q. Shi

GPIbα promoter (IbF8). In their highest-expressing hBF8 transgenic line, h38/F8^{null}, FVIII was detected in platelet releasates with a level corresponding to about 9 % of the antigen and 3 % of the activity in normal mouse plasma as determined by ELISA and Coatest assays. This platelet FVIII completely restored hemostasis in hemophilia A mice in a $FeCl_3$ carotid artery injury model, achieving an occlusive time similar to that obtained from wild-type animals. The cuticular injury model and whole blood clotting time confirmed that the hemophilic phenotype was improved in transgenic mice. Further studies by Yarovoi et al. demonstrated that FVIII is still stored in platelet α-granules even in the absence of VWF and that platelet-derived FVIII without VWF can still rescue the hemophilic phenotype in hemophilia A mice in the absence of inhibitors, and the clinical efficacy was similar to that in the presence of VWF although the level of platelet FVIII was significantly reduced (Yarovoi et al. 2005).

To compare the clinical efficacy of platelet FVIII to plasma FVIII, Gewirtz et al. infused a mixture of monoclonal antibodies into either IbF8 transgenic mice, line h38/F8^{null}, with platelet-FVIII expression or FVIII^{null} mice pre-infused with recombinant human FVIII (rhF8) (Gewirtz et al. 2008). Under those conditions, Gewirtz and co-workers found that platelet FVIII provided marginally better clot-forming activity in the $FeCl_3$-induced thrombosis model (Gewirtz et al. 2008). There is a difference in outcome between studies conducted by Shi et al. utilizing a tail-clipping injury model comparing the efficacy of platelet FVIII from 2bF8^{tg} mice and plasma FVIII in the presence of inhibitors (Shi et al. 2006, 2008) and those of Gewirtz and co-workers (Gewirtz et al. 2008). Studies by Shi et al. demonstrated that platelet FVIII was dramatically more effective than equivalent levels of infused FVIII when inhibitors were infused into the circulation prior to FVIII to mimic the clinical situation of FVIII protein replacement therapy in an inhibitor patient. Further studies showed that the different outcomes were driven by the order of infusions of rhF8 and inhibitors (Shi et al. 2012). Infusing of rhF8 into FVIII^{null} mice first followed by antibody infusion allows pre-association of infused FVIII with endogenous VWF in plasma into a protective VWF/FVIII complex before exposure to inhibitors. Even though pre-infusing rhF8 into FVIII^{null} mice followed by antibody infusion is not really quite analogous to the treatment of an inhibitor patient where FVIII is infused into a milieu of pre-existing polyclonal inhibitory antibodies, data from Gewirtz and co-workers' studies (Gewirtz et al. 2008) indicate that the preformed VWF/FVIII complex in platelets (intracellular) is more effective than the complex in plasma (extracellular) when faced with antibodies, suggesting that the properties of both platelets and VWF are important in platelet gene therapy of hemophilia A with inhibitors.

Another study by Neyman et al. using the IbF8 transgenic model, line h38/F8^{null}, showed that the clots formed in IbF8 transgenic mice had a tendency toward more embolization than those generated in FVIII^{null} mice receiving full-length recombinant FVIII infusion in a laser-induced cremaster vessel injury model (Neyman et al. 2008). Subsequently, Greene et al. developed additional transgenic lines in

which FVIII variants including IR8 (inactivation resistant F8) and cBF8 (canine B-domain deleted FVIII) were expressed under control of the same GPIbα promoter. The level of platelet FVIII in cBF8 transgenic mice was low, only 30 % of the hBF8 or IR8, but it significantly decreased clot embolization in the cremaster injury model (Greene et al. 2010).

The PF4 Promoter-Driven Model

Damon et al. generated a transgenic mouse model in which a rat PF4 promoter was used to direct human B-domain deleted FVIII expression (Damon et al. 2008). FVIII expression was confined to platelets and functional FVIII activity was detected by a chromogenic assay in the sonicated platelet lysates from transgenic mice with a level of 122 mU/10^9 platelets. Their studies demonstrated that platelet-derived FVIII is in an inactive form that requires thrombin cleavage for activation. Ectopic expression and storage of FVIII does not affect phosphatidylserine exposure nor α-granule release of endogenous platelet protein, e.g., factor V/Va. Their studies showed that infusion of thrombopoietin into transgenic mice resulted in a reduction of the amount of FVIII per platelet and clinical efficacy in hemostasis was completely abolished, although the total amount of circulating platelet FVIII was not affected. It is unclear why thrombopoietin-induced thrombocytopoiesis diminished the clinical efficacy of platelet-derived FVIII in this transgenic model.

Taken together, the studies using the transgenic approach provide proof of principle that platelet-specific expression could be successful for treating hemophilia A even in the presence of inhibitors.

Lentivirus-Mediated Platelet-Specific Gene Therapy of Hemophilia A

To apply the platelet-derived FVIII approach as a clinically translatable gene therapy model, efficient gene transfer and stable expression of FVIII are critical. Since HSCs are the preferable target for gene transfer and lentivirus can efficiently transduce stem cells, utilizing lentiviral vectors to introduce a FVIII expression cassette driven by a platelet-specific promoter should make it possible to establish long-term FVIII expression specifically in megakaryocytes/platelets.

Non-inhibitor Model Studies

Shi et al. used a lentivirus-mediated gene transfer system to deliver the 2bF8 expression cassette into HSCs, resulting in FVIII expression in platelets (Shi et al. 2007). These studies demonstrated that transplantation of 2bF8 lentivirus-transduced bone marrow cells into $FVIII^{null}$ mice preconditioned with 11Gy total body irradiation (TBI) resulted in sustained therapeutic levels of platelet FVIII and restored hemostasis with neither inhibitory nor non-inhibitory antibody development. The expression levels of platelet FVIII in transduced recipients (0.60 ± 0.26 mU/10^8 platelets) were similar to those obtained in $2bF8^{tg}$ mice, which were generated by embryonic stem (ES) cell-mediated transgenesis (Shi et al. 2006). Serial transplants demonstrated that platelet-FVIII levels were maintained after sequential bone marrow transplantation, confirming that long-term repopulating HSCs were successfully transduced. These studies build the foundation for lentivirus-mediated platelet-specific gene therapy.

Greene et al. developed lentiviral vectors harboring hBF8, IR8, or cBF8 under control of the GPIbα promoter and introduced FVIII expression by bone marrow transduction and transplantation into $FVIII^{null}$ mice preconditioned with 10Gy TBI (Greene et al. 2010). They found that the level of platelet-FVIII expression in transduced recipients was about 50 % of the transgenic mice with hBF8 or IR8 cassettes, but similar low levels were observed in both transgenic and transduced mice with the cBF8 cassette. Hemostasis was improved in transduced recipients, with better outcomes using IR8 and cBF8 than with hBF8. Further studies from the same group showed that the low level of FVIII expression in cBF8-transduced recipients was associated with greater megakaryocyte apoptosis than in hBF8-transduced animals. When the furin cleavage site in hBF8 was modified by substituting His for Arg of 1645, the hemostatic efficacy of platelet-derived hBF8 was significantly improved in the cremaster laser injury model (Greene et al. 2014).

Inhibitor Model Studies

To investigate whether lentiviral gene delivery to HSCs can efficiently introduce therapeutic levels of platelet FVIII in hemophilia A mice with pre-existing anti-FVIII immunity, Kuether et al. transduced enriched HSCs (Sca 1^+) cells from rhF8-immunized $FVIII^{null}$ mice with 2bF8 lentivirus followed by transplantation into rhF8-immunized littermates (Kuether et al. 2012). Sustained therapeutic levels of platelet-FVIII expression were obtained, while inhibitor titers declined with time. Hemostatic improvement in the treated animals was confirmed by the tail-clip survival test and the electrolyte-induced injury model. The level of platelet-FVIII expression in the inhibitor model was not significantly different from the non-inhibitor model (1.56 ± 0.56 mU/10^8 platelets vs. 1.46 ± 0.43 mU/10^8 platelets) when a myeloablative conditioning regimen of 11Gy total body irradiation (TBI) was employed. There was a wide range of FVIII expression levels among recipients, ranging from 0.36 mU/10^8 platelets to 6.18 mU/10^8 platelets. When LAM-PCR (linear amplification-

mediated PCR) was used to survey the proviral DNA integration sites in 2bF8-transduced animals, 39 genomic insertion sites were identified in six primary recipients. No overrepresented insertion sites were noted, although one (*Mds1*) corresponds to a common integration site for γ-retroviral vectors (Calmels et al. 2005) and another, *Arid1a*, is a proto-oncogene presented in the Mouse Retrovirus-Tagged Cancer Gene Database.

In this study (Kuether et al. 2012), Kuether et al. also evaluated the efficacy of non-myeloablative conditioning regimens, including sublethal TBI and busulfan chemotherapy, in platelet gene therapy. The levels of platelet FVIII in the group conditioned with a non-myeloablative TBI regimen (6.6Gy) were not significantly different from the group conditioned with myeloablative TBI (11Gy). Busulfan, an alkylating agent with potent effects on primitive hematopoietic cells, used as a conditioning alone resulted in therapeutic levels of platelet-FVIII expression in a 2bF8-transduced non-inhibitor model. However, in the inhibitor model, some form of additional immune suppression, e.g., antithymocyte globulin or a low dose of TBI, was required for efficacy. These studies demonstrated that 2bF8 lentiviral gene delivery to HSCs can introduce sufficient therapeutic levels of platelet-FVIII expression in hemophilia A mice even with pre-existing immunity, and importantly with non-myeloablative conditioning, suggesting that platelet gene therapy may be a promising strategy for gene therapy of hemophilia A even in the high-risk setting of pre-existing inhibitors.

Dog Model Studies

To further evaluate the efficacy of platelet gene therapy of hemophilia A, Du et al. applied a 2bF8 gene therapy protocol to hemophilia A dogs (DU et al. 2013). Autologous HSCs ($CD34^+$) were enriched from G-CSF (granulocyte colony stimulation factor) and SCF (stem cell factor)-mobilized peripheral blood of hemophilia A dogs, transduced with 2bF8 lentivirus (renamed as -889ITGA2B-BDDFVIII-WPTS in this study) ex vivo, and transplanted back into animals preconditioned with busulfan. Cyclosporine and mycophenolate mofetil were administered for about 90 days after transplantation to prevent immune responses. FVIII was detected in 2bF8 lentivirus-transduced dog platelets and was stored in α-granules even though no VWF is present in canine platelets (Nichols et al. 1995; Sanders Jr. et al. 1995). In this study, Du and co-worker also examined whether adding a truncated VWF propeptide, which is known to have a capacity to reroute unrelated secreted protein to a storage pathway (Haberichter et al. 2002), into the construct (-673ITGA2B-VWFSPD2-BDDFVIII-WPTS) would affect the expression and storage of FVIII in canine platelets. It appeared that FVIII was stored better in α-granules of platelets in animal that received -673ITGA2B-VWFSPD2-BDDFVIII-WPTS lentivirus-transduced HSCs as determined by electron microscopy, but the platelet-FVIII expression level was similar to that obtained in animals receiving regular 2bF8 lentivirus-transduced HSCs. The levels of platelet-FVIII expression ranged from 5 to 9 $mU/10^8$ platelets. The occurrence of severe bleeding episodes was prevented in all three dogs for at least 2.5 years after transplantation of 2bF8-transduced autologous HSCs. Similar to results in the unimmunized hemophilia A mouse model (Shi et al. 2007), no anti-FVIII antibodies were detected in transduced dogs. These data demonstrate that 2bF8 lentivirus-mediated HSC transduction followed by autologous transplantation can introduce sustained therapeutic levels of platelet FVIII resulting in hemostatic improvement in hemophilia A dogs. Whether the vector containing VWF propeptide would be beneficial for gene therapy of hemophilia A in other species including humans, in which platelets already contain endogenous VWF, will need to be further investigated.

Human Cell Studies

To evaluate the feasibility of 2bF8 lentivirus-mediated human platelet gene therapy for hemophilia A, Shi et al. developed an immunocompromised hemophilia A recipient mouse model [NOD.Cg-Prkdc^{scid}Il2rg^{tm1Wjl}/SzJ FVIII^{null} (NSGF8KO)] and human cord blood (hCB)-derived HSCs were used as a target for gene transfer (Shi et al. 2014). $CD34^+$ hCB-derived HSCs were transduced with 2bF8 lentivirus ex vivo and *xeno*transplanted into NSGF8KO mice preconditioned with busulfan. Platelet FVIII was detected in all recipients for as long as human platelet chimerism persisted. Electron microscopy demonstrated that FVIII was colocalized with VWF in transduced human platelets. Tail-clipping tests and whole blood clotting time confirmed that hemostasis was improved in NSGF8KO mice that received 2bF8-transduced human HSCs (hHSCs). When nonrestrictive LAM-PCR was used to analyze 2bF8LV insertion sites, no identified integration sites were located within known proto-oncogenes in human hematopoiesis. Altogether, data from the human cell studies demonstrate the feasibility of 2bF8 lentiviral gene delivery to hHSCs to introduce FVIII expression in human platelets and that human platelet FVIII can improve hemostasis in hemophilia A mice.

In Vivo Selection to Enhance Platelet-FVIII Expression

With a goal of improving platelet-FVIII expression and reducing potential risks associated with platelet gene therapy, e.g., integrational mutagenesis and toxicities associated with preconditioning, Schroeder et al. developed a vector, 2bF8/MGMT, which harbors dual genes, the 2bF8 gene and a drug resistance gene, the MGMPTP140K cassette

(Schroeder et al. 2014). With this vector, platelet-FVIII expression can be induced by transduction of HSCs at a low MOI (multiplicity of infection) followed by transplantation into $FVIII^{null}$ mice preconditioned with a non-myeloablative regimen. The transduced cells can be enriched in vivo by treatment with O^6-benzylguanine (BG) followed by 1,3-bis-2 chloroethyl-1-nitrosourea (BCNU) which selectively kills untransduced hematopoietic cells, and thereby platelet-FVIII expression is enhanced. Even using a low MOI of 1 and sublethal 6.6Gy TBI, the level of platelet-FVIII expression in recipients after in vivo selection reached 4.3 ± 5.5 mU/10^8 platelets, which is 2.9-fold higher than that obtained from nonselectable 2bF8LV using an MOI of 10 with lethal 11Gy TBI (Kuether et al. 2012). When an MOI of 10 was used for transduction, the level of platelet-FVIII expression in BG/BCNU-treated transduced 2bF8/MGMT recipients reached 14.2 ± 12.1 mU/10^8 platelets. The highest platelet-FVIII expression was 35 mU/10^8 platelets, which corresponds to 70 % of FVIII:C in whole blood in normal mice. Phenotypic correction of the $FVIII^{null}$ coagulation defect in treated animals was confirmed by a tail bleeding test and ROTEM analysis of the whole blood clotting time. Importantly, there were no anti-FVIII antibodies detected in the BG/BCNU-treated transduced recipients even after rhF8 challenge, indicating that anti-FVIII immune tolerance is induced in treated animals.

Inducing Platelet-FVIII Expression Via In Situ Transduction of HSCs

To avoid preconditioning, Wang and co-workers (2015) developed a platelet gene therapy protocol through intraosseous delivery of a lentiviral vector, which harbors hFVIII/N6 [human FVIII with a partial B-domain, an N-terminal 226 amino acid stretch (N6)] cassette under control of a human GPIbα promoter (G-F8-LV) or a ubiquitous human elongation factor 1α (EF-1α) promoter (E-F8-LV), to transduce bone marrow cells in situ. Lentiviral vectors were directly injected into $FVIII^{null}$ mouse tibia through the join. The studies showed that 3–20 % FVIII activity was detected in plasma initially by a modified activated partial thromboplastin time (aPTT) assay in the animals receiving intraosseous infusion of E-F8-LV, but drop to undetectable levels within 2–3 months due to anti-FVIII immune response. In contrast, platelets containing FVIII were detectable in animals that received intraosseous infusion of G-F8-LV up to 160 days. FVIII antigen level was about 1 mU/10^8 platelets in the non-inhibitor model and 0.74 mU/10^8 platelets in the inhibitor model when 2.2×10^7 ifu/animal of G-F8-LV was infused. These studies demonstrate that platelet-FVIII expression can be achieved through in situ transduction of bone marrow cells when FVIII expression is restricted in platelet lineage.

Altogether, these studies demonstrate that induction of therapeutic levels of platelet-FVIII expression can be successfully achieved using lentivirus-mediated platelet-specific gene delivery to HSCs in hemophilia A even with pre-existing anti-FVIII immunity.

Platelet-Specific Gene Therapy of Hemophilia B

Hemophilia B is also an X chromosome-linked recessive bleeding disorder, which results from a factor IX (FIX) deficiency. It occurs at a frequency of 1/10,000 worldwide. Protein replacement therapy is effective, but it has similar problems as hemophilia A. Although the incidence of anti-FIX inhibitory antibody development is lower in hemophilia B patients after protein therapy, allergic reactions or anaphylaxis is very common in patients with inhibitors, limiting the use of protein infusion and increasing the risk of morbidity and mortality (Jadhav and Warrier 2000; Lusher 2000; Shibata et al. 2003; Franchini et al. 2009). Hemophilia B is a prime disease model for gene therapy. It is well known that FIX is a vitamin K-dependent protein that is normally synthesized by hepatocytes. Current clinical trials using adeno-associated virus serotype 8 (AAV8)-mediated liver-restricted FIX expression are very encouraging (Nathwani et al. 2011; Nathwani et al. 2014). Phase 1 trials showed that dose-dependent expression levels of FIX in circulation were achieved in severe hemophilia B patients after single dose vector administration and the bleeding diathesis was significantly improved. However, for individuals with severe liver disease or neutralizing antibodies to AAV, which are present in 30–50 % of the population (Calcedo et al. 2009; Calcedo et al. 2011), an alternative gene therapy approach might be desirable.

Studies from platelet-targeted FVIII expression have demonstrated that transgene FVIII is stored in platelet α-granules even in the absence of VWF. The hypothesis is that ectopic expression of FIX to platelets will also result in FIX storage in platelet α-granules and that stored FIX will be released locally at site of vascular injury to improve hemostasis in hemophilia B. To investigate the potential of platelet gene therapy of hemophilia B, Zhang and co-workers constructed a lentiviral vector (2bF9) in which hFIX expression cassette was under control of the α_{IIb} promoter and a transgenic model with platelet-specific FIX expression was generated by 2bF9 lentivirus-mediated transgenesis. Studies using this transgenic model demonstrated that 90 % of FIX is stored in platelet α-granules and is releasable by agonists and that platelet-derived FIX can rescue the bleeding phenotype in hemophilia B mice. Studies demonstrated that platelet FIX is completely carboxylated and has functional activity, indicating that megakaryocytes/platelets have the capacity to carboxylate the newly synthesized FIX protein

precursor to functional FIX protein. Hemostatic efficacy can be transferred by platelet transfusion or bone marrow transplantation. However, unlike platelet-derived FVIII, the hemostasis efficacy of platelet FIX is limited in the presence of anti-FIX inhibitors. The reason that platelet FIX behaves differently than platelet FVIII in the face of inhibitors could be the lack of a carrier protein to protect FIX as VWF protects FVIII, so antibodies can freely bind to FIX once they encounter each other in the plasma when FIX is released from activated platelets. This would be similar to 2bF8 on VWF and FVIII double knockout background. Indeed, without VWF, the clinical efficacy of platelet FVIII is abolished in the presence of anti-FVIII inhibitors (Shi et al. 2015).

Although platelet-derived FIX does not maintain clinical efficacy in the face of inhibitors, targeting FIX expression to platelets could still be a new strategy for gene therapy of hemophilia B. Chen and co-workers used 2bF9 lentiviral gene delivery to HSCs by transduction followed by transplantation to introduce platelet-specific FIX expression in hemophilia B mice (Chen et al. 2014). Sustained therapeutic levels of platelet-FIX expression were obtained in all recipients that received 2bF9-transduced HSCs. Flow cytometry analysis demonstrated that 6–39 % of platelets expressed FIX in transduced recipients, which was sufficient to rescue the bleeding diathesis in FIX^{null} mice in tail-clipping models, including the tail-clip survival test and a tail bleeding test. Sequential bone marrow transplantation demonstrated that platelet-FIX expression in secondary recipients was sustained, confirming that long-term engrafting HSCs were successfully modified. Importantly, none of the 2bF9-transduced recipients developed anti-FIX antibodies. Only one of nine recipients developed a low titer of inhibitors even after challenge with rhF9 in the presence of adjuvant. These data demonstrate that targeting FIX expression to platelets can not only restore hemostasis but also induce immune tolerance in hemophilia B mice, suggesting that platelet gene therapy may be a promising strategy for gene therapy of hemophilia B in humans.

The Safety Issues in Platelet Gene Therapy of Hemophilia

There are some concerns related to lentiviral gene delivery in platelet gene therapy. One major concern is the immune response to transgene product or viral proteins that may result in gene therapy failure because the transfected cells may be eliminated if cellular responses occur or the functional bioactivity of transgene protein may be inactivated if a humoral response is induced. It has been reported that immune responses are a problem in lentivirus-mediated HSC gene therapy when FVIII transgene expression was directed by ubiquitous promoters (Kootstra et al. 2003; Wang et al. 2015). This problem is not encountered when transgene expression is targeted to and stored in platelets. Instead, lentivirus-mediated platelet-specific gene therapy improves hemostasis but also induces immune tolerance in both hemophilia A and B mouse models (Schroeder et al. 2014; Chen et al. 2014).

The other significant concern is insertion site-related mutagenesis that is a potential risk associated with gene therapy utilizing any integrating vector. The advanced self-inactivating design of lentiviral vectors and the differences in integration site selection between lentiviral and oncoretroviral vectors may reduce the risk of insertional mutagenesis. Oncoretroviral vectors tend to integrate preferential nearby promoter-proximal regions, with hot spots in proto-oncogenes or genes related to cell proliferation. In contrast, lentiviral vectors appear to integrate more randomly into open chromatin without hot spots (Beard et al. 2007; Montini et al. 2006). While the studies utilizing LAM-PCR to survey 2bF8 integrants showed that there are no overrepresented insertion sites in animals that received 2bF8-transduced HSCs from mice (Kuether et al. 2012), dogs (DU et al. 2013), or humans (Shi et al. 2014), onco-mutagenesis resulting from random integration of transgene into the genome remains a potential risk in lentivirus-mediated gene transfer. Further studies using high-throughput techniques to more thoroughly determine the integration repertoire of these vectors are required.

In addition, the occurrence of abnormal on apoptosis in megakaryocytes when FVIII is ectopically expressed has been reported (Greene et al. 2014). Studies done by Poncz and co-workers showed that platelet-targeted FVIII expression, especially canine FVIII, under control of the GPIbα gene promoter increases apoptosis in transduced megakaryocytes, resulting in a 30 % reduction of platelet counts in transduced recipients (Greene et al. 2014). This does not seem to be the case when FVIII expression is driven by the α_{IIb} promoter. Studies by Schroeder et al. using the 2bF8/MGMT system have demonstrated that platelet number in lentivirus-transduced animals had fully recovered within 8 weeks after transplantation when a non-myeloablative conditioning regimen was applied and platelet counts were normal in transduced animals even with FVIII expression as high as 14.18 ± 12.05 mU per 10^8 platelets after in vivo drug selection, which corresponds to about 23 % of FVIII activity in normal mouse whole blood (Schroeder et al. 2014). It is unclear whether the cellular toxicity of FVIII expression in megakaryocytes is a specific phenotype driven by the GPIbα promoter, and therefore, further studies are warranted.

Whether ectopic expression of FVIII or FIX in platelets would have a potential thrombotic risk is also an important

safety issue that needs to be addressed before applying platelet gene therapy protocols to the clinic.

Summary

In summary, studies from preclinical trials using animal models have demonstrated the feasibility of platelet delivery of therapeutics for disease treatment through genetic manipulation of HSCs. Targeting FVIII or FIX expression and storage to platelets is a promising strategy for gene therapy, with potential to not only improve hemostasis but also induce immune tolerance in hemophilia. In a clinical scenario, patient-derived stem cells would be harvested from mobilized peripheral blood or cord blood for ex vivo introduction of a corrected FVIII or FIX gene driven by a platelet-specific promoter, followed by autologous transplantation. This is a promising approach for gene therapy of hemophilia A patients with inhibitors as well as non-hemophilic patients with acquired inhibitory antibodies who can also have life-threatening clinical bleeding which is difficult to treat by conventional therapies.

Take Home Messages

- Targeting FVIII or FIX expression and storage to platelets is a promising strategy for gene therapy, with potential to not only improve hemostasis but also induce immune tolerance in hemophilia.
- FVIII can be specifically expressed and stored together with its carrier protein VWF in platelets α-granules when it is driven by a platelet-specific promoter.
- Platelet-targeted FVIII expression can rescue the bleeding phenotype in hemophilia A even in the presence of anti-FVIII inhibitory antibodies.
- Without VWF, platelet-FVIII levels significantly decrease and the clinical efficacy is abolished in the presence of inhibitors.
- Platelet-targeted FIX expression can rescue the bleeding phenotype in hemophilia B mice, but the efficacy is limited in the presence of anti-FIX inhibitory antibodies.
- Platelet-specific gene therapy can induce immune tolerance in both hemophilia A and hemophilia B mice.
